honeycombing supervenes. In contrast to other pneumoconioses, lymph node enlargement and progressive massive fibrosis do not occur. Pathologically, the alterations seen in asbestosis cannot be differentiated from many other interstitial fibrotic disorders except for the presence of asbestos bodies and uncoated asbestos fibers.

PATHOGENESIS

Asbestos fibers are deposited at airway bifurcations and in respiratory bronchioles and alveoli by impaction, sedimentation, and interception. Fibers then migrate into the interstitium, in part via an uptake process involving type I alveolar epithelial cells. This causes alveolar macrophages to accumulate in the alveolar ducts, peribronchiolar interstitium, and alveolar spaces, constituting an alveolar macrophage alveolitis. Following this initial macrophage alveolitis, most fibers are cleared, leaving the lungs unscarred. If clearance is incomplete, fibrosis can ensue. The degree of fibrosis in asbestosis relates, in general, to the lung dust burden. If the dust load is small, the tissue reaction may be limited and the disease may be mild and not progress. If the retained dust load is great, tissue reaction and macrophage alveolitis are proportionately more intense, greater injury occurs, and chronic and progressive lung disease can develop.

The macrophage alveolitis that is seen in early stages of asbestosis results from monocyte recruitment from the blood and in situ macrophage replication. These cells appear to play an important role in the pathogenesis of the inflammation and fibrosis seen in this disorder. Morphologically, they express an activated phenotype characterized by cellular multinucleation and a striking increase in membrane ruffling, surface blebbing, and lysosomes and phagolysosomes.[9] These macrophages are presumably attempting to engulf and clear the asbestos fibers. This process is not uniformly successful, however. First, the fibers induce apoptosis in the cells. Although the coating of asbestos fibers to form asbestos bodies makes them less toxic, the vast majority of fibers in the lung remain uncoated. Second, the long fibers cannot be completely phagocytosed. Finally, chrysotile asbestos fibers tend to split longitudinally. This generates additional fibers that can multiply the asbestos effect even after exposure has ceased. As a result, asbestos has a prolonged residence, surprising mobility, and penetrates the interstitium of the distal lung.

These characteristics probably contribute to the pathogenesis of the disease, since – in contrast to inert particles, which can be ingested by macrophages and cleared without generating a significant response – asbestos fibers stimulate macrophages to produce a variety of important cytokines and growth factors. Both asbestos and silica are phagocytosed by alveolar macrophages, which then activates them to release cytokines, growth factors, and oxidants. These include platelet-derived growth factor (PDGF), and insulin-like growth factor-1 (IGF-1), transforming growth factor-β, and cytokines interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), and IL-8, the matrix molecule fibronectin, oxygen free radicals, and matrix metalloproteinases.[10–12] The oxygen radicals contribute to tissue injury via direct cell cytotoxicity and lipid peroxidation of membrane components. The IL-8 recruits neutrophils to sites of disease activity. The PDGF, IGF-1, IL-1, TNF-α, and fibronectin contribute to tissue fibrosis by stimulating fibroblast proliferation and chemotaxis and collagen biosynthesis.[8] In vitro exposure of mononuclear phagocytes to silica, asbestos, or coal activates transcription factors including AP-1 and NF-κB with subsequent release of cytokines and growth factors.

Bronchoalveolar lavage (BAL) in asbestosis has demonstrated an alveolar macrophage alveolitis with a modest increase in neutrophils.[11] This neutrophilia correlates with the finding of rales on physical examination and oxygenation parameters and is apt to be more pronounced in patients with advanced disease. In patients with asbestosis, ^{67}gallium lung scans may also be positive. Clinically apparent asbestosis occurs only after a significant latent period. However, studies using BAL, CT scanning, and ^{67}gallium scanning have demonstrated that inflammatory events occur well before the onset of clinical disease. Thus, it is likely that the initial exposure induces inflammation and injury that persist through the latent or subclinical phase and develops into the clinical disease diagnosed by classic radiography and other techniques. Current concepts of the pathogenesis of the disease link inflammation and fibrosis in a causal fashion.

EPIDEMIOLOGY

The prevalence of parenchymal asbestosis among asbestos workers increases as the length of employment increases. This is illustrated in an early report in which investigators analyzed the chest radiographs of 1117 New York and New Jersey asbestos insulation workers. They found asbestosis in 10% of the workers who had been employed for 10 to 19 years, in 73% of those who had worked for 20 to 29 years, and in 92% of those who had worked 40 or more years.[13] A similar dose–response relationship was found in the asbestos cement industry. Among "bystanders" (i.e., among sheet metal workers who worked in close proximity to insulation workers) the overall prevalence of asbestos-related changes was 31%, including 9% who had only pleural abnormalities and 12% who had parenchymal abnormalities.[14] Among those who had been in the trade for 40 years or more, 41.5% had radiographic signs of asbestos-related disease.

Cigarette smoking can affect the expression of asbestosis.[15] Smokers without dust exposure may have a few irregular radiographic opacities, probably representing acute or chronic bronchitis or bronchiectatic changes in the lung parenchyma. Both smokers and ex-smokers have a higher frequency of asbestos-related irregular opacities on their chest radiographs than do their nonsmoking colleagues. Smoking does not alter the expression of asbestos-induced pleural fibrosis. However, cigarette smoking may interfere with the clearance of inhaled asbestos, thereby potentiating the effects of the dust in the lung.

NATURAL HISTORY

Following asbestos exposure, asbestosis becomes evident only after an appreciable latent period. The duration of exposure and its intensity influence the prevalence of radiographically evident parenchymal pulmonary fibrosis. Because work sites around the world increasingly meet recommended control levels, high-level exposure to asbestos is now uncommon and clinical asbestosis is becoming a less severe disease that manifests after a longer latent interval. In Western Australian crocidolite workers, a median of 14 years elapsed before asbestosis was detectable radiographically (range, 2–34 years). In retired Quebec chrysotile miners and millers, the frequency of pleuroparenchymal lesions was 31%, and progression of parenchymal opacities occurred in 9.3%; progression was confined to the more heavily exposed group.[16]

One approach to the study of low-level exposure is to evaluate the outcome from short-term exposure. In such a study in an amosite asbestos factory, employment for even as little as 1 month resulted in a 20% prevalence of parenchymal opacities: one-third of the participants had pleural abnormalities after 20 years of follow-up; it is significant that both "first attacks" and progression of established radiographic abnormalities occurred 20 and more years after exposure had ceased.[17]

Radiographic asbestosis, once established, may remain static or progress. Rarely has regression been recorded. The factors that determine the outcome are poorly understood. The level and duration of exposure (i.e., cumulative exposure) appear to be prognostic factors. Progression is also considerably more common in persons who already have radiographic abnormalities. This fact provides the basis for the advice that further exposure is to be avoided once the diagnosis of parenchymal asbestosis has been made.

CLINICAL AND PHYSIOLOGICAL FEATURES

Dyspnea on exertion is the earliest, most consistently reported, and frequently the most distressing symptom of asbestosis. Often

dyspnea is accompanied by a persistent cough, which can be spasmodic, with sputum production. Chest tightness is not uncommon, and wheezing also can occur. In a cross-sectional survey of 816 asbestos-exposed workers using a respiratory symptoms questionnaire, cough, phlegm, wheeze, and dyspnea were inversely related to pulmonary function.[18] Cough, phlegm, and chronic bronchitis were associated with a 2% to 8% reduction in FVC and FEV_1; the reduction in these measurements was more significant with wheeze and dyspnea, which caused an 11% to 17% reduction. Similarly, the prevalence of dyspnea on the level less than one block among asbestos insulators increased in stepwise fashion from 19% in patients with category 1 chest radiographic abnormalities to 35% in patients with category 2 chest radiographs and to 49% in patients with category 3 radiographic abnormalities.[19]

Rales are a distinctive feature of asbestosis. They are usually bilateral, late to paninspiratory in timing, heard best at the posterior lung bases, and not cleared by coughing. They differ in quality and timing from the crackles of bronchitis, which tend to be fewer and earlier. The crackles of asbestosis appear first at the bases in the midaxillary line and tend to spread toward the posterior bases. In prevalence surveys, approximately 83% of patients with higher radiographic categories of asbestosis had bilateral rales. In a study of 42 patients with a clinical diagnosis of asbestosis, in 40 the chest radiograph showed at least 1/0 profusion of irregular opacities, 36 had rales, 36 had dyspnea, and 22 had digital clubbing.[20]

The characteristic pulmonary function changes of asbestosis are a restrictive impairment with a reduction in lung volumes (especially FVC and total lung capacity), decreased lung diffusing capacity (D_{LCO}), and arterial hypoxemia.[21] Large-airway function, as reflected in the FEV_1/FVC ratio, is generally well preserved. In one of the earliest studies, approximately 50% of asbestos workers had a reduced FVC and the vital capacity was decreased, on average, by 18% as predicted over the next 10 years. Among the 1117 asbestos insulators in New York and New Jersey, the frequency of an abnormal FVC increased to more than 50% as follow-up was prolonged. In a larger cohort of 2611 asbestos insulators, the FVC percent predicted decreased as the profusion of irregular opacities on the chest radiograph increased; pleural thickening exaggerated the decrease for each category of profusion. For each category of profusion, diffuse pleural thickening caused a further decrease (at least 10%) in FVC percent predicted compared to circumscribed plaques.[22]

Mild airway obstruction can also be seen in nonsmokers with asbestosis.[23] These patients usually have a restrictive pattern of lung function, increased isoflow volume, and increased upstream resistance at low lung volumes. Open lung biopsies from a limited number of these patients suggest that these obstructive findings may be due to peribronchiolar fibrosis, since they revealed peribronchiolar infiltrates with macrophages and fibrosis that extended into the adjacent interstitium. Therefore, it is not surprising that lesser grades of asbestosis can show a mixed restrictive and obstructive abnormality.

Long-term medical surveillance is recommended for all asbestos-exposed persons, especially those with radiographic abnormalities. Periodic physiological assessments play an important role in these evaluations. Prospective assessments of asbestosis should include spirometry as most useful, and diffusing capacity to assess alveolo–capillary function.

■ RADIOGRAPHIC FEATURES

In asbestosis, digital radiography reveals bilateral diffuse reticulonodular opacities, predominantly in the lower lung zones.[5] The International Classification of the Radiographs of the Pneumoconioses uses the term *small irregular opacities* to describe the irregular linear shadows that develop in the lung parenchyma and obscure the normal bronchovascular branching pattern seen in disease-free lungs. This schema categorized the irregular or rounded opacities found on conventional PA chest radiographs according to size and expressed them on a 12-point scale. Category 0 was defined as a normal radiograph and category 1 as mild asbestosis. Typically, a profusion of irregular opacities at the level of 1/0 is taken as the break point between normal and abnormal. Moderate asbestosis and advanced asbestosis were defined as category 2 and 3 chest radiographs, respectively. As duration from onset and intensity of exposure increase, there is an increase in prevalence and severity of asbestosis as reflected in the chest radiograph.

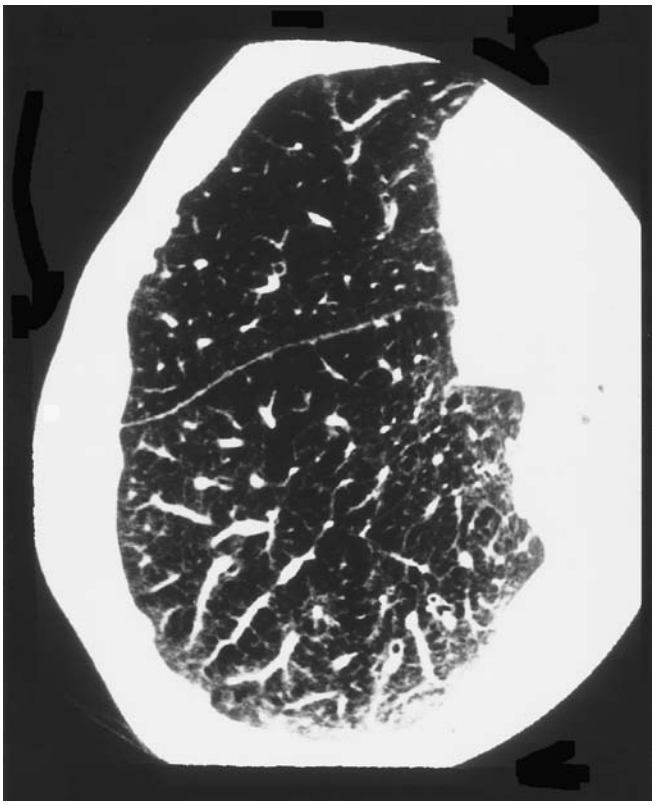

Figure 86-4 HRCT scan with irregular opacities of the lung parenchyma and interlobar structure. The PA chest radiograph was graded 2/1 on the ILO International Classification of the Radiographs of the Pneumoconioses. *(Used with permission of Dr. David Naidich.)*

CT scanning has improved the sensitivity for detecting asbestos-related lesions (Fig. 86-4). It eliminates a common problem with digital chest radiographs—that is, the superimposition of pleural abnormalities over parenchymal lesions. It also enhances the attenuation discrimination for parenchymal opacities. As a result of more than 300 HRCT evaluations of persons with asbestos exposure, five HRCT features of asbestosis have been identified: (1) Curvilinear subpleural lines, (2) increased intralobular septa, (3) dependent opacities, (4) parenchymal bands and interlobular core structures, and (5) honeycombing. These changes have been corroborated by histological examination.[24] In asbestos-exposed workers, abnormal HRCT has been shown to correlate with restrictive physiological abnormalities and abnormal diffusing capacities. HRCT is also extremely sensitive in documenting the asbestos-related pleural abnormalities discussed earlier. The presence of pleural plaques (particularly if they are bilateral) provides useful evidence that the parenchymal process is asbestos-related. Hilar node enlargement is not a feature of asbestosis, and progressive massive fibrosis is also uncommon.

■ DIAGNOSIS

Asbestosis is defined as parenchymal fibrosis, with or without pleural thickening, usually associated with dyspnea, bibasilar rales, and

pulmonary function changes. To diagnose this disorder, one must establish the presence of pulmonary fibrosis and determine whether exposure has occurred of a duration and intensity sufficient to put the person at risk. A profusion of irregular opacities at the level of 1/0 is used as the break point between normal and abnormal in the evaluation of lung fields on the chest radiographs of asbestos-exposed persons. When radiographic or lung function changes are marginal, CT scanning often reveals characteristic parenchymal abnormalities as well as pleural plaques and/or pleural fibrosis. These lesions, particularly when bilateral, are strongly suggestive of asbestosis. The diagnosis of asbestosis must always be based on the chronological occupational history with potential exposures. The features of the history that need to be defined include the duration, onset, type, and intensity of exposure. In taking the occupational history, it is important to keep in mind that intensity of exposure can be heavy even if duration of exposure is short. For example, heavy exposures were experienced by shipyard workers engaged in insulation application or removal in contained areas for brief periods aboard ship and by asbestos insulators during their apprenticeship when they unloaded asbestos sacks into troughs and mixed asbestos cement. Short, intense exposures of this sort, which lasted from several months to 1 or 2 years, can be sufficient to cause asbestosis. Exposures over 10 to 20 years are, however, usually necessary. The timing of the exposure is also relevant. Industrial hygiene controls in the 1960s and 1970s, especially in the construction trades, were not widely applied or enforced. Cohort studies have identified latency to be an important factor, with the prevalence of asbestosis increasing with time since the onset of exposure.

The specificity of the diagnosis of asbestosis increases with the number of consistent findings on chest film, the number of clinical features present (e.g., symptoms, signs, and pulmonary function changes), and the significance and strength of the history of exposure. The more significant the asbestos exposure the greater accuracy is the diagnosis. The more trivial the asbestos exposure, the less likely it is to be causal. Misclassification and diagnostic difficulty occur in patients with a heavy cigarette smoking history and concurrent emphysema (which also reduces the diffusing capacity). Patients with idiopathic pulmonary fibrosis (IPF) may have a history of asbestos exposure. These patients tend to be younger, however, and their asbestos exposure is usually casual, brief, and recent and can often be discounted. If an open lung biopsy is available one or more asbestos bodies per high power field (Fig. 86-5) or an asbestos fiber count per milligram of dry lung can be helpful to distinguish from IPF. In the absence of an adequate exposure history or in the presence of a confusing clinical presentation, biopsy material may be helpful in identifying the nature of the disease. It allows the pulmonary interstitial process to be compared to the known features of asbestosis and other interstitial disorders. Uncoated asbestos fibers are much more common than asbestos bodies, exceeding the frequency of coated fibers by anything from 5- to 10,000-fold. Although other inhaled particles may also become coated, most coated fibers found in human lungs have an asbestos core. Thus, the presence of asbestos bodies or asbestos fibers is considered the hallmark of exposure, past or current. Asbestos bodies can also be detected in BAL samples. Asbestos bodies in BAL correlate with heavy exposure, reduced lung function consistent with interstitial lung disease, and asbestosis.[25] This is illustrated in a large series of 563 patients: Those with asbestosis had a mean of 120 asbestos bodies per milliliter; those with pleural disease, 5 asbestos bodies per milliliter; and those with malignant mesothelioma or lung cancer, 8 asbestos bodies per milliliter of lavage fluid. Of 49 patients with more than 100 asbestos bodies per milliliter of lavage fluid, 30 had asbestosis, 8 had pleural disease, 13 had mesothelioma or lung cancer, and 3 had an exposure history only. Others have estimated that one asbestos body per milliliter of BAL fluid correlates with 1000 to 3000 asbestos bodies per gram of dry lung tissue.

■ TREATMENT AND PROGNOSIS

Major causes of morbidity and mortality in patients with asbestosis include the progression of the underlying lung disease and the development of lung cancer and malignant mesothelioma. Longitudinal observations of asbestos-exposed trade workers have demonstrated accelerated declines in pulmonary function. In a study of 77 workers with a mean of 31 ± 1 years of occupational exposure, linear regression demonstrated a mean annual decline of 92 ± 28 mL/y in FVC, 66 ± 22 mL/y in FEV_1, and 14 ± 53 mL/y in total lung capacity.[26] At present, there is no established treatment for this disorder. Because of the risk of lung cancer and mesothelioma, medical surveillance with CT scans for those who also smoke >30 pack-years and age >55 years on an annual basis is recommended.[27] Blood biomarkers for proteins or autoantibodies may assist in distinguishing benign nodules from malignant.

MALIGNANT MESOTHELIOMA

Malignant mesothelioma is an important complication of asbestos exposure, as discussed below.

■ PATHOLOGY

Malignant pleural mesothelioma occurs in persons who have an exposure history to asbestos fibers, with 85% of men having an occupational history and 50% of women. In its early stage, the mesothelioma appears as multiple, small, grayish nodules on the visceral and parietal pleura that evolve to coalesce and form larger masses of tumors. These tumors then invade thoracic and other structures by direct extension. Fewer than 25% of malignant mesotheliomas are peritoneal in origin.

Mesotheliomas are conventionally classified into three histological patterns: Epithelial, sarcomatous, and mixed or biphasic; these patterns account for 50%, 20%, and 30%, respectively. The epithelial variant – in which neoplastic cells are arranged in papillary, tubular, or solid nest configurations – is most easily confused with metastatic adenocarcinoma. The sarcomatous variant has spindle-shaped cells that may be pleomorphic, with considerable mitotic activity.

The pathological diagnosis of malignant mesothelioma may be difficult. In particular, the differentiation of malignant mesotheliomas, adenocarcinomas, and other tumors may be problematic. Histochemistry and immunohistochemistry may be helpful in making the distinction. Thus, in contrast to mesotheliomas, adenocarcinomas contain neutral mucin that stains positive with the periodic acid–Schiff stain and is often resistant to diastase. Hyaluronic acid, the major acid mucopolysaccharide in mesotheliomas, can be identified with the Alcian blue or colloidal iron stain. Removal by prior digestion with hyaluronidase increases the specificity of the reaction. In contrast, adenocarcinomas are negative for Alcian blue and colloidal iron. Mesothelial cells contain cytoskeletal filaments, including cytokeratin and vimentin; staining for these structures is not specific, since other tumor types are also positive. Carcinoembryonic antigen is absent in malignant mesothelioma but is present in up to 90% of adenocarcinomas. Similarly, the monoclonal antibody B72.3, generated against a membrane fraction of human metastatic breast cancer, was positive in 19 of 22 pulmonary adenocarcinomas but none of 20 mesotheliomas. Monoclonal antibody Leu MI is frequently positive in lung carcinomas and nonreactive with mesotheliomas.[28]

The ultrastructural features of malignant mesotheliomas are also noteworthy. Malignant mesotheliomas contain abundant tonofilaments, often organized into perinuclear bundles, and long, sinuous, slender surface microvilli. The microvilli sometimes show secondary and tertiary branching and may interdigitate with stromal collagen. Malignant mesothelial cells produce collagen, a prominent feature of the sarcomatous variant.

Malignant mesotheliomas are locally invasive, spreading along the pleural wall and invading the lung, mediastinal lymph nodes, and other thoracic and nearby structures. At autopsy, tumor may be found in the diaphragm, heart, liver, spleen, adrenals, gastrointestinal tract serosa, bone, pancreas, and kidneys. Between 50% and 80% of patients also have metastases.

About 10% of patients with a malignant mesothelioma are alive at 24 months. Survival is significantly longer for patients with an epithelial subtype or with a pleural rather than a peritoneal mesothelioma, and for those under 65 years of age.

The incidence of mesothelioma is increasing because of the cohort exposed to asbestos between 1940 and 1970. Incidence rates vary from a low of 11 to 13 per million per year in the United States to 33 per million per year in South Africa and to 66 per million per year in Western Australia.[29] These rates reflect mining and manufacturing industries and the location of crocidolite mines. Although the peak incidence in the United States may have passed since imports decreased after 1945, imports of asbestos in the United Kingdom reached their peak in the 1960s to 1970s. Thus, the peak of mesothelioma deaths in the United Kingdom is expected to occur in 2020, when up to 1% of men may die of the disease. Chrysotile was the major asbestos import to the United Kingdom, and half of this material went into the construction industry. Amosite was the leading amphibole import, and most of it went into insulation board. Thus, workers in the construction industry in the United Kingdom seem to be at greatest risk.

EPIDEMIOLOGY

In 1960, Wagner et al.[30] published a landmark paper demonstrating an association between malignant mesothelioma and asbestos exposure. They reported on 33 patients from South Africa, 28 of whom were exposed in the crocidolite mining region and 4 of whom were exposed in asbestos factories. They observed that mesotheliomas occurred 20 to 40 years after exposure to asbestos dust and found asbestos bodies in lung tissue from 8 of 10 patients from whom lung tissue was available for study. Subsequently, the importance of direct asbestos exposure was confirmed and the potential importance of indirect exposure to asbestos was recognized.

Evaluations of asbestos fiber content have shown a clear association between asbestos exposure and the occurrence of mesothelioma.[31] Epidemiological studies have shown crocidolite to be a potent fiber type among South African and Western Australian asbestos miners and millers. Most mesotheliomas have occurred from chrysotile–amphibole mixtures, since chrysotile is the most common fiber in commercial use. The incidence of malignant mesotheliomas among chrysotile workers who came before the Workers' Compensation Board of Quebec was similar to that in western Australian crocidolite miners. Studies of Canadian cohorts have also indicated that high concentrations of chrysotile, or tremolite, are required to cause mesothelioma, and further suggest that chrysotile has weaker biopersistence than does tremolite, which is merely a contaminant in most ores. In the United States, amosite is the predominant amphibole found in lung tissue: In one study it was identified in 81% of 90 patients with mesothelioma; in this population, it accounted for 58% of all fibers at least 5 μm in length. Finally, there is no association between smoking and malignant mesothelioma.

An epidemic of mesothelioma was reported in the Cappadocia region of Turkey where 40% of deaths were caused by the disease in several villages.[32] The exposure was to erionite, an aluminum silicate fibrous zeolite, and villagers used the stone to build their homes, whitewash their walls, and carved rooms in the soft volcanic tuff. There also appeared to be a family concordance beyond the household exposure.[33] Evaluation of some mesotheliomas has also found evidence of simian virus 40. SV40 is a DNA tumor virus that causes mesothelioma in hamsters and has been detected in several human mesotheliomas. Asbestos fibers appear to increase SV40-mediated transformation of human mesothelial cells in vitro. In an in vivo demonstration of cocarcinogenicity of SV40 and asbestos fibers, mice containing high copy numbers of SV40 viral oncogene rapidly developed fast-growing mesothelioma following asbestos challenge. This virus can bind the retinoblastoma transcription factor that could inhibit p53 function, and promote carcinogenesis.

PATHOGENESIS

Insight into the pathogenesis of malignant mesothelioma has come from experiments in which asbestos fibers were introduced into the pleural space of animals. These studies have demonstrated that amosite, anthophyllite, crocidolite, and Canadian chrysotile can all cause these pleural malignancies. Studies of fiber size in animals have shown that the most carcinogenic fibers are biopersistent, 0.1 to 1.0 μm in diameter and more than 8 μm in length. Inspection of electron micrographs of asbestos fibers has shown that crocidolite and amosite possess needlelike characteristics, whereas anthophyllite has a more boxlike appearance and chrysotile has a long, curly appearance. These variations in size are also consistent with epidemiological studies indicating that crocidolite and amosite may have greater risk for mesothelioma than do other types of asbestos.

One theory concerning the mechanism of asbestos-induced carcinogenesis focuses on the observation that asbestos fibers become entangled in the mitotic spindle during interphase, thereby causing chromosomal abnormalities. Electron microscopic evaluations have shown fibers penetrating between multiple lobes of the nucleus and associating, along their length, with the outer surface of the nuclear envelope. Structural chromosomal abnormalities in mesothelioma are clonal and complex, and include both chromosomal gains (chromosome 22) and losses (chromosome 7). Deletions of the short arm of chromosome 3, the break point 1p11 to p22, chromosome 17,

and structural and numeric changes in chromosome 7 have been described. In asbestos insulators, sister chromatid exchanges in circulating lymphocytes are increased: Larger chromosomes are more susceptible, and in the largest chromosome group, there is a significant interactive effect between asbestos exposure and cigarette smoking.

Cell lines established from malignant mesotheliomas have been shown to constitutively upregulate the PDGF B-chain gene and, to a lesser extent, the PDGF A-chain gene. High levels of transforming growth factor and IGF-1 bioactivity have been reported for cell lines derived from malignant mesotheliomas. These growth factors contribute to the considerable matrix formation that accompanies mesothelial tumors and promote mesothelioma cell proliferation.

CLINICAL AND RADIOGRAPHIC FEATURES

Pleural mesotheliomas are found mainly in males (ratio, between 3 and 4 to 1) and are most commonly diagnosed in patients between 50 and 70 years of age. Chest pain is the most common symptom experienced by patients with mesotheliomas. Dyspnea is next in frequency. Less common symptoms are cough, weight loss, and fever. A pleural effusion is usually present and can be massive. The effusion is an exudate, can be hemorrhagic, and may have high levels of hyaluronic acid (Fig. 86-6). Malignant mesothelioma is locally invasive, spreading along the pleural wall and invading the lung and nearby structures. Metastases are less common but can give rise to symptoms due to tumor in the diaphragm, heart, liver, spleen, adrenals, gastrointestinal tract, bone, pancreas, and kidneys. The paraneoplastic syndromes of inappropriate antidiuretic hormone secretion, clubbing, or hypoglycemia are reported. Thrombocytosis is common (90% in one series) and thromboembolic complications can occur. Ascites and weight loss are characteristic features of peritoneal mesothelioma.

A variety of radiographic abnormalities are found in malignant mesothelioma. They include a thick pleural peel along the lateral chest wall that can extend to the apex with an irregular nodular surface, multiple pleural nodules or masses, plaque-like opacities, and pleural effusion(s). As the disease progresses, the lung parenchyma may be involved, the affected hemithorax may decrease in size, and the mediastinal or hilar nodes may be invaded. Pericardial thickening or effusion, abdominal extension, and chest wall invasion are common. The HRCT can help in differentiating pleural effusion from tumor and in determining the extent of tumor progression. The presence of asbestosis or of pleural plaques on the opposite side can assist in establishing the diagnosis of malignant mesothelioma.

DIAGNOSIS

The diagnosis of malignant mesothelioma requires cytological and immunohistological validation. Calretinin, cytokeratin 5/6, and WT1 are the best positive markers for differentiating mesothelioma from pulmonary adenocarcinoma, and the best negative markers are CEA, MOC-31, and B72.3.[34] Obtaining a cytological diagnosis from the pleural exudate is difficult because reactive mesothelial cells and malignant cells are not easy to distinguish. Biopsy is required. Because mesothelioma has been shown to invade the needle track, open biopsy is preferable. Thoracoscopy is the procedure of choice in establishing the diagnosis of mesothelioma.

Noninvasive biomarkers include plasma soluble mesothelin, osteopontin, and fibulin-3.[35,36,28] The receiver operating curve (ROC) for plasma fibulin-3 levels had a sensitivity of 96.7% and a specificity of 95.5% at a cutoff value of 52.8 ng of fibulin-3 per milliliter and blinded validation revealed an area under the curve (AUC) of 0.87 for plasma specimens from 96 asbestos-exposed persons as compared with 48 patients with mesothelioma.[35] An AUC of 0.5 is no different between the groups and an increased AUC greater than 0.7 is increasingly more sensitive toward 1.0, which is perfect sensitivity and specificity for the test in question. These blood tests can distinguish patients with malignant mesothelioma from asbestosis and pleural plaques as well as other causes of malignant pleural effusion such as lung and breast cancer.

TREATMENT AND PROGNOSIS

Median survival time is approximately 8 to 12 months for all patients with malignant mesothelioma. Overall, fewer than 10% of patients are alive at 5 years. Extrapleural pneumonectomy, combined with radiation therapy, may result in improved survival. Chemotherapy with gemcitabine and carboplatin or pemetrexed and cisplatin may improve survival. Immunotherapy with intrapleural or gene therapy with interferons has produced occasional complete or partial responses.

Interventions, such as gene therapy or the use of cytokines, for the treatment of malignant mesothelioma are currently being investigated.[37,38] In 89 patients, the intrapleural instillation of γ-interferon twice weekly for 8 weeks resulted in 8 histologically confirmed complete responses and 9 partial responses, with at least a 50% reduction in tumor size.[39] The overall response rate was 20%, increasing to 45% in stage I disease. In 23 patients, a phase I clinical trial of continuous infusion into the pleural space of recombinant IL-2, revealed two partial and seven stable disease out of 21 evaluable patients.[40] Gene therapy using a replication-defective adenovirus carrying the herpes simplex–thymidine kinase (HSV*tk*) gene followed by the antiviral drug ganciclovir, was used successfully in a phase I clinical trial to treat malignant mesothelioma.[41] There was HSV*tk* gene transfer in 11 of 20 evaluable individuals in a dose-related fashion using RT-PCR, in situ hybridization, immunohistochemistry, and immunoblotting.[41] However, humoral and cell-mediated immune responses that developed against viral surface proteins and gene transfer were noted only in superficial cells compromised the therapeutic effectiveness of this approach.[42] Also, the thymidine kinase gene in vivo had no effect on promoting regression of the tumor. Another promising area of research is intrapleural administration of adenoviral interferon-α2b, which resulted in tumor regression in five patients including one dramatic example of partial tumor regression at sites not in contiguity with vector infusion.[43]

LUNG CANCER

In addition to mesothelioma, lung cancer is another well recognized malignant complication of asbestos exposure.

EPIDEMIOLOGY

The association between asbestos exposure and the development of lung cancer was highlighted by Sir Richard Doll's 1955 epidemiological cohort study of 113 men exposed to asbestos for 20 years reported 11 deaths due to lung cancer (compared with 0.8 expected).[44] All of

the individuals who died of lung cancer had evidence of asbestosis. In 1965, a retrospective cohort study in two asbestos insulator unions in the United States reported that deaths from lung cancer were 6.8 times the expected rate and that the incidence of lung cancer increased with time after exposure. In 1968, a follow-up of men in this cohort demonstrated an important synergy between asbestos exposure and cigarette smoking, since the risk of lung cancer was almost entirely borne by those who had a history of cigarette smoking.[45]

The largest survey of asbestos-related deaths evaluated a North American asbestos insulator cohort that reported a threefold excess of lung cancer deaths.[46] Comparatively few of these excess deaths were observed among those less than 25 years after the start of exposure. Lung cancer peaked at 30 years from exposure and mesothelioma at 45 years. In contrast, death rates from asbestosis increased progressively with time. This study confirmed the multiplicative effect of smoking plus asbestos exposure on the risk of lung cancer. Moreover, it showed that deaths from lung cancer dropped by almost two-thirds for asbestos insulators who subsequently stopped smoking. A recent follow-up of the North American insulator cohort from 1981 to 2008 found the following: 19% of the deaths were caused by lung cancer; the rate ratio of lung cancer in nonsmokers was 3.6 (95% Confidence Interval [CI] 1.7–7.6) and by asbestosis in nonsmokers was 7.40 (95% CI 4.0–13.7); the joint effect of smoking and asbestos alone was additive (rate ratio 14.4) and with asbestosis, supra-additive (rate ratio 36.8).[47] Insulator lung cancer mortality halved within 10 years of smoking cessation and converged with that of never-smokers 30 years after smoking cessation.

Additional insights were provided by a study of amosite workers who were exposed to concentrations of 50 fibers per milliliter.[48] These patients experienced a fivefold increase in lung cancer. Long-term follow-up showed: (1) a latency period of about 20 years before the increase in cancer occurred; (2) the greater the dose or the longer the exposure, the greater risk of developing lung cancer; and (3) the greater the dose or exposure time, the shorter the latency period before the tumor developed. Malignancies were also noted in the wives and children of these workers who were exposed to asbestos in the household, primarily on work clothes. In addition, men employed for less than 1 month between 1941 and 1945 developed lung cancer at an increased rate. Studies of a variety of other cohorts have confirmed the increased incidence of lung cancer in asbestos-exposed populations. They have also demonstrated an increased frequency of cancer of the larynx; in the latter, asbestos has been found in laryngeal tissue. As in the case of cancer of the lung, cigarette smoking has a strong association with the occurrence of these laryngeal malignancies.

Epidemiological studies have also provided information about dose–response relationships and about the importance of asbestos-processing techniques and fiber type in the pathogenesis of pulmonary malignancies. A number of investigators have observed linear dose–response relationships for lung cancer. Different dose–response relationships have, however, been found in other studies. These differences may be the result of differences in processing techniques. For example, studies in a South Carolina plant demonstrated that the steeper dose–response relationship of miners versus textile weavers was probably due to the manufacturing process, which resulted in high levels of brief exposure during the opening of asbestos bags and the sudden separation of the asbestos fibers.[49] Similarly, differences in lung cancer mortality in asbestos cement product plants in Louisiana were found to be associated with the addition, in one of these plants, of crocidolite to the asbestos cement pipe mixture. The risk of lung cancer increases most clearly with cumulative asbestos exposure.

PATHOLOGY

Asbestos-related lung cancers are not distinct from lung cancers that occur in cigarette smokers and otherwise normal persons in type, nature, or location. All histological types of lung cancer occur with increased frequency, but adenocarcinoma has the highest incidence. In the vast majority of patients, there is histological evidence of asbestosis and asbestos bodies are frequently found. Asbestos-related lung cancer can occur in the absence of asbestosis.

PATHOGENESIS

Animal experiments using several types of asbestos have succeeded in reproducing pulmonary malignancies. In one study, approximately one-third of rats exposed by inhalation to asbestos (amosite, anthophyllite, crocidolite, Canadian chrysotile, or Rhodesian chrysotile) for periods ranging from 1 day to 24 months developed adenocarcinomas or squamous cell carcinomas of the lung.[50] In these experiments, a clear dose–response relationship existed between asbestos dose and the occurrence of tumors. The mechanisms responsible for the induction of these malignancies are poorly understood. However, DNA injury and activation of nuclear transcription factors may play an important role. The former appears to relate to the physical properties of the asbestos fibers, which enable DNA, RNA, and chromatin to bind to asbestos. Crocidolite asbestos causes double-strand DNA breaks in small airway epithelial cells, which is the site for asbestos-induced fibrosis and carcinogenesis.[51] Reactive oxygen species may also play an important role in this process, since chrysotile asbestos, along with cigarette smoke, synergistically increases the number of breaks in DNA strands, and oxidant scavengers—such as mannitol, catalase, iron chelators, and dimethylsulfoxide prevent this DNA damage. Asbestos also induces nuclear factor-κB DNA binding in tracheal epithelial cells in vitro. NF-κB is an important transcription factor for cytokines, growth factors, and protooncogenes that could contribute in a variety of ways to malignant transformation. Alveolar macrophages also release TNF-α after phagocytosis of asbestos fibers, and TNF-α induces NF-κB in human mesothelial cells leading to increased survival (antiapoptosis).[52] These mesothelial cells exhibit increased mitotic index and metaphases have prematurely separated chromatids or other chromatid abnormalities in vitro cell culture.

CLINICAL FEATURES

The patterns of presentation of lung cancer among asbestos workers are similar to those of high-risk patients: cough, chest pain, dyspnea, hemoptysis, recurrent bouts of pneumonia, and localized wheezing. However, patients can also be asymptomatic at the time of initial discovery, the abnormality being noted on a routine or screening CT scan. Other manifestations of carcinoma – such as rib invasion, shoulder–arm pain, and paraneoplastic syndromes – can also occur in asbestos-related malignancies.

Individuals with asbestosis have an increased risk of lung cancer.[53] Most patients with lung cancer in the Quebec asbestos mining district had small parenchymal opacities on the chest radiograph before death. In amphibole miners from South Africa with carcinoma of the lung who were evaluated by stepwise regression analysis for exposure variables, asbestosis was by far the most striking variable. Moreover, a dose–response relationship was found between the severity of asbestosis and the frequency of lung cancer.[54] In the North American insulator cohort, 18% of the patients who died of lung cancer did not have radiographic evidence of parenchymal fibrosis.[54] Similarly, in a case control study of 271 patients with lung cancer, a small but definite increase in cancer risk was noted in patients whose chest radiographs were not definitely abnormal (0/1 or less).[55] This study indicated that asbestos exposures that do not cause small opacities on the chest radiograph may nevertheless increase the risk of lung cancer.

RADIOGRAPHIC FEATURES

The radiographic manifestations of asbestos-induced lung cancers do not differ, per se, from those of lung cancers associated with other carcinogens. Mass lesions, atelectasis, postobstructive pneumonia, and pleural effusions are all seen. As noted earlier, these lesions are

frequently superimposed on a background of asbestosis or asbestos-induced pleural abnormalities. Confusion with lung cancer may arise from en face pleural plaques or rounded atelectasis. In contrast to lung cancer, however, these abnormalities are stable over time. The helical CT scan, which can evaluate the chest in a single breath, can increase the early detection rate of lung cancer in this high-risk patient population.[27]

DIAGNOSIS

The principles employed in the diagnosis of lung cancer in asbestos workers are identical to those in the diagnosis of pulmonary malignancies in patients exposed to other carcinogenic agents. Appropriate cytological or histological specimens are required. This can be accomplished by sputum analysis or by bronchoscopy with brushings, biopsy, or lavage. Transthoracic needle aspirates, thoracoscopic parenchymal biopsies, or open lung biopsies may be required for definitive diagnosis.

TREATMENT AND PROGNOSIS

The therapeutic approaches utilized for asbestos-related lung cancers are similar to those employed for lung cancers induced under other circumstances. When one is dealing with non–small-cell malignancies, patient operability and resectability need to be evaluated and, if appropriate, surgical extirpation undertaken. The impact of other asbestos-related pulmonary processes must always be taken into account. For example, severe asbestosis may limit operability, and diffuse pleural thickening may make surgical intervention problematic.

EFFORTS AT ASBESTOS CONTROL

In order to control the risk of exposure to asbestos, the Occupational Safety and Health Administration's Permissible Exposure Level not to be exceeded is 0.1 fiber/mL over an 8-hour time-weighted–average.

Industrial hygiene efforts to control exposure have focused on engineering controls, including enclosure of the process lines, especially all sites where asbestos is introduced into a system, increasing ventilation, and the use of wet manufacturing methods. Personal respirators are used as a last resort in achieving control of exposure in the workplace. Most of the insulation-manufacturing industry has switched to alternative materials, especially fibrous glass, rock and slag wool, and refractory ceramic fibers. Animal experiments have generally shown these asbestos substitutes to be safe, except that refractory ceramic fibers were able to produce mesotheliomas in hamsters.

CONCLUSIONS

The asbestos-related diseases should be confined to history with the banning of asbestos in many countries and substitution of other insulating products. However, we have the legacy of past exposures and the continuation of exposures during renovation and destruction of asbestos-containing buildings and products. It continues to be an important area of compensation for workers developing mesothelioma, and for continued research on the mechanisms of fibrosis and carcinogenesis. Biomarkers for detection of lung cancer and mesothelioma are important for early diagnosis. Finally, the global control of asbestos should be a priority for international organizations since there is no further reason for asbestos to remain in commerce.

CHAPTER 87

Chronic Beryllium Disease and Hard-Metal Lung Diseases

Mary Elizabeth Kreider
Milton D. Rossman

CHRONIC BERYLLIUM DISEASE

Beryllium is the lightest metal and has an atomic number 4. Gem stones, such as aquamarine, emerald, and beryl contain beryllium and have been recognized since ancient times. But beryllium, as an element, was first discovered in 1798 by the French chemist, Vauquelin and reduced to its metallic form; subsequently, it was named beryllium in 1828 by the German metallurgist, Wohler. Beryllium became a commercial product when it was used as an alloy first with aluminum and later with copper, nickel, and cobalt after World War I. The industry grew in the 1930s due to the increased use of beryllium–copper products during World War II and the use of beryllium oxide in the refractory and fluorescent lamp industries. During and after World War II, beryllium was used in the nuclear industry because of its ability to function as a neutron multiplier. Beryllium was used for both civilian nuclear reactors and for military weapons.

With an increased industrial need for beryllium, acute chemical pneumonitis was first described by Weber and Engelhardt[1] in Germany in 1933 and in the United States by van Ordstrand et al. in 1943.[2] This condition was usually limited to the upper respiratory tract, though it could extend to the bronchi, bronchioli, and alveoli if there was sufficient exposure. This condition peaked in the 1940s and will not only be seen if there are plant explosions or other serious lapses in procedures.[3] The last reported possible case in the United States occurred in the early 1980s.

A second pulmonary complication of beryllium exposure was first described by Hardy and Tabershaw[4] in 1946. This disease differed from the acute chemical pneumonitis because of the delayed onset, granulomatous response, and chronic course. Now known as chronic beryllium disease (CBD), this condition is a hypersensitivity reaction to beryllium and is the major hazard facing beryllium workers today.

CLINICAL PRESENTATION

CBD is primarily a pulmonary granulomatous disorder. Although involvement of other organ systems has been reported (e.g., lymph node, skin, and liver), the lungs are the principal organ affected and account for the morbidity and mortality of this disease.[5,6] In the early stages, CBD may be asymptomatic. A positive blood proliferative response to beryllium (evidence for beryllium hypersensitivity) may be the earliest sign of CBD.[7,8] Radiologic changes can also be detected on routine chest radiographs. Symptomatic disease usually begins with nonspecific respiratory complaints, such as dyspnea and cough. Early in the disease process, routine chest radiography may not be helpful. Pulmonary function testing early in the disease may be normal or have an isolated abnormality of the diffusing capacity (D_{LCO}).[9] As the disease progresses, symptoms become more characteristic for chronic interstitial lung disease (ILD) with a nonproductive cough, substernal burning pain, and progressive exertional dyspnea. At this stage dry bibasilar crackles are observed on physical examination. A rare patient may have asthmatic-type complaints and physical findings. With advanced disease progressive weakness, easy fatigability, dyspnea at rest, anorexia, and weight loss may occur and acrocyanosis and clubbing may be observed. As cor pulmonale develops, peripheral edema, hepatomegaly, and distended neck veins are seen.[10] Fever is unusual but can be seen. Hypercalcemia and nephrocalcinosis, hyperuricemia, joint pains, and severe cachexia have been described. Severe liver involvement has not been seen, but liver granulomas with mild elevation of the liver function tests occur. Skin involvement may occur in 10% to 30% of cases and frequently involves small granulomatous nodules on the hands, arms, and chest.[5]

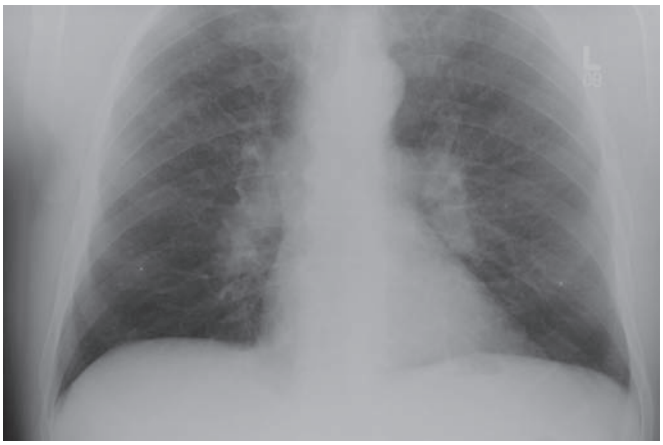
RADIOGRAPHY

Radiographic changes in CBD are nonspecific and cannot be differentiated from sarcoidosis (Fig. 87-1). The most common radiographic abnormalities are diffuse round and reticular abnormalities.[11,12] While most patients have both round and reticular nodules, opacities may be only round or only reticular. These opacities are usually present diffusely throughout the lungs but may be confined to the upper lobes. Hilar adenopathy similar to what is commonly observed in sarcoidosis may also be seen in up to 50% of cases. However, the large "potato type" node involvement is not seen. As the disease advances, radiologic evidence of scarring and retraction can be seen. The hila are retracted upward and conglomerate mass and emphysematous bullae may be present. Gross architectural distortion can occur from severe fibrosis. Pleural thickening can be seen in the presence of long-standing disease. In early disease, complete resolution of radiographic abnormalities can occur secondary to corticosteroid therapy and may recur as the corticosteroids are tapered.[13] Complete spontaneous disappearance of the radiographic lesions has not been observed. The computed tomographic appearance of CBD includes upper lobe or diffuse fibrosis, pulmonary nodularity, and hilar and mediastinal adenopathy. However, in biopsy-proven CBD the computed tomographic findings may be normal or demonstrate ground-glass changes.

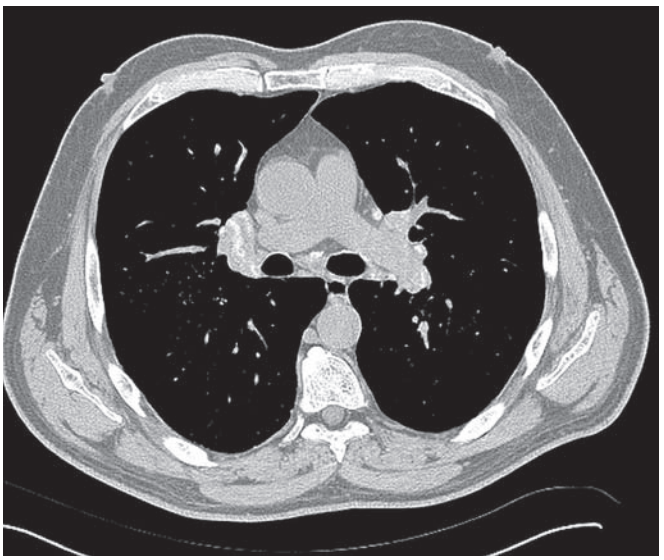
IMMUNOPATHOGENESIS

There are three important characteristics of CBD. First, this disease is usually associated with industrial exposure to beryllium. The only cases that have been described in nonindustrial workers have been in individuals who lived near beryllium plants and were either exposed to the airborne emissions from the plant or from family members who brought contaminated work clothes into the home.[14,15] All other cases have been described in individuals who have been involved in the heating, grinding, abrading, or handling of beryllium metals, alloys, salts, or oxides. In addition, workers not directly handling beryllium may be exposed from processes occurring near them. Industrial hygienic practices today include efforts to remove potential airborne beryllium at the source to prevent beryllium from becoming airborne, limiting the number of workers with potential exposure to beryllium, limiting skin exposure, and trying to keep the airborne levels as low as possible.[16] Recently, the Department of Energy has used 0.2 $\mu g/m^3$ as an action level because of the repeated reports of CBD with possible exposure below the Occupational Safety and Health Administration (OSHA) recommended threshold level of 2 $\mu g/m^3$/8 h shift.[17]

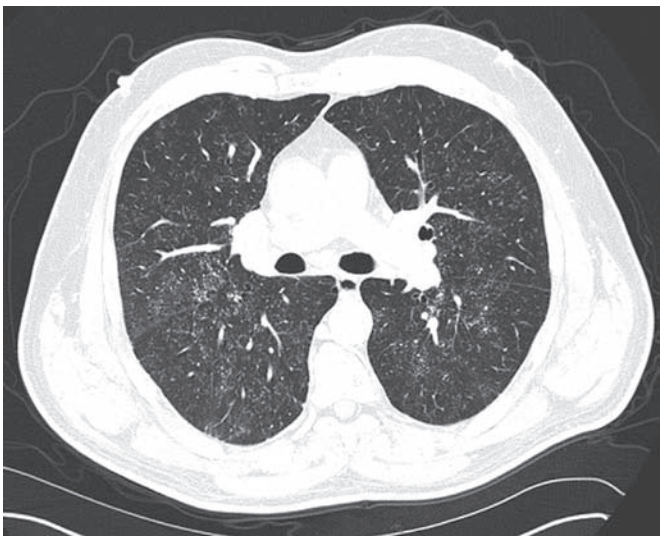
A second important characteristic of CBD is the long time interval or latency that occurs between initial exposure and the onset of disease.[14] The average time to the onset of clinical symptoms is 10 years. This fact combined with the lack of a clear-cut



A



B



C

Figure 87-1 A 61-year-old male smoker who had worked at a beryllium processing facility for 20 years. He had a productive cough for 10 years but denied any shortness of breath. He had a positive response of both his blood and BAL cells to beryllium (stimulation index [SI] for blood beryllium lymphocyte proliferation test [BeLPT] = 13.8 [NI < 3.0], SI for BAL BeLPT = 306 [NI < 5.0]). His BAL also demonstrated a marked lymphocytosis (cell yield = 6 × 105 cells/mL [NI < 3.0 × 105 cells/mL], lymphocytes = 55.2% [NI <20%]). **A.** Chest radiograph demonstrating nodular interstitial disease with adenopathy. **B.** Chest CT mediastinal window demonstrating calcified bilateral hilar and mediastinal lymph nodes. **C.** Chest CT lung window demonstrating a diffuse fine nodular pattern of interstitial lung disease that was most prominent in the mid and upper lung zones.

dose–response relationship to CBD has hampered efforts to determine a safe level of beryllium. Thus, it is uncertain whether a peak exposure level or a total accumulated dose is more important for the development of CBD. Individuals have been described (i.e., secretaries with apparently little exposure) who have worked in industry for less than 1 year and yet still develop disease years to decades later.

A third important characteristic of CBD is that not all exposed workers will develop the disease. Only 1% to 8% of exposed workers will ever develop the disease.[14] This percentage appears to have remained the same despite dramatic efforts by industry to reduce the potential exposure in their workers. This last characteristic of CBD is most likely due to a genetic predisposition.

The suspicion that an immunologic reaction to beryllium caused CBD was based on the following observations: (1) Beryllium painted on the skin (patch testing) could elicit delayed-type hypersensitivity reactions in patients with CBD.[18] However, because of the concern that patch testing could sensitize individuals to beryllium, skin testing has not been widely used. (2) CBD was associated with "immunologic granuloma." (3) Finally, animal studies demonstrated that a hypersensitivity could be demonstrated in animals and that this could be passed with cells.[19]

In vitro studies that simulated patch testing were developed in the 1970s and applied to patients with CBD.[20,21] The blood cells from a large percent of patients with CBD had positive proliferative responses to beryllium. In addition, after stimulation with beryllium, blood cells from many patients with CBD could release the lymphokine, macrophage inhibition factor. However, all patients with CBD did not have positive responses with their blood cells.[22]

The confirmation that CBD was due to a cell-mediated response to beryllium came in the 1980s when cells harvested from the bronchoalveolar lavage fluid (BALF) from patients with CBD were examined.[23] Not only was a marked increase in the number and percent of CD4+ T lymphocytes in the BALF noted, but also a positive proliferative response of bronchoalveolar lymphocytes to beryllium was observed. Positive proliferative responses to beryllium were observed in all cases of CBD and negative responses were noted in beryllium workers with biopsy-proven, non-beryllium lung disease, patients with sarcoidosis and no history of beryllium exposure, and normal volunteers.[24,25] Not only did all patients with CBD have a positive proliferative response of their bronchoalveolar cells to beryllium, but this response was more pronounced in their lung cells than their blood cells. The accumulation of beryllium-specific cells in the

lungs of patients with CBD has been confirmed and shown to be due to effector memory T cells[26] that produce TH1 cytokines (IL-2, γ-interferon, TNFα).[27,28] The T-cell response to beryllium is oligoclonal[29] and the response can be blocked by anti-HLA DP antibodies and requires the presence of HLA-DP2 antigen presenting cells.[30]

The CD4+ T-cell response to beryllium suggested that specific HLA class II molecules might be involved in CBD, since HLA class II molecules present antigenic peptides to CD4+ T cells. A strong association of CBD with the marker HLA DPB1-glu 69 was first shown by Richeldi et al.[31] and subsequently confirmed in three other laboratories.[32–34] However, rather than just a marker for CBD, this marker appears to be associated with the ability to develop an immune response to beryllium. The less frequent alleles that code for DPB1-glu 69 appear to be more associated with beryllium sensitization and disease than the more common alleles.[35,36] The crystal structure of HLA-DP2 has been solved[37] and helps to explain the association with beryllium disease. βGlu 69 lies in a pocket that is accessible to beryllium. In addition, two additional acidic amino acids, βGlu 26 and βGlu 69, lie in this pocket. Mutation of any one of these three amino acids eliminated the ability of the molecule to present beryllium to sensitized T cells. A similar molecule on DR may be responsible for the development of beryllium sensitization in those who do not have HLA DPB1-glu 69.[35] Additional genes probably account for the progression from beryllium sensitization to disease. Polymorphisms on a number of genes including IL-1 A,[38] CC chemokine receptor 5,[39] BTNL2 in DP glu 69 negative individuals,[40] and TGFb1[41] have been identified as a possibility progression factor for the development of CBD. No association has been found with TNFα promoter regions[42] or the TNFα gene.[43]

The previously mentioned studies suggest the following model for the pathogenesis of CBD. Beryllium is inhaled and deposited in the periphery of the lung. Beryllium, either alone as a crystal or combined with a normal lung protein(s), is bound by glu 69–containing DPB1 molecules and presented to beryllium-specific T cells. The beryllium protein or beryllium crystal is poorly digestible and cannot be removed by the immune response. Persistent inflammation leads to granuloma formation. The cells of the granuloma secrete enzymes that cause tissue destruction and fibrosis.

DIAGNOSIS

Because of the frequent need for corticosteroid treatment of patients with CBD, all patients should have tissue confirmation of their diagnosis. A confirmed diagnosis of CBD requires demonstration of a granulomatous reaction secondary to beryllium hypersensitivity. The former requires biopsy material. The latter can be most convincingly demonstrated by testing the proliferative response of bronchoalveolar cells to beryllium. If bronchoalveolar lavage (BAL) cells cannot be easily or safely obtained, testing of blood proliferative responses to beryllium is a reasonable alternative. Laboratories performing these tests are listed in Table 87-1. In cases where biopsy demonstration of granulomatous inflammation is not possible, radiologic evidence of granulomatous inflammation may substitute.

Because immunologic tests of beryllium hypersensitivity have been available only since the late 1980s, their use for screening worker populations is not clear. However, studies to date indicate that blood proliferative response to beryllium is the most sensitive screening test for CBD. The major difficulty with using the blood proliferative response to beryllium as a screening tool is that not all individuals with beryllium sensitization will go on to develop CBD. In addition, the number of workers with beryllium sensitization that ultimately develop symptomatic CBD that requires treatment is unknown but may be relatively low[8] and is probably less than 10%.

In addition, the justification for a screening test requires that there must be some action that will alter the course of the disease.

Although it is generally believed that early treatment of CBD will alter the natural course of this condition, this is not certain.[44] In addition, removal from further exposure, a prudent but unproven practice, is possible for current workers but would not be applicable to former workers. Thus, the strongest recommendation for use of the beryllium lymphocyte proliferation test as a screening test can be made for current workers. Recommendations for screening former workers and residents of communities with past beryllium exposure from the ambient air are less certain. Nevertheless, because the risk of developing CBD is lifelong, the question of appropriate screening for exposed individuals' remains.

DIFFERENTIAL DIAGNOSIS

The major challenge to making the diagnosis of CBD is to think of the possibility of beryllium exposure. Most cases of CBD that are misdiagnosed are diagnosed as sarcoidosis because either the exposure to beryllium was not known by the patient or the physician failed to elicit an occupational history. In 84 cases of sarcoidosis with a history of possible beryllium exposure, a final diagnosis of CBD was made in 34 with a mean delay from the diagnosis of sarcoidosis of 4 years.[45] A similar search for cases of beryllium disease in a cohort of sarcoidosis patients, failed to identify any cases of beryllium disease.[46] Because the radiographic and clinical presentation of CBD (Table 87-2) is similar to sarcoidosis,[47] the differential diagnosis includes upper-lobe fibrotic processes (Table 87-3). In addition, as for sarcoidosis, other causes of granulomatous disease must be searched for and eliminated. The differential between

TABLE 87-2 Comparison of Chronic Beryllium Disease and Sarcoidosis

Manifestations	Sarcoidosis	Chronic Beryllium Disease
Erythema nodosum	10–20%	Absent
Hilar adenopathy	50–75%	<50%
Peripheral adenopathy	Occasional	Rare
Hypercalcemia	Occasional	Rare
Nephrocalcinosis	Rare	Rare
Bone changes	In chronic disease	Absent
Parotid involvement	Occasional	Absent
Posterior uveitis	Occasional	Absent
Liver involvement	Common	Frequent
Splenomegaly	Rare	Rare
Skin	Uncommon	Unusual
CNS	Occasional	Absent
Response to steroids	Only active disease	Only active disease

Idiopathic pulmonary fibrosis

sarcoidosis and CBD depends upon the result of the proliferation test to beryllium. Patients with sarcoidosis do not respond to blood proliferation to beryllium, while CBD patients do. Cases of sarcoidosis among beryllium workers can be diagnosed in this manner. However, caution should always be used and repeatedly negative blood and lung tests should be determined before accepting a case of granulomatous lung disease in a beryllium worker as sarcoidosis.

TREATMENT

No standard approach to the use of corticosteroids has been adopted in the treatment of CBD.[48–50] Because of the side effects, corticosteroids should be reserved for patients with documented pulmonary impairment or those with progressive deterioration. Doses of corticosteroids should be tapered to the lowest dose that controls signs of active disease. Monitoring of patients with chest radiographs, pulmonary function tests, and exercise tests may be useful. Most cases of CBD will be arrested with corticosteroid treatment. In cases of corticosteroid resistance or end-stage disease discovered at initial diagnosis, lung transplantation may be a reasonable approach.

Little data are available on the use of steroid sparing medications.[51] A recent trial of the anti-TNFα antibody showed no significant clinical response in a very small cohort.[52]

The long-term prognosis for CBD is uncertain. Follow-up of cases that were diagnosed in the 1940s and 1950s suggest that the mortality of the disease might be as high as 30%.[5] Whether a similar mortality will be present in patients with disease diagnosed since the 1990s is not certain. Newer techniques to diagnose CBD (immunologic testing) enable the disease to be detected earlier. The natural history of this condition detected at the presymptomatic stage is unknown. The two major questions are whether or not the disease detected early is inevitably progressive and whether the disease will be more responsive to corticosteroid therapy.

BERYLLIUM AND LUNG CANCER

Animal studies have clearly indicated that beryllium is carcinogenic. Whether beryllium is carcinogenic in humans is not clear. A National Institute for Occupational Safety and Health (NIOSH) study suggests that a small increase in lung cancer (SMR = 1.17)[53] may occur in beryllium workers. However, this finding has been challenged because of the poor data with regard to cigarette smoking.[54] This issue will remain controversial, as additional studies are not currently planned. Whatever the risk of cancer is in beryllium workers, the more significant medical concern is CBD.

HARD-METAL LUNG DISEASE

Hard metal is an alloy of tungsten carbide in a matrix of cobalt into which smaller amounts of chromium, molybdenum, nickel, niobium, tantalum, titanium, and/or vanadium may be added. These components are milled to a fine powder, mixed together, pressed into the desired shape, and heated under pressure between 800° and 1000°C, yielding a product with a chalk-like consistency. The material may then undergo additional machining before being baked at 1500°C, which is above the melting point of cobalt and leads to the formation of an alloy that is 90% to 95% as hard as a diamond.[55] Because of this property, hard metal is an important component in cutting tools, drill bits, armor plate, and jet engine parts.

Hard metal was developed in the 1920s, and ILD was first reported in hard-metal workers in 1940.[56] Lung disease has been noted to occur in those working in both the initial production of hard metal and the machining and maintenance of hard-metal tool components. In addition, although hard metal is not used in the diamond-polishing industry, a similar spectrum of disease has been reported in diamond polishers using steel polishing disks whose cutting surfaces consist of microdiamonds cemented into a fine cobalt mesh.[57] In contrast, workers in the cobalt-producing industry, who are more likely to be exposed to cobalt alone, may develop occupational asthma but appear to be much less likely to develop ILD.

The industrial processes associated with hard-metal lung disease produce respirable fine metallic dust particles. They also produce metallic ions that accumulate in the coolants used in the metalworking procedure and are absorbed through the skin or inhaled in vaporized coolant fluids. To counteract these exposures, the American Conference of Government Industrial Hygienists (ACGIH) have established current permissible exposure limits for cobalt metal, dust, and fumes at an 8-hour threshold-weighted average (TWA) of 0.02 mg/m^3. NIOSH recommends an exposure limit of 0.05 mg/m^3 as a TWA for a 10-hour workday and a 40-hour workweek and OSHA requires an 8-hour TWA of 0.1 mg/m^3.[58]

CLINICAL MANIFESTATIONS IN HARD METAL—AND COBALT—EXPOSED PERSONS

A variety of respiratory syndromes have been associated with exposure to hard metal, most commonly: (1) asthmatic reactions; (2) a form of hypersensitivity lung disease; and (3) interstitial pulmonary fibrosis. The last two forms may be a continuum of the same process with subclinical or unrecognized hypersensitivity alveolitis proceeding to the development of fibrotic lung disease. Hard-metal disease (HMD) has been used to describe all types of lung disease but is most often used to reference the parenchymal or ILD rather than the airway-related manifestations of hard-metal inhalations.

INTERSTITIAL LUNG DISEASE

Interstitial lung disease (ILD) has been seen in hard-metal workers and diamond polishers. Studies have attempted to determine the prevalence of ILD among hard-metal workers. The studies have been frequently limited by lack of appropriate control groups, loss of former workers who may have left the plant due to illness, inconsistent disease detection/definitions, and small numbers. However, despite these limitations it is clear that ILD develops in a small minority of exposed workers. Estimates range from 0.7% to 12.9% in cross-sectional studies.[59–64] A more recent longitudinal study found no ILD in its cohort but it was a small study with more recent exposure and may represent the effects of limiting exposure levels.[65] Reports of exposure intensity, duration, and immediacy have varied a great deal. For instance, in one review of 100 cases of HMD the duration of exposure varied from 1 to 30 years and 1 case was diagnosed 40 years after a 3-year exposure had ceased.[66] Nonsmokers and former smokers also appear to be at higher risk.[67] Interestingly, most studies suggest that workers exposed to cobalt alone without tungsten and other metals do not appear to develop ILD. A few cases of diamond polishers exposed to cobalt alone who have developed ILD have been reported, but this appears to be fairly rare.[68]

In some patients, HMD presents as a hypersensitivity pneumonitis, or allergic alveolitis. These patients manifest fever, anorexia, cough, dyspnea, inspiratory crackles, and fine reticulonodular infiltrates on chest radiograph. Pulmonary function testing typically shows a restrictive pattern, with a reduced D_{LCO}. Symptoms may resolve when exposure is discontinued but may recur with reexposure.[69] Over time, progressive dyspnea, lung function impairment, and interstitial fibrosis may develop. Fibrosis may also occur in the absence of antecedent symptoms. Patients with advanced disease exhibit weight loss, hypoxemia, digital clubbing, pulmonary hypertension, and cor pulmonale.

The histopathologic manifestations of the interstitial disease in these patients can be varied with findings consistent with bronchiolitis, desquamative interstitial pneumonitis, usual interstitial fibrosis, and giant-cell interstitial pneumonitis (GIP). Granuloma formation is infrequent. Lung biopsies may show heterogeneous patchy involvement with foci of active alveolitis, fibrosis, and normal parenchyma. Bronchiolitis may be seen in areas with and without active alveolitis. GIP is characterized by lymphoplasmacytic infiltration, epithelial desquamation, and the presence of numerous multinucleated giant cells in the alveolar spaces.[70] These giant cells are formed by both actively phagocytic alveolar macrophages and type II pneumocytes. Infiltration with eosinophils has also been described. Analysis of BALF may demonstrate hypercellularity with increased numbers of macrophages and giant cells. A relative or absolute increase in the number of lymphocytes with a reduced CD4/CD8 ratio as well as increased numbers of neutrophils, eosinophils, and mast cells, may also be seen. In addition, the multinucleated giant cells can also be found in the BALF, which can be diagnostic of hard-metal lung disease without requiring a surgical lung biopsy.[71,72] One study found that a high number of eosinophils in the BAL that persisted after cessation of exposure and on therapy was associated with a poorer outcome.[72] Electron microscopy with energy dispersive X-ray analysis (EDAX) of the particulate material present in biopsy specimens may demonstrate the presence of the elements used to form hard metal. Because of its high solubility, significant amounts of cobalt is often not present.[66]

Naqvi et al.[66] reviewed 100 cases of HMD identified either by the histologic presence of GIP or with a quantitative EDAX analysis containing tungsten at concentrations greater than 2×10^6 particles per cm^3 of lung tissues. Of these, 59 had changes diagnostic of GIP. In more advanced cases, there were changes of end-stage fibrosis and honeycombing with or without characteristic GIP lesions. Only four cases demonstrated granulomas and of those two also had changes of GIP. They examined 746 cases of ILDs examined by EDAX and found a striking correlation of tungsten with the finding of GIP with higher levels of tungsten being more likely to have GIP. Cobalt was detected in only 36 patients in the larger cohort. Only those who had tungsten present in addition to the cobalt had GIP findings on pathology. They concluded that the presence or absence of cobalt was not useful in diagnosing or excluding HMD. Few studies have looked at the radiography of HMD. Many of the screening studies of cobalt workers rely on plain chest radiographs and use the profusion score of the International Labour Office (ILO). However, a consistent description of the typical findings has not been offered. More recently, with the advent of computed tomography (CT) scans a few case reports have described the CT findings of patients with HMD. Like the pathology, these findings show a wide variability and can include end-stage honeycombing with cystic changes and traction bronchiectasis, to less impressive reticulation and even areas of ground-glass opacities.[73] No pathognomonic finding has been described.

Treatment for this disease consists of discontinuation of exposure and administration of systemic corticosteroids. There is a case report of a patient responding to high dose of inhaled corticosteroids alone.[74] Although no clinical trials have been performed, dosage and duration of treatment similar to those used in other forms of active alveolitis or fibrosis should be considered. Patients with active alveolitis may show a dramatic response to steroids, whereas patients with more prominent fibrosis may show minimal response despite prolonged steroid treatment.[55] Fibrosis can also progress despite cessation of exposure. GIP has been observed to recur after lung transplantation despite cessation of occupational exposure.[66,75]

OCCUPATIONAL ASTHMA

In contradistinction from ILD, asthma can occur in workers exposed to cobalt alone without tungsten.[76,77] The reported prevalence of asthma or wheezing related to cobalt or hard-metal exposure is also low and ranges from 6.6% to 10.9%.[64,76,78] This variation may be attributed to different levels of exposure and the criteria used by various authors to define occupational asthma. As with other forms of occupational asthma, patients may note cough, wheezing, dyspnea, chest tightness, conjunctivitis, and rhinitis. Throughout the workday, symptoms may increase in severity and a progressive decline in peak flow may be demonstrated. Symptoms usually abate during weekends or vacations and often resolve when exposure is discontinued. Upper-airway symptoms may result from either direct airway irritation or atopic responses.

In addition to demonstrating an association between workplace exposure and symptoms, the diagnosis may be confirmed by bronchoprovocation testing (BPT) with cobalt or cobalt salts. Testing with cobalt salts is preferable, as it is much easier to control dosage and delivery of soluble ion solutions than those of particulate substances. Immediate or delayed airway reactivity to cobalt chloride may be observed after BPT.[79] Tungsten carbide has not been shown to produce bronchoconstriction. A positive radioimmunosorbent test (RAST) to cobalt-conjugated human serum albumin has also been reported in some patients, suggesting a type I allergic response. Skin patch testing with cobalt salts does not appear to be of use in diagnosing hard-metal asthma.[79]

Some studies have suggested a dose–response relationship between higher levels of cobalt exposures and lower forced expiratory volume in 1 second (FEV_1) on spirometry and symptoms of asthma.[64,77,80] A twofold increase in the relative odds ratio for work-related wheezing was noted when cobalt exposure exceeded 0.05 mg/m^3.[64] However, asthma and reductions in FEV_1 have been seen at levels below the allowable limit of 0.05 mg/m^3.[81,82] This suggests that the current permissible exposure limit may not protect all workers against the development of cobalt-induced asthma. Because of findings of this sort, baseline evaluations and employee screenings should be performed in workers exposed to hard-metal dust. A reasonable strategy would include assessments for symptoms of rhinitis, conjunctivitis, wheezing, dyspnea, or chest tightness; the relationship of symptoms to work hours; smoking history; physical examination; pulmonary function testing; and chest radiography. In patients with symptoms or findings suggestive of occupational asthma, peak flow monitoring during working and nonworking hours should be performed and other causes of pulmonary function deterioration ruled out. Specific BPT and RAST results may provide additional positive criteria for diagnosis. Personal employee air sampling and measurement of urinary cobalt levels can provide information about ongoing exposure.[83] The workplace should also be examined for levels of cobalt exposure and employee protective practices. However, there may also be long-term respiratory health effects independent of the development of asthma. One recent longitudinal study found that those smokers with higher exposure had a greater fall in their FEV_1 over 10 years than those with less exposure. However, the contribution of the cobalt exposure to the overall expected decline was relatively modest (103 mL in addition to a 518 mL from smoking alone in the highest exposure group).[65]

Treatment for occupational asthma related to cobalt includes control of exposure as well as medical therapy with bronchodilators

and inhaled corticosteroids. Systemic corticosteroid treatment is usually not required.[55]

LUNG CANCER

Cobalt and cobalt-containing compounds have been shown to cause cancer in rats after local injection and intratracheal instillation.[84] The International Agency for Research on Cancer reviewed the evidence for the carcinogenicity of cobalt in 1991 and concluded that although there was sufficient evidence for the carcinogenicity of cobalt metal powder and cobalt oxide in experimental animals, there was inadequate evidence for the carcinogenicity of cobalt and cobalt compounds in humans.[84] Since that publication, however, there have been studies suggesting a relationship. One study of 709 French hard-metal workers found an excess of lung cancer mortality in their workers and the excess was greater in workers with the highest levels of exposures though no relationship with duration of exposure was found.[85] However, this study was not powered to examine the effect of smoking as well so firm conclusions could not be drawn. A second study by the same group of researchers found a twofold higher risk of lung cancer among subjects exposed to both tungsten and cobalt and the odds ratio increased with cumulative exposure.[86] This study was able to adjust for smoking and found the relationship between hard metal and lung cancer held. A more recent study of one of the same plants was published in 2000 and examined mortality again from lung cancer with greater adjustment for smoking and exposure by job matrix.[87] They found an elevated standardized mortality rate that increased with increasing duration, intensity, and cumulative dose of exposure to hard-metal dust. The excess was almost exclusively in subjects exposed to unsintered hard-metal dust.

MECHANISMS OF INJURY

The pathogenesis of the hard-metal–associated lung diseases is poorly understood. There are two predominant hypotheses for the pathogenesis of hard-metal lung toxicity: (1) hypersensitivity with lymphocyte-driven toxicity; and (2) free-radical and cytokine-mediated injury.

Several authors point out the similarities of hard-metal lung disease and hypersensitivity lung disease including the ability of cobalt to function as a hapten in complex with albumin and cause a contact dermatitis.[88] BAL studies of both exposed workers and those with HMD have shown increased lymphocytes with reduction of the helper/suppressor T-cell ratios.[89] In addition, in at least one subject with HMD, a lymphocyte transformation test was found to be positive in the presence of cobalt.[90] Finally, a recent report suggests an association between a glutamic acid residue in position 69 of the HLA-DP beta chain and susceptibility to HMD.[91] This is similar to CBD, a known hypersensitivity disorder.

However, there are features of this disease that do not suggest a hypersensitivity reaction as the mechanism for the disease. Perhaps most obviously is the fact that granulomas, the hallmark of chronic hypersensitivity pneumonitis, are not typically found on biopsy. In addition, the finding that both cobalt and tungsten are required for most (though not all) cases of hard-metal lung disease requires explanation. In vitro studies using peritoneal and alveolar macrophages from rats and mice have demonstrated that the combination of tungsten carbide and cobalt is highly cytotoxic, while cobalt and tungsten carbide alone produce minimal or no cytotoxicity.[92] In addition, the acute lung toxicity of tungsten carbide plus cobalt is much higher than that of each component after intratracheal instillation in rats.[93]

Lison[88] has proposed a mechanism that might explain this interaction. He suggests that tungsten carbide can act as an electron carrier to transfer electrons from cobalt to oxygen. This then leads to the production of free radicals and reactive oxygen species, which, in turn, causes pulmonary damage. Differences in susceptibility to disease would therefore be due to differences in subjects' antioxidant defenses. Further research is required to elucidate the pathophysiology behind hard-metal lung disease.

SUMMARY

This chapter addresses, two metals that cause lung injury. Both beryllium and hard metal can cause interstitial pulmonary inflammation that is immune mediated. Beryllium results in a chronic cell–mediated response that is mediated by CD4+ T cells and results in granuloma formation. The mechanism of hard metal's interstitial inflammatory response is less clear but results in a giant-cell interstitial pneumonia. However, both metals have also been implicated in lung cancer and acute toxicity and hard metal has been associated with an asthmatic reaction. Improved diagnostic approaches to these conditions have resulted in earlier diagnosis and recognition of harmful workplace exposures.

CHAPTER 88

Coal Workers' Lung Diseases and Silicosis

Robert C. Stansbury
Edward L. Petsonk
John E. Parker

COAL WORKERS' LUNG DISEASES

Coal miners are at risk for developing several distinct clinical illnesses in relation to their occupational exposures. Historically, some names applied to these conditions were miners' asthma, phthisis, anthracosis, and in Scotland, miners' black lung. It was recognized early that these afflictions were related to the occupation of mining; however, it was not until the development of specialized techniques such as chest radiography, pulmonary function testing, the discovery of the tubercle bacillus, and sophisticated histologic examination of tissue that respiratory diseases affecting miners could be separated and defined. Recent advances in the understanding of respiratory health issues in coal miners have focused on the spectrum of disease caused by inhalation of coal mine dust, termed coal mine dust lung disease (CMDLD).[1]

CMDLD includes the classic occupational interstitial lung diseases, such as coal worker's pneumoconiosis (CWP), silicosis, and mixed dust pneumoconiosis, but also includes the more recently described entity labeled dust-related diffuse fibrosis (DDF).[1] CMDLD is a preventable occupational disease that results from inhalation of coal mine dust into the lungs leading to parenchymal and airway damage, not only from the foreign material itself but also the tissue's reaction to the dust.[1,2] This disease process was identified as early as the 1800s, but became much more prevalent as coal production increased during the industrial revolution. Unfortunately, disability from coal mine dust exposure went mostly unrecognized by medical authorities in the United States through the first part of the 20th century. Congress finally passed comprehensive legislation with the Federal Coal Mine Health and Safety Act of 1969. This Act went above and beyond previous legislation by providing for the first mandatory standards for working conditions in US mines, a system for enforcement, and ongoing monitoring of miner health, as well as a mechanism for seeking financial compensation for coal miners who could demonstrate total disability arising from their dust exposure (aka "black lung").[3]

Since the time of this landmark legislation further acts by Congress and enforcement agencies have improved miners' working conditions, which now fall under the purview of the Mine Safety and Health Administration (MSHA). Much of our improved understanding of the nature and extent of lung disease associated with mining coal in the United States over the past half century comes from the large number of studies performed by the National Institute for Occupational Safety and Health (NIOSH). Despite increased understanding of CWP and reports of stable or improved dust levels in mines, dust-related respiratory disease remains a significant burden. Most worrisome are recent data suggesting that contemporary dust exposure is leading to rapidly progressive pneumoconiosis particularly in young miners, with a significant impact on pulmonary function and premature death.[4]

COAL AND COAL MINING

Coal is not a pure mineral. It is a spectrum of carbonaceous rocks derived from the accumulation of vegetation sedimented under swampy conditions and subjected to extreme pressure over long periods of time. Coals are characterized by rank, which relates to geologic age, hardness, carbon content, and the amount of heat released (BTUs) when they are burned. Thus, peat is the lowest rank (softest) coal, being geologically the newest, and anthracite is the highest rank (hardest) and oldest type of coal.

Coal may be found in outcroppings and in seams that vary from a few feet to several thousand feet below the surface. Surface or strip mining, which currently accounts for the majority of US coal production, involves removal of the overburden and mining the coal seams with large earth-moving equipment. In some areas of the eastern United States, mountaintop removal mining has become a dominant form of mining. Mountaintop mining involves first removal of all vegetation and soil, and then drilling and blasting through hundreds of feet of strata to access the coal seam. The excess rock and soil is placed in the steep stream beds along the mountainsides, creating areas called valley fills. Occasionally, surface mining is also performed by boring into coal outcrops with an auger. Dust levels measured in the air at surface mines have generally been lower than in underground mines, with a few notable exceptions, but miners who work exclusively at surface operations may still develop advanced forms of pneumoconiosis (discussed below).[5,6] Coal outcrops of sufficient size can be mined deep into the hillsides. Deep seams are accessed through vertical shafts drilled from the surface to the coal seam where the mining process then follows the seam through a series of more or less horizontal tunnels. Shaft drilling, which is frequently performed under contract for mine operators, may present an important silicosis hazard. A majority of the approximately 92,000 coal miners in the US work at underground mines,[3] although deep mines produce somewhat less than half of the coal mined; in China, there are about six million underground miners.[1]

Respirable dust concentration, coal rank, types of mining work, mining category, and duration of exposure are known risk factors for the development of pneumoconiosis.[7] Dust exposure varies significantly between specific tasks within the mines. In underground mining, airborne dust is generally highest during work at the coal-cutting face, where coal is removed from intact seams. Miners involved in roof support (termed roof bolters; see Fig. 88-1), miners who do not use protective respiratory equipment, workers exposed to explosive blasting fumes, and those who use stored mine water for dust suppression spray are all at increased risk for accelerated loss of lung function.[8]

Many miners also have exposure to respirable crystalline silica, placing them at risk for silicosis and or concurrent CWP/silicosis.[9] In particular, silicosis has been recognized among miners performing roof bolting, and drilling operations, as well as motormen who operate underground coal trains and use sand for traction on the rails.[10,11] Workers in some aboveground coal mining operations also may have important exposure to dusts.[5,12] These include workers at tipples and preparation plants, where crushing, sizing, washing, and blending of coal is done, and coal is stored or loaded onto ships, railroad cars, or river barges. At surface coal mines, drilling rigs are used to bore holes in which explosives are placed. Equipment operators may be exposed to silica and silicate dusts from the rock strata, representing a risk for silicosis or mixed dust pneumoconiosis, rather than CWP (Fig. 88-1).

EPIDEMIOLOGY OF LUNG DISEASES IN US COAL MINERS

The first major survey of the health of American coal workers was conducted by the US Public Health Service from 1969 to 1971, evaluating symptoms, lung function, and chest radiographic findings. This study included over 9000 miners at 31 underground mines (2 were anthracite mines; 29 were bituminous mines). Participation in the survey was over 90%. The mines were chosen to represent different geographic areas, coal seams, and mining methods. After this initial study, three subsequent surveys have been conducted to evaluate miners at these and other US mines.

Results of radiographic surveillance from the 1970s through the mid-1990s showed a marked decline in the prevalence of CMDLD.[13,14] The decreased prevalence was a source of great optimism that government regulations and oversight was resulting in improvement in miners' respiratory health. Unfortunately the decline has not continued. Since about 1995, the observed prevalence of CMDLD among miners who participate in health surveillance has been increasing (see Fig. 88-2).[15] In response to this troubling finding, availability of health surveillance for miners was increased. When data from underground miner health surveillance are compared to reported dust measurements, CWP prevalence is less than expected in some regions but substantially greater than expected in others, with some miners experiencing rapid progression of disease.[16]

RADIOGRAPHIC FINDINGS

Radiographic epidemiologic studies and surveillance findings for underground coal miners have been reported over the last four decades. As part of these activities, each miner's chest radiograph is independently interpreted by at least two qualified physicians, using the International Labour Office (ILO) pneumoconiosis classification system (see Table 88-1 for the definition of ILO terminology).[17] Radiographic data from the initial health surveys showed an overall prevalence of simple and complicated CWP of nearly 30%. There was variation in prevalence by region of the country and the type (rank) of coal mined.[18] Enforcement of dust control measures in the United States, fully enacted in 1973, resulted in a declining pneumoconiosis attack rate. This decreased prevalence was confirmed

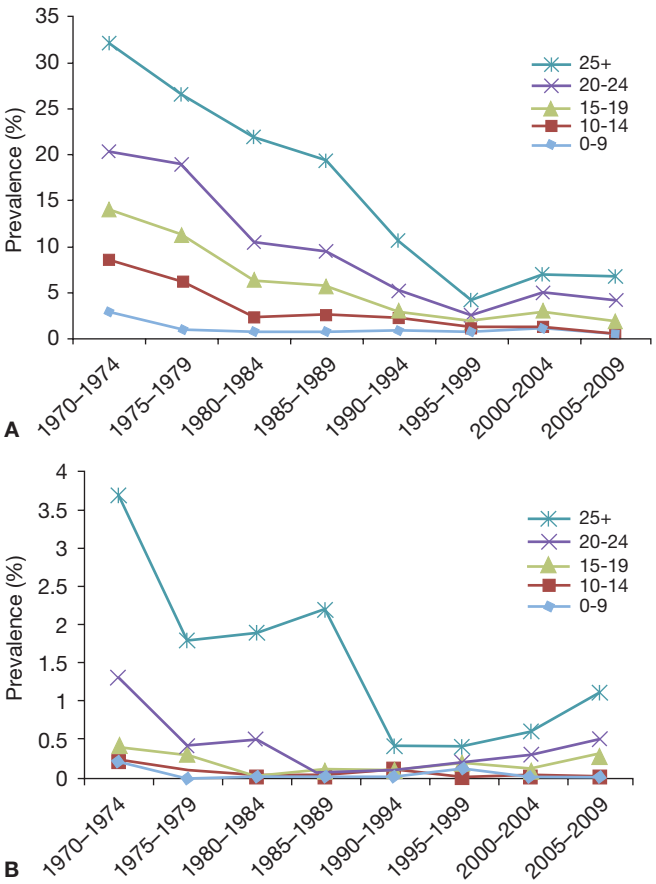

Figure 88-2 Proportion of miners examined in the NIOSH Coal Workers' X-ray Surveillance Program from 1970–2009 with Coal Workers' Pneumoconiosis category 1 or greater (**A**) or progressive massive fibrosis (**B**), by tenure in underground coal mining. *(Adapted with permission from Attfield MD. Centers for Disease Control and Prevention: Current Intelligence Bulletin 64: Coal Mine Dust Exposures and Associated Health Outcomes—A Review of Information Published Since 1995. TABLE 88-1 Definitions of Terminology Used by the International Labour Office Classification to Describe Pneumoconiotic Opacities

ILO Term	Opacity Width	Opacity Type
P	≤1.5 mm	Small rounded
Q	1.5–3 mm	Small rounded
R	≥3–10 mm	Small rounded
S	≤1.5 mm	Linear/irregular
T	1.5–3 mm	Linear/irregular
U	≥3–10 mm	Linear/irregular
A	≥10–50 mm	Large
B	≥50–RUZ mm	Large
C	≥RUZ	Large

RUZ, Right upper (lung) zone.
Source: Data from International Labour Office. Guidelines for the use of the ILO international classification of radiographs of pneumoconiosis. Revised edition 2011. Geneva, Switzerland: International Labour Office; 2011.

through the federally mandated chest radiographic surveillance program for underground US miners.[13,14] Between 1973 and 1978, CWP was found in about one-third of the miners who participated in the program and had worked 25 years or more underground.[14] By 1995 to 1999, only 1 in 25 (4.2%) of these miners showed radiographic evidence of CWP (Table 2011 to 2012 in reference 14).

Regrettably, continued surveillance by NIOSH has revealed a significant increase in the prevalence of radiographic pneumoconiosis (to 7%) in 2005 to 2009 for miners with more than 25 years tenure, since hitting its nadir in the late 1990s.[14] The rate of progressive massive fibrosis (PMF) has also tripled to 1.1% after reaching its low point over a decade ago.[18] Also of interest is the elevated disease prevalence among workers at smaller mines.[19]

Perhaps the most concerning findings of ongoing surveillance studies have been the frequency of rapidly progressive radiographic disease in certain mining populations. During their 2005 analysis, Antao et al. found that in miners with pneumoconiosis, about 35% had rapidly progressive disease. This rapid progression was defined as an increase of greater than one ILO subcategory over 5 years.[16] More worrisome is the fact that 15% developed PMF, the most advanced and debilitating form of the disease. Current studies are now underway to assess the reason(s) for this rapidly progressive form of CMDLD.

Radiographic analysis has been complemented by ventilatory lung function testing as an integral component of respiratory health studies of the mining population. Early reports strived to identify a relationship between radiographic disease and spirometry results. Multiple studies in the United States and abroad have subsequently evaluated the relationship between radiographically evident CMDLD and lung function.[20–22] Although several earlier studies did not associate lung function impairment with uncomplicated CWP, recent analysis has identified significant ventilatory deficits among coal miners with small radiographic opacities, in addition to the important decrements in lung function that have been observed in miners with the large radiographic shadows (>10 mm) of PMF.[4,22,23]

Studies in the United States and Great Britain evaluated lung function with respect to the miners' cumulative dust exposure, and have helped to clarify the adverse effect of dust on coal miners' lung function.[24–26] Miners show a progressively greater risk of lung function loss with increasing cumulative dust exposure, independent of the chest radiographic findings of CWP. The forced expiratory volume in 1 second (FEV_1) loss is most severe in those who work for many years at the dustiest jobs. Among smoking miners, the effects of tobacco smoke appear to be additive and of similar magnitude to the dust effect. Studies of FEV_1 decline have demonstrated essential equivalence between 1 year of work in a job at the coal face and 1 year of cigarette smoking: no disproportionate dust effect has been noted in relation to tobacco use. Also, there is evidence that miners experience a more rapid loss in spirometric function parameters during their first few years of mining, with slower dust-related declines after that time.[27]

In summary, the epidemiologic evidence has shown that coal miners experience ventilatory lung function loss with increasing exposure to dust, either in the presence or absence of radiographic CWP. Among smoking miners, the effects of tobacco and dust appear to be additive. Although, on average, the functional losses associated with either dust or smoking are small, it is estimated that after 35 years of work at the current permissible limit, dust exposures will cause a clinically important FEV_1 loss in 8 out of 100 nonsmoking coal miners. Higher exposures result in greater losses. When chronic bronchitis is present, there is an additional FEV_1 reduction averaging 200 to 250 mL.[7,27] With simple CWP, and especially when PMF is present, an additional ventilatory deficit is likely.

Investigations into miner mortality have been completed in both the United States and Britain. Findings from both countries have been generally consistent, and reveal that the miners experience increased mortality attributable to pneumoconiosis, emphysema, chronic bronchitis, and ischemic heart disease.[28–33] Radiographic findings of advanced CWP (PMF) consistently affect mortality, especially in categories B and C (see Table 88-1 for definition of ILO terminology) whereas among miners with simple CWP, decreases in survival were smaller. Accelerated FEV_1 decline is also associated with increased mortality from both cardiovascular and respiratory causes.[30] Miners' risks of dying from the obstructive airway diseases of emphysema and chronic bronchitis exhibit a different geographic pattern than the mortality from CWP, suggesting that these dust effects have different mechanisms.[31] Attfield and Kuempel[32] analyzed the mortality experience over 22 to 24 years among 8899 working coal miners. Their results revealed increased mortality from nonviolent causes, nonmalignant respiratory disease, and accidents, and confirmed previous results indicating that exposure to coal mine dust leads to increased mortality in the absence of tobacco smoke exposure.

Troubling recent data regarding miners with both rapidly declining lung function and rapid progression of radiographic disease seem to have also had mortality implications. A NIOSH report from 2009 revealed a substantial increase after 2006 in years of potential life lost (YPLL) before age 65 years associated with CWP.[2] A recent study looked at data over the past decade (at current exposure levels). Investigators found rapidly progressive pneumoconiosis and massive fibrosis in relatively young West Virginia coal miners that led not only to important lung dysfunction but also premature death.[4] More documentation for the high risk of contemporary coal mine exposures comes from investigations into mining accidents. Lung tissue analysis was performed on 24 victims of a recent mine explosion. Seventy-one percent (17/24) had autopsy evidence of CMDLD and 16 of the 17 miners with CWP had started working after the modern dust limits were put into effect.[34] The implications of these new studies are incompletely understood, but it is obvious that contemporary miners are still developing severe and fatal CMDLD.

PATHOLOGY OF COAL MINERS' LUNG DISEASES

Heppleston[35] identified the coal macule as a fundamental histopathologic finding in CMDLD in 1953 (Fig. 88-3). In his discussion he described the macule as consisting of a focal collection of coal dust

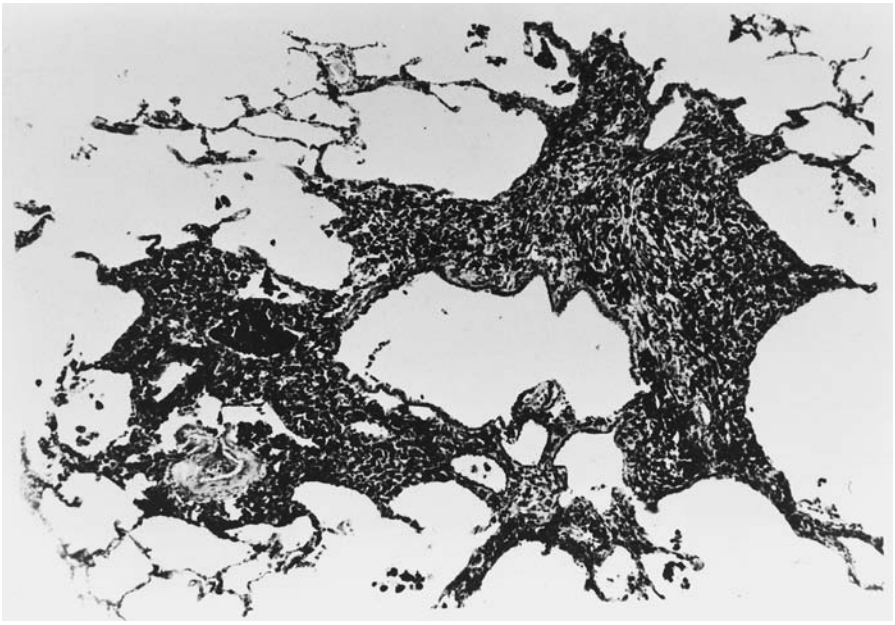

Figure 88-3 A coal macule, microscopic section. *(Used with permission of Dr. Val Vallyathan, National Institute for Occupational Safety and Health, Morgantown, WV.)*

in pigment-laden macrophages around the respiratory bronchioles and tapering off toward the alveolar duct. A fine network of reticulin is present in the early stages and may include a small amount of collagen depending upon the character of the dust.[36] Centriacinar emphysema, the dilation and injury of lung gas exchange units, is observed with increased prevalence in the lungs of coal miners. Focal emphysema is the form of centriacinar emphysema that is seen as an integral part of the lesion of simple CWP. It is characterized by enlargement of the airspaces immediately adjacent to the dust macule. The pathologic severity of the emphysema is proportional to the miner's cumulative dust exposure and increases with increasing lung dust retention.[37–39] Muscular thickening of pulmonary arteries, in conjunction with hypertrophy of the right ventricle, can be observed with both simple and complicated CWP, and is increasingly prominent when CWP is associated with other lung disorders.[40] The development of pulmonary hypertension secondary to these changes may have a profound adverse effect on miner mortality.[41] Pathologic changes in the airways consistent with chronic bronchitis, including enlargement of mucus glands, have also been documented in miners' lungs.[42]

Central to the biology of CMDLD (discussed below) is the alveolar macrophage.[43–45] Dust particles that travel to the distal airways (beyond the mucociliary escalator) are engulfed by alveolar macrophages and removed from the airways and lung parenchyma via lymphatics. With extended excessive dust exposure, this system is overwhelmed and coal mine dusts as well as dust-laden macrophages begin to accumulate in the airway walls and interstitium. Recent evidence suggests that important lung functional losses observed during coal mining work may at least in part be related to this dust reaction in the small airways.[46] With ongoing dust deposition and inadequate clearance mechanisms, these lung lesions increase in size and number. These larger fibrotic lesions are called coal nodules and are palpable in lung specimens, whereas coal macules are not. Palpable coal nodules are classified as micronodular up to 7 mm in diameter and macronodular from 7 mm and larger.[47]

A less common form of CMDLD and silicosis labeled DDF has been increasingly recognized. This finding had previously been interpreted as representing the development of usual interstitial pneumonitis (UIP) in miners. Recognition of a pulmonary fibrosis pattern related to CMDLD has been supported by case reports and several studies.[48–50] In their position paper the Industrial Injuries Advisory Council (IIAC) found "there is good evidence for a form of interstitial fibrosis which is really part of the disease process of CWP and is not typical of cases of interstitial fibrosis in noncoal workers." DDF has been described in pathologic terms as a bridging fibrosis connecting various stages of CMDLD lesions and/or lesions of silicosis, and has been found in approximately 12% of coal miners at autopsy.[50] An occupational history is of utmost importance to the proper clinical recognition of DDF as opposed to UIP.[1] This distinction is of importance both from a prognostic and management standpoint.

At autopsy, complicated CWP (PMF) is confirmed when one or more nodules in a lung specimen are noted to attain a size of 2 cm or greater in diameter.[47] The 2 cm is an arbitrary choice of a minimal diameter that permits better correlation with clinical and radiographic measurements. (In fact, when radiographic pneumoconiotic shadows are >1 cm, PMF is said to be present.) Lesions are solid, heavily pigmented, and rubbery to hard. They tend to occur symmetrically, but may be asymmetrical, and may cavitate.[51,52] Airways and vessels adjacent to the lesions may be distorted, and within the lesions, they are destroyed. PMF generally occurs in association with background pathologic changes of simple CWP.[53]

BIOLOGY OF COAL WORKERS' PNEUMOCONIOSIS

Numerous studies have evaluated the relationship of coal mine dust exposure and activation of immunologic and inflammatory mechanisms. Soutar et al.[54] reported a study of serum antinuclear antibodies (ANA) and rheumatoid factor (RF) among 109 miners with radiographic evidence of pneumoconiosis attending the London Pneumoconiosis Panel. They reported positive ANA in 17% and RF in 10% of the miners whereas about 2% to 3% positive ANA was expected in a healthy male population. The prevalence of ANA was 9% in simple CWP and 27% in those with category C (PMF). A similar trend was seen with RF, ranging from 6% in simple CWP to 18% in category C. Combining both ANA and RF resulted in prevalences of positive results in 13% of the miners with simple CWP and 45% of those with category C CWP.

Studies of serum immunoglobulins were conducted by Hahon et al.[55] among 155 US coal miners with chest radiographs demonstrating simple CWP, Caplan syndrome (an atypical clinical presentation of pneumoconiosis associated with features of rheumatoid arthritis), or PMF. Among miners with PMF, those mining anthracite coal had

significantly higher serum concentrations of C3, α1-antitrypsin, IgA, and IgG compared to miners from bituminous regions. Compared to normal controls, the miners had elevated C3, α1-antitrypsin, and IgG values. There were few differences in these serum proteins among the miners with simple CWP. The authors did not find any association between the elevated immunoglobulins and FEV_1.

Over the past decade much research has been undertaken to understand the mechanism(s) of coal mine dust–induced inflammation. Compared to controls, miners with CMDLD have been shown to have elevations in both serum and bronchoalveolar lavage (BAL) of several cytokines, which play an important role in lung inflammation and fibrosis, including IL-1β, IL-6, and TNF-α.[56,57] Inflammation resulting from oxidative stress has also been suggested in both human and animal data.[58,59] One potential contributor to miners' increased oxidative stress is the level of bioavailable iron. Iron has the known potential to catalyze oxidant formation through its interaction with oxygen or hydrogen peroxide. The potential of bioavailable iron to induce oxidative stress has been associated ecologically with regional variations of CMDLD prevalence.[60]

Although immunomodulation and inflammation play an important role in the development of CMDLD, the underlying host susceptibilities that lead one miner to develop severe disease in a given environment while another miner may have a relatively minimal disease burden remain elusive. Genetic studies have been unable to identify specific markers of susceptibility to CMDLD, although one study suggested certain polymorphisms of IL-18 may be protective.[61–63] Continued studies on the mechanisms of CMDLD and understanding of disease susceptibility are important, given recent trends in CMDLD epidemiology.

CLINICAL FEATURES OF COAL WORKERS' LUNG DISEASES

Reflecting the diverse lung pathology associated with coal mine dust exposure, it is not surprising that the clinical presentation of the disease may be quite variable. Miners with simple CWP, perhaps detected through a screening radiograph, may deny significant respiratory symptoms. With increased dust exposures, chronic cough and sputum production are more common, regardless of the presence or absence of simple pneumoconiosis.[64] These symptoms are likely related to bronchitic changes in the large airways, including thickening of the airway wall with mucus gland enlargement and hypersecretion that result from continued inhalation of dust particles presenting a chronic burden to the mucociliary escalator.[42,65] A study by Henneberger and Attfield[66] reported symptoms of chronic bronchitis in 35% of seasoned US miners.

Emphysema has been shown to be more common in miners than nonminers, even after controlling for smoking status, and increases with increasing cumulative dust exposure.[37] As would be expected, with more severe airflow obstruction or advanced pneumoconiosis, dyspnea, cough, and sputum production are frequent. The physiologic importance of the small airway lesions from dust exposure has been debated. A pathologic label of mineral dust-related airway disease has been used to describe a lesion of pigmentation and fibrosis specific to walls of the respiratory bronchioles among workers exposed to mineral dusts.[67]

Less commonly, edema of the lower extremities, and findings consistent with cor pulmonale/pulmonary hypertension may occur.[40,41,68] An exceedingly rare but unique clinical manifestation of CMDLD is melanoptysis (expectoration of black sputum). Melanoptysis may be a very worrisome symptom for patients, but is the harmless result of excavation and liquefaction of a PMF lesion.[69]

Clubbing and crackles have not generally been considered features of coal miners' lung diseases, and if noted, should prompt further studies. However, a series of 38 cases of a chronic interstitial pneumonia among coal miners has recently been reported. The clinical findings in these atypical cases included crackles, finger clubbing, restrictive impairment, diffusion block, and neutrophilic BAL.[70] Studies have not associated CWP with an increased risk for development of coexisting mycobacterial infection, in contrast to silicosis, where the risk is well documented. However, in a minority of coal miners, the lungs show classic silicotic nodules.[71] Certainly, coal miners with progressive infiltrates or cavitary lesions in PMF should undergo thorough sputum examination for typical and atypical mycobacteria.[72]

RADIOLOGY OF COAL WORKERS' PNEUMOCONIOSIS

The diagnosis of CWP can be made with confidence based on the classic radiographic findings and the presence of an adequate history (at least 10 years) of coal mine dust exposure without the need for histological confirmation.[1] The radiographic opacities of CMDLD have been well described and are classified according to the ILO system.[17] This system includes a set of standard radiographs, which can facilitate an accurate and consistent approach to recognizing and categorizing the radiographic changes associated with dust exposure. Traditionally analog chest films were used in the classification scheme. This practice changed in 2011 to include classification of digitally acquired images on a high-resolution medical viewing system.[73] Digital systems can provide equivalent results in the recognition and classification of the pneumoconioses, when applied according to professional recommendations.[73,74] The radiograph in simple pneumoconiosis shows small pneumoconiotic opacities, ranging in size from pinhead up to 9 mm in diameter. In a study of working US coal miners with radiographic small opacities, 62% showed mainly rounded small opacities while 38% had predominantly irregular opacities.[75] Irregular opacities were more common in lower lung zones. PMF is characterized by one or more opacities in the lung fields greater than 1 cm. Complicated pneumoconiosis is more commonly seen in the upper lung zones, but is confined to the middle and/or lower zones in about one-fourth of cases.[76,77] Although there are some limitations to the use of standard posteroanterior CXR in the diagnosis of simple CWP and of PMF, standard radiographic evaluation of CMDLD remains important for diagnosis, surveillance, compensation, and disease prevention.[78]

Computed tomography (CT) scanning in coal miners may reveal parenchymal nodules and emphysema when standard radiographs are normal.[79,80] In atypical cases, CT scans may show ground-glass opacities and honeycombing, at times without nodular findings typical of CWP.[70] Radiographic evidence of bronchiectasis has also been reported in coal miners, particularly among those with CWP.[81] CT scanning is currently not recommended in the surveillance of exposed miners, but is likely of use in symptomatic miners with normal plain chest radiography or in miners where alternate diagnoses are being considered.[82] A proposed pneumoconiosis classification scheme for CT has shown good reliability, but has yet to be widely adopted.[83]

Several schemes have been used for classifying the radiographic shadows of pneumoconiosis in epidemiologic studies; currently the ILO 2011 Classification of Radiographs of the Pneumoconioses is the most widely accepted (Table 88-1).[17] When using the ILO system, simple pneumoconiosis is divided into major categories 0, 1, 2, and 3 according to the profusion of small opacities (number per unit area) in the lung fields. Each major category, including 0, is subdivided into 3 subcategories, providing a full range of 12 categories of simple CWP. A reading of category 1/0 indicates the definite presence of opacities consistent with pneumoconiosis. Complicated pneumoconiosis (PMF) is divided into categories A, B, and C, based on the size of the large opacities. The classification also permits documentations of other findings that may be associated with the shadows of simple or complicated pneumoconiosis, such as tuberculosis, cor pulmonale, collapse, consolidation, and emphysema. A system of training and examinations (http://www.cdc.gov/niosh/topics/chestradiography/breader-info.html) is available for physicians who wish to document competence in application of the ILO Classification.

TABLE 88-2 Top 10 Industries and Occupations with Significantly Elevated Proportionate Mortality Ratios for Silicosis, 26 States, 1985–1999. CDC/NIOSH National Occupational Respiratory Mortality System

Industries	Occupations
Metal mining	Miscellaneous metal and plastic-processing machine operators
Miscellaneous nonmetallic mineral and stone products	Hand molders and shapers, except jewelers
Pottery and related products	Hand molding, casting, and forming occupations
Nonmetallic mining and quarrying, except fuel	Crushing and grinding machine operators
Iron and steel foundries	Molding and casting machine operators
Structural clay products	Mining engineers
Coal mining	Mining machine operators
Miscellaneous fabricated metal products	Mining occupations, not elsewhere classified
Miscellaneous retail stores	Supervisors, extractive occupations
Blast furnaces, steelworks, rolling, and finishing mills	Construction trades, not elsewhere classified

The clinician may be presented with the diagnostic dilemma of distinguishing primary or metastatic lung neoplasia from an unusual presentation of PMF or Caplan syndrome. When typical large opacities of PMF occur symmetrically and bilaterally on a background of simple CWP, one can be confident that the lesions are unlikely to represent neoplastic disease. Prior radiographs from medical screening programs are often obtainable, and can help confirm stability or progression over a long time interval. Positron emission tomography with fluorodeoxyglucose (FDG-PET) scanning may be useful in differentiating PMF lesions from malignancy when the mass lesion has a low level of glucose metabolism, although some massive pneumoconiotic lesions may demonstrate an uptake of fluorodeoxyglucose similar to neoplasms.[84] On magnetic resonance imaging (MRI) with contrast enhancement, the pattern of change over time in signal intensity has been reported to be a differential criterion in this setting.[84,85] When the imaging workup is equivocal, the differentiation of PMF from neoplasm may be impossible without a biopsy. In this case, patients with CMDLD who are deemed potential candidates for therapy should undergo biopsy of the suspicious lesion. Hemorrhagic complications may occur during biopsy of PMF lesions due to their vascular nature.

■ LUNG FUNCTION AND RESPIRATORY IMPAIRMENT IN COAL MINERS

As discussed earlier, CMDLD encompasses a spectrum of diseases caused by inhalation of coal mine dust that results in several pathologic processes (simple and complicated CWP, silicosis, DDF, chronic bronchitis, mineral dust airway disease, emphysema, and dust-related airflow limitation), each of which may contribute to adverse physiologic consequences. In an individual miner, the pattern and severity of impairment found will be related to such recognized factors as the intensity and duration of respirable dust exposure, geologic factors (e.g., coal rank, silica content), residence time of dust in the lung, and exposure to other respiratory hazards (e.g., tobacco smoke).[7,8,20–27,31] In miners with airway hyperresponsiveness, greater functional deficits and an increased risk of symptoms may be expected.[86,87] Several other mining exposures may also contribute to lung function loss in coal miners, including gases from underground explosive blasting and aerosols of potentially contaminated water used for dust control.[8] Additional factors implicated in underground coal miners' accelerated lung function declines include weight gain, childhood pneumonia, and childhood environmental smoke exposures.[8]

Ventilatory Function

As CMDLD can manifest pathologically as disease of the lung parenchyma, small airways, and/or large airways, the corresponding physiologic defects appreciated on lung function testing may include obstructive, restrictive, or mixed defects.[46,88] The predominant functional abnormality in a given exposed miner will depend on the relative contribution of emphysema, airway disease, and fibrosis in the individual. Epidemiologic studies, as discussed earlier, have extensively documented the occurrence of exposure-related deficits in FEV_1 and forced vital capacity (FVC) in coal miners.[7,24–27,89,90] Although the magnitude of dust-related decline has varied between studies, an important subgroup of miners with accelerated decrements in lung function (FEV_1 decrease of >60 mL/y) has been identified. These miners were found to have more chest illnesses, respiratory symptoms, and a greater risk of death from cardiovascular or nonmalignant respiratory disease than were their cohorts with more stable lung function.[30] Airflow obstruction developing during coal mining has been associated with physiologic evidence of increased resistance to airflow in small (<2 mm internal diameter) airways, including abnormal airflow at low lung volumes and reduced density dependence of maximum expiratory flows.[46] Not surprisingly, deficits in lung function have also been documented in US surface coal miners.[15]

Gas Exchange

Diffusing capacity has been studied in relation to radiographic changes of coal worker's pneumoconiosis.[90–92] The small rounded opacities seen in miners with simple CWP have not generally been associated with measurable reductions in diffusion capacity, and large opacities of complicated CWP are not predictably associated with decreased diffusion. In contrast, miners with irregular opacities may have significant impairment in diffusion capacity, and abnormalities of gas exchange have been associated with increasing coal mine dust exposure independent of radiographic changes. Investigators have demonstrated a significant correlation between subjective measures of breathlessness and measurements of diffusion capacity, which may not be consistently observed with other pulmonary function parameters including FEV_1.[91] Gas exchange on exercise has also been investigated in coal miners.[40,41,93–95] Many reports have been based on patients referred for disability evaluations, and thus suffer from ill-defined selection biases. Exposure–response relationships are also unclear with respect to findings in these series. Exertional hypoxia, pulmonary arterial hypertension,

and excess ventilation have frequently been observed in miners, particularly those with complicated CWP or airflow obstruction.[1] However, the proportion of miners who show exertional gas exchange abnormalities in the absence of either PMF or clinically important airflow obstruction is still a topic of investigation.

SPECIAL STUDIES

BAL has been used in studying pathogenetic mechanisms in the pulmonary pathology in CWP. Rom et al.[96] reported BAL results for 15 symptomatic, nonsmoking coal miners with simple CWP. They found no significant difference between miners and controls in the number of cells recovered, the percentage distribution, and in the release of superoxide anion or hydrogen peroxide. This contrasted with the findings in subjects with asbestosis and silicosis, whose values for spontaneous release of superoxide and hydrogen peroxide were significantly higher than controls. With regard to fibronectin and alveolar macrophage–derived growth factor, the miners with CWP had values that were elevated above controls and not different from the values obtained in subjects with asbestosis and silicosis.

Wallaert et al.[44] demonstrated significantly increased total number of lung cells recovered from 25 miners with simple and complicated CWP, as well as increased percentages of alveolar macrophages, lymphocytes, and neutrophils. Alveolar cells from miners with simple and complicated CWP spontaneously released significantly more superoxide, demonstrated by chemiluminescence, than controls.

MANAGEMENT OF COAL WORKERS' LUNG DISEASES

There is no specific therapy for CMDLD. Whole lung lavage has been evaluated, but studies to date have not adequately defined the risks, benefits, and role in CMDLD management.[97] Thus, the crux of management is directed toward prevention, early recognition, and treatment of complications. The major clinical challenges are the recognition and management of airflow obstruction, respiratory infection, hypoxemia, respiratory failure, cor pulmonale, arrhythmias, and pneumothorax.

After implementation of the current mandated permissible exposure limit (PEL) of 2 milligrams per cubic meter (mg/m^3) of respirable coal mine dust and improvements in mine dust control methods, the prevalence of CMDLD appeared to have been decreasing.[14] The recent epidemiologic findings of significantly increasing prevalence and rapid progression to severe disease in CMDLD should motivate workers to assure continuous control of dust, participate in medical surveillance programs, and exercise their rights to frequent dust measurements and job transfer when necessary. Previous surveillance programs have monitored worker lung health with chest radiographs every 5 years. The current health risks for coal workers necessitate not only chest imaging but also spirometry (every 1–3 years), to provide an opportunity to protect lung health through early detection of rapid functional declines.[98] Identification of rapidly declining lung function or worsening radiographic disease should prompt strict dust controls and transfer to low dust jobs when available. These workers should also be carefully advised about the risks of further dust exposures. Mine management and workers must assure that ventilation systems, water sprays, and other dust capture devices that are mandated by federal law are operating throughout the workshift and their effectiveness is continuously monitored.

Workers presenting with respiratory symptoms should have careful evaluation. Initial history and examination should be supplemented by a chest radiograph, spirometry with bronchodilators, diffusing capacity, electrocardiogram, and resting arterial blood-gas measurement as indicated.[99] A comprehensive initial evaluation of the pulmonary system allows accurate assessment of the worker's respiratory health status, and serves as a starting point for documenting the response to therapy or progression of disease. For miners who smoke, cessation is important regardless of symptoms, radiographic abnormalities, or functional status. Physician encouragement to stop smoking should be supplemented by support from smoking cessation groups, use of nicotine replacement, pharmacologic aids, and behavior modification techniques.[99]

Symptomatic reversible airflow obstruction may benefit from treatment with inhaled and oral bronchodilators. Patients with severe obstruction and inadequate improvement from the usual measures should be considered for a monitored trial of corticosteroids. If improvement is objectively documented, continuation of inhaled and, rarely, oral steroids may be of benefit. Hypoxemia can be a serious complication in advanced pneumoconiosis. It may be present at rest, with exercise, or during sleep. Chronic hypoxemia can lead to additional complications including polycythemia, pulmonary hypertension, cor pulmonale, and cerebral dysfunction. Therapy with low-flow oxygen is indicated when arterial oxygen tension is 55 torr or less. Oxygen therapy in this setting may improve exercise tolerance, reduce dyspnea, and prevent arrhythmias, polycythemia, and heart failure.[100] Patients with functional abnormalities and/or radiographic CWP should receive appropriate immunization with influenza and pneumococcal vaccines.[101] Bacterial and viral episodes of bronchitis or pneumonia should be promptly recognized and appropriately treated.

Patients with complicated pneumoconiosis, especially those who have been exposed to silica as well as coal mine dust, deserve special attention with regard to mycobacterial infection.[72] These patients are considered at higher risk of TB than the general US population; thus a purified protein derivative test with >10 mm of induration is considered positive.[102] Patients with a history of weight loss, fever, sweats, or malaise should be promptly investigated with chest radiographs and sputum examination for acid-fast bacilli stains and cultures. Occasionally, the sputum may be negative and mycobacterial infection can only be documented by fiberoptic bronchoscopy with brushings and washings. Active tuberculosis in patients with CWP can, in general, be successfully treated with the usual drug regimens provided rifampin is one of the drugs used. However, some authorities would recommend that in coal miners with a significant history of concurrent silica exposure (such as motormen, roof bolters, drillers, and shaft development workers), the treatment regimens for tuberculosis should be more prolonged, and long-term follow-up is indicated in view of several reports of recurrent pulmonary tuberculosis in patients with PMF after completion of apparently adequate therapy.[103]

Respiratory failure may complicate advanced disease in coal miners, as it does in other chronic respiratory diseases. Ventilatory support measures are indicated when the failure is precipitated by a treatable complication. The application of ventilatory support measures should be clarified in advanced directives before the need arises.

Clinicians need to assess the contribution of occupational dust exposures to ventilatory impairments in their patients with a history of coal mine exposure. Factors that can assist in this include a careful work history with documentation of the mining region, duration and categories of coal mine employment, as well as the duration and intensity of any tobacco smoking. Factors associated with an increased risk of a clinically important dust effect are a history of prolonged exposures in dusty jobs, exposures to higher rank coals, a younger age at first employment, and the finding of radiographic changes of CWP. Physicians should assist their patients with job-related impairments in obtaining appropriate compensation through state and national programs.[104]

SILICOSIS

Silicosis is a fibrosing disease of the lungs caused by the inhalation, retention, and pulmonary reaction to crystalline silica.[105] Despite knowledge of the cause of this disorder (inhalation of

dust-containing respirable crystalline silica), this serious and potentially fatal occupational lung disease remains prevalent throughout the world.[106] Silica, or silicon dioxide, is the predominant component of the Earth's crust.[105] Occupational exposure to silica particles of respirable size (aerodynamic diameter of 0.5 to 5 μ) has classically been associated with mining, quarrying, drilling, tunneling, and abrasive blasting with quartz-containing materials (sandblasting).[107–109] Many other occupations (Table 88-1) have potential for silica exposure and development of disease.[105] Because silica sand is inexpensive, accessible, and versatile, millions of workers throughout the world are at risk of disease. Occasionally, silicosis is reported from nonoccupational environmental exposures.[110] The disease is often unrecognized and underreported, and thus its true prevalence is substantially underestimated.[106] Fatal cases of silicosis and multiple cases from the same worksite continue to be recognized.[110,111]

DEFINITION

Silicosis is an occupational lung disease attributable to the inhalation of silicon dioxide, commonly known as silica, in crystalline forms, usually as quartz, but also as other important crystalline forms of silica (i.e., cristobalite and tridymite).[112] These forms are also called "free silica" to distinguish them from the silicates. The silica content in different rock formations, such as sandstone, granite, and slate, varies from 20% to nearly 100%.

WORKERS IN HIGH-RISK OCCUPATIONS AND INDUSTRIES

Silicosis is considered the oldest occupational lung disease (alluded to by Hippocrates and Pliny), while new cases are still reported in both the developed and developing world.[113–117] Workers' respiratory health is at risk whenever the Earth's crust is disturbed, or silica-containing rock or sand is used or processed. Without adequate dust controls, silica exposures in many mechanized industrial processes can be a major cause of morbidity and mortality.[117,118] For instance, after introduction of pneumatic tools in the early 1900s, Vermont granite workers experienced "appallingly high mortality from silicosis and silicotuberculosis," which prompted the state government to enforce dust exposure limits in this industry.[119,120] The type of silica exposure appears to affect the risk of disease—processes such as drilling or sandblasting represent an increased risk of silicosis.[121,122] Even brief periods of exposure to high levels of freshly fractured silica can result in a lifetime increased risk for disease.[123,124] Silicosis frequently develops or progresses after exposures have ceased.[124] In both developed and developing nations, workers in mining, quarrying, tunneling, abrasive blasting, construction, and foundry work continue to develop silicosis.[105] Silicosis also continues to be diagnosed among workers from industries and work settings not previously recognized to offer a risk, reflecting the nearly ubiquitous presence of silica.[111,125]

FORMS OF SILICOSIS: EXPOSURE HISTORY AND CLINICOPATHOLOGIC DESCRIPTIONS

Chronic, accelerated, and acute forms of silicosis have been well characterized.[126] These clinical and pathologic expressions of the disease reflect differing exposure intensities, latency periods, and natural histories. The chronic or classic form usually follows 15 or more years of exposure to respirable dust-containing quartz.[127] Accelerated silicosis results from heavier exposures and develops more rapidly than the chronic form, often with a latency of 5 to 10 years.[127] It generally progresses inexorably even after exposure is interrupted. The acute form of silicosis is a consequence of exposures to high levels of respirable dust which contain silica.[128] The exposure period is usually from several months up to about 5 years, and the clinical course one of rapid progression.

Chronic (or classic) silicosis may be asymptomatic or result in insidiously progressive exertional dyspnea or cough (often mistakenly attributed to the aging process).[113,126] Radiographs show small (<10 mm) rounded opacities predominantly in the upper lung zones.[17,84] The pathologic hallmark in the lungs of patients with the chronic form is the silicotic nodule. The lesion is characterized by a cell-free central area of concentrically arranged, whorled hyalinized collagen fibers, surrounded by cellular connective tissue with reticulin fibers (Fig. 88-4).[129] When examined under polarized light, the silicotic nodule shows birefringent particles, most

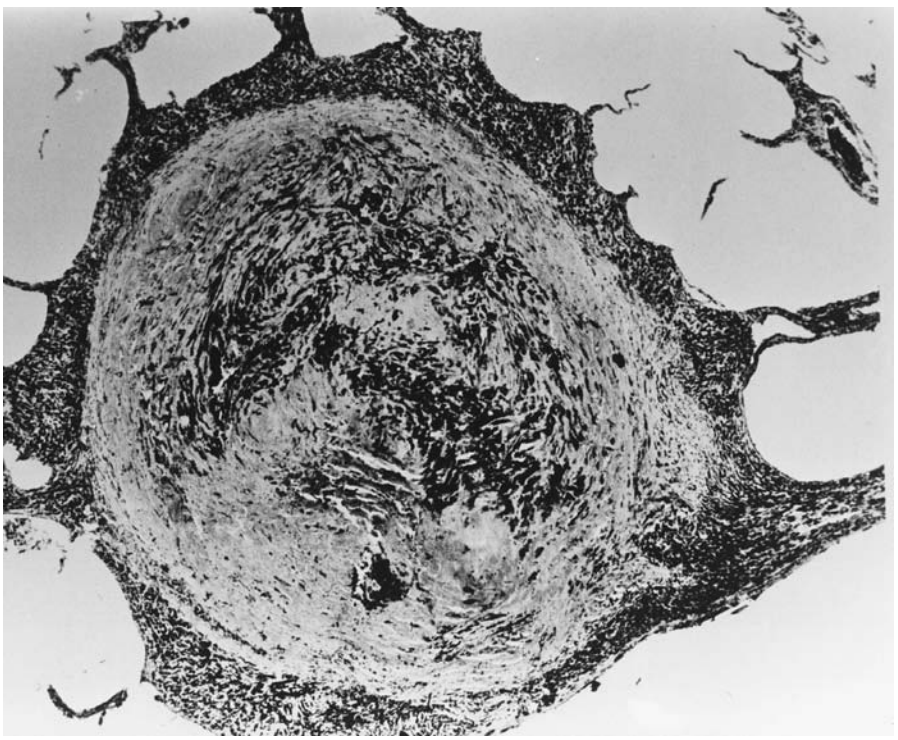

Figure 88-4 Lung pathology showing a classic silicotic nodule. (See text for description.) *(Used with permission of Dr. Val Vallyathan, National Institute for Occupational Safety and Health, Morgantown, WV.)*

Figure 88-5 Radiographic changes of progressive massive fibrosis in a worker with complicated silicosis.

prominent in the periphery.[130] Electron microscopy using specialized techniques can identify the specific mineral content of the particles, but is rarely needed for routine diagnostic purposes.[131] Silicotic nodules in the visceral pleura, regional lymph nodes, and occasionally in other organs, may also result from exposure.[132] The small lung nodules of chronic silicosis may coalesce and result in larger shadows on the chest radiograph (>10 mm), heralding the onset of complicated or conglomerate silicosis (often referred to as PMF) (Fig. 88-5).[17,133] This progressive illness may begin after dust exposure has ceased.[134]

PMF is frequently associated with a clinically important compromise of lung structure and function, and as a consequence, symptoms of exertional dyspnea and reduced functional status.[135,136] Common laboratory findings include a diminished carbon monoxide diffusing capacity, reduced arterial oxygen tension at rest or with exercise, and classically a restrictive pattern on spirometry and lung volume measurement.[105,137,138] Concomitant dust-induced bronchitis or distortion of the bronchial tree may also result in productive cough and multiple studies have now confirmed the presence of airflow obstruction in many patients with silica exposure with or without radiographic silicosis.[137–140] Recurrent bacterial infections may occur.[141] Weight loss and cavitation of the large opacities may herald tuberculosis or other mycobacterial infection.[105] Pneumothorax may be a life-threatening complication, since the lung may be difficult to reexpand.[142] Hypoxemic respiratory failure, cor pulmonale, and congestive heart failure are common late findings.

Accelerated silicosis results from exposures that are more intense and of shorter (5–10 years) duration than in the chronic form, while symptoms, radiographic findings, physiologic measurements, and lung pathology are similar.[143] Deterioration in lung function is more rapid, and mycobacterial infection more common. Findings consistent with autoimmune diseases, including scleroderma, rheumatoid arthritis, antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, autoimmune hemolytic anemia, dermatopolymyositis, or systemic lupus, may be seen in association with silicosis, more often in the accelerated type.[144–147] The progression of radiographic abnormalities and functional impairment can be very rapid when autoimmune disease occurs with silicosis.[141]

Acute silicosis develops within a few months up to about 5 years after a massive inhalation of silica.[145] Dramatic dyspnea, weakness, and weight loss are often presenting symptoms.[143] Unlike chronic forms of silicosis, chest radiographs show diffuse alveolar filling, with a lower lung zone predominance.[148,149] Air bronchograms may be present. Histology resembles pulmonary alveolar proteinosis, with occasional extrapulmonary (renal and hepatic) abnormalities.[145,150–152] The usual clinical course is rapid progression to severe hypoxemic respiratory failure and death.

Tuberculosis may complicate silica exposure alone, and all forms of silicosis, but risk is greatest with acute and accelerated disease.[153,154] Both tuberculosis and nontuberculous (atypical) mycobacterial infections are seen.[127,155]

Even in the absence of radiographic silicosis, silica-exposed workers may also develop other diseases associated with occupational dust exposure, such as chronic bronchitis and the associated emphysema. Progressive declines in lung function have been documented in workers from inhalation of silica and other occupational mineral dust exposures.[139]

PATHOGENESIS AND THE ASSOCIATION WITH TUBERCULOSIS

The precise mechanism of silica toxicity is uncertain, but it is thought to be mediated by generation of reactive oxygen species, both by the surface of silica particles themselves and by activation of alveolar macrophages.[122,156–158] Disease risk is related to the intensity and duration of the exposure; however, there is growing evidence that freshly fractured silica is more toxic than aged silica-containing dusts, perhaps related to reactive groups on the surface cleavage plane.[159] An abundance of evidence implicates the interaction between the pulmonary alveolar macrophage and silica particles deposited in the lung. Release of chemotactic factors (particularly the IL-1 signaling pathway) and inflammatory mediators, such as tumor necrosis factor, result in recruitment of polymorphonuclear leukocytes, lymphocytes, and additional macrophages.[105,112,160,161] The result of this cascade is chronic lung inflammation and eventually fibrosis. The central acellular zone of the silicotic nodule is surrounded by whorls of collagen and fibroblasts, and an active peripheral zone composed of macrophages, fibroblasts, plasma cells, and silica particles (Fig. 88-5).[145] Silica induces macrophage apoptosis, allowing the phagocytosed silica particle to be reintroduced into lung tissues and generate another cycle of phagocytosis and inflammation.[112,162] A large number of mediators have been implicated in the ongoing inflammation and fibrosis associated with silica exposure. These include IL-1B, TNF-α, TGF-β, fibronectin, and a family of inflammatory cytokines known as chemokines.[163–169] A recent study by Sellamuthu et al.[169] investigated mechanisms of crystalline silica–induced pulmonary toxicity by evaluating global gene expression in a human alveolar basal carcinoma epithelial cell line. Their results confirmed the involvement of previously identified molecular targets involved in silica toxicity, but also identified novel molecular pathways likely involved in toxicity. Upregulation of genes that encode for inflammatory cytokines/chemokines that function as chemoattractants, recruit inflammatory cells, especially PMNs, into the lungs, appear to provide mechanisms for propagation and acceleration of initial silica-induced tissue damage.

In acute silicosis, in contrast to the chronic forms, the alveolar space is filled with amorphous lipoproteinaceous material that stains with periodic acid-Schiff (PAS) regent,[151,152] possibly related to abnormal handling and accumulation of pulmonary surfactant.[170–172]

As mentioned earlier among coal miners, DDF has been described in pathologic terms as a bridging fibrosis connecting various lesions of silicosis. This interstitial fibrosis appears to be a unique response in some silica-exposed individuals and is not thought to represent the concurrent development of UIP.

Immune system dysfunction is well described in association with silicosis, including increased prevalence of circulating immune complexes as well as increased production of serum autoantibodies, such as antinuclear antibody and RF.[173,174] The susceptibility of silicotic workers to infections, including tuberculosis and Nocardia asteroides, is likely related to the toxic effect of silica on pulmonary macrophages.[141,175] Thus, silica appears to activate humoral immunity (in a dysregulated manner), while impairing cell-mediated immunity.

Chen et al.[176] studied three cohorts of miners in different industries all with silica exposure. These researchers observed differences in the exposure-related risk of silicosis across the three cohorts. This epidemiologic finding lends support to the basic science literature suggesting that silica dust characteristics, in addition to cumulative respirable silica dust exposure, may affect the risk of silicosis.

CLINICAL PICTURE OF SILICOSIS

When silicosis is symptomatic, the primary symptom is usually dyspnea, first noted with activity or exercise and later, also at rest. However, in the absence of other respiratory disease, shortness of breath may be absent and the presentation may be an asymptomatic worker with an abnormal chest radiograph. The radiograph may at times show quite advanced disease with only minimal symptoms. The appearance or progression of dyspnea may herald the development of complications including tuberculosis, airway obstruction, PMF, or cor pulmonale. Productive cough is often present, secondary to chronic bronchitis from occupational dust exposure, tobacco use, or both. Cough may at times also be attributed to pressure on the trachea or mainstem bronchi from large masses of silicotic lymph nodes.

Other chest symptoms are less common. Hemoptysis is rare and should raise concern for complicating disorders, such as pulmonary neoplasms or mycobacterial infection. Wheeze and chest tightness may occur in silicosis, but usually associated with bronchitis or airflow obstruction. Chest pain and finger clubbing are not typically features of silicosis. Systemic symptoms, such as fever and weight loss, suggest complicating infection or neoplastic disease. Advanced forms of silicosis are associated with progressive respiratory failure with or without cor pulmonale. Few physical signs may be noted unless complications are present; inspiratory crackles are often absent.

RADIOGRAPHIC PATTERNS IN SILICOSIS

The earliest radiographic signs of uncomplicated silicosis are generally small, rounded opacities. These can be categorized using the ILO International Classification of Radiographs of Pneumoconioses by size, shape, and profusion category.[17] In silicosis, rounded opacities of the "q" and "r" type dominate (see Table 88-1 above). Other patterns have also been described, including linear or irregular shadows. The opacities seen on the radiograph represent the summation of pathologic silicotic nodules and associated changes. They are usually found to predominate initially in the upper lung zones and may progress to involve other zones.[84] Hilar lymphadenopathy is also noted, sometimes before nodular parenchymal shadows.[84] Eggshell calcification of the lymph nodes is strongly suggestive of silicosis in the appropriate clinical context, although this feature is uncommon.[177] The development of PMF is indicated by large radiographic opacities, which are categorized by size as A, B, or C (see Table 88-1), using the ILO classification.[17] PMF lesions tend to contract to the upper lung zones, leaving areas of compensatory emphysema at their margins and in the lung bases.[84] The contraction process causes small pneumoconiotic opacities that previously were evident on the radiograph to become less visible or at times disappear. Pleural abnormalities are occasionally observed on routine chest radiographs with silicosis; however, CT scanning often documents localized pleural thickening, particularly in association with conglomerate lesions.[178] Pleural effusions are less frequently noted. The radiographic distinction between large pneumoconiotic lesions and lung malignancies may be difficult, particularly if no earlier radiographs are available. As in complicated CWP, FDG-PET scanning may sometimes be helpful in this distinction, but false positives occur.[179–181] Cavitation or a rapid change in the radiographic appearance of a large silicotic lesion may be due to ischemic necrosis, but should always prompt a vigorous search for mycobacterial disease. Acute silicosis may present with an alveolar filling pattern and rapid development of complicated mass lesions.[148]

LUNG FUNCTIONAL ABNORMALITIES IN SILICOSIS

Pulmonary function tests, including spirometry and diffusing capacity, are helpful in the clinical evaluation of individuals with suspected silicosis. Spirometry may also be of value in early recognition of the health effects from occupational dust exposures, as it may detect physiologic abnormalities that may precede radiographic changes.[182] No specific or characteristic pattern of ventilatory impairment is present in silicosis. Spirometry may be normal, or when abnormal, the tracings may show obstruction, restriction, or a mixed pattern.[182] Numerous studies have investigated the impact of silica dust exposure and lung function.[182–185] These data suggest that obstruction may indeed be the more common finding. Silica and mixed dust exposures may lead to clinically important airflow limitation independent of radiographic abnormality; however there is some evidence that lung function deficits are more associated with silica-related emphysema than nodularity on imaging.[135] Functional changes tend to be more marked with advanced radiologic categories.[135] However, no good correlation exists between radiographic abnormalities and ventilatory impairment, and workers experience lung function loss proportionate to the duration and intensity of silica dust exposure.[137] Diffusing impairment may also occur in the absence of ventilatory impairment. In acute and accelerated silicosis, functional changes generally occur earlier, are more marked, and progress more rapidly.[149,186–188] In acute silicosis, radiographic progression is accompanied by increasing ventilatory impairment and gas exchange abnormalities, which leads to respiratory failure and eventually to death from intractable hypoxemia.[141]

COMPLICATIONS AND SPECIAL DIAGNOSTIC ISSUES IN SILICOSIS

With a history of sufficient exposure and a characteristic radiograph, the diagnosis of silicosis is generally not difficult to establish. Challenges arise when the radiologic features are unusual or the history of exposure is not recognized. Lung biopsy is rarely required to establish the diagnosis. However, tissue samples may be helpful in some clinical settings when complications are present or the differential diagnosis includes tuberculosis, neoplasm, or PMF. Biopsy material should be sent for culture, and in research settings, dust analysis may be a useful additional measure. When tissue is required, open or thoracoscopic lung biopsies are generally necessary for adequate material for examination, to assure satisfactory hemostasis, and due to concern about life-threatening pneumothorax in the fibrotic lung.[189] Some evidence suggests BAL and transbronchial biopsy may be of diagnostic aid in some cases where the diagnosis of silicosis is not straight forward.[189]

Vigilance for infectious complications, especially tuberculosis and other mycobacteria, cannot be overemphasized. Any fever, weight loss, worsening symptoms, or radiographic changes should trigger a workup to exclude this treatable problem. In acute silicosis, Nocardia and fungal infections must be considered.[141]

In 1997, the International Agency for Research on Cancer (IARC) reclassified crystalline silica as a Group I carcinogen. This new designation indicates IARC found "sufficient data" to determine

that crystalline silica in the form of quartz or cristobalite dust is carcinogenic to humans.[190] Uncertainty remains over the pathogenic mechanisms for the development of lung cancer in silica-exposed populations, and the relationship between silicosis (or lung fibrosis) and cancer continues to be studied. IARC noted that a link to carcinogenicity was not detected in every type of industrial exposure, and may be related to an interaction between the silica dust and other environmental factors.[190] Regardless of the mechanism, there is ample evidence confirming a causal link between occupational exposure to silica and lung cancer.

A relationship between renal complications and silica exposure has been suspected since the early 20th century.[191] A 2002 study reported a 5.1% excess risk of end-stage renal disease (ESRD) and a 1.8% excess risk of death from kidney disease in individuals exposed to silica.[192] Glomerulonephritis and nephrotic syndrome have been described in association with silica exposure.[144,193–195] The specific mechanism(s) of renal injury is not completely understood, but evidence suggests injury may occur by both direct (silica particulate in the kidney) and indirect insults (immunologic injury by immune complex formation).[144,195]

Several autoimmune diseases are clearly linked with silica dust exposure.[196,200] Perhaps the most well known of these is scleroderma, first reported in the 1910s and subsequently described by Erasmus (sometimes referred to as Erasmus syndrome) in 1957 from investigations into South African gold miners.[197,198] A study analyzing the prevalence of connective tissue disease in silicosis between 1985 to 2006 reported a 24-fold risk of developing scleroderma among silicotics compared to the general population.[144] This study also found two- to eightfold risks for rheumatoid arthritis and systemic lupus erythematosus, as well as a striking increased prevalence of ANCA-associated vasculitis. A Finnish study also suggested a strong association between silica exposure and rheumatoid arthritis.[199] An earlier NIOSH review of the health implications of silica exposure cited the most commonly associated autoimmune diseases to be scleroderma, systemic lupus erythematosus (lupus), rheumatoid arthritis, autoimmune hemolytic anemia, and dermatomyositis or dermatopolymyositis.[143]

PREVENTION OF SILICOSIS

Prevention remains the principal goal in dealing with this occupational lung disease. Despite the current OSHA PEL for respirable crystalline silica of 100 $\mu g/m^3$ as an 8-hour time-weighted average, silica-exposed workers continue to develop disease.[200,201] NIOSH since 1974 has recommended the PEL be reduced to 50 $\mu g/m^3$ as a time-weighted average for up to 10 hours/d.[200] Effective exposure controls are available for most processes, and include process enclosure, wet abrasive techniques, and local exhaust ventilation, combined with a comprehensive approach to personal protection. Where possible, less hazardous agents should be substituted for silica. Unfortunately, noncompliance with the current permissive exposure limit appears common in many work environments.[202,203] Both employers and workers must remain vigilant regarding the hazards of silica dust exposure and control measures.

If silicosis is recognized in a worker, termination of any continuing exposures is advisable. Unfortunately, the disease often will progress even without further silica exposure. The finding of a case of silicosis is a "sentinel health event" and should prompt a thorough evaluation of workplace exposures and control measures by a competent authority, with the goal of recognizing the sources of the hazard and protecting other workers who may continue to be at risk.

MEDICAL SCREENING AND SURVEILLANCE IN SILICOSIS

Workers exposed to silica and other mineral dusts should be monitored on a regular basis for adverse health effects as a supplement to, but not a substitute for, exposure monitoring and control. Health screening commonly includes periodic evaluation of respiratory symptoms, spirometric abnormalities, and radiographic changes. There is evidence that, if silicosis subsequently develops, workers who have participated in periodic health monitoring experience reduced severity of disease.[204] Evaluation for tuberculosis infection should also be performed. Historically, this was done using intradermal skin testing, although new diagnostic techniques useful in the screening and diagnosis of TB termed interferon gamma release assays (IGRAs) have come to market. While not specifically studied in the silica-exposed population, studies in general populations suggest equal if not great specificity and sensitivity in comparison to standard dermal screening for TB. The advantages offered by these tests include: (1) no interference with the BCG vaccine, (2) subjective interpretation is avoided, (3) a second appointment for reading the results is avoided, (4) the test incorporates a positive control that provides valuable information for interpreting an apparently negative test as either a true negative or indeterminate as a result of technical errors or immunosuppression.[205] In addition to reporting of health surveillance results to the individual workers, health data from all workers at a plant or operation should be periodically analyzed (e.g., every 1–3 years) to assess the adequacy of prevention activities.

THERAPY, MANAGEMENT OF COMPLICATIONS, AND CONTROL OF SILICOSIS

When prevention has been unsuccessful and silicosis has developed, therapy is directed largely at detecting and treating complications. Therapeutic measures are similar to those commonly used in the management of airflow obstruction, infection, pneumothorax, hypoxemia, and respiratory failure complicating other pulmonary disease. Historically, there have been a number of unsuccessful attempts to find a drug treatment that can reverse silicosis.[206,207] Whole lung lavage has been attempted with the hope of removing dust, inflammatory cells, and other mediators to potentially ameliorate disease progression.[97] Currently, there are no data to confirm that this or any other therapy alters the natural progression of human silicosis. Because of the high prevalence of disease in some countries, investigations of combinations of drugs and other interventions continue.

For workers with a diagnosis of silicosis, further exposure to silica-containing dusts is undesirable. If the disease is advanced, or has occurred after a relatively short exposure (i.e., <15 years), then further dust exposure should be assiduously avoided. Advice on job reassignment should be considered in the context of the worker's age, symptoms, functional status, and the current working conditions and measured silica exposures. Patients with silicosis may have few symptoms or findings early in the disease; however, physicians should be aware that many states have a strict time limit, dating from the physician's recognition of findings of silicosis, regarding application for workers' compensation and reimbursement of medical costs.

In the medical management of silicosis, vigilance for complicating infection, especially tuberculosis, is critical. The use of bacillus Calmette-Guérin (BCG) vaccine in the tuberculin-negative silicotic patient is not recommended, but the use of preventive isoniazid (INH) therapy in the tuberculin-positive silicotic patient is advised.[208] The diagnosis of active tuberculosis infection in patients with silicosis can be difficult. Clinical symptoms of weight loss, fever, sweats, and malaise should prompt radiographic evaluation and sputum acid-fast bacilli stains and cultures.[209] Radiographic changes with infection may be subtle and atypical. Enlargement or cavitation in conglomerate lesions or nodular opacities is of particular concern. Bacteriologic studies on expectorated sputum are indicated, but may not be reliable in silicotuberculosis because expectoration may produce only scant numbers of active organisms. Fiberoptic bronchoscopy for additional specimens for culture and

study may be helpful in establishing a diagnosis of active disease. The use of multidrug therapy for suspected active disease is justified at a lower level of suspicion in silicotics, compared to the non-silicotic patient, due to the difficulty in firmly establishing evidence for active infection. To obtain satisfactory results in the presence of silicosis, antituberculous treatment must be more prolonged, with regimens lasting at least 8 months.[103] A multiplicative increase in risk of mycobacterial infection is associated with the combination of silicosis and human immunodeficiency virus (HIV) infection, as has been encountered in South African gold miners.[210] Coinfection with HIV and tuberculosis may also have an adverse impact on progression of silicosis and lung function decline.[211] These infections represent major clinical and public health challenges.[212] Prolonged treatment is essential, and there is potential for both adverse drug reactions and interactions between antiretroviral and antituberculous therapy. Recommended approaches continue to evolve, and clinicians should consult the latest authoritative recommendations.

Ventilatory support for respiratory failure may be indicated when precipitated by a treatable complication. Pneumothorax, spontaneous and ventilator related, is usually treated by chest tube insertion. Bronchopleural fistula may develop, and surgical consultation and management should be considered.

Acute silicosis may rapidly progress to respiratory failure. When this disease resembles pulmonary alveolar proteinosis and severe hypoxemia is present, aggressive therapy has included massive whole lung lavage with the patient under general anesthesia in an attempt to improve gas exchange and remove alveolar debris. Although appealing in concept, the efficacy of whole lung lavage has not been established.[213] Glucocorticoid therapy has also been used for acute silicosis; however, it is also of unproven benefit.[214,215]

Some younger patients with end-stage silicosis may be considered candidates for lung or heart–lung transplantation by centers experienced with this expensive and high-risk procedure.[216] Early referral and evaluation for this intervention may be offered to selected patients.

The discussion of an aggressive and high-technology therapeutic intervention such as transplantation serves to dramatically underscore the serious and potentially fatal nature of silicosis, as well as emphasize the crucial role for primary prevention. The control of silicosis ultimately depends upon the control of workplace dust exposures. This is accomplished by rigorous and conscientious application of fundamental occupational hygiene and engineering principles, with a commitment to the preservation of worker health.

PREVENTION STRATEGIES FOR COAL WORKERS' LUNG DISEASES AND SILICOSIS

The control of coal workers' lung diseases and silicosis in both the developed and developing world requires comprehensive prevention strategies, including exposure control, medical surveillance, research, and education. Example approaches include the following:

- Major efforts must be directed to installation of effective engineering controls and improvements in work practices to progressively reduce dust exposures to recommended levels. These efforts are labeled primary prevention. In selected situations, personal respiratory protection can also play a role, particularly during short-term operations or unusual/emergency conditions, and while engineering controls are being modified or improved. The use of respirators will only be effective when part of a professionally managed comprehensive respiratory protection program, and should never be relied upon outside of such a program.
- Primary prevention should involve ongoing dust exposure monitoring, and include mechanisms for feedback to modify and improve working conditions if exposures are measured above recommended levels. Even exposure at currently permissible levels has been recognized to represent a risk of disease.
- Secondary prevention through medical screening and surveillance should be designed to benefit the individual worker and other potentially exposed workers. Illness identified through medical screening represents a failure of primary prevention, and thus should trigger feedback to those responsible for environmental monitoring, exposure controls, and work practice evaluations.
- Education about the respiratory health hazards from uncontrolled exposures to silica and coal mine dust must be available to workers, employers, managers, and healthcare providers.
- Information on the cumulative burden of disease should be monitored over time for both silica and coal mine dust.
- Research into mining-related lung diseases should be encouraged, to improve recognition, monitoring, exposure reduction, and therapy, and to increase understanding of pathogenesis. Research efforts should supplement, not displace, attention to dust control.
- Clinicians who recognize coal-related diseases or silicosis in their patients should attempt to determine whether ongoing workplace exposures present a continuing risk to current workers, while maintaining the confidentiality of the patient–physician relationship. Assistance in this can often be obtained through local or state health departments, occupational medicine groups, and federal agencies. Reporting of occupational diseases is required in many states.

CONCLUSIONS

Although much is known about the causes, pathogenesis, natural history, and prevention of dust-related respiratory diseases, the pneumoconioses remain important causes of morbidity and mortality in the United States and throughout the world. Healthcare providers need to maintain medical vigilance and familiarity with the clinical features and management of these disorders, especially those whose clinical practice includes persons with significant mining or industrial employment. When patients are exposed to occupational lung hazards, they should be provided effective workplace protections, respiratory health monitoring, timely and accurate recognition and management of dust diseases and their complications, and referrals for public health evaluations and equitable compensation whenever appropriate.

CHAPTER 89

Occupational Asthma, Byssinosis, and Industrial Bronchitis

J. Allen D. Cooper

Inhalation of dusts, fumes, and organic substances at the workplace can cause a number of pulmonary syndromes.[1–4] The lung parenchyma and airways, as well as the pleura, can be affected by inhalation of foreign substances. This chapter discusses reactions of the large airways to inhalation of toxic substances present in the workplace. Lung parenchymal and pleural reactions, as well as obliterative bronchiolitis in response to inhaled materials, are discussed elsewhere in this text. Occupational airway disease can manifest itself as chronic bronchitis with variable airway hyperreactivity (industrial bronchitis or asthma-like syndrome), or with asthma accompanied by persistent hyperreactivity of the airways (occupational asthma). Some occupational exposures can cause both industrial bronchitis and asthma whereas others cause only one or the other. Cotton dust is the most common cause of industrial bronchitis without occupational asthma. Grain dust can cause both industrial bronchitis and asthma. In this chapter, general and specific issues regarding industrial bronchitis and occupational asthma are discussed.

INDUSTRIAL BRONCHITIS

Two important causes of industrial bronchitis - byssinosis and grain dust exposure - are discussed below.

BYSSINOSIS

Adverse pulmonary reactions in cotton workers have been recognized for more than 100 years. In 1831, Kay[5] described chest tightness and fever that commonly occurred on Monday after workers had been off work over the weekend. It was because of this observation that the term *Monday morning fever* was coined. The term *byssinosis* was proposed by the French physician Proust[6] and is derived from the Greek word meaning linen or fine flax. Over the years, as cotton mills appeared in more and more countries, the association of chronic bronchitis with cotton dust exposure was confirmed.

Epidemiology

There is no doubt that recurrent exposure to cotton dust causes acute and chronic bronchitis. In a prospective study, 16% of cotton mill workers in South Carolina developed symptoms of chronic bronchitis,[7] as compared to only 1% of appropriate controls in the region. A very recent study[8] of textile workers in Pakistan confirmed this finding; 16.7% of workers complained of frequent cough and 26.6% of workers had frequent phlegm production. Another recent study of cotton textile workers in China[9] found that the frequency of symptoms of byssinosis increased from 7.6% at baseline to 15.3% after 15 years of working in the textile mill. In this latter study, airway flow rates decreased significantly over time in textile workers when compared to silk workers. The appearance of symptoms during work or worsening of pulmonary function tests during the work shift predicted this accelerated loss of pulmonary function. The association between the length of time working in a textile mill and the onset of symptoms was also confirmed in the study from Pakistan.

Overall textile employment has dropped over the past few years but there are still over 200,000 employed in this industry in the United States.[10] These individuals are at risk for the developing symptoms due to inhalation of cotton dust. Flax and hemp workers are also at risk for developing the disease. Clinical studies suggest that approximately 65% of the general population will react significantly to de novo inhalation of components of cotton dust. Therefore, the majority of individuals who begin employment that entails the processing of cotton, flax, or hemp are at risk for developing respiratory symptoms. Why some individuals are more susceptible than others to the respiratory effects of cotton dust is unclear.

Certain jobs in the textile mill are associated with a higher risk for the development of bronchitis. Ginning, opening, or carding work carries a higher degree of risk. In addition, workers who clean out or maintain the various machines that divide up and clean the cotton are especially prone to developing symptoms. These are particularly high-risk jobs because of the high levels of cotton dust generated during the cleaning procedures. Strippers and grinders, who maintain the carding machinery that cleans and aligns the cotton, are also at risk for the development of symptoms. Indeed, in the past, byssinosis was called "strippers' asthma." In the recent study out of Pakistan, the job of spinning carried a higher risk for the development of respiratory symptoms than weaving.[8]

Clinical Presentation, Risk Factors, and Stages of Byssinosis

Shortness of breath often occurs on the day back to work at the textile mill after several days off, such as on a Monday after being off over the weekend. Overtime workers can develop more persistent symptoms. Schilling[11] has graded byssinosis (Table 89-1) to allow comparison of symptomatology with physiological parameters. Using this grading system, it has been established that workers with a higher grade of symptoms tend to have a more rapid decline in pulmonary function. Risk factors for developing higher grades of byssinosis include length of employment in a cotton mill and level of cotton dust exposure. Tobacco smoking has been shown to be synergistic with exposure to cotton dust in producing chronic bronchitis. There is evidence that exposure to cotton dust without cigarette smoking causes chronic pulmonary disability, approximately 7% of exposed individuals will develop irreversible airway obstruction that cannot be explained by smoking.[10] The degree of decrease in flow rates in function tests before and after work predicts chronic effects.[9]

Pulmonary Function Test Abnormalities

Characteristically,[10] byssinosis is associated with a reduction in the forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1) on the day of return to work after an absence. The degree of reduction in these parameters increases over the workday. This change is generally more severe on the first day of work after an absence and attenuates on subsequent continuous workdays. The

TABLE 89-1 Clinical Grading of Byssinosis as Proposed by Schilling

Grade 0	No symptoms on first day of work
Grade 1/2	Occasional chest tightness or irritation of respiratory tract on the first workday of week
Grade 1	Chest tightness on every first day of work week
Grade 2	Chest tightness on first and other days of work week
Grade 3	Chest tightness on first and other days of work week and physiological evidence of permanent disability

TABLE 89-2 Evidence that Bacterial Endotoxin is the Causative Agent in Byssinosis

1. Measurable levels of endotoxin can be detected in cotton dust.
2. Inhaled endotoxin can induce airway inflammation in animals and humans.
3. In a controlled setting, ambient levels of endotoxin correlate with degree of airflow reduction occurring in a simulated carding room.
4. Repeated inhalation of endotoxin results in an attenuation of the airway response similar to that noted in patients with byssinosis.
5. Measures that reduce levels of ambient endotoxin reduce the incidence of byssinosis.

mechanism by which this developed tolerance occurs is unknown although there are studies demonstrating that the inflammatory effects of endotoxin, the purported causative agent of byssinosis, attenuate with repeat exposure.

Pathology and Pathogenesis of Byssinosis

The histopathology of byssinosis[12] is similar to that of the bronchitis that is induced by tobacco smoke—with hyperplasia of mucus glands and infiltration of the bronchi with polymorphonuclear neutrophils. Several animal studies have demonstrated that different components of cotton dust can recruit neutrophils into bronchi. In addition, components of cotton dust can also stimulate resident pulmonary cells, such as mast cells and macrophages, to release molecules that attract neutrophils.

There is now a large amount of information that points to a lipopolysaccharide (endotoxin) produced by bacterial contaminants of cotton as the causative agent of byssinosis. The evidence for this is listed in Table 89-2. The most compelling study that examines this issue was presented by Castellan et al.,[13] who demonstrated that ambient concentrations of endotoxin in a simulated carding room correlated with reduction in airway flow rates in a time frame similar to that which occurs after exposure to cotton dust in the workplace. An interesting related finding is that byssinosis is less prevalent in Australia, probably because of the lower level of endotoxin in cotton grown in this drier climate.[10] The acquired tolerance during the work week displayed by patients with byssinosis can be simulated by administration of multiple aerosols of endotoxin in animals.[10,13]

Treatment and Prevention

The most important interventions for byssinosis are removal of the symptomatic individual from the offending work environment and reduction in cotton dust as a preventative measure.[10] Screening pulmonary function testing at the workplace is important to identify susceptible individuals who exhibit airflow abnormalities. In addition, since the 1970s, measures have been taken in developed countries to control cotton dust levels in textile mills. One measure has been to steam-clean cotton while it is still in the bale. In 1970, Burlington Industries began a program for dust control and annual medical surveillance. With this program, the incidence of symptoms of byssinosis dropped from 4.5% in 1970 to 0.6% in 1979. In addition, the number of employees who had a significant decrease in FEV_1 over the work shift decreased from 18% in 1971 to 3.5% in 1979. Similar measures have been taken in other textile plants, with good success in controlling byssinosis. Unfortunately these measures have not been implemented worldwide, and there remains a significant prevalence of byssinosis outside of the United States.

GRAIN DUST–INDUCED INDUSTRIAL BRONCHITIS

Exposure to grain dust can also result in the development of chronic bronchitis.[14] This can occur in conjunction with development of organic dust toxic syndrome, a term recently proposed to describe a noninfectious febrile illness associated with chills, malaise, myalgia, dry cough, dyspnea, headache, and nausea that occurs after organic dust exposure. Not only grain workers, but farmers are susceptible to development of this syndrome. Between 4% and 11% of grain workers show a reduction in FEV_1 of 10% or greater over the work shift. This reduction in flow rates is directly related to the amount of dust in the air. Studies have suggested that the component of grain dust responsible for causing airway symptoms is also endotoxin, the apparent active component of cotton dust. Grain dust extract, possibly its endotoxin contaminant, can activate complement, and this may be a mechanism by which grain dust induces inflammation in bronchi. However, in contrast to cotton dust, grain dust can, in sensitive individuals, also precipitate an acute drop in airway flow rates[14] rather than the slow reduction in flow rates similar to that precipitated by cotton dust. This finding suggests that airway reactions to grain dust may be heterogeneous. Grain dust also tends to produce skin abnormalities in affected individuals, in contrast to cotton dust, which generally does not cause skin reactions.[14]

OCCUPATIONAL ASTHMA

Below are considered the definition of occupational asthma, its risk factors, clinical presentation, mechanisms, diagnosis, and management. In addition, multiple specific examples of occupational asthma are discussed.

DEFINITION AND LIST OF OFFENDING AGENTS

Occupational asthma is characterized by variable airway obstruction resulting from exposure to ambient dusts, vapors, gases, or fumes incidentally present at a workplace.[15] Bronchial hyperresponsiveness to nonspecific agents, such as methacholine or histamine, is usually present in these patients. An important differentiation is between the true occupational asthma caused de novo by the offending agent and underlying asthma exacerbated by the offending agent (work exacerbated asthma [WEA]). The 1995 American College of Chest Physicians (ACCP)[4] consensus statement for the diagnosis of occupational asthma includes several criteria that can be used for the definitive or probable diagnosis of the disease (Table 89-3). A more recent (2007)[16] consensus statement further defines steps in

TABLE 89-3 ACCP Case Definition of Occupational Asthma

A. Physician diagnosis of asthma
B. Onset of asthma after entering workplace
C. Association between symptoms of asthma and work
D. One of the following:
1. Workplace exposure to agent known to cause occupational asthma
2. Work-related changes in FEV_1 or PEF
3. Work-related changes in bronchial responsiveness
4. Positive response to specific inhalation challenge test
5. Onset of asthma with a clear association with a symptomatic exposure to an inhaled irritant agent in the workplace
Definite occupational asthma requires A, B, C, and D(2) or D(3) or D(4) or D(5)
Likely occupational asthma requires A, B, C, and D(1)

FEV_1, forced expiratory volume in 1 s; PEF, peak expiratory flow.

TABLE 89-4 ACCP Consensus Statement Regarding Diagnosis and Management of Work-Related Asthma

1.	In all individuals with new-onset or worsening asthma, take a history to screen for work-related asthma (WRA), occupational asthma (OA), and work-exacerbated asthma (WEA).
2.	Obtain a history of job duties, exposures, industry, use of protective devices/equipment, and the presence of respiratory disease in coworkers; and consult material safety data sheets (MSDS) that list many recognized hazardous agents. Document the onset and timing of symptoms, medication use, and lung function, and their temporal relationship to periods at and away from work.
3.	Perform additional objective tests when feasible (e.g., serial peak-flow recordings, serial methacholine challenges, immunologic assessments, induced sputum testing, and SICs) to improve the diagnostic probability.
4.	In individuals with suspected WRA who are currently working at the job in question, record serial measurements of peak flow as part of the diagnostic evaluation and ask the patient to record these optimally a minimum of four times daily, for at least 2 wk at work and 2 wk off work.
5.	In individuals with OA, working at the job in question, perform a methacholine challenge test or obtain comparable measurements of nonspecific airway responsiveness during a working period, and repeat it during a period (optimally, at least 2 wk) away from the work exposure to identify work-related changes.
6.	In individuals with OA, perform immunologic tests (skin prick testing or in vitro specific IgE assays) to identify sensitization to specific work allergens when these tests are technically reliable and available.
7.	For all individuals with WRA, attempt better control of exposures. Remove patients from further exposure to the causative agent in addition to providing other asthma management.
8.	For workers who are potentially exposed to sensitizers or uncontrolled levels of irritants, the panel advises primary prevention through the control of exposures (e.g., elimination, substitution, process modification, respirator use, and engineering control).
9.	An individual diagnosis of OA represents a potential sentinel health event. Evaluate the workplace to identify and prevent other cases of OA.

diagnosis and management of work-related asthma (occupational asthma and work exacerbated asthma) (Table 89-4).

Several hundred agents[17] have been reported to cause occupational asthma. Agents that have been associated with induction of occupational asthma can be conveniently grouped into categories of high- and low–molecular-weight (MW) compounds (Table 89-5). All of these agents tend to sensitize the individual, so that low ambient concentrations of the substance can ultimately cause significant bronchoconstriction. In addition, certain agents can cause direct irritant-related bronchoconstriction and airway hyperreactivity. Because the number of agents associated with occupational asthma is large and expanding, several websites have been established to allow health-care providers to obtain up-to-date information on agents that induce occupational disorders. One of these is www.occupationalasthma.com

RISK FACTORS

Atopy appears to be the major risk factor for developing occupational asthma, particularly when the inciting agent is a high-MW compound that induces an antibody response. Family or personal history of atopy appears to put the subject at risk. Because low-MW agents can induce asthma through nonallergic as well as allergic mechanisms, atopy may not be as important with these agents. Smoking is also a risk factor for the development of occupational asthma, particularly in workers exposed to platinum salts and anhydride compounds.[3] There have been several studies documenting that workers who smoke have a higher incidence of asthmatic reactions to specific airborne agents, possibly due to overall higher immunoglobulin E (IgE) levels in smokers as compared with nonsmokers.[3] There may also be genetic factors that predispose to occupational asthma. Major histocompatibility complex class II proteins are important for development of occupational asthma due to acid anhydrides, diisocyanates, western red cedar, platinum salts, latex, and animal proteins.[18] Certain glutathione S-transferase and N-acetyltransferase genotypes also predict development of occupational asthma in certain settings.[18]

CLINICAL PRESENTATIONS

Occupational asthma presents in a similar manner as other forms of asthma. If the physician does not maintain a high index of suspicion, symptoms will be treated but the inciting agent will not be identified. Two general forms of occupational asthma have been identified: one in which symptoms occur after a period of exposure to the inciting agent (occupational asthma with latency) and another in which symptoms develop immediately with exposure to the agent (occupational asthma without latency or irritant-induced asthma or reactive airway dysfunction syndrome). In general, the former syndrome is associated with a true allergic reaction to the offending agent while the latter is generally mediated nonimmunologically.

Occupational Asthma with Latency

Most commonly patients who develop occupational asthma do so after a period of exposure to the inciting agent. Agents that induce this sort of pattern include high- and low-MW molecules. Individuals are usually exposed to the agent for weeks to months before developing symptoms. With the appearance of symptoms, nonspecific airway hyperreactivity, determined by methacholine or histamine challenge, is present. Also with appearance of symptoms, the individual develops airway reactivity to low ambient concentrations of the offending agent. Therefore, exposure to very low concentrations of the material in the workplace precipitates severe bronchoconstriction in these patients. Controlled simulated exposure with the offending agent will elicit bronchoconstriction in patients with this syndrome, especially when asthma is due to a high-MW molecule.[16,19]

Occupational Asthma without Latency (Irritant-Induced Asthma, Reactive Airway Dysfunction Syndrome)

This syndrome[20] is less common but can be devastating. Symptoms develop within hours of exposure. Pathological changes are generally similar to those occurring in the syndrome of occupational asthma with latency, although epithelial changes such as desquamation and subepithelial fibrosis may be more prominent. Agents that commonly cause this syndrome are irritant gases or fumes such as chlorine or ammonia (see Chapter 90). In addition, certain agents such as acid anhydrides and isocyanates can cause occupational asthma with and without latency. Reactive airway dysfunction syndrome is a form of occupational asthma without latency. The criteria for diagnosis of this syndrome are listed in Table 89-6.

TABLE 89-5 Causes of Occupational Asthma

Categories	Occupations at Risk	Major Putative Component
High–molecular-weight compounds		
Animal products	Animal handlers Veterinarians	Pelt or urinary proteins
Seafoods	Crab or prawn processors Oyster farmers	Water-extractable proteins
Insects	Entomologists Grain workers Laboratory workers River workers Flight crews	Insect proteins
Plants	Grain handlers Bakers Tea workers Brewery chemists Tobacco manufacturers	Extractable plant proteins
Biologic enzymes	Detergent industry workers Bakers Pharmaceutical workers	*Bacillus subtilis*, trypsin, pancreatin, papain, pepsin
Latex	Health care workers Doll manufacturers Glove makers	Latex rubber extract
Gums	Printers Gum manufacturers	Gum acacia Gum tragacanth
Low–molecular-weight compounds		
Diisocyanates	Polyurethane workers Plastic workers Foundry workers Spray painters	Isocyanate-protein complex
Anhydrides	Epoxy resin workers Plastics workers	Phthalic anhydride-protein complexes
Wood dust	Carpenters Sawmill workers	Plicatic acid (western red cedar) Wood dust extracts
Fluxes	Aluminum solderers Electronics workers	Aminoethylethanolamine
Pharmaceuticals	Pharmaceutical manufacturers	Antibiotics, psyllium, piperazine
Fixatives	Hospital workers	Formaldehyde, glutaraldehyde
Diesel exhaust	Farmers, diesel mechanics	Nitrogen oxides, sulfur dioxide, particulates

TABLE 89-6 Diagnostic Criteria for Reactive Airway Dysfunction Syndrome (RADS)

1. There is an absence of pre-existing respiratory disorder, asthma symptomatology, or a history of asthma in remission and an exclusion of conditions that can simulate asthma.
2. The onset of asthma occurs after a single exposure or an accident.
3. The exposure is to an irritant vapor, gas, fumes, or smoke in very high concentrations.
4. The onset of asthma symptoms develops within minutes to hours and less than 24 h after the exposure.
5. There is a positive methacholine challenge test finding or equivalent test, which signifies hyperreactive airways, following the exposure.
6. There may or may not be airflow obstruction confirmed with pulmonary function testing.
7. There is exclusion of another pulmonary disorder that explains the symptoms and findings.

MECHANISMS AND PATHOLOGY

Both high- and low- molecular weight compounds may promote development of occupational asthma.

High–Molecular-Weight Compounds

Most commonly, high-MW compounds, usually proteins produced at the workplace, induce asthma through IgE-dependent classic immediate hypersensitivity reactions. Specific serum IgE antibodies to the protein can usually be demonstrated and skin tests using extracts of the substance show positive results. Atopic individuals are more at risk for developing the syndrome. Because specific IgE antibodies must be produced in this setting, the latent period for developing the reaction can be long, sometimes several months or years. Pathologically, asthma due to high-MW compounds is associated with bronchial infiltration of lymphocytes and eosinophils, indistinguishable from other forms of allergic asthma. Specific IgE antibodies to occupation-related allergens trigger mast cell degranulation in a similar manner as in the nonoccupational setting. In severe cases, bronchial epithelial desquamation and subepithelial fibrosis are exhibited pathologically.[18]

Low–Molecular-Weight Compound

These agents also tend to cause IgE-dependent bronchoconstriction. However, in contrast to higher-MW agents, specific IgE or IgG antibodies produced in these individuals are directed at the low-MW compound coupled to a protein within the serum.[16,18] There is also some evidence that low-MW compounds induce asthma through IgE-independent mechanisms, possibly by affecting T lymphocytes directly, as shown for cobalt and nickel salts as well as isocyanates.[18] Interestingly, the bronchial pathology is similar whether or not the response is an IgE-dependent reaction.[18] In addition, certain low-MW compounds can directly affect chemical pathways that are involved in airway tone. For example, organophosphates have been shown to induce bronchoconstriction through anticholinergic effects.[16] Other agents may cause asthma simply through irritation of the airways.[18]

DIAGNOSIS

Key components in the evaluation of suspected occupational asthma are discussed below.

History

A high index of suspicion for occupational causes must always be present when patients with new-onset asthma are being evaluated. Because asthma can be induced by remote exposure to a substance, the current and previous occupational history is very important. Computerized lists of exposures that occur at various workplaces are available (www.occupationalasthma.com), and these facilitate this process. Included in the history should be the documentation of specific jobs of the individual at the specific workplace as well as potential exposures during performance of those jobs. The history can be verified through the use of material safety data sheets (MSDS), forms that contain information about a particular agent, including identification, hazard(s) identification, composition/information on ingredients, first-aid measures, fire-fighting measures, accidental release measures, handling and storage, exposure controls/personal protection, physical and chemical properties, stability and reactivity, toxicological information, ecological information, disposal considerations, transport information, and regulatory information, as well as industrial hygiene data and employee health records from the workplace. Once suspect agents are identified, any previous reports of their association with work-related asthma can be searched on available websites such as www.occupationalasthma.com. Clinical history that suggests occupation-related asthma includes symptoms that occur at work and improves when the patient is away from work for a period of time, as during vacations. The duration of symptoms prior to removal from the offending environment is important for predicting prognosis. Those individuals who have had symptoms for a longer period of time are more likely to develop chronic symptoms that do not remit after exposure has been discontinued.[21] It should be noted that many compounds induce a late reaction, several hours after exposure. Therefore, the relationship between exposure and symptoms may not be entirely apparent to the patient. Questions should also be asked regarding other causes of obstructive pulmonary disease. Questions regarding a history of tobacco use are important. A past history or family history of asthma may suggest that the patient's symptoms are not occupation related. Therefore, questions to establish the degree of respiratory symptomatology before beginning a particular job are important. Questions aimed at assessing cardiac or upper-airway abnormalities are also very important.

Physical Examination

Signs of atopy should be assessed. As in cases of asthma due to other causes, the pulmonary examination may be entirely normal when the patient is seen outside of the workplace. However, wheezing, either during quiet respiration or on a forced maneuver, suggests airflow obstruction. Signs of dermatitis particularly in the case of latex sensitivity may support the diagnosis of work-related disease.[3,22]

Skin and Immunologic Tests

General atopy is a risk factor for developing certain forms of occupational asthma when it is due to high-MW compounds. Therefore, routine skin testing, using a panel of allergens, for wheal-and-flare reactions can be useful. In addition, extracts of a compound that is suspected to cause occupational asthma in a particular patient can be used for skin testing. Extracts from flour, animal by-products, coffee, and other sources have been used for skin testing in various studies.[3,18] Specific IgE antibodies to extracts that contain high-MW compounds or to low-MW compounds coupled to a serum protein, such as albumin, can also be detected by the radioallergosorbent test (RAST) or enzyme-linked immunoadsorbent assay (ELISA).[3,18] In addition, specific IgE antibodies to low-MW compounds have been detected in patients with asthma due to these compounds.[3,18] However, positive results in all of these tests do not necessarily indicate that disease is due to the specific agent; they simply suggest sensitization. Results of all of these tests must be evaluated in the context of the individual patient.

Pulmonary Function Tests

Patients with workplace-induced asthma may present with normal pulmonary function tests when they are away from the inciting agent. For this reason, pulmonary function tests should be assessed in the light of the time that has elapsed since the patient was exposed to a suspected agent. Pulmonary function tests pre- and postwork can be very helpful in objectively evaluating respiratory function in relation to work.

Peak-flow monitors are useful in the assessment of workplace-related symptoms because they can be used in a job. Initially, peak-flow measurements should be determined at least four times per day: on awakening, at the beginning and end of work, and before bed. Similarly, timed measurements should also be performed on days that the subject is off work. Three measurements at each time period should be made and recorded; two of these should be within 20 L/min of each other to demonstrate reproducibility. Measurements should be performed each day over at least 4 weeks. In addition to this regimen, a more intense regimen of peak-flow measurements every 2 hours has been proposed by Burge et al.,[23] but this schedule may be too cumbersome to be practical, and studies have suggested that a protocol using measurements performed four times a day is as predictive.[16]

Because peak-flow measurements are very effort dependent, they should be supplemented by other methods for assessing the degree of impairment. It is always important to document that patients who

are being evaluated for occupational asthma are not malingering in order to obtain compensation. When pulmonary function is assessed in these patients, technicians should be alerted that a work-related disorder is suspected, so that they can evaluate the patient's effort. In addition, reproducibility of the repeated maneuvers can be useful in determining the degree of effort. If peak-flow measurements suggest that there is an airway reaction to a substance at the workplace, a technician with a portable spirometer can be sent to the workplace to measure FVC and FEV_1 at hourly intervals during work.

Bronchial Provocation Tests

Patients who develop occupational asthma invariably develop bronchial hyperreactivity to nonspecific agents such as methacholine and histamine. An arbitrary cutoff of a provocative concentration producing a 20% decline in FEV_1 (PC_{20}) of 8 to 16 mg/mL of methacholine has been chosen.[24] In patients with normal spirograms at presentation, a bronchial challenge with either of these agents may be necessary for diagnosis. Such a challenge can also be used to choose the concentration(s) of specific allergen that should be employed in a specific bronchial provocation test, since studies have shown a good correlation between the degree of nonspecific bronchial reactivity and responses to specific allergens.[16]

Specific simulated bronchoprovocation can be a valuable tool to determine whether a patient's symptoms are due to a particular agent. This maneuver should be performed only by an experienced physician because it carries some risks, particularly prolonged bronchospasm that requires therapy. Bronchodilator and anti-inflammatory medication should be withheld prior to the exposure, which should be performed in a whole-body chamber that allows more reproducibility of the work situation. Exposure levels should start low and gradually increase to levels that are consistent with ambient levels in the subject's workplace.[19]

Patterns of bronchoconstriction after exposure to specific agents can differ.[19] The two most common patterns are an immediate reaction, occurring within a few minutes of challenge and peaking at 10 to 15 minutes after challenge, and a late reaction, occurring several hours after challenge and peaking at 5 to 8 hours (Fig. 89-1). These responses can be seen individually or together in a given patient. Less frequent patterns have also been noted. One of these involves a reduction in flow rates 1 hour after challenge, with resolution 3 to 4 hours after exposure.[19] In another, a reduction in flow rates occurs much later, the day after the exposure, and occasionally recurrent abnormalities can be manifest for several days.[19] Recurrent symptoms of nocturnal asthma for several days have also been reported after exposure to a number of agents.[19]

MANAGEMENT

Once it has been determined that an individual has developed asthma due to exposure in the workplace, he or she should be removed from the offending environment. In some instances, reduction in exposure at the workplace can allow the worker to continue gainful employment without having progressive respiratory symptoms. Although some studies[25] have suggested the use of certain therapeutic agents, such as inhaled cromolyn for bakers' asthma, which can inhibit physiological changes triggered by the offending agent, protection is not complete. Because it is sometimes difficult to convince the patient to change jobs, an alternative to this is the use of a protective mask to prevent airway exposure to the offending agent. The inciting agent dictates the type of protective headgear employed. For example, subjects working with low-MW compounds require helmet respirators with an isolated air source to prevent exposure while exposure to high-MW compounds can generally be avoided with simple high-efficiency particulate air mask. If the subject continues to work in the implicated environment, pulmonary function tests should be done frequently to rule out progressive physiological impairment. Unfortunately as few as 33% of patients with occupational asthma recover even with complete avoidance from the offending substance.[3] In addition, data that protective masks/respirators can prevent the problem are sparse.

DISABILITY DETERMINATION

Documentation of impairment associated with objective physiological changes that occur predominantly in the workplace suggests an occupation-related disorder. Patients with asthma due to an occupational exposure should be referred to the appropriate compensation or review board. The American Thoracic Society[26] and the American Medical Association[27] have developed guidelines for the evaluation of impairment and disability due to this disorder. Determination of initial impairment should be made after optimal treatment of the asthma has been delivered. Impairment should be assessed using lung function tests, or measurements of airway hyperresponsiveness using: methacholine or histamine; documentation of the type and amount of medication required to treat the patient; and observation of the effect of the disease on the patient's life-style.

SPECIFIC EXAMPLES

Multiple examples of occupational asthma are described below.

Animal Handlers' and Pet Shop Workers' Asthma

For several years it has been known that there is a high incidence of asthma and rhinitis among workers in animal-care facilities.[28–30] There is also expanding information that up to 22% of pet shop workers develop respiratory symptoms at work. Development of symptoms in animal handlers tends to occur following months or years of exposure. Symptoms of asthma are often preceded by rhinitis, conjunctivitis, or urticaria that occur primarily at work. In one study, 56% of individuals who had been exposed to laboratory animals for 3 months or more complained of respiratory symptoms.[28,29] Skin testing with animal-associated allergens may be helpful in determining individuals at risk for developing this syndrome. In addition, a prior history of atopy, elevated serum IgE levels, and positive skin tests against nonanimal environmental allergens also predict the development of asthma in animal

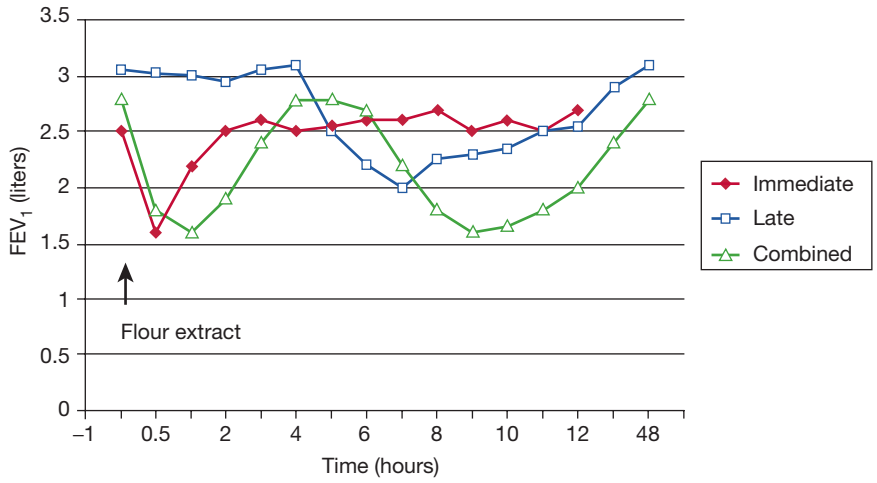

Figure 89-1 Examples of early, late, and combined reactions to inhalation of a specific agent (in this case, flour extract) implicated in causing occupational asthma. Flow rates are plotted versus time after inhalational exposure.

handlers. Approximately one-third of individuals with a history of atopy develop asthma when exposed to laboratory animals for more than 3 months. Although multiple allergens – including molecules found in the pelt, serum, and urine of the animal – may be involved, a major allergen is the rat urinary allergen. In one study, specific IgE antibody to this protein correlated very well with reported asthmatic symptoms in animal handlers.[28,29] Serum IgG antibody to this protein was also present in animal handlers with symptoms, but it was additionally present in a significant number of asymptomatic subjects as well.[28,29] Anti-rat urinary protein IgG antibody appeared to be simply a marker of exposure, while IgE antibody was integrally associated with onset of asthma.[28,29]

Avoidance of exposure to laboratory or pet shop animals is the best treatment for this condition. Although one study has documented that airway reactivity in animal handlers does not tend to worsen in these individuals even if they remain on the job,[29] chronic exposure probably perpetuates airway inflammation. If the individual cannot avoid the exposure, use of a helmet respirator, enabling him or her to completely avoid inhalation of the protein allergen, can prevent symptoms. Worker education regarding avoidance of airborne allergens can also be useful in controlling symptoms.

Bakers' Asthma

Cereal flours induce a specific IgE reaction in a high percentage of exposed subjects.[31] Epidemiological studies of bakers' asthma have been most complete in Germany, where it has been shown that IgE-mediated immediate skin test reactivity in bakers is directly related to their time in service. One study has shown that 20% of bakers' apprentices develop positive skin tests after 5 years of service.[31] However, exposed individuals can develop specific IgE antibodies and skin test reactivity to flour antigens without developing asthma, suggesting these tests are mainly a parameter of exposure.[31] In one study, however, the percentage of bakers with documented occupation-related airway disease had a much higher concentration of IgE antibody than did unselected bakers who had been employed for a similar period of time.[31] Overall, 7% to 20% of bakers develop allergic symptoms, including asthma, that occur predominantly in the workplace.[31] Symptoms can be minimized by using properly occlusive masks, although most subjects find these devices difficult to wear during the entire work shift. Airway reactions to inhaled flour dust allergens can also be reduced by pretreatment with cromolyn sodium. However, no studies have documented that cromolyn can reduce symptoms at the workplace or prevent chronic respiratory abnormalities from developing.

Asthma due to Latex

Urticaria and asthma occur in a small number of individuals who are exposed to rubber latex by wearing gloves or working in doll factories.[22,32,33] Risk factors for developing sensitization to latex are frequent use of disposable gloves, the presence of prior atopic disease, and prior or current hand dermatitis. Approximately 80% of patients with asthma due to latex develop contact urticaria upon wearing gloves, a large percentage of patients also report rhinitis and conjunctivitis upon exposure to latex.[22,32,33] Skin tests using extracts of latex are usually positive in affected individuals.[22,32,33] Treatment is limited to avoidance of latex-based products. One study has shown that measures implemented to reduce exposure while working, such as use of powder-free gloves, can allow a sensitized individual to continue to remain on the job.[22,32,33] In fact, with institution of the general use of powder-free latex gloves and use of latex gloves only if necessary for dexterity, the incidence of latex-associated asthma has diminished.

Asthma due to Acid Anhydrides

These low-MW compounds are used in numerous industries,[34,35] including the curing of epoxy and alkyl resins, production of plasticizers and adhesives, and the manufacture of drugs. Specific acid anhydride compounds used include trimellitic acid (TMA), phthalic acid (PA), tetrachlorophthalic acid (TCPA), and malic acid (MA). All of these compounds have been associated with induction of asthma.[35] TMA exposure has been associated with several different syndromes: an irritant syndrome, early asthma and rhinitis, late-onset dyspnea with systemic symptoms (TMA flu), and pulmonary infiltrates with hemoptysis.[35] The irritant syndrome does not require a latency period, whereas the other three syndromes require a period of exposure to the acid anhydride prior to development. Asthma caused by these compounds appears to be due to the development of specific antibodies to the acid anhydride coupled to a body protein. Specific IgE and IgG antibodies to TMA coupled to human serum albumin have been noted.[35] In one study, total IgE levels were a good parameter of exposure, whereas specific IgE levels correlated with symptoms of asthma and skin test positivity.[36] The absence of a specific IgE antibody to TMA strongly argues against TMA as the cause of asthma in a particular patient. Another study has shown that IgG in serum from sensitized patients can trigger histamine release by basophils.[18] In contrast to asthma caused by high-MW compounds, atopy does not appear to be a definite risk factor for development of asthma due to acid anhydrides. However, a history of smoking may be a risk for the development of asthma due to these agents. Removal of the employee from the environment is the best form of therapy for the disorder. Employee education regarding exposure can also be useful. Even with removal from the offending environment, affected subjects may continue to have symptoms for as many as 5 years after changing work. Specific IgE antibody may also be detected several years after discontinuation of exposure.

Isocyanate-Induced Asthma

Isocyanates are highly reactive chemicals used in a number of industries.[17] Prominent in this regard is their use in the production of polyurethane, which is found in paints, varnishes, flexible foams, and adhesives. Major forms of isocyanates include toluene diisocyanate (TDI), diphenyl methane diisocyanate (MDI), and hexamethylene diisocyanate (HDI). Exposure to TDI has been most often associated with the development of asthma, and TDI is also the most chemically reactive isocyanate.[37–39] Overall 5% to 30% of workers exposed to TDI develop airway symptoms.[34,37–41] There is some evidence that human leukocyte antigen (HLA) class II alleles are associated with increased risk for the development of isocyanate-induced asthma.[37] In addition, asthma due to TDI is associated with the Ile^{105}/Ile^{105} phenotype of glutathione-S-transferase enzyme protein, whereas the Val^{105}/Val^{105} protects against asthma in this setting.[38] Also, slow acetylator genotypes of the N-acetyltransferase gene have an increased risk of diisocyanate-induced asthma.[18]

Isocyanates can also cause an airway irritation syndrome similar to that due to acid anhydrides, occurring without significant time latency.[39] In one reported case, a patient was exposed to large concentrations of TDI and developed airway symptoms within hours of the exposure. Twelve years after exposure, the patient continued to manifest hyperactivity to TDI as nonspecific airway hyperreactivity.[40] More commonly, isocyanates induce an asthma syndrome that develops after exposure to the substance for weeks to years.[39] When subjects develop asthma due to these agents, they also manifest bronchoconstriction after exposure to the substances in a controlled setting, such as an exposure chamber; usually these individuals will also manifest nonspecific airway reactivity to methacholine or histamine.[39] Isocyanates may also induce chronic airway abnormalities in the absence of symptoms. One study, which examined the decremental fall in flow rates in workers exposed to TDI, predicted a 2-L greater loss in FEV_1 over 40 years in these workers as compared with controls.[39,40]

Isocyanates cause asthma by inducing intense airway inflammation.[39] Bronchoalveolar lavage studies have demonstrated increased numbers of neutrophils and eosinophils in the airways of subjects

with asthma due to isocyanates, particularly those who manifest a late airway reaction upon controlled exposure. Bronchial biopsies of affected patients also show intense inflammation, much of which is lymphocytic.[39] Why inflammation is induced by these agents is controversial as there are studies suggesting that isocyanates may interact directly with elements that modulate inflammation, but because of the latency period that is commonly required prior to the development of isocyanate-induced asthma, an immunologic mechanism is likely. Lymphocyte-mediated and humoral responses have been proposed.[39] One study has demonstrated specific IgE and IgG antibodies to isocyanates coupled to human serum albumin in sera of individuals with symptoms and positive inhalation challenge tests with isocyanates.[18] Although the levels of both of these subclasses of immunoglobulins tend to correlate with airway responsiveness to the isocyanate, the IgG level tends to be more predictive.[41]

As with other forms of occupational asthma, the most efficacious treatment for individuals affected with isocyanate-induced asthma is removal from the offending environment. Once the individual has become sensitized, very low concentrations of the particular agent can induce bronchospasm, so that transfer of the individual to an area that is in close proximity to an area of isocyanate use is not an effective management. Bronchoconstriction following controlled isocyanate exposure can be attenuated by inhaled or oral corticosteroids. However, use of these agents should not replace removal of the patient from exposure at work. Use of respirators prophylactically in areas with high concentrations of isocyanates is important to prevent the development of asthma. There have been reports of persistent isocyanate-induced asthma even after removal of the subject from the offending environment. One study reported persistent respiratory symptoms in 83% of workers who had been away from isocyanate exposure for 4 years.[39,40] Another study demonstrated that 7 of 12 subjects with TDI-induced asthma continued to have nonspecific airway hyperreactivity 2 years after removal from the work environment.[40]

Asthma in Emergency Responders at the World Trade Center

Approximately 25% of firefighters who responded to the World Trade Center collapse developed airway hyperreactivity to methacholine from exposure to respirable particles, possibly because of high alkalinity of the dust.[21] The predominant symptom associated with this exposure was cough. One study showed that airway hyperreactivity shortly after the disaster predicted airway hyperreactivity 6 months later.[21]

Asthma due to Western Red Cedar Wood Dust

Asthma can occur due to chronic wood dust exposure.[17,42] Although a number of woods are associated with this problem, the syndrome due to western red cedar is best characterized and the causative agent within the dust has been identified.[42] Overall 5% of workers who are exposed to western red cedar dust develop symptoms of wheezing and cough after a latency period of months to years.[42] The mean latency period prior to the development of symptoms is 50 months. Workers who develop the syndrome usually have nonspecific airway hyperreactivity to methacholine or histamine. In addition, a specific airway reaction to plicatic acid, a component of the wood dust, is usually present and manifested by an early or late reduction in flow rates after exposure.[42]

Mechanisms of western red cedar-induced asthma are not totally defined. Plicatic acid, which makes up approximately 50% of the total extractable fraction of the wood dust, induces bronchoconstriction in affected subjects.[42] Subjects who manifest an early and late airway response to inhalation of plicatic acid generally have had a longer exposure to the western red cedar dust. Specific IgE antibodies to plicatic acid coupled with human serum albumin have also been detected in 28% to 40% of subjects with the syndrome.[42]

Like other forms of occupational asthma due to low-MW compounds, subjects with asthma due to western red cedar can continue to have symptoms even when they are removed from the offending environment. In one study, 60% of affected individuals continued to have symptoms after leaving the industry.[3] For this reason, the identification of individuals and specific jobs that place individuals at risk is important. Use of protective devices may reduce exposure and subsequent development of asthma due to this dust, but this has not been systematically addressed.

Asthma due to Metal Salts

Platinum used in electroplating, platinum refinery, and jewelry making has been noted to cause asthma.[17] Smoking is a risk factor for the development of asthma due to this metal. Airway responses to preparations of complex salts of platinum have been documented in affected workers. In addition, positive skin-prick tests and specific IgE antibodies to platinum conjugated to albumin have been found.[43] Exposure to nickel, chromium, cobalt, vanadium, and tungsten carbide has also been associated with the development of asthma.[43] Welders are commonly exposed to nickel fumes while welding stainless steel.

Soldering Flux Asthma

Various fluxes – including aluminum solder flux, which contains aminoethylethanolamine and colophony[17] – have been associated with, and thought to cause asthma. One study documented occupational asthma in 21% of workers in the plant of a manufacturer of consumer electronics.[44] Colophony fumes can also induce bronchoconstriction in affected individuals when given as a controlled exposure.[17] Mechanism of airway reactivity to colophony fumes may be irritant properties of the fumes or a specific immunologic reaction to pine resin.[44]

Diesel Exhaust Exposure

Mounting evidence suggests that air pollution contributes to the rising incidence of asthma.[45] Certain occupations place workers in environments of higher diesel exhaust,[46,47] one component of air pollution that causes asthma, and there is some evidence that this is associated with induction of asthma. One study examined specific exposures in farmers and found that diesel exhaust and solvent exposure correlated with onset of asthma.[47] Another study from England showed a relationship between diesel exhaust exposure at work and asthma.[46]

SUMMARY

Since the beginning of the Industrial Age, workplace exposures have adversely affected human beings. Effects of substances inhaled at the workplace are becoming increasingly apparent with marked expansion of agents that have been associated with lung damage. Exposures that affect the airways with subsequent development of bronchitis or asthma cause a large degree of disability and subsequent cost to society through increased health-care costs and inability to work. This chapter describes major causes of these airway syndromes in the hope that treating clinicians can recognize them early and improve outcomes.

CHAPTER 90

Acute and Chronic Responses to Toxic Inhalations

Jian Jing
David A. Schwartz

INTRODUCTION

The lungs and airways are in constant contact with the outside world and thus, are especially vulnerable to toxic substances present in the environment. Within seconds of exposure to an inhaled toxin, pathologic events occur that may cause immediate distress, systemic illness lasting days, or even lead to the development of chronic lung disease. This chapter discusses the pathology and pathophysiology that can result from various inhaled toxins, and also highlights the role of several common and medically significant toxic inhalants that are known to cause acute and chronic pathophysiologic responses in the lung. The chapter also discusses several systemic syndromes caused by acute toxic inhalations. The scope of this chapter does not include chronic exposure to low levels of toxins.

DETERMINANTS AND MECHANISMS OF IRRITANT-INDUCED PULMONARY INJURY

Inhaled toxins exist in many forms and may be categorized by taking into account their physical properties. General categories include gases, vapors, fumes, aerosols, and smoke. A variety of factors determine the pathologic results of a toxic inhalation: the size of inhaled particles, the solubility of the inhaled substance in water, the concentration of the inhalant in ambient air, the duration of exposure, the presence or absence of ventilation, and a variety of host factors (age, smoking status, comorbid diseases, use of respiratory protection, and perhaps even genetic susceptibility). While toxic inhalants provoke a broad range of chemical and biologic activities that contribute to pathogenesis, their physical properties, namely their particle size and water solubility, are of fundamental importance in determining the site and severity of pulmonary injury. Tables 90-1 to 90-3 summarizes the physical properties of the discussed inhalants that substantially affect the resulting pathogenesis of these agents.

The size of aerosolized particles is of critical importance in inhaled toxin pathogenesis. In general, larger aerosolized particles are more likely to deposit on the nasopharynx via impaction and not gain access to the lower airways, while smaller particles are able to penetrate smaller airways and effect toxicity at the level of the alveolus. Aerosolized particles larger than 30 to 80 μm are not inhalable through the nose,[1] and particles larger than 5 μm typically do not reach the alveoli.[2] Ultrafine particles (those <0.1 μm) have been specifically implicated in the toxicity due to the agents of polymer fume fever.[3] Inhaled particles may have direct toxic effects themselves, or they may function as vehicles for adsorbed gaseous agents that are toxic to terminal bronchioles and alveolar cells.

In addition to particle size, the relative solubility of an inhalant in water determines where along the respiratory tract toxicity will occur. Substances with high water solubility, such as ammonia, sulfur dioxide, and hydrochloric acid, provoke immediate and evident injury to the conjunctiva and mucosal surfaces of the upper airways; they are largely absorbed by the mucus lining the pharynx and larynx and often react there to form caustic acids and alkalis. The provoked symptoms quickly prompt exposed individuals to flee the area or contain the source of exposure, reducing the duration of exposure. These compounds can also activate irritant receptors in the upper airways, provoking a bronchoconstrictor reflex that may further limit access of the inhalant to lower airways.[4] In contrast, compounds like phosgene and ozone have low water solubility and thus fail to cause immediate irritation, promoting longer exposure to the

TABLE 90-1 Definitions of Types of Inhaled Substances

Gas: a formless state of matter in which molecules move freely about and completely occupy the space of enclosure
Aerosol: a relatively stable suspension of liquid droplets or solid particles in a gaseous medium
Coarse particles: particles between 1 and 10 μm
Fine particles: particles between 0.1 and 1 μm
Ultrafine particles: particles less than 0.1 μm
Vapor: the gaseous form of a substance that normally exists as a liquid or solid and that generally can be changed back to a liquid or solid by either increasing ambient pressure or decreasing the temperature.
Fume: an aerosol of solid particles generally less than 0.1 μm in size that arises from a chemical reaction or condensation of vapors, usually after volatilization from molten materials.
Smoke: the volatilized gaseous and particulate products of combustion; the particles are generally less than 0.5 μm in size and do not settle readily.

TABLE 90-2 Water Solubility and Mechanisms of Lung Injury of Gaseous Respiratory Irritants

Irritant Gas	Water Solubility	Mechanism of Injury
Ammonia	High	Alkali burns
Chlorine	Intermediate	Acid burns, reactive oxygen species, reactive nitrogen species
Hydrogen chloride	High	Acid burns
Oxides of nitrogen	Low	Acid burns, reactive oxygen species, reactive nitrogen species
Ozone	Low	Reactive oxygen species, reactive nitrogen species
Phosgene	Low	Acid burns, reactive oxygen species, protein acetylation
Sulfur dioxide	High	Acid burns, reactive oxygen species

inhalant and deeper penetration of the lower airways. Compounds of intermediate solubility, for example, chlorine gas, typically have pathologic effects throughout the respiratory tract. These differences in solubility can be overcome by differences in concentration and duration of inhalant exposure: virtually any inhaled toxin (even the most soluble agents) can cause diffuse damage of the respiratory tract by overwhelming the absorptive capacity of the upper respiratory tract. Furthermore, adsorption of a toxic gas on particulate matter may permit a toxin access to otherwise unreachable airways.

Host factors also play a significant role in predicting an individual's response to a toxic inhalation. Underlying pulmonary or extrapulmonary disease may worsen a patient's response to an exposure. Children deposit a smaller fraction of inhaled particles in their nasopharynx than adults and thus may be at elevated risk of lower airway exposure and pathology[5]; moreover, as some gases (such as chlorine and sulfur dioxide) are heavier than air, children may be subjected to a longer duration and higher concentration of gas than adults near the same site of toxin release. With particles greater than 0.5 μm, breathing through one's nose increases upper airway particle deposition compared to mouth-breathing; this difference is absent with particles less than 0.5 μm.[6] Tobacco smoking impairs ciliary clearance and cellular defense, limiting the exposed patient's ability to clear inhaled particles and prolonging exposure. Patients with increased minute ventilation (such as those panicking at the scene of an irritant gas release) are at elevated risk of increased exposure and toxicity. An emerging literature in experiments with inbred strains of mice suggests that genetic variants may alter the risk of responding to various inhaled toxins.[7]

Injury from toxic inhalation may occur via a number of mechanisms. If the concentration of the inhalant is high enough and if ventilation is inadequate, simple asphyxiation due to displacement of atmospheric oxygen may occur. The reflex bronchoconstriction triggered by upper airway irritant receptor activation may itself cause inadequate oxygen inhalation. Cell injury from acute toxin exposure typically occurs via nonimmunologic mechanisms of injury and inflammation, generally via formation of an acid (chlorine, oxides of nitrogen, phosgene, and sulfur dioxide), an alkali (ammonia), or reactive oxygen or nitrogen species (ozone, oxides of nitrogen and chlorine). Acid formation results in coagulation of underlying tissue, while alkali exposure causes a liquefaction of mucosa and characteristically deep lesions within the airways. Reactive oxygen and nitrogen species and their derivatives achieve local tissue damage via lipid peroxidation and protein oxidation, and may cause similar toxicity systemically.[8] Free radicals may be direct derivatives of inhaled substances, or they may be released by alveolar macrophages that are activated by inhalant exposure.[9] All three types of tissue damage generally lead to an increase in expression of proinflammatory cytokines that can perpetuate the acute injury and may be responsible for the development of later sequelae. Disruption and repair of injured airway epithelial tissue may compromise the host's defenses against further infectious or irritant substances. A role played by the innate immune system in disease progression is evident in the case of endotoxin exposure in organic dust toxin syndrome (ODTS, below), and may be a host factor in the response to ozone and nitrogen dioxide.[7,10]

PATHOGENESIS AND CLINICAL PRESENTATION OF TOXIC INHALATION INJURY

Mechanisms of disease and clinical manifestations based on respiratory site exposure are considered below.

UPPER AIRWAY

Effects of toxins on the upper airways are typically sudden and short-lived compared to those more distal along the respiratory tract; chronic pathology in this region is unusual. Compounds that provoke a response in the nose, pharynx, and larynx tend to be particulate with relatively large average particle size or gases with high water solubility. Acids, alkalis, and reactive oxygen and nitrogen species may all cause tissue injury in this region depending on the inhaled compound and its reactions along airway epithelium. Characteristic tissue injury depends on dosage and ranges from slight edema of the nasopharynx and larynx to epithelial ulceration and frank hemorrhage. Once the airway epithelia are compromised, it fails to function as a protective barrier against the environment. Underlying inflammatory cells, nerves, muscles, and blood vessels become exposed, which may further the inflammatory response. An obstructive response to some irritants starts to occur at concentrations only barely perceivable as irritating.[11]

The typical presentation of patients with acute exposure of irritant substances to the upper airways includes burning sensations of the nasal passages and throat, copious sputum production, coughing, and sneezing. Extrapulmonary manifestations include burning of the eyes, profuse lacrimation, headache, and dizziness. The most serious risk in the exposed patient is airway obstruction due to reflex bronchospasm or laryngospasm, mucosal edema, increased secretions, and sloughed epithelial cells. Patients presenting with hoarseness or stridor should be carefully observed for further evidence of airway compromise. Though inhalational injury confined to the upper airways tends to be self-limited with no or few long-term sequelae, a chronic rhinitis following irritant exposure, *reactive upper airway dysfunction syndrome* (RUDS) has been described[12] and was observed among World Trade Center rescue workers following the attacks of September 11, 2001.[13]

Patients with acute toxic exposure to the upper airways should be immediately removed from the source, which may require removal of the patient's clothes. The patient's airway should be secured and monitored; racemic epinephrine may be used, but it should not delay endotracheal intubation if necessary. Frequent suction may be required. Profuse amounts of water should be irrigated over exposed surfaces. Supplemental oxygen should be provided if appropriate. Patients with extensive upper airway edema may benefit from corticosteroids,[14] though this is unsupported by clinical trials. Ophthalmologic consultation should be sought for management of eye exposure.

CONDUCTING AIRWAYS

Acute or chronic effects on the airways may be observed.

Acute Injury

As is the case with the upper airways, the conducting airways protect their submucosal structures with epithelium that may be compromised by acute inhalational injury. The resulting edema, inflammation, and bronchoconstriction may be life-threatening if it results in

an obstructed airway, and without its epithelial barrier the airway is vulnerable to infections and other environmental pathologies. This damage to the epithelium appears to occur at the tight junction interface between cells,[15–17] resulting in increased epithelial permeability to other irritants, which gain direct access to effector cells within the subepithelial mucosa. Resulting bronchospasm may cause ventilation–perfusion mismatch. The smooth muscle of the airways can be hyperresponsive in the hours and days following irritant exposure, an effect probably mediated by the neutrophilic and eosinophilic inflammatory response inhalational injury provokes.[18,19]

Conducting airway injury may manifest as intrathoracic airflow obstruction hours after the initial insult. Patients with histories of exposure who present with any evidence of respiratory compromise should be hospitalized for observation, even if asymptomatic. Findings of concern include expiratory wheezing, decreased airflow on peak expiratory flow measurement or spirometry, abnormalities of gas exchange or an abnormal chest X-ray. Likewise, patients with complaints of dyspnea or chest tightness should be observed carefully and treated symptomatically with inhaled steroids and bronchodilators, even in the absence of objective findings. When significant airflow obstruction is present, systemic steroids may be of some utility.

Chronic Injury

Two forms of chronic injury include reactive airways dysfunction syndrome and vocal cord dysfunction.

Reactive Airway Dysfunction Syndrome A persistent asthma-like disease following acute exposure to an irritant inhalant, known as *reactive airway dysfunction syndrome* (RADS, or "Brooks syndrome") was named in 1985[20] but observed among World War I soldiers exposed to war gases.[21] Investigation and diagnosis of the disease is generally limited by the absence of spirometry results in patients prior to exposure and the presence of confounding factors (e.g., cigarette smoking), but numerous reports exist of previously asymptomatic patients experiencing hyperreactive airway disease presenting soon after a single toxic exposure and persisting for months or years.[20,22–29] RADS is distinguished from immunologic occupational asthma in that it follows a single exposure and does not follow a latency period of sensitization to the offending substance.

The pathogenesis of RADS likely begins with the initial injury to and desquamation of the epithelium, which results in hemorrhage and edema followed by inflammatory changes, and finally long-term structural changes of the airways involving epithelial regeneration and fibrosis.[30,31] Ensuing airway narrowing may be due to mucosal edema, inflammation, or structural changes to the architecture of the bronchial wall.[32]

RADS typically presents abruptly within 24 hours following exposure with the classic symptoms of obstructive airway disease: wheezing, chest tightness, dyspnea, and cough. The symptoms and obstructive findings on examination and spirometry are relieved by bronchodilators, though not as effectively as in other types of reactive airway disease (perhaps due to chronic fibrotic remodeling of the conducting airways). The disease can persist for months and, may, in some instances, be permanent.[33] A recent case report shows that a patient with severe unremitting symptoms of RADS for 5 years following an ammonia exposure responded to high-dose oral vitamin D supplements.[34] Anecdotally, inhaled corticosteroids have shown benefit in relieving airflow obstruction.[30] Systemic corticosteroids have been proven beneficial in an animal model of RADS.[35]

Vocal Cord Dysfunction Vocal cord dysfunction may also follow a single acute irritant exposure and may be confused with RADS.[36,37] The disorder may be caused by reflex response to nerve stimulation by irritants.[38] Patients suspected of having RADS who do not respond appropriately to bronchodilators should be evaluated for vocal cord dysfunction; direct laryngoscopy is the gold standard for diagnosis.[37]

■ LOWER AIRWAYS AND PULMONARY PARENCHYMA

The lower airways and lung parenchyma are primary sites for inhalational injury. Effects may be acute or chronic.

Acute Injury

Though all toxic inhalants are capable of producing distal airway disease at extreme concentrations and durations, the gases most likely to do so are those with low water solubility like phosgene and nitrogen dioxide, which bypass reflex bronchoconstriction and absorption by upper airway mucus (Fig. 90-1). The initial pathologic events in distal airways are caused by the cellular toxicity of the inhaled agent and its derivatives, which compromise the impermeability of the alveolar–capillary interface.[39] Some of this cytotoxicity may be derived indirectly from reactive oxygen species released from activated inflammatory cells.[9] In the absence of an intact alveolar–capillary interface, profound pulmonary edema may develop that impairs gas exchange and can prove fatal. The severity of this pulmonary edema, which typically presents after a latent period of several hours following the initial insult, is likely dose-related. This process may cause no more than slight dyspnea and cough with a mild alveolar infiltrate, or it may progress via diffuse alveolar damage to acute respiratory distress syndrome (ARDS). For this reason, patients with exposure to gases capable of causing distal airway disease should be hospitalized and monitored for symptoms of respiratory distress and with serial chest X-rays for at least 24 hours following exposure. Development of ARDS from toxin exposure likely shares a common pathway with other causes of acute lung injury, and management is similar: supportive care with mechanical ventilation, careful control of blood glucose, surveillance for infection, and deep vein thrombosis prophylaxis. Diuresis, intravenous corticosteroids, prone positioning, nitric oxide inhalation, and exogenous surfactant are all unsupported by clinical trials but potentially of some benefit. Diffuse bronchiolitis has also been reported following acute exposure.[40]

Chronic Injury

Two forms of chronic injury include bronchiolitis obliterans and bronchiolitis obliterans organizing pneumonia.

Bronchiolitis Obliterans Bronchiolitis obliterans (BO) is a well-documented but infrequent long-term sequela of toxic gas exposure, especially of nitrogen dioxide (Refer to Chapter 54)[41,42] but also to ammonia,[43] mercury,[44] and sulfur dioxide.[45,46] The disease typically presents 1 to 3 weeks following the initial lung injury and pulmonary edema (Fig. 90-2). The interim is often free of symptoms. When BO does develop, patients may present with dyspnea on exertion or obstructive findings on spirometry. Physical examination may be either unremarkable or remarkable only for early inspiratory crackles. Chest X-ray will either be normal or demonstrate hyperinflation. Pulmonary function tests typically demonstrate airflow obstruction that may in some cases also be associated with restrictive defects. On biopsy, granulation tissue will be seen in the lumen of small airways and bronchiole walls may be obliterated by fibrous scarring. Corticosteroids may be of benefit in preventing or alleviating BO if administered early in the course of the disease,[47] though this is controversial.

BO Organizing Pneumonia BO organizing pneumonia (BOOP) is another observed delayed sequela of toxic inhalation.[48,49] Patients present in the weeks following exposure with fever, a persistent and nonproductive cough, sore throat, and malaise. Late inspiratory crackles may be observed. Chest X-ray may reveal bilateral patchy "ground-glass" densities that start as focal lesions but may coalesce with time. Pulmonary function tests generally reveal a restrictive process with decreased diffusion capacity. Histologically, granulation tissue extends past the terminal bronchioles and into the alveolar spaces, sometimes with interstitial scarring. BOOP and BO are probably both chronic results of the initial inflammatory response

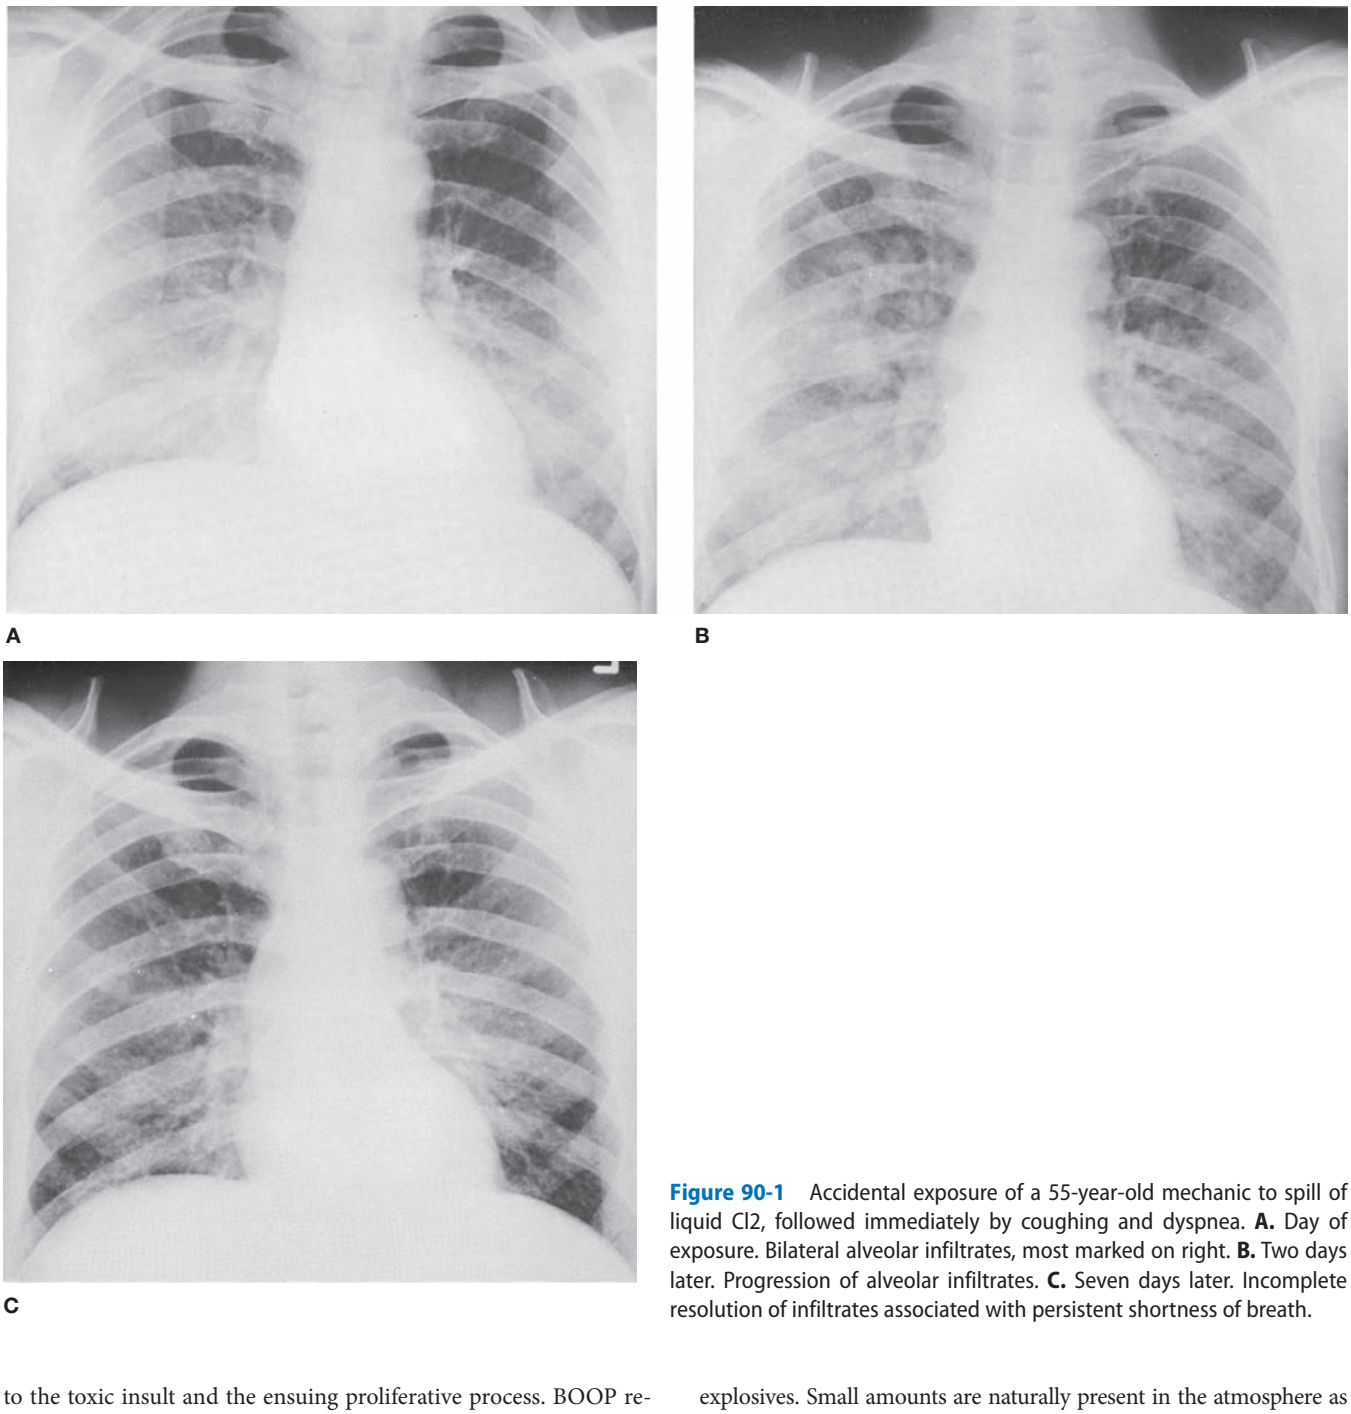

Figure 90-1 Accidental exposure of a 55-year-old mechanic to spill of liquid Cl2, followed immediately by coughing and dyspnea. **A.** Day of exposure. Bilateral alveolar infiltrates, most marked on right. **B.** Two days later. Progression of alveolar infiltrates. **C.** Seven days later. Incomplete resolution of infiltrates associated with persistent shortness of breath.

to the toxic insult and the ensuing proliferative process. BOOP responds well to corticosteroids,[50] though a small number of patients may develop progressive fibrosis. Duration of therapy should be guided by the patient's clinical status.

EFFECTS OF SPECIFIC INHALED TOXINS ON THE RESPIRATORY SYSTEM

The respiratory consequences of inhalation of commonly encountered toxins are discussed individually below.

AMMONIA

Ammonia (NH_3) is a stable colorless gas at room temperature and a water-soluble nitrogen-containing compound that ranks among the most commonly spilled hazardous substances (Table 90-4).[51] Familiar to all as a household cleaner, it also has countless uses in industry: as a chemical coolant used for refrigeration, as a fertilizer, as a fixative in photocopiers, and in the manufacture of polymers and explosives. Small amounts are naturally present in the atmosphere as products of the putrefaction of vegetable and animal proteins. The smell of concentrated ammonia (as low as 5 ppm) is immediately recognizable. Due to the prevalence of ammonia in household cleaners and to its use in smelling salts (which exploit the noxious effect of ammonia on nasal membranes to arouse consciousness), the odor threshold may extend to over 50 ppm because of the olfactory fatigue and adaption.[52,53] Ammonia is frequently dissolved into water for storage and transportation, and vaporizes readily on exposure to air. Most inhalation exposures are the result of accidental releases, including tank leaks and transportation mishaps,[54–56] and most exposures occur in the industrial workplace.[57] A recently reported source of exposure is via fumes produced in clandestine methamphetamine laboratories.[58]

The mechanisms of toxicity to the respiratory system involve both direct irritation and alkaline chemical burns. Ammonia tends to affect the proximal airways, where it reacts rapidly with the water present on mucosal surfaces to form ammonium hydroxide, causing tissue liquefaction. This necrosis liberates formerly intracellular

Diffuse pulmonary fibrosis and honeycombing, most marked in the peripheral portions of the lungs. **B.** Sagittal section of lung from same patient showing markedly dilated airspaces. Microscopic sections revealed bronchiolitis obliterans and chronic interstitial pulmonary fibrosis. **C.** Normal lung from a 43-year-old man who died suddenly. The difference between (**B**) and (**C**) in the alveolar portions of the lungs is striking. *(Used with permission of Dr. R. Ochs.)*

TABLE 90-4 Pulmonary Manifestations of Toxin Inhalation

		Acute Clinical Manifestations		Chronic Clinical Manifestations	
Substance	Onset	Upper airway irritation	Pneumonitis, ARDS	Bronchiolitis obliterans, BOOP	RADS
Irritant gases					
Ammonia	Minutes	Severe	+	+	+
Chlorine	Minutes to hours	Moderate	+	–	+
Hydrogen chloride	Minutes	Severe	+	–	+
Oxides of nitrogen	Hours	Mild	+	+	+
Ozone	Minutes to hours	Mild	+	–	–
Phosgene	Hours	Mild	+	–	+
Sulfur dioxide	Minutes	Severe	+	+	+
Metals					
Cadmium	Hours	Mild	+	–	–
Mercury	Hours	Mild	+	+	–
Zinc chloride	Minutes	Mild	+	–	+
Zinc oxide	Hours	Mild	+	–	–

+, exposure reported to be associated with clinical entity; –, exposure as yet not reported to be associated with clinical entity.

water, which serves as further reactant for ammonia, perpetuating the reaction. In addition to the alkali burns caused by the generated ammonium hydroxide, thermal burns can result from the heat generated by this exothermic reaction. The resulting injury, typical of alkali burns, penetrates deeply. The initial injury to the mucosa of the oropharynx can cause edema, hemorrhage, sloughing of tissue, and increased secretions that can bring about fatal upper airway obstruction. Ammonia is directly caustic to airways at concentrations of 1000 ppm and higher.

Though concentrated at the proximal airways, the effects of ammonia have been observed at all levels of the respiratory tract. The penetration of the gas to the smaller airways and alveoli is a function of its concentration and the duration of exposure. Reported acute conditions associated with ammonia exposure include pulmonary edema, laryngitis/tracheobronchitis, bronchiolitis, and bronchopneumonia; reported chronic sequelae include bronchiectasis, bronchospasm/asthma (termed RADS), and chronic obstructive pulmonary disease.[59] There are several reports of interstitial lung disease following a single exposure to ammonia.[57] A biphasic pattern of pulmonary response to ammonia inhalation has been reported, characterized by initial, acute pneumonitis that may clear over the next 2 to 3 days, followed in some individuals by the gradual development of airway obstruction and respiratory failure.[54] There may be a correlation between the development of a bacterial superinfection after exposure with the ensuing emergence of bronchiectasis.[60] In one review of published case reports, 21% of patients with acute ammonia inhalation died within 60 days of exposure.[59] The most common causes of death were laryngeal edema and obstruction, noncardiogenic pulmonary edema, and extensive pneumonic complications.

Management of a patient who has experienced ammonia inhalation requires removing him or her from the source of the irritant, securing the airway, and immediately irrigating all exposed surfaces (especially the eyes) with copious amounts of water. Humidified oxygen should be administered early. Airway management aggressiveness depends on the extent of complications such as laryngeal edema, pulmonary edema, hemoptysis, or respiratory failure that occur.[61] Rales detected on physical examination are predictive of the subsequent hospital course, even in the absence of hypoxemia and chest X-ray abnormalities.[54] Medical management is largely supportive. Aerosolized bronchodilators together with corticosteroids can be administered to treat bronchospasm. Corticosteroids and antibiotics are both frequently used, but both are unproven in human trials.

CHLORINE, CHLORAMINES, AND HYDROCHLORIC ACID

Chlorine (Cl_2) is a common gas of intermediate water solubility. The first reports of its toxicity followed its use as an agent of chemical warfare in World War I, and war gassings remain the largest historical source of chlorine gas exposure.[62] Most exposures since then have occurred in the industrial setting, where chlorine is used in the manufacture of paper, cloth, antiseptics, and other products.[63] More common in the household is the liberation of chloramines and other toxic chlorine derivatives from the reaction of chlorine-containing products (such as hypochlorite bleach) with ammonia or products containing hydrochloric or phosphoric acid. Numerous exposures to chlorine gas have occurred near swimming pools, where chlorine-releasing agents (e.g., calcium hypochlorite and chlorinated isocyanuritic acids) are used in water purification.[40] Chlorine gas is greenish-yellow in color and is heavier than air; though its odor is distinct, patient exposure to it may be prolonged compared to other toxic gases due to its delayed irritation of mucosal surfaces and its high density, which keeps it low to the ground.

The pathogenicity of chlorine gas derives directly from elemental chlorine's effects on the respiratory tract and indirectly from its reaction with water to form hydrochloric acid (HCl) and hypochlorous acid (HOCl). The character and distribution of injury from chlorine exposure varies according to duration of exposure and the relative concentrations of elemental chlorine and its derivative compounds. HCl and HOCl possess considerable water solubility and are responsible for the tissue damage sustained by the upper airways and ocular conjunctivae. Irritation to trigeminal nerve endings caused by these compounds can cause a reflex bronchoconstriction that may contribute to compromise airway diameter.[64] In addition to causing the tissue coagulation typical of acid exposures (described above), these compounds ionize and enter cells, where they may form reactive oxygen species. HOCl has been shown to react with nitrite (NO_2^-) to produce reactive nitrogen-containing compounds able to nitrate, chlorinate, and dimerize phenolic amino acids.[65] As nitrite and nitric oxide (its parent compound) levels are elevated at sites of tissue inflammation, this potentially is another mechanism of injury.[66] Though lower

respiratory tract irritation has been reported following high-level exposures, less than 5% of inhaled chlorine gas penetrates beyond the upper airways.[67] Fatal dosages from chlorine inhalation have ranged from 50 to 2000 ppm.[40]

The immediate clinical manifestations of acute chlorine exposure are typical of irritants of its solubility: rhinitis, cough, dyspnea, wheezing, and chest tightness, along with conjunctivitis and skin irritation.[68] When chlorine gas exposure has resulted acutely in death, autopsies have revealed diffuse ulcerative tracheobronchitis, pulmonary edema, thrombi within pulmonary vessels, and denudation of respiratory tract epithelium.[69] Acute respiratory symptoms are more prevalent and severe among patients who already have chronic respiratory disease. In 2005, a derailment train released 40 to 60 tons of chlorine gas near a small town in South Carolina. Nine people died and 71 were hospitalized. The majority of people (>90%) had respiratory symptoms including wheezing, rales/crackles, cough, decreased breathing sound, rhonchi, and labored breathing. Autopsy findings revealed the causes of death included asphyxia, lactic acidosis, and acute respiratory failure.[70]

The lasting respiratory sequelae of chlorine gas exposure have been described since the years following use of the gas in World War I.[71] Reported long-term pulmonary diseases following exposure have included both restrictive and obstructive processes, frequently resolving to normal function within a month and almost always before 2 years following exposure. RADS may be an infrequent sequela of high-level exposures to chlorine.[22,72]

Patients who have been exposed to chlorine gas should be managed according to the severity of their presenting symptoms similarly to other victims of irritant inhalation. The treatment for lung injury is primarily supportive care including humidified oxygen administration, lung protective mechanical ventilation, and pharmacologic therapy. Nebulized sodium bicarbonate has shown promise as a useful treatment,[73] but lacks supporting clinical trials and showed no outcome benefit in a relatively large observational study of chloramine gas exposure.[74] Beta-agonist bronchodilators and corticosteroid are frequently used and are probably of benefit. The reported benefit of corticosteroid administration is anecdotal[69] and unconfirmed by clinical trial.

SULFUR DIOXIDE

Sulfur dioxide is a heavy, colorless, and highly water-soluble gas that has the distinct, pungent odor of burnt matches. It is generated in the combustion of coal and petroleum and is often used as a preservative in alcoholic beverages and fruit. Industrial exposures have occurred around ore smelting, metal smelting, oil refining, sugar refining, and the bleaching of wool and wood pulp. In 1930, 63 people died and thousands became ill in the narrow Meuse River Valley of Belgium due to the trapped high concentrations of sulfur dioxide from the waste products of industry resources (United States Environmental Protection Agency). Sulfur dioxide is among the most harmful gases released to the atmosphere during volcanic eruptions[75]; in 1986 the gases emitted from one eruption killed nearly 2000 people in Cameroon.[76] Sulfur dioxide's great density keeps it low to the ground and slow to dissipate from sites of release; thus children may be at an increased risk of exposure.

Sulfur dioxide reacts with water present on mucus membrane to form sulfuric acid, which causes tissue coagulation underlying exposed surfaces. Sulfuric acid also further dissociates into hydrogen ions, sulfite, and bisulfite,[77] which can then react with oxygen to produce reactive oxygen species; ensuing lipid peroxidation may be a contributing mechanism of injury to immediate tissues and elsewhere.[8,78]

Sulfur dioxide is detectible to humans at 3 to 5 ppm and is lethal at levels exceeding 400 ppm for 1 minute.[79] High water solubility makes sulfur dioxide primarily an upper airway irritant. The direct irritant of bisulfate iron inhibits mucociliary transport.[80] The irritation-induced parasympathetic stimulation leads to smooth muscle contraction and mucosal secretion. Exposures of high enough intensity can irritate both upper and lower airways. Patients exposed typically present with dyspnea, burning of the nose and throat, rhinorrhea, cough, and airway obstruction.[81] Proximal airway injury is characterized by acute denudation of the airway mucosa without inflammatory cell infiltrates. When lower airways are exposed, alveoli fill with fluid due to noncardiogenic pulmonary edema and the clinical picture is consistent with ARDS. Alveolar architecture is generally preserved. Extremely high-intensity acute exposures can lead within minutes to death from respiratory failure due to a combination of alveolar hemorrhage and edema, possible reflex vagal stimulation, and the asphyxiating effect of high concentrations of sulfur dioxide.[82] RADS has been reported following single sulfur dioxide exposure[29]; bronchitis has also been observed.[83] One pattern of postexposure progression reported is a rapid recovery followed several weeks later by the onset of irreversible airflow obstruction due to BO.[82] Care for patients who have been exposed to sulfur dioxide is supportive: humidified supplemental oxygen, bronchodilators, and intubation and ventilation if necessary. The use of corticosteroids in the setting of ARDS following sulfur dioxide exposure has not been shown to be of benefit, but a trial is not unreasonable. Antibiotics may be reserved for use upon evidence of infectious complications.

NITROGEN OXIDES

Nitrogen oxides are ubiquitous air pollutants, released from automobile engines and the combustion of coal and petroleum, and are present in cigarette smoke. High-level acute exposure is most likely to occur in industrial settings, including mining, acetylene welding, and explosives manufacturing. A well-known form of exposure occurs in "Silo-filler's disease," in which farmers inhale concentrated nitrogen dioxide gas released within silos by decomposing nitrogenous biomaterial.[41,84] Exposures to high levels of nitrogen dioxide have been attributed to blast furnaces,[40] anesthetic gases,[85] military incidents,[86,87] and ice-hockey arenas (secondary to combustion byproducts from ice-resurfacing machines).[88–91] Nitrogen dioxide is a liquid at room temperature and a reddish-brown gas above 70°F. The acrid smell of nitrogen dioxide makes the inhalation exposure to be avoided at low concentration. Thus, short-term (1 hour peak) nitrogen dioxide concentration outdoor is unlikely to exceed 0.2 ppm.[92] However, low concentrations at 4 ppm may anesthetize the nose, resulting in overexposure.

Nitrogen dioxide is hydrolyzed by the water on mucosal surfaces to form nitric and nitrous acids, though much of its toxicity is explained via the free radical activity of nitrogen dioxide itself and the nitrites and nitrates that derive from it.[93] Though the predominant site of toxicity from nitrogen dioxide exposure is the interface of the terminal bronchioles and alveolar membranes,[94] the relative insolubility of nitrogen dioxide in water ensures that enough gas penetrates the upper airways such that injury can occur virtually anywhere along the respiratory tract.[95] Nitrogen dioxide itself is a reactive nitrogen species that, along with other reactive derivatives, is capable of lipid peroxidation and protein oxidation,[96] both of which may be significant contributors to the gas toxicity via disruption of the cell membrane. Mice with defective toll-like receptor 4 expression exhibit a lessened response to nitrogen dioxide exposure compared to normal strains,[10] suggesting that the patient's innate immunity may play a role in disease development. There is also evidence that nitrogen dioxide exposure is mutagenic to lung cells.[97]

The initial effects of nitrogen dioxide exposure are relatively benign at all but very elevated concentrations, that is, cough, fatigue, and, occasionally, nausea. Recent studies suggest that exposure of nitrogen dioxide in the first year of life increase the risk of persistent cough and developing asthma.[98,99] With high-intensity exposure, patients may also experience headache and chest tightness, though

even these symptoms tend to resolve promptly. Nitrogen dioxide is less irritating to mucosal surfaces than other toxic inhalants. Symptoms typically abate for a period of hours before an intense pulmonary edema consistent with ARDS occurs due to increased capillary permeability following extensive damage to vascular and airway epithelia. Patients who survive this are at risk for the development of BO and BOOP 1 to 4 weeks following exposure.[42]

This clinical course of nitrogen dioxide toxicity demands vigilant monitoring on the part of medical personnel. Patients who are relatively asymptomatic following exposure may rapidly progress to ARDS within hours or severe obstructive BO within weeks. Treatment is largely supportive. In animal studies, antioxidant administration has proven protective against lung injury following nitrogen dioxide exposure,[100] suggesting that aerosolized antioxidant medications are potentially of some utility in humans. Interestingly, nitric oxide (NO) has been used successfully as a pulmonary vasodilator in the treatment of ARDS following acute nitrogen dioxide toxicity.[84] Individuals who survive the initial lung injury still require close following with serial assessment of pulmonary mechanics and gas exchange over the ensuing several weeks. Patients exhibiting evidence of progressive airflow obstruction may benefit from corticosteroids to prevent or decrease the severity of BO.

PHOSGENE

Phosgene (carbonyl chloride, $COCl_2$), like nitrogen dioxide, has relatively low water solubility and penetrates deeply to the alveolar spaces. It is colorless, lacks a strong odor (in high concentrations it is reported to smell like moldy hay) and is not irritating to the nasal and oral mucosa. These traits were notoriously exploited in World War I, when phosgene was used by both sides of the conflict as a weapon, resulting in tens of thousands of fatalities. Modern uses include the production of pesticides, polyurethane resin, toluene diisocyanate, pharmaceutical products, and dyes. It can also be produced accidentally via the heat decomposition of various solvents, paint removers, dry-cleaning fluids, and methylene chloride.[101,102] Small amounts can naturally occur from the breakdown and combustion of organochlorine compounds, such as those used in refrigeration systems.

Phosgene reacts with water to form hydrochloric acid and carbon dioxide, but its limited solubility results in little hydrolysis in the upper airways. In the relatively moist alveolar air spaces, however, the resulting acid is destructive of alveolar walls and small vessels, resulting in epithelial necrosis. Phosgene's lack of irritability in the upper airways precludes the reflex bronchoconstriction provoked by other toxic gases, ensuring open passage of the gas to the alveoli. Phosgene also causes tissue damage by rapidly acetylating the amino, hydroxyl, and sulfhydryl groups of proteins, resulting in protein denaturation and structural compromise of cell membranes,[103] leading to a breakdown of the blood–air interface. Lipid peroxidation has also been shown to occur, and antioxidant therapy has been shown to attenuate phosgene's effects in animal models.[104]

On exposure to phosgene, patients may experience chest tightness, wheezing, or cough; some victims experience no immediate symptoms. Following exposure, the patient experiences a latent period of 30 minutes to 8 hours before the onset of symptoms. The duration of this latent period is thought to be inversely proportional to both the severity of exposure and the ensuing severity of disease.[103] The latent period is typically followed by pulmonary edema: the patient experiences dyspnea, cough and respiratory distress, and rales and cyanosis are appreciable on physical examination. Though survival for patients with acute phosgene exposure is good, numerous long-term sequelae have been reported, including prolonged exertional dyspnea, chronic bronchitis, and emphysema.[105]

During the latent period following exposure, numerous therapeutic options exist that may prevent or lessen the severity of pulmonary edema. Early intervention with antioxidant (N-acetylcysteine) has been shown to be beneficial in animal models by reducing free radical species and preventing biologic mediator–induced inflammation.[104] Ibuprofen, aminophylline, and isoproterenol have all proven beneficial in animal models.[106] Corticosteroids are frequently used but of unproven benefit.[107] There is no benefit from nebulized steroid when administered 1 hour after exposure, or methylprednisolone if administered intravenously ≥6 hours after exposure. Intravenous bolus of high-dose corticosteroid (e.g., methylprednisolone 1 g) may be considered if presentation is <6 hours, although no experimental data are available.[108] The experiments from animal models suggested nebulized furosemide for pulmonary edema should be avoided following phosgene exposure.[109] Nebulized salbutamol treatment following phosgene is also not recommended.[110]

OZONE

Ozone (O_3) is a colorless, odorless gas of low water solubility. It is found throughout the atmosphere and occurs in greatest concentrations in the stratosphere, where it is protective against ultraviolet radiation. It is the main oxidant pollutant in smog and can reach hazardous levels at ground levels on days with elevated atmospheric temperature. Atmospheric levels are known to aggravate chronic lung diseases such as asthma[111] and chronic obstructive pulmonary disease.[112] Acute toxic exposures are associated with its uses in industry, including bleaching of fabrics, disinfecting water and surfaces, and the manufacture of plastics. Reports of acute ozone exposure have been reported in an airplane cabin on a high-altitude flight.[113]

Ozone is extremely reactive, and is almost entirely consumed before crossing a single bilayer membrane.[114] It results in the formation of reactive nitrogen species[115,116] and probably causes toxicity via the oxidation of membrane lipids.[117] Pre-exposure to ozone resulted in enhanced airway hyperresponsiveness (AHR), increased concentrations of total protein and proinflammatory cytokines in whole-lung lavage, and reduced inflammatory cell recruitment to the lower airways. Molecular mechanisms include enhancement of LPS- and LTA-mediated signaling in lung tissue.[118,119] Studies in humans have shown that exposure to ambient levels of ozone can selectively impair epithelial permeability,[120] and that this loss of epithelial integrity is parallel to, but not necessarily coupled with, increased inflammation in the lower respiratory tract.[121,122] Ozone induces epithelial necrosis and airway inflammation[122] and in severe exposures can cause dyspnea, cyanosis, and pulmonary edema. A genetic component to the response to ozone through innate immune signaling has been reported.[123] Treatment is supportive and no specific therapies have been shown to be beneficial.

CADMIUM

Cadmium is a highly corrosion-resistant metal with many industrial applications. Most cadmium is used in nickel–cadmium batteries, though it is also found in alkaline accumulators, electroplating, bearings, solder, and as a barrier around nuclear fission generators. It is present in many metal ores, and cadmium-containing pigments are used in paints, artists' colors, rubber, plastics, printing inks, wallpaper, leather, glass, and enamels. Most inhalations occur in workers who are involved with soldering, brazing, smelting, and refining.[124] The heating of sheet metal electroplated in a cadmium cyanide bath has been reported to cause cadmium toxicity.[125]

The mechanisms involved with the acute lung injury due to cadmium inhalation are not well defined. Some studies suggested that cadmium-induced alveolar cell apoptosis is mediated by FasL and caspase-dependent mitochondrial apoptosis pathways in animal models.[126] Decreased adhesion molecular E-cadherin in epithelial cells of the alveoli and small bronchioles and of VE-cadherin in vascular endothelial cells were found in mouse models post

exposure to cadmium.[127] Postmortem examinations of individuals who died after accidental acute inhalation exposure have revealed tracheobronchitis, consolidated lungs, denuded bronchial epithelium, intra-alveolar hemorrhage, and the presence of macrophages in the alveolar spaces.[128] It is known that cadmium inhibits the synthesis of plasma alpha 1-antitrypsin,[129] which may explain the correlation between cadmium exposure and the later development of emphysema.[130] Rats exposed to cadmium fumes and cadmium chloride aerosols develop pulmonary edema and on necropsy show increased numbers of alveolar type II cells.[124]

When cadmium-containing materials are heated, cadmium vapors and cadmium oxide fumes are released. Patients who are exposed initially present similarly to those with metal fume fever (see below): They are asymptomatic for several hours before developing fever, malaise, and myalgias.[124] These constitutional symptoms are often accompanied by, or shortly followed by, respiratory distress, including cough, chest tightness, and dyspnea. Cadmium may be detected in the urine if the identity of the toxin is uncertain.[131] Fatal cases have been remarkable for initial pneumonitis that relentlessly progresses to ARDS and eventual death from respiratory failure.[128] Management is supportive; there are no specific treatments for cadmium inhalation. Formoterol and ipratropium bromide have been shown to partially protect the lungs against inflammation by reducing neutrophilic infiltration in rats.[132]

MERCURY

Though mercury has a low solubility in distilled water, its solubility increases in contact with plasma or whole blood, as at the blood–air interface. Sources of mercury gas exposure are primarily industrial and include ore smelting, cement production, fur and felt hat manufacture, fossil fuel combustion, and gold extraction. Mercury is found within the silver amalgam used by dentists, and a number of exposures, including several with fatal outcomes, have occurred in the home during amateur attempts to extract precious metals from amalgams that also contain mercury.[133,134]

Like phosgene and cadmium, mercury vapor has little or no immediate upper airway or mucosal surface irritant effects, and as a result exposed individuals may inadvertently remain in an area where the harmful vapors are present. The fatal level of mercury vapor to humans is not known. An exposure to more than 1 to 2 mg/m^3 of elemental mercury vapor for a few hours causes acute chemical bronchiolitis and pneumonitis.[130] Typical clinical presentations include symptoms of cough, dyspnea, and respiratory distress that develop 12 to 24 hours post exposure. These initial symptoms are sometimes accompanied by fever, nausea, vomiting, diarrhea, and a metallic taste in the mouth, similar to what is often experienced by individuals with metal fume fever and associated transient pneumonitis. In fact, mercury vapor inhalation can be mistaken for metal fume fever or influenza. Symptoms of mercury vapor inhalation do not, however, spontaneously resolve as with metal fume fever. Instead, the pneumonitis may progress to ARDS; death has been preceded in several reports by tension pneumothorax.[134,135] The toxicity of mercury vapors within the lung is thought to be due in part to the irritant effects of oxidized mercurous and mercuric ions[136] and to the disruption of enzyme systems containing sulfhydryl groups.[134] Mercury coagulates protein, blocks cellular metabolism of carbohydrates at the pyruvic oxidase level, and as a result produces a metabolic acidosis.[133] Lung pathology following acute exposure reveals pulmonary edema, capillary damage, and the desquamation and proliferation of airway epithelium followed by an obliteration of airspaces.[137] Early CT imaging in patients with acute mercury poisoning reveal ground-glass opacification, alveolar consolidation, and ill-defined nodules. These abnormalities were resolved in follow-up CT scans 30 days after exposure.[138] Inhaled mercury vapor is absorbed rapidly into the blood, where it can achieve systemic toxicity; renal, hepatic, and nervous system pathology have been reported.[139,140] Patients surviving the acute injury typically experience resolution of their symptoms within a week following onset, but have also progressed to develop interstitial fibrosis.[141,142] Mortality due to exposure may be increased in children.[143]

Blood levels of mercury may reflect acute uptake, and urine levels can monitor chronic stores. Treatment of mercury inhalation is supportive and addresses the acute lung injury. Mechanical ventilation, including positive pressure and high frequency oscillating ventilation, may be beneficial in the treatment of mercury-induced ARDS.[143] Early vigorous administration of steroids can decrease the inflammation and delay or prevent the progression to severe interstitial pulmonary fibrosis in mildly affected patients.[144] Chelating agents, such as dimercaprol and d-penicillamine, are frequently used to increase the rate of mercury excretion after ingestion, but have not been shown to affect the outcome of the acute lung injury.[134,144]

ZINC CHLORIDE

Zinc chloride ($ZnCl_2$, or hexite) is odorless, a major ingredient of smoke bombs and smoke-generating devices, and has been responsible for numerous toxic and fatal exposures.[145–148] The compound forms when zinc oxide is ignited with hexachlorethane. Toxic inhalations have occurred in settings in which individuals have inhaled smoke in confined spaces, in most instances without functional protective breathing apparatus (Fig. 90-3). The smoke effect tends to contribute to the duration of exposure by obscuring vision, sometimes resulting in directional disorientation and the inability to quickly escape the area of exposure.

When inhaled, zinc chloride is in particulate form with an average particle size of 0.1 μm, small enough to allow large amounts of it to penetrate through to the lower respiratory tract. After depositing on the airway and alveolar surfaces, zinc chloride reacts with water to form hydrochloric acid and zinc oxychloride. This directly causes irritation of exposed mucosal surfaces and is the probable mechanism behind the diffuse lung injury observed on exposure.[149] The irritation of the mucus membrane of the respiratory tract leads to symptoms, which include burning sensation, coughing, wheezing, laryngitis, shortness of breath, headache, nausea, and vomiting.

Zinc chloride inhalation is commonly followed by tracheobronchitis and pneumonitis, reflecting the sites of particle deposition. Patients experience cough, dyspnea, and chest tightness followed by a period of relative stabilization before progressing to ARDS.[146–148] Chest imaging may be initially normal but can reveal pleural effusions, pneumomediastinum, and bilateral infiltrates consistent with pneumonitis. There is evidence that prominence of ground-glass opacities observed on high-resolution CT imaging is predictive of both severity of exposure and length of hospital stay.[148]

A urine zinc level may confirm the diagnosis of zinc inhalation toxicity. Patients should be monitored for progression to ARDS and treated with supplemental oxygen and mechanical ventilation if indicated. The administration of high doses of N-acetylcysteine may accelerate systemic zinc clearance[150] and thereby spare some oxidant-induced lung injury, though this is unsupported by clinical experience.[146] Since zinc inhalation is locally deposited in the respiratory tract rather than in systemic zinc overdose, the effect of N-acetylcysteine is questionable.[150] Corticosteroid use is similarly controversial. The aim to reduce overwhelming inflammation by early administration of intravenous steroid was offset by the risk of ARDS in patients with sepsis.[151]

MACE AND TEAR GAS

"Tear gas" is actually not gas but a compound of toxic chemical irritants collectively given the names chloroacetophenone (CN or "chemical mace"), *ortho*-chlorobenzylidene malonitrile (CS) and

	1 week	3 weeks	12 weeks

FEV_1	2.2 (52%)	3.0 (69%)	4.7 (107%)
FEV_1/FVC	88%	75%	83%
TLC	3.6 (61%)	4.9 (82%)	6.9 (114%)
RV	1.1 (90%)	1.3 (106%)	1.2 (94%)
DLCO	14 (44%)	19.1 (58%)	48.7 (141%)

Figure 90-3 Chest computed tomography (CT) scan and pulmonary function tests obtained on a person with inhalation injury after a smoke bomb was ignited in an underground cave. The CT scans were obtained 1 week and 12 weeks after the accident and demonstrated extensive interstitial lung disease, which resolved on radiographs. The pulmonary function tests obtained 1, 3, and 12 weeks after the exposure demonstrated marked restrictive lung function and abnormal gas exchange, which also resolved within 3 months of exposure.

oleoresin capsicum (OC or "pepper spray"). All three agents are used by military and law enforcement agencies to control crowds and individuals, making use of their intense and immediate irritant effects on mucus membranes and lacrimal glands. Exposure to any of them results in immediate rhinorrhea, mucositis, chemical conjunctivitis, and profuse lacrimation.[152,153] Immediate pulmonary effects include an intense burning sensation in the upper airways, reflex airway constriction, chest tightness, dyspnea, and cough. Exposure may also provoke nausea, headache, and photophobia. Delayed contact allergy, leukodermia, or exacerbation of pre-existing dermatitis has also been described in case reports.[154] Severity of response depends on the concentration of the agent used, the duration of exposure and the presence or absence of ventilation and protective breathing apparatus.

The effects of tear gas are predominantly due to its upper airway irritant effects, and thus lower airway injury and parenchymal disease are rarely observed. Auscultation of the chest is typically clear, and the chest radiograph is usually without abnormality. Case reports of severe pulmonary disease exist, describing pneumonitis, pulmonary edema, RADS, and acute bronchospasm in an asthmatic.[155–158] These cases have in common prolonged periods of exposure with poor ventilation. A fatal hypersensitivity reaction to CS has been reported.[159]

Due to the possible secondary contamination of healthcare staff, the initial medical management of patients exposed to tear gases consist primarily of nonspecific chemical decontamination and symptomatic therapy.[160] The most immediate concern in the treatment of tear gas exposure is maintenance of a patent airway. Mucosal surfaces should be irrigated profusely, and suction may be useful in clearing the copious oral and nasal secretions that may compromise the airway. Humidified O_2 should be administered. Beta-agonists and ipratropium aerosols should be used in the presence of bronchospasm[161,162]; no benefit from corticosteroids has been observed. Patients with prolonged or intense exposure should be monitored carefully for evidence of progression to significant respiratory disease.

SYSTEMIC ILLNESS FROM INHALED TOXINS

Systemic, flu-like illness lasting under 2 days has been observed in patients exposed to organic dusts and fumes of heated metals and fluorocarbons. The disease course is self-limited and in all cases appears to be cytokine mediated.

METAL FUME FEVER

Since its first description by Potissier in 1822,[163] metal fume fever has been known by a number of other names: brazier's disease, spelter shakes, brass chills, zinc chills, welder's ague, copper fever, foundry fever, and Monday morning fever. It is a self-limited syndrome characterized by the delayed onset of fever, chills, myalgias, and generalized malaise following exposure to fumes that contain

metal oxides. Specific fumes that have been blamed include those of beryllium, cadmium, copper, magnesium, nickel, silver, and zinc. Welders are at the highest risk for developing metal fume fever, though it has been reported in other metalworking occupations including soldering, brazing, cutting, metallizing, forging, melting, and casting. Episodes of varying severity of metal fume fever may be experienced by between 20% and 35% of all welders.[164,165] Exposure is typically associated with confined spaces and poor ventilation. An estimated 2000 cases of metal fume fever are reported each year in the United States.[166]

The typical course of metal fume fever begins with sensations of dry throat and a sweet or metallic taste. Fever, chills, and myalgias develop from 4 to 8 hours after exposure and spontaneously resolve within 48 hours. Respiratory-related symptoms of chest tightness, nonproductive cough, and dyspnea are sometimes observed. Laboratory findings are remarkable for transient leukocytosis; chest X-ray is typically normal, though findings consistent with pneumonitis have been observed. Pulmonary function tests are usually normal, though obstructive and restrictive deficits, as well as abnormalities of diffusion, have been reported. Repeated exposure appears to lead to tachyphylaxis; however, this tolerance is transient and only persists through the work week. The name "Monday morning fever" refers to the recurrence of acute disease on return to exposure following a short period of absence.[167] A proposed mechanism of the observed tolerance to metal fumes involves the increased synthesis of toxic metal–binding protein metallothionein in exposed patients.[168] The disease has been mistaken for influenza, atypical or community-acquired pneumonia, and a malaria-like illness because of overlapping presenting symptoms. The diagnosis is based primarily upon a history of exposure to metal oxide fumes. Metal fume fever is generally thought to have no long-term sequelae. An association between it and the later development of occupational asthma has been observed,[165] but a prospective study failed to show that a history of metal fume fever is predictive of later bronchial hyperresponsiveness.[169]

The pathogenesis of metal fume fever appears to involve an increase in proinflammatory cytokine activity in the lung; increased bronchoalveolar lavage fluid concentrations of tumor necrosis factor (TNF), interleukin-6 (IL-6), and interleukin-8 (IL-8) have been reported in subjects exposed to zinc oxide fumes,[170] probably produced by pulmonary macrophages.[171] Following exposure, bronchoalveolar lavage TNF-alpha levels peak earlier than other cytokines, suggesting that its role may be central to disease progression.[170] Of the numerous components of metal fumes, it appears to be the soluble transition metal particles, which generate reactive oxygen species and deplete glutathione stores, that are responsible for the fumes' cytotoxicity.[172] Gene expression profiling of lung injury following welding fume exposure in a monkey model has been reported to aid in understanding the inflammatory response of lung tissues.[173]

The treatment of metal fume fever is supportive, including bedrest, antipyretics, and analgesics. Metal fume fever must be distinguished from acute metal fume toxicity, as with cadmium or mercury, which can present similarly to metal fume fever but fails to resolve and instead progresses to respiratory distress. Prevention of metal fume fever involves provision of adequate ventilation, fume removal devices, and respiratory protection for workers in environments where metal oxide fumes are generated.

POLYMER FUME FEVER

A syndrome similar to but less common than metal fume fever, polymer fume fever was first reported in 1951.[174] Fluorocarbon polymers are a class of compounds that are commonly used as nonstick coatings on cooking equipment (polytetrafluoroethylene [PTFE, or Teflon®] is a famous example) but are also used as mold-release sprays, lubricants, and fabric or leather treatments.[175] When fluorocarbon polymers are heated to over 300°C, fumes are produced that include carbonyl fluoride, perfluorinated alkanes, hydrofluoric acid, and carbon dioxide.[175] Extremely small particles capable of reaching alveolar sacs may also contribute to disease progression.[176]

Polymer fume fever presents similarly to metal fume fever: Initial symptoms include dry throat, rhinitis, chest tightness, and conjunctivitis. Constitutional symptoms (fever, chills, myalgias) typically follow exposure by about 4 to 8 hours and spontaneously resolve within 1 day. As with metal fume fever, a leukocytosis is observed concurrent with the patient's constitutional symptoms. Individuals with pre-existing obstructive lung disease may experience worsening obstruction after recurrent exposures to polymer fumes.[177] Pneumonitis is more frequently observed than with metal fume fever, perhaps due to release of hydrofluoric acid. Tachyphylaxis, a hallmark observation of metal fume fever, is not observed in polymer fume fever, suggesting that different mechanisms are responsible for the two diseases.[177] As with metal fume fever, the systemic response to particle inhalation appears to be cytokine mediated.[178]

Though exposure to pyrolized fluoropolymers occurs in industrial settings where it may be immediately suspected in the context of respiratory complaints, it also occurs in homes and via less obvious means of exposure. In one report, within an hour of an empty PTFE-coated pan being heated on a stove, five exposed pet birds died and their owner contracted polymer fume fever.[179] Numerous reports have suggested that workers with skin exposed to fluoropolymers may have contracted polymer fume fever via smoking their self-contaminated tobacco.[180–182] Others may have contracted the disease via igniting their marijuana with cotton that had previously been impregnated with hairspray.[183] Several recent episodes of polymer fume fever have occurred following exposure via the waterproofing spray used on horse rugs.[184]

Treatment of polymer fume fever is supportive. Workers exposed to fluoropolymers should both be provided adequate ventilation and also instructed of the risk of indirect exposure via skin contamination. Strict hand-washing should be required and tobacco smoking should be especially discouraged after exposure.

ORGANIC DUST TOXIC SYNDROME

Another systemic illness caused by inhalational exposure is organic dust toxic syndrome (ODTS), also known as silo unloader's syndrome, atypical farmer's lung, pulmonary mycotoxicosis, and toxic pneumonitis. As with metal fume fever and polymer fume fever, ODTS is a self-limited disease that presents with fever, chills, and myalgias several hours after exposure to the offending agent, in this case organic dusts.[185,186] As with the other systemic diseases discussed, ODTS typically resolves spontaneously within 48 hours following exposure. However, patients with underlying lung conditions may lead to incomplete or delayed recovery.[187]

Agricultural workers are at the highest risk for contracting ODTS, as it commonly follows exposure to hay or corn silage–containing silos, spoiled animal feed, and swine confinement facilities. Other settings of ODTS have included a college fraternity party in which hay was laid on the floor,[188] a storehouse containing moldy oranges,[189] a waste-sorting plant,[190] a print-shop in which an air humidifier was colonized with gram-negative bacteria, fungi, and amoebae,[191] and following exposure to woodchip mulch.[192] Lifetime risk of contracting ODTS may be around 19% for farmers with exposure to organic dust.[193]

The specific agent or agents within organic dust responsible for ODTS have not been fully characterized. An epidemiologic study in 2007 suggested contaminated mulch was implicated as the source of presumed ODTS among urban landscape workers, highlighting that ODTS is not limited to rural agricultural settings.[194]

Bacterial cell wall components, endotoxin and peptidoglycan, are thought to play prominent roles.[195,196] Workers handling grass, cereal, or vegetable seeds are at risk of exposure to high levels of endotoxin-containing seed dust.[197] Fungal spores and actinomyces also are likely contributors to pathogenicity,[198] and an ODTS-like response can be provoked with endotoxin-free grain extracts.[199] The disease process is likely initiated or provoked by activation of the patient's innate immune system by organic dust components, such as endotoxin's activation of toll-like receptor 4. Cytokine expression increases following organic dust exposure, especially of proinflammatory cytokines such as tumor necrosis factor-alpha (TNF-alpha) and interleukin-6 (IL-6),[200] suggesting a means by which local activation of innate immunity may provoke the observed systemic manifestations. Interleukin-1 (IL-1) is also thought to play a critical role in ODTS development.[201] An intriguing correlation has been observed between patients with celiac disease and the development of ODTS,[202] suggesting that some underlying disorder, perhaps a hyperactivity of innate immunity, may increase a patient's susceptibility to both.

Patients with ODTS frequently present with no findings on chest examination, though bibasilar crackles and scattered wheezes may be appreciated. A neutrophil-predominant leukocytosis is frequently found, and mild hypoxemia and bilateral infiltrates on chest X-ray have been reported. Though bronchoalveolar lavage may initially reveal a predominance of neutrophils, a lymphocytic response may come to dominate the BAL cellular population.[186]

ODTS needs to be clinically distinguished from hypersensitivity pneumonitis (HP), which is also provoked by inhaled organic dust. HP typically follows low levels of exposure after a period of sensitization, while ODTS is an acute reaction to high levels of organic dust, potentially on first exposure. HP is a restrictive process detectable by pulmonary function testing, while ODTS sometimes presents with transient airflow obstruction and often with no appreciable functional abnormality. The early BAL findings in ODTS are overwhelmingly neutrophilic, unlike the lymphocytic findings in HP.

Treatment of ODTS is symptomatic. Unlike with HP, corticosteroids appear to be of only marginal benefit in the treatment of ODTS.[203]

SUMMARY

Toxic inhalations may be due to numerous agents and produce a broad spectrum of pulmonary and systemic injuries.[204–205] Treatment is largely supportive and should be guided by the patient's clinical status. Specific attention should be paid to the patency of the airway following acute upper airway exposures, and providers should be aware of the risk of the development of severe pulmonary disease following an asymptomatic latent period. Given the unpredictable clinical course of these exposures, cautious monitoring of exposed patients is prudent. Materials safety data sheets and the National Library of Medicine's TOXNET (http://toxnet.nlm.nih.gov/) are excellent information resources for specific toxins.

CHAPTER 91

Indoor and Outdoor Air Pollution

David Q. Rich
Jonathan M. Samet
Mark J. Utell

Both indoor and outdoor air pollution are of concern to pulmonary physicians. Exposures to indoor and outdoor air pollutants may both exacerbate and cause respiratory diseases and also increase the population's risk for morbidity and mortality from malignant and nonmalignant diseases. This chapter provides a broad introduction to indoor and outdoor air pollution. It begins with a brief review of the emergence of indoor and outdoor air pollution as clinical and public health issues. The chapter then considers general principles and concepts related to inhalation injury, exposure, and health outcomes. The health consequences of indoor and outdoor air pollution are covered separately, although this distinction is artificial, given the penetration of outdoor pollutants into indoor environments and the overlap between the pollutants found in indoor and outdoor locations. The chapter concludes by considering two issues of direct concern to clinicians: susceptible populations and control strategies, both at the public health and individual levels. Pulmonary physicians have a key role in advising their patients and in carrying out research relevant to air quality management.

OVERVIEW

Air pollution has probably had adverse effects on health throughout history. The use of fire for heating and cooking brought exposure to smoke, a problem that persists today for the billions who still use biomass fuels, and the rise of cities concentrated the emissions of pollutants from dwellings and manufacturing facilities within restricted locales. Industrialization and electric power generation brought new point sources of pollution; that is, localized sources such as power plants, and sometimes immense emissions of combustion by-products, particles, nitrogen oxides (NOx), and sulfur oxides into areas where people lived and worked. During the twentieth century, mobile sources, including cars, trucks, and other fossil fuel–powered vehicles, created a new type of pollution – photochemical pollution, or "smog" – first recognized in the Los Angeles air basin in the 1940s. The unprecedented growth of some urban areas to form "megacities," such as Mexico City, São Paulo, and Shanghai, has led to unrelenting air pollution from massive vehicle fleets, snarled traffic, and polluting industries and power plants. During the twentieth century, there was increasing recognition that the air pollution problem extends into indoor environments. In less-developed countries, exposure to smoke from biomass fuel combustion (e.g., open burning of wood for heating and cooking inside the home) is widespread, as it was in past centuries. In the more developed countries, indoor pollutants are generated by human activities (e.g., cooking, personal care products, etc.) and released from the materials used for construction and in furnishings, and often maintained at unhealthy concentrations by building designs that seal pollutants within.

Health effects of air pollution have long been of concern. During the reign of Edward I (1272–1307), the pollution of London by coal smoke prompted a royal proclamation banning burning of "sea coal" in open furnaces.[1] In 1661, John Evelyn published *Fumifugium or the Aer and Smoake of London Dissipated*, describing an approach to the control of air pollution in London. However, air pollution was not regulated in England until approximately two centuries later with the passage of the Smoke Nuisance Abatement Act and the Alkali Act, directed at industrial pollution. In the United States, recognition of the public health dimensions of air pollution began in the middle of the twentieth century, driven by the rising problem of smog in southern California and the 1948 air pollution episode in Donora, Pennsylvania, which caused 20 excess deaths and thousands of illnesses.[2] The first national legislation, the Air Pollution Control Act, was passed in the mid-1950s; the original Clean Air Act was passed in 1963[3] and most recently revised in 1990.[4] It provides a comprehensive structure for air quality management in the United States.

The modern era of air pollution research and control dates to the episodes in Donora and other cities, during which extremely high levels of pollution caused clearly evident excess deaths. The most dramatic episode was the London Fog of 1952, which caused thousands of excess deaths.[5] These catastrophic episodes led to regulations for the control of outdoor air pollution and to the conduct of research designed to develop evidence on the health effects of outdoor air pollution as a foundation for control measures. The research included characterization of the pollutants in outdoor air as to their sources, concentrations, and chemical and physical properties; toxicological investigation on the injury caused by air pollutants and the underlying mechanisms; and epidemiological studies of the health effects of air pollution in the community. These approaches remain fundamental to research on air pollution. We now have a large body of evidence on the health effects of air pollution gained over more than a half-century of investigation and complex regulations that limit emissions and control concentrations of key pollutants in outdoor air. These evidence-driven regulations have had substantial impact on air quality in the United States, driving down levels of the most prominent pollutants (Fig. 91-1).[6]

In spite of these improvements in air quality, as indexed by specific pollutants, air pollution remains a significant public health concern. Epidemiological studies show that adverse health effects still occur at concentrations frequently observed and at the upper end of the range of the National Ambient Air Quality Standards (NAAQS). In addition, the approach of regulating concentrations of individual pollutants has left the problem of air pollution mixtures unsolved. One mixture of particular concern is that associated with high-density traffic.[7] Studies conducted over the last two decades have linked this mixture to diverse adverse health effects, including lung cancer, allergies and asthma, respiratory symptoms, reduced lung function, and a variety of cardiovascular consequences. Global warming, a consequence of massive pollution of the atmosphere by "greenhouse" gases, has direct and indirect health consequences.[8]

The health effects of indoor air pollution are a more recent concern.[9] Only limited measurements were made of indoor air contaminant levels before the 1970s, and the findings of the first large-scale studies of the health effects of indoor air pollution were not reported until the late 1960s and early 1970s. Pollutants of initial interest included secondhand smoke (SHS) or environmental tobacco smoke (ETS), the mixture of sidestream smoke and exhaled mainstream smoke inhaled involuntarily by nonsmokers, and nitrogen dioxide (NO_2) generated by gas cooking stoves and

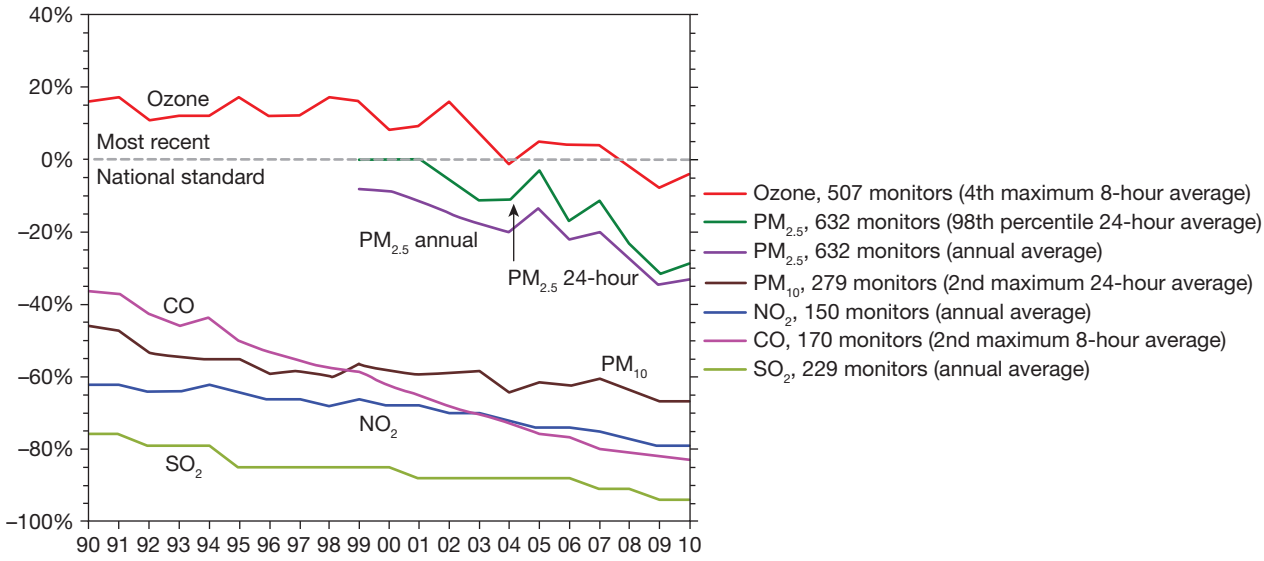

Figure 91-1 Comparison of national levels of the six common pollutants to the most recent National Ambient Air Quality Standards, 1990–2010. National levels are averaged across all monitors with complete data for the time period.

ranges and by space heaters. Research soon broadened to biological agents, volatile organic compounds (VOCs), and two respiratory carcinogens—radon and asbestos (for further discussion on asbestos, see Chapter 86). Concern about the potential health effects of indoor air pollution was heightened by the design and construction of buildings with reduced exchange of indoor with outdoor air for the purpose of energy conservation; the reduction of air exchange was anticipated to diminish dilution and thereby increase indoor air pollutant concentrations. Beginning in the 1970s, outbreaks of nonspecific complaints started to occur among workers, who attributed their symptoms to the indoor environments in which they worked. Now referred to as *sick building syndrome (SBS)*, these outbreaks continue but seemingly in smaller numbers than 10 years ago. Another syndrome, *multiple chemical sensitivity*, has also been linked to indoor air pollution; persons with this controversial syndrome, who may obtain consultation from pulmonary specialists, often report debilitating symptoms after exposure to indoor air contaminants, even at levels that may be considered generally safe. Another concern is disease resulting from potential exposure to mold in homes, particularly following water damage. The flooding of many homes in the Gulf States and New Jersey and New York by catastrophic hurricanes has served to reinforce the potential for chronic exposure to mold.

Control of indoor air pollution has been enacted primarily through nonregulatory approaches,[9] as the Environmental Protection Agency (EPA) does not directly regulate the levels of pollutants in indoor air. The cornerstone of the control of indoor air pollution has been education of the public, manufacturers, and employers on approaches for reducing exposures and for reducing emissions from indoor sources. The EPA has given a guideline value for an acceptable indoor radon concentration; it has also proposed that all homes be tested for radon and the homes modified if the concentration is above the guideline.[10] The handling of asbestos in schools was regulated under the Asbestos Hazard Emergency Reduction Act, and the agency has classified ETS as a class A carcinogen. A rising number of states and municipalities have banned smoking in public places and workplaces. For the majority of households with one or more smokers, some sort of policy is in place to address smoking, either by limiting it to specific locations or not allowing it indoors.

The literature on air pollution is now voluminous and has been published in a broad array of journals and technical reports. Of necessity, this chapter is selective in its review; emphasis has been placed on the most relevant findings for clinicians and on the newer literature. The documents prepared by the EPA on the six "criteria" pollutants (sulfur dioxide [SO_2], particulate matter, NO_2, carbon monoxide [CO], ozone [O_3], and lead) offer encyclopedic reviews that are updated periodically (Table 91-1). Key documents on specific pollutants are cited within the appropriate sections of this chapter.

TABLE 91-1 Criteria Pollutants, Sources, and National Ambient Air Quality Standards (NAAQS)

Pollutant	Sources	Primary Standards	Averaging Time[a]
Sulfur dioxide	Coal and petroleum combustion, smelting, and other manufacturing	75 ppb	1 h
PM_{10}	Coal and petroleum combustion, vehicles, industry, surface dust	150 μg/m^3	24 h
$PM_{2.5}$	Fuel combustion from automobiles, power plants, wood burning, industrial processes, and diesel-powered vehicles	12.0 μg/m^3	Annual (arithmetic mean)
Nitrogen dioxide	Coal and petroleum combustion, vehicles, industry	100 ppb	1 h
Carbon monoxide	Coal and petroleum combustion, vehicles	35 ppm (40 μg/m^3) 9 ppm (10 μg/m^3)	1 h 8 h
Ozone	Secondary formation from NO_2 and hydrocarbons	0.075 ppm	8 h
Lead	Gasoline, lead-containing dust	0.15 μg/m^3	Rolling 3-mo average

[a]*Averaging time denotes the defined time period over which concentration is measured and averaged.*

GENERAL PRINCIPLES AND CONCEPTS

Adverse responses to air pollutants reflect exposure and the delivery of the dose of the injurious agent to the target site within the respiratory tract. Air pollutants cause disease through various mechanisms. This section of the chapter covers principles of inhalation injury and the related spectrum of adverse health effects; it also covers principles of exposure assessment. The research methods used to characterize the effects of air pollutants are also detailed.

PRINCIPLES OF INHALATION INJURY

Atmospheric pollutants, whether indoors or outdoors, exist in both gaseous and particulate forms. In evaluating clinical consequences of specific exposures, the clinician should recognize that penetration into and retention within the respiratory tract of toxic gases can vary widely, depending on the physical properties of the gas (e.g., solubility), the concentration of the gas in the inspired air, the rate and depth of ventilation, and the extent to which the material is reactive. Gases that are highly water soluble, such as SO_2, are almost completely extracted by the upper airways of healthy subjects during brief exposures at rest. In contrast, removal of less water-soluble gases, such as NO_2 or O_3, is much less complete, and these gases may penetrate to the airways and alveoli of the respiratory tract. CO is poorly soluble in water and is not removed in the upper airways. On reaching the lung, CO diffuses across the alveolar–capillary membrane and then binds avidly to hemoglobin.

Exercise greatly augments penetration of gases into the deep lung and, thus, the total dose of pollutants delivered to targets in the airways. Exercise increases the dose directly by increasing minute ventilation; also, because many people switch from the nasal to the oral breathing route during moderate to heavy exercise, the more efficient pollutant removal in the nasal passages is replaced by the less efficient removal in the oral airway.

Particulate pollutants usually occur in nature as aerosols. Small liquid droplets or solid particles are dispersed in the atmosphere with sufficient stability to remain in an aerosol suspension. Examples of common aerosols are sulfuric acid mists and sulfate and nitrate salts formed from SO_2 and NO_2, respectively. Deposition of inhaled particles depends on many factors, including the aerodynamic properties of the particle (primarily size), airway anatomy, and breathing pattern. Particles greater than 10 μm are effectively filtered out in the nose and nasopharynx, where these relatively large particles are deposited efficiently because of impaction against surfaces and gravitational forces. Particles trapped in the nose and nasopharynx are cleared in secretions and coughed out or swallowed. Particles less than 10 μm in aerodynamic diameter (PM_{10}) may be deposited in the tracheobronchial tree; deposition in the lung's alveoli is maximal for particles less than 1 to 2 μm in diameter. Particles less than 0.5 μm move by diffusion to the alveolar level, where they collide with gas molecules by brownian movement and are impacted on alveolar surfaces. Recent interest has focused on both environmental and artificial particles in the so-called "ultrafine" range, that is, particles less than 100 nm in size; despite their extremely small size, high deposition has been found in the respiratory tract and total deposition increases as the particles get smaller. Removal of particles from the larger airways by the mucociliary apparatus is efficient and occurs within hours of deposition; clearance from the deep lung by alveolar macrophages is much slower, requiring days to months. Although particulate matter toxicity has been primarily linked with fine particles, recent studies have indicated that both the ultrafine[11] and the coarse fractions[12] are associated with adverse cardiopulmonary effects.

The mechanisms by which inhaled gases and particles injure the lung are diverse and not yet fully understood. Oxidant gases, O_3 and NO_2, cause inflammation of the respiratory epithelium, presumably through the production of toxic oxidant species and release of potent mediators. SO_2 is also an irritant gas. The response to particles likely depends on the chemical and physical nature of the particles. Oxidizing compounds on particles may dissolve into tissue fluids and induce an inflammatory response. Organic materials on particles may also produce inflammation or act as initiators or promoters of cancer. Particles, once thought to only adversely affect the lungs, may also trigger acute cardiovascular events, in part through effects on pulmonary inflammation and on pulmonary reflexes, via oxidative stress, endothelial dysfunction, autonomic dysfunction, platelet activation, coagulation, etc. A recent review by the American Heart Association discusses these mechanisms and studies of air pollution effects on them in greater detail.[13] The respiratory track, of course, is exposed to multiple pollutants, and interactions among them may synergistically increase effects. Exposure to oxidant gases, for example, enhances responses to inhaled allergens.

ADVERSE HEALTH EFFECTS OF AIR POLLUTION: CLINICAL AND PUBLIC HEALTH CONCERNS

The spectrum of adverse effects of air pollution is broad, ranging from the consequences of acute and dramatic exposures, which may cause death, to far more subtle and chronic effects on disease risk and well-being. This spectrum has been conceptualized as a pyramid with mortality at its tip and an increasingly common set of morbidities as the base. Perhaps the most common "adverse" effect is a loss of well-being from the diminished aesthetic value of a polluted environment. Clinicians are more likely to be concerned with the less common, more acute effects with clinical consequences—acute responses, often in asthmatics, for which a link to air pollution exposure may be made by history or challenge testing; the more subtle and long-term consequences are typically a focus for public health researchers and regulators. Nevertheless, clinicians may be asked to assess risks of long-term exposures or to estimate the contribution of exposures to disease causation in a particular patient. They may also be asked to guide their communities in evaluating air pollution as a local public health problem.

To interpret the scientific evidence on the effects of air pollution, clinicians need a framework for determining whether an effect is "adverse." Judgment on the adversity of responses is societal and reflective of prevalent valuations and perceptions of risk. The Clean Air Act uses the term "adverse" without definition. If a broad construct of health is used that includes a state of well-being as a component, adverse effects of air pollution include not only clinically evident disease but also more subtle symptom responses and physiological effects that may compromise well-being or increase the risk of disease. In a report issued in 2000, a committee of the American Thoracic Society (ATS) offered guidelines for defining adverse respiratory health effects in epidemiological studies of outdoor air pollution.[14] The committee turned to a medical basis for this determination, defining adverse respiratory health effects as medically significant physiological or pathological changes. Increasingly, research focuses on preclinical markers and whether acute changes in panels of markers constitute an adverse health impact remain uncertain.

Indoor air pollution has a broad range of effects as well (Table 91-2).[15] Cases of clinically evident disease caused by indoor air pollution occur, and an unquestionable causal link can often be established for specific persons from a careful history or appropriate diagnostic testing, as with hypersensitivity pneumonitis. Indoor air pollution can also exacerbate chronic respiratory diseases—for example, house dust mite antigen and asthma in house dust mite-allergic persons. More subtle effects have become an increasing concern as we have learned that indoor air pollution can adversely affect comfort and increase risk for future disease; consequently, even the perception of exposure to indoor pollutants may adversely affect well-being. Radon and asbestos, for example, are respiratory carcinogens, which are presumed to increase risk of lung cancer.

TABLE 91-2 A Classification of the Adverse Effects of Indoor Air Pollution

Clinically evident diseases: Diseases for which the usual methods of clinical evaluation can establish a causal link to an indoor air pollutant
Exacerbation of disease: The clinical status of already established disease is exacerbated by indoor air pollution
Increased risk for diseases: Diseases for which epidemiological or other evidence establishes increased risk in exposed persons; however, the usual clinical methods indicative of injury typically cannot establish the causal link in an individual patient
Physiological impairment: Transient or persistent effects on a measure of physiological functioning that are of insufficient magnitude to cause clinical disease
Symptom responses: Subjectively reported responses that can be linked to indoor pollutants or are attributed to indoor pollutants
Perception of unacceptable indoor air quality: Sensing of indoor air quality as uncomfortable to an unacceptable degree
Perception of exposure to indoor air pollutants: Awareness of exposure to one or more pollutants with an unacceptable level of concern about exposure

CONCEPTS OF TIME–ACTIVITY AND TOTAL PERSONAL EXPOSURE

Definitions of concentration, exposure, and dose are fundamental to considering the health effects of air pollution and steps to reduce risk.[16] *Concentration* refers to the amount of material present in air. *Exposure* constitutes contact with a material at a portal of entry into the body—the respiratory tract, gastrointestinal tract, and skin. For the lung, exposure would constitute the time spent in contaminated air. Exposure is calculated as the unit of concentration multiplied by time. *Dose* refers to the amount of material that enters the body; *biologically effective dose* is the amount of material reaching target sites for injury—for example, the mass of respirable particles delivered to the small airways. For example, the concentration of particles less than 10 μm in aerodynamic diameter (PM_{10}) might be 100 $\mu g/m^3$. A person spending 10 hours at this concentration would have an exposure of 10-hour times 100 $\mu g/m^3$, or 1000 $\mu g/m^3 \times h$. Assuming lung deposition to be 50% of the total mass and a minute volume of 10 L/min, the deposited dose of PM_{10} would be 300 μg (0.5 × 100 $\mu g/m^3$ × 10 L/min × 600 min × 0.001 L/m^3). For most inhaled pollutants, dose will vary with activity level which drives ventilation rate.

With regard to impact on health, *total personal exposure* to a pollutant is the relevant index of exposure, not the exposures received separately within indoor and outdoor environments. The total personal exposure of a person to a pollutant can be conceptualized as the time-weighted average pollutant concentration in the "microenvironments" in which the person spends time (Fig. 91-2).[17] The microenvironments are locations having relatively constant concentration of the pollutant during the time spent there. The principal microenvironments contributing to total personal exposure are those with relatively high concentrations or in which relatively large amounts of time are spent. For example, for exposure to particles, key microenvironments might include an office in which smoking is allowed and an urban environment in which a home is located and time is spent outdoors and indoors. New sensing approaches are facilitating more refined studies of activity levels and air pollution and will sharpen understanding of where and when the most risky exposures take place.

Studies of time–activity patterns indicate that residents of more developed countries spend most of their time indoors and, consequently, personal exposures to many pollutants take place largely in indoor microenvironments. However, pollutants generated by outdoor sources do penetrate indoors, so indoor microenvironments can contribute to exposures to pollutants typically considered outdoor pollutants, such as particles and CO. Data on time use in a number of countries showed that people spend an average of 65% to 75% of their time inside their residences and more than 90% of time indoors, counting time at home, work, and elsewhere. Data from a 1987 to 1988 survey of Californians show a similar pattern, with employed adults averaging 15 hours per day indoors at home and 6 hours per day in other indoor settings. In the California study, school-age children spent an average of 18 hours indoors at home.[18] National data from 1992 to 1994 were very similar.[19] While these data emphasize the predominance of indoor microenvironments in determining exposures to many pollutants, exposure outdoors may be the predominant determinant of dose for some pollutants. For example, the dose of O_3 (which generally has low indoor levels) received by the lung's airways may be dominated by exposure received outdoors, particularly for people exercising or working outdoors.

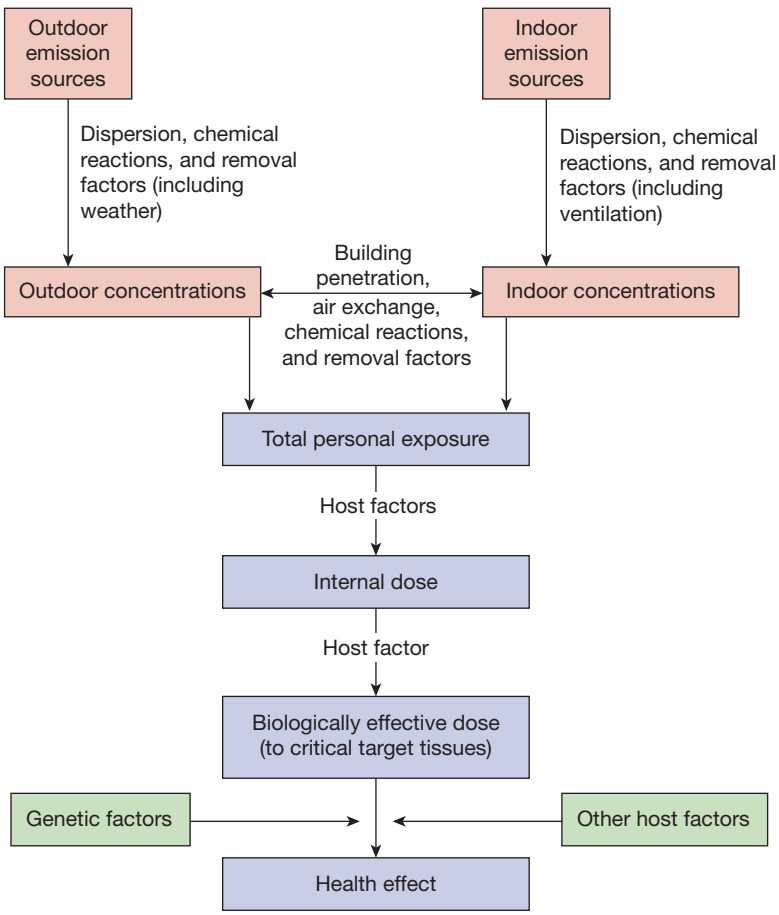

Figure 91-2 Framework for conceptualizing exposure, dose, and health effects from outdoor and indoor air pollution. *(Based on National Research Council data.)*

RESEARCH APPROACHES TO AIR POLLUTION

Our understanding of the health effects of air pollution derives from a tripartite research approach: characterization of atmospheric pollutants and exposures, toxicological studies, and epidemiological studies. These approaches are complementary. There has long been research on the physical and chemical properties of air pollutants, and more recently, exposure assessment has emerged as a separate research discipline. The tools of the exposure assessor include questionnaires that capture activities and time use, personal and area monitoring of air pollution levels, statistical models using these data to estimate exposures, and increasingly sophisticated biomarkers of exposure and dose.[16] There is anticipation that new high-throughput technologies will facilitate data-rich measurement of "the exposome," a variety of biomarkers that will complement the existing approaches.

Toxicological studies are often conducted to characterize the hazards of air pollutants; research may entail exposures of animals to one or more pollutants to assess patterns of injury and disease risk. Increasingly, toxicological approaches are used to characterize the relationship between exposure and dose and the mechanisms underlying injury. This mechanistic information addresses the appropriateness of extrapolating from animal studies to humans, particularly if parallel data from humans are available on dosimetry and mechanisms. Toxicological studies in which volunteers are exposed to pollutants in a controlled setting (e.g., exposure chamber or exposure room sealed off), often referred to as *clinical studies,* have proved to be an informative approach for investigating the acute consequences of pollution exposure. Such studies have been carried out using gases, for example, NO_2 and SO_2, and particles, including concentrated ambient particles and ultrafine particles (UFPs). In addition to healthy volunteers, groups in the population considered susceptible to the effects of the pollutant(s) of concern may be selected for investigation—for example, persons with asthma, chronic obstructive pulmonary disease (COPD), or coronary artery disease. Of necessity, exposures in clinical studies are of brief duration and ethically limited to levels that will have limited, transient effects. In addition to monitoring symptoms and physiological measures, clinical studies may be strengthened by a more invasive collection of biological specimens, using phlebotomy, nasal lavage, or fiberoptic bronchoscopy with biopsy of the mucosa or bronchoalveolar lavage (BAL), to elucidate mechanisms of injury. Molecular approaches using microarrays to analyze changes in gene expression are now being applied to cells (e.g., macrophages and blood monocytes) removed from humans following controlled exposure to pollutants. Clinical studies are also incorporating analyses to identify genetic polymorphisms that determine susceptibility to air pollutants.

There is also growing expectation for using high-throughput testing for assessing the toxicity of various chemicals including air pollutants. Various types of assays are being developed for this purpose; such testing is considered the cornerstone for future predictive toxicology. These approaches envision increased efficiency in toxicity testing and decreased animal usage by transitioning from lengthy in vivo testing to in vitro toxicity assays on human cells or cell lines with mechanistic quantitative parameters. Risk assessment in the exposed human population would focus on avoiding significant perturbations in these toxicity pathways.[20]

Epidemiological studies provide an assessment of the adverse effects of pollution exposures under the circumstances of "real world" exposure.[17] The principal epidemiological study designs used for air pollution research include the following: cross-sectional studies or surveys; short-term cohort studies with intensive measurements of exposures and outcomes (i.e., panel studies); longer-term cohort studies directed at mortality and chronic disease risk[21]; time-series studies that assess short-term changes in outcomes (e.g., daily mortality counts) in relation to changes in daily air pollution levels[22]; and case-crossover studies that contrast the pollution exposure for an individual subject right before he or she had a health event to air pollution exposures of that same subject at other times when that person did not have that health event.[23] There have been several landmark cohort studies, such as the Six Cities Study[24] and the Children's Health Study,[25] but few studies of this design are likely to be implemented in the future, at least in countries like the United States where air pollution levels have declined substantially in recent decades. In part because of feasibility, time-series studies of morbidity and mortality are the most frequent.

The findings of epidemiological studies of air pollution have direct public health and regulatory relevance. The exposures are inherently representative of those received in the community, and the pollutants are inhaled in the form of the complex mixtures that actually exist in indoor and outdoor air. In addition, the community members in a study can be selected from the full spectrum of potentially susceptible subjects. There are, however, weaknesses to the epidemiological approach. Exposures to pollutants may be difficult to measure accurately, particularly past exposures that are used to study current health status. Hence, exposure estimates in epidemiological studies are subject to substantial error, both random and systematic. Generally such errors are likely to lead to underestimation of risk but overestimation is also possible. The effects of other exposures that are correlated with the air pollution exposure of interest and are themselves a predictor of the health outcome of interest, termed *confounding factors,* may not be sufficiently controlled, and thus when not accounted for in the analysis, may artefactually increase or decrease the apparent effect of air pollution exposure. Epidemiological studies having inadequate sample size and, therefore, limited statistical power may supply imprecise and uninformative estimates of risk and not precisely answer public health questions.

The technique of quantitative risk assessment has been increasingly applied to estimate the burden of disease associated with air pollution, particularly carcinogens.[26] The 1990 Clean Air Act amendments include specific provisions on the use of risk assessment, particularly in regard to the hazardous air pollutants regulated under Section 112 of the Act. This process integrates the information on exposure and dose response to provide a characterization of the impact of an environmental agent on the population's health; as the evidence is systematically reviewed in the conduct of a risk assessment, gaps in the evidence and attendant uncertainties are identified, and assumptions are made to fill the gaps.[26] The approach was also used by the World Health Organization in its Global Burden of Disease estimates, which covered indoor and outdoor air pollution.

Risk assessment can be conceptualized as comprising the four steps outlined in the seminal 1983 report of the National Research Council (Table 91-3).[27] A full risk assessment can be a large undertaking, requiring review of all relevant data and mathematical modeling to characterize the risk. It should be undertaken with a clear framing of the questions to be addressed. In a risk assessment, gaps in the scientific evidence, which are sources of uncertainty, are

TABLE 91-3 Steps in Risk Assessment

Hazard identification: The determination of whether an agent is causally linked to the health effect of concern
Dose–response assessment: The determination of the relation between level of exposure and risk of the health effect
Exposure assessment: Description of the extent of human exposure
Risk characterization: Description of the human risk, including uncertainties

catalogued and used to estimate the level of confidence to attach to the risk characterization. The findings of risk assessment guide *risk management*, the process by which decisions are made about the need for risk reduction and the approaches to be implemented to reduce risks. Risk management means choosing among the options to control risk and balancing risk reduction, costs, and technological capability for reducing exposure. Uncertainties in the scientific information that have been catalogued in the risk assessment process may cloud risk management and introduce ambiguity regarding the optimum strategy. Nevertheless, risk managers need to make decisions in the face of uncertainty.

Understanding the effects of complex mixtures of pollutants in indoor and outdoor air has proved particularly daunting for researchers. Exposures to pollutants rarely occur singly, without simultaneous exposures to other pollutants in the relevant microenvironments. Many outdoor sources inherently produce complex pollutant mixtures; for example, power plants release particles, NOx, and sulfur oxides, and vehicle exhaust contains CO, NOx, particles, and hydrocarbons. Indoor air is inevitably contaminated by complex mixtures, reflecting the multiplicity of sources in indoor environments. Synergistic or antagonistic interactions between components of complex pollutant mixtures could produce unanticipated effects, based on the toxicity of individual components.

OUTDOOR AIR POLLUTION

Outdoor air pollutants have diverse sources, both artificial and natural. This section begins with a review of the sources and then considers the effects of the principal artificial outdoor pollutants. The pollutants are grouped according to their designation by the EPA.

OVERVIEW: SOURCES AND CLASSIFICATION OF OUTDOOR AIR POLLUTION

Many pollutants, from both artificial and natural sources, can be found in outdoor air. Some naturally occurring pollutants in outdoor air are well documented as causing or exacerbating pulmonary diseases—for example, pollens and fungi. This chapter does not address these biological agents but considers the artificial pollutants. Researchers have focused more attention on the effects of artificial pollutants, which may reach potentially hazardous levels in urban areas or near-point sources, such as power plants, smelters, or manufacturing facilities. In the United States, the principal outdoor pollutants are generally classified within the framework provided by the Clean Air Act, which identifies two sets of air pollutants, "criteria" pollutants (Table 91-1) and "toxic" air pollutants. The term *criteria* refers to the standard-setting process for these pollutants, which requires preparation of a criteria document reviewing all relevant evidence every 5 years. The criteria pollutants include primarily combustion-related pollutants (SO_2, NO_2, CO, and particles), the secondary pollutant O_3, and lead. The toxic pollutants are predominantly carcinogens, such as asbestos and radionuclides, and irritants. The sources are diverse but principally comprise industrial emissions and waste products. Examples of these pollutants are benzene, chlordane, ethylene oxide, hydrochloric acid, methane, parathion, propylene oxide, toluene, and vinyl chloride.

These two groups of pollutants are regulated through different mechanisms. For the criteria pollutants, NAAQS are set after extensive review of all relevant evidence. The standards must afford protection to the entire population, including those with heightened susceptibility, and offer an "adequate margin of safety." For the hazardous pollutants, standards for maximum concentrations are intended to provide a margin of safety. The Clean Air Act includes mechanisms for achieving levels within the standards and enforcement. In spite of existing federal standards for ambient air quality, excesses are common in many areas of the country, most often for O_3. Although the pollutants are considered in the following section on an individual basis, it should be re-emphasized that exposures of the population occur most often to mixtures, and synergism among individual pollutants may increase the effects of the mixture beyond the expected effect based on the components.

OUTDOOR AIR POLLUTANTS: EXPOSURES AND HEALTH EFFECTS

The pollutants covered in this section are of public health significance throughout the world. Sulfur oxides, particles, NOx, and CO are generated by combustion and are typically found together in the complex air pollutant mixtures in outdoor environments. O_3 is a secondary pollutant. While the pollutants are considered individually, exposures to them typically occur in the form of inhaled mixtures.

Sulfur Dioxide

Sulfur oxides are produced by combustion of fuels containing sulfur, such as coal from the Eastern United States and crude petroleum. Because of changing patterns of fuel use, reduction of acid emissions to control acid rain, and various other control strategies, pollution with sulfur oxides is far less prevalent nationally, while remaining important in some locales with point sources. Smelting of ores containing sulfur is also a prominent source in some regions, such as the southwestern United States. In the past, scientific research and regulatory concern in relation to the sulfur oxides were directed primarily at the health effects of SO_2, the criteria pollutant regulated by the EPA. SO_2 is a water-soluble gas that is effectively scrubbed from inspired air by the upper airway. Exercise, however, may increase the inhaled dose by its effect on minute ventilation and the switch to the oral breathing route. This pollutant has been shown to have adverse effects without concomitant exposures to other pollutants.[28,29] In fact, exposures of volunteers to SO_2 alone show that the gas may have adverse respiratory effects. Asthmatics are particularly sensitive, with some asthmatics having more severe health responses at a particular concentration than others with asthma (see below for specific examples). Significant exposures to SO_2 alone might result from plumes released by smelters processing sulfur-containing ores or from other industrial processes.

Exposures to SO_2 in outdoor air occur primarily with simultaneous exposures to other combustion-related pollutants, including NOx and particles. Heavy industry and coal-burning power plants are predominant sources for this type of pollutant mixture. Tall smokestacks for power plants, used to control local pollutant concentrations, release sulfur oxides and NOx high into the atmosphere, where residence time is prolonged. Through a series of chemical reactions, the sulfur oxides and NOx form acidic sulfate and nitrate particles, which may undergo long-range transport.[30] These acidic particles represent a regional air pollution problem—blanketing, for example, the Central and Northeastern United States and portions of Canada. Fortunately, concentrations of SO_2 have fallen in the United States, in part due to controls implemented under the Environmental Protection Agency's Acid Rain Program, and from changing patterns of fuel use and energy generation. From 1983 to 2002, the average annual concentration fell about 50%. The effects of particulate air pollution and acidic aerosols are considered separately below. This section considers the effects of gaseous SO_2.

Asthmatics are particularly susceptible to SO_2, responding to exposure in chambers with increased airway resistance and reduced levels of lung function. With exercise and hyperventilation, which increase the dose delivered to the respiratory tract, some asthmatics are adversely affected at levels common in ambient air and well below those that might occur transiently with direct exposure to the plume from a power plant or factory. Inhalation of SO_2 produces an immediate response within minutes and does not provoke delayed reactions several hours later or repetitive nocturnal attacks. The decrements in lung function on breathing of SO_2 may be sufficient to produce symptoms of dyspnea, wheezing, and chest tightness. The

bronchoconstriction resolves within an hour of exposure, and peak bronchoconstrictor responses may lessen on repeated challenge after a short recovery period. Responses to SO_2 can be partly blocked by pretreatment with cromolyn sodium and anticholinergics and can be reversed by β-adrenergic agonists. Sequential exposures to SO_2 and oxidant gases (O_3 and NO_2) have been performed in asthmatics; these clinical studies have provided little evidence of synergistic interactions in reducing airway function. Although some asthmatics have been shown to be affected by SO_2 with exposure at low concentrations in the laboratory,[31] complementary epidemiological data have not been reported that document parallel community morbidity.

Epidemiological studies from Hong Kong have examined the consequences of a major reduction in sulfur content in fuels over a very short period of time.[32] The investigators found an associated substantial reduction in health effects (childhood respiratory disease and all age mortality outcomes). Daily SO_2 was significantly associated with daily mortality in 12 Canadian cities with an average concentration of only 5 μg/m^3.[33] Nevertheless, there is still considerable uncertainty as to whether SO_2 is the pollutant responsible for the observed adverse effects or, rather, a surrogate indicator for UFPs or some other correlated substance. For example, in Germany[34] and the Netherlands[35] a strong reduction of SO_2 concentrations occurred over a decade. Although mortality decreased with time, the association of SO_2 and mortality was judged as noncausal and attributed to a similar time trend of particulate matter. Wichmann et al. [34] in Germany considered the persistence of the SO_2 effect as artifact because the SO_2 concentration was much below levels at which effects were usually expected. Furthermore, the results for SO_2 were inconsistent with those from earlier studies conducted in Erfurt. They concluded that both fine particles (represented by particle mass) and UFPs (represented by particle number) showed independent effects on mortality at ambient concentrations. Comparable associations for gaseous pollutants were interpreted as artifacts of collinearity with particles from the same sources.

Nitrogen Dioxide

NOx, like sulfur oxides, are produced by combustion processes (i.e., primary pollutants) and contribute to the formation of aerosols.[28–30] Even though NO_2 is regulated by the EPA as a criteria pollutant, substantial personal exposure in the United States occurs in indoor microenvironments contaminated by unvented gas stoves and space heaters. The principal source of NO_2 in outdoor air is motor vehicle emissions, but power plants and industrial sources may also contribute. There have been few locations where point sources were strong enough to make NO_2 alone a source of concern. The health effects of NO_2 released into outdoor air probably arise principally from the formation of secondary pollutants. NO_2 is an essential precursor of O_3, and one of the principal pathways by which NO_2 in outdoor air adversely affects respiratory health may be through the formation of O_3. The NOx also secondarily form acidic nitrate particles.

NO_2 is an oxidant gas of low solubility that penetrates to the small airways and alveoli of the lung. The toxicological evidence at exposures far greater than typically sustained in indoor and outdoor environments suggests that NO_2 exposure can impair lung defenses against respiratory pathogens and cause airway inflammation, with associated effects on lung function and respiratory symptoms. In animal models, exposure to NO_2 increases mortality after challenge with bacterial respiratory pathogens. Therefore, a wide range of health effects are of concern, including increased risk for respiratory infections, respiratory symptoms, reduced lung function, exacerbation of chronic respiratory diseases as well as acute cardiovascular responses including myocardial infarction. These studies and other evidence on indoor exposures are considered separately in the section on indoor air pollution. Several more recent studies link NO_2 to indicators of morbidity, but the findings are inconsistent and are unlikely to reflect NO_2 acting by itself. Interpretation of findings related to NO_2 is complicated by its role in the formation of O_3 and the importance of vehicular emissions as a source in most locations, making NO_2 concentration a surrogate for the mixture of traffic-related pollutants.

A number of clinical studies have been performed to investigate the acute effects of NO_2 by itself on persons with asthma.[36] These studies were performed to assess the need for a short-term standard for outdoor NO_2 concentration, as the present NAAQS provide only an annual standard for NO_2. NO_2 could plausibly affect airway responsiveness by causing airway inflammation. The findings of the clinical studies have been inconsistent, and the discrepancies between the "positive" and "negative" studies have not been readily explained. The EPA published its most recent assessment of the evidence in the form of an Integrated Science Assessment in 2008.[37] That review concluded that NO_2 is associated with increased airway responsiveness, citing the findings of epidemiological studies. As a result, NO_2 exposure is thought to increase respiratory symptoms on a short-term basis and to contribute to respiratory morbidity. Persons with asthma or COPD may represent groups with increased susceptibility to short-term outdoor exposure to NO_2.

Particles

Particles in outdoor air have numerous natural and artificial sources, including the same combustion processes that produce SO_2 and NO_2. Particles are suspended in air by the action of wind on crustal material and road dust. The artificial sources are diverse and include power plants, industry, and motor vehicles, including diesel-powered vehicles that emit particles in the inhalable size range. Particles, of course, are present in indoor and outdoor air. Consequently, personal exposures to particles reflect both indoor and outdoor microenvironments. In addition, outdoor particles, particularly those of smaller size, penetrate indoors.

The artificial particles are primary (i.e., emitted directly by combustion or other processes), or secondary (i.e., formed through chemical and physical transformation of gaseous pollutants, such as NO_2 and SO_2). Because of the diversity of sources, particles have a rich mixture/composition that may be quite variable, spatially and temporally. The toxicity of particles in a particular place thus reflects the source mix, which includes both local sources and those contributing to the regional background pollution (i.e., pollution generated elsewhere but transported to this and other locations via prevailing winds). In the Eastern United States, for example, much of the regional background of $PM_{2.5}$ comes from transport of power plant emissions from the central portion of the country. Hypotheses proposed on the determinants of particle toxicity have focused on issues related to particle acidity, particle content of transition metals,[38] organic compounds on particles (e.g., diesel particles), bioaerosols, and particle size (e.g., UFPs: particles less than 100 nm in aerodynamic diameter[39]; coarse particles [$PM_{10-2.5}$]: particles between 2.5 and 10 μm in mass). Metals associated with particulate matter are capable of causing pulmonary inflammation and injury and the same chemical properties that allow metals to function as catalysts in reactions with molecular oxygen can generate oxygen-based free radicals and cause oxidative stress. UFPs have a high specific surface area and carry an increased burden of reactive oxygen species. They may be particularly important with regard to cardiovascular effects because of their potential for evading clearance mechanisms, and for entering the lung interstitium and vascular space. Coarse particles, by virtue of their size, are less likely to reach the alveoli. However, they have been associated with increased cardiovascular emergency department visits, and increased respiratory emergency department visits, with the most consistent evidence shown in children. Some, but not all, clinical studies and toxicological studies have also provided evidence for respiratory effects, including pulmonary inflammation and decreased pulmonary function.

Historically, particle concentrations in outdoor air have been measured with several different techniques and over recent decades these technologies have been refined and directed at biologically relevant size fractions. Until 1987, the EPA specified the measurement of total suspended particulates (TSPs), which included particles well above the inhalable size range. In 1987, the reference method for the NAAQS was changed to particulate matter less than 10 μm in aerodynamic diameter (PM_{10}), and in 1997 24-hour and annual standards were added for $PM_{2.5}$. The PM_{10} standard, challenged in court, was set aside in a Supreme Court decision, and in 2005, the EPA proposed a standard for coarse mixes in urban areas, $PM_{10-2.5}$. This set of standards makes no provision with regard to the chemical composition of the particles. Equivalent mass concentrations of particles are hypothesized to have differing toxicity, depending on acidity, content of metals, or carcinogenic potency. The characteristics of particles that determine their toxicity are a focus of current research. The size distribution below the 10 and 2.5 μm cutoffs may also affect toxicity through its consequence for sites of deposition. In addition, the ultrafine component contributes little to the mass and the number count or surface area, but may turn out to be an important metric.

Nationally PM_{10} concentrations have decreased 31% since 1988, mainly in regions of the country that had higher concentrations such as the Northwest (39%), the Southwest (33%), and Southern California (35%). Since 1999, $PM_{2.5}$ concentrations have decreased 10% nationally. $PM_{2.5}$ has decreased the most in regions with the highest concentrations to start with, such as the Southeast (20%), Southern California (16%), and the industrial Midwest (9%). Except for the Northeast, most regions of the country have had at least modest declines from 1999 to 2003. Nationally these declines in PM_{10} and $PM_{2.5}$ have continued through 2010 **(Fig. 91-1)**.

A recent paper has suggested that these reductions in particulate air pollution during the 1980s and 1990s have led to measurable improvements in life expectancy in the United States.[40] They estimated that for each 10 $\mu g/m^3$ reduction in air pollution seen during this time in the United States (many areas in the country saw substantially larger reductions than this, and some regions smaller changes), the average gain in life expectancy was 0.61 years (7.3 months). This gain in life expectancy was independent of changes in socioeconomic status and other lifestyle factors. Further, they concluded that as much as 15% of the total life expectancy increase seen during this time in these areas, was attributable to the air pollution reductions.

There have been extensive epidemiological and toxicological investigations of the effects of particles on health since the air pollution disasters of mid-century.[28,29] The toxicological studies have used a range of approaches, from exposing volunteers to generated particles or concentrated air particles, to animal exposures, and to diverse in vitro assays. This extensive body of evidence shows that particles are injurious and indicates mechanisms by which particles could cause adverse effects on the respiratory and cardiovascular systems.

The epidemiological studies have addressed the relationship between exposures to particles and short- and long-term variations in mortality, both from all causes and from cardiovascular and respiratory causes. The studies have also addressed the relationship between exposures to particles and diverse indicators of respiratory morbidity, including the frequency of respiratory symptoms and illnesses, level of lung function and rates of lung function growth and decline, and outpatient visits and inpatient admissions. More recently, studies have examined if and by what mechanisms particles may trigger acute cardiovascular and cerebrovascular events (e.g., myocardial infarction, ventricular arrhythmia, and stroke) in both epidemiology studies using outdoor particle concentrations (e.g., PM_{10} or $PM_{2.5}$)[41–43] and clinical studies using controlled particle exposures (e.g., concentrated UFP and concentrated $PM_{2.5}$).[44,45] These studies have identified numerous biomarkers of interacting mechanisms responding to short-term increases in ambient and controlled air pollution exposures including systemic and pulmonary inflammation, oxidative stress, coagulation, vascular dysfunction, and autonomic dysfunction to name a few. A more complete discussion of studies examining these and other mechanisms is provided in two recent American Heart Association statements on air pollution and cardiovascular disease.[13,46] In the studies of particulate air pollution during the 1950s and 1960s, the measures of exposure were general. Some studies included only surrogate measures of exposure, such as location of the place of residence. In spite of such crude exposure measures, these studies found adverse effects of exposure to particulate air pollution and became the basis for establishing air quality standards for particles. The standards were generally considered to be sufficiently protective of public health. Studies linked particulate air pollution to a number of adverse health effects including total, cardiovascular, and respiratory mortality, exacerbation of asthma, hospital admissions, impaired lung function, and upper and lower respiratory symptoms.[47]

As levels of air pollution were reduced in the United States and other Western countries, excess mortality at times of higher concentrations was not readily evident and, since the 1970s, the focus of research and of public health concern has generally shifted to morbidity. However, studies of air pollution and daily variations in mortality, facilitated by new techniques for longitudinal data analysis, have shown statistically significant, positive associations between measures of particle concentration and daily mortality counts for cities in the United States and elsewhere. Several analyses have combined data for multiple cities in the United States, Europe, and Asia including studies in China.[48–57] These analyses pool the information from many locations to estimate precisely the effect of particulate matter and also to examine the variations in risk among the contributing locations. These analyses show a statistically significant effect of airborne particles on mortality, independent of the possible contributions of other pollutants or weather. In interpreting these findings, the extent to which life is lost from these short-term effects is critical. Several prospective studies indicate that life shortening from air pollution may be substantial.

Many complementary studies of morbidity have also been reported. These studies have been directed at clinical indicators, such as hospitalization or the triggering of arrhythmias, myocardial infarction, or sudden death. They have also examined biomarkers and electrocardiographic parameters. A review in 2004,[46] and an update in 2010,[13] both by the American Heart Association, detailed a substantial body of evidence linking particulate air pollution to adverse cardiovascular effects. In addition, in some studies, airborne particles have been shown to adversely affect persons with asthma and COPD. These findings suggest that the present NAAQS for particulate matter may not protect against adverse health effects with the "adequate margin of safety" mandated by the Clean Air Act. They also call into question other national and international standards and have led to tightening of the standards, most recently in 2012 when the $PM_{2.5}$ annual concentration standard was reduced to 12 $\mu g/m^3$.

Guidance to patients related to ambient particulate air pollution calls for tracking when pollution levels are high, either by weather forecasts, EPA alerts, or visible haze and reduced visibility. At such times, it is reasonable to advise patients to reduce outdoor activity, particularly with exercise, and avoid locations where pollution levels may be particularly high, for example, adjacent to busy roadways. Such guidance is particularly appropriate for people susceptible to health effects of air pollution (e.g., people with asthma, COPD, coronary artery disease, and/or hypertension). Although mechanisms of toxicity are not completely understood, avoiding air pollution exposure can only help reduce air pollution-mediated cardiorespiratory morbidity and mortality.

Carbon Monoxide

CO is an invisible gas formed by incomplete combustion of fossil fuels and other organic materials. The most prominent outdoor source is vehicle exhaust; consequently, outdoor concentrations are highly variable in place and time, changing with vehicle density and traffic patterns. Urban locations with high traffic density tend to have the highest concentrations. CO also has indoor sources, such as cooking stoves and tobacco smoke. Exposures to CO can be conveniently assessed by using the level of carboxyhemoglobin (COHb) as a biomarker of exposure or by measuring the concentration of CO in an end-tidal breath sample, following a breath hold.

With the passage of the Clean Air Act, significant reductions in outdoor CO have occurred, reflecting emissions control particularly on vehicles. Between 1980 and 2010, there has been an 82% decrease in ambient CO levels. From 2000 to 2010, CO decreased 54%.[58] In regard to outdoor air, acute effects of CO on susceptible persons have been of particular concern, and the current US standard is intended to protect susceptible persons with coronary artery disease. Inhaled CO binds to hemoglobin with high affinity (more than 200 times greater than for oxygen) to form COHb. The COHb complex is very stable; depending on ambient levels of CO, level of activity, and lung function, the half-life of CO in the body ranges from about 2.5 to 4 hours. The rate of accumulation of ambient CO in the body above endogenous levels is affected by ambient CO concentrations, alveolar ventilation, lung diffusivity, total hemoglobin mass, and COHb level.[59] People with impaired gas exchange (e.g., persons with COPD) have compromised ability to excrete CO.

The binding of CO to hemoglobin reduces oxygen transport by red blood cells to tissues. The binding also displaces oxygen and causes an allosteric change in the hemoglobin molecule, which increases the affinity of heme groups for oxygen. Persons with cardiovascular disease are considered to be at greatest risk from CO exposure. Standard exercise tests on subjects with ischemic heart disease have demonstrated a decreased time interval to the onset of angina at COHb levels ranging from 2% to 6%.[60] The 1-hour 35-ppm and 8-hour 9-ppm federal standards for outdoor air (Table 91-1) were selected to prevent COHb levels from rising above 1.5%, thereby protecting persons with ischemic heart disease from aggravation of myocardial ischemia with onset of angina and attendant loss of exercise capacity. Recent evidence indicates that controlled CO exposure during exercise of patients with stable coronary artery disease can induce subjective and objective evidence of myocardial ischemia earlier in the exposure than during exercise without CO. This effect can be induced at COHb levels as low as 2% to 4%. These studies are relevant to the urban environment, where people may be exposed to sufficient CO to reach blood COHb levels in this range. Furthermore, moderate exercise results in even greater CO uptake. In addition, at a COHb level of 6%, patients with coronary artery disease have an increased frequency of arrhythmias.[61] Fetuses, as well as persons with COPD, may also be harmed by CO, and normal persons may have reduced oxygen uptake during exercise at low levels of CO exposure.[61]

The recent studies from the 2008 Beijing Olympics (discussed below) demonstrated a potential role of CO and perhaps other pollutants in inducing adverse changes in cardiorespiratory biomarkers in a panel of healthy young people. CO levels decreased 48% (together with similar-sized reductions in $PM_{2.5}$, SO_2, NO_2, and other pollutants) from before to during the Olympic Games. These pollutant changes were associated with significant reductions in coagulation biomarkers suggesting a role in thrombosis endothelial dysfunction mechanisms[43] as well as in exhaled breath biomarkers suggesting pollution-induced pulmonary inflammation along with signs of respiratory and systemic oxidative stress.[62] A more recent study[63] from Hong Kong found that lower CO levels were associated with a reduced risk of hospital admissions for respiratory tract infections. It is unclear whether pollutant-related CO exposure causes noncardiac toxicity independently or whether it plays a role in health effects elicited by the air pollution mixture.

Ozone

Photochemical pollution, or "smog," is a complex oxidant mixture produced by the action of sunlight on hydrocarbons and NOx in vehicle exhaust.[28,29] O_3, a secondary pollutant, is invariably present in photochemical pollution, and its concentration serves as an index of the level of this mixture. The problem of tropospheric O_3 pollution, that is, ground level, is distinct from the problem of depletion of the stratospheric ozone layer. Photochemical pollution was first recognized over 50 years ago in southern California, where the combination of sunlight and heavy vehicle travel promotes its formation. O_3 has now become a problem in many other locations, including Western cities with similar sprawling growth and heavy vehicle traffic and the Eastern United States during the summer. O_3 is also produced naturally, but the exposure of concern for health almost exclusively reflects the O_3 created by human activities.

Since 1990, NOx emissions have decreased approximately 25% and VOCs emissions have dropped by about 35%. National ozone levels in 2004 were 11% lower than in 1990 and 21% lower than in 1980 for the 8-hour standard (3-year average of the annual fourth highest daily maximum 8-hour average concentration is less than 0.08 ppm). Between 1990 and 2004 the most significant improvements in air quality were in the Northeast (17% decrease) and Southwest (16% decrease) regions of the country.[64] This decline has continued through 2010 for most of the country, with the larger declines in the Northeast (Fig. 91-3).

The toxicology of O_3 has been extensively investigated. Low-level exposures cause damage to the small airways of experimental animals; the demonstration of subtle fibrosis in one animal model has raised concern about permanent structural alteration in exposed populations. Volunteers exposed to O_3 at concentrations in the range of the present standard – which are often present during pollution episodes – experience transient reductions in lung function; normal subjects have a range of responsiveness that is broad but repeatable for individuals. Evidence of an inflammatory response and biochemical changes in BAL fluid has been detected 18 hours after an experimental exposure to O_3 at levels that are commonly found. Taken together, the progressive decrements in pulmonary mechanics during exposure, coupled with the persistent biochemical changes many hours after cessation of exposure, indicate the potential for chronic effects from repeated inhalation. Surprisingly, in clinical studies, asthmatics have not been shown to have increased susceptibility to O_3 compared with nonasthmatics. The evidence for short-term effects of O_3 exposure on the lung function of normal volunteers has raised concern about possible long-term effects of living in Southern California and other locations with sustained photochemical pollution. Relevant epidemiological data suggest that O_3 may have chronic effects, but these data are not definitive, and a long-term study of southern California children found that O_3 specifically was not associated with reduced lung function growth, although other measures of the air pollution mixture were.[25,65] The same study found evidence that O_3 might contribute to the onset of asthma. Some time-series studies have linked short-term exposure to O_3 to increased risk of mortality.[66]

Although there is some evidence that long-term O_3 exposure is associated with increased respiratory and cardiovascular mortality, less is known about if and how O_3 may impact cardiovascular morbidity. Epidemiology studies have provided inconsistent evidence, with one study reporting increased risk of paroxysmal atrial fibrillation associated with increased O_3 concentrations[67] while several studies of myocardial infarction find no such associations with increased O_3 concentrations.[68] There have been few clinical studies of cardiovascular health effects of O_3 exposure or concentrations.

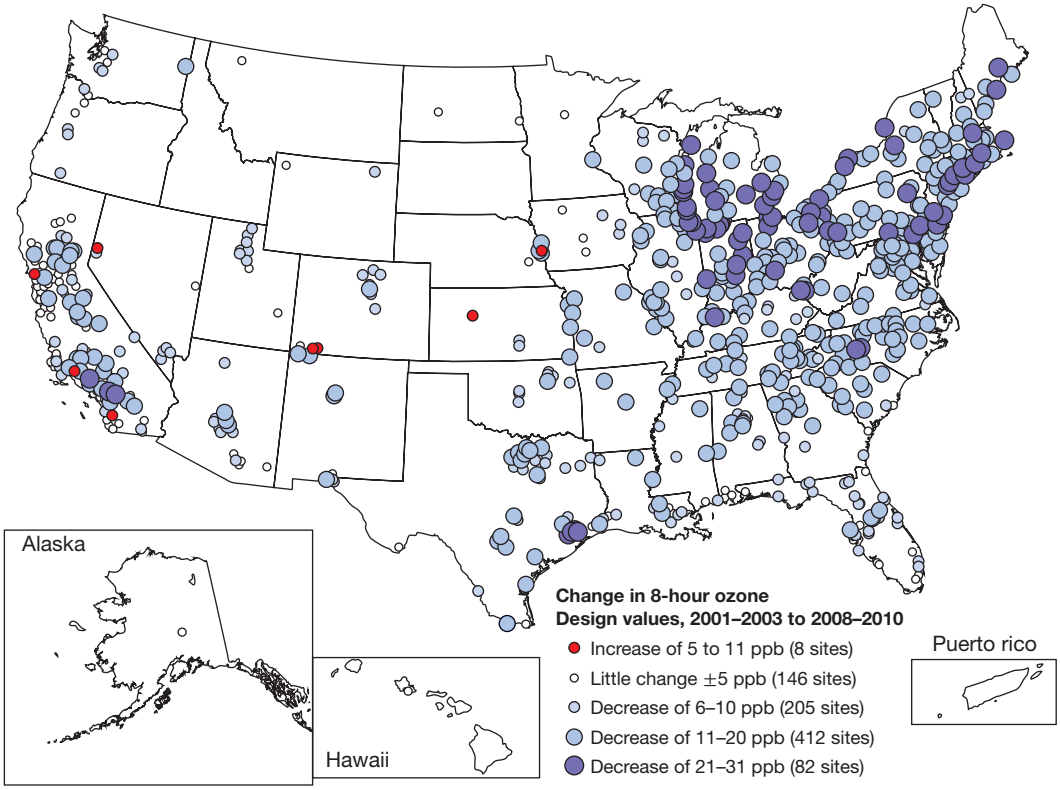

Figure 91-3 Individual monitor 8-hour daily maximum ozone design values, displayed as change from 2001–2003 to 2008–2010.

Recently, a clinical study using "low levels" of O_3 (0.06 and 0.07 ppm for 6.6 hours with exercise) found possible lung function declines following O_3 exposure.[69] A second study with the same two levels of O_3 exposure reported decreased lung function at 0.07 ppm, but not at 0.06 ppm.[70] Based in part on these studies, the 8-hour O_3 standard was reduced to 0.075 ppm. However, there are no studies of cardiovascular responses at these low levels.

Mixtures—Traffic and Diesel Pollution

Much of the health effects research that we discuss in this chapter is based on studies examining individual pollutants, one at a time. For example, in the clinical studies, investigators contrast two exposures (e.g., UFPs at a high concentration with no other pollutants vs. clean air with no UFP or other pollutants) so as to isolate health effects of UFP exposure. In epidemiology studies, researchers typically estimate the risk of a health event associated with an increase in the concentration of one pollutant, even though it is part of a complex mixture. However, none of these pollutants exist in the natural world in isolation. Each day, we are exposed to mixtures of pollutants in various places (at home while cooking food, in a car on the highway, at work in an office or manufacturing facility, etc.). Recently, researchers have begun to look at these air pollution mixtures, both in controlled exposure and epidemiology studies. A review of traffic pollution and related health effects has recently been published.[7]

For example, researchers have studied whether traffic pollution exposure (i.e., gasoline engine emissions, resuspended road dust, tire wear, brake wear) is associated with cardiovascular and respiratory morbidity. One approach for investigating such health effects of traffic pollution is a panel study of people who commute, with health measurements (e.g., blood sample, ECG recording) before, during, and after the time a subject is in the car. Simultaneously, the air pollution levels in the car can be measured, and in statistical analyses, one can determine if the in-vehicle air pollutant levels, which the subject presumably inhaled, were associated with adverse changes in markers measured in the blood and on the ECG. In these panel studies, increased in-vehicle pollution has been associated with adverse changes in numerous cardiovascular biomarkers of inflammation, vascular function, and autonomic function.[71–74] In epidemiological studies, an increased risk of myocardial infarction or ventricular arrhythmias has been associated with being in a car in the previous few hours[75] or even the previous 30 minutes,[76] and with residential distance to major roadways[77] (with people living closer to highways assume to have higher traffic pollution exposure than people living farther from highways). Individual pollutants thought to be markers of traffic pollution (e.g., NO_2, CO, and black carbon) have repeatedly been associated with both cardiovascular and respiratory events, and also with adverse changes in these biomarkers of mechanisms thought to underlie the cardiorespiratory response to pollution. Clinically controlled exposure studies presumably provide the cleanest assessment of health effects of traffic pollution. Evidence clearly suggests that traffic pollution has adverse health effects. However, there is concern that stress and road noise, which may occur at the same time as traffic pollution exposure, may confound these associations.

The impact of diesel exhaust exposure remains another area of concern for adverse cardiopulmonary effects including lung cancer, asthma, and respiratory infections. Several research groups have conducted controlled exposure studies of diesel exhaust, with mixed results. Diesel exhaust is an irritant to which some people are highly sensitive. It has been classified as a human carcinogen by the International Agency for Research on Cancer (IARC), which has concluded that it causes lung cancer. The recently reported Advanced Collaborative Emissions Study (ACES) investigated the cancer and noncancer health effects of subchronic exposures to rats and mice for up to 12 months to diesel exhaust emissions from a heavy-duty diesel engine system compliant with 2007 EPA regulations.[78] In brief, only mild exposure-related effects from detailed histology, pulmonary function, and blood biomarker studies were found. In contrast to the pollutant levels in the "traditional diesel,"

the levels of PM, SO_2, and VOCs in the "new" diesel engines were quite low. A future report on exposures up to 24 months should provide additional insight regarding toxicity of diesel exhaust.

In summary, research methods to study the health effects of these traffic pollutant mixtures, in animal, clinical, and population settings, are being refined. As such, our ability to understand if and how these mixtures impact our health will be greatly improved in the years to come. More work is needed to confirm these adverse effects of traffic, but clearly reducing time exposed to vehicle exhaust would be beneficial.

Lead

Exposure to lead may occur through many environmental media, including ambient air. At present, ingestion is the principal pathway of concern in the United States. Fortunately, in the United States the importance of ambient air as a source of exposure of the population to lead has diminished with the removal of lead from gasoline. Children are particularly vulnerable to lead exposure. Even levels previously considered safe have been associated with adverse neurological effects, and there has been a progressive tightening of recommendations of blood lead levels by the Centers for Disease Control and Prevention. More recent data have linked lead exposure with osteoporosis and possible arthritis.[79] In adults, bone mineral density has shown an inverse association with blood lead levels.[80]

Toxic Air Pollutants

The toxic air pollutants are predominantly carcinogens, but they also include a variety of other toxins. Approximately 200 "hazardous pollutants" are listed as air toxins in the 1990 Clean Air Act amendments. Examples of the hazardous pollutants are asbestos, benzene, cadmium compounds, chlorine, formaldehyde, and nickel. Although the sources are diverse, emission releases tend to be localized, often at industrial sites, or from municipal incinerators or waste sites. The health consequences of these agents are diverse, and include cancer and noncancer effects. Formaldehyde, a ubiquitous pollutant in urban areas, causes cancer of the nasopharynx, exacerbates asthma, and is an irritant to the eyes and upper airway.

Only a small proportion of lung cancers can be attributed to air pollution, even though carcinogens are found widely in outdoor air. For example, polycyclic aromatic hydrocarbons (PAHs), in diesel exhaust, are widely dispersed and present in urban air throughout the world. The PAHs possess mutagenic and carcinogenic activity. But, to date, only limited epidemiological data on risks in humans are available. Analyses of occupational cohorts exposed to diesel exhaust for years are suggestive of a small excess risk of lung cancer.[81] The IARC of the World Health Organization has classified diesel particles as a human carcinogen.[82] Given the difficulties of measuring or estimating exposure, confounding by cigarette smoke and by other occupations, and the small excess numbers of lung cancers, it is difficult to quantify the risk of lung cancer associated with diesel exhaust exposure with a high degree of certainty. Nevertheless, as the percentage of light-duty vehicles powered by diesel fuel in the United States increases, there will be an increasing imperative to determine the carcinogenicity of the PAHs and diesel exhaust. There is also current concern that new types of fuels may introduce additional carcinogens into outdoor air. However, on the more positive side, the ACES discussed earlier has demonstrated the potential with engineering controls to dramatically reduce emissions even from the heavy-duty diesel engines and their potential adverse health effects.[78]

INDOOR AIR POLLUTANTS AND HEALTH EFFECTS

Indoor environments are contaminated by numerous air pollutants, including outdoor air pollutants that have penetrated indoors and indoor air pollutants generated by the numerous indoor sources. This section reviews exposures and health effects of the principal indoor pollutants. The organic compounds and biological agents include myriad individual agents that may adversely affect health. As for outdoor air pollution, clinicians should consider that exposures to indoor air pollutants typically occur as exposures to mixtures, rather than as single agents.

OVERVIEW: SOURCES AND CLASSIFICATION OF INDOOR AIR POLLUTION

Indoor air pollution has myriad sources, including the materials from which the space is constructed, its furnishings, processes operating within the environment, biological agents, and even the occupants. Outdoor air pollutants can also penetrate indoors, as can soil gas, which may contain radon and termiticides. The broad source headings are combustion, evaporation, abrasion, biological, and radon (Table 91-4). The principal combustion sources are gas cooking stoves, burning cigarettes, fireplaces and wood stoves, and unvented space heaters. Evaporation of VOCs from materials and products leads to ubiquitous contamination by these agents. Abrasion of friable asbestos is a principal source of this indoor contaminant. The biological agents are heterogeneous, extending from infectious organisms to pets and the occupants themselves. Radon comes primarily from soil gas.

The concentration of an indoor contaminant depends on the strength of its source, the rate of removal, the volume of the space, and the rate of exchange of air between the space and outdoors. This *mass-balance* formulation indicates that the concentration of a contaminant might be reduced by limiting source strength, increasing removal rate, or increasing exchange between indoor and outdoor air.

In the typical modern building, the exchange of indoor with outdoor air is accomplished by a central heating, ventilating, and air-conditioning (HVAC) system. These systems are diverse, although all have the same purpose: the delivery of air of acceptable quality to building occupants.[83] The volume of air to be delivered follows the recommendation of standards set by the American Society of Heating, Refrigerating, and Air-Conditioning Engineers. In most new high-rise buildings, occupants can no longer control the temperature of the work environment and cannot open windows to increase air exchange. Most residences, however, still rely on natural ventilation.

Carbon Monoxide

CO, a by-product of combustion of fuels, is released indoors by cooking and heating devices and also by smoking. Surveys conducted several decades ago of urban population exposures in Denver, Colorado, and Washington, DC, indicate that residential concentrations of CO are typically low, ranging from 2 to 4 ppm during the winter, when windows of homes are generally closed and the homes heated.[59] People living in homes with gas cooking ranges and those living with smokers have slightly higher levels of personal exposure. Measurements in the surveys of CO in commercial and institutional buildings showed concentrations in the same range as in residences. The CO in residences and public buildings without combustion sources primarily reflects entry of motor vehicle exhaust from outdoor air into buildings through natural and mechanical ventilation. Intake vents at street level bring co-contaminated air into buildings. Elevated levels have been measured in commercial buildings with drive-in window operations (e.g., banks), buildings with underground parking garages, and enclosed ice rinks with ice-resurfacing machines without emission controls.

Acute and chronic health effects may be caused by CO exposure. About 500 accidental deaths in the United States are attributed annually to asphyxiation by CO inhalation and approximately 15,000 people are treated each year in emergency departments for CO exposure. The majority of the nonfatal cases occur in residences, with about 20% associated with faulty furnaces. A small proportion of cases occur in public buildings having faulty, unvented, or

TABLE 91-4 Sources of Common Air Contaminants

Contaminant	Source
Asbestos	
Chrysotile	Some wall and ceiling insulation installed between 1930 and 1950
Crocidolite	Old insulation on heating pipes and equipment
Amosite	Old wood stove door gaskets
Tremolite	Some vinyl floor tiles
	Drywall joint-finishing material and textured paint purchased before 1977
	Cement–asbestos millboard and exterior wall shingles
	Some sprayed and troweled ceiling-finishing plaster installed between 1945 and 1973
	Sprayed onto some structural steel beams as fire retardant
Combustion by-products	
Carbon monoxide	Gas ranges
Nitrogen dioxide	Wood and coal stoves
Sulfur dioxide	Gas and propane engines
Particulate soot	Fireplaces
Nitrogenated compounds	Backdrafting of exhaust flues
	Candles and incense
Tobacco smoke	
Carbon monoxide	Cigarettes
Nitrogen dioxide	Pipes
Carbon dioxide	Cigars
Hydrogen cyanide	
Nitrosamines	
Aromatic hydrocarbons	
Benzo(a)pyrene	
Particles	
Benzene	
Formaldehyde	
Nicotine	
Formaldehyde	Some particle board, plywood, pressed board, paneling
	Some carpeting and carpet backing
	Some furniture and dyed materials
	Urea-formaldehyde insulating foam
	Some household cleaners and deodorizers
	Combustion (gas, tobacco, wood)
	Some glues and resins
	Tobacco smoke
	Cosmetics
	Permanent-press textiles

Contaminant	Source
Biological organisms	
Fungal spores	Mold, mildew, and other fungi
Bacteria	Humidifiers with stagnant water
Virus	Water-damaged surfaces and materials
Pollens	Condensing coils and drip pans in HVAC systems
Arthropods	Drainage pans in refrigerators
Protozoa	Some thermophiles on dirty heating coils
	Animals
	Rodents
	Insects
	Humans
Radon	
Radon gas and radon progeny	Radon gas emanating from soil, rocks, and water that diffuses through cracks and holes in the foundation and floor
	Radon in well water
	Radon in natural gas used near the source wells
	Some building materials such as granite
Volatile organic compounds	
Alkanes	Solvents and cleaning compounds
Aromatic hydrocarbons	Paints
Esters	Glues and resins
Alcohols	Spray propellants
Aldehydes	Fabric softeners and deodorizers
Ketones	Combustion
	Dry-cleaning fluids
	Some fabrics and furnishings
	Stored gasoline
	Outgassing from water
	Some building materials
	Waxes and polishing compounds
	Pens and markers
	Binders and plasticizers

improperly ventilated combustion sources, such as charcoal stoves.[84] The most common symptoms are nonspecific and include headache, nausea, and dizziness.

The level of CO in the blood is a useful biomarker of dose, and the health effects of exposure to CO can be related to COHb levels. In nonsmokers who are not exposed to CO in the environment, COHb levels are approximately 0.5%. This endogenous COHb comes from catabolism of hemoglobin and heme-containing enzymes of the liver. In comparison, COHb levels of cigarette smokers average about 4% and may be much higher. Frank CO poisoning, as

manifest in headache, loss of motor control, and coma, generally occurs with COHb levels above 20%. Clinicians have proposed the concept of "occult" CO poisoning, arising from persistent exposure to low levels of CO in indoor environments. Headache and dizziness, early symptoms of CO poisoning, have been associated with COHb levels greater than 10%. Increased levels of COHb resulting from indoor exposures may, at times, extend to values at which clinical testing has demonstrated cardiovascular and neurobehavioral effects. The Centers for Disease Control and Prevention recommend use of battery-powered CO detectors in homes to avoid CO exposure.

Nitrogen Dioxide

In the United States, with the exception of a few urban areas where outdoor NO_2 levels are high, indoor environments are the predominant determinant of total individual exposure.[85] Residential exposures from unvented gas cooking stoves and kerosene space heaters are the major sources contributing to total individual exposure. Although vented to the outside by building codes, gas furnaces and water heaters may pollute residences because of flue gas spillage and backdrafting caused by improper installation, maintenance, and weather conditions.

Levels in residences and the determinants of these levels have been characterized in many regions of the United States. Indoor NO_2 levels are generally increased during the winter, when homes are closed; they may also be high in the summer, when homes are closed for air conditioning. During cooking, concentrations may reach 1000 ppb while the stove is in use, resulting in substantial, but brief, exposures for persons near the stove. High indoor NO_2 concentrations have been documented in small inner-city apartments and when an oven is used for heating. Data on NO_2 levels in commercial and institutional buildings are very limited, but they generally show low levels consistent with the lack of indoor sources. High concentrations of NO_2 have been measured in ice-skating rinks, contaminated by emissions from resurfacing machines without emissions controls.

Oxidant injury has been postulated to be the principal mechanism by which NO_2 damages the lung. Inhaled NO_2 is thought to combine with water in the lung to form nitric acid (HNO_3) and nitrous acid (HNO_2). At high concentrations, NO_2 causes extensive lung injury in animals and humans. Fatal pulmonary edema and bronchopneumonia have been reported at extremely high concentrations; lower concentrations are associated with bronchitis, bronchiolitis, and pneumonia.

Experimental evidence indicates that NO_2 exposure adversely affects lung defense mechanisms.[36,85] In experimental models, NO_2 affects mucociliary clearance, the alveolar macrophage, and the immune system. In animal experiments employing challenge with respiratory pathogens, exposure to NO_2 reduces clearance of infecting organisms and increases the mortality of the experimental animals.[6] Adverse effects in these animal experiments have been demonstrated at concentrations that are an order of magnitude greater than those typically found in indoor environments.[36,37]

The health effects of indoor NO_2 have been investigated primarily in studies directed at the consequences of indoor exposures for children.[36,85] The toxicology of NO_2 implies that a wide variety of health effects are of potential concern, including reduced efficacy of host defenses against infectious organisms and the consequent increased risk of infection, exacerbation of asthma and COPD, and respiratory tract inflammation with respiratory symptoms and a reduction in lung function. In spite of extensive investigation using laboratory and epidemiological approaches, the evidence still remains inconclusive with respect to each of these health outcomes.

The hypothesis that NO_2 increases the risk for respiratory infection has received the most intensive investigation. A number of epidemiological studies have compared the occurrence of respiratory infections in children in homes having gas stoves and higher concentrations of NO_2 with the occurrence in children in homes with electric stoves and lower concentrations of NO_2. In a cohort study of infants at risk for asthma, NO_2 exposure during the first year of life was associated with respiratory symptoms including wheeze, cough, and shortness of breath.[86] The findings of these studies have been inconsistent, largely because of the methodological complexities of investigating this association. Experimental exposures also have failed to provide consistent evidence that NO_2 increases infectivity in humans.[87]

Inflammation of the airways by NO_2 could plausibly be associated with increased respiratory symptoms and reduced lung function. These potential adverse effects of NO_2 have been examined using data from epidemiological studies of children and adults. Many of these studies have included large numbers of participants studied cross-sectionally. The health outcome measures (e.g., reports of symptoms and levels of spirometric lung function) have been compared for participants living in homes with NO_2 sources, such as gas stoves and space heaters, and participants living in homes without such sources. Despite the number of such studies, there is no clear pattern of results. A meta-analysis using data from 11 studies found that a long-term increase in NO_2 exposure of approximately 15 ppb, consistent with the presence of a gas stove in the home, is associated with a 20% increase in the risk of respiratory illness in children.[88]

Inflammation of airways would be expected to worsen the health status of persons with asthma. Short-term effects of NO_2 exposures on asthmatics have been studied by exposing volunteers and following the level of pulmonary function and nonspecific airway responsiveness. The evidence has been conflicting,[36] and the findings are of limited generality because of the inclusion of relatively mild asthmatics in most studies.

The NO_2 exposures typically found in indoor and outdoor environments are not likely to cause clinically relevant effects for most persons with asthma. However, recent studies indicate that exposure to NO_2, in combination with allergens, may adversely affect persons with asthma. Studies have shown that exposure to NO_2 increases the response to challenge with specific allergen at levels as low as 0.40 ppm.[89] A study of asthmatic children in the United Kingdom showed that exposure to NO_2 increased the severity of virus-caused exacerbations.[90] An experimental study in Australia of reduction of NO_2 exposures in schools showed that symptom rates in asthmatic children dropped following reduction of NO_2 concentration in the classroom.[91] Thus, for persons with asthma, indoor NO_2 from unvented combustion sources could increase the adverse effects of exposure to common indoor allergens, such as those associated with house dust mites, cats, and cockroaches, and to viral pathogens. Little information is available on the effects of NO_2 exposure on persons with COPD.

Secondhand Smoke

Although the prevalence of smoking in the United States has decreased among adults to 19% in 2011,[92] smoking remains common in public places and homes. *Secondhand smoke* (SHS) is a term now widely used to refer to the combination of sidestream smoke that is released from the cigarette's burning end and the mainstream smoke exhaled by the smoker. Survey and biomarkers data on SHS exposure for nonsmokers and children have documented widespread exposures, but the most recent evidence shows substantial declines in exposure to SHS. Blood levels of cotinine, the nicotine biomarker, dropped sharply from years 1999–2000 to 2007–2008 among nonsmoking participants in the National Health and Nutrition Examination Survey (NHANES).[93] In the first survey, most participants had a detectable cotinine value, but a majority did not in the more recent report. If smokers are present, exposure received indoors at home may dominate total personal exposures of involuntary smokers for particles and some gaseous pollutants, such as benzene.[94]

TABLE 91-5 Established Health Effects of Involuntary Exposure to Tobacco Smoke

Decrement in pulmonary function growth in childhood
Increased frequency of acute lower respiratory illness in early childhood
Increase in respiratory illness in children
Increased frequency of middle-ear disease
Increased severity of asthma episodes and symptoms
Onset of asthma
Sudden infant death syndrome
Lung cancer in nonsmokers
Coronary heart disease
Reduced birth weight

Hundreds of chemical compounds have been identified in cigarette smoke; the indicators most often used to quantify its presence in the environment are respirable suspended particles (RSP), particles of mean aerodynamic diameter of less than 2.5 μm, CO, and nicotine, which is in the vapor phase of SHS.[95] Nicotine is a highly specific marker for the presence of tobacco smoke; it can be monitored with both active and passive techniques. Largely because RSP can be readily monitored with area and personal sampling methods, levels of RSP have been widely used as a marker for SHS. The data show that smoking in the home approximately doubles the 24-hour average indoor RSP concentration. Much higher short-term exposures, not reflected in these longer-term integrated measurements, must occur in homes when smoking is actually taking place. Data on SHS levels in public buildings have shown high short-term measurements in bowling alleys, at cocktail parties, in bars, and in other locations with a high density of smokers.

The adverse effects of SHS have been assessed in the context of the voluminous evidence on active smoking and health and of the detailed characterizations that have been made of the composition and toxicology of mainstream and sidestream cigarette smoke. Associations of SHS with disease and other adverse outcomes have been demonstrated (Table 91-5).[95] The evidence has been reviewed by a number of expert panels, with the repeated conclusion that SHS causes both malignant and nonmalignant diseases in nonsmokers.

Studies of children of smoking parents provided the first warning of the adverse effects of SHS on nonsmokers. Maternal smoking was found to increase risk of infants for lower respiratory tract illnesses, and smoking by household members, particularly the mother, was shown to increase the incidence of chronic respiratory symptoms and reduce the rate of lung growth in children.[95] Children with asthma whose parents smoke have heightened airway responsiveness and increased morbidity, as documented by indexes of medical care utilization. Exposure to SHS is also a suspected cause of asthma, and infants of smoking parents have increased airway responsiveness shortly after birth. Epidemiological studies show that parental smoking is associated with persistent middle-ear effusions and other ear problems.[95]

Exposure to SHS was first linked to lung cancer in never smokers in two reports published in 1981.[96,97] Numerous epidemiological studies have addressed this association, and the weight of the evidence shows a consistent positive association between living with a smoker and the risk of lung cancer. By 1986, the evidence led to conclusions of the IARC,[98] the US Surgeon General,[99] and the US National Research Council[100] that SHS causes lung cancer in never smokers. The risk of lung cancer is increased by approximately 20% for never-smoking women married to smokers. Based on review of the epidemiological evidence, as well as the supporting toxicological data, the EPA classified SHS as a class A carcinogen, a designation applied to agents causally linked to cancer.

Additional health effects of SHS have now been identified. A number of epidemiological studies have shown that marriage to a smoker increases risk for ischemic heart disease.[95] Although the evidence is not as extensive as for the respiratory consequences of SHS exposure, the American Heart Association, the United Kingdom's Scientific Committee on Tobacco, and the EPA of the State of California have concluded that SHS exposure is a cause of cardiovascular disease and death. Estimates have been made that SHS causes between 23,000 and 70,000 cardiovascular disease–related deaths annually. Cited mechanisms include promotion of atherosclerosis, increased platelet aggregation, endothelial cell damage, and the consequences of CO exposure. SHS exposure at home and in the workplace has been linked to reduced lung function in some studies.

Recently, research has been published on "thirdhand smoke," referring to surface-deposited components (e.g., on clothing, furniture, and other surfaces) of tobacco smoke and metabolic byproducts of these components.[101] Thirdhand smoke is neither smoke nor a pollutant present in the air, rather, it is composed of various compounds, many that are volatile or semivolatile, that may have a long-lived presence following deposition. Experimental research and field specimens show that these compounds may be long lived and undergo chemical transformations. Thirdhand smoke components may be absorbed via the skin or through ingestion of components on the hands or on contaminated objects that young children put into their mouths.[101]

Wood Smoke

The presence of wood smoke indoors can be assessed by measurements of particles, organic compounds, and CO. Available data for developed countries suggest that the routine operation of a properly installed and maintained wood stove does not greatly affect indoor air quality, and outdoor air contaminated with wood smoke of neighbors can enter and pollute the interior air of homes without wood stoves. By contrast, in developing countries, biomass fuel combustion for cooking and space heating leads to very high exposures for large numbers of households around the world and also contributes to outdoor air pollution.

Wood smoke is a complex mixture, both in its physical and chemical characteristics and in its toxicological properties. The toxicology of some components of wood smoke, such as benzo(*a*)pyrene, other polycyclic organic compounds, and NOx, has been extensively studied. Little research, however, has addressed the toxicology of wood smoke as a complex mixture.

Some of the epidemiological evidence on the health effects of wood smoke is derived from investigations in developing countries, where intense smoke exposure results from the use of cooking fires in poorly ventilated dwellings. Studies from less developed countries suggest that smoke exposure adversely affects children and adults, increasing the occurrence of acute respiratory illness in children and chronic respiratory morbidity in children and adults. The occurrence of COPD in never-smoking women exposed to wood smoke has been described as well.

In developed countries (e.g., northern states of the United States), wood burning is becoming more prevalent as a heating source due to the improvement in home wood burning technologies and the need for less expensive and renewable alternative fuels. Recreational wood burning (e.g., open outdoor fire pits, bonfires, etc.) also remains prevalent. In the winter during cold periods, when there are more often stagnant air masses and temperature inversions, outdoor wood smoke particulate matter concentrations may remain elevated

TABLE 91-6 Common Organic Chemicals and Their Sources

Chemicals	Measured Peak Nonoccupational Exposure (μg/m^3)	Major Sources of Exposure
Volatile chemicals		
Benzene	1000	Smoking, auto exhaust, passive smoking, driving, pumping gas
Tetrachloroethylene	1000	Wearing or storing dry-cleaned clothes, visiting dry cleaners
p-Dichlorobenzene	1000	Room deodorizers, moth cakes
Chloroform	250	Showering (10-min average)
	50	Washing clothes, dishes
Methylene chloride	500,000	Paint stripping, solvent usage
1,1,1-Trichloroethane	1000	Wearing or storing dry-cleaned clothes, aerosol sprays, fabric protectors
Trichloroethylene	100	Unknown (cosmetics, electronic parts)
Carbon tetrachloride	100	Industrial strength cleansers
Aromatic hydrocarbons	1000	Paints, adhesives, gasoline, combustion sources
Toluene, xylenes, ethylbenzene, trimethylbenzenes		
Aliphatic hydrocarbons	1000	Paints, adhesives, gasoline, combustion sources
Octane, decane, undecane		
Terpenes	1000	Scented deodorizers, polishes, fabrics, fabric softeners, cigarettes, food, and beverages
Limonene, *a*-pinene		
Semivolatile chemicals		
Chlorpyrifos (Dursban)	10	Insecticide
Chlordane, heptachlor	100	Termiticide
Diazinon	100	Insecticide
Polychlorinated biphenyls (PCBs)		Transformers, fluorescent ballasts, ceiling tiles
Polycyclic aromatic hydrocarbons (PAHs)	1	Combustion products (smoking, wood burning, kerosene heaters)

for extended time periods. Further, indoor wood smoke exposure may be quite high if proper ventilation is not used. Data from health effect studies suggest that increased particulate air pollutant concentrations from wood smoke are associated with respiratory health effects, but a recent review concluded there was no evidence that wood smoke particles infer more or less toxicity than particles from other sources.[102]

There has been limited work examining cardiovascular health effects of wood smoke exposure. Studies done in occupationally exposed firefighters and studies using controlled wood smoke exposures have had mixed results, with some, but not all, reporting increased pulmonary and systemic inflammation and hemostatic responses.[103–108] However, studies have generally not reported increases in acute cardiovascular events in populations exposed to forest fire smoke.[109–112] In cities where wood smoke particle concentrations are a large component of particulate air pollution in the winter (likely from wood being burned for indoor heating), increased concentrations have been associated with increased cardiorespiratory hospital admissions.[113–115] Other community-wide and in-home intervention studies have examined whether efforts to reduce pollution levels improve health. These studies have generally reported improved levels of inflammatory, endothelial function, blood pressure, and myocardial ischemia biomarkers, as well as reduced cardiorespiratory mortality associated with reduced wood smoke exposures and concentrations.[116–119] Although these studies suggest that wood smoke may impact cardiovascular outcomes, the evidence is not conclusive. But again, reducing exposure to wood smoke is likely beneficial.

Organic Compounds

Organic compounds are ubiquitous indoors, where they are released from furnishings and equipment, construction materials, and consumer and office products (Table 91-6).[94] The organic compounds found in indoor air can be grouped by boiling point range as volatile (0–240 °C), semivolatile (240–380°C), and particulate (greater than 380°C). The volatile and semivolatile organic compounds are most relevant to human health. VOCs exist as vapors over the normal range of air temperatures and pressures, whereas semivolatile organic compounds are liquids or solids but also evaporate.

Hundreds of organic compounds have been identified in indoor air.[94] Although many of these agents are also released by outdoor sources such as chemical plants, indoor concentrations and sources have been shown to determine personal exposures to most of the organic compounds. The Total Exposure Assessment Methodology (TEAM) study conducted by the EPA showed the dominant contributions of indoor sources to personal exposures, even in locations with outdoor air polluted by industry.[120] For example, benzene, a human carcinogen, may be emitted into outdoor air by industry and from gasoline. Among cigarette smokers in the TEAM study, however, the main source of personal exposure was benzene in mainstream cigarette smoke; passive smokers are also exposed to benzene.

Formaldehyde, used in hundreds of products, is one of the most ubiquitous indoor organic compounds. The largest use of formaldehyde is in preparation of urea and phenol-formaldehyde resins, which are used to bond laminated wood products and to bind the wood chips in particle board. Formaldehyde-containing

wood products are used as shelving, counters, bookcases, cabinets, floors, and wall coverings in homes, offices, and public buildings. Formaldehyde resins are also used to treat paper products and fabrics and are constituents of numerous other consumer products. Formaldehyde is an irritant to which some people are highly sensitive. Formaldehyde has been classified as a human carcinogen by the IARC, which concluded that formaldehyde causes nasopharyngeal cancer and also leukemia.[121]

The health risks of the organic compounds are diverse; the organics found in indoor air include several dozen carcinogens and mutagens (e.g., benzene), irritants (e.g., formaldehyde and terpenes), and neurotoxins (e.g., aromatic compounds). Despite the potential risks of the organic compounds in indoor air, few studies have shown specific exposure–disease associations, largely because of the difficulty of characterizing exposures and identifying effects of components of complex mixtures in indoor air. Indoor exposures to organics may contribute to the risks for several cancers, although few epidemiological studies have been directed specifically at assessing cancer risk in relation to indoor exposures to organics.

Radon

Radon-222, a noble gas, is in the decay chain of naturally occurring uranium-238. It decays with a half-life of 3.8 days into a series of short-lived progeny: polonium-218, lead-214, bismuth-214, and polonium-214. Irradiation of respiratory epithelial cells by alpha particles released by polonium-218 and polonium-214 damages cellular DNA and causes lung cancer. The principal source of radon in buildings is naturally occurring gas in soil.[122] The driving pressure for entry of soil gas into a building is the pressure gradient established by a structure across the soil. The soil gas enters through openings, such as sump pump wells, drains, cracks, and utility access holes. In most locales, building materials and water used in the home do not contribute significantly to concentrations of radon indoors. Because radium, the parent radioisotope for radon, is ubiquitous, radon is present in outdoor air and in higher concentrations in indoor environments.

Extensive data on radon concentrations in homes in the United States show that the average value is about 1.5 picocuries per liter (pCi/L). Homes with high concentrations have been identified in all states, although the proportion exceeding the EPA's action guideline of 4 pCi/L is variable among the states. In a national survey conducted from 1988 to 1991, the EPA measured radon concentration in 6000 randomly selected homes in the United States. About 4% of homes were estimated to exceed the guideline of 4 pCi/L annual average.

Exposure to radon progeny, the short-lived decay products of radon, has been causally linked to increased risk of lung cancer in uranium miners and other underground workers.[123] Measurements made since the 1970s in the United States and elsewhere have shown that radon is present in most homes and can reach high concentrations – as high as those in underground mines – with a documented excess of lung cancer. Current risk models that assume that the risk follows a linear nonthreshold relationship imply that even values under current guidelines cause a significant number of lung cancer cases. Thus, any exposure is assumed to convey some risk, an assumption supported by experimental data. In addition, epidemiological studies of indoor radon confirm that indoor radon concentration is positively associated with radon risk.[124,125]

The hazard posed by exposure to radon progeny in indoor air has been characterized primarily through risk estimation procedures. In the most widely applied risk assessment approach, the risks for the general population are projected by extrapolating risks observed in the studies of miners to the general population. The risk of radon indoors has also been directly estimated by carrying out case-control studies in the general populations. Estimates obtained by pooling the results of these studies are consistent with the extrapolated risks from studies in miners. Use of such models leads to the conclusion that radon contributes significantly to the incidence of lung cancer in the population. The burden of radon-related lung cancer in the general population reflects, in part, the synergism between radon and cigarette smoking assumed in the models.

One risk model is based on a pooled analysis of data from 11 epidemiological studies of male miners, including 68,000 who accounted for more than 2700 cancer deaths.[123] The analysis showed a positive linear relationship between the risk of lung cancer and occupational radon exposure, down to exposures only a fewfold greater than average lifetime exposure from indoor radon. Lung cancer risk was found to decline with increasing age and time since exposure; the risk was also found to increase as the rate of exposure decreased—the so-called inverse dose-rate effect. When the model was applied to the US population, indoor exposure to radon at home was estimated to be responsible for about 12% of lung cancer deaths in the United States. Of the 15,000 to 22,000 lung cancer deaths attributed to radon in 1995, about 85% were assigned to smokers and 15% to never smokers.

The substantial lung cancer burden attributed to indoor radon has led to programs for reduction of exposure. The program in the United States, conducted by the EPA, calls for voluntary measurement of radon levels in single-family homes and modification if the annual concentration exceeds the agency's guideline level of 4 pCi/L.[126] Two types of passive measurement devices are available: short-term devices, which make measurements for a few days, and long-term devices, which make measurements for periods of months up to a year. The short-term devices, primarily charcoal canisters, are often used when a measurement is quickly needed during a real estate transaction; the longer-term devices incorporate a piece of plastic that is etched by alpha particles released by progeny.

Fortunately, increased radon concentrations can be lowered, often by such simple measures as sealing basement cracks and sump holes. Approaches also include ventilating the basement to the outside and, for homes built on concrete slabs, by providing a system to exhaust the soil gas from beneath the slab. In areas having a high potential for indoor radon problems, radon-resistant construction techniques can be applied in anticipation of high levels.

The success of the EPA's program for managing the indoor radon problem rests on voluntary action by the public. To engage the public, the Agency has developed a risk communication strategy that uses the media, voluntary health agencies (e.g., the American Lung Association), and healthcare providers. Its pamphlet, "A Citizen's Guide to Radon," informs readers about the risks and the recommended approaches for managing them.[126]

Asbestos and Artificial Fibers

Asbestos, comprising several fibrous inorganic materials characterized by chemical formulation and crystalline structure, has been used extensively in building materials since the beginning of the last century because of its high tensile strength and thermal properties (see also Chapter 86). The broad categories of use are thermal and acoustic insulation, fire protection, and reinforcement of building products. In addition to its use in acoustic ceiling tiles and vinyl floor tiles, asbestos has been used in paints and wall and ceiling plaster; until banned in the late 1970s, asbestos materials were used to coat pipes, boilers, and steel structural beams.

Asbestos-containing materials are present in homes, offices, and schools. The EPA has estimated that 20% of the nation's buildings, or about 733,000 buildings (not including schools and residential dwellings with fewer than 10 units), contain some asbestos materials.[127]

Asbestos had been used widely in ceiling tiles, pipe wrap, plaster, floor tiles, shingles, and sprayed-on insulation, among other applications. Release of fibers from these materials may result from impact, abrasion, fallout, vibration, air erosion, and fire damage.[127] Water damage and the normal aging of binders, leading to the friability of the material, increase the likelihood of release.

Asbestos-contaminated surface dust may contribute to airborne concentrations in buildings.

Artificial mineral fibers are now used increasingly as substitutes for asbestos in building materials. These are fibrous inorganic substances made primarily from rock, clay, slag, or glass; the principal types are glass fibers (comprising glass wool and glass filaments), rock wool, slag wool, and ceramic fibers. Fiberglass and glass wool refer to silica-based vitreous fibers manufactured by a number of different processes. The different types of fibers vary in their chemistry and dimensions, as well as in their durability in vivo. Because they are physically fibrous, there is concern about the same health effects as for asbestos.

An enlarging database on airborne asbestos concentrations in buildings demonstrates extremely low average values under the conditions of normal building use.[127,128] Occupant risk is determined by exposures to airborne fibers, rather than the presence of asbestos-containing materials in the building. Surveys of asbestos concentrations in commercial buildings demonstrate very low fiber concentrations under normal conditions. The Literature Review Panel Report published by the Health Effects Institute, Asbestos Research Committee, compiled all published data, as well as previously unpublished information, on buildings sampled for litigation and for other purposes. The total data set included 1377 measurements made by transmission electron microscopy in 198 buildings. For fibers greater than 5 mm in length, which are considered most relevant to disease risk,[129] the mean and median concentrations were low, at approximately 0.001 fiber per milliliter, or three or more orders of magnitude lower than concentrations in the occupational settings of the past. Individual buildings with levels much higher than the typical values in the data assembled by the Health Effects Institute, Asbestos Research Committee, have been reported.

For office workers, visitors to buildings, and schoolchildren and teachers, mesothelioma and lung cancer are the principal health effects of concern; asbestosis would not be expected at usual exposures for these building occupants. The risks of indoor asbestos for the general population have been estimated by extrapolation of risks for occupationally exposed persons. Uncertainty is inherent in this approach, but the risks cannot be directly investigated by epidemiological methods. The Literature Review Panel Report of the Health Effects Institute, Asbestos Research Committee, has estimated risks for various scenarios of exposure (Table 91-7).

Custodial and maintenance workers in buildings with asbestos-containing materials may be exposed to higher levels of asbestos than other building occupants, since their activities disturb the materials and release fibers. These workers may be at particular risk if they are unaware that asbestos-containing materials are present or are untrained in dealing with these materials. Several studies have shown that custodial and maintenance workers may have pleural plaques and possibly asbestosis, causing concern that a "third wave" of asbestos-caused disease could occur in such workers.

Because of the morphological and toxicological comparability of asbestos and artificial mineral fibers, there has been concern that exposure to artificial mineral fibers could produce the same diseases caused by asbestos. The relevant epidemiological data from exposed workers are less extensive than for asbestos. Animal studies have shown the fibers that are long and thin to be carcinogenic. The health risk of artificial mineral fibers for exposures of building occupants remains uncertain.

In 2002, IARC re-evaluated the carcinogenic risk of airborne artificial vitreous fibers.[130] Epidemiological studies as well as research conducted on newer fibers, were evaluated. Pulmonary morbidity studies among production workers in the United States and Europe have demonstrated an absence of interstitial fibrosis. IARC concluded that only the more biopersistent materials, such as refractory ceramic fiber (RCF), remain classified as possible human carcinogens. Continuous glass filaments and the more commonly used vitreous fiber wools, such as insulation glass wool, rock wool, and slag wool, are now considered not classifiable as to their carcinogenicity to humans. Nevertheless, to date, no data are available linking RCF with tumors in humans. The one mortality study of RCF workers showed no excess mortality for all deaths, all cancers, or malignancies or diseases of the respiratory system including mesothelioma.[131]

TABLE 91-7 Estimated Lifetime Cancer Risks for Different Scenarios of Exposure to Airborne Asbestos Fibers[a]

Conditions	Premature Cancer Deaths (Lifetime Risks) per Million Exposed Persons
Lifetime, continuous outdoor exposure	
0.00001 fiber/mL from birth (rural)	4
0.00001 fiber/mL (high urban)	40
Exposure in a school containing ACM, from age 5 to 18 y (180 d/y, 5 h/d)	
0.0005 fiber/mL (average)[b]	6
0.005 fiber/mL (high)[b]	60
Exposure in a public building containing ACM, from age 25 to 45 y (240 d/y, 8 h/d)	
0.0002 fiber/mL (average)[b]	4
0.002 fiber/mL (high)[b]	40
Occupational exposure from age 25 to 45 y	
0.1 fiber/mL (current occupational levels)[c]	2000
10 fiber/mL (historical industrial exposures)	200,000

ACM, asbestos-containing material.

[a]This table represents the combined risk (average for males and females) estimated for lung cancer and mesothelioma for building occupants exposed to airborne asbestos fibers under the circumstances specified. These estimates should be interpreted with caution because of the reservations concerning the reliability of the estimates of average levels and of the risk assessment models.

[b]The "average" levels for the sampled schools and buildings represent the means of building averages for the buildings reviewed herein. The "high" levels for schools and public buildings, shown as 10 times the average, are approximately equal to the average airborne levels of asbestos recorded in approximately 5% of schools and buildings with asbestos-containing materials. If the single highest sample value is excluded from calculation of the average indoor asbestos concentration in public and commercial buildings, the average value is reduced from 0.00021 to 0.00008 fiber/mL, and the lifetime risk is approximately halved.

[c]The concentration shown (0.1 fiber/mL) represents the permissible exposure limit proposed by the U.S. Occupational Safety and Health Administration. Actual worker exposure, expected to be lower, will depend on a variety of factors, including work practices and use and efficiency of respiratory protective equipment.

Biological Agents

Indoor allergens and microbes – the principal biological agents in indoor air relevant to human health – have diverse sources, both indoors and outdoors (Table 91-8). Indoor levels of allergens and microbes may be increased by accumulation of materials indoors, such as human and animal dander, and growth of fungi and bacteria

TABLE 91-8 Sources of Biological Air Pollutants

Acarids
Dust mites and spiders
Insects
Cockroaches, crickets, beetles, fleas, moths, flies, and midges
Domestic animals
Cats, dogs, other mammals, and birds
Rodents
Wild
Mice and rats
Pets
Mice, gerbils, and guinea pigs
Fungi
Indoors (growing on interior surfaces or in air-conditioning systems)
Penicillium, Aspergillus, Rhizopus, and *Cladosporium*
Outdoors
Numerous species entering with incoming air
Pollens
Derived from outdoor plants or plant materials brought inside
Bacteria
Legionella (introduced into ventilation systems by cooling towers and standing water reservoirs)

on interior surfaces or in air-conditioning systems. Indoor pollen is derived almost entirely from outdoor plants, and fungal spores from outdoors may also enter the indoor environment on air infiltration or inadvertently on people, animals, or objects.

Some of the most severe and prevalent indoor biological pollution problems result from the growth of microorganisms on interior surfaces that are wet and moist. Substrates which provide a source of both carbon and water can support the growth of microorganisms. High relative humidity, in excess of 70%, promotes condensation on interior surfaces (e.g., cool exterior walls or windowsills). Leaks from water pipes and roofs can also provide consistent sources of moisture. Other moisture sources are humidifiers, vaporizers, and air conditioners; once contaminated, these devices can distribute fungal fragments, spores, and dissolved allergens into room air. Mold has been a problem in homes flooded by storms.

In recent years, the growth of molds in home, school, and office environments has been cited as the cause of a wide variety of human ailments and disabilities. So-called "toxic mold" has become a prominent topic in the lay press and is increasingly the basis for litigation when individuals, families, or building occupants believe they have been harmed by exposure to indoor molds.

Molds and other fungi may adversely affect human health through allergy or infection. Some species of fungi, including some molds, are known to be capable of producing secondary metabolites, or mycotoxins and, possibly, of causing respiratory disease via a toxic syndrome. A controversial issue regarding mold in the home is that of "idiopathic pulmonary hemorrhage" associated with *Stachybotrys chartarum*. Following an initial report of 10 cases in Cleveland in 1994,[132] additional case reports followed, linking mold exposure or mycotoxins with pulmonary hemorrhage in infants. Recent critical reviews of the literature have concluded that indoor airborne levels of microorganisms are only weakly correlated with human disease or building-related symptoms and that a causal relationship has not been established between these complaints and indoor exposures to *S. chartarum*.[133]

Limited information exists on levels of microbial particles in air. Indoor levels and, hence, personal exposure are highly variable and are probably affected by activities such as vacuuming, sweeping, dusting, making beds, scrubbing contaminated surfaces, and using electric fans. Further, airborne and dust concentrations of allergens probably have limited value for assessing the contribution of a particular allergen in causing disease. Factors such as aerodynamic behavior, respirability, solubility, and cross-reactivity with other allergens are also important in the process of immunological sensitization and the development of allergic disease.[134]

Dust mites (*Dermatophagoides pteronyssinus, Dermatophagoides farinae*, and *Euroglyphus maynei*) are commonly found in houses and are important sources of allergens, particularly for persons with asthma.[134] These mites are approximately 0.3 mm in length and live in carpets, upholstered furniture, mattresses, and bedding, where they eat skin scales. Two major dust mite allergens have been identified, *Der p* I and *Der p* II. These proteins are derived from digestive enzymes in the gut of the mite and are found in high concentrations in the fecal pellets. Vacuum sampling and immunological assays indicate that in the home, the highest levels of allergen occur in the bedroom in carpeting, mattresses, and bedding.

Domestic cockroaches, including the German cockroach, *Blattella germanica*, are commonly found indoors and represent another source of allergen in residences, particularly in infested inner-city housing. Fecal material and saliva contain large amounts of the allergens *Bla g* I and *Bla g* II. In inner-city homes, mice infestations may contaminate residences with the mUS antigen.

Cats and dogs are prevalent sources of allergen exposures. *Fel d* I is the most significant allergen associated with cats, and high levels of this protein are found in cat dander and fur and also in saliva and urine. The median level of *Fel d* I in samples of settled household dust in homes with a cat are reported to range from 6 to 130,000 ng/g of dust, with a median level of 31,000 ng of *Fel d* I/g of dust.[135] In homes without a cat, much lower levels are observed, ranging from 2 to 7500 ng (median 63 ng) of *Fel d* I/g of dust; the antigen is persistent in indoor environments for long periods after a cat is no longer indoors.[135] The presence of the allergen in the dust of homes and buildings in which cats are not kept suggests that the allergen can be transported on clothing. The major dog allergen, *Can f* I, is present in dog fur and saliva and is a relatively stable protein that may persist in dust for a long time. The content of *Can f* I in household dust from homes with a dog ranges from 10 to 10,000 μg/g of dust, compared with <0.3 to 23 μg/g of dust in homes without a dog.[136]

Mouse allergen, a cause of asthma in laboratory workers, is prevalent in homes. A national study of inner-city childhood asthma found widespread contamination with this allergen and frequent positivity to the allergen on skin testing.[137]

Fungi are present in the air of virtually all homes and public buildings. Commonly isolated genera include *Cladosporium, Penicillium, Alternaria, Epicoccum, Aspergillus,* and *Drechslera.*

Biological agents in indoor air may cause disease through various mechanisms, including direct toxicity, infections, and immune hyperresponsiveness. A complete review of these diverse effects is beyond the scope of this chapter. Selected examples of diseases caused by biological agents are given; more extensive information is available in published reviews.[138]

The presence of dampness and mold, determined by questionnaire, has been associated with upper respiratory symptoms and eye irritation in large studies of children in the United States and elsewhere. These associations were adjusted for known determinants of respiratory symptoms, including maternal smoking, city, child's age and sex, and parent education. There are also similar findings in adults. A systematic review concluded that dampness in buildings contributes to adverse health effects in persons with and without

atopy, but a specific causal agent cannot be identified.[139] The evidence on dampness was reviewed by an Institute of Medicine committee which did not find the evidence to be sufficient to conclude that dampness causes respiratory symptoms or asthma.[140]

Allergic rhinitis, or "hay fever," is common, affecting approximately 20% or more adults in the United States. Identification of the specific indoor allergen associated with the symptoms may be accomplished by skin testing and in vitro measurement of antibody (radioallergosorbent test [RAST]). Many persons with asthma are sensitive to specific antigens from pollens, animal fur, fungi spores, and house dust. The risk of acute or severe attacks of asthma is increased in residences with levels of *Der p* I in excess of 10 μg/g of house dust, and asthmatic patients have been reported to show a 25% prevalence of skin test positively to cat or dog allergen extracts. Building-related allergic respiratory disease and epidemic asthma have been reported in office buildings in association with air-handling systems and humidifiers contaminated with bacteria and fungi.

Avian proteins are present in bird excreta (e.g., the droppings of pet birds such as parakeets), and fungal spores of thermophilic actinomycetes, *Aspergillus* species, *Penicillium* species, and *Aureobasidium* species may contaminate the indoor environment and cause hypersensitivity pneumonitis. A careful review of symptom pattern in relation to home and work environments and site evaluation may be needed to identify the source of exposure.

The bacterium *Legionella pneumophila,* the agent of Legionnaires' disease, causes an often fatal pneumonia associated with exposure to the bacterium in aerosols of cooling towers and air-handling systems and in humidifiers and spas.[141] It exemplifies a respiratory pathogen associated primarily with indoor environments, in both source and transmission. Of course, indoor environments are the locus of transmission of many infectious respiratory diseases, including influenza and tuberculosis. The risk of diseases depends on the strength of sources and the level of ventilation. A low air exchange rate increased the risk for pneumococcal infection among inmates in a large county jail.

CLINICAL SYNDROMES ASSOCIATED WITH INDOOR ENVIRONMENTS

During the last 20 years, complaints attributable to indoor environments have generally been classified into one of two broad groups: specific building-related illnesses and SBS.

Building-related illnesses have a number of etiologies, but the specific agent responsible for causing the disease is present in the indoor environment, for example, hypersensitivity pneumonitis caused by fungi in the ventilation system or Legionnaires' disease resulting from transmission of the organism that grows in cooling tower water.

SBS refers to nonspecific health problems related to indoor air quality in nonindustrial buildings. Irritation of mucosal surfaces and neurotoxic effects may contribute to the nonspecific symptom complex that often include headache, fatigue, and difficulty concentrating. Atopic individuals have been shown to have lower irritant thresholds than nonatopics. Multiple factors, including specific exposures, inadequate ventilation, and poor building maintenance have been linked to SBS. Panel studies in Denmark have found that complaints were most often attributed to the ventilation system, SHS, office machines, and other sources.[142]

SUSCEPTIBLE POPULATIONS

To fully protect public health, we need to characterize variation in risk associated with pollution exposure across the population along with the determinants of that variation. Vulnerability refers to factors that increase potential for exposure. Susceptibility refers to individual factors that increase risk at any given level of exposure. Increased susceptibility implies a greater health response at any given level of exposure. Factors associated with increased susceptibility include certain chronic diseases and selected genotypes. The concept of environmental justice is linked to vulnerability, as disadvantaged groups are more likely to have higher exposures.

The legislative history of the Clean Air Act mandated that the primary NAAQS were to be set low enough to protect the health of all susceptible groups within the population except those requiring life-support systems. Only two diseases, asthma and emphysema, were specifically identified in the Clean Air Act as associated with increased susceptibility. Other groups in the population, accounting for large numbers of people, are also considered to be at increased risk from air pollutants: persons with coronary artery disease and, possibly, peripheral vascular disease; infants and the elderly in general; and children with chronic pulmonary ailments such as cystic fibrosis and bronchopulmonary dysplasia.

In this section, we consider the evidence concerning these susceptible groups (Table 91-9). Pulmonologists are likely to be asked about the consequences of pollution exposures by persons with chronic lung diseases. Patients may report being adversely affected by exposures and may request guidance concerning control measures—for example, purchase of an air-cleaning device or additional medication use when exposed.

CLINICAL STUDIES IN ASTHMA AND COPD

Clinical studies have provided much of the evidence on the acute effects of pollutants on persons with chronic respiratory diseases. Controlled laboratory studies of volunteers have attempted to identify specific effects of individual pollutants, as assessed primarily by

TABLE 91-9 Populations Considered Susceptible to Air Pollution

Population	Potential Mechanism	Consequences
Asthmatics	Increased airway responsiveness	Increased risk for exacerbation and respiratory symptoms
Cigarette smokers	Impaired defense and clearance, lung injury	Increased damage through synergism
Elderly	Impaired respiratory defenses	Increased risk for respiratory infection
	Reduced functional reserve	Increased risk for clinically significant effects on function
Infants	Immature defense mechanisms of the lung	Increased risk for respiratory infection
Persons with coronary heart disease	Impaired myocardial oxygenation	Increased risk for myocardial ischemia
Persons with chronic obstructive pulmonary disease	Reduced level of lung function	Increased risk for clinically significant effects on function
	Increased pulmonary and systemic inflammation	Increased risk for myocardial ischemia

pulmonary mechanics; however, other end points, including symptoms, have been assessed.

The most striking effect of acute exposure to SO_2 at concentrations less than 1.0 ppm is the induction of bronchoconstriction in asthmatics after exposures lasting only 5 minutes. In contrast, inhalation of concentrations of SO_2 in excess of 5 ppm causes only small decrements in airway function in normal subjects. Lung function responses to SO_2 in asthmatics are greater when SO_2 exposure is accompanied by increased ventilation, usually stimulated by exercise. SO_2-induced bronchoconstriction can be exacerbated by breathing cold or dry air and oral (vs. nasal) breathing. The SO_2 bronchoconstrictor response can be reduced or inhibited in asthmatics by anticholinergic agents, mast cell stabilizers, or β-agonist bronchodilators.

Inhalation of acidic aerosols generally produces little alteration in pulmonary function in normal subjects, even permissible exposure limit of 1 mg/m^3 in the workplace. As with SO_2, asthmatic subjects have been found to be susceptible to the effects of acidic aerosol exposure, although different laboratories have found differing concentrations for threshold exposure. Adult asthmatics exposed to aerosols of 450 and 1000 μg/m^3 of H_2SO_4 demonstrate decrements in specific airway conductance. Adolescent asthmatics appear to be more sensitive to the effects of acidic aerosols than adult asthmatics. Decrements of lung function have been observed in adolescents at levels as low as 70 μg/m^3, concentrations occasionally noted in outdoor air and an order of magnitude lower than the level at which effects are observed in normal subjects. The apparent difference in sensitivity of adult and adolescent asthmatics may also be due to differences in the research protocols. In these studies, young asthmatics showed functional decrements at exposure levels that corresponded to near-peak outdoor levels in the northeastern United States. Field studies in summer camps of both normal and asthmatic children reported decrements in pulmonary function during pollution episodes that included exposure to increased levels of acidic aerosols, supporting the concern that children and adolescents may be particularly susceptible to effects of acidic atmospheres.

Although several controlled human studies have found asthmatics to be responsive to low levels of NO_2, the findings have not been consistent. The conflicting results among these studies are probably related to the differences in subject selection and exposure protocols. Persons with COPD may represent a group with increased susceptibility to short-term exposure to NO_2. Further study of the issue is needed.

Consonant with the provisions of the Clean Air Act and with its legislative history, a group that appears to be at potential risk from exposure to O_3 consists of those characterized as having pre-existing respiratory disease. In the case of asthmatics, however, emerging data from controlled studies indicate no greater responsiveness to O_3 in mild asthmatics than in normal, healthy populations. Pretreatment of healthy volunteers with β-adrenergic agents before O_3 exposure and exercise does not prevent bronchoconstriction, whereas pretreatment with atropine or indomethacin reduces the decrement in lung function. Since exercise greatly potentiates the response to O_3, the best strategy for clinical management includes avoiding outdoor exercise during periods of high O_3 pollution.

CLINICAL AND EPIDEMIOLOGICAL STUDIES IN HEART DISEASE

Persons with coronary heart disease have also been identified as a group at risk from increased levels of air pollution. In the presence of coronary artery disease, there is limited ability to increase coronary blood flow in response to increased myocardial oxygen consumption during exercise. When myocardial blood flow is not sufficient to meet oxygen demand, the myocardium becomes ischemic, resulting in angina pectoris, ECG changes, or both. Several recent studies conducted at relatively low COHb levels have investigated the effects of CO exposure on exercise capacity and the occurrence of myocardial ischemia. These studies found a decrease in the time to the occurrence of myocardial ischemia in persons with coronary artery disease during exercise after CO exposure. The lowest CO dose to produce a decrease in time to the onset of angina was associated with a 2% COHb level. In this study, there was a mean decrease of 4.2% in the time to angina and a mean decrease of 5.1% in the time to ECG changes, indicative of myocardial ischemia at 2% COHb compared to control (air exposure) days; greater effects were noted at 3.9% COHb.[60] Clinical studies have shown a significant dose–response relationship for the individual differences in time to the onset of ECG changes at increasing COHb levels. In addition, at a COHb level of 6%, patients with coronary artery disease experience an increase in the frequency of arrhythmias. Of note, at the same low levels of COHb, adverse effects have been observed in humans but not in animals.[61] Older people and very young individuals may also be at a heightened susceptibility to air pollution–mediated cardiovascular effects due to weakened defense mechanisms, existing comorbid conditions, or growth and development in the case of infants and children and diminished reserves in the case of older adults. Epidemiological studies examining associations between outdoor air pollution levels and cardiovascular morbidity and mortality have examined whether patients with other comorbid conditions are more susceptible to air pollution effects than patients without these conditions.[143] For example, although it has been hypothesized that patients with type 2 diabetes, with its underlying vascular dysfunction, are more susceptible to air pollution health effects, the evidence is not conclusive.[144,145] However as another example, several studies have documented that patients with COPD may be more susceptible to cardiovascular effects (e.g., myocardial infarction) of air pollution, perhaps due to a heightened inflammatory state. For example, one study found that the risk of a myocardial infarction associated with increased fine particle concentrations was four times higher in people who had COPD compared to people without COPD.[146]

Although mostly done to investigate mechanisms by which air pollution exposure may cause a health effect, studies have also examined whether several genetic polymorphisms either protect or give an individual increased susceptibility to these cardiorespiratory health effects. For example, individuals without a polymorphism to protect against oxidative stress (e.g., glutathione S-transferase mu 1 [GSTM1] null) may be more responsive to air pollution health effects than individuals with wild type GSTM1.[147] More work is needed, however, before we understand these as generic markers of susceptibility. In summary, existing respiratory and cardiovascular conditions may make a patient susceptible to air pollution–mediated health effects, as several mechanisms thought to be involved in mediating a cardiovascular health response to air pollution may already be activated.

CONTROL STRATEGIES

Controlling the health effects of indoor and outdoor air pollution requires strategies oriented toward populations and toward individual patients. Clinicians can make practical recommendations to their patients to reduce risk for disease and for exacerbation of established disease. Clinicians may serve as consultants or as advocates in seeking to reduce the effects of indoor and outdoor air pollutants through population-oriented control approaches.

PATIENT-ORIENTED STRATEGIES

Approaches for limiting the health risks of breathing polluted ambient air have received little investigation. Present understanding of the determinants of exposure suggests that modifying time–activity patterns to limit time outside during episodes of pollution represents the most effective strategy. The levels of some reactive

TABLE 91-10 Questions and Answers About Indoor Air Pollution

Question	Answer
Do air cleaners work?	Air cleaners have not yet been shown to have direct health benefits.
Should the radon concentration in my home be measured?	Yes, radon can be readily measured at relatively low cost, and mitigation is feasible.
Should the air ducts in my home be cleaned?	There is no evidence on health benefits of cleaning air ducts.
Will controlling mites be beneficial?	Controlling mite levels is beneficial for persons with mite-sensitive asthma.
Should my home be humidified?	Humidification may increase allergen levels.

pollutants tend to be lower indoors than outdoors. O_3 levels in buildings are lower than outdoor levels, but they can be driven upward by increasing the rate of exchange of indoor with outdoor air. There is potential for O_3 oxidation products in indoor environments to increase toxicity but few data are available to support the hypothesis. Fine acid aerosols can penetrate indoors, but neutralization by ammonia produced by occupants, pets, and household products may reduce concentrations. Other types of particles in outdoor air may also enter indoor air, but concentrations of particles of outdoor origin, measured indoors, are generally lower indoors. Nevertheless, healthcare providers can reasonably advise patients to stay indoors during pollution episodes. Vigorous exercise outdoors, which increases the dose of pollution delivered to the respiratory tract, should also be avoided at such times.

Susceptible patients should be counseled concerning the nature and degree of their susceptibility. The use of medication should follow the usual clinical indications, and therapeutic regimens should not be adjusted because of the occurrence of a pollution episode without evidence of an adverse effect on symptoms or function. In the laboratory, inhalation of cromolyn sodium and bronchodilating agents blocks the response to some pollutants, but use of these drugs solely because of exposure to air pollution cannot be advised.

Respiratory protective equipment has been developed for use in the workplace to minimize exposure to toxic gases and particles. Many of these devices, particularly those likely to be most effective, add to the work of breathing and cannot be tolerated by persons with respiratory disease. Under most circumstances, healthcare providers should not suggest respiratory protection as a method for reducing the risks of ambient air pollution. Similarly, air cleaners have not been shown to have health benefits, whether directed at indoor pollutants generated by indoor sources or at those brought in with outside air.

Pulmonologists may be concerned with diverse issues related to the control of indoor air pollution, ranging from answering patients' questions about pollutant health effects and control, to management of complex problems in large buildings. Some commonly asked questions and answers that reasonably reflect the state of the evidence are provided in (Table 91-10). The clinically relevant microenvironments are numerous, including the home, the workplace, public buildings, and places where leisure time is spent.

Workplace problems, such as the "SBS," may be particularly challenging. The healthcare provider needs to establish the connection between the workplace and the occurrence of symptoms and then seek a solution that includes identifying and remediating the responsible factors in the workplace. The diagnostic task requires a sufficient awareness of the possible causal role of the indoor environment (Fig. 91-4). Resolution may require an evaluation and intervention by indoor air quality professionals. The physician may be unable to resolve the patient's symptoms without motivating a building evaluation and resolution of underlying problems. Guidance for the clinician has been offered by the ATS.[148–150]

COMMUNITY-ORIENTED STRATEGIES

Frequently, communities become concerned about the effect of particular local sources—for example, a power plant or manufacturing facility or vehicle depot. In Beijing, China, during the 2008 Summer Olympics, the air pollution concentrations, normally much higher than in the United States and other western European countries, were drastically reduced during the Olympic and Paralympic Games, by restricting automobile use, and shutting down construction and industrial emissions in Beijing and the surrounding provinces. These air pollution reductions were associated with improved levels of biomarkers of inflammation, coagulation, vascular function, pulmonary inflammation, and function in a panel of otherwise healthy, young, medical residents living in central Beijing.[43,62] Thus, community strategies to reduce pollution can have a beneficial health impact.

Exposures to air pollutants and other environmental contaminants may disproportionately affect disadvantaged communities. The term "environmental justice" is used in addressing inequities between poorer and more well-to-do communities. Concern about the health risks may quickly lead to controversy and litigation. Thus, understanding the health risks posed by local sources may be difficult and may require skills in community health, as well as in epidemiology and toxicology. Local physicians may become active through concerns about the health of their patients or as advocates for the community's environment or for the polluting facility. Most often the dimensions of such complex problems exceed the skills of local physicians. Involvement may be appropriate, but guidance should be obtained from appropriate public health and environmental agencies.

In 1976, the EPA proposed cautionary statements for public reporting of outdoor air quality – the Pollutant Standards Index – for criteria pollutants. In the 1999 revision, the name was changed to the air quality index (AQI). The index provides AQI levels, descriptors of air quality, and guidelines for cautionary statements, based on levels of air pollution in comparison to the NAAQS. The AQI is color coded into six categories of decreasing air quality: green (good), yellow (moderate), orange (unhealthy for sensitive groups), red (unhealthy), purple (very unhealthy), and maroon (hazardous). Air pollution forecasts are now widely available on local or national TV, radio or newspaper reports, and on the Weather Channel and EPA websites (http://www.weather.com/) and (http://airnow.gov/), respectively. Notification by email is available through www.enviroflash.info. The actions taken when "alert levels" are reached or expected to be reached include the issuance of health advisories (or cautionary statements) to the public. The EPA's advice is intended to be applied by local air pollution agencies in preparing daily air quality summaries for dissemination to the media and in providing useful guidelines for physicians and public health officials.

With the amendments to the Clean Air Act in 1970 enhancing the regulatory role of the legislation, we have witnessed a remarkable increase in our understanding of the sources, dosimetry,

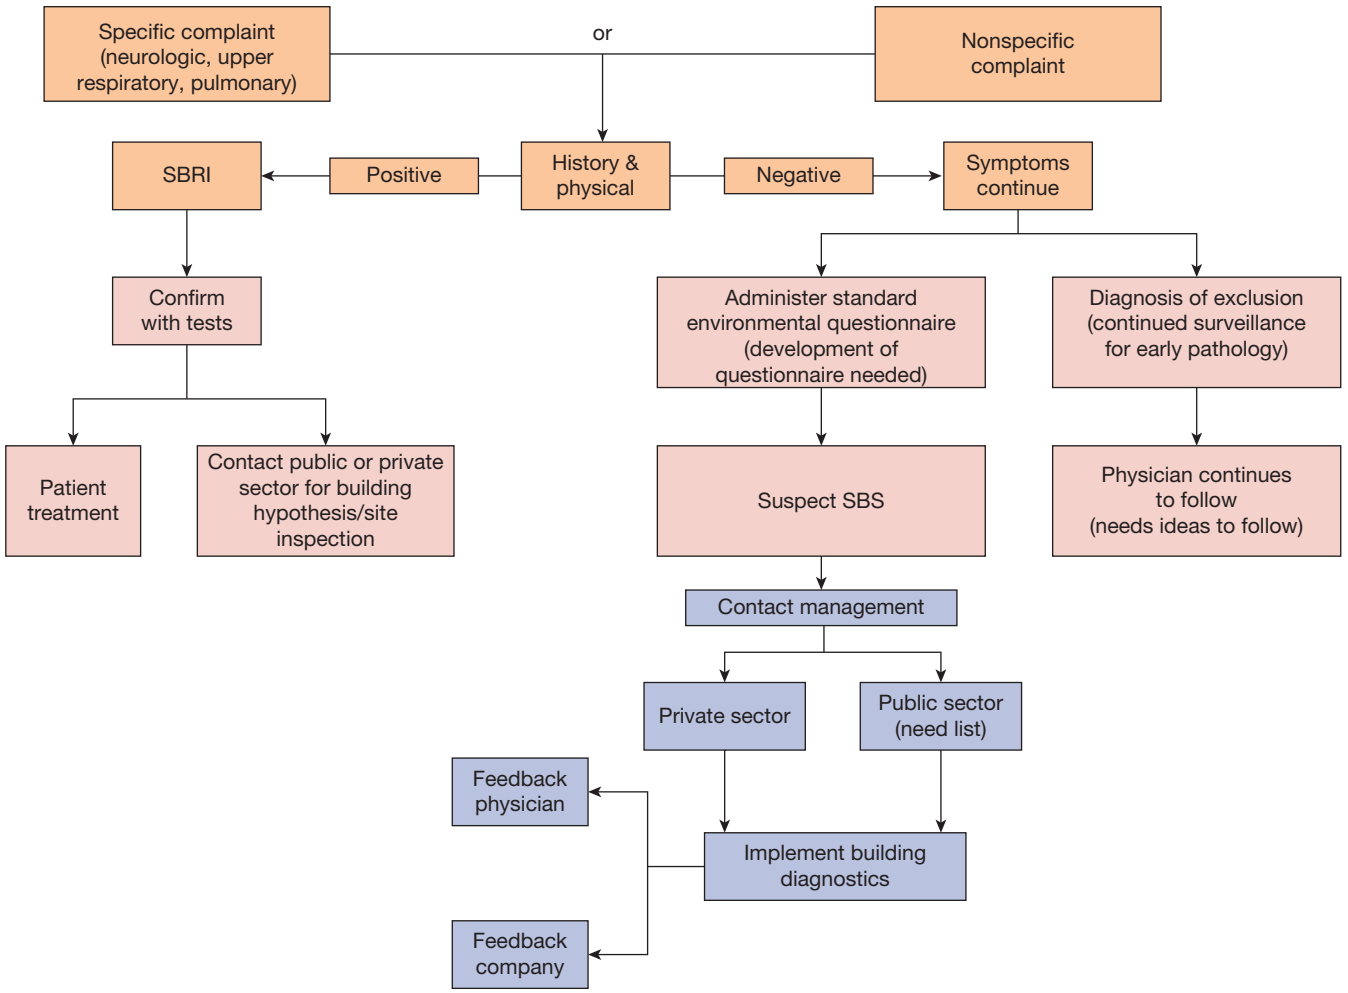

Figure 91-4 Medical approach to patient with complaints possibly related to indoor air pollution without an antecedent diagnosis. SBRI, specific building-related illnesses; SBS, sick building syndrome. *(Based on American Thoracic Society data.)*

pharmacokinetics, and health effects of not only the critical air pollutants but also a large number of indoor and other unregulated pollutants. Reductions in auto emissions and more efficient engines, cleaner fuels, removal of lead from gasoline, and smoking bans in indoor environments are just a few of the interventions, together with tighter standards, that have resulted in improved air quality. For the future, a multipollutant approach to controlling air pollution, rather than a pollutant by pollutant approach, is anticipated. The interplay between science and policy continues to play in protecting the public health from a variety of toxic indoor and outdoor pollutants.

CHAPTER 92

High-Altitude Physiology and Clinical Disorders

Kingman P. Strohl
Cynthia M. Beall
Nikolaus C. Netzer

INTRODUCTION

Altitude physiology typically focuses on people above 2500 m; ~8000 ft. Altitudes above that are sometimes subdivided into very high (3500–5500 m; ~11,500–18,000 ft) and extreme (>5500 m; >18,000 ft). An estimated 40 million people travel each year to altitudes >2500 m (~8000 ft),[1] and as many or more travel to altitude for leisure and sports, and work in mines, military or border operations, and the like. Altitude medicine considers the clinical disorders associated with acclimatization by the travelers, workers and migrants, and with adaptation by people with lifetimes or populations with millennia of residence (an estimated 83 million people).[2]

With a hurried ascent, many (~80%) will report a transient headache (high-altitude headache or [HAH]), and some will develop one of three forms of acute high-altitude illness: acute mountain sickness (AMS) and HAH, high-altitude cerebral edema (HACE), and high-altitude pulmonary edema (HAPE).[3,4] AMS (see Table 92-1) and HAH are annoying and interfere with activity and work, however, HACE and HAPE can be fatal with mortality rates approaching 30%.[5–7] Among some residents, chronic mountain sickness (CMS) and right ventricular hypertrophy develop over months to years of residence at altitude. Birth weights are generally lower and the rate of small-for-gestational-age babies and congenital heart defects are higher than that in lowland populations.[4]

Hypoxemia (FIO_2 equivalent to ~17% O_2 at 2500 m, down to ~8% O_2 at the summit of Everest) causes the physiologic responses and illnesses. Altitude-related exposure to cold and extreme exercise may also contribute to illness. Other environmental features may include UV radiation, trauma, and infection that are not covered in this chapter. Finally, dealing with illness in a remote area can be challenging. For example, facilities for management of clinical disorders in remote areas or evacuation to a lower altitude may be limited.

CONSIDERATIONS OF EXPOSURE AND TIMECOURSE

Individual responses to hypobaric hypoxia may be conceptualized along a time continuum of interrelated phases: acute (immediate to 3–5 days in which acute illnesses present), subacute (over weeks leading toward acclimatization), chronic (years), and lifelong residence (Fig. 92-1). The reduction in environmental oxygen as a result of altitude exposure lowers the oxygen available for gas exchange in the lungs (PA_{O_2}), arterial oxygen (Pa_{O_2}), and cellular oxidative phosphorylation for adenosine triphosphate (ATP) production.

Oxygen levels in the atmosphere were extremely low; rose about 2.5 million years ago in the Great Oxidation event and then rose sharply.[8] Over the past 600 million years, oxygen levels have varied from as low as ~12% to as high as ~30%.[8,10] All multicellular animals[11] have genetically encoded oxygen homeostasis pathways. We have a common ancestry and therefore share many elements of the response to hypoxia. People moved to live at high altitudes in the past 100,000 years and evolutionary forces have resulted in different strategies of adaptation in different populations.[12]

RESPONSES TO HYPOBARIC HYPOXIA

Important adaptations to hypobaric hypoxia are considered below.

Ventilatory Adaptations

An increase in ventilation is an immediate vital, mammalian response. It results in a decrease in alveolar CO_2 in order to increase PA_{O_2}, thus mitigating decreases in vascular oxygen delivery at altitude compared to sea level (Fig. 92-2).

The sensor initiating the acute response is the carotid body at the bifurcation of the internal and external carotid arteries. Ablation of the carotid body attenuates the acute response to altitude exposure.[13]

Blood flowing through the carotid body comes from the lungs via the carotid artery, where the oxygen pressure is typically 80 to 100 mm Hg. Carotid body afferent activity rises significantly as arterial oxygen pressure falls below 60 mm Hg.[13] However, oxygen pressure in the mitochondria is much lower, as oxygen has to diffuse across vessels and interstitial spaces and is extracted by cells for a number of metabolic processes. In the microvessels of the carotid body, the average oxygen pressure is about 50 mm Hg with minimal values likely near 20 mm Hg. It is reasonable to expect an average mitochondrial oxygen pressure of about 40 mm Hg and a minimum

TABLE 92-1 Lake Louise Symptom Score Self-Report Questionnaire. Fill Out Before and Each Morning Upon Exposure to Altitude or on a Trek

Symptoms	Severity	Points
Headache	No headache	0
	Mild headache	1
	Moderate headache	2
	Severe headache, incapacitating	3
Gastrointestinal	No gastrointestinal symptoms	0
	Poor appetite or nausea	1
	Moderate nausea or vomiting	2
	Severe nausea or vomiting, incapacitating	3
Fatigue and/or weakness	Not tired or weak	0
	Mild fatigue/weakness	1
	Moderate fatigue/weakness	2
	Severe fatigue/weakness, incapacitating	3
Dizziness/ lightheadedness	Not dizzy	0
	Mild dizziness	1
	Moderate dizziness	2
	Severe dizziness, incapacitating	3
Difficulty of sleeping	Slept as well as usual	0
	Did not sleep as well as usual	1
	Woke up many times, poor night's sleep	2
	Unable to sleep	3

Add up the responses to each of the questions of the self-report score. A diagnosis of AMS is based on a recent rise in altitude, the presence of a headache with the presence of at least one other symptom, and a total score of >3 with no evidence for other reason of symptoms.

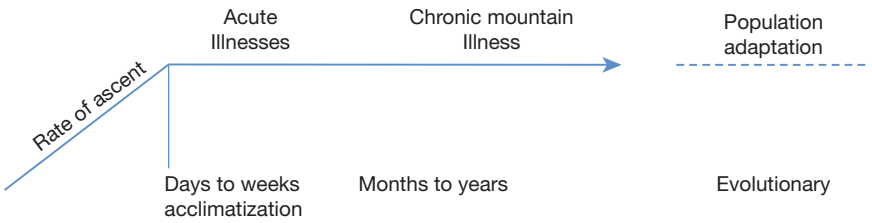

Figure 92-1 Individuals respond to altitude with time-dependent acclimatization and illness expression, and populations living at altitude exhibit adaptations that differ according to population ancestry.

of about 15 mm Hg. If this seems low, in the liver and spleen average tissue values are measured at less than 12 to 15 mm Hg.[14] Thus, tissue in the carotid body may be exposed to oxygen pressure significantly less than typical levels of arterial oxygen pressure ~80 mm Hg.

Oxygen level is major driver of carotid body response although carotid body afferent activity can also be stimulated, at least transiently, by changes in carbon dioxide or hydrogen ion concentrations. Respiration is stimulated by decreasing the [ATP]/[ADP][Pi] ratio and, as a result, the rate of respiration does not decrease until oxygen deprivation is severe enough to cripple metabolism.[14] Decreased availability of oxygen first affects the ability of mitochondria to maintain the [ATP]/[ADP][Pi] ratio, a measure of energy available when ATP is hydrolyzed to adenosine diphosphate (ADP) and inorganic phosphate (Pi). Mitochondrial ATP synthesis is tightly coupled to oxygen consumption; that is, mitochondria respire only fast enough to replenish ATP as it is used. However, other responses to lowered oxygen levels are engaged depending on the duration and severity of the oxygen deprivation. Cellular oxygen–sensor responses activate short- and long-term energy savings and cellular protection mechanisms.[15]

In the first few minutes of exposure, as $P_{A_{O_2}}$ decreases to below ~60 mm Hg, ventilation increases, resulting in a decrease in $P_{A_{CO_2}}$.[13,16] In the carotid body, low O_2 and high CO_2 interact synergistically to depolarize glomus cells and produce an action potential; the ventilatory effects of concurrent hypoxia and hypercapnia are greater than the sum of the two stimuli applied separately. As the $P_{A_{O_2}}$ level declines, the relationship between the sensory afferent nerve activity and $P_{A_{CO_2}}$ becomes increasingly steeper, leading to higher ventilatory drive. The physiologic response to acute exposure is an abrupt increase in ventilation (Fig. 92-3), which continues to increase over days. After a few days adaptations take place in the brainstem controller through circuit adaptations so that ventilation is increased with reductions in $P_{A_{CO_2}}$ at all levels of $P_{A_{O_2}}$, and the afferent responses from the carotid body also reflect this change in responsiveness to chemoreception even when there is a near restoration of pH. Even though this organ's response is pathognomonic of the acclimatization process in response to altitude-associated chronic hypoxia, there is bidirectional, efferent as well as afferent, communication so that attributing the entire physiologic response to the carotid body is problematic.

Hypoxic chemotransduction in the carotid body requires release of excitatory transmitters that activate afferent sensory neurons.[17] Cellular events including bioenergetic, biosynthetic, and conformational cause the chemotransduction.[18] Mechanisms implicated include oxygen-sensitive ion channels, reactive oxygen species and the "redox" state of the cell, and direct effect of oxygen to alter the conformation of a protein, such as NADPH oxidase 4, an enzyme encoded by the NOX4 gene. This phagocyte-type oxidase has been postulated as an oxygen sensor of sorts because its activation is linearly and steeply dependent on oxygen availability. A cascade of immediate intracellular effects will initiate changes in afferent information from the carotid body to the medulla that will lead to the increased tidal volume and respiratory frequency.[19]

A physical remodeling of ventilatory control begins soon after exposure through changes in gene expression. In blood vessels this includes growth factors such as vascular endothelial growth factor *(VEGF)*. The main pathway for such hypoxic responses is mediated by the hypoxia-inducible transcription factor 1 alpha (HIF-1α).[15] HIF-1α is the oxygen-dependent subunit of the HIF-1 heterodimer, considered the master regulator of oxygen homeostasis that initiates transcription of over 100 hypoxia-inducible genes, that have hypoxia response elements. Under normoxia, HIF-1α is formed continuously and degraded in the cytoplasm. HIF-1α is hydroxylated by the enzyme prolyl hydroxylases prior to its degradation. The prolyl hydroxylases have a relatively high Km for oxygen; hydroxylation leads to degradation under physiologic conditions. Decreased oxygen pressure results in significant accumulation of HIF-1α in less than 2 minutes; HIF-1α is rapidly degraded upon reoxygenation.

Central controllers can be affected directly and indirectly by oxygen availability, but over time neurotransmitter expression correlates with changes in gain and changes in gene expression with some additive epigenetic changes.[20] Within days of exposure, there is a progressive increase in sensitivity but a downregulation of the magnitude of the ventilatory response by the brainstem networks that integrate afferent information.[21] At 4300 m, hyperventilation increases over the first few days and then over 1 to 2 weeks despite metabolic compensation to the respiratory alkalosis.[22] The acclimatized person will continue to hyperventilate when returned to normoxia, a phenomenon not observed during the very first hour of hypoxic exposure. pH compensation to hypocapnia occurs in 2 to 4 days and a mild alkalinity persists over the following weeks. The ventilatory response to chronic hypoxia consists of both

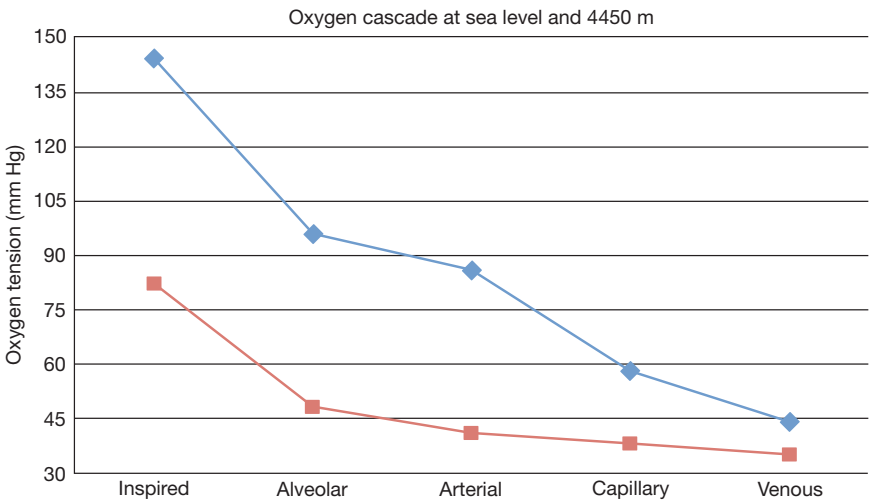

Figure 92-2 Oxygen tension is lower along the axis of oxygen delivery at 4540 m or ~15,000 ft *(red line)* as compared with sea level *(blue line)*. *(Adapted from Hurtado A. Animals in high altitudes: resident man. In: Dill DB, ed. Handbook of Physiology. Section 4: adaptation to the Environment. Washington, D.C.: American Physiological Society;1964:843–859.)*

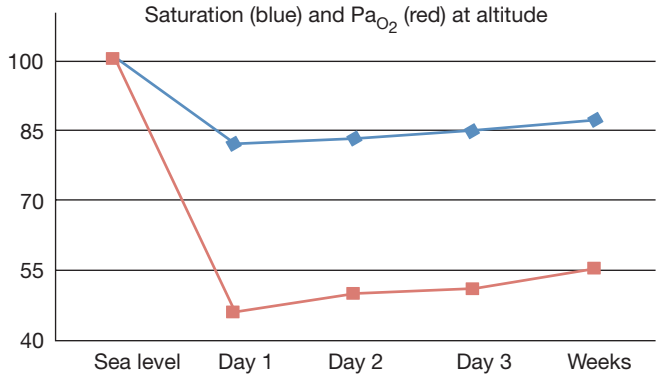

Figure 92-3 The figure illustrates the problem with hypoxemia encountered with acute altitude exposure. Values of arterial oxygen saturation (*blue*, % O_2 saturation) and arterial oxygen tension (Pa_{O_2}) before, during the first few days at altitude, and after weeks of residence.

frequency and tidal volume changes. Acclimatized individuals will return to nearly normal control arterial acid–base status within 24 to 48 hours of normoxia, following acclimatization to 4300 m.

Thus, the transition points from acute to subacute to full acclimatization in the ventilatory domain blend from one to another.[23] Acclimatization results from cellular and system responses that improve oxygen delivery. Ventilatory responses are complemented by systemic ones, including erythrocytosis and new blood vessel formation that further assist in increasing oxygen delivery to peripheral tissues. For instance, HIF-1α affects a variety of "hypoxic response elements" with downstream effects on many hypoxic response proteins including erythropoietin.[24] Some actions of erythropoietin result in increases in hemoglobin levels, and thus will affect oxygen carrying capacity in the blood and an improvement in oxygen delivery, lasting weeks to months. People with a mutation limiting HIF-1 degradation have high baseline ventilation and exaggerated ventilatory response to hypoxia, as well as chronic polycythemia under nomroxia.[25]

SLEEP AND PERIODIC BREATHING

Healthy people at altitude may develop a pattern of regularly recurring periods of hyperpnea and apnea. This phenomenon results from a dynamic interaction among elements in two separate feedback loops, one through peripheral and the other through central chemoreceptor reflexes, with contributions by cardiac output and brain blood flow.[26] Periodic breathing occurs during wakefulness but is especially evident in sleep, and apneas and hypopneas of the nonobstructive type are reported as occurring almost equally in non-REM and REM sleep in health subjects.[27] Recurrent central apneas will occur during sleep at modest altitude (>2500 m), and is a manifestation of increased alveolar ventilation (hyperpnea) from hypoxia producing hypocapnia competing with a normal elevation in the apneic (carbon dioxide) threshold with sleep.[28] The apneas or hypopneas produce a fall in arterial oxygen and a rise in carbon dioxide and lead to arousals from sleep during the hyperpneic phase.[29] The alternating hyperpnea and apnea produce an oscillatory pattern of oxygen saturation, with the nadir of oxygen saturation playing some role in susceptibility to HAPE and HACE.[30]

At altitudes above 3000 m, the quality of both REM and non-REM sleep is impaired by arousals often associated with periodic breathing;[31] at extreme altitude (above 5500 m) length of and number of apneas decrease due to a high frequency of breathing. The reason for this phenomenon could represent a greater relative influence of central oxygen–chemosensitive sites over afferent information on peripheral hypoxia and hypocapnia.[32,33] With acclimatization, the sleep pattern tends to become more normal; however, periodic breathing during non-REM sleep may persist over a week or more.[30]

THE PULMONARY CIRCULATION

Moderate-to-severe pulmonary hypertension (both systolic and diastolic) is a common finding in all the altitude-related diseases.[4] Although pulmonary blood vessels are extensively supplied with sympathetic (vasoconstrictor) and parasympathetic (vasodilator) fibers, regulation of vasomotor tone is largely due to the local effects of oxygen and carbon dioxide. At altitude the entire lung is hypoxic and CO_2 levels are low as a consequence of hyperventilation; as a result, altitude is a model of whole lung hypoxic, hypocapnic pulmonary vascular vasoconstrictive responses.[4] Acute vasoconstriction over a few hours is a physiologic response and can be reversed as soon as the hypoxia is lifted. With days to weeks of hypoxic exposure there occurs a structural remodeling of pulmonary arterioles and an increase in resting pulmonary arterial pressure and pulmonary vascular resistance; hence pulmonary artery pressure does not decline immediately with restoration of normoxia. With return to sea level after weeks to months, right ventricular hypertrophy and pulmonary vascular pressures will return to normal over several weeks.[4]

Andean highlanders have high pulmonary artery pressures and do not restore pulmonary artery pressure or right ventricular hypertrophy to normal levels after returning to sea level or normal oxygen tensions. In contrast, Tibetan highlanders have minimal elevation of pulmonary artery pressure and do not exhibit the vesicular changes of the Andean highlanders.[34]

The pulmonary circulation is a high-flow, low-pressure system.[35] Based upon a balance of hydrostatic and oncotic pressure gradients across pulmonary capillary microvessels, and by Na^+ pumps, the pulmonary interstitium and alveolar spaces are maintained in a "dry" state. At high altitude, while respiratory mechanics do not change appreciably, changes in hemodynamics due to vasoconstriction and high shear stress are dramatic and in certain individuals lead to acute presentations of pulmonary edema.[4]

FLUID HOMEOSTASIS

Dermal edema is seen in faces of many, but not all mountaineers at high altitude[36] and in the retinal vessels of almost all individuals.[37] Lung edema, cerebral edema, and peripheral edema are the hallmarks of disease. Extravasation may also result from loss of tight channels due to oxidative stress and free radicals or a direct effect of hypoxia on ion channels.[38] Local dysregulation of the renin–angiotensin–aldosterone system is proposed to play a role in this generalized response.[39,40]

ERYTHROPOIESIS AND HEMOGLOBIN AFFINITY

An increase in the number of red blood cells occurs with acute exposure owing to an increase in EPO synthesis in response to HIF-1 and HIF-2.[41,42] This acclimatization response takes a week or so and is reversible upon return to low altitudes. With chronic hypoxia, there are an increased number of erythrocytes and an increase in oxygen content among upward migrants such as Colorado residents and among Andean highlanders. Tibetan highlanders have minimal or no erythrocytosis owing to the high frequencies of variants in EPAS1 (HIF-2α) associating with lower hemoglobin concentration.[43]

Several studies have considered the potential for a change in oxygen affinity. The increase in ventilation results in decreases in alveolar and arterial P_{CO_2} and arterial $[H^+]$; concomitantly, serum levels of 2,3-diphosphoglycerate (2,3-DPG) are increased. While the reductions in Pa_{CO_2} and $[H^+]$ increase hemoglobin affinity for O_2, increases in 2,3-DPG diminish the affinity; loading and unloading of O_2 from hemoglobin depends upon the balance of these factors.[44] Humans, native to the Andes or Himalayan mountains, also can increase $O(_2)$ affinity, not because of a fundamental difference in hemoglobin structure or function, but because of extreme hyperventilation and alkalosis.[45]

COMMON CLINICAL DISORDERS OF HIGH ALTITUDE

Altitude-related clinical disorders are well recognized. They may be observed occasionally at altitudes as low as 8000 ft (2500 m), however their frequency increases with increasing altitude. A recent clinical practice review is available from the Medical Commission of International Mountaineering and Climbing Federation (UIAA).[46] Information about high-altitude travel for those with pulmonary disease is also available.[47]

HIGH-ALTITUDE HEADACHE

High-altitude headache (HAH) is very common, and is exacerbated by insufficient hydration in the setting of increased water loss with hyperventilation, overexertion, and insufficient energy intake, particularly in those who have experienced HAH on a previous visit to altitude. Vasodilation from hypocapnia may also contribute, but there is little evidence for brain edema in those without neurologic symptoms.[48,49] Acetaminophen or ibuprofen with hydration will improve this symptom.[50]

ACUTE MOUNTAIN SICKNESS

Acute mountain sickness (AMS) occurs after 4 to 36 hours of altitude exposure. Symptoms are headache (usually frontal), nausea, vomiting, irritability, malaise, insomnia, and poor climbing performance. Symptoms frequently occur first or are more severe the morning after the first night at altitude. Sleep-disordered breathing contributes to the severity of AMS in the morning after the first night at high altitude.[51] AMS is usually self-limited, but can be ameliorated by drug therapy.

Many mechanisms have been proposed (Fig. 92-4). Studies target one or another potentially identifying marker or therapeutic pathway, but few believe that only one factor produces one or more of the altitude illnesses.

Incidence

The incidence of AMS is altitude- and time-dependent.[52] The incidence is ~30% on same-day, several-hour car trips to the Hawaiian or Colorado mountains (3000–4300 m).[7,53] It occurs in 10% of those at 2500 m and 51% at 4500 to 5000 m on multiday trips.[7] A survey of Alpine walkers at overnight huts noted an incidence of 9% at 2850 m, 13% at 3050 m, 34% at 3650 m, and 53% at 4559 m.[54] Among trekkers en route to an Everest base camp, the incidence was 43% at 4300 m, and higher in those who had flown into an airstrip at 2800 m (49%) than those who had walked in all the way (31%).[55]

The Lake Louise Symptom Score Questionnaire (Table 92-1) is the most common and useful self-administered tool to determine the severity of AMS and provides a score for the five signature symptoms rating them from 1 (mild) to 4 (severe). A score of 4 and more is considered AMS, a score of 10 and more is considered severe and requires immediate intervention.[56,57] Copies should be included as equipment of any trekking group to high altitude.[58] Confounders affect such scoring systems; for instance, a hangover will give a positive AMS score even at sea level. So there is a need for context and allowance for confounding factors. On the other hand, day-trippers, trekkers, and physicians unaware of the high prevalence of AMS may mistake symptoms for signs of viral illness, food intolerance, poor sleep, intense exercise, or jet lag.

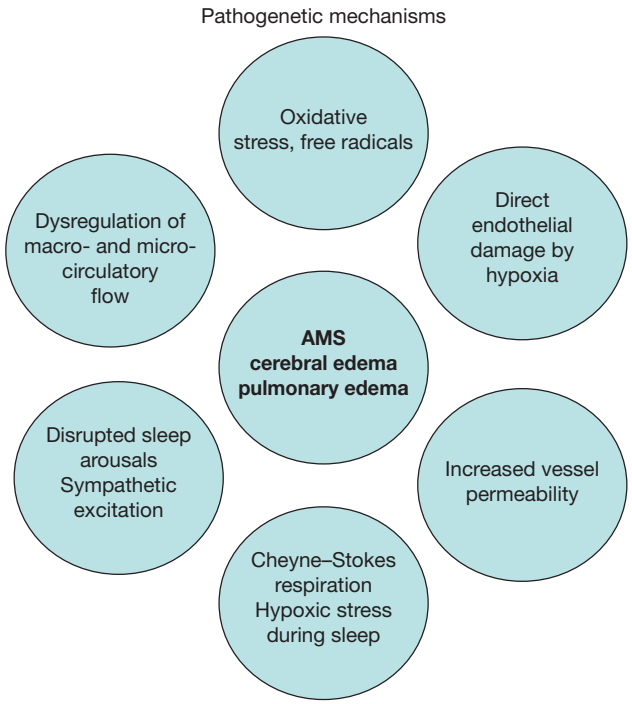

Figure 92-4 Evidence for several mechanisms for AMS, HACE, and HAPE.

Risk Factors

For novices, the altitude and speed of ascent on a previous trip should be considered, as rapid ascent to altitude appears to affect everybody.[4,58] Women may be less likely to get AMS than men,[59] and there are hints that teenagers and young adults have a higher incidence of AMS than adults.[60] Other clinical features reported in the literature include history of migraine, persistence of a patent foramen ovale, Down syndrome, congenital pulmonary abnormalities, perinatal pulmonary vascular insult, and Holmes–Adie syndrome, a rare disorder of autonomic control.[61]

Response to challenge with hypoxia improves risk assessment but is not routine.[62] A recent report on a fairly large cohort found factors independently associated with severe high-altitude illness were a previous history of acute illness, ascent greater than 400 m/d, history of migraine, ventilatory response to hypoxia at exercise less than 0.78 L/min, and desaturation at exercise in hypoxia equal to or greater than 22%.[63] Chemosensitivity parameters (high desaturation and low ventilatory response to hypoxia at exercise) improved the discrimination ability in this prediction model.

While AMS is an environmentally mediated disorder, there are individual differences in risk. The concept is that AMS is a polygenic disorder in which genotype contributes to capacity to rapidly and efficiently acclimatize to altitude; nevertheless, the mechanisms by which this occurs have yet to be elucidated.[64]

Preventive Medicine

The most common internal medicine diseases like diabetes, arterial hypertension, WHO Class II COPD, elevated lipid profiles, mild coronary artery disease, renal insufficiency, etc. are no reason to cancel a trip to high altitude if the same preventive and treatment measures are taken during the travel as they are at home and the traveler is aware of his/her symptoms and how they might change during the trip.[46] Exercise-induced asthma can be exacerbated at altitude due to increased ventilation (increased heat exchange). Known disease of more than mild severity (COPD, sleep apnea, heart failure, etc.) may be a relative contraindication for travel for pleasure,[47] although there are reports of the successful use of supplemental oxygen. The arterial hypoxemia at high altitude poses a risk of faster disease progression in those with pre-existing kidney disease. An inability to diurese increases the risk of developing acute altitude illness in patients with chronic kidney disease.[65]

Drug interactions require consideration.[50] Acetazolamide is the most widely used drug intervention against AMS or HACE.[1] It can cause problems for patients with renal failure (reduced elimination and increasing metabolic acidosis), hepatic insufficiency (ammonium ion toxicity), COPD (dyspnea), and pregnant women (accumulating effect with natural higher progesterone levels followed by

dyspnea). Patients taking aspirin (acetylsalicylic acid) on a regular basis have reduced acetazolamide elimination and increased central nervous system penetration with toxicity. Phosphodiesterase inhibitors sildenafil and tadalafil use should be accompanied with the usual caution about a danger of serious hypotension in those also treated with nitrates.[38] One study that patients on β-blockers had significantly reduced oxygen saturation and increased heart work with a reduced exercise tolerance in hypoxia compared to control.[66] The mechanisms were not explored but the recommendation was made to consider a switch in the antihypertensive drug regimen.

Preacclimatization in hypobaric chambers and normobaric hypoxic rooms reduces the risk of acquiring altitude illness on site, if it happens within a week before the trip.[67] If more facilities become available, preacclimatization could become a method of prevention for the leisure traveler or businessman, especially those who reach high altitude by plane.

However, the *key element* is to limit the elevation change per day to less than 400 m/d.[63,68] A slow rate of ascent is the best way to prevent AMS. A suggested rule is that above 3000 m (10,000 ft), ascent should be at a rate less than 300 m (1000 ft) per day, with a "rest" day (i.e., no additional ascent) every 3 days. This rate will be too fast for some and unnecessarily slow for others.[58] For direct travel to an altitude between 2500 m and 3000 m, stay at that altitude for two days and then ascend with a speed of 300 m per day.[38] Well-trained people ascend too fast and are more vulnerable. This need for acclimatization also implies that those in a "Kilimanjaro in 5 days tour" have no chance for safe acclimatization and are at a high risk for acute altitude illnesses.

An additional rule is, "If symptoms of AMS develop, go no higher. If they become severe, go down." Individuals who ascend to high altitude should be advised to limit their activity for the first few days upon ascent. Adequate hydration should be encouraged, and 2 L of extra fluid per day is a common rule of thumb.

Prophylactic administration of acetazolamide is advisable for anyone with a prior history of AMS. Use of acetazolamide (250 mg at bedtime or 125 mg bid) for several days after arrival may improve sleep and ability to function during the day. Some suggest starting the drug 2 to 3 days before arrival.[46] Corticosteroids (e.g., dexamethasone at a dose of 4 mg every 6 hours) is recommended as an alternative for individuals unable to take acetazolamide (e.g., those with sulfa allergy).[46] The drug is continued for a few days at altitude.

Treatment

Mild AMS is self-limiting and usually lasts about 3 days, so treatment is not mandatory. A placebo-controlled trial found ibuprofen was useful, while the information on aspirin or acetaminophen is anecdotal.[46] If the symptoms progress, the patient should descend (Fig. 92-5). If descent is delayed, acetazolamide is generally considered first-line treatment; dexamethasone can be used in sulfa-allergic individuals. A combination of the two agents can be used for rapidly evolving symptoms. For sleep disturbances, temazepam is effective in reducing recurrent central apnea and arousals, and appears safe to use, without any measurable adverse effects the next day.[69] Based on the ability of iron to influence cellular oxygen sensing pathways, one randomized, double-blind, placebo-controlled trial found that intravenous iron supplementation protected against the symptoms of AMS in healthy volunteers.[70] This is however impractical for common use.

HIGH-ALTITUDE CEREBRAL EDEMA

If the "mild" edema in the brain worsens toward compression of brain structure, the status of high-altitude cerebral edema (HACE) is reached. HACE can occur even in the relative absence of AMS symptoms. Signature symptoms are dizziness, severe almost unbearable headache, and vomiting. Ataxia is common, and some propose that a positive Romberg sign, the inability to stand straight with the feet together and the eyes closed, is an essential feature.[71] Somnolence, stupor, and changes in pupillary responsiveness mark the onset of a fatal stage. Concurrent signs of pulmonary edema may also be noted. In the absence of treatment, the condition will progress to coma and mortality will be high.

Descent is critical. While awaiting evacuation, supplemental oxygen should be given. Every 1% increase in oxygen concentration above 21% reduces the equivalent altitude by about 300 m. Several hours in a portable hyperbaric chamber may buy time and be potentially useful as a life-saving measure while descent is arranged;[61] however, the beneficial effects of the portable chamber (Fig. 92-6) may develop more slowly in HACE than in HAPE, especially in severe cases.[6] Administration of dexamethasone (4–8 mg), intramuscularly in severe cases, or orally in less severe cases, helps reduce cerebral edema and should be given while awaiting evacuation; doses can be repeated every 6 hours.[3]

HIGH-ALTITUDE PULMONARY EDEMA

A typical patient is a fit young man who has climbed rapidly and is energetic on arrival.[72] Moderate symptoms of AMS may be present initially as the individual becomes more breathless (Fig. 92-5). A cough develops, which is initially dry, then productive of frothy white sputum, later becoming blood tinged. The climber may complain of chest discomfort. The pulse and respiratory rate are increased, and auscultation of the chest reveals crackles at the bases. An elevated jugular venous pressure and peripheral edema may be seen, and a right ventricular heave and accentuated pulmonary component of the second heart sound may be detected. Over a few hours, the patient's condition may deteriorate further, with additional increases in pulse and respiratory rate. As breathing becomes "bubbly" due to pulmonary edema, cyanosis develops. In the absence of definitive treatment, hypoxemia progresses to respiratory failure, and coma and death ensue.

High-altitude pulmonary edema (HAPE) may occur independently of AMS. The symptoms are like those of pulmonary edema at sea level. HAPE requires a substantial medical intervention. Prevalence estimates are 0.5% to 2.0% of those rapidly ascending to altitude. Individuals with a previous history of HAPE are at greater risk of all altitude-related disorders.[3,4] Some demonstrate a "threshold" effect in which repeated ascents to a particular altitude are

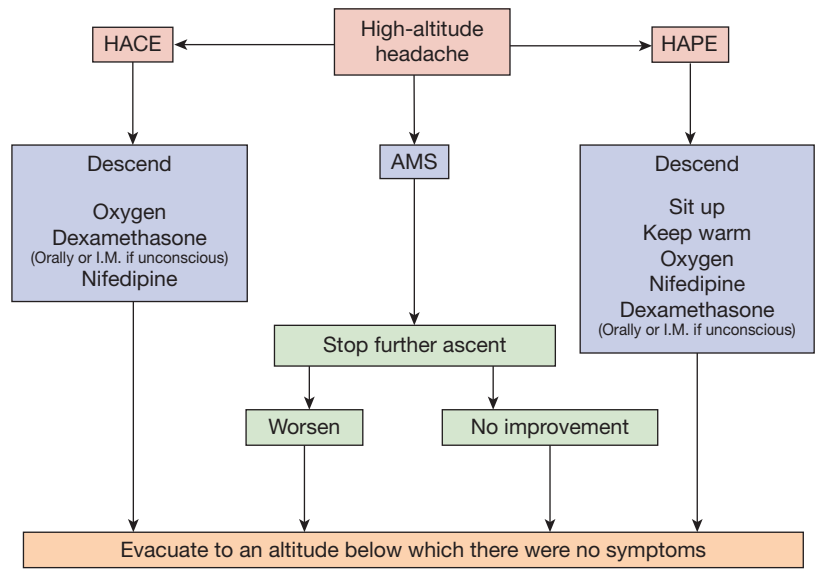

Figure 92-5 Pathway for management of acute altitude illnesses.

Figure 92-6 Shown is a portable hyperbaric chamber, in which higher oxygen concentrations are reached through inflation of the chamber to a higher barometric pressure. It has demonstrated utility for acute intervention of AMS and HAPE, until rapid descent by helicopter or porter is possible. The use of these chambers requires a nonclaustrophobic patient, fit comrades, and a flat surface. *(© N. Netzer, MD.)*

associated with development of HAPE, but lower altitudes are not. Individuals residing at high altitude who descend and then return to high altitude are susceptible.

Mechanism

HAPE is caused by migration of fluid into extravasal space through endothelial damage along with shear stresses produced by increased cardiac output and pulmonary artery pressure. The most popular hypothesis is that susceptible subjects experience the hypoxic pulmonary artery vasoconstrictor response that is uneven throughout the lung.[3] In some areas, where there is a greater degree of vasoconstriction, blood flow is reduced and the areas are protected from development of pulmonary edema. In those areas in which vasoconstriction is less marked, increased blood flow is associated with edema formation, perhaps through flow-related capillary damage, or sheer stress on vessel walls, or increased intracapillary pressure. In addition, various kinins that have been identified in the edema fluid are likely to increase permeability and to recruit leukocytes.[47]

Prevention

In those who have experienced HAPE before, use of nifedipine prophylactically (slow-release formulation, 20 mg twice daily prior to ascent, then three times daily) appears to lower significantly the incidence of HAPE.[3,61] Mean systolic pulmonary artery pressure is lowered with this approach suggesting effects on smooth muscle relaxation. The drug appears to be ineffective in preventing AMS. Prophylactic use of an inhaled β-agonist may reduce the risk of HAPE.[46,47]

Treatment

Descent is critical for survival. Initial medical treatment while the subject awaits descent includes strict rest and supplemental oxygen (Fig. 92-4). Although not yet studied in a well-controlled trial, nifedipine (10 mg sublingually) may be used. If clinically significant hypotension does not occur with the first dose of nifedipine, its administration can be repeated every 15 to 30 minutes.[3,61] Phosphodiesterase inhibitors sildenafil and tadalafil are becoming fashionable drugs in the treatment of HAPE,[39] but a consensus of evidence is not available.[3,61] Anecdotally there are beneficial effects of a portable hyperbaric chamber (Fig. 92-6),[6] again a temporary measure while descent is arranged.

■ CHRONIC MOUNTAIN SICKNESS

In the 1920s, Carlos Monge reported cases of polycythemia in high-altitude residents of the Andes (Monge disease), and in 1942, Hurtado published detailed observations of eight cases, including symptomatology and hematologic changes.[73] The defining feature is extreme polycythemia, with hemoglobin concentrations as high as 23 g/dL and hematocrits as high as 83%. Patients may have vague neuropsychological complaints, including headache, dizziness, somnolence, fatigue, difficulty in concentration, and loss of mental acuity. Irritability, depression, and even hallucinations are reported. Dyspnea on exertion is not common, but poor exercise tolerance is. The condition of CMS is quite different from AMS.[74] Excessive erythrocytosis associated with a lower oxygen saturation and hypoxic ventilatory response with relative hypercapnia are the main features of CMS, followed by right ventricular enlargement, pulmonary hypertension, and remodeling of pulmonary arterioles.

Risk Factors

Age, sex, and obesity are risk factors in Andean but not Tibetan populations. In an ecologic study of 108 Chinese highland military units stationed in Tibet for months to years, the rate of CMS ranged from ~1% to ~37% and was higher among rural construction units or those with poorer medical facilities.[75] CMS is more common in males, and in civilian populations may develop in middle and later life.[73] There may be some risk to children born at altitude but with a low birth weight for age or whose mothers had problematic pregnancies.[76]

Descent to sea level is the definitive treatment. However, for those who wish to remain at altitude for family or economic reasons, phlebotomy and administration of supplemental oxygen are beneficial.[73] Phlebotomy improves many of the neuropsychological symptoms, and in some patients pulmonary gas exchange and exercise performance are also improved.

The foundation underlying therapeutic agents for CMS, as well as the clinical evidence existing so far on their usefulness in the treatment of CMS, is sparse, compared to the work on acute illness.[73] In the Andean ACE inhibition can effectively and safely ameliorate altitude polycythemia while also reducing proteinuria.[77] There is a literature on respiratory stimulants but these studies are less rigorous. Medroxyprogesterone has been employed with some success; side effects, including loss of libido, limit its use.[73] Although acetazolamide has been used in prevention of AMS, trials addressing its use in CMS are lacking. However, the drug may be useful in improving oxygen saturation during sleep and by this mechanism reducing hematocrit. Further studies are necessary in establishing the role, if any, of sildenafil and related compounds used in acute illnesses in patients with CMS.

■ OTHER DISORDERS OF ALTITUDE RESIDENCE

Pulmonary arterial hypertension may develop over months to years of residence at altitude. There is an interesting literature on susceptibility factors.[78] One line of research has identified genetic polymorphisms in the ACE pathway associated with increased hypoxic responses and/or development of pulmonary hypertension.[79] Another line of work has focused on receptor functions, in particular a downregulation in the function of the β-adrenergic receptor system, found in altitude populations but not at sea level, for instance the pulmonary hypertension in the setting of mitral

stenosis.[80] A third may involve a perinatal predisposition for development of high-altitude chronic illnesses, in a way that some adult chronic diseases at sea level also have perinatal origins. An intriguing publication suggested that gestational age, preterm birth, preeclampsia in the mother, or a diagnosis of neonatal hypoxia, and impaired growth in utero raises susceptibility to adult disease through a reduced fetal growth of pulmonary vessels and/or an epigenetic effect of perinatal hypoxia.[76] Medications (phosphodiesterase inhibitors and prostaglandin agents) have been shown to alter pulmonary artery pressures in those born at high altitude and susceptible to pulmonary hypertension, but most of these studies are in smaller groups in a single population.[81–84]

Studies in permanent residents suggest that altitude may aggravate complications of pregnancy and prenatal life. Examples include fetal growth retardation and an increased incidence of the complications of preeclampsia and neonatal hyperbilirubinemia.[85] Mechanisms are not well understood and interventions in this population have not been performed.[86] Presumably measures such as prenatal care, vitamin supplements, and identification of known risk factors can be implemented in these populations, which often do not have the public health systems seen in Western lowland populations.

CONCLUSIONS

Altitude physiology encompasses the responses to acute and chronic residence above 2500 m. With a hurried ascent, many healthy people will report a transient headache (HAH), and some will develop one of three forms of acute high-altitude illness: AMS with or without HAH, HACE, and HAPE. In some residents, CMS and right ventricular hypertrophy develop over months to years of residence at altitude. While altitude-related exposure to cold and UV radiation, and exercise, trauma and infection are present and could contribute, in the main hypoxemia causes these physiologic responses and illnesses. Rapid descent is the optimal treatment, although there are some medications that could be considered. Oxygen is a cue to which many proteins in the cell and physiologic systems respond. These elements and their biologic pathways account for actions of drugs that have evidence for efficacy or empiric use; however, major gaps in understanding remain.

CHAPTER 93

Diving Injuries and Air Embolism

Christopher Logue

During the winter of 1942–1943, Jacques Cousteau and Emile Gagnan collaborated to develop and patent the first commercially successful open-circuit self-contained underwater breathing apparatus (SCUBA), which was later named the Aqua Lung. The apparatus consisted of a demand valve regulator that could be attached to a portable cylinder containing stored compressed breathing gas. The regulator reduced the relatively high pressure of the stored gas to ambient pressure, which could then be breathed by a diver submersed in water. Prior to the development of reliable SCUBA equipment, divers were limited by surface supplied breathing gas requiring direct and continuous surface support.

The mass production of SCUBA diving equipment revolutionized underwater exploration. While this was a significant development for the military and commercial diving communities, it marks the beginning of the sport diving era. SCUBA diving has since evolved into a popular recreational activity.

Although diving-related injuries were described prior to the development of modern-day SCUBA equipment, their relative importance increased as more divers became equipped to explore the underwater world. The most accurate available statistics of diving-related injuries are published online by the Divers Alert Network (DAN) in an Annual Review of Recreational Scuba Diving Injuries and Fatalities.

A recent detailed and thorough analysis of 947 recreational SCUBA diving fatalities from 1992 to 2003 identified the cause of death (COD) along with triggers, disabling agents, and disabling injuries that contributed to the COD.[1] The leading COD was drowning (70%), but the identifiable disabling injuries that contributed to the COD told a more useful story. The most common disabling injuries included: asphyxia with no preceding disabling injury (33%), arterial gas embolism (AGE) (29%), cardiac events (26%), trauma (5%), decompression sickness (DCS) (3%), unexplained loss of consciousness (2%), and inappropriate gas mixture (2%). In addition, risk factors associated with each disabling injury were identified (Table 93-1).

Of all the possible causes of diving-related injuries, this chapter focuses only on those caused by dissolved or embolic gas. In addition, this chapter includes a discussion of nondiving-related gas embolism. A number of excellent sources for review of diving-related injuries are available.[2–7]

FUNDAMENTAL CONCEPTS

Before presenting individual clinical entities, fundamental concepts related to pressure and the behavior of gases are reviewed.

PRESSURE

Pressure is defined as force per unit area. The air-containing atmosphere of the earth applies pressure to any object within it. At sea level this pressure is defined as one atmosphere (1 ATM). One atmosphere is equivalent to 760 torr (mm Hg), 29.92 in Hg, 14.7 psi, 101.3 kPa, or 1.013 bar. Most of the world's population lives at or near sea level and rarely experiences significant changes in

TABLE 93-1 Disabling Injuries and Associated Risk Factors Contributing to the Cause of Death in Recreational Diving Fatalities

Disabling Injuries	Risk Factors (Odds Ratio)
Asphyxia	• Entrapment (>30) • Running out of gas (15.9) • Buoyancy/equipment problems (4.5)
Arterial gas embolism	• Emergency ascent (>30)
Cardiac events	• Previous cardiovascular disease (10.5) • Older than 40 y (5.9)
Trauma	• Rough water (2.6)
Decompression sickness	• Diving deeper than 180 fsw (>30) • Diving alone (17.2) • Emergency ascent with omitted decompression (16.0)
Unexplained loss of consciousness	• Diabetes (12.0)

ambient pressure. Divers are unique in that they experience significant increases in ambient pressure as they descend through the water column. Every 33 ft of sea water (fsw) through which a diver descends adds an additional 1 ATM of pressure. By the time a diver reaches a depth of 99 fsw, he or she has added an additional 3 ATM to the earth's atmospheric pressure. The diver experiences a pressure of 4 atmospheres absolute (4 ATA) at this depth. The pressure subsequently decreases as the diver ascends back to the surface.

BOYLE'S LAW

Originally described by Sir Robert Boyle in 1662, Boyle's Law describes the relationship between pressure and volume of a fixed amount of an ideal gas given that the temperature of the system remains constant (Video 93-1), stating that pressure and volume are inversely proportional. It is important to note that because the relationship is exponential, larger changes in volume occur with changes in pressure over a range of lower pressure values.

BAROTRAUMA

Barotrauma is physical damage to tissues within the body that occurs as a result of changing ambient pressure. Tissues that contain air spaces are at risk. Barotrauma can be considered a physiological ramification of Boyle's Law.

Middle ear barotrauma (MEB) is the most common diving-related injury. As a diver descends in the water column he or she must be able to equalize the pressure within the air-containing middle ear space to the surrounding increasing ambient pressure. If the pressure cannot be equalized by adding gas to the space during descent, the volume within the middle ear space will contract according to Boyle's Law. Proper eustachian tube function is critically important in the prevention of MEB; divers can utilize different maneuvers to assist in the equalization of middle ear pressures.

Video 93-1 This animation demonstrates the inverse relationship between pressure and volume of an ideal gas given a fixed mass and constant temperature. Note from the graph that the relationship is exponential. Larger changes in volume are noted with pressure changes at the smaller pressure values. Also, note that the density of the gas increases with increased pressure. *Access at www.fishmansonline.com*

The most common manifestation of MEB is ear pain experienced during descent. Other manifestations include changes in the appearance of the tympanic membrane with possible rupture, the evolution of a middle ear effusion (with or without blood), decreased hearing, and mild vertigo. Injuries associated with MEB are usually transient and reversible. Treatment is supportive and may include the use of decongestants, along with avoiding further changes in ambient pressure.

Other less frequent forms of barotrauma include situations where gas becomes trapped in the sinuses, gastrointestinal tract, and within a tooth filling. Pulmonary barotrauma is discussed later in the chapter.

DALTON'S LAW OF PARTIAL PRESSURES

Originally described by John Dalton in 1801, Dalton's Law states that the total pressure exerted by a gas mixture is equal to the sum of the partial pressures of each individual gas component.

$$P_{absolute} = pN_2 + pO_2 + pCO_2 + \ldots$$

The partial pressure of a gas component within the mixture can be determined by multiplying the fraction of the component gas by the absolute pressure. For example:

$$pN_2 = F_iN_2 \times P_{absolute}$$

It is important to note that as absolute pressure increases, so does the partial pressure of each individual gas component within the gas mixture. A SCUBA diver breathing air (78% N_2, 21% O_2) descending to a depth of 99 fsw (4 ATA) is exposed to elevated partial pressures of each of the component gases within the mixture. The partial pressure of nitrogen in the inspired air at this depth is significantly increased (~3.1 ATM).

There are physiological ramifications of exposure to elevated partial pressures of specific gases. Exposure to elevated partial pressures of nitrogen causes nitrogen narcosis and provides a pressure gradient, driving dissolved nitrogen into tissues of the body. Exposure to elevated partial pressures of oxygen causes oxygen toxicity, which can manifest as seizure activity and loss of consciousness without warning. This becomes a significant concern for divers breathing mixtures with increased F_iO_2 or those who dive to extreme depth.

HENRY'S LAW

Originally described by William Henry in 1803, Henry's Law states that the amount of a given gas that dissolves in a liquid is directly proportional to the partial pressure of that gas in equilibrium with that liquid given at constant temperature. An alternative explanation is that the solubility of a gas in a liquid is directly proportional to the partial pressure of the gas above the liquid.

An air-breathing diver descending in the water column experiences a pressure gradient which drives dissolved nitrogen into the tissues based on Dalton's Law; in addition, the solubility of nitrogen within the tissues also increases according to Henry's Law. During decompression the amount of nitrogen that can remain dissolved decreases, favoring transition to gas phase and the evolution of gas bubbles.

An understanding of both Dalton's Law and Henry's Law is important because these laws contribute to inert gas (i.e., nitrogen) exchange. The tissues of a diver will load or "on-gas" inert gas during compression and with time at depth. Unloading or "off-gassing" occurs during decompression and with time once the diver has reached the surface again.

Physiological ramifications of Henry's Law include DCS, which is discussed later in the chapter.

DECOMPRESSION ILLNESS

The term decompression illness (DCI) refers to disease processes caused by gas bubbles that result from a reduction in ambient pressure. The term includes both dysbaric AGE and DCS.

PULMONARY BAROTRAUMA

If a diver were to descend while holding his or her breath, the gas within the lungs would be compressed progressively while maintaining a volume that is inversely proportional to the increasing pressure. In order to prevent collapse of the lung to less than residual volume, with tearing of pulmonary parenchyma and blood vessels, the diver is obliged to breathe an oxygen-containing gas mixture at a pressure equal to that of the surrounding water. During return to normal atmospheric pressure, compressed gas within the lungs expands exponentially and must be exhaled if alveolar rupture is to be avoided.

The greatest danger of alveolar bursting occurs during ascent in the shallowest depth range because of the exponential inverse relationship between pressure and volume according to Boyle's Law. Fatal AGE associated with breathing compressed gas has been reported following ascent from a depth of only 4 fsw.[8]

POSSIBLE SEQUELAE OF ALVEOLAR RUPTURE DURING DECOMPRESSION

The sequelae of pulmonary overpressure accidents are determined by the nature and severity of associated tissue trauma as well as by the volume of expanding extra-alveolar gas. Following rupture of alveolar septa, expanding gas enters the interstitial spaces and dissects along perivascular sheaths to enter the mediastinum. Mediastinal gas may further dissect into the pericardial sac, the retroperitoneal space, or the subcutaneous tissues of the neck. Gas also may enter the pleural space to cause a pneumothorax.

Mediastinal emphysema is often associated with mild substernal discomfort that may be described as a dull ache or a feeling of tightness. Deep inspiration, coughing, or swallowing may exacerbate symptoms, and pain may radiate to the shoulders, neck, or back. Unless extensive, mediastinal emphysema is rarely associated with dyspnea, tachypnea, or other signs of respiratory distress. Gas volumes within the pericardial sac or retroperitoneal space are seldom large enough to be clinically significant.

Subcutaneous emphysema from pulmonary barotrauma causes swelling and crepitance in the neck and supraclavicular fossae. These signs may be associated with sore throat, dysphagia, or a change in voice tone. Subcutaneous gas can be demonstrated radiographically (Fig. 93-1). If symptoms of mediastinal or subcutaneous emphysema are bothersome, resolution of gas can be hastened by breathing 100% oxygen at normal atmospheric pressure. Recompression therapy is not recommended as it may exacerbate the underlying lung injury and add compressed gas to the spaces followed by expansion during decompression from treatment.

Surprisingly, pneumothorax is not a frequent complication of diving-related pulmonary barotrauma. In one series of submarine escape ascents, pneumothorax occurred in only 5% to 10% of the divers who had lung overinflation syndromes and suffered cerebral AGE.[9] Recompression of an individual who is known to have a pneumothorax should be avoided if possible. However, it may be necessary if neurological symptoms or other manifestations of AGE are present. Insertion of a thoracostomy tube prior to recompression treatment is recommended.

Conversion from an untreated simple pneumothorax to a tension pneumothorax can occur during recompression therapy in a hyperbaric chamber. This will occur if a tear in the visceral pleura remains open during compression, thereby allowing compressed gas to enter the pleural space. If the air in the pleural space becomes effectively sealed prior to or during decompression, the gas will expand to compress the lung and interfere with venous return. Severe dyspnea, cyanosis, and hypotension may occur. This is an emergency that requires immediate recompression to relieve symptoms and insertion of a chest tube before decompression is resumed. Alternatively, a pneumothorax can be managed by needle decompression and the use of a flutter (one-way) valve.

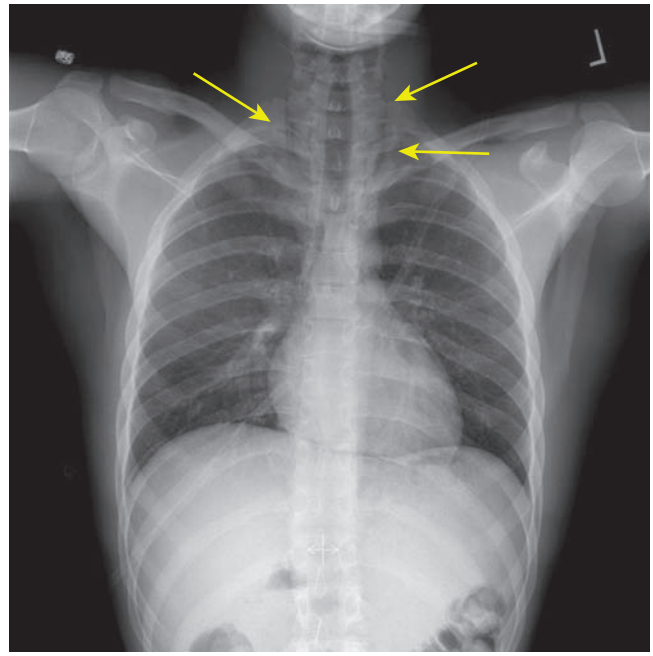

Figure 93-1 Subcutaneous emphysema *(arrows)* secondary to pulmonary barotrauma is demonstrated radiographically. This novice diver, participating in his initial training dives, was attempting to equalize his middle ear pressures using a forced valsalva maneuver during ascent.

DYSBARIC ARTERIAL GAS EMBOLISM

When expanding extra-alveolar gas is forced down a pressure gradient into torn septal vessels, it traverses the pulmonary veins to the left atrium and left ventricle, from which it is ejected into the systemic circulation as foamy particles or discrete bubbles. Distribution of the gas emboli is determined by their buoyancy relative to blood and orientation of the body with respect to gravity. It may also be influenced by local factors such as blood flow and vessel size. With the body in the head-up, erect position, most of the embolic gas travels to the brain.

Although the precipitating event for dysbaric AGE is presumed to be due to pulmonary overinflation injury, demonstrable radiographic evidence of pulmonary barotrauma is not always seen. In one series of divers suffering symptomatic AGE, radiographic evidence of pulmonary barotrauma was demonstrated in only 42% of cases.[10]

Clinical manifestations of dysbaric AGE have been grouped into two categories based on the initial presentation and response to treatment. About 5% of the divers who experience AGE are critically injured and often die even when recompression is initiated within minutes.[11] These individuals develop apnea, unconsciousness, and cardiac arrest during ascent or immediately after surfacing from a dive. The most likely cause of this frequently lethal condition is massive volumes of gas in the central circulation.

The majority of patients with dysbaric AGE present with neurological signs and symptoms, but spontaneous respiration and heart rate are maintained. Just as in the more seriously injured divers, onset of symptoms occurs during ascent or within minutes after surfacing. The clinical spectrum of neurological disturbances ranges from focal signs such as monoparesis or discrete sensory deficits to diffuse brain dysfunction, as manifested by confusion, stupor, or coma. In response to prompt recompression and hyperbaric oxygenation, most patients have complete resolution of all neurological deficits.

For reasons that are not well understood, a subgroup of these patients will fail to respond completely or will experience initial improvement followed by recurrence of the presenting signs and symptoms secondary to delayed cerebral edema.[12] The probability of

incomplete response or recurrence is increased as the time between onset of symptoms and initiation of definitive therapy is prolonged.

The true incidence of cerebral AGE may be higher than that established on the basis of historical and physical findings alone, as electroencephalographic evidence of abnormal neuronal activity has been demonstrated after submarine escape training ascents in the absence of associated clinical manifestations.[13]

IATROGENIC AND ACCIDENTAL ARTERIAL GAS EMBOLISM

Accidental AGE is a serious and sometimes lethal complication of many procedures that are widely used in modern medicine.[14] It is often misdiagnosed or recognized only after a delay of several hours. Most cases of AGE present with focal or diffuse manifestations of brain ischemia. Management is often made more difficult by the existence of concurrent medical or surgical complications. In many patients, hyperbaric oxygen therapy, if administered promptly, completely reverses all neurological deficits. It is generally remarkably efficacious even when initiated after a delay of several hours. For a list of surgical procedures that have been associated with iatrogenic AGE, see Table 93-2.

AGE has also been reported in association with penetrating chest trauma and blast injuries.[15] Other accidental causes of AGE reported in the literature include inhalation of pressurized helium,[16] ingestion of hydrogen peroxide,[17] oral sex during pregnancy,[18] and sexual intercourse after vaginal delivery.[19]

TABLE 93-2 Procedures Associated with Iatrogenic Gas Embolism

Neurosurgical
• Craniotomy in the sitting position
• Procedures involving the posterior fossa
• Spinal surgery (fusion and laminectomy)
Cardiovascular
• Cardiac surgery (including CABG and angioplasty)
• Carotid endarterectomy
• Cardiopulmonary resuscitation
Pulmonary
• Lung biopsy
• Thoracentesis
• Thoracotomy
• Mechanical ventilation after endotracheal intubation
Orthopedic
• Total hip arthroplasty
• Arthroscopy
Gastrointestinal
• Laparoscopy (including laparoscopic cholecystectomy)
• ERCP
• Liver transplantation
• Percutaneous liver puncture
Gynecological
• Therapeutic (or criminal) abortion
• Hysteroscopy
• Cesarean section
Urologic
• Transurethral prostatectomy
Vascular access
• Central venous catheter placement and removal
• Hemodialysis
• CT auto-injector

DECOMPRESSION SICKNESS

DCS occurs when ambient pressure is reduced too rapidly to allow the inert gas dissolved in blood and body tissues to remain in physical solution. It usually occurs in the diver after inadequate decompression from prolonged exposure to increased ambient pressures, but it can also occur in the aviator or astronaut who is exposed to high altitude or space with blood and body tissues that are saturated with inert gas at normal atmospheric pressure. The minimum depth necessary to produce DCS in an air breathing diver with a prolonged exposure time (saturation dive) is between 20 and 25 fsw. Dive tables or dive computers are routinely used to lower risk of DCS. Time limits based upon depth for a single (nonrepetitive) air dive without the requirement of staged decompression according to the US Navy are shown in Table 93-3.

Although the precipitating cause of DCS seems to be the evolution of dissolved inert gas from body fluids, neither the physical mechanisms nor the locations of bubble formation are completely understood. Both intravascular and extravascular bubbles have been found in animals exposed to severe decompression stress. Intravascular bubbles are more likely formed in veins than in arteries, due to the greater hydrostatic pressure in the latter vessels. Primary effects caused by the physical presence of undissolved gas in vivo include the obstruction of blood vessels and the mechanical disruption of tissue. In addition, there are secondary effects, caused by tissue reactions to intravascular or extravascular bubbles, which include the concurrent activations of cellular components, such as leukocytes and platelets, and biochemical pathways, such as the complement, coagulation, and kinin systems.[20] Recent literature has demonstrated that circulating levels of microparticles significantly increase after decompression stress and may play a significant role in the pathophysiological process.[21]

It is also possible during or after decompression from a dive to have circulating venous bubbles, as detected by Doppler ultrasonography, without precipitating the onset of DCS (Audio 93-1).[22] Right to left shunting of venous gas emboli through a patent foramen ovale or other anatomic anomaly may increase risk of DCS.

Musculoskeletal pain in one or more extremities is the most common symptom of DCS especially in military divers, commercial divers, and caisson workers. Sport divers more commonly present with neurological symptoms or signs as the chief complaint. These apparent patterns may reflect both the reluctance of professional divers to report neurological symptoms due to the related occupational penalties and the tendency of many recreational divers to delay seeking medical assistance until neurological symptoms occur.

Neurological and pain-only manifestations of DCS appear to have different latencies. Among divers who present with neurological involvement, about 50% become symptomatic within 10 minutes of surfacing, and over 90% are symptomatic within 3 hours.[23] In about 90% of divers who present with musculoskeletal pain only, symptoms occur within 6 hours after the dive.[24] Onset of symptoms 36 hours or more after the dive has been reported, but delays

Audio 93-1 Doppler ultrasonic recordings of venous gas bubbles detected in divers following decompression. **A.** Demonstrates a low bubble score detected in the subclavian vein. **B.** Demonstrates a high bubble score also detected in the subclavian vein. The divers in these examples did not suffer clinical signs or symptoms of decompression sickness. *Access at www.fishmansonline.com*

**The letter group designation to be used for repetitive diving if your dive time is beyond than the times listed in the table for that depth.*
Recommended time limits for each depth without requiring stage decompression are shown. Repetitive group designation is used if repetitive diving is planned.

exceeding 24 hours are extremely rare. Delayed symptom onset sometimes occurs during flight in commercial aircraft that may have cabin altitude exposures in the range of 5000 to 8000 ft too soon after diving. It is generally recommended that flying should be delayed for at least 24 hours after diving.

Clinical manifestations of neurological DCS usually reflect involvement of the spinal cord at the lower thoracic or upper lumbar levels. Paresthesias and sensory deficits may occur with or without associated weakness or paralysis. Transient or persistent abdominal pain may be present. Bladder or bowel dysfunction may occur alone or with associated signs.

DCS may also manifest with cutaneous changes sometimes referred to as skin bends. The most common type is a nonspecific erythematous, macular rash involving the trunk. Urticaria can also occur. As a general rule, these forms of skin bends are considered mild manifestations of decompression stress, resolve with normobaric oxygen, and do not require recompression therapy in the absence of other signs or symptoms. However, cutis marmorata, a rash with a reticulated, marbled appearance is almost pathognomonic for DCS and is frequently associated with the development of neurological DCS (Fig. 93-2).

A less common form of DCS that is characterized by vestibular involvement may present with the sudden onset of vertigo and severe impairment of balance. Associated symptoms often include nausea, vomiting, nystagmus, tinnitus, and sensorineural hearing loss. Vestibular DCS can be unusually difficult to treat, as manifested by a slow or incomplete response to aggressive hyperbaric oxygen therapy.

EVALUATION AND MANAGEMENT OF DECOMPRESSION ILLNESS

Obtaining an adequate history is critically important when evaluating an injured diver, as DCS and AGE are clinical diagnoses.

Figure 93-2 Cutis marmorata in a diver suffering from decompression sickness.

Determining the nature, frequency, gas mixtures used, and profiles of the dives leading up to the injury will be helpful. In addition, one must be alert for a history that includes omitted decompression or an uncontrolled, rapid, or emergency ascent. Most modern-day SCUBA divers utilize dive computers, which, when interrogated, will reveal dive profiles and rates of ascent.

The physical examination should be thorough and includes otoscopy to screen for MEB, a skin examination for signs of cutaneous DCS, and a complete neurological examination. Subtle neurological abnormalities are often seen in DCS including an abnormal mini-mental status examination and problems with gait and balance.

Common laboratory abnormalities seen in DCS and AGE include leukocytosis and hemoconcentration. Creatine kinase is frequently elevated in cases of cerebral AGE and correlates well with neurological outcome.[25] A chest radiograph or noncontrast CT scan of the chest should be performed to screen for pulmonary barotrauma especially prior to recompression therapy.

Other than standard ACLS protocols, the mainstay of treatment for both AGE and DCS is supplemental oxygen. The goal should be F_iO_2 as close to 100% as possible. This will improve oxygenation to tissues and provide a gradient diving inert gas out of bubbles and tissues. Unless contraindicated, oral or isotonic intravenous fluids should be administered to replace lost intravascular volume.

Nonsteroidal anti-inflammatory medications may be useful in the management of DCS. A recent randomized trial examining the adjunctive administration of tenoxicam to divers suffering DCS demonstrated a statistically significant reduction in the number of hyperbaric oxygen treatments required to alleviate symptoms.[26]

Lidocaine is a class 1b antiarrhythmic agent and local anesthetic that has been shown to have cerebroprotective effects. Animal models have demonstrated efficacy in both the prevention and treatment of experimental AGE. The successful use of lidocaine along with hyperbaric oxygen therapy as treatment for nondiving-related cerebral arterial gas embolism (CAGE) has been reported.[16] Although more research is needed, current evidence supports the use of lidocaine as an adjunct to recompression therapy for the treatment of CAGE. An appropriate bolus and infusion should be initiated with infusion rates eventually adjusted based on serum concentrations.

HYPERBARIC OXYGEN THERAPY FOR DECOMPRESSION ILLNESS

Hyperbaric oxygen therapy (HBOT) involves the inhalation of 100% oxygen at a pressure greater than 1 ATA. The typical treatment pressure range is 2.0 to 3.0 ATA. Higher treatment pressures are sometimes used when treating severely injured divers or critically ill patients with CAGE. At pressures higher than 3.0 ATA, mixed treatment gases must be utilized including nitrogen–oxygen or helium–oxygen mixtures allowing for adequate hyperoxia while mitigating the risk of oxygen toxicity. HBOT allows for dramatic increases in both arterial (~2000 mm Hg) and tissue (~200–400 mm Hg) oxygen tensions.

Hyperbaric chambers are generally classified as either multiplace or monoplace chambers. Multiplace chambers are compressed with air and capable of treating multiple patients at the same time along with one or more medical attendants who accompany the patient(s) (Fig. 93-3). The patient breathes oxygen through a tightly sealed mask, hood, or endotracheal tube. Monoplace chambers can be compressed with air or oxygen and the patient treated in isolation. Monoplace chambers typically have pressure limitations of 3.0 ATA.

AGE and DCS have different etiologies and clinical presentations; however, similar therapeutic principles are applied in both conditions. Primary aims of therapy in both cases are reduction in bubble volume, acceleration of bubble resolution, and maintenance of tissue oxygenation. Resolution of bubbles in DCS and AGE is

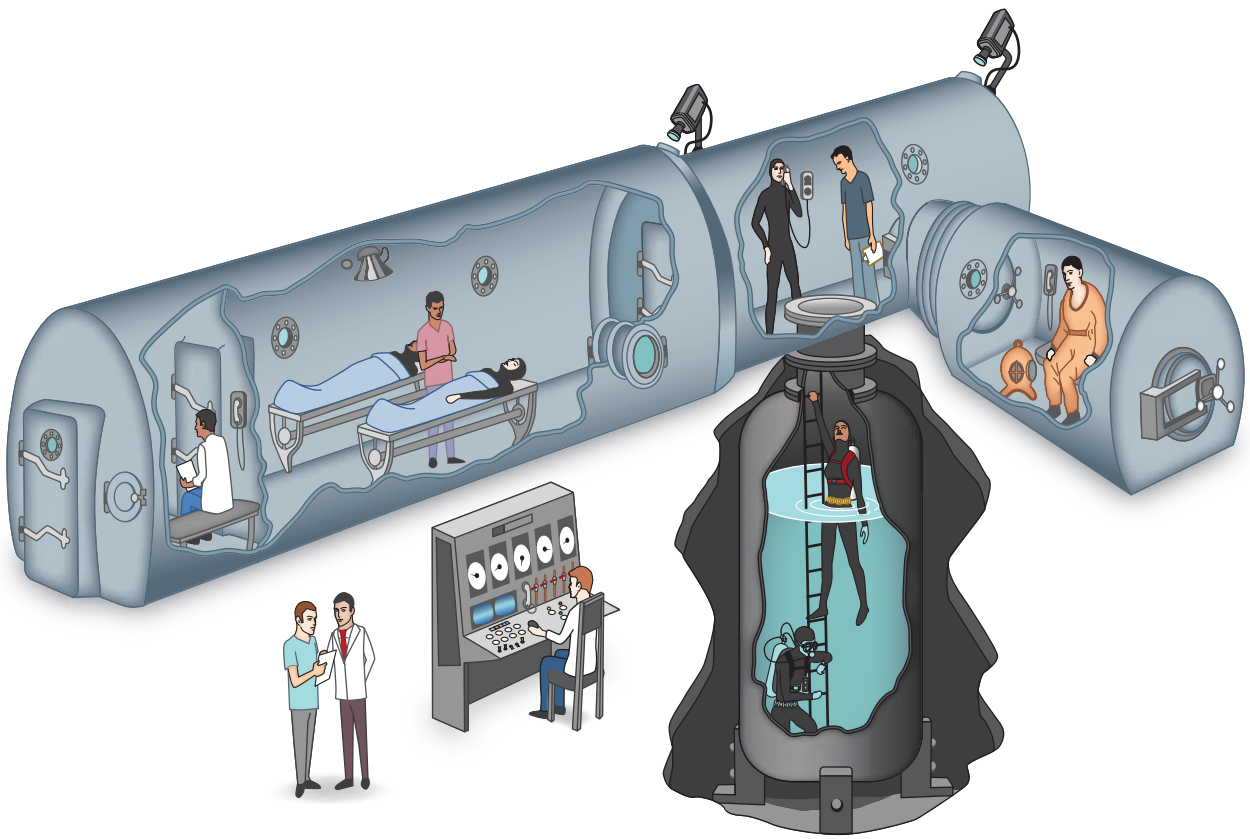

Figure 93-3 A diagram of the multiplace hyperbaric chamber complex at the University of Pennsylvania.

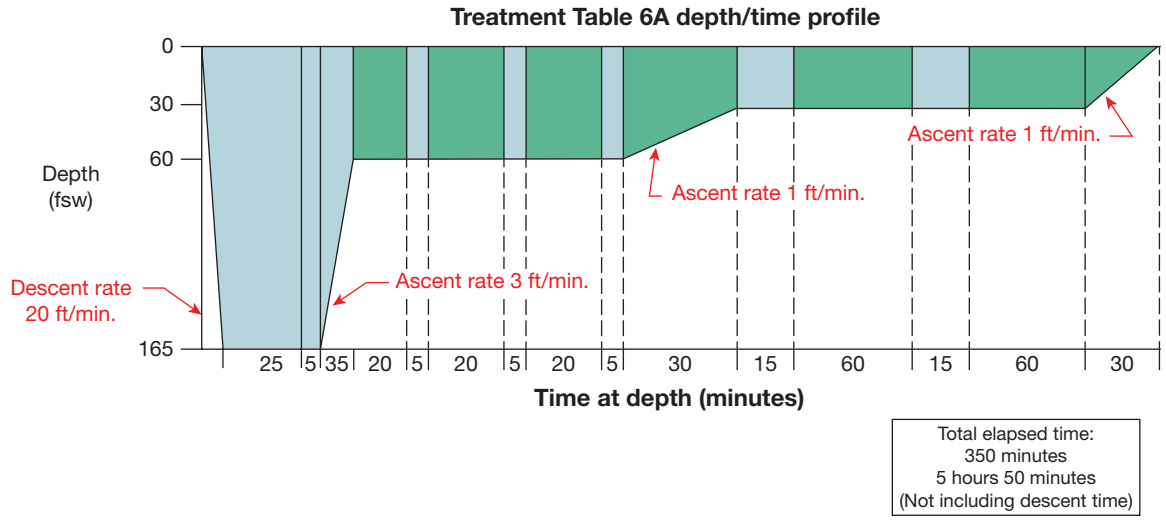

Figure 93-4 US Navy Treatment Table 6A historically used for the treatment of cerebral AGE. Initial compression is to 165 fsw (6.0 ATA). A 50% oxygen mixture is typically administered at this depth. One-hundred percent of oxygen with intermittent air breaks is administered upon arrival at 60 fsw.

greatly hastened by breathing oxygen at increased pressure because the associated elimination of nitrogen from all body tissues and concurrent bubble compression combine to maximize the outward diffusion gradient for bubble nitrogen. The pressure–oxygenation profile historically used to accomplish these aims in CAGE is shown in Figure 93-4.

The rationale for initial compression to 165 fsw (6.0 ATA) is that reduction in bubble sizes to one-sixth of their original volume allows at least some bubbles to traverse capillaries, enter the venous circulation, and be trapped in the lung. Since the patient cannot safely breathe 100% oxygen at 165 fsw, administration of 50% oxygen throughout this phase provides hyperoxygenation at a level slightly greater than that afforded by breathing 100% oxygen at 60 fsw (2.8 ATA). Oxygen is administered with intermittent air breaks throughout the remainder of the therapy to accelerate bubble resolution and maintain tissue oxygenation, while avoiding harmful effects of oxygen toxicity by allowing partial recovery during the air intervals. The profile may be extended in severe cases by adding oxygen intervals at 60 fsw (2.8 ATA) and 30 fsw (1.9 ATA).

The theoretical benefits of compression to pressures beyond 3.0 ATA for the treatment of cerebral AGE have been questioned.[27] In addition, therapeutic mechanisms of HBOT extend beyond the reduction of bubble volume and elimination of inert gas from bubbles and tissues. These beneficial effects are specific to hyperoxia and include the controlled production of reactive oxygen and nitrogen species. In modern times, the most common treatment profile used for treatment of both cerebral AGE and DCS is shown in Figure 93-5. The treatment does not involve compression beyond 2.8 ATA and does not require the use of a multiplace chamber or mixed gas capabilities. This profile may also be extended by adding additional oxygen breathing periods at both 60 and 30 fsw in cases where symptoms are severe or response to treatment is not complete.

LIMITATIONS IMPOSED BY OXYGEN TOXICITY

During oxygen breathing at increased ambient pressures, the rate of intoxication increases progressively in proportion to inspired pO_2 elevation. Duration of oxygen exposure at 1.0 to 2.0 ATA is limited primarily by pulmonary effects of oxygen toxicity. At oxygen pressures of 3.0 ATA or higher, visual impairment and convulsions usually occur before the development of prominent pulmonary toxicity.

Although the toxic effects of oxygen are numerous and varied, they can be avoided by appropriate administration of HBOT. Early stages

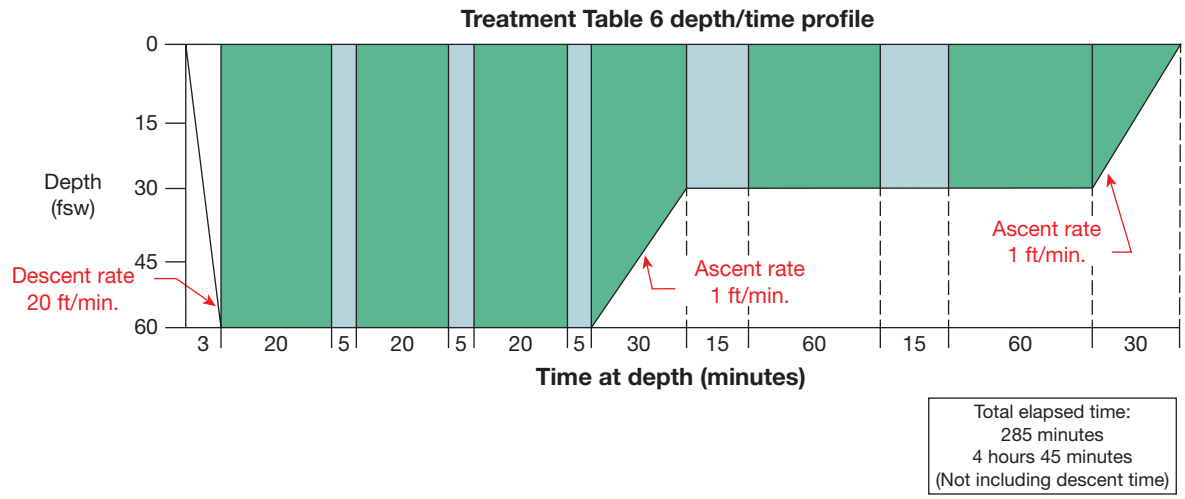

Figure 93-5 US Navy Treatment Table 6 is used for the treatment of DCS and is generally preferred for the treatment of AGE in modern times. The treatment gas is 100% oxygen and air breaks are intermittently provided.

of intoxication, even when associated with symptoms and detectable functional alterations, are fully reversible upon termination of exposure. The onset of toxic effects is delayed effectively by periodic interruption of oxygen exposure with scheduled air breathing periods during HBOT. Supplemental oxygen, unless necessary, should be avoided between hyperbaric oxygen treatments, as it can lead to accelerated pulmonary oxygen toxicity and excessive oxidative stress.

CONCLUSION

Diving injuries, including DCS and dysbaric gas embolism, are pathophysiological processes that occur as a result of changes in ambient pressure. A basic understanding of a few fundamental concepts of applied physics will aid the medical professional during the evaluation and treatment of the injured diver. Iatrogenic gas embolism may occur in association with certain modern-day medical procedures, and early diagnosis and treatment can greatly minimize associated morbidity and mortality.

Administration of supplemental oxygen with referral for HBOT is recommended as the primary treatment option for patients suffering from DCS and AGE. The mechanisms of action of HBOT are complex. Oxygen toxicity can be avoided if the treatment is carefully applied.

CHAPTER 94

Thermal Lung Injury and Acute Smoke Inhalation

Perenlei Enkhbaatar

INTRODUCTION AND EPIDEMIOLOGY

Smoke inhalation is a serious medical problem and continues to have a significant impact on the morbidity and mortality of patients with flame burns. According to the American Burn Association Repository (2012), inhalation injury is present in 17% of patients with flame burns and increases the overall mortality rate of these patients up to 24%, while the mortality of burn patients without inhalation injury is 3%.[1] The presence of smoke inhalation injury prolongs the length of hospital stay 2.5-fold compared to those without smoke inhalation injury (24 days vs. 10 days).[1]

Similar percentages of fire victims who have sustained smoke inhalation appear in several other countries.[2–5] In patients with combined injury, the lung is the critical organ and the progressive respiratory failure associated with pulmonary edema is a pivotal determinant of mortality.[6–8] Although not as lethal, smoke inhalation alone is a serious problem. It is estimated by the World Health Organization that there are over one billion people who develop airway and pulmonary inflammation as a result of inhaling smoke from indoor cooking fires, forest fires, and burning of crops.[9,10]

The inhalation of smoke has been of interest for a number of years, especially as a result of the use of gas warfare. In the 1940s there were two very large fires that focused interest on the inhalation of smoke in fire victims. The first was a fire at a nightclub in Boston called the Cocoanut Grove, where a large number of people were trapped in a burning building and consequently sustained severe inhalation injury.[11,12] It is interesting that in recent times a similar fire occurred in a nightclub near Boston in Rhode Island. The second occurred in Texas City across the bay from Galveston, Texas.[13] Here a ship exploded in a harbor and set off a chain of explosions and fires among some 50 refineries and chemical plants, resulting in over 2,000 hospital admissions of patients with smoke inhalation alone, those with burn injuries, many of whom who had simultaneously inhaled smoke as well. At any rate these two disasters led to the establishments of centers for the care of burn victims and to research into the pathophysiology of burn injury. In many ways the burn victims of the 9/11 disaster were similar to these individuals since the burns and inhalation involved combustion of petroleum products.[14,15] Approximately half (49%) of 790 victims who survived the World Trade Center attack had an inhalation injury.[15,16]

TOXIC SMOKE COMPOUNDS

The fire environment contains a number of toxic compounds, each of which is discussed in this section.

Inhalation injury is caused by steam or toxic inhalants such as fumes, gases, and mists. Fumes consist of small particles dispersed in air with various irritants or cytotoxic chemicals adherent to the particles. Mists consist of aerosolized irritant or cytotoxic liquids. Smoke consists of a combination of fumes, gases, mists, and hot air. Heat, toxic gases, and low oxygen levels are most common causes of death in a fire scene. A large variety of toxic gases and chemicals can be generated depending on the fire environment (Table 94-1).

TABLE 94-1 Origin of Selected Toxic Compounds[17]

Gases and Chemicals	Material	Source
Carbon monoxide	Polyvinyl chloride	Upholstery, wire/pipe coating, wall, floor, furniture coverings
	Cellulose	Clothing, fabric
		Wood, paper, cotton
Cyanide	Wool, silk	Clothing, fabric, blankets, furniture
	Polyurethane	Insulation, upholstery material
	Polyacrylonitrile	Appliances, engineering, plastics
	Polyamide	Carpeting, clothing
	Melamine resins	Household and kitchen goods
Hydrogen chloride	Polyvinyl chloride	Upholstery, wire/pipe coating, wall, floor, furniture coverings
	Polyester	Clothing, fabric
Phosgene	Polyvinyl chloride	Upholstery, wire/pipe coating, wall, floor, furniture coverings
Ammonia	Wool, silk	Clothing, fabric, blankets, furniture
	Polyurethane	Insulation, upholstery material
	Polyamide	Carpeting, clothing
	Melamine resins	Household and kitchen goods
Sulfur dioxide	Rubber	Tires
Hydrogen sulfide	Wool, silk	Clothing, fabric, blankets, furniture
Acrolein	Cellulose	Wood, paper, cotton, jute
	Polypropylene	Upholstery, carpeting
	Acrylics	Aircraft windows, textiles, wall coverings
Formaldehyde	Melamine resins	Household and kitchen goods
Isocyanates	Polyurethane	Insulation, upholstery material
Acrylonitriles	Polyurethane	Insulation, upholstery material

Source: Modified with permission from Prien T, Traber DL. Toxic smoke compounds and inhalation injury–a review. Burns Incl Therm Inj. 1988;14(6):451–460.

Many of these compounds may act together to increase mortality, especially carbon monoxide and hydrogen cyanide[17,18] in which a synergism has been found to increase tissue hypoxia and acidosis[18] and perhaps also decrease cerebral oxygen consumption and metabolism.[19,20] Hydrogen sulfide would also be predicted to synergize with carbon monoxide since both cyanide and hydrogen sulfide are inhibitors of mitochondrial cytochrome oxidase. Victims may be incapacitated by the blinding and irritating effects of smoke, as well as the decreasing oxygen concentration that occurs with combustion and results in progressive hypoxia.

Inhalation injury can be classified as (1) upper airway injury, (2) lower airways and pulmonary parenchymal injury, and (3) systemic toxicity. The extent of inhalation damage depends on fire environment: the ignition source, temperature, concentration, and solubility of the toxic gases generated. For instance, thermal and chemical compounds usually cause upper airway injury. The water-soluble materials such as acrolein and the other aldehydes damage the proximal airways and set off reactions that are inflammatory to the bronchi and parenchyma, whereas agents with lower water solubility such as chlorine, phosgene, nitrogen oxide, and nitrogen dioxide or N_2O_3 or even N_2O_4 are more likely to cause insidious injury.[21] Toxic gases such as carbon monoxide and cyanide rarely damage the airway but affect gas exchange, producing more systemic effects. Thus, it is important to obtain information relative to the source of the fire and the combustion products generated when treating a fire victim (see Table 94-1). It is also important to know the duration of exposure and the extent to which the fire victim was in an enclosed area because this relates to the dose of toxic materials presented.

CARBON MONOXIDE

Carbon monoxide (CO) is an odorless, colorless gas that is produced by incomplete combustion of many fuels, especially cellulolytic (cellulose products) such as wood, paper, and cotton.[22] Carbon monoxide toxicity remains one of the most frequent immediate causes of death following smoke-induced inhalation injury. There are 50,000 estimated annual visits to emergency department in the United States as a result of CO poisoning.[23] The predominant toxic effect of CO is its binding to hemoglobin to form carboxyhemoglobin (COHb). The affinity of CO for hemoglobin is ~200 to 250 times higher than that of oxygen.[24] Inhalation of a 0.1% CO mixture may result in generation of a COHb level as high as 50%. The correlation of inhaled CO and COHb levels is summarized in Table 94-2.

The competitive binding of CO to hemoglobin reduces delivery of oxygen to tissues leading to severe hypoxia, especially of most vulnerable organs such as brain and heart. The oxygen–hemoglobin dissociation curve loses its sigmoid shape and is shifted to the left, thus further impairing tissue oxygen availability.[17] In addition, ability of CO to bind to intracellular cytochromes and to other metalloproteins contributes to CO toxicity. This competitive inhibition with cytochrome oxidase enzyme systems (most notably cytochromes a and P-450) results in an inability of cellular systems to use oxygen.[27] Shimazu et al. have shown that extravascular binding of CO to cytochromes and other structures accounts for 10% to 15% of total-body CO stores, which explains the two-compartment elimination of CO from the circulation.[28] CO also inhibits cytochrome c oxidase activity in lymphocytes. The electron chain dysfunction by CO may cause electron leakage, leading to superoxide production and mitochondrial oxidative stress. Additionally, the excessive nitric oxide and its byproduct peroxynitrite, lipid peroxidation, apoptosis, and delayed inflammation[29–32] contribute to the CO toxicity at both systemic and cellular levels.

Symptoms and Diagnosis

The symptoms predominantly manifest in organs and systems with high oxygen utilization. The severity of clinical manifestations is varied depending on the concentration of CO. For instance, the central nervous system symptoms such as headache, confusion, and collapse may occur when the blood COHb level is from 40% to 50%. Symptoms such as unconsciousness, intermittent convulsions, and respiratory failure may occur if COHb level exceeds 60%, and eventually leading to death if exposure continues. The cardiovascular manifestations result in tachycardia, increase in cardiac output, dysrhythmias, myocardial ischemia, and hypotension depending on the severity of poisoning. The correlations of clinical manifestations and severity of CO poisoning are summarized in Table 94-3.

Blumenthal[35] correlated the clinical signs and symptoms of CO poisoning to the concentration of the inhaled CO: headache and dizziness—up to 100 ppm, 0.01% air concentration, loss of judgment, confusion, and disorientation—up to 200 ppm, 0.02%, and nausea, vomiting, fatigue, confusion, disorientation, visual disturbance, syncope, up to the onset of coma—800 ppm, 0.08% to 12,800 ppm, 1.28%.

Diagnosis should be based on direct measurement of COHb levels in arterial or venous blood by co-oximetry. Portable breath analyzers may be used at the scene. Inability to differentiate oxyhemoglobin from COHb limits the use of pulse oximeters. Although there are some controversies on its reliability, the fingertip pulse co-oximetry, a new technology available since 2005, can be used at the scene of the fire for measurement of COHb.[36] The use of blood gas analyzers that estimate SO_2 based on measurement of dissolved

PO_2 should be avoided. The measurements of acid–base balance, plasma lactate levels, and bicarbonate are helpful in management of CO poisoning with accompanying lactic or metabolic acidosis. It is important to note that high oxygen concentrations are usually administered to the victim in transit to the hospital, and some delay from cessation of exposure to measurement of CO may limit evaluation of the true extent of exposure.[37] A nomogram has been developed that can relate the COHb levels of a patient to the values that may have been present at the time of smoke inhalation; this can be used to estimate the true degree of inhalation injury.[38]

Treatment

The half-life of COHb is 320 minutes (adult male) in room air and ~74 minutes in a person breathing normobaric 100% oxygen at 1 atmosphere.[39,40] Those values are 30% less in females.[41] Therefore, all fire victims should be isolated from fire site and given 100% oxygen on route to the hospital. This allows delivery of an inspired oxygen concentration of 50% to 60%, which is usually adequate. To adequately treat a CO poisoning it is also important to establish COHb level as early as it is possible. In patients with loss of consciousness, cyanosis, or an inability to maintain the airway, 100% oxygen should be delivered via mechanical ventilation through endotracheal tube until COHb levels drop below 10% to 15%. The alternative method to rapidly decrease COHb is hyperbaric oxygen therapy (HBOT) (see Chapter 93). The HBOT allows CO to dissociate from cytochromes a and a3, and to increase PO_2 despite impaired hemoglobin function.[42,43] Chou et al. reported that children with CO poisoning alone who are treated with HBOT are at low risk for dying regardless of initial COHb level.[44] However, there is some debate on use of HBOT especially in patients with burn injury. Because of difficulty of physiological monitoring and providing emergency procedures in small chambers, unstable hemodynamic conditions and other complications such as seizures, or aspiration of severely burned patients limit the use of HBOT.[45]

■ HYDROGEN CYANIDE

Hydrogen cyanide is a colorless gas with the odor of bitter almonds. However, it is difficult to detect it at the site of the fire. Cyanide is a likely weapon for terrorists because of its notoriety, lethality, and availability. Hydrogen cyanide is produced in fires involving nitrogen-containing polymers (upholstery, furniture, nylon, wool, silk, and acrylics) and may produce rapid and lethal incapacitation of a victim at the fire source.[46] Toxicity of cyanide is produced by inhibition of cellular oxygenation with resultant tissue anoxia, which is caused by reversible inhibition of cytochrome c oxidase.[37] It is toxic to a number of enzyme systems. The mechanism includes combination with essential metal ions, formation of cyanohydrins with carbonyl compounds, and the sequestration of sulfur as thiocyanate. However, the main target enzyme is cytochrome c oxidase, the terminal oxidase of the respiratory chain, and involves interaction with the ferric ion of cytochrome a_3.[47]

Symptoms and Diagnosis

Diagnosis at the fire scene may be difficult. Poisoning leads to central nervous system, respiratory, and cardiovascular dysfunction resulting from inhibition of oxidative phosphorylation. It may result in dyspnea, tachypnea, vomiting, bradycardia, hypotension, coma, and seizures. Electrocardiographic S-T segment elevation, which mimics an acute myocardial infarction, may be suggestive.[48] Laboratory findings of anion gap metabolic acidosis and lacticacidemia aid in confirming the diagnosis.[47] The lactic acidosis that is not rapidly responsive to oxygen therapy may be a good indicator of cyanide poisoning.[38,49] Also, an elevated mixed venous saturation is suggestive of cyanide toxicity. Cyanide increases ventilation through the carotid body with peripheral chemoreceptor stimulation. Increasing ventilation may augment toxicity in the early stages. Correlations of blood cyanide concentrations with clinical symptoms are summarized in Table 94-4.

TABLE 94-4 Hydrogen Cyanide Concentrations in Air and Associated Symptoms in Humans[33,50]

HCN Concentration (ppm)	Symptoms
0.2–5.0	Threshold of odor
10 (maximum allowed concentration)	Mild irritation of mucus membranes
18–36	Slight symptoms (headache) after several hours, irritation of throat
45-54	Tolerated for 1/2–1 h without difficulty of breathing
100	Death in 1 h
110–135	Fatal in 1/2–1 h
181	Fatal in 10 min
280	Immediately fatal

Salt Lake City, University of Utah, 1973.

Hydrogen cyanide is found routinely in low levels in the blood of healthy individuals at levels of 0.02 μg/mL in nonsmokers and 0.04 μg/mL in smokers. Toxicity at a level of 0.1 μg/mL and at 1.0 μg/mL death is likely.[51]

Treatment

Fire victims suspected to have cyanide poisoning should be removed from exposure and fully decontaminated. All victims should be given pure oxygen (100%) and resuscitated properly if cardiopulmonary failure is present. Oxygen therapy appears to have strong positive effect; however, HBOT is not recommended for the reasons previously mentioned.[47,51] Cyanide is metabolized by hepatic rhodanese, which catalyzes the donation of sulfur from the sulfane pool to cyanide to form nontoxic thiocyanate. The half-life time of cyanide is approximately 1 to 3 hours in humans.[49,52] Although there is still controversy surrounding the treatment of cyanide poisoning, there are few antidotes available that can be used by first responders. Kelocyanor (dicobalt edetate) may be useful, but is dangerous, and requires experts to administer it.[53] The following agents may be considered in an intensive care setting.

■ METHEMOGLOBIN GENERATORS

The therapeutic goal is to convert the ferrous ion of hemoglobin to ferric ion. The resultant methemoglobin chelates cyanide to form cyanmethemoglobin (cyanide has a greater affinity for binding with methemoglobin and thus, is displaced from cytochrome oxidase). The drugs of choice in this group are sodium nitrite (intravenously) and amyl nitrite (inhaled). These drugs reduce oxygen-carrying capacity; therefore, they should be used with caution especially in patients with concomitant CO poisoning, which induces COHb that may further compromise oxygen transport. These drugs should be also used with precautions in patients with burn shock, because they are also vasodilators and can cause hypotension. In addition, there is little evidence to suggest these measures are effective, and cardiac toxicity in people with heart disease may be problematic.[54] Thus, the methemoglobin generators should be used with extra precautions, carefully weighing patient conditions and comorbidities.

■ SULFUR DONORS

The therapeutic goal is to convert cyanide to thiocyanate. The drug of choice in this group is sodium thiosulfate (intravenously). Toxicity is minimal other than an osmotic diuretic action, which

may be beneficial. However, the onset of action is quite slow. Therefore, it should be used as a second-line therapy.[17,55]

■ DIRECT BINDING AGENTS

These are based on cobalt chemistry and chelate the cyanide ion directly. Hydroxocobalamin is the precursor of vitamin B_{12} and has very little toxicity.[17,51] Minor adverse effects include transient chromaturia, alterations in renal function, reddish skin discoloration, hypertension, and rarely allergic reactions.[56,57] It detoxifies cyanide by binding with it and forming cyanocobalamin, which is then excreted in the urine. The drug is currently approved for use in the United States by the Food and Drug Administration (FDA). However, there is a controversy around its efficacy.

PATHOPHYSIOLOGY

The pathophysiologic consequences of smoke inhalation on the tracheobronchial tree and lung parenchyma are discussed below.

■ TRACHEOBRONCHIAL TREE

In normal conditions, the airway provides a protective barrier against toxic agents and bacteria, maintaining a sterile lung environment. It also facilitates airflow within the lung to ensure efficient gas exchange. Following smoke inhalation, the normal function of the airway is compromised. With rare exceptions such as inhalation of steam, injury to the airway is usually from the chemicals in smoke. The heat capacity of air is low and the bronchial circulation is very efficient in warming or cooling the airway gases so that most gases are at body temperature as they pass the glottis.[58] Flames must be in almost direct contact with the airway to induce thermal injury.[59] The chemicals in smoke are dependent on the materials that are being burned; however, for the most part the host response is similar. In most instances biological materials such as cotton fabric, wood, grass, or products of these such as cattle feces (commonly used as fuel in third world countries) are the fuel for the fire. These contain caustic materials such as reactive oxygen (ROS) and nitrogen species (RNS) as well as organic acids and aldehydes.[60] These chemicals interact with the airway to induce an initial response to trigger an inflammatory response.

Although the degree of airway dysfunction may vary depending on the severity of inhalation injury, it can generally be characterized by few major pathologic alterations that lead to the narrowing/occlusion of the airway lumen reducing or preventing the normal alveolar gas exchange. The factors leading to the airway lumen narrowing are (1) airway hyperemia; (2) formation of an airway obstructive cast; (3) increased mucus secretion; and (4) bronchospasm (see Fig. 94-1). Airway inflammation plays a major role in the overall response to inhalation injury.

Hyperemia of the airway is such a consistent bronchoscopic finding in smoke inhalation that it is used to diagnose the injury.[61,62] Other variables that are used include injury in an enclosed space, singed nasal hair, and soot in sputum. However, these latter injuries may be present but the subject may still not develop the signs of pulmonary edema characteristic of inhalation injury.

The normal bronchial blood circulation is about 1% of cardiac output. Following the smoke inhalation, the airway blood flow rapidly increases resulting in airway wall edema and protein rich plasma leak into the airways. The data presented in Figure 94-2 confirm the dramatic (10–15 fold) increase in tracheal (A) and bronchial (B) blood flow following smoke inhalation that leads to the airway wall edema as confirmed by the macroscopic picture, which clearly illustrates the severe edema formation in the tracheal soft tissue compared to the trachea of an uninjured sheep (C). Many of the studies concerning bronchial circulation following smoke inhalation injury have been performed in sheep, because these animals have a

Blood flow was determined by microsphere injection technique. Data are expressed as ±SEM. *$p < 0.05$ versus sham. *Closed circles* represent sheep without injury (sham smoke), and *closed squares* represent sheep with smoke inhalation. **C, D.** Macroscopic pictures of trachea taken 48 hours after sham smoke (**C**) and smoke inhalation (**D**) in sheep.

single bronchial artery[63] and a single lymphatic draining the lung that allows the measure of pulmonary transvascular fluid flux.[64] Abdi et al. reported a 10-fold increase in bronchial blood flow within 20 minutes of smoke inhalation in sheep.[65] These same animals demonstrate a sixfold increase in pulmonary transvascular fluid flux and a fall in $Pa_{O_2}/FI_{O_2} \leq 300$ but these were delayed to 24 hours. Similar findings have been reported in patients with smoke inhalation alone or the combination of a large cutaneous thermal injury and smoke inhalation.[66] A few investigators have also demonstrated ~10- to 20-fold increases of airway blood flow depending on the anatomical localization of the airways using the same model.[67–69] These changes in blood flow are associated with increased bronchial microvascular permeability to protein and small particles[70] and increased pressure.[71] The ablation of the bronchial blood flow either by a ligation of the bronchial artery or the nebulization of adrenergic agonist epinephrine significantly improved the pulmonary gas exchange in the sheep smoke inhalation and burn injury model.[67,69,72,73] Simultaneous with the changes in the function of the bronchial microvasculature, there is a loss or shedding of the bronchial columnar epithelium.[74,75] As noted, these changes result in a perfuse transudate with a protein content similar to an ultrafiltrate of the plasma.[76]

The augmented airway circulation not only leads to the airway wall edema, but also contributes to the formation of airway obstructive casts. In conditions where the basement membrane is impaired due to smoke inhalation, the increased airway blood flow leads to the massive airway transudation. This transudate, containing procoagulants combines with copious secretions from the goblet cells and leukocytes[77] to form a solid airway obstructive cast. Airway obstructive casts not only reduce/prevent normal air passage, but also become a perfect culture media for bacterial growth. In Figure 94-3, massive airway obstructive casts from human following smoke inhalation injury are shown. The airway obstructive casts, positive for submucosal gland mucus 5B (MUC5B), occupy most of the airway lumen and prevents the normal aeration of the alveoli (Fig. 4A and B).

Early in the response these secretions are fluid and form a foamy material in the airway that many mistake for severe pulmonary edema in human patients.[78] After several hours, this transudate/exudate solidifies or clots in the presence of fibrin, forming firm obstructive materials in the airways. Figure 94-4C shows a presence of fibrin in the airway as a part of the obstructive cast. The mechanism of airway obstructive cast formation is illustrated in Figure 94-5 (cartoon on obstruction). These obstructive materials formed in the upper airway may migrate to the lower airways and alveoli.[77] This obstructive material is problematic from several standpoints. In some rare instances of severe airway injury these materials can induce total obstruction causing a life-threatening problem (Fig. 94-3). The presence of fibrin makes the removal of airway obstructive cast extremely difficult. Occlusion of some of the bronchi

or bronchioles in association with high production of NO can lead to a loss of hypoxic pulmonary vasoconstriction and thus increased shunt fraction. Loss of hypoxic pulmonary vasoconstriction with inhalation injury has been reported.[79] Finally, if single bronchi are occluded while the patient is on a volume limited-ventilated ventilator, there could be overstretch and barotrauma to the alveoli of the nonoccluded portion of the lung. In Figure 94-6, high-resolution computed tomographic (upper panel) and magnetic resonance (lower panel) images illustrate massive airway obstructive casts and edema surrounding the trachea, main bronchi, and great vessels.

The airway is also richly innervated with vasomotor and sensory nerve endings.[80] It is known that these fibers release neuropeptides in response to caustic materials.[81] Neuropeptide release can cause activation of nitric oxide synthase, stimulate chemokine activity, and change microvascular permeability.[82] The resultant activities lead to the formation of reactive oxygen and nitrogen species. Some of the latter are very potent oxidants that can damage DNA. Damage

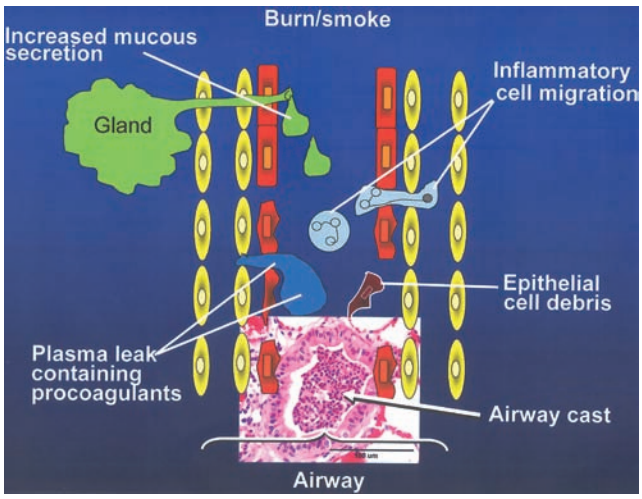

Figure 94-5 The pathophysiological process involved in the formation of the airway obstructive material following injury. Sheep lung tissue was taken for histological analysis 48 hours after combined burn and smoke inhalation injury.

to DNA causes the activation of a repair enzyme poly(ADP-ribose) polymerase (PARP). This enzyme depletes the cell of high-energy phosphates and causes the activation of nuclear factor–kappaB (NF-κB). Activation of the nuclear factor causes the upregulation of iNOS and IL-8, thus creating accelerated production of reactive oxygen and nitrogen species (Fig. 94-1).[43] NO and 3-nitrotyrosine, an index of reactive nitrogen species, and iNOS mRNA and protein have been reported to be elevated in the airway after smoke inhalation.[83] Poly(ADP-ribose) [PAR], the product of the constitutive enzyme PAR polymerase, was identified in the lung tissues following smoke inhalation combined with burn[84] and pneumonia.[85] Inhibition of PARP prevented the formation of PAR, the upregulation of NF-κB and the formation of 3-nitrotyrosine.[84] Airway inflammation is not seen in a typical asthma model in the presence of a PARP inhibitor or in mice lacking the PARP gene.[86]

LUNG PARENCHYMA

As noted earlier the lung parenchyma changes, as reflected by reduced Pa_{O_2}/FI_{O_2}, reduced compliance, and increased edema formation are delayed. The delay is dependent on the severity of airway injury. Lung injury is associated with an increased pulmonary transvascular fluid flux.[83] The degree of transvascular fluid is proportional to the duration of smoke exposure[67] and is independent of the levels of CO in the inhalant gas.[87] The factors responsible for fluid leak are codified in the Starling–Landis equation.[88,89] The variables of this equation relate fluid movement to pressure and permeability variations. With inhalation of smoke there is a reduction in refection coefficient (permeability to protein), an increase in filtration coefficient (permeability to small particles), and an increase in pulmonary microvascular pressure.[90–92] Figure 94-7 demonstrates that pulmonary transvascular fluid flux in sheep following smoke inhalation is due to changes in both microvascular permeability and pressure. It appears that microvascular changes are responsible for early event.

Animals that had been exposed to smoke inhalation injury were also noted to have reduced Pa_{O_2}/FI_{O_2}. The change in this variable showed a good relationship to the histologic injury scores and the changes in transvascular fluid flux.[84] In addition, there was a loss of hypoxic pulmonary vasoconstriction in the injured animals that would help to explain the poor oxygenation.[85]

As in the airway the injury is markedly reduced by the administration of an iNOS or PARP inhibitors and is associated with the reduction of PAR and 3-nitrotyrosine.[68,83,93]

The venous outflow of the bronchial circulation drains into the pulmonary microcirculation at the precapillary level.[94] The fact that initial damage to the airway appeared to drive the pathophysiology of the parenchyma led investigators to hypothesize that the bronchial blood might deliver cytotoxic materials or cells into the pulmonary microcirculation. To test this hypothesis, several investigators have tied off the bronchial artery of sheep and then exposed the animals to smoke.[70,67,95] The hypothesis was affirmed in these studies; lung parenchymal changes were reduced. Recently, Lange et al. demonstrated that nebulized epinephrine attenuated smoke inhalation–induced increases in both tracheal and bronchial blood flow and improved pulmonary gas exchange.[69]

What could be the linkage among the airway, the bronchial venous drainage, and parenchymal injury to the lung? Neutrophils activated in the bronchial circulation flow out into the bronchial venous drainage. Activated polymorphonuclear cells (PMN) especially neutrophils are stiff. The diameter of neutrophils that have been fixed is approximately 7 μm.[96] Since these cells have been dehydrated in alcohol as part of the fixation process, unfixed cells are much larger, on the order of 12 μm. The pulmonary capillary is small with an average diameter of 6 μm.[96] Normally, the large neutrophil can traverse the pulmonary capillary by changing the

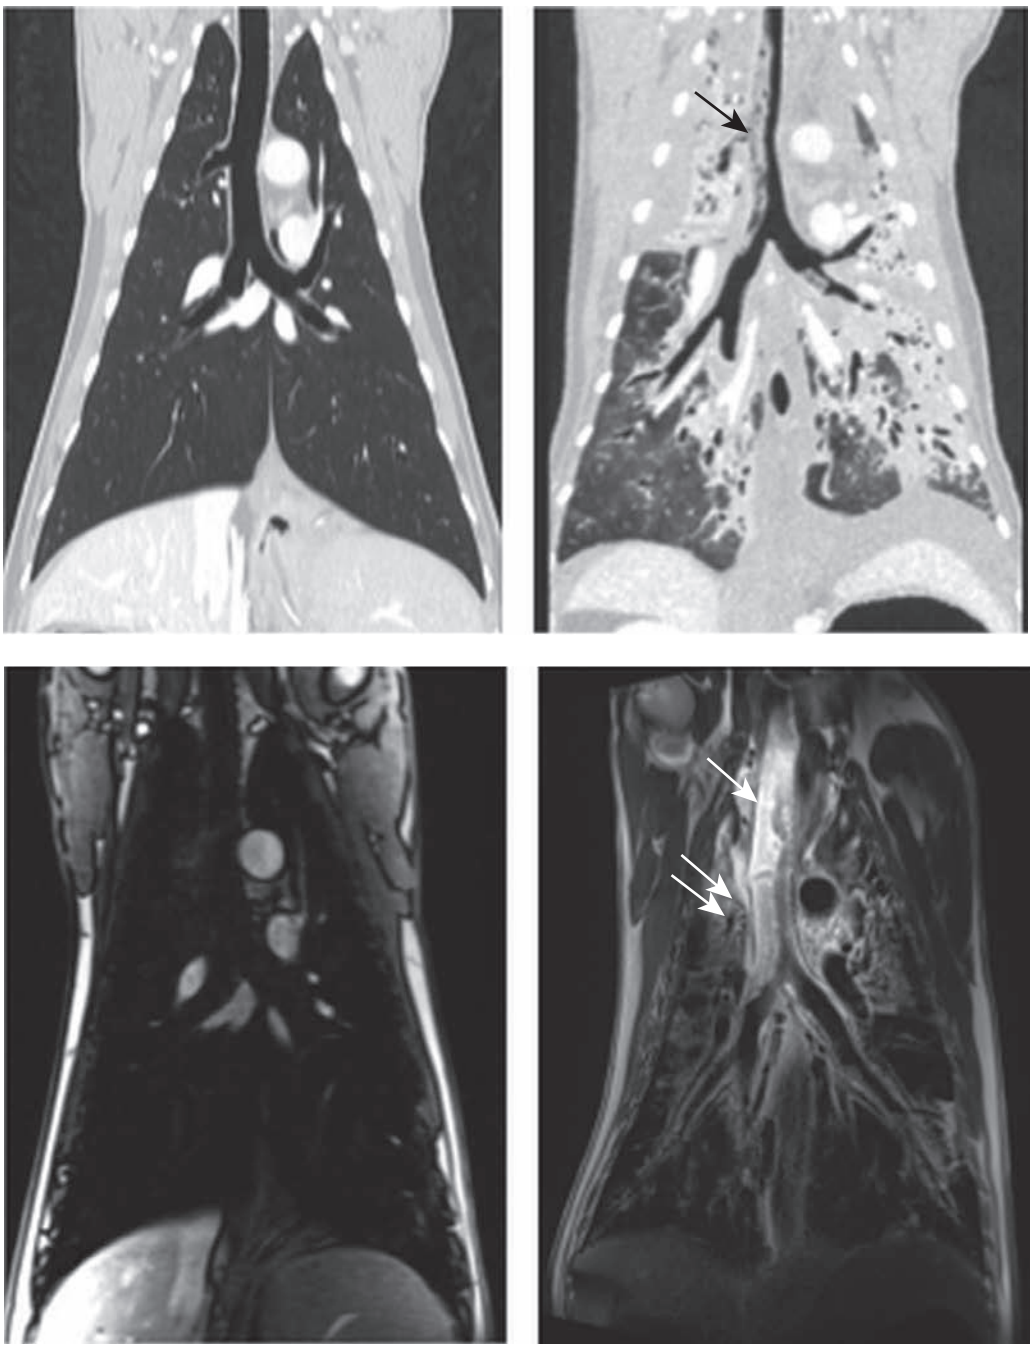

Figure 94-6 Coronal reformatted computed tomographic *(upper panels)* and magnetic resonance *(lower panels)* images before (images on left) and after (24 hours) (images on the right) the cotton smoke inhalation in sheep show casts in the upper airway *(single black arrow)*, including accessory right upper lobe causing its collapse. shape. However, when many neutrophils have been activated in the bronchial areas, their F-actin is activated and the cells are stiff and cannot deform. These stiff cells are carried to the pulmonary microvasculature, where they are impaled by the narrow pulmonary capillaries. The activated neutrophils release ROS and proteases that damage the parenchyma. The following evidence supports this concept of neutrophil cytotoxicity. Oxidative processes are well known following inhalation injury. There is lipid peroxidation and release of proteolytic enzymes following injury.[97–99] Administration of protease inhibitors or scavengers of ROS reduces the response to smoke inhalation[97,100–102] when activated PMNs lose the L-selectin on their surface. This L-selectin shedding is prevented by the treatment with an L-selectin antibody.[103] Treatment of the cells with an antibody to L-selectin prevents the changes in transvascular fluid flux and other aspects of parenchymal damage.[104] The final proof of this hypothesis was to deplete the animals of their neutrophils and determine how this affected the response to inhalation injury. In these studies of sheep depleted of their leukocytes, a high percentage of the parenchymal response to smoke inhalation was blocked.[105]

In addition to the depletion of antioxidants, it has also been reported that burned patients are depleted of arginine.[106] When arginine levels are low nitric oxide synthase produces superoxide rather than nitric oxide.[107] Administration of arginine may assist in reducing the oxidation that occurs with inhalation injury. However, the necessity of administering the arginine as arginine hydrochloride (because of solubility) limits the amount that may be given

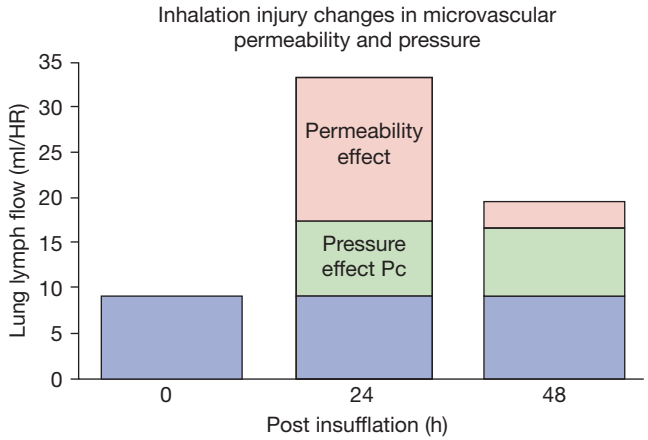

Figure 94-7 Diagram showing portion of edema resulting from either changes in pulmonary microvascular permeability or pressure at 24 and 48 hours after inhalation injury. *(Data from Isago T, Fujioka K, Traber LD, et al. intravenously without producing acidosis. Efficacy of arginine supplementation was demonstrated only in animal models of burn and smoke inhalation injury.[108]

Smoke inhalation injury, especially when it is combined with cutaneous burns, causes both local airway and systemic coagulopathy.[109,110–112] The hypercoagulable state in burn patients during the initial 24 hours is associated with high levels of activated factor VII (FVIIa), thrombin–antithrombin complex (TAT), PAI-1, and low levels of antithrombin.[113] Taken together the results of the previously mentioned studies could suggest, that a high rate of fibrin or thrombin formation and their diffuse deposition in the microvasculature during the first days following injury, accompanied by a relatively ineffective fibrinolysis due to excess PAI-1 could play an important pathophysiological role in the development of organ dysfunction.

TREATMENT

The treatment of smoke inhalation is complex. There is no defined and uniformly accepted standard treatment for smoke inhalation injury. The airway is a major concern immediately after the inhalation injury. The airway management is very difficult in patients with combined burn and inhalation injuries. Intubation of patients with burns of soft tissues of the face, oral pharynx, and neck is challenging. Burn injury to these soft tissues results in an almost immediate and severe edema and swelling.[114] Intubation in such an individual requires great skill. Securing the tube is also difficult. Accidental removal of the endotracheal tube can easily happen and is lethal. Often burns and/or the chemicals in smoke can damage the larynx, and placement of the tube can cause damage and delay healing of such a wound. Tracheostomy is sometimes performed, but also can be difficult if it has to be placed through burned skin on the neck. For information on this, the reader is referred to the chapters of Fitzpatrick and Cioffi as well as Mlcak and Herndon, in Herndon's *Total Burn Care*.[115,116]

To counter obstruction, vigorous airway toilet should be performed. The airway cast material contains fibrin. Experimentally, the use of heparin has been reported to be effective in reducing airway obstruction.[117] Many burn units nebulize heparin into the airway of their patients with inhalation injury.[118] Of note, heparin requires the presence of antithrombin to be effective, and this factor has been reported to be deficient following burn injury.[111,119] Consequently, antithrombin has been reported to be effective in these situations in animal studies.[111,112,120,121–123] Intravenous administration of antithrombin has also been shown to reduce mortality and morbidity of burn patients.[124] Antithrombin may also act as an anti-inflammatory agent.[125] Because the concomitant heparin prevents antithrombin's anti-inflammatory effects, administration of these compounds by different routes was suggested in translational large animal studies, that is, heparin via nebulization and systemic administration of antithrombin, to achieve maximum local (airway) anticoagulant and systemic anti-inflammatory effects.[111,126] Tasaki et al. also reported beneficial effects of nebulized heparin combined with intravenous infusion of anti-inflammatory agents.[127]

Once obstructive materials have formed in the airway anticoagulant therapy (heparin and antithrombin) is ineffective in removing them. Animal studies have demonstrated that tissue plasminogen activator could be effective in removing these materials.[110] Aerosolized tissue plasminogen activator has also been reported to be effective in removing bronchial obstructive material in patients who have had Fontan procedures (surgical procedures for complex congenital heart diseases named after Dr. Fontan).[128,129]

To alleviate airway smooth muscle spasm, nebulized albuterol as a bronchodilator was successfully used in both an animal model of smoke inhalation and burn patients with concomitant smoke inhalation.[130,131] Other bronchodilators such as nebulized tiotropium bromide and epinephrine were shown to be beneficial in the animal model of inhalation injury.[69,132]

Because of almost immediate airway hyperemia following smoke inhalation, the use of nebulized agents that modulate augmented airway blood flow may be of particular importance. Lange et al. recently reported that nebulized epinephrine, a nonspecific adrenergic agonist reduced both trachea and bronchi blood flow and improved arterial oxygenation in a sheep model of cotton smoke injury.[69] Nebulized epinephrine may be of particular interest in management of inhalation injury, since it has both alpha (vasoconstriction) and beta (bronchodilation) effects. However, further studies are needed for the safety of such a therapy minimizing its systemic effects to be established. The importance of reducing airway hyperemia has been repeatedly shown in animal models by ablating the bronchial artery.[67,70,72,73,133] The local administration of the various compounds to the bronchial artery that attenuate augmented bronchial circulation and inflammation prevents many pathological changes following smoke and burn injury in sheep.[134–136] Although such therapies (ligation and cannulation of bronchial artery for drug infusion) are not feasible in clinical practice, these findings strongly suggest the critical role of airway dysfunction (hyperemia, inflammation) in the pathophysiology of lung injury after smoke inhalation. These findings also suggest the crucial importance of efficient airway management in alleviating severe lung injury following smoke inhalation.

Many other drugs have also proved effective in reducing the injury to the lung parenchyma of animal models of inhalation injury, including cyclooxygenase inhibitors,[137] iNOS inhibitors,[68] PARP inhibitors[84] and free radical scavengers,[100] as well as the anticoagulant factors[111,126] mentioned earlier. However, only the latter are in clinical use and/or have been studied in clinical trials.[124,138]

Mechanical ventilation should be indicated in case of respiratory failure. However, in many instances conventional methods of ventilation can no longer sustain the pulmonary function of burned patients. Extracorporeal membrane oxygenation has been used in these patients with some success.[139] Techniques have now been developed in animal models of inhalation injury that involve a unique form of CO_2 removal called arterial venous CO_2 removal or AVCOR. Off the shelf CO_2 removal devices, used in extracorporal bypass and cardiopulmonary bypass, have been modified to be driven by the subject's own arterial pressure.[140] These were tested in animal models and shown to be very successful in reducing pathophysiology, morbidity, mortality, and days of ventilatory support of models of inhalation injury.[141–143]

Finally, some pretreatment for smoke inhalation can be accomplished. People who are chronically exposed to smoke such as farmers who burn crops, individuals with fires in their huts, and fire fighters may benefit from pretreatment. There are reports that individuals who are chronically exposed to smoke are depleted of their antioxidants.[144] Consequently, supplementation of antioxidants should be considered.[144]

CONCLUSION

The diagnosis and treatment of smoke inhalation injury are complex. There are neither existing standardized criteria for the diagnosis of smoke inhalation injury nor specific pharmacological agents developed against this malady. Multicenter, prospective, randomized, and large scale clinical trials are needed to test the efficacy and safety of promising pharmacological agents from basic science and translational studies—nebulized fibrinolytics, anticoagulants, beta or mixed beta and alpha-adrenergic agonists, and antioxidants. These multicenter clinical trials may also help scientists and clinicians reach concurrence upon the uniformly characterized diagnostic standard.

ACKNOLWEDGMENTS

Dedicated to the memory of Dr. Daniel L. Traber who was my mentor and the coauthor of this chapter in the previous edition.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Following a brief overview of the topic, we present a discussion on the frequency of noninfectious complications, associated risk factors, and the impact of noninfectious complications on outcome.

OVERVIEW

Important considerations in hematopoietic stem cell transplantation are discussed below. Subsequently, solid organ transplantation is discussed in a separate section.

Hematopoietic stem cell transplantation (HSCT) primarily is used to treat hematological and lymphoid cancers, selected solid tumors, and nonneoplastic diseases including autoimmune disorders, amyloidosis, and aplastic anemia.[1] Over 30,000 autologous and 25,000 allogeneic HSCTs are performed annually worldwide.[2] The most common graft source is peripheral blood.[2] Other graft sources include bone marrow and cord blood. A total of 7892 allogeneic and 12047 autologous HSCTs were performed in 2011 in the United States.[2] The main indications for autologous transplant include multiple myeloma and lymphomas, and allogeneic transplant is most commonly performed for acute and chronic leukemia, lymphoma, and myelodysplastic syndrome. A conditioning regimen is employed before transplantation to eradicate malignant cells and, in allogeneic transplantation, to induce immunosuppression that permits engraftment.[1] Some patients are also given total-body irradiation for myeloablation and immunosuppression. The conditioning regimen can be termed myeloablative, reduced intensity, or nonmyeloablative.[3]

Following HSCT, the immune system recovers along predictable patterns depending on the underlying disorder, stem cell source, and complications such as graft versus host disease (GVHD).[4] Recovery occurs faster in autologous recipients, in those who receive peripheral blood stem cell grafts, and after nonmyeloablative conditioning. The posttransplant period is divided into three phases: Pre-engraftment, early posttransplant, and late posttransplant.[5] The pre-engraftment phase (0–30 days) is characterized by neutropenia and breaks in the mucocutaneous barriers. The early post-engraftment phase (30–100 days) is dominated by impaired cell-mediated immunity. The impact of this cell-mediated defect is determined by the development of GVHD and the corresponding immunosuppressant medications. The late posttransplant phase (>100 days) is characterized by defects in cell-mediated and humoral immunity, as well as function of the reticuloendothelial system in allogeneic transplant recipients. The development of noninfectious pulmonary complications follows characteristic temporal patterns.[6] Pulmonary edema, diffuse alveolar hemorrhage (DAH), and peri-engraftment respiratory distress syndrome (PERDS) usually occur during the first 30 days posttransplant (Fig. 95-1). Idiopathic pneumonia syndrome (IPS) can occur at any time following transplant.

The mortality of patients following HSCT is high and depends on the underlying disease and type of transplant.[2] Patients receiving human leukocyte antigen (HLA)-identical sibling transplants for acute myelogenous leukemia (AML) in remission have a 100-day mortality rate of 7% to 9%, compared with 22% for patients with active leukemia at the time of transplantation. Early mortality after an unrelated donor transplant is higher than after an HLA-identical sibling transplant, but the rate also depends on the disease and stage. The causes of death in the first 100 days posttransplant mainly relate to the primary disease, GVHD, infection, and end-organ damage. IPS accounts for 1% to 5% of deaths. After an autologous transplant, recurrence or progression of primary disease is the most commonly reported cause of death. Among allogeneic transplant recipients, unrelated donor transplants have fewer deaths related to the primary disease; however, deaths related to organ failure and infections are more frequent.

FREQUENCY OF NONINFECTIOUS PULMONARY COMPLICATIONS

Many pulmonary complications occur in HSCT recipients (Table 95-1). Earlier reports identified pulmonary complications in 30%

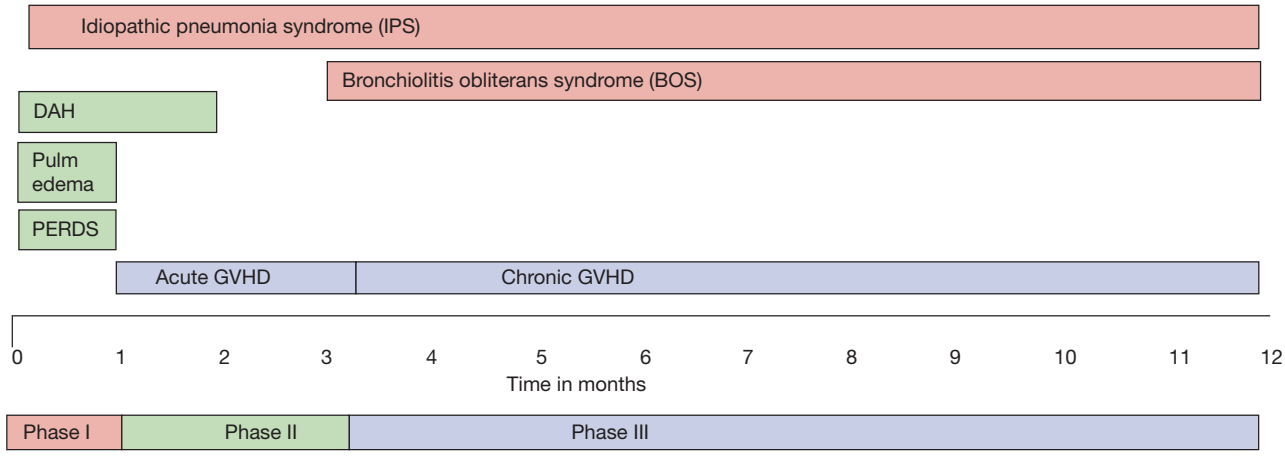

Figure 95-1 The temporal pattern of major noninfectious pulmonary complications following hematopoietic stem cell transplantation.

TABLE 95-1 Noninfectious Pulmonary Complications in the HSCT Recipient

Isolated abnormality in pulmonary function
Bronchiolitis obliterans syndrome
Bronchiolitis obliterans organizing pneumonia
Idiopathic pulmonary syndrome
Delayed pulmonary toxicity syndrome
Diffuse alveolar hemorrhage
Peri-engraftment respiratory distress syndrome
Pulmonary cytolytic thrombotic syndrome
Pulmonary venoocclusive disease
Progressive pulmonary fibrosis
Pulmonary hypertension
Hepatopulmonary syndrome
Pulmonary alveolar proteinosis
Eosinophilic pneumonia

Graft vs. host disease

to 60% of HSCT recipients.[7–9] Recent publications suggest changes in the pattern and frequency. In a study of 70 patients, pulmonary complications developed in 18 (25.7%), of whom only 2 had noninfectious pulmonary complications, one cryptogenic organizing pneumonia (COP), and another IPS.[10] In a study of T-cell–depleted HSCT recipients, pulmonary complications developed in 16.5%.[11] In a more recent report of autologous HSCT recipients, pulmonary complications developed in 27.6%, with noninfectious diagnoses in 10.2%.[12] The reported rates of respiratory failure in allogeneic HSCT recipients also have declined over time.[13]

In a group of pediatric HSCT recipients, pulmonary complications were found in 90 of 363 (25%).[14] In a study of pediatric allogeneic HSCT recipients, late-onset noninfectious pulmonary complications developed in 10 of 97 (10.3%), including 8 COP and 2 IPS.[15] In autopsy series, the rate of pulmonary complications exceeds 80%.[16,17]

RISK FACTORS FOR NONINFECTIOUS PULMONARY COMPLICATIONS

Several factors have been implicated as risk factors for pulmonary complication in HSCT recipients (Table 95-2).[5,11,14,15,18–23] It is controversial whether impaired pulmonary function before stem cell transplant is a risk factor for the development of early posttransplant respiratory failure and mortality. Studies that have examined the predictive value of pretransplant pulmonary function tests suggest that poor lung function before transplant increases the risk for posttransplant pulmonary complications[24–28] and mortality.[25,29,30] These findings were not confirmed in a large study.[31] In addition, these analyses disagreed on which pretransplant lung function parameters were the strongest predictors of pulmonary complications and mortality, and they were limited by relatively small cohorts. A retrospective analysis of 2852 HSCT recipients assessed the association of pretransplant FEV_1, FVC, total lung capacity (TLC), diffusing capacity for carbon monoxide (D_{LCO}), and the development of early respiratory failure and mortality.[32] Patients who developed early respiratory failure were more likely to have impaired lung function prior to transplant. Univariate analysis demonstrated that pretransplant FEV_1, FVC, TLC, and D_{LCO} were more likely to be reduced among patients who developed early respiratory failure.[32] In a recent report of 1243 autologous HSCT recipients, pretransplant D_{LCO} and underlying disease were the only independent risk factors for the development of pulmonary complications.[12] In a study of 307 autologous and allogeneic HSCT recipients, 170 developed venoocclusive disease of the liver, and this was associated with reduced pretransplant D_{LCO}.[33] Advanced stage of the underlying disease at transplant is associated with the development of late-onset noninfectious pulmonary complications.[22] Nonmyeloablative conditioning is associated with reduced pulmonary complications.[34] Also, the incidence of pulmonary complications is low after T-cell–depleted stem cell transplant.[11] Due to the absence of GVHD and the infrequent use of immunosuppressant medications and radiation therapy, noninfectious complications are less common in the autologous HSCT recipient.

IMPACT OF PULMONARY COMPLICATIONS ON PATIENT OUTCOME

The mortality rate of allogeneic HSCT recipients has declined over time.[13] A 2006 report found median survival of 41 weeks for patients with pulmonary complications compared with 350 weeks for those without complications.[11] In patients who survived beyond 2 years after transplant, pulmonary complications accounted for 5% of the subsequent deaths, and patients with pulmonary complications had a 15-fold increased risk of death.[35] In a study of pediatric allogeneic HSCT recipients, the 5-year posttransplant survival of patients with noninfectious pulmonary complications was 28.0% compared with 87.2% of those without complications.[15] In an autopsy study of HSCT recipients, pulmonary complications were the only cause of death in 64% and one of multiple causes in 10%.[16] There is controversy in the provision of intensive care for severe pulmonary complications. Respiratory failure accounts for about one-third of ICU admissions following HSCT, and early reports observed nearly 100% short-term mortality for HSCT recipients requiring ventilator support. More recent series report improving outcomes, with overall hospital mortality approximately 50% after ICU admission, and mortality 75% to 85% following mechanical ventilation.[36–38] Worse outcomes are associated with advanced underlying disease, GVHD, multiple organ failure, and the need for vasopressors. Intensive care and aggressive management are usually warranted in the acute situation, especially during the engraftment period, to assess for potentially reversible conditions.

APPROACH TO THE DIAGNOSIS OF NONINFECTIOUS PULMONARY COMPLICATIONS

The diagnostic approach to HSCT recipient with suspected noninfectious pulmonary complications should follow a systematic approach.[6] Recipients with respiratory symptoms and signs usually

are evaluated with a chest radiograph followed by high-resolution computed tomography (HRCT). If the radiographic evaluation fails to reveal pulmonary infiltrates, especially in allogeneic recipients, PFT should be performed to assess for bronchiolitis obliterans syndrome (BOS). For patients with pulmonary infiltrates, noninvasive tests should be performed for infections and other causes. Noninvasive approaches include sputum for microbiology studies, blood culture, blood aspergillus assay, cytomegalovirus (CMV) viral load testing, and urine antigen for *Legionella pneumophila* and *Pneumococcus pneumonia*.[39] If noninvasive testing is nondiagnostic, invasive techniques should be considered, balancing the risk–benefit ratio. The invasive approach usually relies on fiberoptic bronchoscopy with bronchoalveolar lavage (BAL) and occasionally transbronchial lung biopsy. Other invasive procedures such as image-guided transthoracic needle aspiration and video-assisted thoracoscopic biopsy rarely may be needed.[40]

PULMONARY FUNCTION ABNORMALITIES FOLLOWING HSCT

Although the value of pretransplant PFT in predicting posttransplant outcome is somewhat controversial, many institutions perform pretransplant PFT as a baseline reference on all recipients, and posttransplant testing for allogeneic recipients.[26,41,42] Some patients develop PFT abnormalities in the absence of respiratory symptoms.[43] Restrictive and obstructive ventilatory defects, and gas transfer abnormalities are frequent long-term sequelae following allogeneic transplantation. A systematic review of data regarding allogeneic HSCT recipients reported decreased D_{LCO} in 83%, restriction in 35%, and obstruction in 23%.[44] A more recent study of over 500 allogeneic HSCT recipients documented somewhat lower frequencies: Impaired D_{LCO} in 35%, restriction in 12%, and obstruction in only 6% of long-term survivors.[45] While the frequency of restrictive defect and of impaired D_{LCO} appeared constant over time, this study suggested a declining frequency of airflow obstruction. HSCT recipients with IPS and COP present with restrictive pulmonary function impairment, and those with BOS demonstrate airflow obstruction.[46] The development of any posttransplant PFT abnormality is associated with increased risk of death.[24,25,45,47]

Risk factors for the development of PFT abnormalities following HSCT include smoking history, pretransplant pulmonary infection, viral infection in the early posttransplant period, older age, underlying disease, pretransplant chemotherapy and conditioning regimen, GVHD, and HLA mismatch.[29,48–50] Respiratory muscle weakness, an alternative cause of restrictive PFT abnormalities, was reported in 52% of allogeneic HSCT recipients in a retrospective study.[51] Risk factors for respiratory muscle weakness include chemotherapy, total-body irradiation, high-dose corticosteroids, immobility, and GVHD.[51]

UPPER AIRWAY COMPLICATIONS

Significant injury to the mucosal barrier occurs in about 75% of HSCT recipients.[52] Total-body irradiation, allogeneic transplant, leukemia, and delayed neutrophil engraftment are risk factors for mucositis.[53] Upper airway inflammation due to mucositis may lead to laryngeal edema, dysphagia, and aspiration pneumonia. Life-threatening upper airway complications are more common in children.[54,55] More severe mucositis is associated with an increased risk of secondary infection, requirement for narcotics, longer duration of parenteral nutrition and hospital length of stay, and increased overall mortality.[53,56] Upper airway injury in HSCT recipients is usually managed with supportive care, including local symptomatic therapy and endotracheal intubation in severe cases.

BRONCHIOLITIS OBLITERANS

Bronchiolitis obliterans (BO) is an inflammatory and fibroproliferative process primarily affecting the small airways that leads to the presence of airflow limitation.[57] Although BO can be idiopathic, it is more often associated with connective tissue disease, inhaled toxins, infections, drugs, chronic rejection following lung transplantation, and chronic GVHD.[57–59] GVHD is a frequent complication of allogeneic HSCT, and is commonly associated with lung disease.[48,59–61] The pulmonary manifestations of GVHD include diffuse alveolar damage, lymphocytic bronchitis/bronchiolitis with interstitial pneumonitis, COP, and BO.[62] BO has only rarely been reported in autologous HSCT recipients.[63]

Frequency

The rate of BO varies among studies, depending on patient population. The lack of precise definition and uniform diagnostic criteria contribute to these variations. Although some studies have included pathological findings, most of the reported cases of the syndrome in HSCT recipients were defined by the presence of airflow limitation in the appropriate clinical setting.[48]

In a previous review of nine studies including 2152 allogeneic HSCT recipients, BO was reported in 8.3%, with a range of 6% to 20% in long-term survivors.[58] In seven more recent studies, including 5543 allogeneic HSCT recipients, the average BO rate was 3.7%, with range of 2.6% to 10.3%.[11,22,60,61,64–66]

Risk Factors

Several factors are implicated as risks for BO.[58] The most common is GVHD.[25,61,64,65,67,68] In one study of allogeneic HSCT recipients, 6% of those with chronic GVHD developed BO compared to none without GVHD.[69] Data from the International Bone Marrow Registry of 6275 adults with leukemia who received HLA-matched sibling transplant from 1989 to 1997, and survived at least for 100 days, showed that BO was associated with busulfan-based conditioning, time from disease diagnosis to transplant of 14 months or longer, peripheral blood stem cell source, transplant from female donor to male recipient, acute GVHD, and interstitial pneumonia.[67] Older recipient or donor age, methotrexate use, and serum immunoglobulin deficiency are also implicated to be risk factors for BO.[25,61,69–72] While pulmonary infections are common in patients with BO, it is not clear whether they are causally related or result from associated immunodeficiency.

Pathogenesis

Little is known about the pathogenesis of BO. Early in the syndrome, bronchiolar inflammation has been identified.[62,73] The histopathology begins with lymphocyte inflammation around small vessels and the respiratory epithelial lining of the small airways, followed by epithelial cell necrosis and mucosal denudation.[68] Two different forms of BO have been described, distinguished by their response to azithromycin: A responsive, neutrophilic, partially reversible form and a nonresponsive fibroproliferative variant.[74,75] The association between BO and chronic GVHD has led to the hypothesis that host bronchiolar epithelial cells serve as target for donor cytotoxic T lymphocytes.[76] Alternative explanations include recurrent aspiration of oral material due to esophagitis associated with GVHD, abnormal local immunoglobulin secretory function in the lungs, or unrecognized infection.[69,76] The variations in histopathology, bronchoalveolar cell differential, clinical course, and the frequency of associated pulmonary infection suggest that the pathogenesis is multifactorial.[76,77] BO in HSCT recipients resembles chronic allograft rejection in lung transplant recipients at immunological, pathological, and physiological levels.[78] T-cell–mediated recognition of alloantigens expressed in the lung tissue plays a central role.[68] In one study, none of the HSCT recipients with T-cell depletion developed BO.[79]

Clinical Findings

From several reports, the onset of BO occurs at a median 328 to 335 days and range 48 to 1690 days following HSCT.[60,64,65,70,72,79] In

the International Bone Marrow Registry of 6275 allogeneic HSCT recipients with leukemia, median time (range) from transplant to BO is 431 (65–2244) days.[67] Twenty percent of the patients with BO had no respiratory symptoms at the time of the first abnormal pulmonary test. The absence of symptoms has been observed during the mild stage of BO.[80] Typical respiratory symptoms include dry cough, dyspnea and exercise intolerance.[70,72,81] The physical finding of wheezing may be detected in about 40%.[70] Unlike COP, fever is absent in BO. Since these symptoms are nonspecific, a complete history, including prior medications and infections, and thorough physical examination focusing on signs of chronic GVHD should be obtained.

Diagnosis

The clinical criteria that have been most widely used for the diagnosis of BO in the HSCT population include $FEV_1/FVC < 0.7$ and $FEV_1 < 75\%$ of predicted; evidence of air trapping, small airway thickening, or bronchiectasis on HRCT of the chest (with inspiratory and expiratory cuts); residual volume >120% of predicted; and absence of infection in the respiratory tract.[46,82] While definitive diagnosis ideally would include demonstration of histological evidence of BO, this almost always would require a surgical lung biopsy since the yield of transbronchial biopsy for this entity is extremely low. Because it is difficult to establish a histological diagnosis of BO by minimally invasive means, a surrogate functional diagnostic schema based on FEV_1 decline was developed, referred to as BOS. BOS is defined as the presence of airflow limitation leading to a decline in FEV_1 of at least 20% compared to baseline, in the absence of identifiable causes (e.g., infection). Based on the magnitude of decline in FEV_1, BOS is classified into stages as follows: stage 1 (FEV_1 66%–80% of peak posttransplant baseline), stage 2 (FEV_1 51%–65% of baseline), and stage 3 (FEV_1 <50% of baseline).[83] This classification scheme was initially devised exclusively for lung transplant recipients and has not yet been widely applied to the HSCT population. Thus, its utility in defining severity or prognosis in this population remains to be established.

In HSCT recipients with suspected BO, laboratory evaluation should be undertaken to exclude infection and complications of GVHD. Complete blood count with differential, blood urea nitrogen, creatinine, total bilirubin, hepatic transaminases, immunoglobulin levels and subclasses, and urinalysis are recommended.[76] Chest radiograph is usually normal or may show hyperinflation.[70,78,84–86] Inspiratory and expiratory HRCT of the chest should be included as part of BO evaluation.[80] HRCT of the chest typically shows mosaic attenuation due to air trapping (most pronounced on expiratory images), often accompanied by vascular attenuation, bronchiectasis, and bronchiolectasis (Fig. 95-2).[78,85,87–89] GVHD is a risk factor for sinusitis in HSCT recipients.[90] Since timely treatment of the sinusitis may lead to clinical improvement, radiological investigation including CT of the sinuses is recommended.[76,90–93]

BAL is used in suspected BO to exclude infection and to assess the patterns of lung inflammation. In one study of seven HSCT patients with airflow obstruction, BAL showed predominantly neutrophilic inflammation in four, lymphocytic in two, and a mixed pattern in one.[77] Because BO involves respiratory and membranous bronchioles, transbronchial lung biopsy is usually inadequate for diagnosis. Video-assisted thoracoscopic lung biopsy is a gold standard for definitive diagnosis, but is rarely pursued if other typical clinical–radiographic features are present.[80] The pathology shows damage to the bronchiolar epithelium, fibrinous obliteration of bronchiolar lumen, inflammation between epithelium and smooth muscle, and pulmonary fibrosis (Fig. 95-3).[78,81,94,95] Peribronchiolar inflammatory cellular infiltrates consisting of neutrophils and lymphocytes may be present.[96]

Treatment

There is insufficient evidence to support specific recommendations for the treatment of BO.[68] First-line treatment usually involves corticosteroids.[46] Prednisone 1 to 1.5 mg/kg/d, or its equivalent, is given for 4 to 6 weeks and if respiratory status remains stable, therapy is tapered and discontinued in 6 to 12 months. However, clinical responses are observed in only about 20% of patients and treatment success often does not persist.[63,68,70,78,85,89,97] Immunosuppressive drugs used to treat BO associated with GVHD include cyclosporine, azathioprine, tacrolimus, and mycophenolate.[46,76] The typical dose of azathioprine is 2 to 3 mg/kg/d, not to exceed 200 mg. Cyclosporine or tacrolimus dose is adjusted according to serum levels.[58]

Inhaled corticosteroids are used commonly to treat BO, but data are limited. A study comparing a combination of inhaled fluticasone, oral azithromycin, and montelukast in 9 patients with BOS against a historical control of 14 patients treated with high-dose corticosteroids showed no difference between the groups.[98] Another study of 13 HSCT recipients with BO showed improvement in lung function and symptoms.[99] These encouraging results provide potential for less toxic therapeutic options, but require confirmation in a larger group of patients with a longer follow-up period.

Macrolides have immunomodulatory effects that may halt disease progression in BO.[100] Although the mechanism of action is not fully understood, it seems that it not only leads to a reduction of neutrophil inflammation,[74,101] but also has prokinetic properties on the upper gastrointestinal tract, reducing gastroesophageal

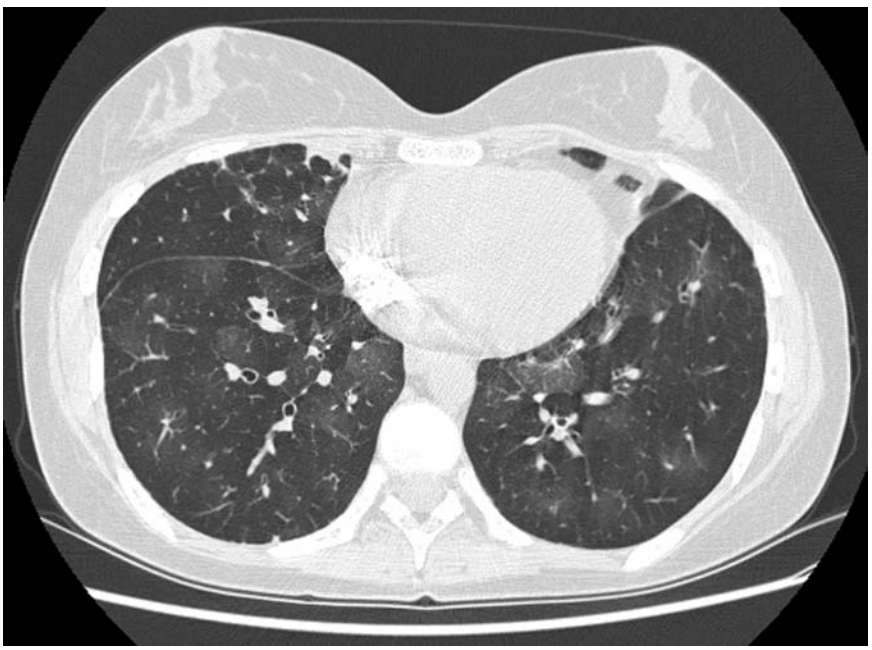

Figure 95-2 Computed tomography scan expiratory views of a patient with bronchiolitis obliterans following HSCT, showing mosaic attenuation associated with air trapping *(darker areas)*, bronchial thickening, and mild bronchiectasis.

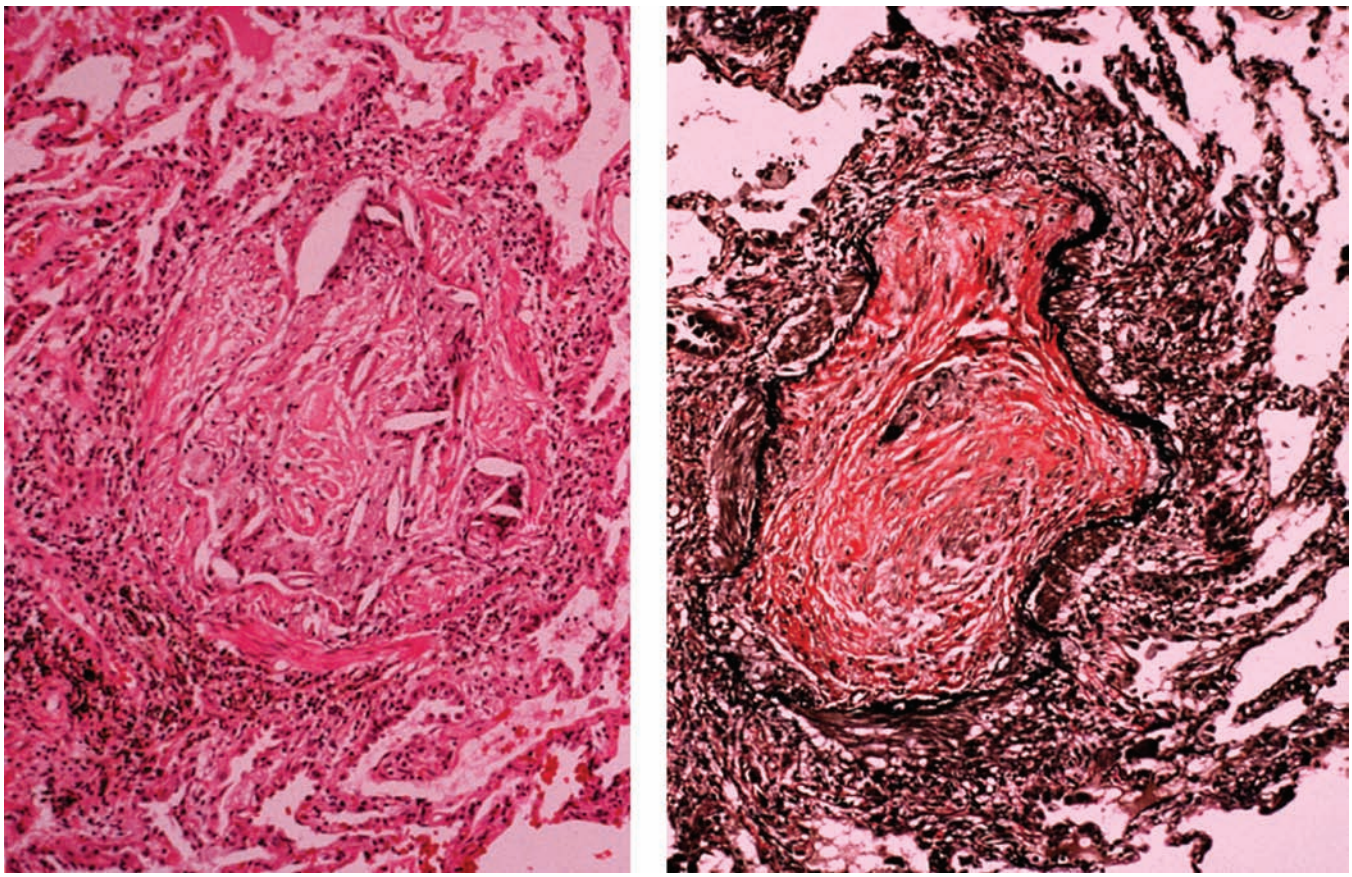

Figure 95-3 Lung pathology in bronchiolitis obliterans, showing inflammation and obliteration of the airway lumen, associated with fibrous connective tissue (hematoxylin and eosin stain, left; Verhoeff–Van Gieson elastic stain, right).

reflux, another risk factor for BO.[102] Macrolides are commonly used to treat diffuse panbronchiolitis.[103–107] There are case series documenting the beneficial role of macrolides for the treatment of BOS in lung transplant recipients.[108] There are even less data addressing the role of macrolides in HSCT recipients with BO. In a series of eight patients treated with azithromycin 500 mg daily for 3 days, followed by 250 mg three times each week for 12 weeks, clinical improvement was achieved in seven patients.[109] In a report of 10 HSCT recipients with BOS, azithromycin was not associated with improvement in lung function.[110] Treatment of BOS in eight HSCT recipients with formoterol, azithromycin, and montelukast showed that this regimen may spare the use of high-dose systemic steroids.[98] In a recent randomized double-blinded placebo-controlled trial of HSCT recipients with BOS, 10 were treated with oral azithromycin 250 mg daily while 12 were treated with placebo for 12 weeks.[111] There were no significant differences in outcome between the two groups. Overall, there is insufficient evidence to substantiate the use of macrolides in the treatment of HSCT patients with BO.

Leukotrienes are eicosanoid lipid mediators that contribute to the inflammatory processes in the development of asthma, alveolitis, pulmonary fibrosis, and BO following lung transplantation, and promote bronchoconstriction, as well as eosinophil and neutrophil recruitment.[112] There are limited data addressing the role of the leukotriene receptor antagonist montelukast in the treatment of BO. In a pilot study of 19 patients with refractory chronic GVHD, montelukast 10 mg daily was administered for a mean of 10 months.[112] Overall improvement was observed in 15 of the 19 patients. In a prospective study comparing the combination of fluticasone, azithromycin, and montelukast against high-dose corticosteroids, there was no difference in lung function between the groups.[98] However, with the montelukast combination, it was possible to taper systemic corticosteroids rapidly.

There are limited data regarding tumor necrosis factor (TNF) blockade in the treatment of BO. There is a case report of biopsy-proven BO after HSCT in a child who was treated with infliximab after failed corticosteroid therapy.[113] The pulmonary symptoms and spirometric abnormalities resolved and the patient remained asymptomatic for several months.

The anti-CD4 monoclonal antibody, rituximab, has been used in refractory chronic GVHD. In one study, rituximab resulted in reduced systemic corticosteroid use.[114] Improvement in lung function was noted in three of eight patients. In a phase II prospective multicenter study of HSCT recipients with steroid-refractory chronic GVHD, 37 patients were treated with weekly infusion of rituximab for 4 weeks followed by monthly infusion for 4 months.[115] The treatment was complicated by infections and relapse. Only one of 11 patients showed partial response in the lung.

Extracorporeal photochemotherapy (ECP), or photopheresis, an immunomodulatory therapy developed for treating cutaneous T-cell lymphoma, has shown promise in treating chronic GVHD in uncontrolled studies.[116] In this procedure, white blood cells are removed and exposed to ultraviolet radiation after pretreatment with a psoralen derivative, leading to cell death. In a retrospective study of 14 allogeneic HSCT recipients with extensive chronic GVHD, ECP was administered three times weekly on alternating days.[116] Improvement in the pulmonary manifestations was noted in 1 of the 3 patients and systemic corticosteroid was tapered in 11 of the 14. In another study, nine allogeneic HSCT recipients with BO were treated with ECP.[117] Six of nine (67%) patients responded

after a median of 25 days. No ECP-related complications occurred. ECP stabilized rapidly declining pulmonary function tests in about two-thirds of patients with severe and refractory BO.

If otherwise successful HSCT is complicated by end-stage lung disease from BO, lung transplantation may be considered. There are insufficient data addressing this issue, with several single case reports.[118–124] In a cross-sectional study of 313 lung transplant recipients, 3 were performed for BO in allogeneic HSCT recipients.[123] Lung transplants from living donors have also been reported in this setting.[121,124,125]

Prognosis

The prognosis of BO in HSCT recipients is poor. Fewer than 20% improve and 65% die within 3 years of diagnosis.[61,64,80,97,113] The rate of decline in FEV_1 is widely variable and rapid deterioration is associated with increased mortality.[70] Despite treatment, improvement in lung function is noted in only 8% to 20%.[58] The reported case fatality rates vary widely, ranging from 14% to 100% with a mean of 61%.[58] In one study of allogeneic HSCT recipients with GVHD, the 3-year mortality rate of those with BO was 65% compared to 44% of those without BO.[70] In a more recent study, the 5-year survival of HSCT recipients with BO from the time of diagnosis was 45.4%, significantly less than those without (77.5%, $p < 0.001$).[65] The mortality of BO has not improved over the last two decades.[80]

■ PERI-ENGRAFTMENT RESPIRATORY DISTRESS SYNDROME

PERDS is the pulmonary manifestation of engraftment syndrome in HSCT recipients.[126] The engraftment syndrome is characterized by skin rash, noninfectious pulmonary infiltrates, fever, diarrhea, and capillary leak during the peri-engraftment period.[127–129] Engraftment syndrome develops in 7% to 53% of HSCT recipients.[127,128,130,131] Among 152 autologous HSCT recipients supported by either granulocyte or granulocyte macrophage colony–stimulating factors, engraftment syndrome developed in 20 (13%).[132] Although most of the studies reporting engraftment syndrome are in autologous HSCT recipients, it also occurs after allogeneic transplantation.[133,134] In two recent studies, pulmonary manifestations were reported in 18 of 61 (30%) patients with engraftment syndrome.[127,131]

Frequency, Risk Factors, and Pathogenesis

There is only one study that addressed PERDS specifically and reported an occurrence in 4.6% of 416 autologous HSCT recipients.[126] Using similar criteria in the same institution, a recent study reported PERDS in 52 of 1243 (4.2%) autologous HSCT recipients.[12]

Earlier studies of the engraftment syndrome noted possible relationships with the underlying disease, therapies prior to transplant, stem cell dose and source, growth factor use, amphotericin administration, and rate of engraftment.[130,133,135] In one study focusing specifically on PERDS, there was no association with demographics, type and stage of underlying disease, conditioning regimen, graft source, use of cytokines either for stem cell mobilization or after transplant, viral serologies, pretransplant pulmonary function, or laboratory values.[126]

The pathogenesis of PERDS is not well defined, but is believed to represent a complex interaction between conditioning-related endothelial damage and the cytokine release associated with neutrophil and lymphocyte recovery.[126] Tissue infiltration by neutrophils has been shown to occur earlier than their appearance in the peripheral blood.[136]

Clinical Findings

In 19 patients with PERDS, median duration from transplant to onset of symptoms or radiographic pulmonary infiltrates was 11 days (range, 4–25).[126] The median duration to neutrophil engraftment was also 11 days after transplant (range, 8–25). Symptoms and signs occurred within 5 days of neutrophil engraftment. Dyspnea was the initial symptom in all patients, and fever was present in 12 patients (63%).

Diagnostic Evaluation

PERDS is considered in the presence of fever (>38.3°C) and pulmonary injury with evidence of hypoxemia (Sa_{O_2} <90%) and/or pulmonary infiltrates on chest radiograph, in the absence of clinical cardiac dysfunction or infection, all occurring within 5 days of neutrophil engraftment (defined as absolute neutrophil count of more than 500/mL on consecutive days).[126] The median white blood cell count at the time of symptom onset is 1.3×10^9/L (range, 0.2–29.6) and the median neutrophil count is 0.7×10^9/L (range, 0.1–28.6). Chest radiographs show bilateral infiltrates in the majority. In one study, BAL was performed to exclude pulmonary infections, but in a more recent study, BAL was not performed if noninvasive evaluation was considered adequate.[12] Transbronchial lung biopsy cannot be performed safely in most HSCT recipients during the peri-engraftment period because of thrombocytopenia. Surgical lung biopsy may show diffuse alveolar damage, but is rarely necessary.[126]

Treatment

In the only study focusing on PERDS, 11 patients received high-dose corticosteroid therapy, including 5 of the 6 who required mechanical ventilation.[126] Ten patients experienced clinical improvement, which occurred within 24 hours in five cases, and over 2 to 4 days in the remainder. The rapid response to corticosteroid treatment and the fact that such a therapy was delayed until after intubation in all the mechanically ventilated patients suggested a therapeutic benefit. Among the eight patients who did not receive steroids, one required mechanical ventilation at the onset of symptoms, and subsequently died.[126] The other seven patients recovered and were discharged from the hospital. There was no correlation between gender, age, source of stem cells, mononuclear cell count of the graft, use of posttransplant growth factors, WBC at the onset of symptoms, rate of rise in WBC, amphotericin use, or the need for mechanical ventilation and posttransplant mortality.[126] The mean absolute neutrophil count was significantly higher among patients with evidence of alveolar hemorrhage by BAL. Unlike DAH and IPS, only about one-third of HSCT recipients with PERDS require ICU admission and mechanical ventilation.

■ ACUTE PULMONARY EDEMA

Acute pulmonary edema is common during the neutropenic phase and likely represents a combination of cardiogenic and noncardiogenic factors. Noncardiogenic pulmonary edema has many contributory factors including total-body radiation, induction drugs, and septic episodes. These factors likely damage the capillary endothelium, leading to radiographic findings similar to hydrostatic edema. Patients with hydrostatic pulmonary edema have often received high volumes of fluid for medications, total parenteral nutrition, and multiple blood product transfusions. The heart may also be compromised by chemotherapeutic agents such as Adriamycin and high-dose cyclophosphamide used during induction. In a recent study of 1243 autologous HSCT recipients, acute pulmonary edema was reported in 4.7%.[12] Patients develop weight gain and dyspnea, and bibasilar crackles. Radiographic findings of vascular and hilar indistinctness, symmetric ground-glass/consolidative opacities, enlarged heart, small pleural effusions, and subfissural thickening are typically seen. While pulmonary edema is usually diagnosed by plain chest radiograph, CT findings include prominent pulmonary vessels, interlobular septal thickening, ground-glass attenuation, and pleural effusions. Acute pulmonary edema usually can be prevented and treated with fluid restriction and diuretics.

IDIOPATHIC PNEUMONIA SYNDROME

Important aspects of the idiopathic pneumonia syndrome are considered below, including frequency, risk factors, clinical findings, treatment, and prognosis.

Frequency

The term IPS has been used for many years to describe lung injury without infectious etiology in HSCT recipients. In a 1985 review of pulmonary complications in 4500 HSCT recipients, Krowka et al. reported a 35% frequency of idiopathic pneumonia.[12,137] Another study from a major HSCT center found a rate of 7.3%.[138] The wide variation in the reported incidence of IPS was partly due to the lack of uniform definition and diagnostic criteria. Diagnostic criteria were addressed in 1993 by a workshop sponsored by the National Heart, Lung, and Blood Institute.[139] This workshop defined IPS as widespread alveolar injury in the absence of lower respiratory tract infection.[139] The definition has been updated recently.[140] The current criteria for IPS include evidence of widespread of alveolar injury, absence of active lower respiratory tract infection, and exclusion of cardiac dysfunction, renal failure, or fluid overload.[140] Based on data compiled from several studies of 4496 HSCT recipients, 449 cases of IPS (10%; range 2%–17%) were reported.[138,140–149]

Risk Factors

The probability of developing IPS increases with the number of risk factors.[148] Patients transplanted for aplastic anemia have low risk for IPS.[150] With the advent of prophylaxis for CMV infection, IPS has become a relatively more frequent cause of interstitial pneumonia.[151] Using multiple logistic regression analysis, Kantrow et al.[138] did not find significant difference in the rate of IPS between autologous and allogeneic HSCT recipients. However, a review of selected studies showed 36 of 617 autologous HSCT recipients (5.8%) developed IPS compared to 380 of 3569 allogeneic HSCT recipients (10.6%), a significant difference.[58]

Pathogenesis

Although the pathogenesis of IPS is not well defined, lung injury, inflammation, and cytokine release are implicated.[58] Pulmonary vascular endothelial cell damage, mediated by TNF-α, is linked to the development of experimental IPS.[140,152] Another potential mechanism is parenchymal damage from previous chemoradiation therapy, GVHD, undiagnosed infection, and excessive recruitment and activation of inflammatory cells.[138] The occurrence of IPS after autologous BMT suggests that the pretransplant conditioning regimens, rather than GVHD and CMV infection, are likely to be culprits.[153] Latent and unrecognized infections such as human herpes virus-6 (HHV-6) and systemic activation of inflammatory cytokines during sepsis may also be responsible for lung injury.[138,154–157] Cell-mediated immune injury during GVHD reactions is another possible mechanism.[138] Further, IPS may be the result of persistent proinflammatory events and oxidant responses.[158,159]

Clinical Findings

The median time of onset of IPS is 19 days, range 4 to 106 days, after transplant.[140] Despite the variable onset, the majority of patients present within the first 120 days following HSCT.[138,144] The clinical presentation of IPS includes dyspnea, dry cough, hypoxemia, and nonlobar radiographic infiltrates.[139] The spectrum is broad, ranging from acute respiratory failure to incidental radiographic abnormalities. Because IPS mimics infectious pneumonia, the majority of patients are on antibiotics at the time of diagnosis.

Diagnostic Evaluation

Clinical presentation and radiographic findings cannot be used to differentiate between patients with infectious and idiopathic pneumonia. Pulmonary function testing and computed tomography (CT) of the chest are also nonspecific.[138] More than 90% of patients with IPS have diffuse infiltrates on chest radiograph.[160] Based on the IPS criteria, PERDS and DAH are considered to be subsets of IPS. There is overlap between PERDS and DAH; however, the clinical course and response to corticosteroid therapy differ between these conditions.

Infection should be excluded before the diagnosis of IPS is made. In earlier studies, IPS was diagnosed histologically when biopsy or autopsy of lung tissue showed inflammation without any histological or microbiological evidence of infection.[144,149,150] In a study from Fred Hutchinson Cancer Research Center, 80% of IPS cases were diagnosed without tissue and with infection excluded by BAL, 4% required lung biopsy, and 16% were diagnosed at autopsy.[138] Although the NHLBI workshop accepted BAL as the main method for the exclusion of infection and the diagnosis of IPS, the limitations of this approach in excluding invasive fungus, neoplasms, and other abnormalities of potential therapeutic or prognostic importance are well recognized.[138] When pursued, lung biopsies of patients with IPS show diffuse alveolar damage, organizing or acute pneumonia, and interstitial lymphocytic inflammation.[138,143]

Treatment

There are scarce data addressing the treatment of IPS in HSCT recipients. One study reported three patients with IPS who responded to treatment, which included corticosteroids.[138,143] Despite treatment with methylprednisolone at 1 to 2 mg/kg/d, studies with larger sample sizes have not shown any outcome benefit.[138,160] There are reports of IPS responding to etanercept.[161–163] Currently, the only accepted treatments are supportive care, and prevention and treatment of infection. Lung transplant offers a potential therapeutic option for patients who develop respiratory failure despite treatment, but this option is limited to the rare circumstances of a patient without other comorbidities and for whom the transplant was considered curative to have definitively eradicated the underlying disease process.[120]

Prognosis

The clinical course of IPS is commonly complicated by infections, including viral and fungal pneumonias.[138,160] Other complications include pneumothorax, pneumomediastinum, subcutaneous emphysema, and pulmonary fibrosis. Autoimmune polyserositis involving the pleura and pericardium has also been reported.[164]

Patients often develop severe hypoxemia and require assisted ventilation.[165] In a review of selected studies, the overall mortality of 388 HSCT recipients with IPS was 74%, with a range of 60% to 86%.[138,144,148–150,160] The 1-year survival rate is less than 15%.[138,160] Infectious complications and nonpulmonary organ failure contribute to the high mortality rate.[138,160] For those who require mechanical ventilation, the hospital mortality may exceed 95%.[138]

DIFFUSE ALVEOLAR HEMORRHAGE

Although pulmonary infections can cause alveolar hemorrhage, the term DAH in the HSCT recipient is reserved for alveolar hemorrhage of noninfectious etiology.

Frequency

The frequency of DAH has varied among reported series because of differences in patient mix and diagnostic criteria.[166] Factors that influence the incidence of DAH have changed over time and among HSCT centers. In a review of several studies that included 3806 HSCT recipients, the cumulative frequency of DAH was 5%, ranging from 2% to 14% in the individual series.[166] Among 692 HSCT recipients who underwent bronchoscopy, DAH was reported in 97 (14%), with a range between 1% and 23%.[126,167–173] In patients admitted to the intensive care unit for respiratory failure, the prevalence of DAH may exceed 40%.[174,175] DAH has been reported in approximately 10% of autopsies of HSCT recipients.[16,17]

Risk Factors

Pretransplant chemotherapy and conditioning regimen, total-body irradiation, thoracic irradiation, and older age are associated with DAH.[9,153,176–179] There are conflicting data regarding solid tumors as a risk factor for DAH.[166,180,181] Although DAH occurs in both autologous and allogeneic HSCT recipients, the initial studies included mostly autologous recipients.[153] In data from several reports, however, no significant difference was found in the incidence of DAH between autologous and allogeneic HSCT recipients.[166] Pulmonary function tests have shown no association between the development of DAH and pretransplant PFTs.[153] Pretransplant bronchoscopy has shown a higher number of bronchial neutrophils and eosinophils in patients who develop DAH after HSCT compared with those who do not.[182] White blood cell recovery and renal insufficiency, but not prolonged prothrombin, partial thromboplastin time, or low platelets, are associated with the development of DAH.[9,153] Although most patients with DAH have thrombocytopenia, DAH is not corrected by platelet transfusion.[153]

Pathogenesis

Various conditions, including infections, mitral valve disease, systemic vasculitides, collagen vascular diseases, drugs, and anticoagulation have been implicated as causing alveolar hemorrhage in non-HSCT recipients. The etiology and pathogenesis of DAH in the HSCT recipient have not been clearly established. Lung tissue injury, inflammation, and cytokine release are implicated.[166]

Pretransplant high-dose chemotherapy, thoracic or total-body radiation, and undocumented infections may be responsible for the initial injury to lung tissue. Vascular endothelial swelling and thrombi are found in the autopsies of HSCT recipients with acute hemorrhagic pulmonary edema.[183] The incidence of pulmonary hemorrhage is high in HSCT recipients with GVHD.[179] In addition to the toxicity from therapy for GVHD, antigen-specific injury to endothelium may be a contributing factor to the development of DAH.[184]

Vasculopathy of small muscular arteries and thrombotic microangiopathy have been reported in HSCT recipients with DAH.[185] The vasculopathy manifests as concentric intimal or medial hyperplasia with luminal narrowing, prominent myxoid change, extravasated red blood cells, and the presence of foamy histiocytes. Thrombotic microangiopathy has also been associated with DAH, characterized by fragmented erythrocytes on peripheral smears, decreased hemoglobin and platelet counts, refractoriness to platelet transfusions, and the absence of disseminated intravascular coagulation.[185]

Inflammatory cells are likely to play a role in the development of DAH, and models are characterized by increase in the alveolar leukocytes, platelet microthrombi, damage of alveolar endothelial and epithelial cells, increased turnover rate of alveolar cells, and an increase in the cell number and protein content of the BAL.[186] Pretransplant bronchoscopy has shown increased bronchial inflammatory cells in patients who develop DAH after HSCT, suggesting that bronchial inflammation precedes alveolar inflammation.[182,187] The initial injury is compounded by damage related to the return of inflammatory cells to the lung coincident with marrow recovery.[188] Even in the presence of peripheral leukopenia, neutrophils are seen in the lower respiratory tract of HSCT recipients at the time of DAH.[166] One-third of autologous HSCT recipients with PERDS have DAH.[126] Among the patients with PERDS, those with DAH have higher absolute neutrophil counts than those without DAH.

In allogeneic transplants, donor T cells react to host alloantigens, proliferate, and secrete inflammatory mediators. This response may be amplified by the release of endotoxin from the gut after injury from mucositis or GVHD. It is suggested that the pathophysiology of acute GVHD is a cytokine storm of inflammatory mediators.[189] In autologous HSCT recipients, the generation of cytokines is self-limited and resolves in 7 to 10 days.[189] Despite the more profound release of cytokines in allogeneic HSCT recipients, the frequency of DAH is similar between allogeneic and autologous groups. This may be due to the protective effect of the immunosuppressive agents used for prophylaxis of GVHD in the allogeneic group.

Clinical Findings

The onset of DAH is usually within the first 30 (median between 11 and 19) days after HSCT.[166] However, cases of DAH after the first month of transplant are not uncommon.[179] HSCT recipients with DAH often have dyspnea and dry cough.[153] Although coexistent sepsis and mucositis may obscure the clinical picture, fever is a common finding.[166] Hemoptysis is relatively rare.[9,190] None of 29 patients had hemoptysis in the study by Robbins et al.[153]

Diagnostic Evaluation

DAH is a syndrome with nonspecific clinical and radiological features. Although pulmonary infections can cause alveolar hemorrhage, the term DAH in the HSCT recipient is reserved for alveolar hemorrhage of noninfectious etiology. DAH should be distinguished from localized bleeding caused by bronchitis, bronchiectasis, tumors, or infections. The diagnostic criteria of DAH in the HSCT recipient are (1) evidence of widespread alveolar injury manifested by multilobar pulmonary infiltrates, symptoms and signs of pneumonia, and abnormal pulmonary physiology with increased alveolar to arterial oxygen gradient and restrictive ventilatory defect; (2) absence of infection compatible with the diagnosis; and (3) BAL showing progressively bloodier return from three separate subsegmental bronchi, the presence of 20% or more hemosiderin-laden macrophages in BAL, or the presence of blood in at least 30% of the alveolar surfaces of lung tissue.[166]

Chest radiograph shows diffuse interstitial and alveolar infiltrates, primarily central, and involving predominantly lower and middle lung zones.[191] The earliest radiographic manifestation is the presence of bilateral fine reticular opacities. In the later phase of DAH, 70% of patients develop an alveolar pattern, and the interstitial pattern persists in 30%. Although chest CT may be helpful in patients in whom a focal source of bleeding is suspected, chest CT has a limited role in DAH. The most common CT finding is bilateral ground-glass attenuation or consolidation.[192]

Treatment

Because the pathogenesis of DAH is considered to be an inflammatory response, and based on anecdotal and retrospective studies, HSCT recipients with DAH are treated with systemic corticosteroids.[178,188,193] There are no prospective, randomized clinical trials addressing the treatment of DAH in HSCT recipients. In a retrospective study, Metcalf et al.[188] compared three groups: No corticosteroids, daily methylprednisolone of 30 mg or less, and daily methylprednisolone of more than 30 mg. The mortality rate was lower and fewer patients required invasive mechanical ventilation in the high-dose methylprednisolone group. The high-dose methylprednisolone group received 125 to 250 mg every 6 hours for the first 4 to 5 days, tapered over 2 to 4 weeks. Low-dose methylprednisolone was similar to no steroid therapy. In another study of 15 HSCT recipients with DAH treated with 250 mg to 2 g/d of methylprednisolone, transient clinical improvement was seen in 10 patients; however, the overall mortality of 74% was not significantly different from previous reports.[194]

Although many HSCT recipients may die from other complications, most patients with DAH improve in response to corticosteroid therapy.[166] The dose and duration of corticosteroids are not well standardized. Although immunosuppressive therapy, plasma exchange, and plasmapheresis have been tried in other populations,

there is no evidence to justify their use in HSCT recipients. Fresh frozen plasma transfusion and plasmapheresis yielded inconclusive results in one study.[185] There are reports of allogeneic HSCT recipients with DAH successfully treated with recombinant factor VIIa.[195–197]

Prognosis

DAH is a major complication of HSCT, contributing significantly to morbidity and mortality. The majority of HSCT recipients with DAH require mechanical ventilator support for respiratory failure.[166] HSCT recipients with DAH are at high risk for infectious complications. The reported mortality rate of DAH in HSCT recipients is approximately 80%, with a range between 64% and 100%.[166] Although the initial presentation of DAH in HSCT recipients may be respiratory failure, the most common causes of death are multiple organ failure and sepsis. Respiratory failure with active pulmonary hemorrhage is responsible for fewer than 15% of the deaths. Despite the high mortality rate, long-term survivors of HSCT recipients with DAH can manifest normal pulmonary function.

■ CRYPTOGENIC ORGANIZING PNEUMONIA

Idiopathic bronchiolitis obliterans organizing pneumonia (BOOP) had been widely recognized since Epler introduced the term in 1985.[198] The American Thoracic Society/European Respiratory Society recommended replacing BOOP with COP since it better describes the essential features of the syndrome.[199] COP is characterized by organizing pneumonia in the alveolar ducts and alveoli, with or without bronchiolar involvement.[199] It has clinical features more consistent with pneumonia than airway disease. COP in HSCT patients was first reported in the early 1990s.[200,201] The literature in HSCT recipients is limited to case series, with a maximum of seven patients.[10–12,22,62,85,200–209] Risk factors for COP are not well described, although GVHD may play a role.[202,206,208]

Pathogenesis

The occurrence of COP almost exclusively in allogeneic HSCT recipients with GVHD suggests that it may represent alloimmune-mediated injury to the lung by the transplanted stem cell.[202] In one study of three HSCT recipients with COP, the exhaled nitric oxide level was increased and then declined following improvement.[210] There is also a report suggesting that HLA-B35 may be an important host factor.[211]

Clinical Findings

Most HSCT recipients with COP have GVHD.[85,202,209] However, COP has been reported in allogeneic HSCT recipients in the absence of clinical GVHD.[200,212] The presenting symptoms include dry cough, dyspnea, and fever.[200–202,206] Some patients may present with respiratory failure.[208] The reported onset of COP is between 1 and 13 months following transplant.[85,200–202,205,207,209,212,213] One allogeneic recipient with asymptomatic COP was reported.[85] Physical examination may reveal inspiratory crackles.

Diagnostic Evaluation

COP should be included in the differential diagnosis of bilateral airspace disease in HSCT recipients, especially if they do not respond to antibiotics for presumed pneumonia. Pulmonary function tests usually show restrictive defect, decreased D_{LCO}, and normal airflow.[198,201,202] Arterial blood gases show mild hypoxemia.[202] Chest radiographs and CT show patchy air space consolidation, ground-glass attenuation, and nodular opacities.[86,192,200–203,214] The radiographic abnormalities usually have peripheral distribution.[215] In the appropriate clinical setting, chest CT findings may suggest the diagnosis of COP. However, confirmation requires lung biopsy. Although the diagnosis of COP in the HSCT recipient can be made with transbronchial lung biopsy, about 85% of cases require surgical lung biopsy.[202] Histological confirmation of the diagnosis is desirable as therapy with corticosteroids is usually needed for several months. The histological hallmark of COP is the presence of patchy intraluminal fibrosis, consisting of polypoid plugs of immature fibroblast tissue resembling granulation tissue.[216]

Treatment

Corticosteroid therapy is typically given to HSCT recipients with COP, and about 80% respond favorably.[85,200–202,205,207,209,213] The duration and dosage of corticosteroid therapy have not been clearly defined, but radiographic abnormalities usually clear within 1 to 3 months of initiating corticosteroids.[200,202,207] Based on the experience from non-HSCT recipients with COP, the initial dose of corticosteroid therapy is prednisone 0.75 to 1.5 mg/kg/d, up to 100 mg, or its equivalent, for 1 to 3 months, followed by lower doses for a total duration of 6 to 12 months.[217] There is a report of erythromycin in conjunction with corticosteroid used successfully to treat COP in HSCT recipients.[205]

Prognosis

COP in HSCT recipients appears to have a worse prognosis than idiopathic COP. Alasaly et al.[202] found a case fatality rate of 40% in allogeneic HSCT recipients compared to 21% in idiopathic COP. Among 19 reported HSCT recipients with COP, the overall case fatality was 21%.[85,200–202,205,207,209,212,213]

■ DELAYED PULMONARY TOXICITY SYNDROME

Delayed pulmonary toxicity syndrome (DPTS), characterized by interstitial pneumonitis and fibrosis, with clinical presentation delayed for months to years, was described in autologous HSCT recipients with breast cancer who had received high-dose chemotherapy.[218,219] Glutathione depletion with impaired antioxidant defense due to cyclophosphamide and carmustine (BCNU) was implicated in the pathogenesis.[220] The high incidence, low mortality, and good response to corticosteroid treatment distinguish this syndrome from IPS.[219] It developed in about 72% of autologous HSCT recipients who received high-dose chemotherapy for breast cancer.[218] Presentation with cough, dyspnea, fever, and hypoxemia occurred at a median of 45 days after high-dose chemotherapy.[218–221] The D_{LCO} declined to a nadir 15 to 18 weeks following the chemotherapy/transplant.[219] CT scans of 13 patients demonstrated scattered, predominantly peripheral ground-glass or consolidated opacities that occasionally looked nodular or mass-like.[222] Treatment with corticosteroid usually improves lung function in DPTS, and no death has been attributed directly to the syndrome.[218,219] Interferon-γ has been used with improvement in one patient refractory to corticosteroid therapy.[223] Prophylactic treatment with inhaled fluticasone propionate, 880 mg every 24 hours for 12 weeks beginning on the day of starting BCNU-containing conditioning regimen, decreased the incidence of DPTS compared to historical controls.[224] Since the abandonment of HSCT for breast cancer, the frequency of DPTS has declined.

■ PULMONARY CYTOLYTIC THROMBI

Pulmonary cytolytic thrombi (PCT) is a recently described noninfectious pulmonary complication of HSCT recipients.[225,226] PCT occurs almost exclusively in children with acute or chronic GVHD and is characterized by fever and pulmonary nodules. The time of onset ranges from 8 to 343 days (median 72) after transplant.[226] Patients are febrile and some have cough at presentation, but dyspnea has not been noted. Chest radiographs may be normal in 25%. Abnormal chest radiographic findings include nodules, interstitial prominence and atelectasis. Chest CT shows multiple peripheral

pulmonary nodules, ranging from a few millimeters to 4 cm in size.[225–228] BAL is used to exclude infection. Because of the peripheral and intravascular location of the nodules, transbronchial lung biopsy is unlikely to yield a diagnosis. Among 33 HSCT recipients who underwent open lung biopsy for nodular pulmonary lesions, 15 (45%) had PCT.[228] Biopsy of the pulmonary nodules shows a unique pattern of necrotic, basophilic thromboemboli with amorphous material suggestive of cellular breakdown products.[227,229] Most of the patients with PCT improve clinically within 1 to 2 weeks, and radiographically over weeks to months.[226] There have been no reported deaths attributed to PCT. In one study, 9 of the 13 HSCT recipients with PCT were alive at a median follow-up of 1.5 years.[226] All patients received broad-spectrum antibiotics and nine were treated with systemic corticosteroids.[226]

■ OTHER CONDITIONS

Several additional important noninfectious disorders in HSCT are described below.

Pulmonary Venoocclusive Disease

Pulmonary venoocclusive disease (PVOD) is clinically suspected by the presence of pulmonary arterial hypertension, radiographic evidence of pulmonary edema, and normal pulmonary artery occlusion pressure. However, a definite diagnosis requires lung biopsy. The incidence of PVOD in HSCT recipients is not known. In one study, PVOD was reported in one of five HSCT recipients at autopsy.[230] However, no case of PVOD was identified in a recent autopsy of 71 adult HSCT recipients.[17] Approximately 29 HSCT recipients with PVOD have been reported in the literature.[48,231] Most underwent transplant for hematological malignancy, and only two of the 29 patients with PVOD had autologous grafts. Endothelial damage may be responsible for the pathophysiology of PVOD.[232] There is no proven therapy for PVOD; vasodilator agents may be introduced with caution but carry an associated risk of precipitating pulmonary edema.

Pulmonary Alveolar Proteinosis

Pulmonary alveolar proteinosis is characterized by excessive accumulation of surfactant lipoprotein in the alveoli, leading to abnormal gas exchange.[233] It is diagnosed by the presence of periodic acid-Schiff proteinaceous material in BAL fluid. Pulmonary alveolar proteinosis in HSCT recipients is limited to case reports.[17,234–236] Chest radiographs show diffuse infiltrates. The roles of whole lung lavage and aerosolized granulocyte macrophage colony–stimulating factor, therapies employed in the primary form of pulmonary alveolar proteinosis, are unknown in the secondary form seen in HSCT recipients.

Chronic Eosinophilic Pneumonia

There are fewer than 10 case reports of chronic eosinophilic pneumonia in HSCT recipients.[237–240] It occurs in both allogeneic and autologous recipients. Despite good response to steroid therapy in most, one patient had a fatal course.[239]

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is a clinical syndrome characterized by bilateral noncardiogenic pulmonary edema in association with transfusions of blood products. It has been reported following the infusion of allogeneic hematopoietic stem cells during HSCT.[241–243]

Sarcoidosis

Sarcoidosis is uncommon in HSCT recipients. The first reported HSCT recipients with sarcoidosis received stem cells from donors with sarcoidosis.[244] One study reported sarcoidosis in autologous HSCT recipients and allogeneic recipients who received stem cells from donors without sarcoidosis.[245]

SOLID ORGAN TRANSPLANTATION

The era of human solid organ transplantation was inaugurated a half century ago when a kidney harvested from a healthy donor was implanted into the body of his identical twin brother suffering from renal failure. Over the ensuing decades, organ transplantation has evolved to include not only kidney but also heart, liver, lung, intestine, and pancreas replacement. While offering extended survival and enhanced quality of life to many patients with lethal or debilitating conditions, these procedures are accompanied by a multitude of complications. The lungs are particularly vulnerable, subject to the immediate effects of the transplant surgery as well as the infectious, neoplastic, and toxic consequences of the immunosuppressive agents required to maintain the health of the allograft.

This section will focus on noninfectious complications associated with the three most commonly performed solid organ transplant procedures—heart, kidney, and liver transplantation. Noninfectious complications in lung transplant recipients are discussed in Chapter 107 (Lung Transplantation) and infectious complications in immunocompromised hosts, including solid organ transplant recipients, are discussed in Chapter 123 (Pulmonary Infections in the Immunocompromised Host).

■ PERIOPERATIVE COMPLICATIONS

Important perioperative complications seen in liver, heart, and kidney transplantation are considered below.

Liver Transplantation

Ventilatory support beyond 24 hours is required by approximately 10% of recipients immediately following liver transplantation.[246] For those who are successfully extubated, reintubation at some point in the perioperative period occurs in one-third of patients who had initially required greater than 24 hours of ventilatory support and 10% of those initially ventilated for less than 24 hours.[246,247] Both postoperative respiratory failure and the need for reintubation are associated with significantly poorer survival.[247,248]

A number of factors contribute to respiratory failure, including impaired respiratory muscle function from extensive upper abdominal surgery, malnutrition, and debility; marked intravascular volume shifts and volume overload; aggressive blood product support; and a relatively high frequency of postoperative pneumonia. In addition, patients undergoing liver transplantation are often critically ill at the time of transplantation and it is not unusual for patients to have been supported on mechanical ventilation for varying periods of time prior to transplantation. In one study employing multivariate analysis, preoperative risk factors independently associated with an increased risk of postoperative respiratory failure following liver transplantation were diabetes mellitus, impaired renal function, preoperative ventilator support, use of a molecular adsorbent recycling system as an artificial liver support strategy, and deceased donor liver transplantation.[248]

Acute respiratory distress syndrome (ARDS) is a particularly lethal cause of postoperative respiratory failure following liver transplantation. The reported incidence ranges from 4% to 16%, with a mortality rate as high as 80% to 100%.[249] Sepsis is the most common risk factor reported but other potential risk factors include massive blood transfusions, TRALI, aspiration, and the use of OKT3 antilymphocyte therapy. Recipients with fulminant hepatic failure prior to transplantation are predisposed to noncardiogenic pulmonary edema as a component of their liver failure.

Hepatopulmonary syndrome and portopulmonary hypertension are two pulmonary complications of advanced liver disease. Although their onset precedes liver transplantation, these disorders do not immediately or invariably correct following this intervention and they can therefore contribute significantly to morbidity and mortality intraoperatively and in the early postoperative period.

Hepatopulmonary syndrome is defined as the triad of liver disease, arterial hypoxemia, and abnormal intrapulmonary vascular dilatation. The vast majority of cases involve diffuse dilatation of the pulmonary microvasculature at the precapillary and capillary levels. Rarely, discrete macroscopic arteriovenous communications are present. Proof of the presence of intrapulmonary vascular abnormalities is provided by demonstration of systemic uptake of technetium-labeled macroaggregated albumin on radionuclide perfusion imaging or the delayed appearance of bubbles in the left atrium by contrast echocardiography. Diffuse microvascular dilatation is postulated to cause hypoxemia by increasing the distance through which oxygen must diffuse and thereby creating a central stream of inadequately oxygenated red cells. Unlike a true shunt, this process can be partially corrected with administration of 100% oxygen, which serves to increase the pressure gradient favoring transfer of oxygen from the alveolus to the bloodstream. An unusual feature of hepatopulmonary syndrome is the tendency for oxygenation to worsen in the erect as opposed to supine position (orthodeoxia), presumably due to basilar predominance of the vascular abnormalities.

Although hepatopulmonary syndrome was once considered an absolute contraindication to liver transplantation, subsequent demonstration of its resolution following transplantation led to the reversal of this stance. Indeed, liver transplant candidates with severe hepatopulmonary syndrome (Pa_{O_2} <60 mm Hg on room air) are granted additional model for end-stage liver disease (MELD) points and thus receive enhanced priority with regard to organ allocation. Nonetheless, because hypoxemia often does not correct immediately and may in fact dramatically worsen in the early postoperative period, excessive morbidity and mortality was observed among these patients. In a review of 13 published reports encompassing 81 patients with hepatopulmonary syndrome who underwent liver transplantation prior to 1997, refractory hypoxemia contributed significantly to the observed 16% perioperative mortality, and 21% of survivors required prolonged mechanical ventilatory support.[250] In contrast, a more recent report of 21 patients with hepatopulmonary syndrome who underwent liver transplantation between 2002 and 2008 documented a perioperative survival rate of 100% and 1-year survival rate of 93%.[251] Notably, 5 of the 21 patients required prolonged postoperative administration of 100% inspired oxygen for persistent severe hypoxemia. The vast majority of patients who survive to hospital discharge ultimately achieve normal room air oxygen levels, most by 6 months following transplantation.[251] Late recurrence of hepatopulmonary syndrome coincident with deteriorating allograft function has been reported.[250]

Attempts to identify factors predictive of posttransplantation outcome in patients with hepatopulmonary syndrome have yielded conflicting results. Arguedas et al.[252] found that a preoperative arterial oxygen tension on room air of less than or equal to 50 mm Hg and an extrapulmonary shunt fraction of greater than or equal to 20% (calculated based on uptake of tracer in the brain on macroaggregated albumin scintigraphy), each were strong predictors of posttransplant mortality, with positive predictive values of 67% and 64% and negative predictive values of 93% and 100%, respectively. In contrast, Taille et al.[253] were unable to discern any significant relationship between these parameters and postoperative mortality, though they did find a correlation between the magnitude of preoperative hypoxemia and the length of time to achieve a normal oxygen level posttransplantation.

Postoperative care of the patient with persistent hypoxemia due to hepatopulmonary syndrome centers on the administration of supplemental oxygen while awaiting resolution of the disorder. Based on the positional nature of hypoxemia discussed earlier, one group reported improvement in oxygenation in a patient with use of the Trendelenburg position.[254] With the demonstration that nitric oxide is an important mediator of the abnormal vascular dilatation that characterizes hepatopulmonary syndrome, attention has turned to the potential therapeutic role of inhibitors of nitric oxide in treating hypoxemia.[255] Schenk et al.[256] described significant improvement in oxygenation and shunt fraction for up to 10 hours after administration of a single dose of methylene blue to seven patients with advanced cirrhosis and hepatopulmonary syndrome. Brussino et al.[257] administered nebulized N(G)-nitro-L-arginine methyl ester – an inhibitor of nitric oxide synthesis – to a single patient with hepatopulmonary syndrome and demonstrated a marked rise in arterial oxygen tension and a dramatic reduction in the magnitude of bubbles appearing in the left atrium on contrast echocardiography. Although these preliminary observations are promising, additional corroborating studies are necessary before the widespread clinical use of these agents can be recommended. In the rare instances in which discrete arteriovenous malformations are present, coil embolization can be an effective treatment strategy.[258]

Portopulmonary hypertension describes the development of pulmonary hypertension in patients with advanced liver disease and portal hypertension. The diagnosis rests on demonstration of a mean pulmonary artery pressure exceeding 25 mm Hg and a normal pulmonary capillary wedge pressure. Some authors also include the criterion of a pulmonary vascular resistance exceeding 120 dyn • sec/cm^5 to distinguish this syndrome from the more benign and common finding of elevated pulmonary pressures due solely to increased cardiac output. Histologically, the abnormalities in the pulmonary vascular bed are identical to those seen in primary pulmonary hypertension: Medial hypertrophy, intimal fibrosis, and plexiform lesions. While a mechanistic link has yet to be defined, the observation that the prevalence of pulmonary hypertension in patients with liver disease exceeds that of the general population suggests that there is a connection. Portopulmonary hypertension is encountered in 1% to 2% of patients with chronic liver disease and in up to 12.5% of patients referred for liver transplant evaluation.[259]

Although mild pulmonary hypertension does not appear to adversely impact liver transplantation, more significant elevations in pressure are associated with excessive posttransplantation mortality. A retrospective review from the Mayo Clinic and a subsequent multicenter database documented perioperative mortality rates of 0% to 17% among liver transplant recipients with a preoperative mean pulmonary artery pressure below 35 mm Hg. In contrast, perioperative mortality rates were 35% to 40% for patients with a mean pulmonary artery pressure of 35 to 50 mm Hg and 40% to 100% for those with a mean pulmonary artery pressure exceeding 50 mm Hg.[260,261] Most deaths occur intraoperatively or in the immediate postoperative period and are largely attributable to progressive right heart failure and hemodynamic collapse.

Several case series document successful transplantation of patients with severe portopulmonary hypertension who responded favorably to the preoperative initiation of vasodilator agents.[262–264] For such patients, intravenous or inhaled epoprostenol should be employed in the perioperative period. Since pulmonary hypertension tends to persist despite transplantation, these patients frequently require long-term therapy but can often be transitioned to oral vasodilator agents.

Heart Transplantation

Heart transplant recipients are subject to the same generic perioperative pulmonary complications encountered in the general cardiac surgical population. These include atelectasis, pulmonary edema, pleural effusions, and mediastinitis. The risk of respiratory failure and acute lung injury following heart transplantation is relatively low. In a series of 157 consecutive heart transplant procedures, prolonged respiratory failure requiring tracheostomy was reported

in only 7 cases (4.4%); 5 of the 7 cases occurred within the first 6 months following transplantation.[265]

Kidney Transplantation

Kidney transplantation is carried out with relatively few perioperative pulmonary complications, reflecting the use of a lower abdominal incision and the comparatively good health of the recipients. The vast majority of patients are extubated in the operating room. Perioperative respiratory failure was documented in 4% of 178 kidney transplant recipients from the University of Pittsburgh.[266] The most common noninfectious pulmonary complication is hydrostatic pulmonary edema due to impaired salt and water excretion in the setting of early allograft dysfunction or rejection. ARDS, on the other hand, occurs infrequently. In a retrospective review of a national kidney transplant database encompassing over 42,000 transplants, ARDS was documented in only 86 patients (0.2%) and only 1 of these cases occurred within the perioperative period.[267]

■ PLEURAL EFFUSIONS IN LIVER TRANSPLANTATION

Postoperative pleural effusions are present in 40% to 100% of liver transplant recipients.[268,269] Effusions are transudative and are typically right-sided or bilateral but are rarely exclusively on the left. Disruption of diaphragmatic lymphatics during hepatectomy is postulated to be the principal mechanism of fluid accumulation. Other contributing mechanisms include volume overload, hypoalbuminemia, and atelectasis. Effusions may enlarge over the first postoperative week but typically resolve by the third week. The need for drainage because of perceived respiratory compromise has been reported in up to 31% of patients.[249,268,269] Effusions that continue to enlarge beyond the first week, persist beyond 3 weeks, or involve only the left hemithorax should be sampled to rule out other causes. Persistent or enlarging effusions should also prompt consideration of subdiaphragmatic processes including hematoma, biloma, or subphrenic abscess.

■ DIAPHRAGMATIC DISORDERS

Disorders of the diaphragm may be seen following liver or heart transplantation. They are discussed briefly below.

Liver Transplantation

Right-sided diaphragmatic dysfunction following liver transplantation is postulated to result from crush injury to the right phrenic nerve by the suprahepatic vena caval clamp placed during surgery. In one older series of 48 patients, evidence of delayed or absent right-sided phrenic nerve conduction was found in 79% of patients while the left phrenic conducted normally in all cases.[270] In 38% of patients, there was associated right diaphragmatic paralysis documented by ultrasound. Phrenic nerve injury was not associated with increased duration of mechanical ventilatory support or hospital stay. In a subset of patients followed with serial testing, abnormalities in phrenic nerve conduction and diaphragmatic excursion normalized by 9 months after surgery. Newer surgical approaches have been introduced that preserve the suprahepatic inferior vena cava, thereby minimizing the risk of phrenic nerve injury.

Heart Transplantation

Diaphragmatic dysfunction due to phrenic nerve injury occurs in up to 12% of heart transplant recipients.[271] The right phrenic nerve is most prone to injury. Diaphragmatic dysfunction has been associated with an increased risk of postoperative pneumonia and a trend toward increased length of intubation.

Diaphragmatic hernias have been reported in heart transplant recipients who had left ventricular assist devices (LVADs) implanted prior to transplantation. These devices are placed either preperitoneally or intraperitoneally in the left upper quadrant. The inflow cannula penetrates the left hemidiaphragm and attaches to the left ventricle while the outflow cannula emerges from the ascending aorta and crosses anterior to the diaphragm near the midline. At the time of heart transplantation, the LVAD is explanted and the left-sided diaphragmatic defect is routinely repaired. However, repair of the anterior diaphragmatic defect is not necessarily standard practice, as it has been reasoned this would add to the operative time and that midline scarring would naturally close the rent. The incidence of diaphragmatic hernias has been reported to be as high as 16% among heart transplant recipients in whom closure of the anterior midline diaphragmatic defect was not performed, and in all cases the hernia arose at the site of the unrepaired midline defect.[272] In contrast, only 4% to 5% of patients experienced this complication when the surgical procedure was modified to include routine closure of the anterior defect at the time of LVAD explantation.[272,273] Patients with diaphragmatic hernias can be entirely asymptomatic, experience subacute gastrointestinal symptoms (abdominal pain, nausea, vomiting), or present emergently with colonic incarceration. Chest radiographs can be nonspecific, demonstrating only an ill-defined opacity at the base of the right or left lung. More suggestive findings include the presence of air within the opacity or actual visualization of colonic haustra. The diagnosis can usually be established definitively with CT of the chest and abdomen, after administration of oral contrast. Surgical repair, either via conventional laparotomy or performed laparoscopically, is indicated even in asymptomatic cases because of risk of incarceration.

■ NEOPLASTIC DISORDERS

Posttransplant lymphoproliferative disorder (PTLD) is second only to nonmelanoma skin cancers as a leading neoplastic complication of organ transplantation. PTLD encompasses a spectrum of abnormal B-cell–proliferative responses ranging from benign polyclonal hyperplasia to malignant lymphomas. Epstein–Barr virus (EBV) has been identified as the stimulus for B-cell proliferation, which proceeds in an unchecked fashion due to the inadequate cytotoxic T-cell response in the immunosuppressed host. EBV-naïve recipients who acquire primary infection at the time of organ transplantation are at greatest risk of developing PTLD. A higher intensity of immunosuppression and, in particular, the use of antilymphocyte antibody preparations have also been implicated as risk factors. Likely reflecting differences in the magnitude of immunosuppression employed, the incidence of PTLD is only 1% to 2% among kidney and liver transplant recipients but is in the range of 5% to 7% among heart transplant recipients.[274,275] The incidence is greatest within the first year posttransplantation. Among the nonlung organ transplant populations, heart transplant recipients are the most likely to present with intrathoracic involvement, which typically assumes the form of one or multiple pulmonary nodules occasionally accompanied by regional adenopathy or pleural effusions.

Initial treatment involves reduction in the level of immunosuppression to permit partial restoration of host cellular immunity. Such a strategy can lead to regression of tumor in up to two-thirds of solid organ recipients but carries the risk of precipitating acute or chronic allograft rejection.[276] For patients who fail to achieve a complete remission, cannot tolerate reduced immunosuppression, or have widespread disease, immunotherapy with anti-CD20 monoclonal antibodies (rituximab) is the preferred option. Experience with standard chemotherapy has been poor due to the high risk of infection during periods of neutropenia.

The mortality rate attributable to PTLD is not well defined. In multivariate analysis, increased age, elevated lactate dehydrogenase levels, severe organ dysfunction, presence of B symptoms, and multiorgan involvement are independent markers of poor prognosis.[276]

Other malignancies occasionally present in the lungs following transplantation. Bronchogenic carcinoma develops in 2% to 4% of heart transplant recipients.[277] It is unclear whether the development of

lung cancer in the heart transplant population reflects an increased risk or simply represents the expected occurrence rate in a population with a high prevalence of cigarette smoking. Among liver transplant recipients with a pretransplantation history of hepatocellular carcinoma, the lung is the most common site of recurrence. Recurrence usually occurs within 2 years of transplantation and appears radiographically as single or multiple lung nodules. An elevated α-fetoprotein level provides an important clue to the possibility of recurrent disease.

DRUG-INDUCED LUNG DISEASE

Sirolimus, also known as rapamycin, is a potent immunosuppressive agent recently introduced into clinical practice. Since its release, numerous cases of interstitial pneumonitis developing in association with sirolimus administration have been reported.[278,279] The incidence of this complication remains unknown. Initial reports suggested that interstitial pneumonitis was largely a result of excessive sirolimus blood concentrations but more recent reports describe this complication in the setting of therapeutic drug levels.[279,280] Patients typically present with dry cough, progressive dyspnea, fatigue, and weakness; fever and hemoptysis are less commonly present. Radiographic abnormalities include interstitial infiltrates, alveolar consolidation, and nodular opacities. BAL reveals evidence of a lymphocytic alveolitis and, less commonly, of alveolar hemorrhage. Reported findings on transbronchial lung biopsies include bronchiolitis obliterans with organizing pneumonia, interstitial lymphocytic infiltrates, and nonnecrotizing granulomas. Discontinuation of the drug may be sufficient treatment in many cases; corticosteroids have been given to hasten resolution but support for this approach is anecdotal. Conversion from sirolimus to everolimus, an agent that shares similar biochemical features and mechanism of action, has led to resolution of pneumonitis in some cases[281,282] but reports of everolimus-induced pneumonitis have also recently appeared.[283–285]

The murine monoclonal anti-CD3 antibody OKT3 was commonly used in the past for induction immunosuppression and treatment of refractory acute rejection. This agent is associated with a "cytokine release syndrome" that is most pronounced with the first dose and that clinically presents with fever, rigors, nausea, hypotension, and dyspnea. A small number of patients have been reported to develop noncardiogenic pulmonary edema, which rarely can be fatal. Because of its toxicity and the availability of alternative agents, the use of OKT3 has diminished in recent years. The interleukin-2 receptor antagonists basiliximab and daclizumab are being used with increasing frequency as induction agents, in part because of a generally favorable side-effect profile. However, several cases of noncardiogenic pulmonary edema in renal transplant recipients have been reported in association with basiliximab infusion.[286]

PULMONARY METASTATIC CALCIFICATION

Deposition of calcium in the lung parenchyma and other organs is a well-documented complication of chronic renal failure and is postulated to relate to alterations in calcium and phosphate balance and parathyroid hormone secretion.[287] Although renal transplantation should have a mitigating effect, pulmonary metastatic calcification rarely may progress despite successful transplantation[288,289] and may accelerate in association with graft failure.[290,291] Pulmonary metastatic calcification has also been described in liver transplant recipients, with a reported incidence in two series of 5.2% and 47%.[292,293] Renal insufficiency was a common but not universal feature in these patients. Secondary hyperparathyroidism, due to transient hypocalcemia induced by large volume infusion of citrate-containing blood products and, when present, to renal insufficiency, has been offered as a possible mechanism.[293]

Metastatic pulmonary calcification is most often clinically silent but rarely may lead to restrictive lung disease or fulminant respiratory failure.[290,291,294] The major import of this disorder lies in its ability to radiographically mimic more ominous processes such as infection or malignancy. Single or multiple nodular opacities or areas of alveolar consolidation are seen on plain chest radiographs but calcification of these lesions may not be apparent. CT findings include multiple diffuse calcified nodules, diffuse or patchy areas of ground-glass opacity or consolidation, and confluent high-attenuation parenchymal consolidation.[295] The abnormalities are typically most pronounced in the upper lung zones. Calcification is evident by CT in approximately 60% of cases. In the absence of calcification, the demonstration of high-attenuation (>100 HU) parenchymal opacities by CT scan or of increased uptake of tracer in the lung by technetium bone scintigraphy is helpful in establishing a diagnosis. In instances of diagnostic uncertainty, transbronchial or surgical lung biopsy may be necessary. There is no established treatment for pulmonary metastatic calcification but, given the overall favorable prognosis, this is rarely a consideration.

CHAPTER 96

Pulmonary Complications of Sickle Cell Disease

Roberto F. Machado
Mark T. Gladwin

INTRODUCTION

Sickle cell disease (SCD) is one of the most common monogenetic diseases in the world. Sickle cell anemia, the most common and most severe form of SCD, occurs in individuals who are homozygous for a single GAG α GTG substitution in the β-globin gene, resulting in the production of hemoglobin S (HbS). Patients with other types of SCD are compound heterozygotes, having one copy of HbS and one copy of another β-globin mutation, such as hemoglobin SC or HbS-β thalassemia.[1] The presence of concurrent α-thalassemia, which will reduce the intracellular concentration of hemoglobin, also modulates disease severity and accounts for some of the variability in the clinical presentation of patients with SCD.[2] It is estimated that approximately 250,000 children worldwide are born with homozygous sickle cell (HbSS) anemia every year.[3] Approximately 0.15% of African Americans are homozygous for SCD, and 8% have sickle cell trait. In sub-Saharan Africa, up to 40% of the population carry sickle cell trait, and up to 1% of children are born with SCD.[4]

Despite significant improvements in the life expectancy of patients with SCD, estimates of the median age at death range from 42 to 53 years for men and 48 to 58.5 years for women.[5,6] Within this context, pulmonary complications of SCD are common and a major threat to the well-being of patients with SCD, accounting for a large proportion of deaths among these patients.[5,7–9] According to the Cooperative Study of Sickle Cell Disease (CSSCD), a prospective multicenter study of 3764 patients, over 20% of adults likely had fatal pulmonary complications of SCD.[5] Among the 299 patients enrolled in the long-term follow-up study of patients who participated in the Multicenter Study of Hydroxyurea (MSH) in Sickle Cell Anemia, pulmonary disease was the most common cause of mortality, accounting for 28% of all deaths.[10] The numbers likely underestimate the importance of pulmonary disease in risk of death, as pulmonary hypertension (PH) was not diagnosed in these cohorts. Indeed, retrospective evaluation of banked plasma samples from the studies using N-terminal probrain natriuretic peptide (NT-proBNP) as a surrogate for the presence of PH suggested that PH was a major risk factor for death in both the CSSCD and MSH cohorts.[11,12]

When deoxygenated, HbS is much less soluble than normal hemoglobin (HbA).[13,14] Deoxygenated HbS polymerizes and aggregates inside sickle erythrocytes as they traverse the microcirculation. Rigid, dense, and sickled cells can become physically entrapped in the microcirculation, a process that is enhanced by inflammation and integrin molecule expression, causing red cell and leukocyte adhesion to endothelium. Mechanistic studies in transgenic mice expressing exclusively human HbS suggests that microvascular occlusion results in episodic interruption in blood flow, ischemia, and reperfusion injury, with secondary inflammatory, thrombotic, and oxidant stress.[15–22]

In patients, vasoocclusion leads to the frequent episodes of bone pain and acute chest syndrome (ACS) that complicate SCD. Furthermore, the membrane of erythrocytes containing intracellular HbS polymer is constantly exposed to mechanical and oxidant injury as the red cells traverse the microcirculation. Ultimately, cumulative membrane damage shortens red cell life span, so that SCD is characterized by a chronic hemolytic anemia. Intravascular hemolysis releases cell-free hemoglobin into the plasma, which scavenges nitric oxide (NO) and releases red blood cell arginase-1 into the plasma, which, in turn, catabolizes arginine, the substrate for NO synthesis.[23–25] Hence, intravascular hemolysis produces a state of endothelial dysfunction and vascular proliferation, along with prooxidant and proinflammatory stress.[26–28] In effect, intraerthrocytic HbS polymerization leads to downstream vascular inflammation, hemolysis-related vasculopathy, and ischemia–reperfusion organ injury.

Anemia, per se, should also be considered in the evaluation of the cardiopulmonary effects of SCD, since decreasing oxygen

carrying capacity of the blood related to severe anemia can impair cardiopulmonary function. The signs and symptoms induced by anemia depend on the degree of anemia, the rate at which it evolves, the oxygen demands of the patient, and the presence of chronic cardiopulmonary disease. For instance, in resting adults subjected to acute isovolemic anemia, oxygen delivery can be maintained at hemoglobin concentrations as low as 5 g/dL,[29] a finding also noted in individuals with chronic severe anemia.[30,31] Thus, anemia, even when severe, rarely causes heart failure; when it does, it is likely that the high-output failure is superimposed upon an underlying cardiac abnormality.

From the hemodynamic standpoint, as hemoglobin level decreases (particularly with hemoglobin values <7 g/dL), blood viscosity decreases, cardiac output increases, cardiac filling pressures tend to decrease, and systemic and pulmonary vascular resistances decrease substantially. Such abnormalities are readily reversible with red blood cell transfusions.[30–32] Finally, in severe cases, especially in patients with cardiopulmonary disease, anemic hypoxia can also occur as a consequence of reduced ability of blood to participate in gas exchange and oxygen transport. Interestingly, the severity of hemolytic anemia in patients with SCD is strongly correlated with systemic hypoxemia and decreasing arterial hemoglobin oxygen saturation, a finding that is likely related to both increased cardiac output and altered pulmonary vascular perfusion. Alterations in pulmonary vascular perfusion result in impaired ventilation–perfusion matching.[33,34]

ACUTE CHEST SYNDROME

The ACS in SCD is defined as a lung injury syndrome characterized by a new pulmonary infiltrate that (1) is consistent with alveolar consolidation, rather than atelectasis; (2) involves at least one complete lung segment; and (3) is accompanied by chest pain, fever, tachypnea, wheezing, or cough.[35]

EPIDEMIOLOGY

ACS is the second most common cause of hospitalization in patients with SCD, the leading cause of admission to an intensive care unit, and, together with PH, a leading cause of premature death, accounting for 25% of SCD-related mortality in earlier cohorts.[5,8] More recently, increased awareness, the chronic use of hydroxyurea, and the early and aggressive use of transfusion therapy have led to a decrease in ACS-related mortality.[36] For example, in a multicenter trial of inhaled NO for vasoocclusive crisis, only 10% of patients in the study developed ACS, and none required mechanical ventilation or died.[36]

ACS can occur in any of the sickle hemoglobinopathies but it is more common in individuals with HbSS disease. In the CSSCD, a 29% incidence of the ACS was noted in 3751 subjects over a 2-year period, representing an attack rate of 12.8 episodes per 100 patient-years for homozygous HbS disease.[5] The incidence is higher in children than in adults (24.5 events vs. 8.8 events per 100 patient-years). As many as half of episodes of ACS occur in association with vasoocclusive pain crises, and a significant proportion of patients will have a painful event within 2 weeks of the diagnosis of ACS.[37,38] Ten to twenty percent of patients admitted with an acute vasoocclusive pain crisis develop ACS within the first 3 days of hospitalization. Recent studies suggest a much higher rate of ACS following influenza infection.[39–41]

Clinical parameters that appear to increase risk for, or are associated with, development of ACS include: young age, active smoking, environmental smoke exposure,[42] major surgical procedures, acute rib infarcts, avascular necrosis of the hips, pregnancy, use of narcotics, acute anemic events, nocturnal or daytime hypoxemia, and previous pulmonary events.[37,38] In children, a number of studies suggest that asthma is a risk factor for the development of ACS.[43–45] Laboratory parameters in steady state associated with an increased risk for the development of ACS include an elevated white blood cell count, higher steady-state level of hemoglobin, and lower steady-state level of fetal hemoglobin.[37,38]

While a high steady-state level of hemoglobin is a risk factor for ACS, during acute hospitalization for a vasoocclusive crisis, development of the ACS is often preceded by an abrupt drop in hemoglobin (mean decrease of 0.78 g/dL) and increases in markers of hemolysis, for example, lactate dehydrogenase. The platelet count may also fall prior to ACS, and platelet levels lower than 200,000 cells per mL constitute an independent risk factor for the severity of ACS, an increased risk of neurological complications, and the need for mechanical ventilation.

A limited number of studies have addressed the role of candidate gene polymorphisms in patients with ACS. In a small cohort of 134 pediatric patients with SCD, *NOS1* AAT repeat polymorphism in intron 13 was associated with increased risk of ACS.[46] Similarly, in a study of 173 pediatric patients with SCD, individuals homozygous for a *ET-1* T8002 C polymorphism had higher rates of ACS, while those homozygous for a *NOS3* T-786 C polymorphism had lower rates.[47] Finally, in a cohort of 942 children with SCD, a highly polymorphic (GT)n dinucleotide repeat located in the promoter region of *HMOX1*, with long repeat lengths linked to decreased activity and inducibility, was evaluated. After adjusting for sex, age, asthma, percentage of fetal hemoglobin, and α-globin gene deletion, children with two shorter alleles had lower rates of hospitalization for ACS compared with children with longer allele lengths.[48]

PATHOGENESIS

The etiology of ACS is multifactorial. Although a specific cause is not identified in a substantial proportion of patients, three major pathogenetic mechanisms are involved, including infection, bone marrow fat embolization, and direct red cell intravascular sequestration, which cause lung injury and infarction (Table 96-1, Fig. 96-1).

The most common etiology of ACS in both children and adults is infection by a community-acquired pathogen. It has been proposed that community-acquired respiratory infection induces an excessive inflammatory lung injury response in patients with SCD, as SCD mice that express only human HbS show increased susceptibility to inflammatory triggers (lipopolysaccharide and bacteria) and development of lung injury at lower levels of endotoxin that do not adversely affect wild-type mice.[49,50] In addition, more than 80% of adults with SCD report a history of having been admitted to the hospital for "pneumonia."[26]

The National ACS Study Group analyzed 671 episodes of ACS in 538 patients with SCD. Respiratory samples obtained from sputum and BAL were analyzed for viral and bacterial infections.[35] Among the infectious agents identified most commonly (Table 96-1) were atypical bacteria and viruses, including *Chlamydia pneumonia* (29%), *Mycoplasma pneumonia* (20%), *Legionella pneumophila* (2%), respiratory syncytial virus (10%), parvovirus (4%), rhinovirus (3%), parainfluenza virus (2%), influenza A virus (2%), cytomegalovirus (2%), Epstein–Barr virus (1%), and herpes simplex virus (1%). Community-acquired encapsulated bacteria were rarely isolated, despite the fact that patients with homozygous HbS disease rarely have normal splenic function. *Staphylococcus aureus* was isolated in 5% of cases and *Streptococcus pneumonia* in only 4% of cases. Cases of severe ACS related to seasonal influenza have also been described.[39–41]

Fat embolization syndrome occurs as a complication of vasoocclusive pain crisis involving multiple bones, resulting in bone marrow edema, infarction, and necrosis. Fat embolism was identified by the National ACS Study Group as the cause of ACS in 16% of patients. During fat embolization, bone marrow contents are released into the systemic circulation and are trapped in the

TABLE 96-1 Causes of the Acute Chest Syndrome[a]

Cause	All Episodes ($n = 670$)	Age at Episode of Acute Chest Syndrome		
		No. of Episodes (%)		
		0–9 y ($n = 329$)	10–19 y ($n = 188$)	≥20 y ($n = 153$)

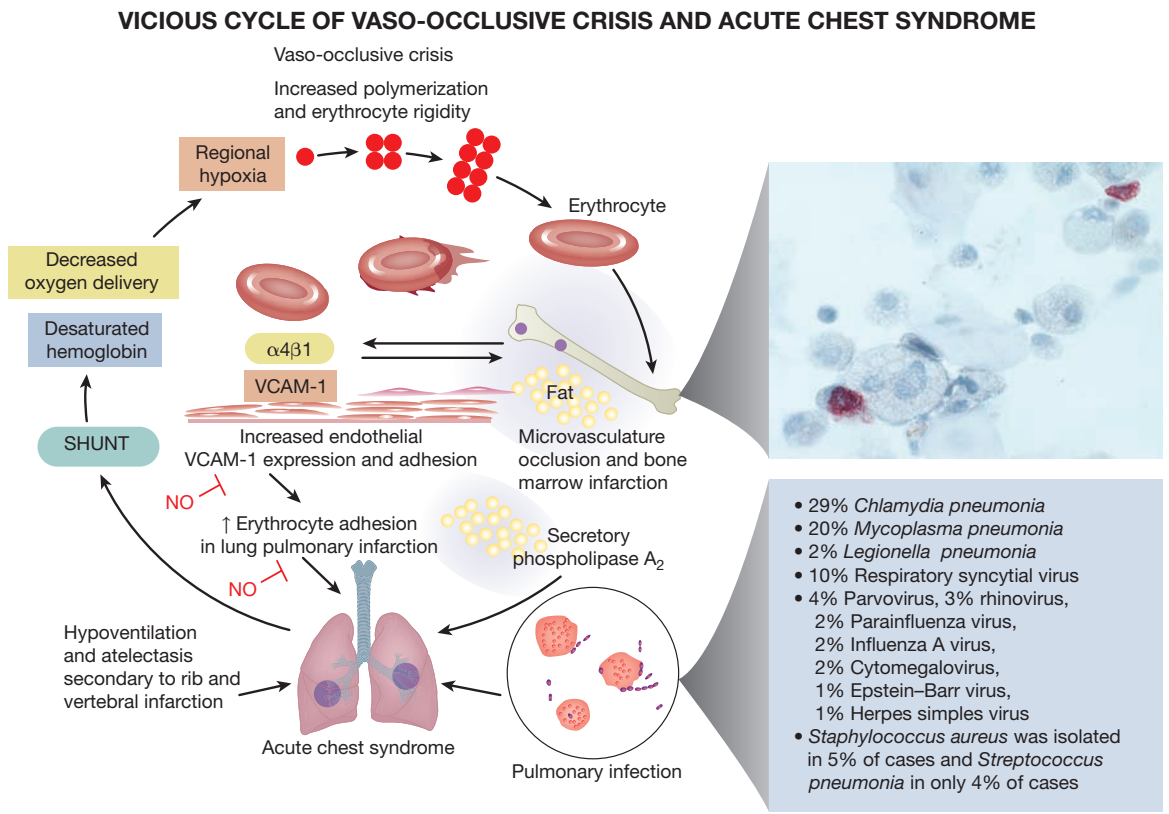

Figure 96-1 Pathogenesis of the acute chest syndrome. Three major mechanisms are associated with the development of ACS: infection, bone marrow fat embolization, and direct red cell intravascular sequestration causing lung injury and infarction. Lung injury results in ventilation–perfusion mismatch and hypoxemia, which leads to increased hemoglobin S polymerization, and erythrocyte vasoocclusion. This worsens bone marrow infarction and pulmonary vasoocclusion to promote a vicious cycle. Fat embolization can be diagnosed by Oil Red O staining of pulmonary alveolar macrophages, revealing the characteristic red lipid inclusions. Common infectious organisms identified in cases of ACS are listed. *(Reproduced with permission from Gladwin MT, Vichinsky E. Pulmonary complications of sickle cell disease. pulmonary circulation, producing acute PH, severe lung inflammation, and hypoxemia (Fig. 96-2).[51–53] Bone marrow fat released into the bloodstream is also converted to free fatty acids by secretory phospholipase A_2, producing direct inflammatory lung injury.[54]

In approximately 20% of patients, direct adhesion of sickled cells in the pulmonary vasculature arising during lung infarction or lung vasoocclusion is associated with the development of ACS; a small fraction of patients develop wedge-shaped infarctions, sometimes followed by central cavitation.[55] In situ pulmonary arterial thrombosis and cellular occlusion also appear to be common in patients with ACS. In a study of 144 episodes of ACS in 125 consecutive patients evaluated using CT angiography, a 17% prevalence of subsegmental thromboembolism was noted; there was no evidence of peripheral venous thrombosis.[56]

A potential role for hemolysis-derived plasma-free hemoglobin and its by-products, such as free heme, has been suggested in the pathogenesis of ACS. Administration of lysed red blood cells into the circulation of sickle cell mice has been shown to increase vascular permeability in the lung without impacting permeability in other organs.[57] Furthermore, preliminary studies have demonstrated that intravenous administration of heme to sickle cell mice induces severe and lethal acute lung injury.[58] In aggregate, these data suggest that plasma-free hemoglobin or heme specifically may directly contribute to lung injury in the context of vasoocclusive crisis and ACS. The relationship between increased intravascular hemolysis and thrombocytopenia (see below) suggests that a possible thrombotic thrombocytopenic purpura–like mechanism may occur in a subset of patients with ACS. In fact, studies have demonstrated that hemoglobin produced during hemolysis may inhibit ADAMTS13 activity.[59–61]

■ CLINICAL FEATURES AND EVALUATION

Eighty percent of patients with ACS present with fever and 62% with cough; approximately 40% have chest pain, tachypnea, dyspnea, and abdominal, arm, leg, rib, or sternal pain.[35] Some of the clinical features of ACS are age dependent, which likely reflects the different disease etiologies in different age groups. Children have a higher proportion of infectious etiologies in comparison to adults, who have fat embolization as a major cause. Most adult patients present with severe extremity or chest pain and develop ACS 24 to 72 hours later. Reactive airway disease is observed in 13% of cases and is much more common in children.[35]

ACS is associated with signs of systemic inflammation. Mean peak temperature is 38.9°C and mean white blood cell count is 23,000 cells per mL. In addition, a drop in hemoglobin level (mean decrease of 0.78 g/dL from steady-state level) and an increase in markers of hemolysis are noted.[35] Thrombocytopenia may also occur; platelet counts less than 200,000 cells per mL appear to be a marker of more severe ACS and are associated with increased risk of neurological complications and need for mechanical ventilation.[35] Secretory phospholipase A_2 levels, that are elevated early in the course of ACS, even before development of radiographic changes, have been used to predict onset of the syndrome.[62]

Some patients manifest evidence of systemic fat embolization. In these cases, ACS is part of the spectrum of the systemic fat emboli syndrome, evident as acute multiorgan system failure (MOSF) (Chapter 142). Patients with MOSF experience acute hypoxic respiratory failure, acute cor pulmonale, renal and hepatic dysfunction, alterations in mental status, seizures, thrombocytopenia, and coagulopathy.[63,64]

The diagnosis of pulmonary fat embolization syndrome is based on identification of Oil Red O–positive lipid accumulations within alveolar macrophages, as the clinical manifestations can be indistinguishable from other causes of ACS (Fig. 96-2). Bronchoscopy has been used as the diagnostic modality of choice for the diagnosis of pulmonary fat embolization syndrome. Interestingly, a study comparing the diagnostic utility of induced sputum sampling of alveolar macrophages with specimens obtained from bronchoalveolar lavage found a significant, albeit modest, correlation between the two ($R = 0.65$).[65] Patients with ACS who have lipid-laden macrophages detected in induced sputum have significantly more extrathoracic pain than those without evidence of fat emboli, more neurological symptoms, a lower platelet count, and higher serum transaminase levels.[65]

The mean length of hospitalization for ACS is 10.5 days, compared with 3 to 4 days for uncomplicated vasoocclusive painful crisis. Large registry studies suggest that 13% of patients require mechanical ventilation. The overall mortality is 3% for all patients and 9% for adults, however, as noted previously, these rates may be

lower in experienced medical centers employing more aggressive and earlier transfusion therapy.

Risk factors for mechanical ventilation and poor outcome include a platelet count less than 200,000 per μL (likely indicative of the fat emboli syndrome), a greater number of lobes involved on the chest radiograph, and a self-reported or medical record–based history of cardiac disease.

Acute cor pulmonale can also complicate the course of ACS. In a study of 84 consecutive patients hospitalized with ACS, 13% manifested right heart failure. This subgroup had significant elevations in B-type natriuretic peptide and troponin I levels and the highest risk for needing mechanical ventilation and death.[66] PH and right heart dysfunction appear to represent major comorbidities in ACS; right heart failure should be considered in those patients presenting with shock or severe hypoxia.

TREATMENT

Since the triggers and risk factors for ACS are well known, preventive strategies in the outpatient setting, clinical surveillance, and aggressive and early therapy are likely to improve prognosis.

Patients with multiple episodes of vasoocclusive crises or a previous history of ACS should be treated with hydroxyurea in the outpatient setting, since its use has been shown to reduce the risk of developing ACS by approximately 50%.[67,68] A chronic transfusion regimen is also effective in reducing the incidence of ACS,[69] as is preoperative blood transfusion in patients undergoing surgical procedures.[70]

In acutely ill patients, specific strategies, such as aggressive pain management and incentive spirometry, can minimize chest wall splinting, mitigating development of atelectasis and alveolar hypoxia. The use of incentive spirometry has been shown to decrease the incidence of new pulmonary infiltrates in patients admitted with vasoocclusive pain affecting the chest wall.[55]

In one small study evaluating the efficacy of prophylactic blood transfusions in patients with serum phospholipase A_2 elevations during vasoocclusive crisis,[71] transfusion eliminated ACS in the study cohort. Larger confirmatory trials are indicated.

We recommend use of empiric antimicrobial therapy in all patients with ACS, given the high prevalence of infectious etiologies. Coverage should include agents effective against atypical bacteria and encapsulated organisms. Important to consider are alternative organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA) and influenza viruses, especially in patients who do not respond to therapy or who develop ACS during influenza season.

Although not demonstrated in randomized trials, blood transfusion remains the mainstay of ACS therapy and is considered standard of care. Acute red cell transfusion increases Pa_{O_2} and hemoglobin oxygen saturation and may rapidly resolve the pulmonary event.[35,72] In the DeNOVO trial,[36] no episodes of ventilator-dependent respiratory failure and no deaths were noted in 30 patients with ACS receiving the current practice of early transfusion therapy. The improved outcomes compare favorably with historical data from the National ACS Study Group.

To avoid the adverse effects of increased blood viscosity and the consequent risk of vasoocclusion, the hemoglobin level should not be raised higher than 11 g/dL with simple transfusion therapy. The National Acute Chest Syndrome Study Group found no significant differences in outcomes between patients treated with simple transfusion or red cell exchange (erythrocytapheresis), suggesting that the former approach is preferred as initial therapy.[35] Patients with high initial hemoglobin concentrations (≥9 g/dL) or patients with severe or rapidly progressive disease should receive erythrocytapheresis. Most importantly, to decrease the risk of delayed hemolytic transfusion reactions related to alloimmunization against minor red blood cell antigens, all transfused blood should be matched to Rh, C, E, and Kell antigens.

Treatment with corticosteroids has been shown to reduce the severity of pain and length of hospitalization, but this therapy is complicated by a high rate of rebound pain and readmission.[73,74] An investigation of the use of a slow, tapering protocol corticosteroids to maintain their beneficial effects while limiting rebound pain and readmission was terminated early because of slow accrual of study patients.[75]

Noninvasive mechanical ventilation (NIMV) has been studied in the setting of ACS. In a prospective, randomized, open single-center study of 67 adult patients with ACS, use of NIMV improved respiratory rate and gas exchange but failed to significantly reduce the number of patients remaining hypoxemic by day 3 of hospitalization; in addition, use of NIMV was associated with greater patient discomfort.[76] In addition, NIMV did not change transfusion rates, pain scores, narcotic dose, or hospital length of stay. In fact, its use prolonged length of stay in the step-down unit.[76]

The DeNOVO trial explored use of inhaled NO for patients with SCD presenting in vasoocclusive crisis. Despite two prior positive small phase II trials,[77,78] the DeNOVO study did not demonstrate an effect of inhaled NO therapy compared with placebo on the duration of pain crisis, narcotic use, pain scores, or development of ACS.[36]

ASTHMA AND AIRWAY REACTIVITY

Asthma is common among patients with SCD, particularly in children. In a prospective study of 291 African-American children with SCD, 17% received a clinical diagnosis of asthma.[43] Interestingly, the reported incidence of airway hyperresponsiveness in children with SCD is much higher, ranging from 40% to 77%, as measured by methacholine, exercise, or cold air challenge tests.[79–81]

Asthma has been associated with multiple complications of SCD, including ACS. Children with SCD and asthma experience almost twice as many episodes of ACS as their counterparts without asthma, even after matching for age, sex, fetal hemoglobin percentage, and lifetime average hematocrit.[43–45,82–85] Several mechanisms have been proposed for this association, including ventilation–perfusion mismatch leading to hypoxemia and sickling, and inflammation causing increased erythrocyte adhesion to vascular endothelium.[86] Asthma is an independent risk factor for mortality in children with SCD, conferring a twofold higher risk of death (hazard ratio, 2.36; confidence interval [CI], 1.21–4.62; $p = 0.01$).[87] The reasons for increased mortality remain unclear, but are likely related to the higher risk of vasoocclusive crises and ACS.

Data on asthma in adults with SCD are scarce. The diagnostic and prognostic significance of the disease in adults is less clear than in children. A study of 31 adults with SCD without a clinical diagnosis of asthma showed an average TLC of 73% predicted, FVC of 79% predicted, and FEV_1 of 75% predicted.[85] Fifteen patients demonstrated bronchial hyperreactivity on methacholine provocation testing; there was evidence of a correlation between bronchial hyperreactivity and previous episodes of ACS. Another cohort study evaluated physician-diagnosed asthma and a history of wheezing in 114 adults with SCD.[88] Although self-reported severe and recurrent wheezing was associated with increased rates of pain, ACS, and risk of death, no relationship was found between a physician-established diagnosis of asthma and these complications.

Although there are no controlled trials of asthma therapy in the SCD population, most experts recommend treatment following generally established guidelines for asthmatics in general.[89] Systemic corticosteroids must be used with caution, however, as corticosteroids appear to induce vasoocclusive crises and ACS in patients with SCD. In fact, the use of corticosteroids in pediatric patients with SCD has been shown to worsen outcomes.

PULMONARY HYPERTENSION

Among the chronic cardiopulmonary complications of SCD, PH, defined as a mean pulmonary artery pressure (mPAP) ≥25 mm Hg, has emerged as the major threat to the well-being and longevity of patients. A number of studies have added significantly to our understanding of the prevalence, underlying pathogenetic mechanisms, and clinical phenotype of patients with PH and SCD. Several screening cohort studies have focused on the prevalence, risk factors, and mortality rate of patients with SCD and PH diagnosed by right heart catheterization.

EPIDEMIOLOGY

Retrospective studies using Doppler echocardiography have demonstrated that 20% to 30% of patients with SCD have an elevated estimated pulmonary artery systolic pressure (PASP) that is two standard deviations above the normal mean value (tricuspid regurgitant jet velocity [TRV] ≥ 2.5 m/s). Approximately 8% to 10% have values three standard deviations above the normal mean (≥3.0 m/s).[64,90] These findings have been corroborated in several prospective studies.

In one study using echocardiographic screening, 23% of patients with SCD had borderline or mild elevations in PASP (defined by a TRV ≥2.5–2.9 m/s and corresponding to a PASP of approximately 30–39 mm Hg), and 9% had moderately to severely elevated pressures (defined by TRV ≥3.0 m/s, corresponding to a PASP of approximately 40–45 mm Hg).[26] Similar rates were found in other studies.[91–94]

In a study of patients enrolled in the MSH, plasma NT-proBNP, a prohormone released by right and left ventricular myocardium under pressure stress, was elevated in 30%, suggesting the presence of elevated pulmonary pressures and right heart strain.[11] Similarly, measurements of NT-proBNP in banked plasma from patients enrolled in the CSSCD from 1978 to 1988 revealed that 27.6% of adults had elevated levels.[12] In both studies, elevated study entry levels of NT-proBNP were independently associated with a higher risk of death in prospective follow-up.

Epidemiological risk factors associated with an elevated TRV include a history of renal or cardiovascular complications, increased systemic systolic blood pressure, abnormalities in markers of hemolytic anemia (anemia; reticulocytosis; and increased lactate dehydrogenase, aspartate aminotransferase, and bilirubin levels), iron overload, cholestatic liver dysfunction (elevations in alkaline phosphatase), renal insufficiency, a history of cutaneous leg ulceration, and, in men, a history of priapism.[11,26] These risk factors have also been observed in more recently published studies using right heart catheterization to diagnose PH.[93,95,96] Surprisingly, in these studies development of an elevated TRV was not associated with the number of vasoocclusive episodes, markers of inflammation, fetal hemoglobin levels, or platelet counts.[11,26] PH determined by right heart catheterization has also been shown not to correlate with episodes of vasoocclusive crisis or ACS, suggesting that this complication arises secondary to hemolytic anemia, rather than recurrent episodes of vasoocclusion. A large screening study of 483 patients with homozygous SS disease conducted in the United States and England reproduced these associations[97]; patients with elevations in Doppler-estimated PASP had more severe hemolytic anemia and renal insufficiency. These patients also had lower arterial oxygen saturation, higher levels of NT-proBNP, and lower 6-minute walk distances. A high Doppler-estimated pulmonary artery pressure was also independent of rates of vasoocclusive disease or ACS, providing further support to the hypothesis that this complication arises secondary to chronic hemolytic anemia and end-organ dysfunction (renal and liver disease), rather than episodes of ACS and related pulmonary fibrosis.

An elevated estimated PASP by Doppler-echocardiographic screening or right heart catheterization is a significant risk factor for death in patients with SCD. The risk appears to be linearly related to the elevation in PASP.[26] In one study, a 14% mortality rate over 2 years was reported in patients with an elevated TRV versus a 3% mortality rate in those with normal TRV.[92] Similarly, in another study, the mortality rate over 2.5 years was 25% in patients with an elevated TRV and less than 2% in those with a normal TRV.[91] Consistent with these data, in a cohort of 632 patients with SCD from the United States and England, 11.2% had TRV ≥3.0 m/sec and 24.1% had NT-proBNP level ≥160 pg/mL. Of 22 deaths during follow-up, 50% had a TRV ≥3.0 m/sec. At 24 months the cumulative survival was 83% with TRV ≥3.0 m/sec and 98% with TRV <3.0 m/sec. The hazard ratios for death were 11.1 (95% CI 4.1–30.1; p <0.0001) for TRV ≥3.0 m/sec, 4.6 (1.8–11.3; p = 0.001) for NT-proBNP ≥160 pg/mL, and 14.9 (5.5–39.9; p <0.0001) for both TRV ≥3.0 m/sec and NT-proBNP ≥160 pg/mL.[98]

Several studies have provided new insights into PH in SCD using the gold standard diagnostic test for the disease—right heart catheterization (Table 96-2).

In a screening study of over 500 patients followed for up to 9 years (median duration of follow-up, 4.4 years),[96] 86 patients underwent right heart catheterization; 56 were diagnosed with PH (10.5%). Similar findings were observed in another screening study of 80 patients (10% prevalence of PH using right heart catheterization).[93] A large screening study of nearly 400 patients with SCD in France[94] demonstrated a prevalence of PH (determined by right heart catheterization) of 6%.

The presence of PH, as documented by right heart catheterization, is a major risk factor for death in patients with SCD, with mortality rates ranging from 23% to 38%.[93,94,96] In one study, a 50% 2-year mortality rate was reported in patients with PH and SCD.[99] Each increase of 10 mm Hg in mean PAP was associated with a 1.7-fold increase in death rate. Autopsy studies suggest that up to 75% of patients with SCD have histological evidence of pulmonary arterial hypertension at the time of death (Fig. 96-3).[100]

Finally, specific hemodynamic predictors of mortality independently associated with mortality include increases in mean PAP, diastolic PAP, diastolic PAP–pulmonary capillary wedge pressure gradient, transpulmonary gradient, and pulmonary vascular resistance. These data strongly suggest that mortality in adults with SCD and PH is proportional to the severity of precapillary PH.[95]

PATHOGENESIS

An association between the development of PH and the intensity of hemolytic anemia has been observed in prospective screening studies of adult patients with SCD,[26,91,92,94,96,97] and in an expanding number of pediatric studies.[101–105] The association suggests that hemolysis is related mechanistically to PH.

Hemolysis releases plasma-free hemoglobin that inactivates the intrinsic vasodilator, NO,[24,25] and arginase-1, which depletes L-arginine, the substrate for NO synthesis.[23] The result of these combined pathological processes is decreased NO bioavailability and "resistance" to NO-dependent vasodilation.[25] In addition, the accumulation of redox-active heme and iron from lysed red blood cells contributes to the generation of reactive oxygen species that can exacerbate thrombosis and vascular proliferative responses.[106]

In situ thrombosis is well documented in patients with pulmonary arterial hypertension and chronic thromboembolism causes chronic thromboembolic PH. A correlation exists between the rate of hemolysis and levels of procoagulant factors in blood in patients with SCD.[107–109] In addition, hemolysis and decreased NO bioavailability induce platelet activation,[110] thrombin generation, and tissue factor activation, which would induce a procoagulant state.[111] Hemolysis is also associated with the formation of red blood cell microvesicles expressing phosphatidylserine, which activate tissue factor, a procoagulant mediator.[109,112]

Splenectomy has been reported to be a risk factor for development of PH,[113] particularly in patients with hemolytic disorders.[114–116] Thus, functional or surgical asplenia may contribute to development of PH in patients with SCD. In addition, loss of splenic function may trigger platelet activation, promoting pulmonary microthrombosis and red cell adhesion to the endothelium.[117] Patients with SCD also have increased levels of cell-free hemoglobin and red cell prothrombotic microvesicles. Following splenectomy, the rate of intravascular hemolysis increases.[109]

Additional mechanisms in the pathogenesis of PH in SCD may be operative. In patients with SCD at clinical baseline or during vaso-occlusive pain crises, plasma endothelin-1 levels are increased.[118] In vitro, sickled erythrocytes increase endothelin-1 production by cultured human endothelial cells. In addition, endothelin receptor A antagonism abolishes the vasoconstrictive effects of media obtained from pulmonary endothelial cells exposed to sickled erythrocytes on aortic rings.[118]

Finally, in theory, a high pulmonary artery pressure may result from the high cardiac output state associated with chronic anemia in SCD. However, this hyperdynamic state does not appear to be a major contributor to significant elevations in pulmonary artery pressure, as reports of PH associated with nonhemolytic anemias are lacking. Conceivably, a high cardiac output state, combined with hemolytic anemia and other risk factors, such as renal insufficiency and iron overload, conspire to drive pathological pulmonary vascular remodeling.

CLINICAL FEATURES AND EVALUATION

The diagnostic evaluation of patients with SCD suspected of having PH should follow the same guidelines established for other causes of PH.[119,120] Given the high prevalence of PH in this population and the associated high mortality, we recommend universal noninvasive screening of all adults using Doppler echocardiography,

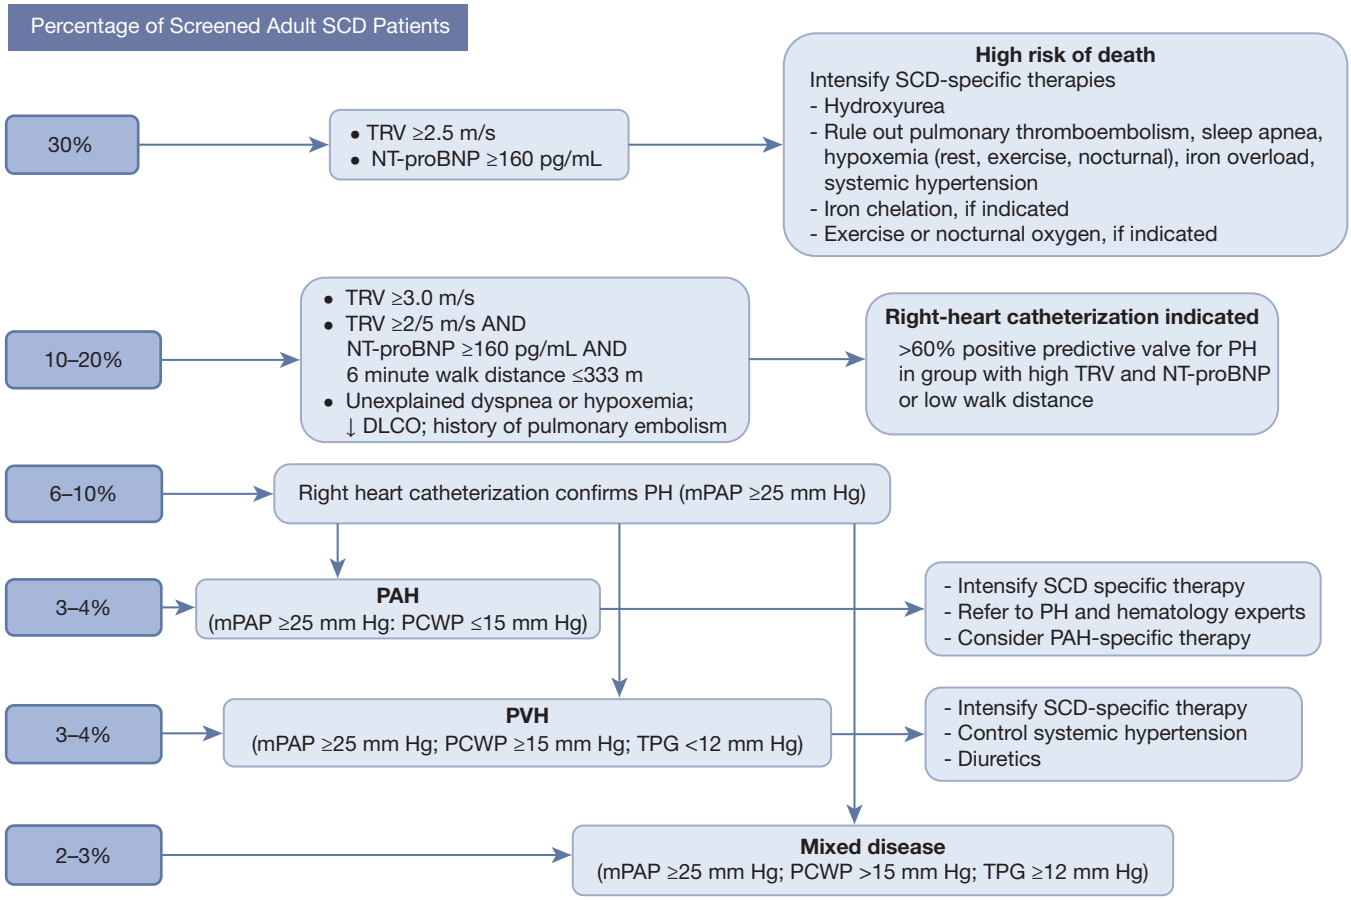

Figure 96-4 Pulmonary hypertension diagnostic algorithm. TPG, transpulmonary gradient; PCWP, pulmonary capillary wedge pressure. *(Reproduced with permission from Miller AC, Gladwin MT: Pulmonary complications of sickle cell disease, Am J Respir Crit Care Med. 2012;185(11):1154–1165.)*

measurement of steady-state plasma NT-proBNP levels, and assessment of functional capacity. In patients with SCD, the echocardiographic estimation of PASP (PASP = 4 × TRV^2 + estimate of the central venous pressure) correlates well with measured PASP by right heart catheterization.[26] While no prospective data on prevalence and risk of PH are available for children, we currently recommend that children with hypoxemia, high hemolytic rate (hemoglobin values <7 g/dL and high LDH), or recurrent ACS, be screened. Importantly, screening should be performed in the steady state, as pulmonary artery pressures rise during vasoocclusive painful crises.[121]

The Doppler echocardiogram is an important tool for population screening and estimation of pulmonary artery pressure, but it cannot be used to diagnose or define PH, which is based on measurement of mPAP via right heart catheterization. A TRV ≥2.5 m/s is associated with a very low specificity for the diagnosis of PH; only 25% of patients with a value greater than 2.5 m/s have PH.[94] A TRV ≥2.9 m/s is associated with a fairly high positive predictive value of 64%, but an unacceptably high false-negative rate of 42%. The positive predictive value for PH for a combination of a TRV ≥2.5 m/s, a high NT-proBNP level (>164.5 pg/mL), and a 6-minute walk distance <333 m is 62%; the false-negative rate is 7%. Based on these data, we propose a PH-screening algorithm for adult patients with SCD (Fig. 96-4).

The diagnosis of PH in patients with SCD may be challenging (Fig. 96-5). Exertional dyspnea, the most typical presentation of PH, is also a cardinal symptom of chronic anemia and other conditions commonly present in patients with SCD, such as left ventricular dysfunction, pulmonary fibrosis, and cirrhosis. Therefore, a high index of suspicion for diagnosis is necessary.

Patients with SCD and PH tend to be older, have higher systolic arterial blood pressure, lower hemoglobin levels, higher indices of hemolysis, lower hemoglobin–oxygen saturation, greater degrees of renal and liver dysfunction, and higher numbers of lifetime red blood cell transfusions.[26] Diagnostic evaluation should also include an aggressive search for other conditions that might contribute to PH, such as iron overload, chronic liver disease, HIV infection, nocturnal hypoxemia, and pulmonary thromboembolism. A diagnostic right heart catheterization is essential to confirm the diagnosis and to exclude diastolic dysfunction.[119] The 6-minute walk test is a useful surrogate for assessing functional capacity in this patient population and inversely correlates with the severity of PH.[122] In spite of this correlation, important to note is that in patients with SCD, noncardiopulmonary factors, such as concurrent pain and avascular necrosis of the hip, can interfere with test performance.

Measurement of NT-proBNP levels may be used as a PH biomarker for diagnosis and risk stratification in patients with SCD.[11] NT-proBNP levels are higher in patients with sickle cell–associated PH and correlate directly with the severity of PH and degree of functional impairment. An NT-proBNP level of 160 pg/mL or greater is associated with PH and is an independent predictor of mortality (risk ratio, 5.1; 95% CI, 2.1–12.5; $p < 0.001$).[11]

Most adult patients with SCD develop abnormal pulmonary function characterized by mild restriction (mean TLC approximately 79% of predicted), abnormal diffusing capacity, and radiographic signs of mild pulmonary fibrosis.[8,123–127] The severity of the defects seems to be slightly greater in those patients with PH.[122] However, in these patients, the degree of pulmonary function abnormalities is rarely severe enough to be a major contributor to the etiology of the PH.

A ventilation–perfusion scan is an indispensable component of the evaluation, since chronic pulmonary thromboembolic disease, if amenable to pulmonary endarterectomy is a potentially curable

form of PH in patients with chronic hemolytic disorders. In the majority of cases, observed scintigraphic evidence of thromboembolic disease is uncommon; the most commonly seen abnormalities are patchy areas of abnormal perfusion, similar to findings described in other forms of PH.[122,128] However, scintigraphic evidence suggestive of chronic thromboembolic PH occurs in approximately 5% of patients with SCD and severe PH,[121] and the PH has been successfully treated surgically in two patients (Fig. 96-6).[129] Consequently, patients should undergo imaging studies, and if findings are suggestive of chronic thromboembolic PH, additional invasive studies (i.e., angiography) are warranted to exclude a potentially surgically treatable condition.

HEMODYNAMIC PROFILES AND ETIOLOGY OF PULMONARY HYPERTENSION IN SICKLE CELL DISEASE

As previously discussed, as hemoglobin level decreases cardiac output increases, filling pressures tend to decrease and systemic and pulmonary vascular resistances decrease. In studies of patients with SCD undergoing right heart catheterization, the mean cardiac output and pulmonary vascular resistance for patients without PH were 10 L/min and 59 dyn s/cm^5, respectively.[31,99,122] It is within the context of these data that one must consider the impact of PH in chronically anemic patients with hemolytic disorders. As such, we believe that it is appropriate to consider a lower upper limit of "normal" pulmonary vascular resistance (such as <160 dyn-s/cm^5) in these patients.

In contrast to patients with traditional forms of pulmonary arterial hypertension (e.g., idiopathic, scleroderma associated), who are symptomatic with mean pulmonary arterial pressures in the range of 50 to 60 mm Hg, in patients with SCD the degree of elevation in mean pulmonary pressures is mild to moderate, in the range of 30 to 40 mm Hg, with mild elevations in pulmonary vascular resistance.[31,93,94,96,99,122] These patients also have coexistent mild elevation in pulmonary capillary wedge pressure, suggesting left heart failure.[31,93,94,96,99,122]

Right heart catheterization data from these multiple studies show that the hemodynamic etiology of the PH in patients with SCD is multifactorial: Pulmonary arterial hypertension (PAH: defined by an mPAP ≥25 mm Hg and a wedge pressure ≤15 mm Hg) is present in 50% of catheterized patients, while pulmonary venous hypertension secondary to left ventricular diastolic dysfunction (PVH: defined by an mPAP ≥25 mm Hg, a wedge pressure >15 mm Hg) is present in 50%.

DIASTOLIC DYSFUNCTION

In response to chronic anemia the left ventricle responds with an increase in stroke volume and chamber dilation. This response leads to increased wall stress and an increase in left ventricular

mass which, in turn, leads to impaired filling, which characterizes diastolic dysfunction. Using echocardiography in a cohort of 141 patients, Sachdev, et al. found that 47% had a high TRV, diastolic dysfunction, or both (29% had a high TRV alone, 11% had diastolic dysfunction and a high TRV, and 7% had diastolic dysfunction alone). An elevated TRV and diastolic dysfunction were associated with a relative risk of death of 5.1 (95% CI, 2.0–13.3) and 4.8 (95% CI, 1.9–12.1), respectively, while the relative risk of death when both were present was 12.0 (95% CI, 3.8–38.1), suggesting that both PH and diastolic dysfunction independently carry additive mortality risk.[130] In addition, in a series of 483 patients with homozygous SCD, markers of diastolic dysfunction were independently associated with a low 6-minute walk distance.[97]

EFFECTS OF PULMONARY HYPERTENSION ON EXERCISE CAPACITY

Patients with SCD appear to be poorly tolerant of even small additional increases in pulmonary artery pressure and pulmonary vascular resistance. When compared to age, gender, and hemoglobin-matched patients with SCD without PH, individuals with PH and mPAP of 36 mm Hg exhibit lower 6-minute walk distance (435 ± 31 vs. 320 ± 20 m; $p = 0.002$) and peak oxygen consumption (50 ± 3% vs. 41 ± 2% of predicted; $p = 0.02$) and higher ventilatory equivalent for CO_2 at anaerobic threshold (31.6 ± 1.5% vs. 39.2 ± 1.6; $p = 0.035$) on cardiopulmonary exercise testing (see Chapter 34).[122] In that study, the 6-minute walk distance was inversely correlated with pulmonary vascular resistance and mPAP, and directly correlated with maximal oxygen consumption, supporting the contribution of increasing pulmonary artery pressures to loss of exercise capacity. A lower exercise capacity (assessed by the 6-minute walk test) in patients with PH has also been demonstrated in larger cohorts of patients with SCD.[93,94,96,97] In addition, in patients with SCD, pulmonary artery pressure and pulmonary vascular resistance sharply rises with exercise, suggesting that pulmonary vascular disease contributes to functional limitation in these patients.[121] In aggregate, these data suggest that in patients with chronic anemia, mild-to-moderate PH has a severe adverse impact on functional and aerobic exercise capacity.

TREATMENT

There are limited data on the specific management of patients with SCD and PH, and most treatment recommendations are based on expert opinion or extrapolated from data derived from other forms of PH.[131] The general approach should include maximization of SCD-specific therapy (i.e., treatment of primary hemoglobinopathy), treatment of hypoxia with chronic oxygen therapy, treatment of associated cardiopulmonary conditions (such as iron overload, chronic liver disease, HIV infection, nocturnal hypoxemia, thromboembolic disorders, left ventricular disease). In patients with SCD with PAH (mean PAP ≥25 mm Hg and wedge pressures <15 mm Hg, with a relatively high pulmonary vascular resistance, e.g., >160 dyn-s/cm^5), PAH-specific therapy can be considered. There are no long-term data on the specific treatment of PH in SCD and the choice of agents is largely empirical and based on the safety profile of the drugs and physician preference. Therapy should be initiated and monitored by a team composed of a PAH specialist and a hematologist specializing in SCD care.

Hydroxyurea has been shown to decrease the incidence of pain episodes and ACS, to reduce the need for transfusions, and to lower overall mortality.[10,67] It is possible that some of the decreases in pulmonary and cardiovascular deaths seen in hydroxyurea-treated patients could be related to an improvement in PH. However, these considerations have to be balanced with the lack of association between fetal hemoglobin levels and the use of hydroxyurea, and protection against the development of PH.[26] For patients with creatinine levels less than 1 mg/dL hydroxyurea is started at a dose of 15 mg/kg/d and titrated up to a maximum of 35 mg/kg/d. Recent detailed treatment guidelines have been published.[68,132] Patients with renal dysfunction tend not to tolerate the myelosuppressant effects of hydroxyurea and in those cases, we recommend the addition of erythropoietin to the regimen. Long-term transfusion therapy lowers the risks of most complications of the disease, including the risks of pulmonary events and central nervous system vasculopathy[133–135]; and might improve cardiopulmonary function and prevent the progression of PH.

The potential benefits of warfarin therapy observed in patients with idiopathic pulmonary arterial hypertension[136] have to be weighed against the risk of hemorrhagic stroke in adults with SCD or hemorrhage in chronically anemic individuals. We believe that the relatively low risk of hemorrhagic stroke (0.21 events per 100 patient-years[137]) compared with the high risk of death in patients with severe PH supports anticoagulation in patients with hemodynamic evidence of pulmonary arterial hypertension or chronic thromboembolic PH and without a specific contraindication.

Sildenafil functions by inhibiting the metabolism of cyclic guanosine monophosphate, the second messenger that mediates the effects of NO. In a series of seven patients with either thalassemia or sickle thalassemia and severe PH treatment with sildenafil from 4 weeks to 48 months resulted in an improvement in TRV, New York Heart Association functional class, and 6-minute walk distance.[138] In another case series, twelve patients with SCD were treated with sildenafil for a mean of 6 months. Mean PASP decreased by 9 mm Hg (95% CI, 0·3–17; $p = 0·047$), 6-minute walk distance improved by 78 m (95% CI, 40–117; $p = 0·003$), mean BNP decreased by 448 pg/mL ($p = 0·002$).[139] These preliminary data were not supported by the results of the Walk-PHaSST study.[140] This 16-week, NIH-sponsored multicenter double-blind placebo-controlled trial of sildenafil in 74 patients with SCD with increased TRV and a low exercise capacity was stopped early, before enrollment of the planned 132 patients, due to a higher percentage of subjects experiencing serious adverse events in the sildenafil arm (45% of sildenafil, 22% placebo, $p = 0.022$). Subject hospitalization for pain was the predominant cause for this difference: 35% sildenafil versus 14% placebo ($p = 0.029$). Although the study was underpowered at the time it was stopped, there was no evidence of a treatment effect on 6MWD (placebo-corrected effect, −9 m; 95% CI, −56 to 38; $p = 0.703$), TRV ($p = 0.503$), or NT-proBNP ($p = 0.410$). Based on these findings, sildenafil and the other PDE5 inhibitors should not be used as first-line agents in patients with SCD and PAH. If used, it should only be in patients on chronic transfusion therapy or very well controlled with hydroxyurea, to limit the apparent effects of these agents on increasing pain.

The published experience with endothelin receptor antagonists in the treatment of PH is also very limited. Minniti, et al.[141] reported on the use of bosentan and ambrisentan in a cohort of 14 patients with SCD and PH documented by heart catheterization. Endothelin antagonist therapy either as monotherapy or in combination with sildenafil resulted in a modest improvement in 6-minute walk distance (baseline 357 ± 22 vs. 398 ± 18 m 6 months posttherapy, $p < 0.05$) as well as lowered NT-proBNP levels and estimated PASP. Adverse events while on therapy occurred in 7 of 14 patients, including increased serum alanine aminotransferase (2), increased peripheral edema (4), rash (1), headache (1), and decreased hemoglobin (2). Only two patients required treatment discontinuation, and few patients experienced multiple side effects. Two randomized multicenter placebo-controlled studies evaluating the role of endothelin receptor antagonism in patients with SCD have been conducted. The ASSET-1 and ASSET-2 studies enrolled patients with pulmonary arterial hypertension and pulmonary venous hypertension, respectively who were randomized to bosentan or placebo. After enrollment of 26 subjects the studies were terminated due to slow site activation and withdrawal of support by the sponsor. In that limited sample of patients bosentan was well tolerated with no significant differences in serious averse events or laboratory tests between patients receiving study drug or placebo but efficacy endpoints could not be formally analyzed.[142]

Prostanoid analogs are the most effective agents for the treatment of pulmonary arterial hypertension. Acute administration of epoprostenol decreases pulmonary artery pressure and pulmonary vascular resistance, and increases cardiac output in patients with PH and SCD,[99] but chronic therapy with these agents has not been described in the literature.

A case of severe pulmonary arterial hypertension related to pulmonary veno-occlusive disease has been reported in a patient with SCD. This patient failed medical therapy and underwent a successful bilateral lung transplantation.[143]

RESTRICTIVE LUNG DISEASE

Repetitive episodes of acute lung injury related to the ACS can result in parenchymal damage and restrictive lung disease (Fig. 96-7). In a study of 310 patients with homozygous SCD, pulmonary function was abnormal in 90% of adult patients.[144] The most common abnormal pattern was a mild restrictive pattern, found in 74% of those patients (TLC of 70 ± 15% predicted). An isolated decreased D_{LCO} was found in 13% (57 ± 20% predicted), persisted when corrected for hemoglobin, and negatively correlated with age. Evidence of obstructive lung disease occurred in only 3% of those studied. Although patients may present with advanced interstitial lung disease, these findings suggest that pulmonary fibrosis secondary to recurrent episodes of ACS tends to be mild in most cases.

SLEEP-DISORDERED BREATHING

Sleep-disordered breathing has been reported in both children and adults with SCD.[145–147] In children, sleep-related upper airway obstruction and hypoxemia are the most common disturbances. In an uncontrolled study, adenotonsillectomy led to symptomatic improvement and amelioration of oxygen desaturation.[148,149] A small study of autoadjusting continuous positive airway pressure (auto-CPAP) with supplemental oxygen also suggests that this therapeutic modality is well tolerated, safe, and effective in pediatric patients with SCD.[150]

Several lines of evidence suggest that nocturnal hypoxemia contributes to the development of neurological events and vasoocclusive crisis via mechanisms that could involve upregulation of several inflammatory endothelial adhesion molecules.[151–153] In addition, nighttime oxygen desaturation is associated with an increase in left ventricular mass and impaired diastolic function as evidenced by a study of 44 children with SCD.[154]

SUMMARY AND CONCLUSIONS

Pulmonary complications are a major cause of morbidity and mortality in patients with SCD and the burden of these complications are likely to become more prevalent as the life expectancy of these patients continues to increase.

Among the acute complications, ACS, which is often complicated by right heart failure, remains a major cause of death in children and adults with SCD. Fortunately, current strategies of early aggressive supportive therapy with antibiotics and red blood cell transfusion appear to have improved outcomes when compared with historical data.

PH is common and the most significant cause of death in adults with SCD. Although the etiology of PH is multifactorial in these patients, pulmonary arterial hypertension appears to be the main driver of morbidity and mortality. Additional studies evaluating pulmonary arterial hypertension–targeted therapy are needed in this complex and high-risk population.

CHAPTER 97

Pulmonary Disorders and Pregnancy

Ghada Bourjeily
Jeffrey Mazer
Andrew Levinson

INTRODUCTION

Nearly six million pregnancies are reported in the United States every year. A number of characteristics of the pregnant population appear to be changing over time. For example, women are becoming pregnant later in their reproductive lives. In addition, with advances in medicine and assisted reproductive technology, women with chronic medical conditions are now able to become pregnant. Consequently, pregnant women are now older and have more comorbid conditions than in past generations. Given the physiologic changes that occur during gestation, pregnancy can be an important stressor to chronic medical conditions. Notably, the health of the pregnancy may be a window into the mother's long-term health.

Labor and delivery constitute a major hemodynamic and respiratory challenge; hence, women with both acute and chronic conditions need to be managed by a multidisciplinary healthcare team, which may include a pulmonologist. This multidisciplinary team should address medical and obstetrical concerns, along with risks and benefits of anesthesia and analgesia, thereby ensuring appropriate management and anticipation of potential complications.

This chapter addresses core pulmonary and cardiovascular physiologic concepts before consideration of important, common clinical entities related to diagnosis and management in pregnancy.

THE PHYSIOLOGY OF PREGNANCY

While the normal physiologic changes of pregnancy are extensive, several areas are of central importance and are considered below. These include changes in respiratory and cardiovascular physiology, normal physiologic developments during labor and delivery, and determinants of fetal oxygenation and ventilation.

RESPIRATORY PHYSIOLOGY

During pregnancy, the respiratory system undergoes changes which range anatomically from the nasopharynx to the lungs.

The effects of increasing levels of estrogen on the nasal mucosa include edema, hyperemia, and glandular hypersecretion. The result is gestational rhinitis, which typically occurs in the last few weeks of pregnancy.

The subcostal angle of the rib cage and the circumference of the chest wall increase due to the effects of relaxin.[1] The diaphragm moves cranially about 4 to 5 cm.[2] These changes occur to accommodate the growing uterus. Diaphragm excursion does not decrease in pregnancy, despite the changes in chest wall configuration. However, due to the higher resting position of the diaphragm, the decreased downward pull of the abdomen, and the aforementioned chest wall changes, functional residual capacity (FRC) decreases by 20% to 30% by late gestation[3] and declines further in the supine position (Table 97-1).[4] The reduction in FRC may be somewhat attenuated when measured using body plethysmography,[5] likely due to the effect of early airway closure during tidal breathing and air trapping.[6] Inspiratory capacity increases and, therefore total lung capacity (TLC) is not significantly changed (Fig. 97-1).[7]

Despite a reduction in FRC and reduced nasopharyngeal caliber, air flow rates and airway resistance do not change in pregnancy, since pregnancy is associated with bronchial smooth muscle relaxation.[8] While the increased cardiac output of pregnancy (see Section "Cardiac Physiology") may increase diffusion capacity, the associated anemia of pregnancy offsets the effect. D_{LCO} is higher in the first trimester (after correcting for alveolar volume and hemoglobin), but it may decline later in pregnancy, reaching a nadir at about 24 to 27 weeks of gestation.[9]

Progesterone is a respiratory stimulant; consequently, minute ventilation in pregnancy increases by about 50% due to an increase in

TABLE 97-1 Physiologic Changes in Pregnancy

Respiratory Parameter	Change	Normal Range in Pregnancy
Arterial blood gas values		
pH	↑	Mild respiratory alkalosis
Pa_{O_2}	↑	Average 100–105
Pa_{CO_2}	↓	Average 28–32
HCO_3	↓	18–22 mEq/L
Alveolar–arterial O_2 gradient	↑	Increase in late gestation to approximately 20 mm Hg
Oxygen consumption	↑	20% increase, further increase during labor and delivery
Minute ventilation	↑	50% increase
Respiratory rate	↔	No change
Tidal volume	↑	40–50% increase
Total lung capacity	↓	4–5% decrease
Functional residual capacity	↓	20% decrease by term
Residual volume	↓	
Vital capacity	↔	
Diffusion capacity	↔	Minimal change
Forced expiratory volume in 1 s	↔	
Peak expiratory flow rate	↔	
Cardiac	**Change**	**Normal Range in Pregnancy**
Blood pressure	↓	10–15 mm Hg decrease in first two trimesters
Blood volume	↑	30–50% increase
Cardiac output	↑↑	5–7 $L/m^2/min$ (40% increase)
Central venous pressure	↔	<13 mm Hg
Colloid oncotic pressure	↓	10–15% decrease
Ejection fraction	↔	70%
Heart rate	↑	Increases by 10–20 bpm
Pulmonary artery pressure	↔	≤25 mm Hg
Pulmonary capillary wedge pressure	↔	<13 mm Hg
Stroke volume	↑	70–100 mL/beat
Systemic vascular resistance	↓	25–30% decrease

↑ Increase, ↓ Decrease, ↔ No change.

tidal volume. Although some studies suggest a progressive increase in minute ventilation during the course of pregnancy,[3] most studies show a sharp increase in the first trimester, with minimal rise after that.[10,11] The ratio of dead space to tidal volume (V_D/V_T) is unchanged in pregnancy, suggesting that dead space is actually also increased. Although the increase in cardiac output seen in pregnancy, coupled with resulting improved perfusion of the lung apices, would suggest that a reduction in dead space should occur, many studies suggest the opposite effect.[12,13]

Arterial oxygen tension increases in pregnancy to about 100 to 105 mm Hg, thereby facilitating oxygen transfer across the placenta.[13] Carbon dioxide tension decreases in pregnancy to 27 to 32 mm Hg, with a resultant increase in bicarbonate excretion and elevation in arterial pH to approximately 7.42 to 7.46. Both Pa_{CO_2} and HCO_3 are mildly lower in the third trimester compared to the first trimester.[14] The chronic respiratory alkalosis of pregnancy causes a rightward shift of the oxyhemoglobin dissociation curve, facilitating oxygen transfer across the placenta.

CARDIAC PHYSIOLOGY

In parallel with growth of the fetus and the accompanying increase in maternal oxygen consumption, pregnancy is accompanied by profound cardiovascular changes. Plasma volume and cardiac output progressively increase throughout gestation and are approximately 30% to 50% higher[15] at term (Fig. 97-2).[16] Heart rate also increases by 20 to 30 beats per minute. Systemic vascular resistance decreases, with a resultant drop in blood pressure in the first half of pregnancy. Despite the increase in cardiac output, pulmonary artery pressures do not change significantly[17] due to a decrease in pulmonary vascular resistance (PVR). Oxygen consumption is increased approximately 20% above prepregnancy levels; the rate of increase in oxygen consumption is faster in pregnant women compared to nonpregnant women performing weight-bearing exercises.[18]

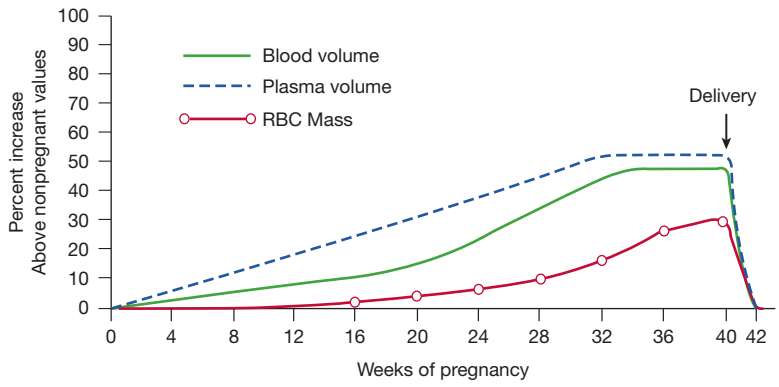

Figure 97-2 Physiologic changes in blood volume, plasma volume, and erythrocyte mass in pregnancy.

LABOR AND DELIVERY

Labor and delivery are associated with additional respiratory and cardiac physiologic changes. Pain, due to contractions and anxiety, leads to increases in oxygen consumption and minute ventilation. Increased minute ventilation leads to further reduction in Pa_{CO_2} which, in cases of tenuous placental reserve, may reduce placental perfusion. In addition, in women with poor respiratory reserve, such as those with poorly controlled asthma or restrictive pulmonary physiology, the additional increase in minute ventilation may lead to respiratory decompensation and respiratory failure. Pain control may help minimize these effects. However, the use of systemic opiates can lead to respiratory depression, whereas targeted regional anesthesia – thereby avoiding an effect on respiratory muscles – may prevent these adverse effects. Physiologic changes occurring in pregnancy quickly reverse in the postpartum period.

Cardiovascular changes in labor, delivery, and the postpartum period include an additional 10% to 15% increase in cardiac output in early labor, with further increases of up to 50% in the second stage of labor.[19] The changes are mediated by autotransfusion, in which 300 to 500 mL of blood is shunted into the systemic maternal circulation with every uterine contraction,[20] and by pain and anxiety.[21,22] Analgesia attenuates the changes. In addition, in the postpartum period, relief of aortocaval compression by the uterus results in an increase in venous return; autotransfusion from the contracting uterus further increases cardiac output. Women with underlying cardiac or pulmonary vascular disease may not tolerate the physiologic changes of labor and delivery. Although scheduled Cesarean-section deliveries may appear to be an attractive option for women with chronic pulmonary or cardiac disease (since they may eliminate the pain and anxiety of contractions), Cesarean-section

deliveries are unlikely to improve outcomes, since autotransfusion occurs with both vaginal and operative deliveries. Furthermore, the immediate fluid shifts that occur in the postpartum period are similar with both vaginal and Cesarean-section deliveries. In addition, operative deliveries are associated with higher rates of surgical and medical complications compared with vaginal deliveries.

FETAL OXYGENATION AND VENTILATION

Uterine blood flow constitutes about 17% of the total cardiac output.[23] The placental vessels are low-resistance, high-capacitance vessels that function at maximal capacity at baseline. Therefore, when a hemodynamic insult occurs, the placental circulation cannot further vasodilate.

Supine positioning in late pregnancy may be associated with significant reduction in cardiac output and may alter the uterine circulation. Fetal oxygenation, like oxygenation of maternal organs, depends on maternal cardiac output, maternal oxygenation, and the fetal oxyhemoglobin dissociation curve. In addition, characteristics of the placenta affect diffusion of oxygen across this organ.

The fetus displays many protective mechanisms for maintaining adequate oxygenation. For example, fetal hemoglobin, which lacks beta chains, is less sensitive to the effects of 2,3-DPG than is adult hemoglobin. Consequently, the fetal oxyhemoglobin dissociation curve is shifted to the left, reflecting an increased oxygen affinity. The fetus also appears to have the ability to shunt blood to vital organs and to decrease oxygen consumption during periods of hypoxia. Despite these protective mechanisms, placental health has an important role in effecting oxygen transport to the fetus.[24]

Clinical conditions that cause a reduction in cardiac output or uterine blood flow (e.g., shock, use of vasoconstricting drugs), oxygen content (e.g., anemia, hypoxemia), oxyhemoglobin saturation (e.g., severe alkalosis, presence of carboxyhemoglobin), or placental perfusion may result in poor fetal oxygenation. Human studies on the optimal maternal oxygen level needed to achieve favorable fetal oxygenation are scarce. Based on available animal data, experts recommend that maternal oxygenation be maintained above a Pa_{O_2} of 70 mm Hg and an oxygen saturation of greater than 95%.

Finally, a gradient for CO_2 of approximately 10 mm Hg between fetal and maternal circulations exists (higher level in the fetus), facilitating CO_2 clearance from the fetal circulation. This fact may influence how best to use permissive hypercapnia in patients who might benefit from this ventilatory strategy. Fetal hypercapnia results in rapid fetal acidemia, increases in intracranial pressure, and a rightward shift of the oxyhemoglobin dissociation curve.

DIAGNOSTIC IMAGING OF THE PREGNANT WOMAN

Use of ionizing radiation is a major concern for most clinicians evaluating a pregnant patient. Risks that need to be considered when ordering an imaging study that involves the use of ionizing radiation are the risk of malignancy and the risk of teratogenicity.

The risk of oncogenicity follows a stochastic effect (nonthreshold effect), suggesting that the risk of malignancy may occur even at low levels of exposure. Based on atomic bomb survivor data, the risk of malignancy following high-dose exposures is indisputable; however, the risk following low doses associated with diagnostic testing is more controversial. This risk is not evenly distributed, as recent data suggest a lower risk of cancer when exposure occurs in utero compared to exposure in childhood.[25]

The risk of teratogenicity, however, does follow a threshold effect. Based on animal and human studies of radiation exposure, a threshold has been determined for congenital malformations and miscarriage. For diagnostic tests resulting in a fetal exposure of 10 cGy or less, the risk of radiation to the embryo is very small when compared to the spontaneous risk. More conservative opinions suggest aiming for a maximum exposure of 5 cGy. With the exception of computed tomography venography, radiation exposure from imaging procedures used for the workup of a patient with a suspected or diagnosed respiratory disorder does not exceed 5 cGy (Table 97-2).[26] As the risk of radiation below 10 cGy is miniscule, medical care of the mother takes priority over the risks of diagnostic radiation exposure to the fetus.[27]

TABLE 97-2 Radiation Exposure to the Fetus Associated with Various Diagnostic Procedures

Diagnostic Test	Radiation Dose (cGy)
Chest radiography	<0.001
Ventilation scintigraphy[28]	0.028–0.051[a]
Perfusion scintigraphy[28] (half dose)	0.014–0.025
CT pulmonary angiography[29]	0.0003–0.0131
Conventional pulmonary angiography	<0.05 via brachial route 0.2–0.3 via femoral route
CT venography	>5
Conventional venography	0.6
Chest Fluoroscopy[27]	<0.01 cGy/min
IR abdominal fluoroscopy[27]	0.6 cGy/min
PET[27]	0.8–1.6

CT, computed tomography; PET, positron emission tomography.
[a]Dependent on agent used.

Another consideration in diagnostic imaging studies includes use of contrast agents. Iodinated contrast media are small molecules that are known to cross the placenta and carry a potential risk of thyroid dysfunction in utero. However, in a study of 350 women who received iodinated contrast in pregnancy, none of the babies born had any significant thyroid dysfunction.[30] The study was, however, performed in the northeast United States, an area where iodine deficiency is rare. Use of iodinated contrast is, therefore, certainly justifiable. However, iodine reserve, timing of the study in pregnancy, and maternal renal function should be considered. Gadolinium is usually used with nonionizing radiation imaging studies and is known to cross the placenta.[31] The effect of gadolinium on the growing fetus is unknown, as human safety data are not available. Hence, use of gadolinium should be reserved for cases where benefit outweighs the potential unknown risk of gadolinium exposure.

Diagnostic studies involving radionuclides expose the fetus to radiation differently than external radiation. Given that radionuclides are excreted by the kidneys and may pool in the bladder, continuous exposure to the fetus may occur after the study has been completed.

PHARMACOTHERAPY CONSIDERATIONS IN THE PREGNANT PATIENT

Over-the-counter drugs and prescription medications are frequently used during pregnancy. Although a number of drugs have been clearly shown to be either teratogenic or safe in pregnancy, insufficient safety data exists for most. Most data on safety for a given drug in pregnancy are based on animal studies, case reports or series, case-control studies, or pregnancy registries. Prospective studies evaluating safety are scarce. Establishing risk is challenging, since a baseline risk of malformation exists for any pregnancy. To clearly define a teratogenic risk, a recurrent syndrome of abnormalities needs to be demonstrated. In addition, in many cases it may be hard to tease out the effect of the medication from the effect of

the disease. Justification of randomization to treatment or placebo groups during pregnancy is challenging. An informed decision by the patient, formulated in the context of discussion with the physician, is key. Integral to the discussion is the patient's understanding of the limitations of the available data and the intricacies of pharmacotherapy in pregnancy.

Placental transfer of medications and their risks depend on maternal drug metabolism, drug molecular size, drug ionization, the agent's lipid solubility, and maturity of the fetal target organ. As a general rule, most drugs cross the placenta. Although most consider the period beyond embryogenesis a safe timeframe to use medication, it is important to recall that the fetal nervous system continues to develop throughout gestation. For this reason, fetal neurologic and behavioral development and function of various organs, such as thyroid or kidney, may be affected by medications administered after the first trimester. Physiologic changes of pregnancy, such as increased plasma volume, increased glomerular filtration rate, and hypoproteinemia may affect medication bioavailability.

The categories of drug safety in pregnancy used by the US Food and Drug Administration (FDA) have several well-established shortcomings. For example, since teratogenicity is not species specific, supportive evidence from human and animal data should not be given equal weight. The risk of drugs in a given category may not be comparable. For instance, drugs in category C either have been shown to demonstrate evidence of adverse effects in animals or lack available animal data. In addition, adverse fetal effects are not all equal, and a mild reduction in fetal weight should not be considered equivalent to a major congenital anomaly. Finally, the FDA categorization does not take into account the risk of the untreated disease. Therefore, the decision for using a drug should be based on principles of efficacy and safety and should encompass consideration of medication risk versus risk of untreated disease. For example, use of a category C drug in a life-threatening situation may be reasonable, whereas use of a category B drug for a self-limited condition, such as an upper respiratory infection, may not.

Breastfeeding is associated with significant benefits to newborns, such as a lower risk of obesity, diabetes, and cardiovascular disease, among others,[32–34] and consideration of drug passage into breast milk is an important consideration. A variety of factors influence drug passage to the neonate. For example, drugs with no oral absorption by the neonate are unlikely to cause systemic effects. Drug levels in breast milk are proportional to those in the maternal serum. Hence, breast milk drug levels vary with timing of maternal drug intake. Drugs with the highest protein binding and lowest lipid solubility are preferable for breastfeeding women.[35] Table 97-3 summarizes data on commonly used drugs in pregnancy and lactation.

INTERVENTIONAL PROCEDURES IN PREGNANCY

Indications for interventional procedures in pregnancy are no different than in the nonpregnant population. In the general population, most interventional procedures are not delayed if they are anticipated to be of clinical importance in patient management. Similar logic should be applied in pregnancy. As with any intervention, the risk of the intervention should be weighed against the risk of an inappropriate diagnosis or untreated disease. For example, the risk of bronchoscopy in pregnancy may be related to the procedure itself, as well as to the sedatives used during the procedure. Medication effects may be even more pronounced in the pregnant patient, given the altered physiology of pregnancy, including drug distribution, response to sedatives, and decreased airway patency. However, the risk is usually minimal.

In pregnant women, an upper airway evaluation should be performed prior to every procedure, given the higher risk of intubation failure in pregnancy. Risk of aspiration may also be increased because of a decrease in lower esophageal and increase in intra-abdominal pressures. To minimize the risk of hypotension and hemodynamic instability during procedures performed in the second half of pregnancy, patients should be positioned supine with a left tilt to relieve the compression of the inferior vena cava by the gravid uterus.

Given the risk of hypoxemia with bronchoscopy,[41] especially when bronchoalveolar lavage is performed,[42] oxygenation should be monitored routinely and supplemental oxygen administered as needed to keep oxygen saturation above 95%. Fetal monitoring should be discussed with the obstetric team; however, in general, fetal monitoring prior to 28 weeks of gestation can be unreliable and difficult to interpret, while monitoring prior to 24 weeks is likely unnecessary.[43] Since pregnant women may more quickly develop hypercapnia and hypoxemia than nonpregnant women,[44] smaller doses of sedation might be considered. Midazolam, meperidine, fentanyl, and lidocaine have not been reported to be associated with congenital malformations.[45]

Fluoroscopy during bronchoscopy can be used in pregnancy, given the low dose of radiation associated with its use (Table 97-2)[26] and the fact that the fetus is not in the radiation field. A discussion with the institution's medical physicist can help keep radiation exposure to a minimum.

Pleural procedures can also be performed in pregnancy, but providers should keep in mind the potential 4 to 5 cm cranial displacement of the diaphragm during pregnancy. Ultrasound guidance may help minimize risks of the procedure.

SMOKING DURING PREGNANCY

Estimates are that 22% of women of reproductive age in the United States smoke. Data from Europe and the United States show that 10.7% to 13.1% of fetuses are exposed to maternal smoking. Although about half of women smokers quit during pregnancy, many start smoking again after delivery. In 1993, the estimated annual cost of maternal conditions attributable to smoking in pregnancy, including the protective effect against preeclampsia, was between $135 and $167 million.[46,47]

Smoking is associated with adverse fetal outcomes. Various mechanisms may be responsible. Placentas from smokers have reduced capillary volume and increased thickness of villous membranes.[48–50] Carboxyhemoglobin is cleared slowly from the fetal circulation and competes with fetal oxyhemoglobin. Amniocytes from smokers have an increased incidence of structural chromosomal abnormalities compared with nonsmokers.[51] In addition, nicotine promotes platelet activation, impairs estrogen synthesis, and can directly impair lung development due to interaction with nicotinic acetylcholine receptors.

Smoking is associated with placental abnormalities, premature rupture of membranes, decreased thyroid function, psychiatric illness, reduced fertility, and conception delay,[52–56] as well as decreased production of milk volume, and lower rates and shorter duration of breastfeeding.[57] Prospective[58] and retrospective studies[59] confirm an association of fetal growth restriction with smoking during pregnancy, even in the first trimester.[60] Both active and secondhand smoke exposures are associated with increased risk of first trimester pregnancy loss.[61]

Babies born to pregnant smokers are also at risk for preterm birth.[62] The association of smoking with a risk of congenital anomalies[63] is a complex issue and may be closely related to maternal genotype. Maternal smoking during pregnancy is also associated with adverse cognitive and behavioral outcomes in the offspring, such as low scholastic achievement, attention deficit and hyperactivity disorder, conduct disorder, regular smoking,[64] wheezing, and asthma.[65] Childhood exposure to secondhand smoke is associated with upper and lower respiratory tract infections, ear infections, sudden infant death syndrome (SIDS), and asthma.[66–68]

Smoking cessation at any point during pregnancy is likely associated with some benefit.[69] Pregnancy offers a unique opportunity for smoking cessation, given the mother's motivation for fetal

well-being and her frequent contact with healthcare providers. Women should be screened for secondhand smoking exposure, as well as potential abuse of other substances and comorbid psychiatric illness. Women should also be followed for smoking abstinence into the postpartum period, given the high rate of smoking relapse.

Pharmacotherapy can be used in pregnancy, but data regarding efficacy and safety are scarce. The US Preventive Services Task Force states that the use of pharmaceuticals has not been sufficiently evaluated to determine their safety or efficacy in pregnancy.[70] Data on nicotine replacement therapy shows conflicting evidence with regard to safety.[71,72] Many trials have been halted in the United States because of either adverse effects or failure to demonstrate effectiveness.[73,74] The Danish National Birth Cohort of 72,761 women showed no significant association between type or duration of nicotine product use and birth weight.[75] Overall, the risk from various chemicals in cigarette smoke likely outweighs the small risk of possible weight reduction from nicotine pharmaceuticals.

Although animal data on the safety of use of varenicline in pregnancy are available, human data are lacking. Varenicline is likely transferred through breast milk; however, data are not available. Bupropion has not been associated with an increase in congenital defects in experimental animal studies. However, pregnancy registry data for bupropion calls attention to a possible association with congenital heart defects.[76] Although bupropion is passed to the fetus in breast milk, based on measurement of infant plasma levels, the dose transmitted is unlikely to be clinically significant.

MANAGEMENT OF ASTHMA DURING PREGNANCY

Asthma is the most common respiratory disease of pregnancy, affecting 4% to 8% of all pregnancies in the United States and almost 12% of pregnancies in the United Kingdom and Australia. Asthma may improve, worsen, or remain unchanged in pregnancy.[77] Predictors of disease course include prepregnancy asthma severity, race, presence of obesity, compliance with medication use, and patient difficulties in accessing antenatal care. Factors contributing to modifications of disease severity include a number of pregnancy-associated conditions: higher prevalence of gastroesophageal reflux disease,[78] nasal congestion,[79] alterations in immunity, and hormonal factors.[80] The rate of asthma exacerbations is increased between 17 and 32 weeks of gestation.[77,81] Improvement in the last few weeks of pregnancy may be related to significantly higher cortisol levels compared with preconception levels.

Poorly controlled asthma may negatively impact some maternal and fetal outcomes. In the largest study performed to date, asthmatic women were more likely to have pregnancies complicated by miscarriage, antepartum and postpartum hemorrhage, anemia, or depression.[82] In a retrospective cohort study performed in 12 clinical centers in the United States, asthmatics experienced increased risk of preeclampsia; gestational diabetes; preterm births, including spontaneous preterm birth; and induced preterm birth.[83] A systematic review of nine studies has shown an increased risk of preterm birth, small for gestational age and low birth weight if the mother has asthma.[84] Babies born to asthmatic mothers may be more likely to have congenital anomalies.[85,86]

Since pregnancy does not affect air flow rates, reductions in peak expiratory flow rate (PEFR) should prompt quick medical evaluation. In a multi-institutional prospective study, lower forced expiratory volume in 1 second (FEV_1), but not symptom control, was associated with adverse perinatal outcomes.[87] These data may be related to the fact that, given the high prevalence of physiologic dyspnea in pregnancy, symptom interpretation both by providers and patients may be difficult without objective measures; hence, the need for close physiologic monitoring is apparent.

Most medications used to treat asthma are safe for use in pregnancy (Table 97-3). An important message to patients is that good asthma control is the main goal, and the risk of medication use is lower than the risk of adverse outcomes from untreated or poorly treated disease. Recent evidence from a double-blind, randomized, controlled trial suggests that pregnant women managed according to a validated treatment algorithm based on measurements of exhaled nitric oxide (FeNO) had fewer exacerbations compared with those treated according to a symptom-based approach.[88]

Patients with more severe disease, or those who suffer an exacerbation close to term, require a detailed labor and delivery plan. Stress dosing with corticosteroids during labor should be considered in patients who have been on prolonged courses of systemic steroids during the pregnancy. Patients with active symptoms or more severe asthma may benefit from regional anesthesia aimed at reducing minute ventilation and oxygen consumption and preventing hyperinflation. If general anesthesia is considered, ketamine and halogenated anesthetics are preferred. Oxytocin and prostaglandin E2 are safe to use. However, other prostaglandins used for induction of labor and morphine and meperidine should be avoided, since they may cause worsening bronchospasm.

CYSTIC FIBROSIS AND PREGNANCY

Cystic fibrosis (CF) impacts fertility in both men and women. Women with CF have various reproductive system abnormalities. Since the CF transmembrane conductance regulator (CFTR) is present in reproductive organs, cervical mucus is thicker and more tenacious, leading to obstruction of the cervical os and impaired sperm penetration. Despite these changes, fertility occurs in women with CF, and affected women should be counseled regarding contraception. Women with higher body weight and higher FEV_1 are more likely to desire and achieve pregnancy.[89] Genetic screening of both mother and father can help assess the risk of CF in the offspring. Preimplantation genetic diagnosis can be performed during assisted reproduction and may help detect embryos affected by the disorder.

In two series reporting on 72 and 90 pregnancies in patients with CF, the need for intravenous antibiotic therapy was 65% to 77%, and higher rates of hospitalization compared to nonpregnant patients were reported.[90,91] FEV_1 may decline during pregnancy in CF, and then improve in some patients following delivery.[92] However, in larger case-controlled series, the FEV_1 decline appears similar to that experienced by nonpregnant patients with CF.[90,93] Reduced FEV_1 appears to be a predictor of adverse outcomes in pregnancy in CF,[91] including early mortality following delivery. Other predictors of decreased survival include maternal colonization with *Burkholderia cepacia* and pancreatic insufficiency.

Increased energy expenditure in pregnancy makes weight gain more challenging. Glucose intolerance and gestational diabetes occur as a result of decreased insulin production, impaired insulin sensitivity, and increased hepatic glucose production.[93,94] Multiple studies have shown an increased risk of preterm delivery,[90,95] possibly related to altered lung function. The risks of fetal demise and birth defects are likely similar to controls.[90,91,93]

Azithromycin, penicillins, and cephalosporins are safe to use in pregnancy. In animal studies, use of fluoroquinolones may be associated with increased risk of abnormal cartilage development; similar effects have not been observed in human studies.[96] Use of tetracyclines is hard to justify in pregnancy, since they result in tooth and bone discoloration. Rifamycins are associated with an increased risk of fetal damage and bleeding in both mother and neonate.[97] Dornase use has been described in pregnancy,[98] but safety data are limited. Safety data on use of pancreatic enzyme replacement therapy are limited,[99,100] but use is likely justifiable. Vitamin replacement can be used in pregnancy; however, vitamin A supplementation should not exceed 10,000 U daily because of teratogenic effects. Although sulfonylureas are likely safe in pregnancy, they are associated with an increased risk of fetal hypoglycemia. Insulin is the preferred glucose-lowering drug.

TABLE 97-3 Drug Safety in Pregnancy and Lactation

	Pregnancy	Lactation
Ambrisentan	Ambrisentan is expected to be teratogenic, given its mechanism of action and known teratogenicity in animal studies. No human data.	Infant risk cannot be ruled out. It is not known whether ambrisentan is excreted into human milk. **AAP:** Not reviewed
Amoxicillin/ Clavulanate	Amoxicillin/clavulanate is acceptable for use during pregnancy. Penicillins are generally considered to be safe for use in nonallergic patients during pregnancy.	No harmful effects have been reported. **AAP:** Maternal Medication Usually Compatible with breastfeeding **Lactation Risk Category:** L1
Azathioprine	Based on human case series, azathioprine is unlikely to increase the risk of congenital anomalies.	Caution is recommended. Monitor the infant closely for signs of immunosuppression, leukopenia, thrombocytopenia, hepatotoxicity, pancreatitis, and other symptoms of 6-mercaptopurine exposure. The risks to the infant are probably low. Recent long-term data suggest that the rate of infections in treated groups is no different from nontreated controls. **Lactation Risk Category:** L3
Beta agonists	Albuterol is listed as preferred beta agonist in 2004 NIH report on treatment of asthma in pregnancy. High doses (32 mg/d) of oral albuterol appeared to prolong gestation in a population of 132 pregnancies.[36] Various birth defects were described in association with albuterol and may have been due to chance. Salmeterol is not expected to increase the risk of congenital malformations. Formoterol is not expected to increase the risk of malformations, but human data are inadequate.	Safe to use in breastfeeding mothers. Use via inhalation is recommended. **AAP:** Not reviewed **Lactation Risk Category:** L1 Safe to use in breastfeeding women. Levels in breast milk very low to undetectable. **AAP:** Not reviewed **Lactation Risk Category:** L2
Bosentan	Bosentan is believed by its manufacturer to increase the risk for congenital anomalies in humans, based on rodent studies and the known mechanism of action of the medication.	No data are available on the transfer into human milk, but based on its structure, bosentan levels in the milk compartment would probably be very low. However given 50% oral bioavailability and high incidence of liver toxicity, great caution is recommended with this product in breastfeeding mothers until we have published milk levels. **Pediatric Concerns:** No data are available. May be dosed down to children weighing at least 22 lb. **Lactation Risk Category:** L4
Budesonide Inhaler	No association with congenital birth defects. Children exposed to inhaled steroids are more likely to develop endocrine, metabolic, and nutritional disorders.	Unlikely clinically relevant concentrations of budesonide reach breast milk. **Lactation Risk Category:** L1
Bupropion (Wellbutrin)	Bupropion has not been associated with an increased risk of congenital defects; however, pregnancy registry data have called attention to a possible weak association with congenital heart defects (not confirmed in other studies).	Bupropion may, in some women, suppress milk production. Some caution is recommended concerning changes to milk supply. **AAP:** Drugs whose effect on nursing infants is unknown but may be of concern
Cephalosporins	Cephalosporins may cross into the fetal circulation in small amounts, but teratogenicity has not been attributed to these agents.	As a highly protein-bound group, the cephalosporins do not pose a significant risk to the nursing infant.
Cyclosporin	Experimental animal studies do not predict an increase in congenital anomalies after pregnancy exposure to cyclosporines. A limited number of human cases are also reassuring.	Cytotoxic drug that may interfere with cellular metabolism of the nursing infant. Close observation of the infant including monitoring of the infants' plasma levels. **AAP:** Possible immune suppression; unknown effect on growth or association with carcinogenesis **Lactation Risk Category:** L3
Epoprostenol sodium	It is unknown if epoprostenol shares any of the abortifacient properties of other prostaglandins. Should it be determined that it does, its use in pregnant women would be strictly contraindicated; therefore, use should be avoided if possible.	Unknown **AAP:** Not reviewed **Lactation Risk Category:** L3
Gentamicin	Ototoxicity and nephrotoxicity in the fetus are theoretical possibilities that have not been confirmed clinically. This agent is known to cross the human placenta at term, but its use is likely justifiable in certain conditions.	**AAP:** Compatible with breastfeeding **Lactation Risk Category:** L2
Iloprost (Ventavis)	No epidemiologic studies of congenital anomalies among infants born to women who were treated with iloprost during pregnancy have been reported. Iloprost has been shown to be teratogenic in rats due to its systemic circulatory effects.	It is not known whether iloprost appears in milk. Increased mortality of nursed rat pups was reported and manufacturer recommends discontinuing nursing in women being treated with iloprost.

TABLE 97-3 Drug Safety in Pregnancy and Lactation *(Continued)*

	Pregnancy	Lactation
Ipratropium bromide	Based on animal studies, ipratropium is not expected to increase the risk of congenital malformations.	Transfer into breast milk in exceedingly small and clinically insignificant levels. **Lactation Risk Category:** L2
Linezolid	Linezolid does not cause congenital malformations in mice and rats, even at high doses. There are no human data.	Minimal human data available. Linezolid is transferred to breast milk with a likely maximal dose of 2 mg/kg daily (with maximal dose for infants being 30 mg/kg daily). **Lactation Risk Category:** L3
Macrolide antibiotics	*Erythromycin* use during pregnancy is unlikely to increase teratogenic risk to the infant, including cardiac and gastrointestinal defects. *Clarithromycin* may increase the risk of adverse pregnancy outcome. In a series of observational studies, *azithromycin* did not cause an increased rate of congenital anomalies when used during pregnancy.	Pyloric stenosis has been reported associated with the use of erythromycin early postpartum. **AAP:** Usually Compatible with breastfeeding **Lactation Risk Category:** L3
Methotrexate	Methotrexate increases the incidence of congenital anomalies in experimental animals and appears to do so in humans as well. Methotrexate is used clinically as an abortifacient[37–39] and in the treatment of ectopic pregnancy. One study indicates a higher risk of fetal malformation in mothers who received methotrexate months prior to becoming pregnant.[40] Therefore, pregnancy should be delayed for at least 3 mo following therapy if either partner is receiving methotrexate.	Methotrexate is believed to be retained in human tissues (particularly neonatal gastrointestinal cells and ovarian cells) for long periods (months). It is apparent that the concentration of methotrexate in human milk is minimal, although due to the toxicity of this agent, it is probably wise to pump and discard the mother's milk for a minimum of 2–4 d. **AAP:** Possible immune suppression; unknown effect on growth or association with carcinogenesis; neutropenia. **Lactation Risk Category:** L3
Nicotine replacement	Nicotine therapy may decrease fetal growth similar to smoking. Some types are however beneficial regarding cigarette consumption, gestational age, and birth weight.	Nicotine is secreted into human milk. Use of replacement products is compatible with breastfeeding. **AAP:** Not reviewed **Lactation Risk Category:** L2
Omalizumab	Data in monkeys are reassuring, but currently, there are no human data. Pregnancy registry exists.	Omalizumab may be secreted into human milk but levels likely very low. Oral bioavailability extremely low. **AAP:** Not reviewed **Lactation Risk Category:** L3
Penicillin	Penicillins are not believed to increase adverse pregnancy outcome. Penicillins accumulate in amniotic fluid during maternal ingestion. No adverse fetal effects have been associated with this process.	Usually compatible with breastfeeding Penicillins are excreted into human milk in small amounts with possible alterations in bowel flora and potential risk of allergic sensitization in the infant.
Prednisone	Prednisone and other glucocorticoids are associated with fetal growth impairment in humans. Prednisone is metabolized by the placenta to a large extent, and minimal doses reach the fetus. Other steroids, such as betamethasone, are less well metabolized by the placenta and are used to enhance lung maturity in pregnancies expected to end preterm. These medications increase oral clefting in experimental animals and may do so in humans in early pregnancy exposure.	Small amounts of most corticosteroids are secreted into breast milk. With prolonged high dose therapy, the infant should be closely monitored for growth and development. **AAP:** Usually Compatible with breastfeeding **Lactation Risk Category:** L2
Quinolones	Quinolones are avoided during pregnancy due to cartilage toxicity demonstrated in experimental animals. Human data are not supportive.	Quinolones are secreted in milk. Infants should be observed for changes in gut flora, Candida overgrowth, or diarrhea. The use of quinolones in the pediatric population is increasing due to minimal evidence of cartilage toxicity. **AAP:** Not reviewed **Lactation Risk Category:** L2
Sildenafil	Based on experimental animal studies, sildenafil does not appear to increase the risk of congenital malformations in exposed pregnancies.	There is insufficient data to determine the safety of sildenafil in human lactation.
Tacrolimus	Based on experimental animal studies and human case reports, tacrolimus is not expected to increase the risk of congenital anomalies. Hypertension, prematurity, and neonatal hyperkalemia have been suggested by case reports as possible adverse effects.	According to the manufacturer, tacrolimus is excreted in breast milk and should be avoided during lactation. However, studies in lactating mothers suggest the exclusively breastfed infant would receive less than 0.2% of the pediatric dosage for organ transplant rejection. **AAP:** Not reviewed **Lactation Risk Category:** L3

(continued)

TABLE 97-3 Drug Safety in Pregnancy and Lactation *(Continued)*

	Pregnancy	Lactation
Treprostinil	Based on experimental animal studies with subcutaneous treprostinil, adverse effects in pregnancy are not anticipated. Human data and data on drug inhalation are lacking.	Manufacturer states that no reports describing the use of treprostinil during human lactation are available and the effects on the nursing infant from exposure to the drug in milk are unknown
Vancomycin	Based on experimental animal studies, vancomycin is not expected to increase the risk of congenital malformations. Theoretical concern exists regarding ototoxicity and nephrotoxicity, but supportive evidence in humans is not available.	Only low levels are secreted into human milk. Its poor absorption from the infant's gastrointestinal tract would limit its systemic absorption. Low levels in infant could provide alterations of gastrointestinal flora. **AAP:** Not reviewed **Lactation Risk Category:** L1
Varenicline (Chantix)	Based on experimental animal studies, use of varenicline during pregnancy is not expected to increase the risk of congenital malformations. Human data are not available.	There have been no studies performed on the transfer of varenicline into human milk. **Lactation Risk Category:** L4

Vaginal delivery is the expected mode of delivery in CF unless other indications for Cesarean section exist. Epidural anesthesia may help with minimizing minute ventilation and oxygen consumption in patients with reduced lung function. Breastfeeding may not be advisable for women with poor nutritional status.

PNEUMONIA IN THE PREGNANT WOMAN

Pneumonia is one of the leading causes of nonobstetric maternal death in the United States.[101] The risk of pneumonia is increased in pregnant women with comorbid conditions, such as asthma, anemia, HIV infection, and tobacco or substance abuse.[102] Pregnant women may be more susceptible than nonpregnant women to contracting viral infections, and they usually have more severe disease than those who are not pregnant. Immune alterations associated with normal pregnancy may impair the response to infection and increase the risk of certain infections.

Preterm delivery appears to be the most common complication associated with pneumonia. Other potential complications include low birth weight, intrauterine growth restriction, a fetus that is small for gestational age, placental abruption, preeclampsia or eclampsia, and low Apgar scores.[103–105] Varicella infection increases morbidity and mortality in pregnancy and is associated with congenital abnormalities and poor fetal outcomes. Congenital varicella syndrome is associated with high mortality in the first 30 days of life and severe impairment related to neurologic, cardiac, gastrointestinal, and developmental delays in survivors.

In the pregnant patient with pneumonia, antibiotic therapy should be initiated empirically while awaiting confirmatory tests that may aid in narrowing the antimicrobial coverage. During influenza season, antivirals (usually oseltamivir) should be started empirically, as well. Extensive use of oseltamivir during the 2009 H1N1 epidemic was thought not to be associated with any adverse fetal effects. Acyclovir or valacyclovir should be used in patients with a suspicion of varicella pneumonia; those suspected of varicella infection should be admitted for observation. Antibiotic use in the pregnant patient with CF has been discussed previously; Table 97-3 provides additional details. Although use of aminoglycosides or vancomycin theoretically may be associated with hearing and renal dysfunction in the fetus, in most circumstances where there is an indication for one or the other agent, its benefit likely outweighs its risk.

In pregnant women with acute respiratory failure from pneumonia or other causes, decisions regarding oxygenation and ventilation should be predicated on the previously discussed physiology. Airway intubation should be anticipated and performed by the most experienced personnel available, using advanced airway devices and readily accessible equipment, given the high risk of intubation failures in pregnant women.

TUBERCULOSIS: CLINICAL COURSE AND MANAGEMENT DURING PREGNANCY

Tuberculosis (TB) is an important infection of pregnant woman. In the United States, a steady overall decline in the incidence of TB has been observed, but a rise in incidence has been seen in the 15-45 year old age group. As a result, an increase in the prevalence of TB among pregnant woman in certain communities, for example, New York City, has been reported.[106] In sub-Saharan Africa, TB is the third leading cause of maternal death, following sepsis and hypertensive disorders of pregnancy.[107]

Pregnancy was originally believed to worsen the course of TB infection, but this has been shown not to be the case. The risks of TB to the mother and unborn child include intrauterine growth restriction, prematurity, and an increased risk for both maternal and fetal mortality. Transmission of TB to the fetus is also well documented[108–110] and may occur through hematogenous spread, by contiguous spread from endometrial TB, or via aspiration of TB-infected amniotic fluid. If neonatal TB is suspected, placental and endometrial tissue can be examined at the time of delivery; however, a workup of suspected active maternal TB should never be delayed until delivery. The diagnosis of TB in pregnancy often requires a high level of suspicion, since fatigue and malaise can be confused with symptoms of pregnancy.

Pulmonary TB is the most common form of TB in pregnancy, accounting for up to 85% of all cases. Consequently, a chest radiograph can be essential in making the diagnosis. Tuberculin skin testing (TST) is the gold standard for screening during pregnancy[111] studies on use of Quantiferon testing in this population are limited.[112,113] Pregnancy may be an excellent opportunity to screen for latent TB, given patients' frequent contact with healthcare providers and the added motivation for fetal well-being.

Treatment of latent TB infection (LTBI) in pregnancy may be delayed until the postpartum period in pregnant women at low risk for reactivation.[114] This recommendation is based on a study showing a higher risk of INH-induced hepatitis in pregnant women compared with non-concurrent controls.[115] However, in the study noted, the risk of INH-induced fatal hepatitis in both the active treatment and the control group was quite low. Conversion to active TB infection in patients coinfected with HIV is significant; therefore, immediate treatment should be initiated in coinfected patients to avoid placing the neonate, mother, and community at risk.

Active, untreated TB infection in a pregnant woman is more of a hazard than the treatment. When active TB is confirmed, treatment should not be delayed. Treatment is similar to that in the absence of pregnancy. First-line therapies for TB, including rifampin, INH, and ethambutol, have been shown to be safe in pregnancy and unassociated with human fetal malformations.[116,117] INH does carry a risk of acute hepatitis, especially if the patient is treated concomitantly with rifampin. Pyrazinamide is less well studied. Although the World Health Organization (WHO) and the International Union Against Tuberculosis and Lung Disease note that the use of pyrazinamide is justifiable in pregnancy, the Center for Disease Control (CDC) does not recommend it in pregnancy. When drug resistance is suspected, addition of pyrazinamide may be justified. Second-line agents are considered more toxic than first-line agents, and clinical experience to guide their use and safety is lacking. Streptomycin should be avoided because of its fetal ototoxicity, while amikacin and kanamycin carry known fetal nephrotoxicity. Para-aminosalicylic acid (PAS) has been used with INH in the past; there has been no indication of teratogenicity among babies whose mothers received the drug.[112,113,118]

Breastfeeding should not be discouraged in women being treated for TB, unless the mother is thought to be infectious. Since anti-TB drugs are secreted in small concentrations in breast milk, caution should be exercised when breastfeeding newborns that are also being treated for TB, since that may increase the risk of drug toxicity. Transmission via breast milk is, however, quite unlikely, except for rare cases of TB mastitis.

VENOUS THROMBOEMBOLISM: DIAGNOSIS AND MANAGEMENT DURING PREGNANCY

Diagnostic and management approaches for thromboembolic disease, including pulmonary embolism (PE), in the pregnant woman merit special considerations.

DIAGNOSIS OF VENOUS THROMBOEMBOLISM AND PULMONARY EMBOLISM

Venous thromboembolism (VTE) is one of the leading causes of maternal mortality in the developed world and, as such, when suspicion for disease is high, early implementation of therapeutic anticoagulation is important. In pregnancy, the risk of VTE is as high as 7 to 10 times that of nonpregnant, age-matched controls.[119] The risk is disproportionately higher in the postpartum period. In pregnancy, 70% to 85% of deep venous thromboses (DVT) occur in the left leg.[120,121] This is thought to be due to compression of the left iliac vein by the right iliac artery and the gravid uterus. Isolated pelvic DVT is more prevalent in pregnancy compared with the nonpregnant population,[121,122] possibly suggesting a different pathogenesis for the disorder.

The increased risk of VTE during pregnancy is due to stasis, hypercoagulability, and vascular damage. Venous stasis in the lower extremity is secondary to the gravid uterus, as well as hormonally mediated venodilation.[123] Pregnancy is marked by many changes in the coagulation cascade, which lead to a hypercoagulable state.[124] Finally, vascular injury occurs with delivery, thereby augmenting risk in the postpartum period.

Existing clinical pretest probability tools are not validated in pregnancy, and their utility is limited by the physiologic changes of pregnancy.[125] D-Dimer performance characteristics are different in pregnant women, and its measurement in pregnancy without concomitant diagnostic imaging to exclude VTE is unreliable.[126,127]

Testing for symptomatic DVT in pregnant and nonpregnant individuals is similar: Compression ultrasonography (CUS) is the standard of care.[128] In pregnancy, the sensitivity of CUS may not be as high, given the increased risk of pelvic vein thrombosis in pregnant patients.[121] Absence of flow or need for increased pressure during CUS may be suggestive of pelvic vein thrombosis. However, the low sensitivity of CUS in detecting iliac thrombi necessitates use of other imaging studies, such as nonenhanced magnetic resonance venography.

In pregnant women suspected of PE who also have lower extremity symptoms, CUS is the recommended initial test in those who are hemodynamically stable. In women without lower extremity symptoms, American Thoracic Society/Society of Thoracic Radiology guidelines recommend a chest X-ray (CXR) as the next diagnostic step.[129] A CXR may provide an alternative diagnosis and also determine the utility of a perfusion scan. Using the proposed diagnostic algorithm, patients with a normal CXR are next evaluated with a ventilation–perfusion lung scan, whereas those who have an abnormal CXR undergo a multidetector computed tomography-pulmonary angiogram (MDCT-PA).[129] The main advantage of MDCT-PA over a ventilation–perfusion scan is that it provides an alternative diagnosis in 17% to 19% of pregnant women suspected of having a PE.[130] MDCT-PA may be technically limited in up to 20% of pregnant women[131] due to physiologic changes of pregnancy, including a higher plasma volume and heart rate, which affect vascular enhancement. These effects may be more pronounced in obese women and those with multiple gestations. Imaging protocol modifications may help reduce technical limitations of the technique.[132]

MANAGEMENT OF THROMBOEMBOLIC DISEASE IN PREGNANCY

Since the interval between diagnosis of PE and institution of therapeutic anticoagulation has been shown to be an independent predictor of death, early and appropriate treatment is essential. In pregnancy, prognostic assessment tools, such as brain (B-type) natriuretic peptide (BNP), or cardiac echocardiography for evaluation of right ventricular dysfunction, are not well validated. Furthermore, their interpretations are limited by the physiologic changes of pregnancy.[133–135] Additional work in deriving prognostic indictors for thromboembolic disease in pregnancy is needed.

Both unfractionated heparin (UFH) and low–molecular-weight heparin (LMWH) are safe during pregnancy, as they do not cross the placenta. LMWH is superior to UFH for all measured outcomes of VTE—risk of recurrent thrombosis, bleeding, and death.[136,137] Other advantages of LMWH over UFH include a lower risk of heparin-induced thrombocytopenia and thrombosis (HIT) and bone demineralization with subsequent fractures.[138–140]

UFH may still play a role in pregnancy, particularly around labor and delivery, given its shorter duration of action and easy reversibility. Given UFH's increased clearance and volume of distribution (and, therefore, bioavailability), its use in pregnancy should be monitored using measurements of aPTT or, preferably, heparin anti-Xa levels.[141] UFH administered intravenously is the treatment of choice for patients with acute renal failure or if urgent need for drug reversal may be required for delivery.

Dosing and monitoring of LMWH is controversial. Twice-daily dosing is preferred by many experts, guided by weekly anti-Xa levels obtained 3 to 6 hours after a dose. The goal for anti-Xa levels is 0.5 to 1.1 units/mL. LMWH does not appear to increase the risk of peripartum bleeding over UFH. The incidence of peripartum hemorrhage is approximately 0.9% to 1.8%, whereas the risk of antenatal hemorrhage and wound hematoma is less than 1%.[142] Although most available data were derived from the study of enoxaparin, tinzaparin likely has a similar side-effect profile.[143]

The duration of treatment for VTE in pregnancy is not well defined; consequently, recommendations for management are similar to those in the nonpregnant patient. Consensus suggests that therapy for VTE should extend for 6 weeks into the postpartum treatment, since this is a high-risk time for thromboembolism. The total duration beyond that is unclear, but a minimum of 3 months is probably warranted and should be based upon careful assessment of the risk of recurrence.[144,145]

Data on use of thrombolytics in pregnancy are available. The main risk of thrombolysis is maternal bleeding, which is reported to occur in as many as 8.1% of patients treated; no cases of intracranial hemorrhage have been reported.[146] In one series on the use of thrombolytics in pregnancy, although no maternal bleeding was reported, the rate of fetal mortality was 8%.[147] Fetal complications may be related to thromboembolic disease severity, as well as the choice of thrombolytic agent. Alteplase (rt-TPA) does not cross the placenta and carries no risk for teratogenicity. In patients with PE who are hemodynamically stable, use of thrombolytics is controversial (even in the absence of pregnancy) and is generally discouraged. In patients who are hemodynamically unstable, but who cannot undergo systemic thrombolysis, surgical or percutaneous embolectomy are potential therapeutic options when clinical expertise for these procedures is available.[148]

Management of VTE in the peripartum period is complex and requires a detailed labor and delivery plan. The plan should take into consideration the risk of bleeding with full anticoagulation and the risk of recurrent VTE when anticoagulation is withheld. In addition, the need for regional anesthesia should be evaluated. A planned transition from LMWH to UFH near term may be considered, since UFH is more predictably reversed, has a shorter half-life, and easily monitored.[149] A planned induction can ensure a controlled environment for delivery. However, given the unpredictable nature of labor, patients should be instructed to stop their injections at the first sign of labor and to contact their provider for further instructions.

Since a new VTE without treatment during the first month carries a 40% risk of recurrence, patients who are within 2 weeks of expected delivery should be considered for placement of an IVC filter.[150,151] Patients developing a clot between weeks 2 and 4 prior to delivery may be treated with intravenous UFH[152] or an IVC filter. Removable IVC filters can be placed in pregnancy, but they are usually placed above the renal veins. Intravenous UFH should be restarted postpartum as soon as possible.

Warfarin, an oral vitamin K agonist, crosses the placenta, is known to be teratogenic, and increases the risk of intracranial bleeding.[153] Use of warfarin for the treatment of VTE in pregnancy cannot be justified, given the availability of drugs with similar efficacy and better safety.[26] Warfarin is detectable in breast milk, but in clinically insignificant amounts; hence, its use is considered safe in breastfeeding mothers.[154] Use of postpartum intravenous UFH or subcutaneous LMWH as a bridge to warfarin is warranted. It has been shown that use of warfarin alone, without antecedent use of heparin carries about a threefold risk of recurrent VTE.[155]

PULMONARY ARTERIAL HYPERTENSION AND PREGNANCY

Pulmonary arterial hypertension (PAH) is an uncommon disorder that may affect women of childbearing age. PAH may present, or significantly worsen, during pregnancy. The hallmark of PAH is an increase in PVR. The increase in blood volume, cardiac output, and oxygen consumption, and the decrease in systemic vascular resistance seen in pregnancy are poorly tolerated in patients with fixed PVR. These hemodynamic challenges are exacerbated at the time of delivery as a result of uterine contractions, autotransfusion, and increased sympathetic tone, as well as by large fluid shifts in the postpartum period. In affected patients, the normal physiologic changes of pregnancy may lead to right ventricular volume overload and, eventually, right ventricular failure and death.

Two large reviews of a total of 198 pregnancies in women with PAH revealed a mortality range from 17% in patients with idiopathic pulmonary arterial hypertension (iPAH) to 56% in women with other causes of pulmonary hypertension.[156,157] In contemporary case series in which patients were managed with pulmonary-specific vasodilators, substantially better outcomes have been reported. However, these reports may be limited due to publication biases.[158,159] Nearly all fatalities occur in the peripartum period as a result of heart failure, VTE, or sudden death. Due to the limited data and nature of the publications in this field, it remains uncertain if patients with less severe disease (i.e., lower mPAP or PVR) are at lower risk for death than are those with more severe disease, although this has been suggested in a number of reported series.[160,161] Currently, the recommendation remains that patients with even mild PAH should avoid pregnancy.[162] A decision to terminate a pregnancy or to induce delivery in the setting of PAH depends on the timing of diagnosis in gestation and the anticipated physiologic changes. In more advanced pregnancies, termination may not lessen risk of mortality or morbidity.

Given the risk both to mother and baby, contraception is essential in patients with PAH. Options for contraception should be discussed in collaboration with a specialist familiar with both PAH and contraception. As patients with PAH are prothrombotic, estrogen-based contraception should be avoided. Similarly, intrauterine device placement carries a 5% risk of a vasovagal event, which may be fatal in patients with PAH. Thus, device implantation may require hospital admission.[163] In all patients starting treatment with endothelin receptor antagonists (e.g., bosentan, ambrisentan) two forms of contraception are recommended, since these agents are considered teratogenic.

A multidisciplinary team that includes a PAH specialist should manage the patient throughout pregnancy and in the peripartum period. Carefully planned regional anesthesia may carry less risk than general anesthesia.[156,159] Cesarean-section delivery is unlikely to reduce anesthesia risk in women with PAH; in fact, Cesarean section may be associated with a higher risk of medical complications in PAH, including VTE and atelectasis. Throughout pregnancy, close monitoring for worsening right heart failure is essential. Its development may herald the need for hospitalization, institution of bed rest, augmentation of therapy for PAH, emergent delivery, or termination of pregnancy.

Use of medications for PAH in pregnancy is not well studied. Calcium channel blockers have been used successfully and are relatively safe in pregnant patients who have a vasodilator response demonstrated during right heart catheterization.[161] Unfortunately, loss of efficacy of calcium channel blockers over the long-term limits their use, so pulmonary-specific vasodilators may be needed.[164] Pulmonary-specific vasodilators that have been used successfully during pregnancy include prostacyclins (treprostinil or epoprostenol) and phosphodiesterase (PDE) inhibitors (sildenafil and tadalafil).[165,166] Iloprost is teratogenic in animals, although there are reports of its use in pregnancy without teratogenicity.[167,168] Case reports describe successful use of inhaled nitric oxide (iNO) at the time of delivery, but risks to fetus and neonate remain unclear. Since pregnancy is a prothrombotic state, anticoagulation for PAH should be used when indicated, including in those women with PAH who are on prolonged bed rest. LMWH is the preferred agent and should be continued in the postpartum period.

INFILTRATIVE LUNG DISEASES IN PREGNANCY

Only a minority of infiltrative lung diseases (ILD) occur in women of childbearing age. In chronic ILD, preconception counseling is crucial to ensure appropriate disease control at the time of conception and use of medications with good efficacy and good safety profiles.[169] A multidisciplinary approach to these disorders is crucial to achieving improved outcomes.

Patients with a restrictive physiology may develop worsening symptoms in pregnancy due to a number of changes, including, for example, a significant increase in tidal volume. Experts believe that a vital capacity greater than 1 L is associated with a favorable outcome in pregnancy, despite limited supporting evidence. Outcome often depends on the cause of restriction and disease progression during the course of the pregnancy. Patients should be assessed by an expert in obstetric anesthesiology prior to delivery, and a plan developed to avoid both high levels of anesthesia and use of the Trendelenburg position, when possible.

A number of systemic diseases may affect the lungs, producing pulmonary parenchymal and other respiratory and manifestations that may profoundly impact pregnancy.

Rheumatoid arthritis (RA) usually improves in the second and third trimesters[170] and flares in the postpartum period.[171] Convincing evidence that RA results in adverse pregnancy outcomes is lacking.

Systemic lupus erythematosus (SLE) is likely to flare in pregnancy, especially in women with renal involvement and those with poor disease control at the time of conception. The postpartum period confers a particularly high risk of lupus pneumonitis.[172] SLE increases the risk of complications of pregnancy and adverse fetal outcomes, including preeclampsia, spontaneous abortion, growth restriction, and preterm birth.[173–175]

Systemic sclerosis may have devastating consequences in pregnancy. Pregnancy planning and close monitoring can improve maternal and fetal outcomes. Renal crisis is a feared complication that is usually treated with angiotensin converting enzyme (ACE) inhibitors. Given the high morbidity of this condition and the clear advantage of using ACE inhibitors over any other antihypertensive agents, use of these drugs can be justified, despite their known teratogenicity and the risk of neonatal renal dysfunction at birth. Pulmonary hypertension, another complication of systemic sclerosis, should be evaluated prior to pregnancy, and affected patients advised to avoid pregnancy (see Pulmonary Arterial Hypertension, above).

Disease severity in polymyositis and dermatomyositis is likely a predictor of adverse fetal outcomes.[176] General anesthesia should be avoided in patients with polymyositis because of the risk of delayed muscle recovery, arrhythmias, heart failure, and aspiration.

The use of certain medications in pregnancy, such as corticosteroids, azathioprine, hydroxychloroquine, sulfasalazine, and intravenous immunoglobins, is justifiable. Use of tumor necrosis factor (TNF) antagonists is justifiable in rare circumstances. TNF antagonists have been implicated in cases of VATER (verterbral, anal, tracheal, esophageal, and radial anomalies) syndrome.[177] Cyclosporin A is unlikely to have teratogenic effects. Use of methotrexate, cyclophosphamide, mycophenolate mofetil, rituximab, leflunomide, and D-penicillamine should be avoided in pregnancy and alternative agents employed in women planning a pregnancy.

Stable sarcoidosis likely has no significant effects on pregnancy outcomes. However, patients with pulmonary parenchymal disease, extrapulmonary sarcoidosis, or PAH, and those requiring drugs other than corticosteroids for disease suppression tend to have more complicated pregnancies.[178]

Lymphangioleiomyomatosis (LAM) is a rare disorder that affects women of childbearing age. LAM is likely accelerated by exogenous hormones and pregnancy. Pregnancy in LAM is associated with a high incidence of pneumothorax and chylous effusion.[179] It is possible that LAM diagnosed during pregnancy may be a marker of disease severity.[180] The European Respiratory Society guidelines suggest that patients be informed of the risk of complications of LAM, for example, pneumothorax and chylous effusions, prior to pregnancy.[181] Women with more severe disease are less likely to tolerate these complications.

PULMONARY EDEMA

Pulmonary edema during pregnancy is not uncommon, despite the young age of the patients.[182] Plasma oncotic pressures decrease as gestation duration increases and decrease further in the postpartum period. Consequently, pulmonary edema may occur at lower-than-usual hydrostatic pressures during pregnancy. Given the profound hemodynamic changes at the time of labor and delivery and the postpartum period, the vast majority of peripartum cases of pulmonary edema are reported postpartum. Intravenous fluid administration used to counteract the effect of vasodilation caused by regional anesthesia may contribute to its development.

Additional causes of pregnancy-related pulmonary edema include preeclampsia, which may be associated with left ventricular dysfunction; lower oncotic pressure; possible capillary endothelial dysfunction. Tocoltic agents have also been associated with pulmonary edema. Treatment of pulmonary edema in pregnancy is essentially the same as in the nonpregnant population; however, pregnant women are typically responsive to low doses of diuretics (e.g., 10 mg of furosemide administered intravenously). ACE inhibitors are known teratogens and should be avoided. Nitroglycerine and hydralazine may be used.

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism (AFE), also known as anaphylactoid syndrome of pregnancy is a rare, but potentially catastrophic condition characterized by cardiopulmonary collapse and multiorgan dysfunction. Mortality rates between 20% and 90% have been reported. Proposed risk factors for the development of AFE include advanced maternal age, complicated labor and delivery, obstetric interventions, uterine trauma, placental pathologies, and fetal distress.[183] The pathogenesis of AFE remains a subject of debate.

AFE presents as sudden hemodynamic instability, respiratory failure (cardiogenic or noncardiogenic pulmonary edema), disseminated intravascular coagulation, encephalopathy, and seizures. Detection of fetal squamous cells in the pulmonary vasculature is not a specific finding in AFE; it has been reported in asymptomatic women at term.

Treatment of AFE focuses on supportive measures and correction of the initial hemodynamic instability. Immediate Cesarean section, which should be considered in cases of severe, refractory shock, should be promptly performed in hope of improving maternal and fetal outcomes.[184] Use of recombinant factor VII,[185] iNO and other pulmonary vasodilators, exchange transfusion, extracorporeal membrane oxygenation (ECMO), and continuous venovenous hemofiltration (CVVH)[186,187] have been described. However, little supportive evidence is available.

OVARIAN HYPERSTIMULATION SYNDROME

Severe ovarian hyperstimulation syndrome (OHSS) is an uncommon iatrogenic complication of exogenous gonadotropins used in assisted reproduction. Pulmonary complications include pleural effusions and VTE. In the severe stages, massive ovaries and ascites, large pleural effusions, oliguria, hemoconcentration, and VTE can be life-threatening. Risk factors for OHSS include age older than 30 years, high serum estradiol, multiple ovarian follicles, and pregnancy.[188] Research suggests that vascular endothelial growth factor (VEGF), angiotensin-II, and insulin-like growth factor play important roles in the pathogenesis of OHSS by increasing vascular permeability, leading to vascular leakage of albumin, electrolyte imbalances, and rapid accumulation of extravascular fluid, including pleural effusions and ascites. Patients with OHSS are also at a higher risk for VTE and, in particular, a higher prevalence of upper extremity DVT, since estradiol-rich fluid drains through the thoracic duct into upper extremity veins.

Patients with severe symptoms of OHSS should have intravascular volume expansion; the possibility of worsening intra-abdominal hypertension should be kept in mind. Repeated large-volume paracenteses may improve renal perfusion by decreasing abdominal hypertension. Therapeutic thoracenteses may also be needed. Close monitoring for early signs of acute respiratory distress syndrome (ARDS), thromboembolism, and advanced renal failure is recommended. Thromboprophylaxis using UFH or LMWH should be initiated as soon as possible due to the high incidence of thromboembolic complications.[189]

SLEEP-DISORDERED BREATHING AND PREGNANCY

Sleep disruption and sleep disorders are common in pregnancy. This section focuses on sleep-disordered breathing (SDB) and its implications in pregnancy.

Central sleep apnea (CSA) is quite uncommon in pregnant women suspected of SDB, likely because the majority of these women are younger than the typical population with CSA. The prevalence of hypoventilation syndromes in pregnancy compared with the nonpregnant population is not well established.

Pregnancy appears to confer an increased risk for obstructive sleep apnea (OSA). Mallampati scores [190] increase as pregnancy progresses.[191] Due to the effect of estrogens and increased plasma volume, nasal patency is reduced. Upper airway size is smaller in pregnant women with[192] and without preeclampsia[193] compared with nonpregnant controls. The reduction in FRC likely results in a tendency for upper airway collapse.[194] The effects of progesterone on minute ventilation may lead to a more negative inspiratory pressure, resulting in a vacuum effect on the upper airway. On the other hand, progesterone increases the electromyographic activity of the upper airway dilator muscles[195] and enhances their responsiveness to chemical stimuli.[196] In addition, reduced REM sleep,[197] preference for assuming a lateral sleeping position in late gestation,[198] and increased minute ventilation may play protective roles. The balance of these factors favors an increased risk for SDB in pregnancy. Notably, snoring occurs in approximately 35% of pregnant women.[199]

OSA may actually improve in untreated women 3 months after delivery.[200] Most available data on SDB in pregnancy are cross-sectional, primarily because pregnancy is unplanned in about 50% of subjects. Availability of longitudinal data would help clarify whether pregestational and gestational OSA does, in fact, have different clinical consequences.

Lack of significant effort by obstetric providers in screening for SDB, even in obese patients, has been reported.[201] The Berlin questionnaire, a widely used tool in screening the nonpregnant population, appears to have poor positive and negative predictive values in pregnancy.[202] Excessive daytime sleepiness correlates with other symptoms of SDB, such as snoring and witnessed apneas.[203] Chronic hypertension, increased age, obesity, and snoring appear to have good predictive value for diagnosing OSA in high-risk populations.[204] Further validation of a potential predictive model in pregnant populations is needed.

SDB is associated with a variety of medical disorders, which may have a major influence on pregnancy and its course. Gestational hypertension and gestational diabetes are associated with short-term maternal, fetal, and neonatal complications,[205–207] as well as long-term cardiovascular[208] and metabolic outcomes.[209] Hence, the association of these disorders with a modifiable disorder holds the promise of potentially preventing long-term, highly morbid outcomes.

Snoring and OSA have been shown to be associated with a variety of adverse pregnancy outcomes, including gestational hypertension,[199,210–212] gestational diabetes,[199,213–215] and Cesarean deliveries.[199,216,217] Abnormalities in glucose metabolism, longer labor, and Cesarean deliveries are also associated with short sleep duration.[199,214] Mechanistic studies are lacking, and the directionality of the association is not well clarified. The association of SDB with adverse fetal outcomes may be mediated by associated comorbidities. Growth restriction[211] and preterm birth[199,217,218] have been reported in association with snoring, OSA, or poor sleep in some studies. Case reports and case series suggest that fetal decelerations secondary to sleep apnea occur, but a recent study evaluating synchronized limited sleep studies and fetal monitors failed to show a significantly higher prevalence of late decelerations with obstructive events.[202]

Once diagnosed, treatment of OSA is recommended for patients with an apnea–hypopnea index (AHI) >15 or those with AHI >5, who have symptoms that respond to therapy, such as daytime sleepiness. For multiple reasons, specific guidelines on initiation of therapy in pregnancy are not available. To date, no trials have shown that treatment of OSA in pregnancy improves pregnancy or fetal outcomes. This likely contributes to underscreening and underdiagnosis in this population.[201] More so, it is possible that, with weight loss and reversal of pregnancy physiology, the disorder may resolve, or at least improve, in the postpartum period.[200]

Alcohol and cigarette smoking avoidance carry additional pregnancy-specific benefits. Observational studies of positive airway pressure (PAP) therapy have shown improvement in daytime fatigue and daytime somnolence in pregnant women with OSA treated with CPAP and retitrated around midpregnancy.[219] Auto-PAP may circumvent the need for repeat titration with pregnancy progression. In women with preeclampsia, small, randomized trials have shown that in-laboratory PAP therapy improves hemodynamics, uric acid, and cardiac output compared with untreated women.[220,221] Trials evaluating the effect of PAP therapy on pregnancy-specific outcomes are sorely needed to help determine the "urgency" of starting PAP therapy in pregnancy.

SUMMARY

Pregnancy constitutes a distinctive state in a woman's life that presents a number of unique physiologic, diagnostic, and therapeutic challenges. Pregnancy also offers an opportunity for many women to have meaningful interactions with the healthcare system and providers, including those focused on lung health. Prompt diagnostic and therapeutic interventions and close patient monitoring are warranted to help the pregnant woman tolerate the physiologic demands of pregnancy and the hemodynamic and respiratory stressors associated with labor and delivery. Deliberate postponement of a warranted clinical evaluation or intervention until after delivery is rarely the right approach.

CHAPTER 98

Pulmonary Complications of Intra-abdominal Disease

Sonja D. Bartolome
Michael J. Krowka

INTRODUCTION

Intra-abdominal pathology may have distant effects on the pulmonary vascular bed, the pulmonary parenchyma, or the pleural space. This chapter reviews the pulmonary complications of intra-abdominal disease, focusing on the pathology, epidemiology, clinical features, and management. Topics are organized according to the primary abdominal organ system in which the disease is centered.

PULMONARY COMPLICATIONS OF HEPATIC DISEASE

A number of respiratory complications of hepatic disease are well recognized, including portopulmonary hypertension (POPH), hepatopulmonary syndrome (HPS), hepatic hydrothorax (HH), and spontaneous bacterial empyema (SBEM). Each is discussed in the subsequent sections.

PORTOPULMONARY HYPERTENSION

POPH is defined as pulmonary hypertension (PH) occurring in the setting of liver disease, or more specifically, in the setting of portal hypertension.

Epidemiology And Pathogenesis

Approximately 2% to 6% of patients with decompensated liver disease develop POPH.[1–3] Based on multicenter, case-control studies, autoimmune hepatitis and female gender are identified risk factors for the development of POPH; therefore, the role of hormonal and immunologic influences in the pathogenesis of POPH is a focus of investigation.[4,5]

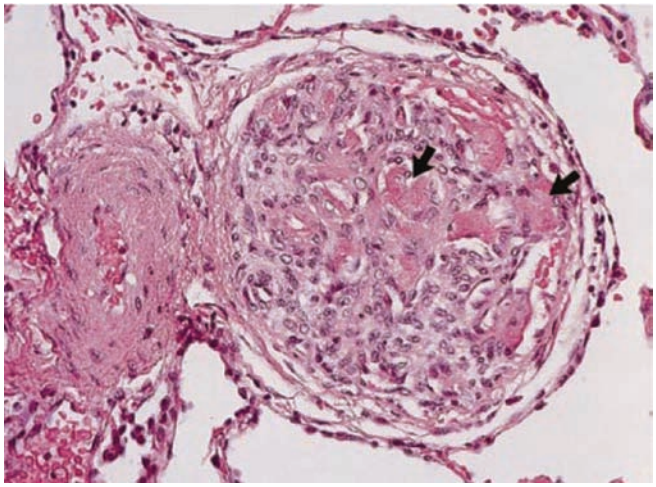

Figure 98-1 Autopsy specimen from a 55-year-old female with cryptogenic cirrhosis and portopulmonary hypertension, showing the plexiform lesion common in pulmonary arterial hypertension. The *arrows* show acute platelet-fibrin thrombi within the plexiform lesion. *(Reproduced with permission from Krowka MJ, Edwards WD. A spectrum of pulmonary vascular pathology in portopulmonary hypertension. Liver Transpl. 2000;6(2):241–242.)*

Patients with POPH have measurable alterations in levels of pulmonary vasoactive substances. For example, prostacyclin is a potent pulmonary vasodilator that also has antithrombotic and antiproliferative properties; levels of prostacyclin are decreased in the lungs of patients with PH. In patients with POPH, loss of endothelial prostacyclin synthase expression compared with normal controls has been demonstrated.[6] Endothelin-1 (ET-1), a pro-proliferative and vasoconstrictive agent implicated in the pathophysiology of other types of PH, has also been shown to be increased in the circulation of patients with POPH.[7]

Histologically, POPH appears to be very similar to other types of PH. POPH is a precapillary pulmonary arteriopathy involving multiple layers of the vessel; specifically, POPH is characterized by smooth muscle hypertrophy, adventitial proliferation, and endothelial cell proliferation. In addition, the plexiform lesions characteristic of other types of PH have been demonstrated in patients with POPH (Fig. 98-1).[8]

The microvascular changes in POPH result in a pulmonary circulation characterized by increased resistance and low capacitance—the antithesis of the normal pulmonary vascular physiology, which is characterized by a low-pressure and high-flow state. The altered physiology constitutes an increased workload to the right ventricle (RV). Early in the disease process, the RV hypertrophies and increases its stroke volume. Over time, these changes become maladaptive, and the RV dilates and becomes dysfunctional. At this stage, the patient demonstrates progressive right ventricular failure. The clinical course of POPH is similar to that seen in other types of PH (see Chapter 72), justifying its placement in Group 1 of the World Health Organization (WHO) Classification (Table 98-1).[9] However, the concomitant presence of end-stage liver disease, with accompanying fluid retention, hypoalbuminemia, coagulopathy, renal dysfunction, and gastrointestinal bleeding, complicates the clinical management of patients.

Clinical Features

Patients with POPH may present with complaints of fatigue and dyspnea with exertion, which are later accompanied by signs and symptoms of right ventricular failure, such as jugular venous distension, lower extremity edema, presyncope, and syncope.[10] The diagnosis can be particularly elusive in the cirrhotic patient, who may have edema from portal hypertension and a spectrum of hemodynamic disturbances. Consequently, the diagnostic workup must be performed carefully to avoid a misdiagnosis of POPH.

TABLE 98-1 Updated Dana Point WHO Classification of PH

Group I, pulmonary arterial hypertension
Idiopathic
Hereditary
Associated with:
Collagen vascular disease
Congenital heart disease
Human immunodeficiency virus
Drugs or toxins
Portal hypertension
Chronic hemolytic anemia
Schistosomiasis
Group II, pulmonary venous hypertension
Systolic dysfunction
Diastolic dysfunction
Valvular disease
Group III, PH associated with respiratory disease/hypoxia
Chronic obstructive pulmonary disease
Interstitial lung disease
Sleep disordered breathing
Alveolar hypoventilation disorders
Chronic exposure to high altitude
Group IV, chronic thromboembolic PH
Group V, PH with unclear/multifactorial mechanism

Source: Adapted with permission from Simonneau G, Robbins IM, Beghetti M, et al. Updated clinical classification of pulmonary hypertension. Journal of the American College of Cardiology. 2009;54(1 Suppl):S43–S54.

The most common hemodynamic derangement in patients with liver disease is not PH, but rather, a state of systemic vasodilation and high cardiac output (CO) induced by splanchnic vasodilation.[3] In these patients, hemodynamics are characterized by increased mean pulmonary artery pressure (mPAP), high CO, low pulmonary capillary wedge pressure (PCWP), and reduced pulmonary vascular resistance (PVR). Affected patients do not have small vessel arteriopathy, but rather, increased pressure resulting from high flow through the pulmonary circulation. This hemodynamic pattern is evident in approximately 35% of liver transplant candidates and is not associated with a poor outcome.[3]

A second abnormal hemodynamic profile present in patients with liver disease reflects volume overload or diastolic dysfunction. With this profile, pulmonary pressures may be elevated, but CO and PCWP are also increased; in addition, PVR is low, indicating pulmonary *venous* hypertension from elevated left heart filling pressures, rather than small vessel pulmonary arteriopathy.

Finally, a third hemodynamic profile that may be seen in POPH is an elevated pulmonary artery pressure, normal PCWP, high PVR, and high, normal, or low CO—depending on the degree of resultant right ventricular failure and liver disease (Table 98-2).

Not infrequently, patients may present with a *combination* of these hemodynamic profiles, for example, POPH with volume overload. In this case, an increased transpulmonary gradient (TPG) >12 mm Hg (TPG = mPAP − PCWP) may suggest existence of combined volume overload and pulmonary arteriopathy. To characterize such complexity, many have suggested that the hemodynamic definition of POPH be expanded to include mPAP >25, TPG >12, and PVR >3 Wood units.

TABLE 98-2 Hemodynamic Patterns in Patients with Liver Disease

	mPAP	CO	PCWP	PVR	TPG
High cardiac output and vasodilated	↑	↑↑	↓	↓↓	N↑
Fluid overload or diastolic dysfunction	↑	N↑	↑↑	N	N
POPH	↑	↑↓	N	↑	↑

mPAP, mean pulmonary artery pressure (normal, <25 mm Hg); PCWP, pulmonary capillary wedge pressure (normal, <15 mm Hg); CO, cardiac output (normal, 4–6 L/min); PVR, pulmonary vascular resistance (normal, <3 Wood units: ([mPAP–PWCP]/CO); TPG, transpulmonary gradient (normal, <12: mPAP-PCWP); N, normal.

Diagnosis

To establish a diagnosis of POPH, objective evidence (increased hepatic vein-free pressure to wedge pressure gradient) or clinical evidence of portal hypertension must be present. The diagnosis of POPH is often first suggested by an echocardiogram, but echocardiography is confounded by the previously noted hemodynamic changes seen in cirrhosis.[11] Therefore, an echocardiographically estimated peak PA pressure >50 mm Hg or signs of significant right ventricular dysfunction should trigger confirmatory right heart catheterization (RHC). A screening series at the Mayo Clinic determined that this threshold for PA pressure was 100% sensitive in diagnosing POPH, and it minimized unnecessary invasive testing in patients with cirrhosis, who often have a hyperdynamic circulation.[3]

Clinical Course

Patients with POPH appear to have worse clinical outcomes than patients with other types of PH. The French registry recorded the outcomes of 154 patients with POPH and included both treated and untreated subjects. Five-year survival was reported in 68% of patients. Multivariate analysis identified advanced Childs–Pugh Scores (B and C) and lower cardiac index as independent risk factors for mortality.[12]

The REVEAL (Registry to Evaluate Early and Long-term PAH Disease Management) registry for PH is an ongoing, multicenter, observational study that has recorded the outcomes of 174 patients with POPH—the largest cohort to date. The data show that patients with POPH have poorer survival and higher all-cause hospitalization rates compared with patients with idiopathic or familial PH, despite the group with POPH having a more favorable initial hemodynamic profile than the others (Fig. 98-2).[13] Furthermore, when data were analyzed to derive a risk score for 1-year mortality for all patients presenting with PH, POPH demonstrated a hazard ratio of 3.6 compared to other etiologies.[14]

Management

POPH is classified as WHO Group I PH, and, therefore, is a treatable category of PH using FDA-approved drugs. However, POPH was excluded from clinical trials assessing use of these agents. Specific data on treatment of POPH are derived from case series and single-center studies, as summarized in the following sections.

Endothelin Antagonists The endothelin antagonists, bosentan and ambrisentan, are established treatments in WHO Group I PAH. Endothelin is a pulmonary vasoconstrictor and pro-proliferative agent, and its antagonism has been shown to improve exercise capacity and hemodynamics in patients with PH. Data on use of these agents specifically in POPH are limited.

Bosentan is a dual endothelin receptor antagonist (ET_A and ET_B). In small, single-center, uncontrolled, observational trials, patients with POPH treated with bosentan have shown improvements in exercise capacity and survival.[15,16] Use of bosentan has been limited in this group due to its well-described hepatotoxicity occurring in a minority of patients (approximately 10%) with PH, but no underlying liver disease. The hepatotoxicity is likely related to the agent's inhibition of a bile salt transporter; the toxicity is reversible with drug discontinuation.[17]

Ambrisentan is a selective ET_A antagonist and is also FDA approved for the treatment of WHO Group I PAH. Hepatotoxicity has not been reported with this agent. A single-center, uncontrolled, observational trial of ambrisentan in POPH from the Mayo Clinic reported a significant improvement in mPAP and PVR with treatment and no hepatotoxic events.[18]

Phosphodiesterase Type 5 Inhibitors Two phosphodiesterase type 5 inhibitors, sildenafil and tadalafil, are currently FDA approved for the treatment of WHO Group I PH. The agents vasodilate the pulmonary vascular bed by inhibiting breakdown of cyclic GMP and work within the nitric oxide pathway. Small, uncontrolled, observational trials reveal that sildenafil in POPH increases 6-minute walk test distance and lowers levels of N-terminal prohormone-brain natriuretic peptide, both of which correlate with a better prognosis in patients with PH.[19] The reported hemodynamic response has been mixed, with one observational trial reporting an improved PVR in three of five patients at 1 year,[20] and another showing improved PVR in all nine patients studied at follow-up, which ranged from 95 to 282 days.[21]

Prostacyclins Prostacyclin analogs are key agents in the treatment of PAH, and they are considered by many to be the agents of choice for the "sickest" patients. These drugs must be given continuously via subcutaneous or intravenous routes, or intermittently in inhaled form. Current FDA-approved prostacyclins for intravenous use are epoprostenol and treprostinil. Treprostinil is also available for subcutaneous or inhalational administration. In the United States, iloprost is available only in the inhaled form, although it is given intravenously in Europe.

Uncontrolled, single-center series have consistently demonstrated that prostacyclin infusions result in significant improvements in mean PAP, CO, and PVR in patients with POPH.[22–24] Furthermore, prostacyclin

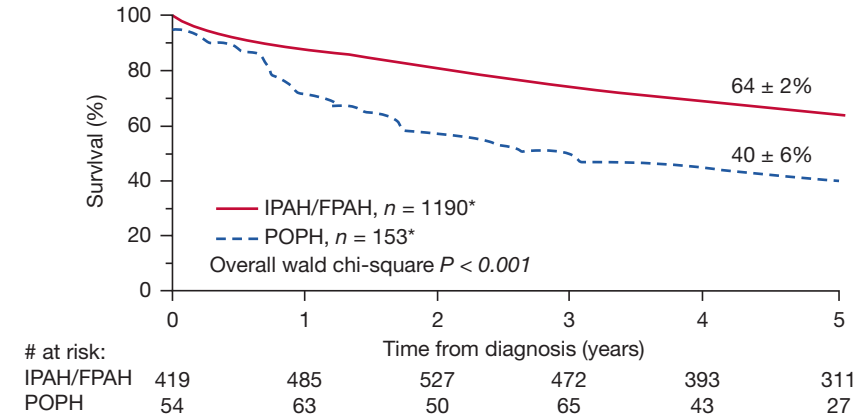

Figure 98-2 Five-year survival from the time of diagnosis of POPH versus IPAH/FPAH. *(Data from REVEAL registry. Only patients enrolled within 5 years of diagnosis were included in the 5 years survival from diagnosis curve. Chest. 2012;141(4):905–915.)*

infusions have been used successfully to improve hemodynamics in patients with POPH in advance of safe pursuit of liver transplantation.[24–27] Limited data are available to support the use of inhalational prostacyclins for POPH. Although iloprost has been shown to improve hemodynamics acutely, long-term effects are less certain.[28]

Liver Transplantation The history of liver transplantation in the setting of POPH is controversial. Early in the history of liver transplantation, the diagnosis of POPH was made in the operating room at the time of the procedure. Patients were neither previously treated for the disease, nor under the care of a medical team familiar with critical care of patients with POPH. Not surprisingly, intraoperative mortality from decompensated right ventricular failure was high.[29] Long-term outcome was also adversely affected. Those with severe PH (sPAP >60 mm Hg) had a 9-month posttransplant survival rate of 58%.[30] Consequently, severe POPH was considered a contraindication to liver transplantation.

With increasing clinical experience and the advent of new treatments for PH, transplant centers began to report both successful liver transplants in patients with POPH, and, in some, regression of the POPH following surgery.[31,32] In 2006, a case series of eight sequential patients with POPH were treated with IV epoprostenol. Of the eight, seven had significant hemodynamic improvement. Six of the seven were listed for liver transplantation, and four of those listed were successfully transplanted. Of those transplanted, survival was 100% at 5 years.[26,32] Furthermore, in a retrospective study based on screening of patients with POPH with RHC, 5-year survival for those not transplanted or treated for PH was 15%, whereas 5-year survival for those who were treated for PH and transplanted was 64%.[33]

Because of the initial poor experiences with POPH patients undergoing liver transplantation, retrospective studies sought to identify risk factors for perioperative mortality. These series have suggested that if a patient has a mean PAP <35 mm Hg and normal right ventricular function, perioperative mortality approaches that of patients without POPH. However, if mean PAP is >50 mm Hg at the time of transplant, mortality approaches 100%.[29,31,34]

Because there is a role for liver transplantation in selected patients with POPH, the United Network for Organ Sharing (UNOS) allows for upgrade points in the model for end-stage liver disease (MELD) score, facilitating liver transplantation. The MELD system prioritizes liver transplantation for the sickest patients, and the exception system allows extra points for those whose mortality risk is not reflected in their MELD score. Currently, the guidelines indicate that if a patient has a confirmed diagnosis of POPH (using mPAP, PVR, and TPG), and they are treated with pulmonary vasodilator therapy to attain an mPAP <35 and a PVR <5 Wood units, they are eligible for a MELD exception to 22 points, with an increase in their MELD by 10% every 3 months, until they are transplanted.

Liver transplantation in these patients should be performed at a center experienced in pulmonary vascular disease, as the perioperative course may be complicated. Even in patients without POPH, a well-described "reperfusion syndrome" may occur at the time of allograft reperfusion. Reperfusion syndrome may cause acute elevations in PAP and may induce acute, decompensated right ventricular failure in patients with POPH.[35,36] The use of intraoperative prostacyclin infusion, inhaled nitric oxide, or intravenous milrinone has been described in this emergent setting; results have been mixed.[37,38]

Limited data exist regarding the clinical course of POPH after liver transplantation. POPH progression, stability, improvement, and resolution have all been reported. In most of the cases, patients are able to wean from their prostacyclin infusion over a period of months, but some remain on oral pulmonary vasodilators. Available data suggest that 40% to 50% of patients may be able to be weaned from all pulmonary vasodilators, given enough time.[24–26]

Summary

POPH is an uncommon complication of liver disease, which is characterized by a progressive pulmonary arteriopathy, and which may result in right ventricular failure and death. Patients with POPH appear to have an increased mortality compared with those with similar levels of liver disease or with other types of PH. Specific protocols for optimal use of, pulmonary vasomodulators for POPH are under investigation. However, patients exhibit improved hemodynamics and exercise capacity when receiving therapy for PH. The role of liver transplantation in this setting is arguable, but transplantation may be performed in carefully selected patients and may cure not only their liver disease, but also their POPH.

■ HEPATOPULMONARY SYNDROME

HPS is a liver-induced pulmonary vascular disorder characterized by a widened alveolar–arterial oxygen gradient. The widened gradient is the result of intrapulmonary vasodilation (IPVD) in the presence of hepatic disease or portal hypertension. Clinically, IPVD may occur with or without overt hypoxemia, depending on the severity of the disease. HPS increases mortality in patients with liver disease, is without specific therapy, and is completely curable with liver transplantation. Therefore, unlike POPH, the presence of significant HPS is considered an indication for liver transplantation.

Epidemiology and Pathogenesis

The prevalence of HPS is reported as 4% to 32% in cohorts of cirrhotic patients undergoing liver transplant evaluation.[39,40] The pathogenesis is poorly understood, but is thought to involve angiogenesis, as well as inadequate synthesis or metabolism by the impaired liver of pulmonary vasoactive substances, such as nitric oxide, prostaglandins, vasoactive intestinal peptide, endothelin, calcitonin, glucagon, substance P, and atrial natriuretic factor.[41–43] Nitric oxide has long been implicated in the pathophysiology of HPS, given its known pulmonary vasodilatory effects.[44–48] Endothelin has also been implicated in the pathophysiology of HPS. Although endothelin is often thought of as a vasoconstricting agent, and its inhibition is a common therapy for PH, endothelin's actions vary widely by the receptor to which it attaches. When ET-1 binds to the ET_A receptor, the effect is pulmonary vasoconstriction. However, when ET-1 attaches to the ET_B receptor, it enhances the activity of endothelial nitric oxide synthase and causes pulmonary vasodilation. In experimental models of HPS, the ET_B receptor has been demonstrated to be upregulated; in these animal models, the experimental HPS was reversed by ET_B receptor blockade.[49,50]

Whatever the underlying mechanism of HPS, patients develop IPVD that causes a ventilation–perfusion mismatch and diffusion limitation to oxygenation because of an increase in vascular diameter. The normal pulmonary capillary is 8 to 15 μm in diameter, but in HPS capillaries may dilate to 15 to 100 μm in diameter. Because of this alteration in the normal structure of the alveolar–capillary units, inhaled oxygen does not reach the center of the blood vessel, and some blood returns to the left heart still deoxygenated. In a very rare subset of patients the hypoxemia is the result of true shunt, and AVMs occur with no communication with alveoli.

Clinical Features

Most patients with HPS present with symptoms of chronic liver disease, and a minority (18% in one trial) present with dyspnea as their primary symptom.[48] Therefore, a high index of suspicion should be maintained to make a timely diagnosis. Patients may complain of platypnea (dyspnea with standing) or have the physical examination finding of orthodeoxia, which is defined as a Pa_{O_2} decrease of 5% or 4 mm Hg upon standing. This combination of findings is attributed to the increases in IPVD in the lung bases, and, therefore, increased ventilation–perfusion mismatch in the standing position. Although

the combination of findings is well described in HPS, it is neither common (occurs in 25% of patients) nor pathognomonic; it also has been noted in patients with atrial septal defects, following pneumonectomy, and post-pulmonary emboli.[51]

On physical examination, patients with HPS may present with spider angiomata, digital clubbing, and peripheral cyanosis.[39] The chest radiograph is often normal, but it may reveal bibasilar increased interstitial markings, which may reflect vascular dilation in the bases.[52] Pulmonary function testing often reveals reduced diffusion capacity for carbon monoxide, which is out of proportion to other pulmonary function abnormalities.[53]

HPS has been reported in patients with both acute and chronic liver diseases. Most commonly, it is described in cirrhotics, but HPS has also been documented in the setting of noncirrhotic portal hypertension and acute and chronic hepatitis.[48,54] The severity of HPS does not correlate with the severity of the underlying liver disease.

Diagnosis

The diagnosis of HPS requires the presence of (1) cirrhosis or portal hypertension, (2) a widened age-corrected alveolar–arterial oxygen gradient (>15 mm Hg), and (3) demonstration of IVPD on a bubble contrast–enhanced transthoracic echocardiogram (TTE).

Bubble contrast–enhanced TTE is the most sensitive test for the detection of IPVD. However, TTE is a qualitative examination in which saline is agitated and then injected into a peripheral vein. The agitation causes formation of microbubbles that are at least 15 μm in diameter. In normals, the microbubbles are trapped within the pulmonary capillary bed and absorbed. However, if IPVD is present, the bubbles traverse the pulmonary capillaries and appear in the left atrium approximately three to six cardiac cycles after their injection. TTE can also identify an intracardiac shunt, in which case, the bubbles appear in the left atrium within the three cardiac cycles.[55]

IPVD may also be detected by technetium-labeled macroaggregated albumin lung perfusion scanning (^{99m}TcMAA). In this examination, ^{99m}TcMAA is injected intravenously and uptake detected in the lungs and brain. In the absence of intrapulmonary or intracardiac shunt, the tracer is trapped within the pulmonary circulation and very little is observed on brain imaging. A fractional uptake >5% is considered abnormal. Although MAA scanning allows quantification of the shunt, it cannot differentiate between intracardiac shunt and IPVD. One additional advantage of the ^{99m}TcMAA scan is that it is specific for HPS, even in the presence of intrinsic lung disease. Therefore, it may help to distinguish hypoxemia from HPS from that due to pulmonary parenchymal disease if both are present. ^{99m}TcMAA scanning is less sensitive than TTE for detecting the presence of HPS, and, as demonstrated in several clinical trials, the magnitude of the shunt detected correlates poorly with the degree of hypoxemia.[55]

Arterial blood gases that quantify Pa_{O_2} and the alveolar–arteriolar oxygen gradient for HPS should be obtained with the patient seated at rest and breathing room air. Due to disease-associated alterations in ventilation–perfusion matching with positional changes, along with a propensity for increased IPVD in the lung bases, hypoxemia may worsen with standing and improve in the supine position. Guidelines published in 2004 by the European Respiratory Society Task Force suggest subclassification of HPS according to level of hypoxemia: Pa_{O_2} >80 mm Hg is considered mild; Pa_{O_2} <80 mm Hg but ≥60 mm Hg is considered moderate; Pa_{O_2} <60 mm Hg but ≥50 mm Hg is considered severe, and Pa_{O_2} <50 mm Hg is considered very severe.[56]

Pulse oximetry is a noninvasive screening method for HPS, which may prompt arterial blood gas analysis. A prospective study of pulse oximetry in cirrhotic patients demonstrated that a threshold Sp_{O_2} <96% was 100% sensitive and 88% specific in detecting patients with HPS and a Pa_{O_2} <70 mm Hg. Application of this threshold cut-point resulted in arterial blood gas testing in 14% of the cohort studied.[57]

Clinical Course

The presence of significant HPS decreases exercise capacity, impairs quality of life, and increases mortality compared with patients without HPS who have a similar severity of liver disease.[58] Furthermore, the majority of patients with HPS progress over time; the average rate of decline in resting Pa_{O_2} is 5 mm Hg/y.[59] In one multicenter, prospective study, patients with HPS had a doubling in risk of death compared with patients without HPS, despite no differences in rates of listing for liver transplantation, performance of liver transplantation, age, sex, or race.[58] A number of centers have implemented screening programs for HPS at the time of liver transplant evaluation. Consequently, a population of patients with IPVD has been identified using screening contrast-enhanced echocardiography without hypoxemia. These patients may not share the poor prognosis of the hypoxemic patients described earlier.[60]

Management

No medical therapy has been shown to improve patients with HPS. Many agents have been tried unsuccessfully, including norfloxacin, β-blockade, nitric oxide inhibitors, nitric oxide, glucocorticoids, cyclooxygenase inhibitors, indomethacin, somatostatin, cyclophosphamide, and plasma exchange.[61] Pentoxifylline, a phosphodiesterase-4 inhibitor that interferes with tumor necrosis factor (TNFα) synthesis, has been demonstrated to have some success in animal models of HPS. In a pilot study of 10 children, 3 months of treatment was associated with a significant increase in Pa_{O_2} (>10 mm Hg in all patients); however, the treatment effect disappeared 3 months after drug discontinuation. In addition, the rate of drug discontinuation was 40% due to side effects.[62] A pilot study of pentoxifylline in adults showed no significant change in Pa_{O_2}. The drug was poorly tolerated due to gastrointestinal toxicity.[63] Supplemental oxygen is often administered in HPS and may ameliorate the symptoms of hypoxemia.

Liver Transplantation Liver transplantation is the only therapy proved to resolve HPS. Long-term follow-up reveals significant improvement or resolution of HPS in 85% of patients who undergo liver transplantation.[64–66] The time required for improvement in oxygenation is variable and may take up to 1 year, or longer.

Hypoxemia due to HPS may complicate the postoperative course in liver transplantation. In one prospective study, the finding of a preoperative Pa_{O_2} <50 and an MAA shunt fraction ≥20% was associated with increased postoperative mortality.[67] However, other reports suggest that liver transplantation may be safely performed in patients with HPS, including those with severe hypoxemia.[68,69]

Because of the increased mortality associated with HPS and the favorable outcome for liver transplantation, the UNOS has instituted a MELD exception guideline for affected patients: If the diagnosis of HPS is confirmed with bubble contrast echocardiography and the patient's Pa_{O_2} is <60 mm Hg, an application for MELD upgrade may be submitted. The upgrade increases the patient's MELD score to 22, regardless of the level of liver disease, with an increase by 10% every 3 months until liver transplantation.[70]

Summary

HPS is a liver-induced pulmonary vascular disorder characterized by intrapulmonary vascular dilation resulting in ventilation–perfusion mismatch and a diffusion limitation for oxygenation. No known medical treatment for HPS exists, and patients with HPS have a poorer prognosis than for patients with liver disease without HPS. HPS is an indication for, and is curable by, liver transplantation.

■ HEPATIC HYDROTHORAX

HH is defined as pleural fluid (>500 mL) occurring in a patient with liver disease in the absence of cardiac or pulmonary dysfunction. HH may complicate management cirrhosis, and it may contribute to morbidity.

Epidemiology and Pathophysiology

HH occurs in 6% to 10% of patients with end-stage liver disease. Its development is related to anatomic defects in the diaphragm, which allow fluid migration down a pressure gradient from the peritoneum into the negative pressure environment of the pleural space.[71,72] It is postulated that as ascites develops, intra-abdominal pressure increases and strains diaphragmatic tissue, which then weakens. Eventually, pleuroperitoneal blebs form and then rupture, creating a communication between the abdominal and pleural cavities. In general, these blebs are <1 cm in diameter and are more common in the right hemidiaphragm, perhaps as a consequence of the more muscular construct of the left hemidiaphragm.[73] Although HH usually occurs in the setting of ascites, HH may be present even when clinically apparent ascites is absent, making the diagnosis more challenging.[74,75]

Clinical Features

HH is right sided in 85% of patients, left sided in 13%, and bilateral in 2%.[75] Pleural fluid analysis generally reveals characteristics consistent with ascitic fluid, with slight alterations due to the increased ability of the pleura to absorb free water. HH is transudative, with a total protein level <2.5 g/dL, lactate dehydrogenase fluid-to-serum ratio <0.5, and a total protein fluid-to-serum ratio <2.5. The serum-to-fluid albumin gradient is generally >1.1 g/dL.[71,75,76] Occasionally, patients present with hepatic chylothorax. In these cases, the fluid is also transudative, but the fluid-to-serum triglyceride level exceeds 1; in addition, the fluid-to-serum cholesterol ratio is high. Hepatic chylothorax is thought to arise from chylous ascites entering the pleural space through the previously described mechanism.[77]

Diagnosis

Diagnostic thoracentesis should be performed in the setting of hepatocellular carcinoma, fever, or pain. A prospective series investigating the clinical utility and risks of thoracentesis in the cirrhotic population demonstrated that 30% of patients have an alternative diagnosis to uncomplicated HH. The most common alternative diagnoses are SBEM (see below), pleural tuberculosis, or adenocarcinoma.[66] In another large prospective series, thoracentesis was safely performed in cirrhotic patients with mild coagulopathy (PT or PTT ≤ 2× normal, platelet count of 50–99,000[per μL]) without prophylactic plasma or platelet transfusion. Hence, the presence of a mild coagulopathy should not delay diagnostic evaluation.[78]

■ SPONTANEOUS BACTERIAL EMPYEMA

SBEM occurs when a previously existing HH becomes infected. The empyema portion of this term is a misnomer, because diagnosis does not require purulent material in the pleural cavity, but rather, refers to an infection diagnosed by pleural fluid cell count analysis. The diagnosis is made if the pleural fluid has a positive culture and the polymorphonuclear neutrophil (PMN) count is >250 cells/mm^3, or, if the culture is negative, the fluid contains >500 PMNs/mm^3. The sensitivity of the culture increases from 33% to 77% if blood culture bottles are directly inoculated at the bedside during the procedure.[79] The incidence of SBEM has been reported as 13% in hospitalized patients with cirrhosis and a pleural effusion. Simultaneous SBP is a risk factor for the development of SBEM; however, up to 40% of cases are not associated with SBP.[79,80] Mortality has been reported as high as 20%. Therefore, clinicians should maintain a high index of suspicion to ensure the diagnosis is made in a timely manner.[81]

The most commonly identified bacterial pathogens in SBEM are *Escherichia coli*, *Klebsiella pneumoniae*, *Streptococcus* species, and *Enterococcus* species. Third-generation cephalosporins are the empiric treatment of choice until culture data are obtained.[82] Chest tube insertion is not recommended unless frank pus is present in the pleural cavity, given the risks of complications from the procedure in this patient population.

Management

Medical and surgical interventions are employed in the management of HH. Each is described briefly in the subsequent sections.

Diuretics As is the case in management of ascites, the mainstay of treatment of HH is the establishment of negative sodium balance. Current guidelines for management of ascites call for a diet that entails 2 g/d sodium restriction, along with the administration of furosemide and spironolactone in a ratio of 40 mg of furosemide to 100 mg of spironolactone daily. Despite aggressive medical management, 20% to 26% of cirrhotics with ascites are refractory to medical treatment.[83]

Thoracentesis Thoracentesis can be performed safely in patients with cirrhosis, even in the face of mild coagulopathy. Therefore, therapeutic thoracentesis may be performed to relieve dyspnea in patients with HH that is refractory to dietary sodium restriction and diuretics. Traditionally, removal of no more than 2 L of fluid is recommended at one time because of the risk of reexpansion pulmonary edema and hypotension. However, whether the risks of large-volume thoracenteses apply to this population of patients is unclear.[84] Large-volume thoracenteses have been performed safely with close patient monitoring and measurement of end-expiratory pleural pressure. The recommended goal for end-expiratory pleural pressure is >−20 cm H_2O.[85] Data in support of use of intravenous infusion of albumin to avoid hypotension during thoracentesis are lacking.

Large-volume paracentesis may also be considered for patients in respiratory distress in patients due to ascites or HH. Paracentesis improves dyspnea and lung function within 2 hours of fluid removal. The procedure may provide symptomatic relief for patients with HH and a lower risk than thoracentesis.[86]

Tube Thoracostomy Although tube thoracostomy may seem an attractive option in patients with recurrent HH, multiple reports have confirmed a high complication rate. Specifically, pneumothorax, hemothorax, empyema, electrolyte abnormalities, and hepatorenal syndrome have all been reported. In one series of 59 patients with cirrhosis and chest tube placement, a complication rate of 80% and mortality rate of 27% were reported. Therefore, this intervention should be avoided.[87]

Transjugular Intrahepatic Portosystemic Shunt Transjugular intrahepatic portosystemic shunt (TIPS) reduces portal pressure by creating a shunt between the portal and hepatic veins. TIPS placement is the treatment of choice for a refractory HH. In a series of 73 patients with refractory HH who underwent TIPS placement, 79% had a complete or partial response to the procedure; long-term survival rates were consistent with the severity of liver disease.[88]

TIPS placement is not appropriate for all patients, despite its success in patients with HH and ascites. Patients with severely decompensated liver disease may decompensate further following the procedure because of the shunt's negative effect on hepatic blood flow. In addition, shunting blood from the portal to hepatic vein increases right atrial and pulmonary artery pressure and may further compromise patients with right-sided heart failure or PH.[89] Therefore, MELD >18, PH, large portal vein thrombus, significant hepatic encephalopathy, advanced age (>70 years), or right-sided heart dysfunction are considered relative contraindications for TIPS placement.[90] In a high-risk patient, the option of liver transplantation should be discussed before proceeding with TIPS, since transplantation can be used as a "safety net" for clinical decompensation. In a carefully selected population with refractory HH, TIPS is the standard of care.

Surgical Intervention Small case series have documented success in treating HH using open thoracotomy or video-assisted thoracoscopy (VATS).[91–94] The procedures are based on identification of

diaphragmatic defects and their closure with subsequent pleurodesis. Surgical pleurodesis has a documented success rate of 73% to 100% in preventing recurrence of HH; however, high complication rates have been noted. In one series of 18 patients, a success rate of 48% was noted, but 3-month mortality was 38.9%.[95] Therefore, although VATS with pleurodesis may be an option for patients with refractory HH, larger trials are needed to assess safety before this procedure is considered a standard recommendation.

Liver Transplantation Liver transplantation is curative for HH and should be the primary intervention for patients with refractory disease. The presence of HH does not affect ventilator days in the immediate postoperative period, nor does it increase long- or short-term posttransplant mortality.[96]

Summary

HH may complicate the clinical course of a patient with cirrhosis. A high index of suspicion is needed to diagnose SBEM and to avoid the high mortality rate associated with this condition. Dietary sodium restriction and diuretic use are the mainstays of therapy for pleural effusion, but refractory patients may require therapeutic thoracentesis or TIPS for control. Ultimately, liver transplantation is curative for refractory HH.

PULMONARY COMPLICATIONS OF GASTROINTESTINAL DISEASE

In addition to the aforementioned pulmonary complications of liver disease, diseases of other intra-abdominal organs may have significant effects on the lungs. These include disorders of the esophagus, bowel, and pancreas. Pulmonary complications of renal disease are discussed separately, below.

■ GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) affects up to 20% of the population.[97] GERD is characterized by reflux of gastric contents into the esophagus due to failure of the protective mechanisms of the upper gastrointestinal tract (see below) and produces symptoms of mucosal damage. In addition to the common symptom of "heartburn," reflux may be associated with a range of extraesophageal symptoms, including chronic cough, asthma, IPF, bronchiectasis, aspiration pneumonia, and COPD.[98]

Pathophysiology

Normally, several antireflux mechanisms protect the esophagus and airways from gastric contents: (1) Esophageal peristalsis allows clearance of regurgitated materials; dysmotility is associated with GERD. Abnormal peristalsis is reported in 40% to 50% of affected patients.[99] (2) The lower esophageal sphincter (LES) creates a barrier between the esophagus and the stomach. An incompetent LES is associated with reflux. (3) The diaphragm helps prevent reflux through external compression of the lower esophagus. Maintenance of a low thoracoabdominal pressure gradient may be important in minimizing reflux. Obese patients have higher incidence of GERD, which may be a reflection of the increase in intra-abdominal pressure that occurs with obesity.[100,101]

GERD-related pulmonary disease occurs with gross aspiration of large volumes of gastric contents, recurrent microaspiration, or, possibly, a GERD-induced reflex that causes an increase in vagal tone and resultant bronchospasm.[102–104]

Diagnosis

Diagnostic testing includes ambulatory esophageal pH monitoring and esophageal impedance testing.

Ambulatory Esophageal pH Monitoring Twenty-four hour ambulatory pH monitoring is considered the "gold-standard" diagnostic maneuver.[105] Until recently, this procedure required a catheter-based system, inserted through the nose and placed near the squamocolumnar junction in the esophagus. Various symptom scoring techniques allow linking of patient symptoms and reflux events to determine an association between the two and potential therapeutic intervention. However, the catheters employed are uncomfortable and external, and data suggest that the catheter, itself, may alter patient activity enough to impede the diagnostic accuracy. Recently, a capsule-based system with wireless data transmission has been developed, allowing increased patient comfort and incremental data collection to aid in the diagnosis of GERD. Currently, the American College of Gastroenterology recommends ambulatory pH monitoring for patients with negative findings on esophagogastroduodenoscopy (EGD) who are being considered for an antireflux procedure, and for those failing therapy with a proton pump inhibitor (PPI). Symptom correlation during the procedure is recommended, although its diagnostic role is unproven for extraesophageal symptoms other than chest pain.

Esophageal Impedance Testing Esophageal impedance testing measures changes in tissue resistance to electrical current generated in adjacent electrodes encompassed within an esophageal catheter assembly. The setup allows for identification of retrograde or anterograde food bolus movement along the esophagus. It does not differentiate between acidic, weakly acidic, or alkaline material and, therefore, the technique is often combined with pH monitoring. Impedance testing is more sensitive than pH monitoring alone for detecting the presence of GERD, although it has not been validated for the evaluation of extraesophageal manifestations of GERD.

Clinical Features

Several potential pulmonary associations of underlying GERD should be considered, including asthma, IPF, and chronic cough.

GERD and Asthma The nature of the relationship between GERD and asthma is a subject of controversy, but GERD is present in 15% to 83% of asthmatics.[106–108] Several mechanisms by which acid reflux may be related to bronchoconstriction have been described in the literature. Acid reflux into the distal esophagus is postulated to cause bronchoconstriction through vagal stimulation.[109,110]

Declines in esophageal and tracheal pH coincide with reduced airflow, suggesting that microaspiration of gastric acid may lead to bronchoconstriction.[111] Interestingly, some studies have actually suggested the converse—that asthma exacerbations promote GERD by increasing the pleural-peritoneal pressure gradient by lowering pleural pressure,[112] by promoting LES relaxation,[113] or, perhaps, by a direct effect of bronchodilators on the LES.[114–116]

Asthma guidelines suggest that GERD be treated in asthmatics who have complaints of heartburn or frequent night-time symptoms. However, in a study of over 400 patients with poorly controlled asthma who received a PPI, treatment had no effect on respiratory exacerbations compared with those who received placebo.[117] Current NIH guidelines suggest that treatment of GERD may improve asthma control, citing grade B evidence.[118]

GERD and Idiopathic Pulmonary Fibrosis Recently, a clinical association has been noted between GERD and IPF; the estimated prevalence of GERD in the IPF population is 90%. This association coincides with a recent shift in thought regarding the etiology of IPF, away from one of active inflammation, and toward one of alveolar injury and maladaptive repair, resulting in fibroblast proliferation and, ultimately, lung fibrosis.[119] A strong association between IPF and GERD has been documented in recent clinical trials.[120–122] In addition, one retrospective review of 14 patients awaiting lung transplantation for IPF-reported stabilization, but not improvement, of lung function with laparoscopic Nissen fundoplication.[123] The mechanistic relationship between IPF and GERD, the best diagnostic modality for assessment, and the optimal treatment algorithm are areas of active investigation. No established guidelines have yet been created.

GERD and Chronic Cough GERD is a well-known cause of chronic cough, and treatment of GERD is considered a mainstay in initial therapy for chronic cough. GERD was identified as a cause of chronic cough in 1981, and since then data have emerged ranking it as the second most common cause.[124,125] Twenty-eight percent of patients with chronic cough that improves with GERD therapy deny typical symptoms of GERD.[126] Although 24-hour esophageal pH monitoring is considered the most sensitive test for GERD in chronic cough, it is expensive and has limitations. Therefore, the most recent American College of Chest Physicians guidelines on the treatment of cough recommend empiric therapy for GERD in patients whose cough is plausibly related to reflux.[127]

Treatment

The three main treatments for GERD are antacids, histamine-2 receptor antagonists (H2RA), and PPIs. PPIs have established efficacy over other options and are now the mainstay of therapy. Surgical therapy using Nissen fundoplication is reserved for refractory cases; it may be performed through an open incision or laparoscopically. Finally, new, less invasive procedures to improve the function of the LES are under investigation.

Summary

GERD is a common condition, affecting up to 20% of the population. The reflux of gastric contents into the esophagus may exacerbate pulmonary conditions such as IPF, asthma, and COPD, but neither a causal relationship nor a significant response to therapy has been documented in any of these conditions. GERD is a frequent cause of chronic cough; treatment with a PPI may ameliorate symptoms in affected patients.

■ INFLAMMATORY BOWEL DISEASE

Pulmonary complications associated with inflammatory bowel disease (IBD) were first described in 1976 in a small series of patients who had both IBD and chronic bronchitis.[128] Since that time, a connection between IBD and pulmonary disease has been increasingly recognized, but the pathophysiology of the relationship remains unclear. Both Crohn's disease and ulcerative colitis (UC) have been associated with a variety of respiratory problems: airway disease, parenchymal lung disease, serositis, and pulmonary vascular disease.

Airway involvement, the most common pulmonary disorder in IBD, may present as bronchiectasis, chronic bronchitis, tracheitis, subglottic stenosis, or, rarely, small airway disease.[129–131] Pulmonary parenchymal involvement is less common, but cryptogenic organizing pneumonia, eosinophilic pneumonia, nonspecific interstitial pneumonitis, necrobiotic nodules, and sarcoidosis have been described in IBD.[129,132,133] In addition, an exudative pleuritis that does not relate to IBD disease activity has been reported.[129] The association between the gastrointestinal and pulmonary "inflammation" is unclear, but the majority of these pulmonary complications appear to be steroid-responsive.[132] Finally, patients with IBD have a higher incidence of thromboembolic events than do age-matched controls; the risk of pulmonary embolism does not appear to be related to disease activity.[134]

PULMONARY COMPLICATIONS OF ACUTE PANCREATITIS

Acute pancreatitis (AP) is an acute inflammation of the pancreas, which may cause both systemic inflammatory response syndrome (SIRS) and multisystem organ dysfunction syndrome (MODS) (see Chapter 142). When MODS accompanies pancreatitis, mortality is reported at 15% to 20%.[135,136] Pulmonary complications of pancreatitis are reported in 75% of cases. The most common presentations are hypoxemia without radiologic abnormalities, pleural effusions or, in the sickest patients, acute respiratory distress syndrome (ARDS).[137,138]

■ HYPOXEMIA

Hypoxemia occurring early in the course of pancreatitis, even prior to development of radiological abnormalities, is well documented and a risk factor for ARDS and increased mortality.[137,139,140] Consequently, hypoxemia is included in the pancreatitis severity scores of both Ranson and Imrie.[141,142]

Several inflammatory mechanisms are implicated in development of the early lung injury of pancreatitis. Increased permeability at the microvasculature leads to alveolar filling and decreased lung compliance. In addition, nitric oxide–related endothelial cell damage occurs, with leukocyte activation and adhesion at the level of the pulmonary microvasculature. Furthermore, the systemic release of pancreatic elastase may contribute to inflammation in the lung parenchyma, and fibrinogen metabolism may allow fibrin deposition in alveoli. Collectively, these processes transform the relatively benign environment of the alveolus into an inflammatory milieu and profoundly affect gas exchange. Early hypoxemia is an independent predictor of poor outcome in AP.[140]

■ PLEURAL EFFUSION

The presence of a pleural effusion is a marker of the severity of pancreatitis and occurs in 84% of patients with severe disease, but in only 8.6% of patients with mild disease.[143] Approximately two-thirds of the effusions are left sided, but they may be bilateral or right sided.[144] The effusion is usually small and may be hemorrhagic. Analysis of pleural fluid reveals a very high amylase and elevations in protein and LDH levels when compared with serum.[145] Pleural effusions in AP may be caused by transdiaphragmatic lymphatic blockage or arise as a sympathetic effusion due to associated inflammation. A rare complication is a pancreaticopleural fistula, in which the pancreatic duct or a pseudocyst empties posteriorly into the retroperitoneum, tracking up the mediastinum and rupturing into the pleural cavity. The resulting effusions are generally massive and require evacuation and correction of the anatomic defect.[146,147] When less than massive, the effusions are treated conservatively and typically resolve with resolution of the pancreatitis.

■ ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS develops in approximately 15% to 20% of patients with AP. When present, mortality rises >50%.[148] The pathophysiologic basis of ARDS in AP is poorly understood, but inflammatory cytokines have been implicated (see Chapter 140). Specifically, trypsin injures the pulmonary vasculature and promotes leukostasis and increased vascular permeability.[149,150] Phospholipase A2 (PLA2), which removes fatty acids from phospholipids, may act on surfactant, contributing to respiratory failure.[151,152] Multiple other mediators have been implicated, including IL-6, IL-8, NO, TNFα, and substance P. Whatever the underlying mechanism, ARDS is the basis for 50% to 90% of deaths in AP.[153] Treatment is supportive and incorporates an alveolar protective ventilator strategy (see Chapter 141).

Summary

AP may cause a SIRS and MODS. One of the early signs of ensuing MODS may be hypoxemia, which is a risk factor for the later development of ARDS and early mortality. Pancreatitis is often accompanied by a pleural effusion, which is exudative and characterized by a high amylase level. In general, these effusions may be handled conservatively. ARDS occurs in 15% to 20% of patients with pancreatitis and is the cause of death in most who do not survive the bout of pancreatitis.

PULMONARY COMPLICATIONS OF RENAL FAILURE

Several notable associations exist between respiratory disease and renal failure, including PH and metastatic pulmonary calcification.

TABLE 98-3 Common Hemodynamic Profiles in Patients with CKD

CKD Associated Condition	mPAP	CO	PCWP	PVR
Chronic volume overload	↑	N	↑↑	N
Anemia	↑	↑	N	N
Increased cardiac output due to AV fistula	↑	↑	N	N↓
Left ventricular dysfunction (usually diastolic)	↑	N	↑	N↑

mPAP, mean pulmonary artery pressure (normal, <25 mm Hg); CO, cardiac output (normal, 4–6 L/min); PCWP, pulmonary capillary wedge pressure (normal, <15 mm Hg); PVR, pulmonary vascular resistance (normal, <3 Wood units: ([MPAP–PWCP]/CO); N, normal.

PULMONARY HYPERTENSION AND RENAL FAILURE

PH associated with chronic kidney disease (CKD) is encompassed within Group 5 of the WHO classification of PH (PH with unclear or multifactorial causes).[154] CKD is defined by a reduced glomerular filtration rate (GFR) <60/mL/min/1/73 m^2) for ≥3 months. Screening for PH in CKD is accomplished using TTE and estimation of right ventricular systolic pressure (RVSP). Generally, RVSP >35 mm Hg is considered "abnormal" in patients with CKD.[154] Subsequent to screening, accurate characterization and definitive diagnosis of PH in CKD requires RHC. Patients with CKD are complex with respect to the many factors, acting individually or in combination, that may increase RVSP (Table 98-3).[155,156]

The frequency of PH in CKD has been reviewed extensively; findings depend on the stage of CKD, dialysis methods and duration, and method of assessment for PH (i.e., TTE vs. RHC).[154] The incidence of PH in CKD varies from 9% to 39% in nondialysis-dependent patients and up to 82% for those on hemodialysis (HD). Patients undergoing peritoneal dialysis appear to have a lower incidence of PH than do patients on HD. WHO Group I Pulmonary artery hypertension (↑MPAP, normal PCWP, ↑PVR) complicating CKD is uncommon (13%) and may only be unmasked by RHC postdialysis.[155] Often, other comorbidities exist, such COPD or sleep apnea, which may contribute to PH.

The finding of PH on TTE in dialysis patients has ranged from 29% to 47% and is associated with increased all-cause mortality.[157,158] In addition, in a study of kidney transplant candidates, 32% of whom had an RVSP >35 mm Hg, pretransplant severity of PH (which was related to time on dialysis) correlated significantly with worsening posttransplant survival at 3 years.[159]

Summary

The pathogenesis of, and optimal treatment regimen for, PH in CKD is poorly understood. The presence of PH is associated with a poor outcome in patients on dialysis and in those who undergo renal transplantation.

METASTATIC PULMONARY CALCIFICATION

Metastatic calcification in the lung is a well-documented complication of CKD that requires HD. It is fairly common, with 60% to 75% of autopsy specimens of patients on HD patients exhibiting disease.[160,161] Despite this common pathologic finding, patients are generally asymptomatic, and only a minority have disease visible on the chest radiograph.[160]

Metastatic calcification in patients with chronic renal failure (CRF) is thought to arise from several mechanisms. Chronic metabolic acidosis from renal failure leaches calcium and phosphate from bone. In addition, when bicarbonate is used for HD, a transient alkalosis may predispose to calcium deposition in tissue.[161,162] Secondary hyperparathyroidism, which is common in CKD, results in increased calcium and phosphate release from bone. Finally, decreased clearance of phosphate due to CKD results in an increased calcium-phosphate product and further salt deposition.[163] Deposition of calcium phosphate, the primary salt, is generally benign. However, the radiographic finding may result in a workup for pulmonary infiltrates. In difficult cases, differentiating metastatic calcification from pneumonia or edema is most definitively done using ^{99m}Tc-MDP bone scintigraphy, which identifies a calcified focus in the lungs.[164] Treatment is centered on lowering the patient's calcium-phosphate product with medication and dialysis. Although the majority of cases are benign in course, some are associated with progressive dyspnea, restrictive physiology, low diffusing capacity, hypoxemia, respiratory failure, and death.[165,166]

Sleep Apnea Syndromes: Central and Obstructive

Grace W. Pien
Ilene M. Rosen
Barry G. Fields

HISTORY OF SLEEP-DISORDERED BREATHING

Sleep-disordered breathing (SDB) is an extremely common medical disorder associated with important morbidity. Recognition of its relevance in medicine is relatively recent, although clinical reports of SDB were first made in the 19th century.[1] Likely influenced by such observations, descriptions of an entity constituting obesity and extreme somnolence were highlighted in the character narratives of the "fat boy" in Charles Dickens' series, *Posthumous Papers of the Pickwick Club,* first published in 1837.[2] Dickens described Joe, the fat boy, as a loud snorer who was obese and excessively somnolent—the classical description of Pickwickian syndrome. Sir William Osler in 1918 was credited with first linking the relationship between obesity and Pickwickian syndrome.[3] In the mid-20th century, further work led to the association of Pickwickian syndrome with alveolar hypoventilation by Burwell et al. in 1956, and periodic cessation of respiration by Drachman and Gumnit in 1962.[4,5]

Over the last 40 years, we have begun to understand the pathogenesis of sleep apnea and have developed effective diagnostic and treatment modalities for this common disorder. Gastaut et al.[6] in 1965 showed that cessation of respiration was due to obstruction of the upper airway, and obstructive sleep apnea (OSA) was recognized. In 1972, a conference organized by Lugaresi and his Bologna (Italy) group entitled "Hypersomnia and Periodic Breathing," served as a springboard for the growth of interest and research in SDB.[7] Guilleminault et al.[8] coined the terms sleep apnea syndrome and obstructive sleep apnea syndrome (OSAS) in 1976 to underscore that airway obstruction during sleep was not restricted to obese subjects.

As the understanding of the etiology of OSA increased, treatment options began to emerge. In 1969, a case report describing treatment of OSA in a patient with tracheostomy was published.[9] The first reports demonstrating reversal of OSA with positive airway pressure (PAP) did not occur until more than 10 years later.[10,11] The role of weight loss and its shortcomings in resolution of OSA was noted by Fishman in 1972.[12]

SLEEP APNEA DEFINITIONS

Adult SDB is present when repetitive apneas (episodes of breathing cessation) and hypopneas (episodes of decrement in airflow) occur during sleep, usually associated with sleep fragmentation, arousals, and reductions in oxygen saturation. Apneas are generally defined as an episode of breathing cessation lasting at least 10 seconds in duration, and can be classified as obstructive (in which there is no airflow despite continued respiratory effort), central (no airflow and no respiratory effort), or mixed (events initially appear central in origin, with respiratory effort occurring during the latter portion of the same episode). Hypopneas are SDB events during which decrements in airflow are observed and can also be obstructive or central in origin. In practice, hypopnea definitions vary substantially according to the degree of airflow limitation expected, the magnitude of oxygen desaturation needed, and by whether the definition includes events associated with arousal but not oxygen desaturation.[13,14] In addition, the term "respiratory effort–related arousal" (RERA) is sometimes used to designate a series of breaths characterized by increasing effort leading to an arousal from sleep that does not meet the criteria for apnea or hypopnea.[15] Although both physiologic and epidemiologic studies have demonstrated that hypopneas produce the same clinical consequences as apneas, evolving hypopnea definitions can make it challenging to compare sleep apnea severity and associated consequences across different study populations.

Currently, the apnea–hypopnea index (AHI, number of apneas and hypopneas per hour of sleep) is the standard metric used to describe the severity of sleep apnea.[13] In older papers, the term respiratory disturbance index (RDI) was often used interchangeably with AHI. More recently, some authors have included the number of RERAs per hour of sleep in the RDI definition, that is, number of apneas, hypopneas, and RERAs per hour of sleep. Nevertheless, neither AHI nor RDI take into consideration other characteristics of SDB such as the magnitude of oxygen desaturation or duration of hypoxia.

OBSTRUCTIVE SLEEP APNEA

OSA is defined by the presence of repetitive episodes of upper airway obstruction during sleep. An AHI of equal to or greater than 5 events/h is commonly used to define OSA, with obstructive or mixed (rather than central) events comprising more than 50% of the total.[14] The OSAS is usually defined by an AHI equal to or greater than 5 events/h and persistent complaints of excessive daytime somnolence, unrefreshing sleep, or fatigue.[16] Other OSA definitions suggest that OSA be recognized if the AHI is at least 10 to 14 events/h, or in cases in which the AHI is between 5 and 14 events/h and documented hypertension, ischemic heart disease, history of stroke, or symptoms of excessive daytime sleepiness, impaired cognition, mood disorders, or insomnia exist.[17,18]

OSA is often classified as mild, moderate, or severe according to the AHI. A common scheme is 5 to 15 (mild), 15 to 30 (moderate), >30 events/h (severe).[14] Some authors have suggested that severity should be defined by associations with adverse clinical outcomes rather than the event index.[19,20] Recent changes in clinical hypopnea definitions by organizing bodies such as the American Academy of Sleep Medicine (AASM) have also provoked debate over parameters of disease severity.[14,21,22]

In the past, the term upper airway resistance syndrome (UARS) has been used to describe symptoms of sleepiness and fatigue in the setting of milder SDB not meeting criteria for apneas and hypopneas.[23] Advances in detection of SDB events (e.g., with nasal pressure) and the inclusion of events associated with arousals in the hypopnea definition have likely eliminated the need to designate UARS as a separate entity.[14,24] These individuals are now likely to be diagnosed with OSA. Debate continues as to whether some nonobese individuals may have a hypersensitive arousal response to repetitive increased respiratory effort that is distinct from OSA.[25,26]

CENTRAL SLEEP APNEA

Central sleep apnea (CSA) is much less common than OSA and is characterized by a transient cessation of rhythmic breathing. It is defined as repeated episodes of apnea in the absence of respiratory muscle effort and is observed on the polysomnogram as an absence of both nasal–oral airflow and thoracoabdominal excursion.[27] A number of etiologies for CSA have been recognized, among which congestive heart failure (CHF) and stroke are the most common. Patients with CSA experience sleep fragmentation and can report similar daytime symptoms to OSA patients.

OBESITY HYPOVENTILATION SYNDROME

Obesity hypoventilation syndrome (OHS), or the Pickwickian syndrome, is defined by obesity, SDB, and hypoventilation with daytime hypercapnia in the absence of other causes for hypoventilation. Thus, OHS should be regarded as a diagnosis of exclusion. Seventy to 90% of patients with OHS have been estimated to have OSA.[28,29] Conversely, 10% to 15% of sleep apnea patients have been noted to have daytime hypercapnia and can be classified as having concomitant OHS.[30] OHS is discussed more fully in Chapter 100.

PATHOGENESIS OF OBSTRUCTIVE SLEEP APNEA

The pathogenesis of OSA involves both anatomic and neurologic components. The upper airway is a complicated structure that performs multiple physiologic functions, including vocalization, respiration, and deglutition. The upper airway extends from the posterior margin of the nasal septum to the larynx and has a paucity of rigid bony support. It is divided into four anatomic regions (Fig. 99-1):

- Nasopharynx: between the nares and the hard palate
- Retropalatal oropharynx: between the hard palate and the caudal margin of the soft palate
- Retroglossal oropharynx: between the caudal margin of the soft palate and the base of the epiglottis
- Hypopharynx: from the base of the tongue to the larynx

The major contributors to the airway boundaries include the soft palate and tongue anteriorly; the pharyngeal constrictor muscles, lymphoid tissue, parapharyngeal fat pads, and mandibular rami laterally; and the pharyngeal constrictor muscles posteriorly.[31,32] The soft tissue and craniofacial (bony) structures in the retropalatal and retroglossal regions contribute to the specific morphology of the airway of a given individual.[32] Collapse of the upper airway reduces its airway intraluminal diameter and increases airway resistance, leading to the apneas and hypopneas that characterize OSA.[33,34] Figure 99-1 displays a midsagittal magnetic resonance image in a normal individual in which the retropalatal and retroglossal regions are outlined. This midsagittal image also highlights the airway, tongue, soft palate, mandible, and subcutaneous fat. The lateral upper airway soft tissue structures of the retropalatal region, that is, the lateral pharyngeal walls and lateral parapharyngeal fat pads, are depicted in Figure 99-2.

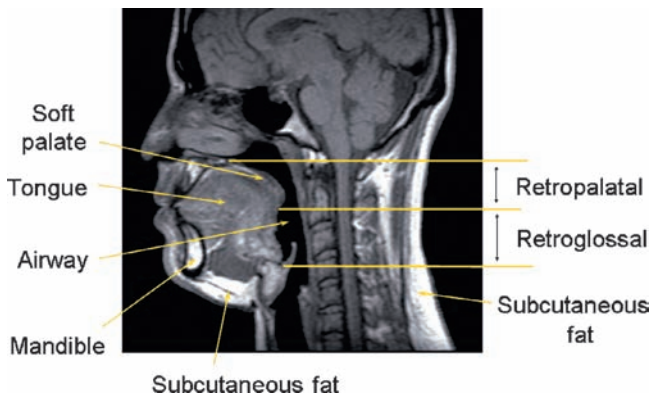

Figure 99-1 Midsagittal magnetic resonance image in a normal individual demonstrating the anatomic regions of the upper airway and relevant craniofacial and soft tissue structures. The retropalatal (RP) region is defined from the level of the hard palate to the distal margin of the soft palate; the retroglossal (RG) region is defined from the distal margin of the soft palate to the base of the epiglottis. In patients with OSA, obstruction usually occurs in the retropalatal or retroglossal levels or at both locations. *(Reproduced with permission from Schwab RJ, Gupta KB, Gefter WB, et al. Upper airway and soft tissue anatomy in normal subjects and patients with sleep-disordered breathing. Significance of the lateral pharyngeal walls. Am J Respir Crit Care Med. 1995;152(5 Pt 1):1673–1689.)*

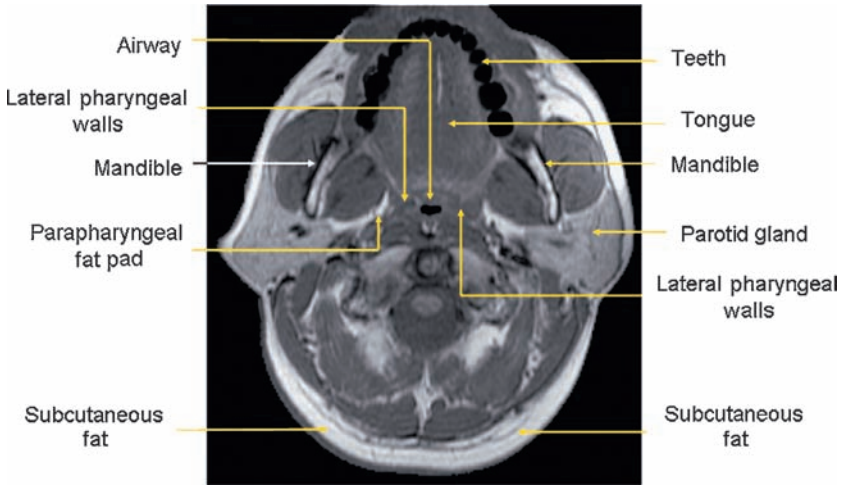

Figure 99-2 Axial MR image at the retropalatal level in a normal subject. The relevant soft tissue and bony structures surrounding the upper airway are highlighted. The tissues immediately lateral to the airway are the lateral pharyngeal walls and the parapharyngeal fat pads. *(Reproduced with permission from Schwab RJ, Gupta KB, Gefter WB, et al. Upper airway and soft tissue anatomy in normal subjects and patients with sleep-disordered breathing. Significance of the lateral pharyngeal walls. Am J Respir Crit Care Med. 1995;152(5 Pt 1): 1673–1689.)*

Anatomical factors are clearly a major contributor to the propensity for airway collapse during sleep. In addition, the critical role of neuromechanical control of the upper airway in the pathophysiology of OSA is becoming increasingly well understood.

ANATOMIC FEATURES THAT PREDISPOSE TO OBSTRUCTIVE SLEEP APNEA

The extrathoracic upper airway lacks a robust support framework of cartilaginous rings and therefore is at risk for collapse due to extraluminal tissue pressure exerted by circumferential craniofacial and soft tissue structures and negative pressure associated with inspiration. Changes in pharyngeal transmural pressure, defined as the difference between the pressure in the airway lumen and the pressure exerted by tissues surrounding the site of collapse, modulate upper airway size. Activity of the pharyngeal dilator muscles offsets extraluminal tissue pressure to help maintain upper airway patency.[35]

Among individuals with sleep apnea, upper airway collapse occurs most commonly in the retropalatal and retroglossal regions, reducing airway intraluminal diameter and increasing airway resistance, which leads to apneas and hypopneas.[36] Multiple potential sites of upper airway collapse have been visualized in many patients with OSA and tend to be reproducible from episode to episode.[37] During wakefulness, upper airway caliber is smaller in patients with sleep apnea compared to normal individuals.[38] Habitual snorers also have generalized narrowing of the pharyngeal lumen compared to normal subjects, regardless of whether they are obese.[32] Nevertheless, smaller upper airway caliber does not entirely explain OSA risk: Men have larger pharyngeal airway cross-sectional area and airway volumes than

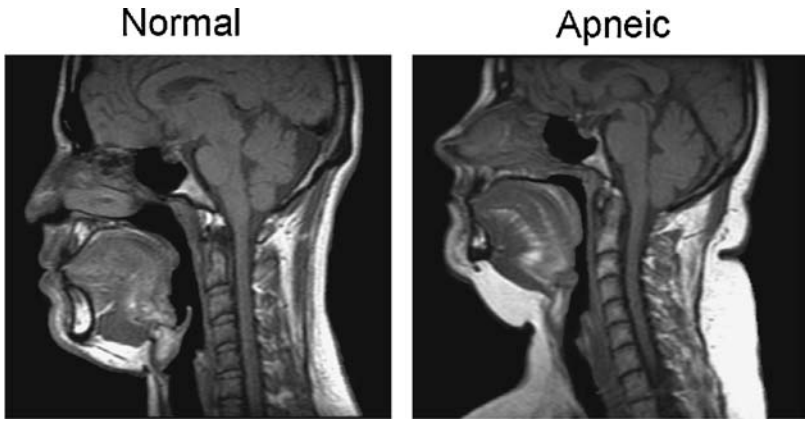

Figure 99-3 Midsagittal magnetic resonance imaging (MRI) of a normal subject on the left and a patient with sleep apnea on the right. The upper airway is smaller in both the retropalatal and retroglossal region in the apneic patient. The soft palate is longer in the apneic patient. The tongue is bigger in the retroglossal region in the patient with sleep apnea. The amount of subcutaneous fat (*white area* at the back of the neck) is greater in the apneic. *(Reproduced with permission from Schwab RJ, Gupta KB, Gefter WB, et al. Upper airway and soft tissue anatomy in normal subjects and patients with sleep-disordered breathing. Significance of the lateral pharyngeal walls. Am J Respir Crit Care Med. 1995;152(5 Pt 1):1673–1689.)*

women, but are more likely to develop sleep apnea. Recently, attention has focused on the role of airway length to explain gender disparity in OSA risk, given observations that men have longer, and thus more collapsible, pharyngeal airways compared to women.[39] A reduction in the lateral diameter of the airway in individuals with OSA, with relative preservation of the anterior–posterior diameter, may also promote upper airway dysfunction.[40]

In population studies, neck circumference is a strong predictor of OSA.[41] Consistent with this observation, individuals with OSA demonstrate an excess of upper airway soft tissue for the space within the craniofacial structures that envelop the pharyngeal lumen. Patients with sleep apnea have larger tongues and longer soft palates than normal subjects (Fig. 99-3).[39,42–44] The larger the volume of the lateral pharyngeal walls, tongue, and total upper airway soft tissue (Fig. 99-4), the greater the likelihood of having OSA; specifically, increased thickness of the lateral pharyngeal walls may contribute to narrowing of the apneic airway.[42] Imaging studies have demonstrated that the total volume of fat surrounding the airway is also greater in apneic individuals compared to BMI-matched normal subjects.[45] These findings suggest that fat deposition in the neck—in the parapharyngeal fat pads, under the mandible, and particularly in the tongue—may similarly reduce upper airway caliber. Increased soft tissue mass may increase tissue pressure, resulting in airway collapse and decreased airway volume.[35]

Variations in craniofacial morphology also influence upper airway configuration. For example, retroposed mandible and increased hyoid–mandibular plane distance have been associated with higher risks of apnea.[46–48]

Changes in upper airway anatomy during the respiratory cycle can influence the propensity for airway collapse during both inspiration and expiration. Using dynamic upper airway imaging with CT, MRI, and nasopharyngoscopy, the airway's geometrical changes have been

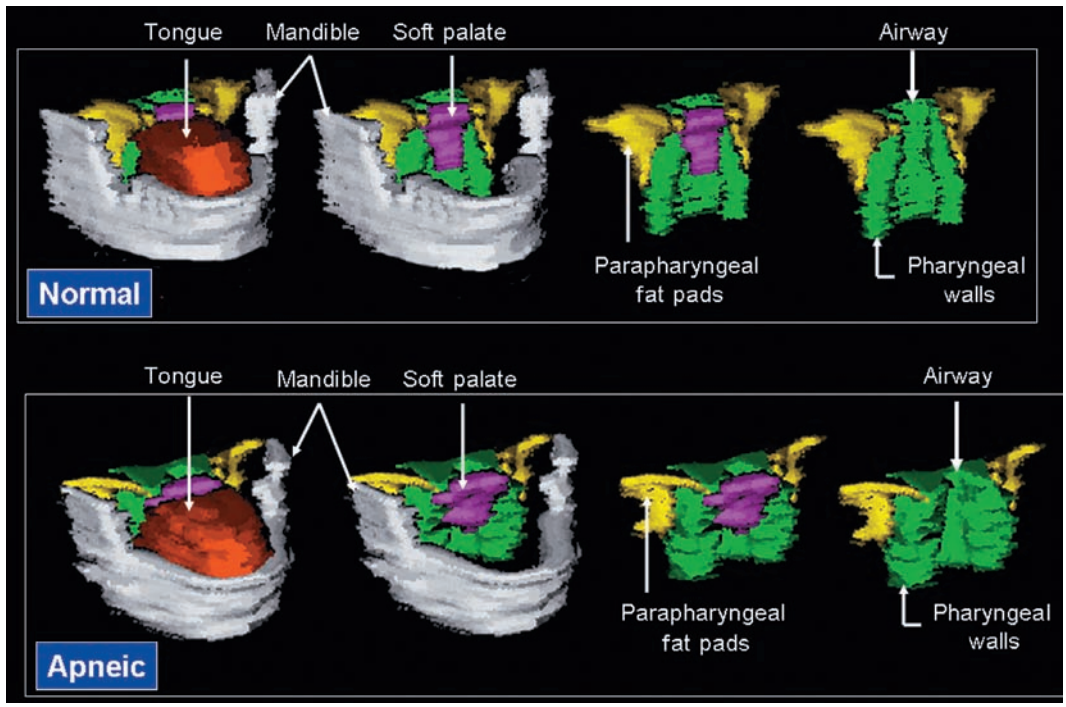

Figure 99-4 Volumetric reconstruction of axial magnetic resonance (MR) images in a normal subject (top panel) and a patient with sleep apnea (bottom panel). The mandible is depicted in *gray*, the tongue in *orange/rust*, the soft palate in *purple*, the lateral parapharyngeal fat pads in *yellow,* and the lateral/posterior pharyngeal walls in *green*. Both subjects had an equivalent body mass index (32.5 kg/m^2). Upper airway caliber is greater in the normal subject than in the patient with sleep apnea. The tongue, soft palate, and lateral pharyngeal walls are all larger in the patient with sleep apnea than in the normal subject. *(Reproduced with permission from Schwab RJ, Pasirstein M, Pierson R, et al. Identification of upper airway anatomic risk factors for obstructive sleep apnea with volumetric magnetic resonance imaging. Am J Respir Crit Care Med. 2003;168(5):522–530.)*

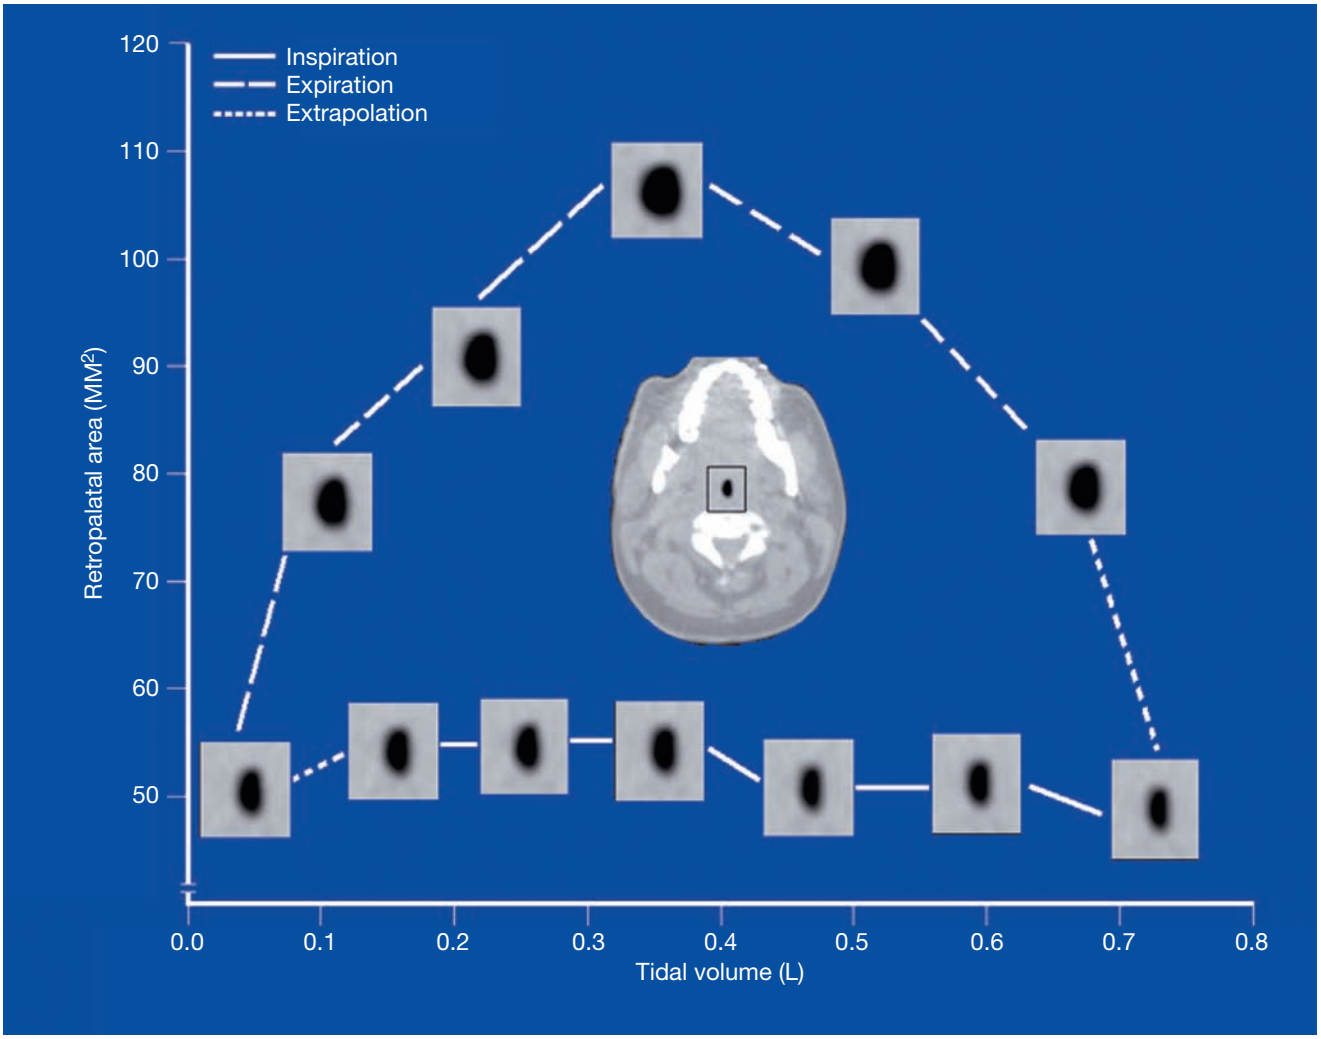

Figure 99-5 Changes in upper airway area as a function of tidal volume during the respiratory cycle using cine CT (computed tomography). Airway caliber is relatively constant in inspiration. Airway size increases in early expiration and decreases in late expiration. *(Reproduced with permission from Schwab RJ, Gefter WB, Hoffman EA, et al. Dynamic upper airway imaging during awake respiration in normal subjects and patients with sleep-disordered breathing. Am Rev Respir Dis. 1993;148(5):1385–1400.)*

partitioned into three phases (Fig. 99-5). During inspiration, upper airway area is relatively constant, implying a balance between muscle dilator activity and negative airway lumen pressure. In early expiration, the activity of airway dilator muscles decreases, intraluminal pressure rises, and the airway widens maximally. At end expiration, upper airway dimensions decrease. Patients with OSA have more narrowing during end expiration compared to normal controls.[40,49,50]

A number of recent studies have also demonstrated that redistribution of extracellular fluid can occur during sleep and in the supine position, leading to significant increases in neck circumference and airway collapsibility, and a reduction in upper airway cross-sectional area.[51–53] The magnitude of fluid redistribution is associated with the degree of SDB, suggesting a contributory role for this mechanism in the development of OSA. However, absolute AHI fell only modestly in a small crossover study in which patients wore compression stockings during the daytime to reduce nocturnal fluid shifts, suggesting that this mechanism does not play a major role in OSA pathogenesis.[54]

■ NEURAL MODULATION OF UPPER AIRWAY PATENCY

During sleep, the balance in transpharyngeal pressure shifts toward upper airway collapse due to reduced upper airway dilator muscle activity. MR images suggest that even among normal individuals, the retropalatal upper airway narrows during sleep (Fig. 99-6). The neural control of the upper airway muscles is complex and involves several neurotransmitters (serotonin, norepinephrine, orexin–acetylcholine, and gamma-aminobutyric acid) that are influenced by sleep itself.[55–57] The most widely studied upper airway muscle is the genioglossus.

Three neural mechanisms have been shown to be operative with regard to genioglossus muscle activity and vulnerability to obstructive apneic events. First, negative airway pressure detected by laryngeal mechanoreceptors activates the genioglossus via increased hypoglossal nerve discharge. This reflex is diminished during non-REM sleep compared to wakefulness, and is further reduced during REM sleep, placing the airway at risk for collapse.[58–61] Recently, a novel, state-sensitive motor inhibitory cholinergic channel that operates at the hypoglossal motor pool has been identified as the principal mechanism of REM sleep pharyngeal motor inhibition.[62] Furthermore, patients with OSA have reduced upper airway reflexes during sleep compared to normal individuals.[63] Whether these differences occur due to individual variability in neuromuscular responses placing some individuals at increased risk for OSA, or whether repetitive injury from snoring vibration or oxidative stress leads to neural or muscular damage have been debated.[64–66]

Second, the upper airway muscles respond to input from the respiratory control center in the medulla, with increases and decreases in activity in proportion to respiratory drive. In situations of ventilatory

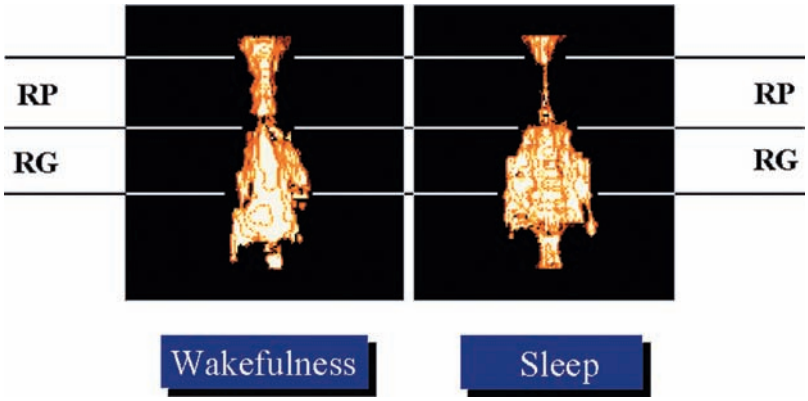

Figure 99-6 Volumetric state–dependent airway imaging in a normal subject using magnetic resonance imaging (MRI). Airway volume during sleep is smaller in the retropalatal (RP) region but not the retroglossal (RG) region. Such images suggest that the upper airway during sleep does not narrow as a homogeneous tube. Nonetheless such images indicate that the upper airway of subjects without sleep apnea narrows during sleep. *(Reproduced with permission from Schwab RJ, Pasirstein M, Pierson R, et al. Identification of upper airway anatomic risk factors for obstructive sleep apnea with volumetric magnetic resonance imaging. Am J Respir Crit Care Med. 2003;168(5):522–530.)*

control instability in which respiratory drive waxes and wanes, diminished upper airway muscle activity can precipitate airway collapse, that is, obstructive apnea.[67,68] Third, neural mechanisms modulating arousal (serotonergic and noradrenergic neurons) have a tonic excitatory influence on genioglossus activity. With the onset of sleep, there is a reduction in arousal-modulated excitatory output to the upper airway musculature.[69,70] During episodes of upper airway collapse, arousal from sleep in response to respiratory activation helps to restore airway patency.[71,72] Although arousals are not always necessary for recovery from upper airway obstruction, patients with OSA have a diminished ability to restore ventilation without cortical arousal compared to nonsnorers.[73]

THE APNEIC EVENT

Occlusion of the airway results in a range of immediate physiologic disturbances. Episodic reductions or cessations in ventilation despite continued respiratory efforts, recurrent episodes of intermittent hypoxemia, and frequent arousals from sleep form the basis for a cascade of downstream perturbations. During obstructive apneas, breathing efforts create abrupt reductions in intrathoracic pressure that can increase atrial natriuretic peptide (ANP) release and left ventricular (LV) transmural pressure, compromise LV filling and increase both preload and afterload.[74–78] Myocardial oxygen demand increases despite reduced coronary blood flow and decreased oxygen delivery due to apnea-related hypoxia.[79] Surges in sympathetic nervous system activity that occur due to apnea, hypoxia, hypercapnia, and arousal result in increased peripheral resistance and cardiac stimulation, which in turn lead to postapneic increases in blood pressure (BP) and heart rate.[80–83] These elevations in sympathetic activity persist during the day in individuals with OSA.[84] Intermittent hypoxemia is associated with increased production of reactive oxygen species and oxidative stress, which can impair endothelially mediated vasodilation, contributing to BP elevation.[85,86] Reactive oxygen species also increase activity of the transcription factor nuclear factor kappa B (NF-κβ), a key component of the inflammatory response.[87] NF-κβ stimulates the production of inflammatory mediators (e.g., C-reactive protein, tumor necrosis factor-α, and interleukins 6 and 8) and adhesion molecules (platelet endothelial adhesion molecule, intercellular adhesion molecules [ICAMs]).[88–92] These effects of intermittent hypoxia are likely to promote endothelial damage and atherosclerosis.[93,94]

Termination of obstructive apneas usually occurs with a transient arousal or awakening from sleep. Arousals are coupled with respiratory effort and involve both chemical (hypoxia) and mechanical (increased respiratory effort against an occluded airway) stimuli.[95,96] Arousal mechanisms can be adversely affected by alterations in chemosensitive systems, ingestion of alcohol, or use of sedatives and hypnotics, leading to prolongation of apneic events.

EPIDEMIOLOGY AND RISK FACTORS FOR OSA

The section focuses on the epidemiology of obstructive sleep apnea and the many risk factor for the disorder.

EPIDEMIOLOGY OF OSA

Estimates of the prevalence of OSA in the general population are variable and dependent on several factors, including the characteristics of the population studied (e.g., obesity, ethnicity), methods used to measure SDB, disease definitions (e.g., hypopnea definition), and the AHI threshold used to define OSA.[17,97,98] In the United States, a landmark community-based population study (the Wisconsin Sleep Cohort Study) published in 1993 reported the prevalence of OSA with daytime sleepiness (i.e., OSAS) to be 4% in men and 2% in women between the ages of 30 and 60.[99] Subsequently, additional epidemiologic studies from a diverse array of countries including Australia, the United States, China, India, Korea, Spain, and Brazil have estimated the prevalence of symptomatic OSA to be between 3% and 8% in men and 1% and 5% in women.[17,99–107] In fact, current prevalence is likely to be substantially higher, given rising rates of obesity and the aging of the population worldwide.[108]

The prevalence of OSA defined by the presence of SDB events alone, without daytime symptoms, is also considerably higher than the prevalence of symptomatic OSA.[17,99,106] For instance, 24% of men and 9% of women in the Wisconsin Sleep Cohort Study had an AHI of at least 5 events/h.[99] However, the impact of milder, asymptomatic OSA on adverse health outcomes remains an area of active debate.

Age

The effect of age on the prevalence of OSA is complex. Population studies have demonstrated that the prevalence of OSA increases through midlife, but then plateaus after age 60 to 65.[109] Furthermore, after controlling for obesity, mean OSA severity may decline with age.[17] Nevertheless, individuals between ages 65 and 100 are more than six times more likely to have OSA compared to men and women 20 to 44 years of age.[17,101] Several studies have observed that the prevalence of SDB is greater than 50% in those at least 65 years of age.[97,106,109,110] These findings have raised questions about whether there is a "survivor effect" for OSA among older adults (i.e., whereby those with OSA who survive to old age are relatively resistant to its adverse effects). Thus, the clinical significance of OSA in the elderly is debated, as is whether a higher threshold should be used to define OSA in this age group.[111]

Gender

Epidemiologic studies demonstrate that the prevalence of OSA is two to three times higher in men than women and that postmenopausal women are at an approximately threefold higher risk for OSA compared to premenopausal women.[17,99,105,112] The lower risk among premenopausal women appears to be related to the effects of reproductive hormones; however, data describing how hormone levels affect upper airway anatomy and function or the control of breathing leading to SDB remain limited.[113–115]

Gender differences in the prevalence of OSA may also be related to differences in body fat distribution. Men exhibit a more central fat distribution, including the neck, thereby increasing the risk for narrowing

and closure of the upper airway.[116–118] Among women, pregnancy poses an additional period of vulnerability for SDB, with important potential consequences for maternal and fetal well-being.[119,120] The prevalence of self-reported snoring increases with advancing pregnancy and has been estimated to be between 14% and 46%.[121,122] Further work is needed to define the incidence, prevalence, and impact of gestational sleep apnea.

Ethnicity

While the majority of population-based prevalence estimates for OSA are derived from Caucasian populations, several recent studies have sought to characterize the burden of OSA in several Asian countries, in South America (Brazil), and among African-Americans and Hispanics in the United States.[102–105,107] In Hong Kong, India, and Korea, the prevalence of OSA is similar to Caucasian population samples, despite the lower prevalence of obesity among Asians. In fact, after controlling the effects of age and obesity, OSA severity appears to be higher among Asians, perhaps due in part to craniofacial characteristics.[123–126]

Among middle-aged African-Americans, the prevalence of OSA is comparable to Caucasians.[109,127] A higher prevalence of OSA has been observed, however, among young African-Americans (<25 years of age) compared to either Caucasians or African-Americans in other age groups.[127,128] Among Hispanics in the United States, snoring is more common than among Caucasians.[129,130] Emerging data suggest that the prevalence of OSA may be higher among Hispanics compared to non-Hispanic whites.[131–133] Data on OSA prevalence in other ethnic groups and countries are relatively sparse at present.

■ RISK FACTORS FOR SLEEP APNEA

Risk factors for OSA are summarized in Table 99-1.

Obesity

After rising dramatically during the last decades of the 20th century, the rate at which obesity is increasing in the United States appears to be slowing or reaching a plateau.[134–137] Worldwide, the prevalence of obesity has nearly doubled since 1980.[138] The increase in obesity prevalence is important because numerous epidemiologic studies have shown that obesity is the strongest risk factor for OSA in adults, and that a dose–response relationship exists between excess body weight and sleep apnea prevalence, such that the prevalence of OSA is greatest among individuals in the highest BMI categories.[17,100–106] Although the majority of these investigations were cross-sectional, several longitudinal studies have demonstrated that weight gain accelerates disease progression. Interestingly, among the elderly, the influence of obesity is diminished compared to its effect in younger adults,[109] which may be due to accelerated mortality among obese individuals with OSA (i.e., survivorship bias) and the greater role of other age-related risk factors for OSA.

Individuals with OSA have been observed to have larger neck circumferences than those without.[41] Imaging studies have demonstrated that obese individuals with OSA have larger soft tissue structures compared to normal individuals, and BMI has been shown to correlate with the percentage of fat deposition within the tongue.[42,139] As noted earlier, the larger size of the soft tissue structures may promote pharyngeal collapse during sleep by increasing tissue pressure on the pharyngeal wall.[43,45,140] In addition to biomechanical effects associated with larger soft tissue structures, obesity is also likely to have important interactions with other risk factors, such as craniofacial characteristics.

Anatomical factors alone, however, do not appear to fully explain the relationship between obesity and the development of OSA. Recent experiments have demonstrated that mice deficient in leptin, a hormone produced by adipocyte tissue that plays a major role in regulating appetite and metabolism, have more collapsible airways independent of weight.[141] Furthermore, leptin replacement can mitigate upper airway obstruction through a combination of peripheral mechanical and central neuromuscular actions. Obese humans, however, are generally leptin resistant and have high circulating levels of leptin, rather than leptin deficiency.[142] Other pathways via which obesity may increase the propensity for OSA include effects on ventilatory control mechanisms; neural compensatory mechanisms that maintain airway patency; and changes in lung volumes. Nonanatomic phenotypic traits such as genioglossus muscle responsiveness, arousal threshold, respiratory control stability, and loop gain appear to be particularly important in determining whether individuals with less collapsible airways manifest OSA.[143]

TABLE 99-1 Risk Factors for Obstructive Sleep Apnea

Obesity (BMI > 30 kg/m^2)
Neck size (collar size >17 inches in males, >16 inches in females)
Gender (male/female 2–3:1)
Genetic factors/family history
Upper airway and craniofacial anatomy
Macroglossia
Lateral peritonsillar narrowing
Elongation/enlargement of the soft palate
Tonsillar hypertrophy
Nasal septal deviation
Retrognathia, micrognathia
Narrowing of the hard palate
Class III/IV modified Mallampati airway
Specific genetic disorders, e.g., Treacher Collins, Down syndrome, Apert syndrome, etc.
Endocrine disorders, i.e., hypothyroidism, polycystic ovarian syndrome, acromegaly
Alcohol, sedative, or hypnotic use

Genetic Factors

Evidence that genetic factors are involved in the pathogenesis of sleep apnea continues to accumulate. A number of studies initially demonstrated the tendency for OSA to aggregate in families.[144,145] More recently, studies utilizing evolving genetic epidemiology techniques have demonstrated increased risk for OSA, independent of obesity, among first-degree relatives in geographically diverse populations in Iceland, Israel, Scotland, and Cleveland (USA).[46,146–148] A recent review documented 50 associations between genetic polymorphisms and OSA that have been identified in over 31 published candidate gene studies (for details, see Varvarigou et al, SLEEP 2011).[149] The majority of these candidate gene studies had inadequate sample sizes. Among these, four of the polymorphisms were observed in at least three separate studies. However, only one gene variant (TNFA rs1800629) remained significantly associated with OSA using meta-analysis techniques.[149] A genome-wide association study in OSA has not yet been published. Ultimately, given the complexity of SDB, many different genes are likely to contribute.

Craniofacial Anatomy

A proportion of patients with OSA are not obese. In nonobese individuals, craniofacial features such as retroposed mandible, micrognathia, and narrowing of the hard palate are the primary risk factors for apnea.[46–48] Furthermore, heritability of craniofacial abnormalities (retroposed mandible, inferior displaced hyoid bone) and upper airway soft tissue structures (tongue volume, lateral pharyngeal walls, and total soft tissue) has been demonstrated in first-degree

relatives and siblings.[46,150,151] These factors may operate in concert or alone to increase the risk of apnea. Genetic disorders associated with craniofacial and/or upper airway soft tissue abnormalities, including Treacher Collins syndrome, Down syndrome, Apert syndrome, and Pierre Robin syndrome, also confer increased risk of SDB.[152]

Endocrine Abnormalities

Individuals with specific endocrine conditions are at risk for OSA. Hypothyroidism, especially when accompanied by myxedema, is associated with both obstructive and CSA due to alterations in muscle function and blunted ventilatory response.[153,154] The presence of a goiter may place the patient at risk for OSA[155]; and thyroid surgery (lobectomy or total thyroidectomy) can improve OSA symptoms including snoring and excessive somnolence.[156] Macroglossia associated with hypothyroidism also contributes to the development of OSA. OSA is common and often severe in patients with acromegaly, presumably related to both osseous and soft tissue changes narrowing the upper airway.[157]

Given the low prevalence of OSA among premenopausal women compared to postmenopausal women and men, the female reproductive hormones appear to have a protective effect on OSA risk. Interestingly, among women with polycystic ovarian syndrome, which is characterized by hyperandrogenism, obesity, and cardiometabolic dysfunction, OSA risk is markedly higher compared to weight-matched controls.[158,159] OSA risk among postmenopausal users of hormone replacement therapy is similar to that of premenopausal women and lower compared to nonhormone users.[17,112] However, due to increased risk of cardiovascular disease and breast cancer and equivocal data from small treatment trials, hormone replacement therapy is not recommended as a treatment for OSA.[160–164]

Other Considerations

Alcohol, which reduces upper airway tone, and sedatives or hypnotics, which reduce the arousal mechanism, can also worsen OSA.[165,166] Each potential risk factor should be considered in the patient evaluation, as it is important to address why an individual has developed sleep apnea.

CLINICAL PRESENTATION AND SCREENING FOR OSA

Elements in the history and physical examination, as well as screening tools useful in establishing a diagnosis of OSA, are discussed below.

■ CLINICAL PRESENTATION

History

The diagnosis of OSA is frequently suggested by the history. Patients with sleep apnea often complain of both daytime and nighttime symptoms (Table 99-2). Bed partners are crucial informants of nocturnal events, and when available, a detailed history from the bed partner is imperative in cases of suspected OSA. Snoring is the cardinal complaint reported by the bed partner. Typically, the snoring is loud, nightly, and has existed for many years. Snoring may be so disruptive that the bed partner can be driven to sleep in another room.[167] A bed partner may report a witnessed apnea that is followed by a loud snort or gasp at the end of the apneic episode. This can be extremely concerning to the partner and serve as the trigger for seeking medical attention.

TABLE 99-2 Clinical Presentation of Obstructive Sleep Apnea

Loud, habitual snoring
Witnessed apneas
Nocturnal awakening
Gasping or choking episodes during sleep
Nocturia
Nocturnal sweating
Unrefreshing sleep, morning headaches
Excessive daytime sleepiness
Automobile or work-related accidents
Irritability, memory loss, personality change
Decreased libido
Impotence

Individuals with OSA may also report snorting or gasping, choking, nocturnal diaphoresis, and restlessness related to airway obstruction.[168,169] A sensation of choking or dyspnea is reported in up to 30% of patients. Frequent nocturnal awakenings related to repetitive airway obstruction lead to sleep fragmentation. Nocturia is fairly common and has been attributed to ANP release in response to apnea-related right atrial stretch.[78] However, while a large community-based epidemiologic study recently found a dose–response relationship between the severity of sleep apnea and levels of brain natriuretic peptide (BNP), this relationship was not observed in a similar analysis performed in a subset of participants from the Sleep Heart Health Study.[170,171]

Repetitive apneic events are not conducive to restorative sleep. Some studies have shown that untreated OSA patients have decreased slow wave sleep (non-REM stage 3) and REM sleep and more sleep stage transitions.[172,173] Thus, individuals with OSA are frequently unrefreshed upon awakening in the morning. Morning headaches are a less common manifestation of sleep apnea. When reported, the possibility of hypercapnia due to OHS should be considered.[174]

Excessive daytime sleepiness is a chief clinical consequence among patients with OSA.[175] Less commonly, patients may report insomnia, with difficulties initiating and maintaining sleep.[176,177] Interestingly, although the proportion of individuals who endorse daytime sleepiness increases with OSA severity, disease severity has proven to correlate only modestly with the degree of excessive somnolence.[178,179] Typically, the excessive daytime sleepiness of individuals with OSA occurs in sedentary situations, for example, following meals, watching television, reading, and during conversation. Driving is particularly problematic in patients with sleep apnea.[180,181] Patients may report falling asleep at red lights or stop signs, drowsiness while driving, and in extreme cases, motor vehicle accidents.[182] Thus, it is imperative to inquire about drowsy driving, which is risky not only to the patient but also to others on the road. The Epworth Sleepiness Scale (Table 99-3), a questionnaire for assessing the degree of subjective sleepiness, is usually elevated in sleep apnea patients (scored 0–24, with >10 considered abnormal) and can be a useful tool for assessing sleepiness in clinical settings.[178] Nevertheless, it is important to appreciate that the presence of excessive daytime somnolence is neither a necessary nor a sufficient condition to make the diagnosis of OSA: Many individuals with an elevated AHI do not report daytime sleepiness and others report sleepiness in the absence of sleep apnea (often due to insufficient sleep).

OSA can also cause symptoms related to cognitive impairment.[183–186] Inattention and deficits in memory and concentration often affect the ability to function at work. Fear of falling asleep inappropriately may limit an individual's willingness to integrate socially.[187] Moreover, patients with sleep apnea and/or their spouses can report irritability, depressive symptoms, and personality change.[188,189] Sexual dysfunction, that is, either decreased libido or impotence, is another common complaint among men with OSA.[190]

Physical Examination

The examination of the patient with suspected OSAS should focus on careful inspection of the head and neck, determination of the presence of obesity (BMI > 30 kg/m^2), and measurement of BP. Neck circumference greater than 17 in (43.2 cm) in men or 16 in (40.6 cm) in women suggests an increased risk for OSA.[191] The evaluation should also include assessment for abnormalities of the shape and size of the

TABLE 99-3 Epworth Sleepiness Scale

In contrast to just feeling tired, how likely are you to doze off or fall asleep in the following situations? (This refers to your usual life in recent times. Even if you have not done some of these things recently, try to work out how they would have affected you.) Use the following scale to choose the most appropriate number for each situation:

0 = Would never doze
1 = Slight chance of dozing
2 = Moderate chance of dozing
3 = High chance of dozing

Situation	Chance of Dozing
Sitting and reading	_____
Watching TV	_____
Sitting inactive in a public place (i.e., a theater or a meeting)	_____
As a passenger in a car for an hour without break	_____
Lying down to rest in the afternoon when circumstances permit	_____
Sitting and talking to someone	_____
Sitting quietly after lunch without alcohol	_____
In a car, while stopping for a few minutes in traffic	_____

craniofacial structures (e.g., mandibular retrognathia, micrognathia, crossbite, narrowing of the hard palate, and dental malocclusion); evaluation for factors contributing to nasal obstruction including nasal asymmetry, polyps, septal deviation, and hypertrophy of the turbinates; and visualization of the pharynx to assess crowding and soft tissue dimensions (macroglossia, tonsillar hypertrophy, lateral peritonsillar wall narrowing, enlarged/elongated uvula, or a narrow, high-arched hard palate). The modified Mallampati classification is often used to describe the patency of the upper airway, with increased risk for sleep apnea observed among individuals with class III or IV airways.[192]

TABLE 99-4 Conditions in which Evaluation for Obstructive Sleep Apnea Should be Considered

Obesity
Systemic hypertension
Myocardial infarction
Cerebrovascular accident
Type 2 diabetes mellitus
Pulmonary hypertension
Polycystic ovarian syndrome

Preoperative anesthesia evaluation

■ SCREENING FOR SLEEP APNEA

Inexpensive tools have been developed to assess the likelihood of apnea. The ability of a number of standardized instruments, such as the Multivariable Apnea Prediction (MAP) Index and the Berlin questionnaire, to identify individuals at risk for sleep apnea have been evaluated.[168,193] The sensitivity and specificity of these questionnaires tend to vary depending on the population studied, the specific cutoffs chosen and the severity of OSA to be identified.[194] Recently, in the surgical preoperative setting, an 8-item questionnaire (STOP-BANG) has been shown to have good predictive value for identifying severe OSA.[195] Other clinical situations in which sleep apnea should be considered in evaluating patients are outlined in Table 99-4.

In the past, overnight pulse oximetry (Fig. 99-7) has been used to screen for OSA.[196,197] Typically, patients with OSA manifest a sawtooth pattern on nocturnal oximetry. However, overnight oximetry does not detect apneas or hypopneas or arousals in the absence of significant oxygen desaturation, rendering the sensitivity of the test suboptimal. Furthermore, abnormal ambulatory overnight oximetry results obtained by general internists based on their initial clinical suspicion for OSA frequently fail to lead to further sleep evaluation.[198]

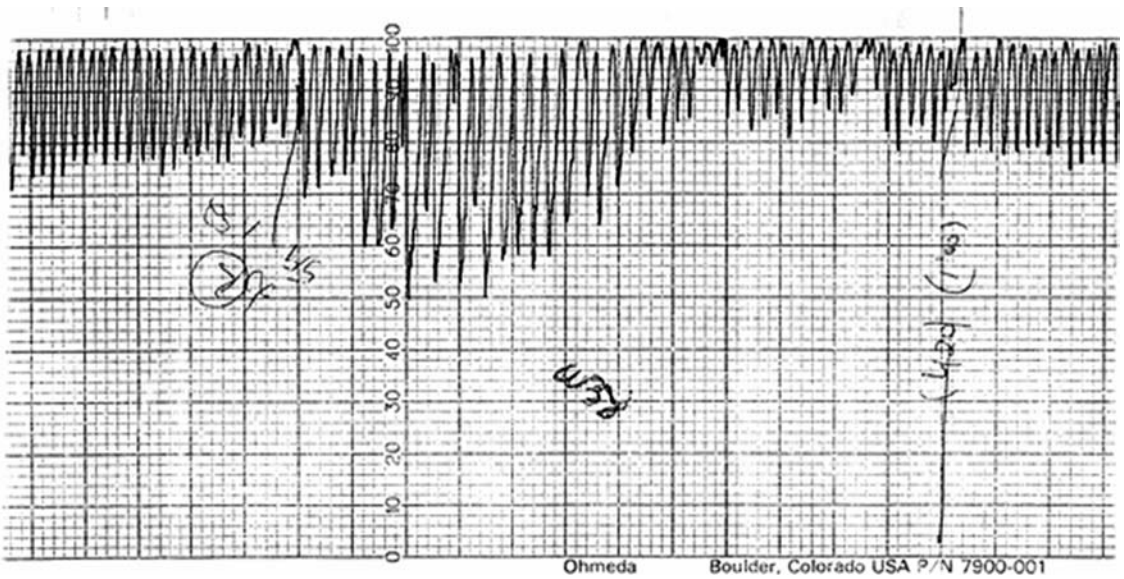

Figure 99-7 Nocturnal oximetry pattern in a patient with obstructive sleep apnea. This patient manifests recurrent oxyhemoglobin desaturations ("sawtooth pattern") that are most severe in REM sleep. Oximetry calibrated from 0% to 100%. Paper speed each small line 1 minute; each *dark black line* 5 minutes.

DIAGNOSIS OF OBSTRUCTIVE SLEEP APNEA

While questionnaires and prediction models (i.e., Epworth Sleepiness Scale, MAP) can assist in OSA risk stratification, objective sleep testing is required to confirm the diagnosis and determine disease severity.[199] Polysomnography (PSG), the gold standard sleep study, records many parameters while the patient sleeps: Electroencephalogram (EEG) to indicate sleep state, electrooculogram (EOG) to monitor eye movements, electromyogram (EMG) to measure muscle activity, oronasal thermistor and nasal pressure sensors to indicate respiratory airflow, chest and waist bands to measure respiratory effort and arterial oxygen saturation (Fig. 99-8) (Video 99-1). These measurements are integrated to provide sleep staging and to indicate apneas, hypopneas, and arousals as depicted in Figures 99-9 and 99-10.

Stratifying disease severity through the AHI is important, given demonstrated linearity between AHI elevations and likelihood of adverse outcomes (e.g., hypertension, cardiovascular mortality, stroke).[200–202] However, despite the ubiquitous use of AHI in OSA diagnosis, the index has some limitations. First, AHI elevations often fail to correlate with sleep quality measures and clinical outcomes.[203] In addition, it does not capture other significant aspects of the disorder, such as the degree of oxyhemoglobin desaturation, nocturnal hypoxemia, hypoventilation (i.e., hypercapnia), or associated sleep disruption. Furthermore, variance in hypopnea definitions has led to substantial disparities in measured severity of SDB.[14,21] Despite these shortcomings, the AHI remains the primary determinant of OSA diagnosis and severity.[199]

While in-laboratory PSG remains the gold standard to establish AHI, limited patient access and relatively high cost have led to increasing use of out-of-center sleep testing—also known as portable or unattended sleep testing (Video 99-2). Typically performed in patients' homes, these sleep studies offer greater convenience at lower cost, and ideally replicate a usual night of sleep. The amount of data procured ranges widely, depending on the AASM-designated type of sleep testing performed (Table 99-5). An in-laboratory PSG as described earlier is designated a Type I study. Overall, Type II and III studies are differentiated by the number of variables measured. The former is a complete unattended home study and measures the same parameters as a Type I study (PSG). The latter typically includes measurement of airflow, respiratory effort, pulse, and sleep position. Since EEG is not obtained, sleep stage information and stage-related events (e.g., arousals) are undetectable. Type IV studies are limited to only one or two parameters, such as pulse rate and oximetry. The United States Centers for Medicare and Medicaid Services outlined guidelines for use of portable sleep testing for OSA diagnosis and treatment initiation in 2009.[18] Portable monitors' accuracy and precision relative to PSG have been easier to question than to demonstrate. Significant differences among monitor brands of the same type, inherent night-to-night variability of AHI which is also noted on in-laboratory PSG, and difficulties keeping pace with emerging technologies have all

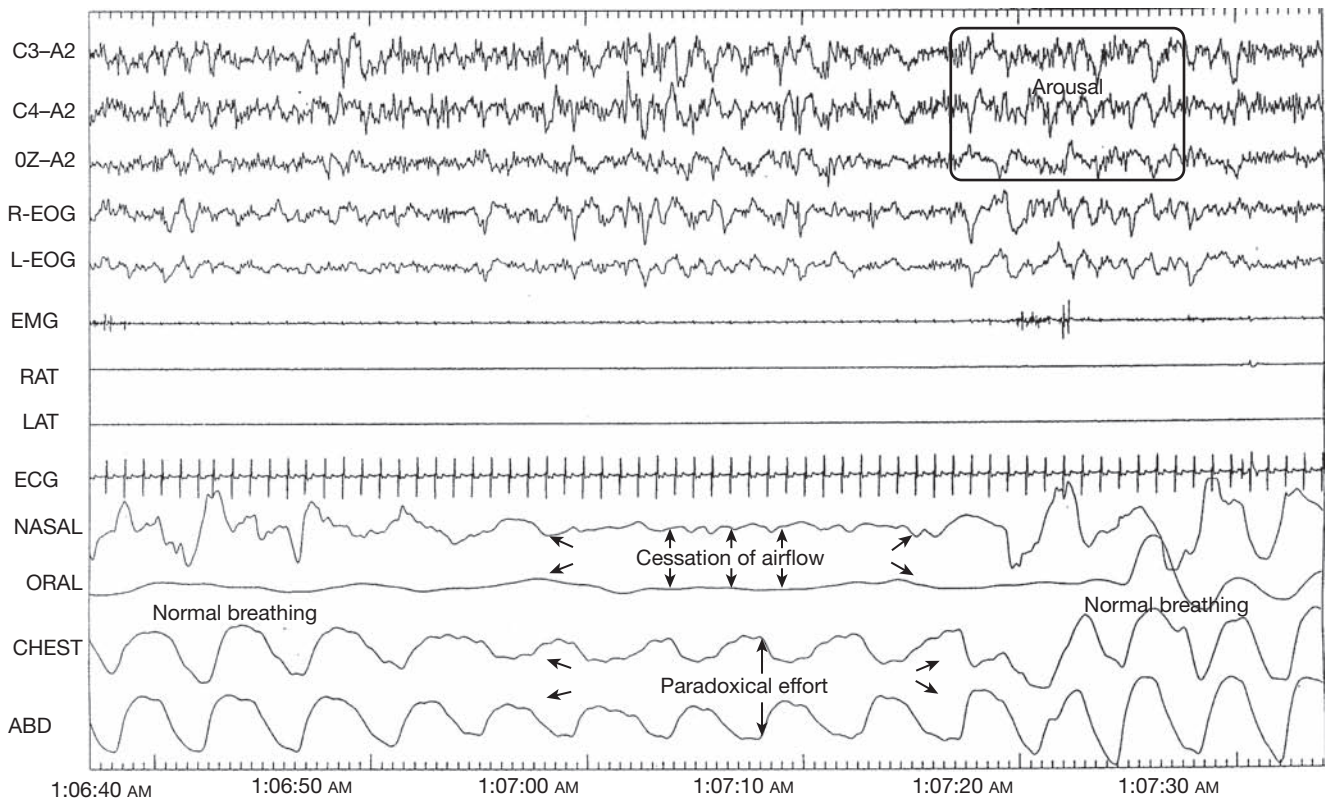

Figure 99-8 Example of an obstructive apnea in a patient with sleep apnea syndrome in stage 2 sleep. The polysomnography traces from the top down are as follows: Three EEG channels (C3–A2, C4–A2, OZ–A2); two EOG channels (R and L); submental electromyogram (EMG); right and left anterior tibialis EMG (RAT, LAT), electrocardiogram (ECG); nasal and oral airflow; chest and abdominal motion (chest & abd). During the apneic episodes, there is abnormal airflow (both oral and nasal) with paradoxical motion of the rib cage and abdomen. At the end of the apneic episode there is a burst of EMG activity at the arousal. Following the arousal, respiration resumes with synchronous movements of the rib cage and abdomen.

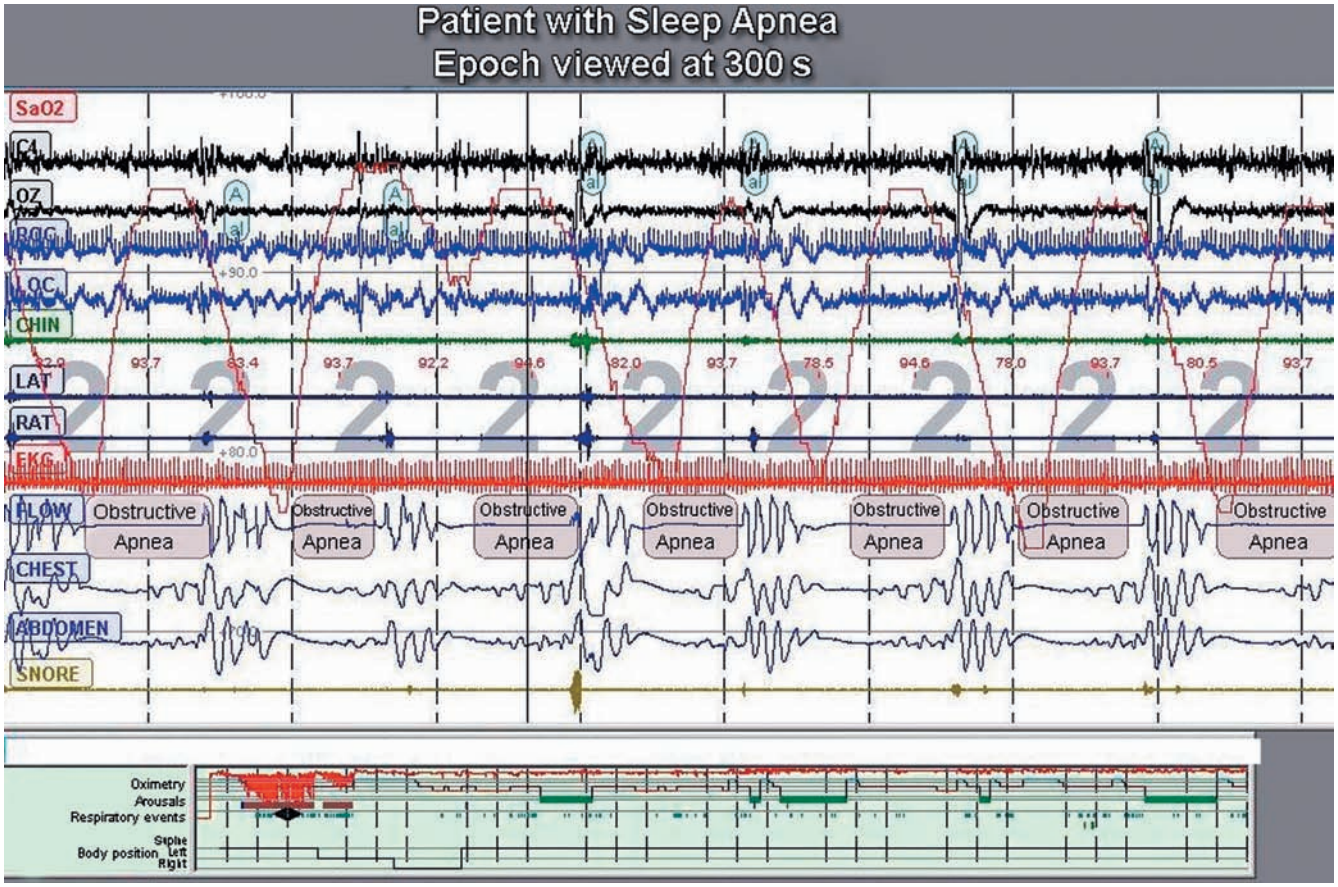

Figure 99-9 Example of a sleep study epoch from a split night sleep study in a patient with severe apnea. The epoch is viewed at 300 seconds. This patient has recurrent apneic events associated with oxyhemoglobin desaturations (recurrent dips in the *red line*). At the bottom of the figure is a hypnogram displaying the sleep data from the entire night. The *black diamond* in the hypnogram shows the time frame for the specific epoch displayed in the top portion of the figure. Later on in the night the patient is started on CPAP and the recurrent apneas and oxyhemoglobin desaturations are abolished (the recurrent desaturations: *red lines* noted in the hypnogram resolve). C4 and OZ are EEG leads; ROC and LOC are the right and left ocular leads; RAT and LAT are the right and left anterior tibialis electromyograms; Sa_{O_2} is the oximetry lead.

TABLE 99-5 Diagnostic Testing Options for Sleep-Disordered Breathing

	Type	Parameters Measured
	I	EEG, EOG, EMG, ECG, airflow, respiratory effort, O_2 saturation, usually video (all conducted in a sleep laboratory with a sleep professional present)
Out-of-center testing	II	Minimum of seven channels including EEG, EOG, chin EMG, ECG/HR, airflow, respiratory effort, and O_2 saturation
	III	Minimum of four channels including ECG/HR, O_2 saturation and at least two channels of respiratory movement or respiratory movement and airflow
	IV	Airflow and/or O_2 saturation[a]

[a]*Centers for Medicare and Medicaid Services require measuring a minimum of three channels, at least one of which is airflow.*

EEG, electroencephalogram; EOG, electrooculogram; EMG, electromyogram; ECG, electrocardiogram, HR, heart rate.

limited research in the field. AHIs determined from Type III studies tend to underestimate PSG indices largely due to absence of EEG leads; PSG AHI is calculated as the number of respiratory events per hour of *sleep*, while Type III monitor AHI is based on hours of *use*. In addition, hypopneas can be underdiagnosed in the absence of EEG (arousals used to score hypopneas cannot be reliably determined). Therefore, portable monitors may have reduced sensitivity to detect OSA, especially in patients with mild disease.[204]

Once the diagnosis is made, treatment decisions among providers (CPAP or no CPAP) are more heterogeneous for patients with portable monitor-diagnosed mild-to-moderate OSA compared to patients diagnosed with OSA of the same severity through PSG.[205] Nevertheless, functional outcomes after treatment have not differed in patients with a high pretest probability for OSA diagnosed using portable monitors, compared to in-laboratory PSG.[206,207]

Guidelines for portable sleep testing were updated in 2007.[208] They recommend that out-of-center sleep testing with a portable monitor be performed only in patients: with high pretest probability of moderate-to-severe OSA without significant comorbidities including CHF, severe COPD, and neuromuscular disease, risk of CSA, or other sleep disorders such as parasomnias or narcolepsy; in whom in-laboratory PSG is not feasible due to immobility, safety, or critical illness; or who need noncontinuous positive airway pressure (non-CPAP) treatment (i.e., oral appliance, upper airway surgery, weight loss) response monitoring.

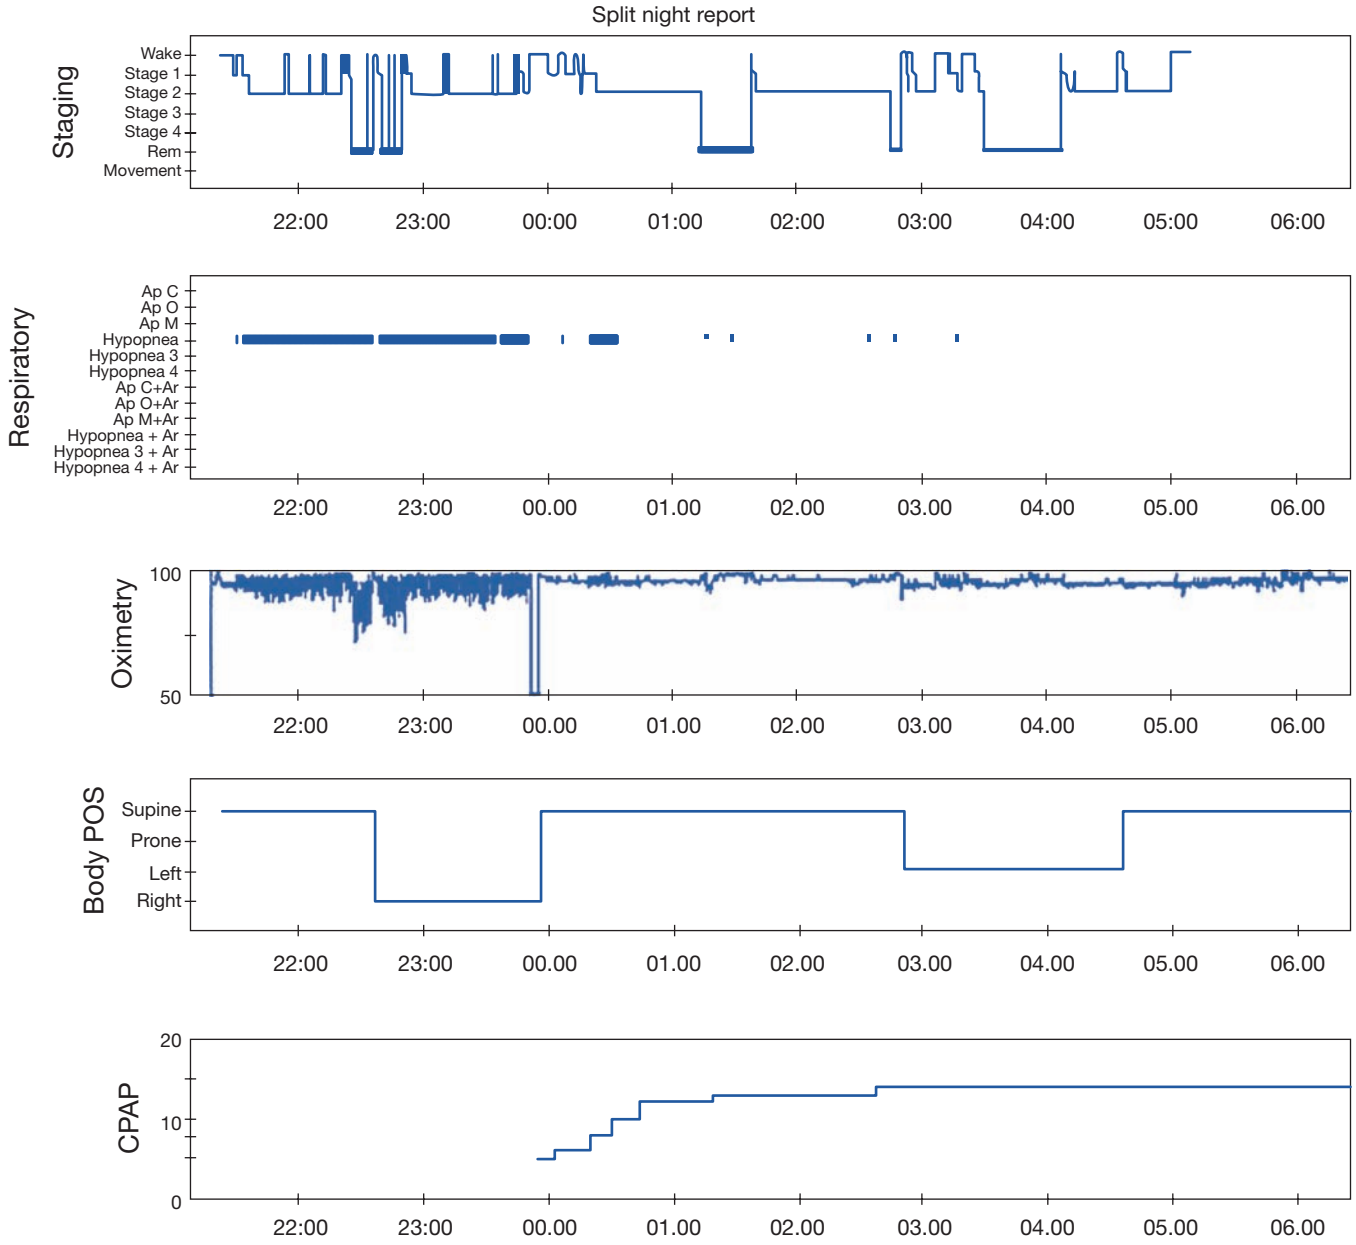

Figure 99-10 Split night hypnogram in a patient with obstructive sleep apnea. The patient has frequent hypopneas with recurrent oxyhemoglobin desaturations until he is started on CPAP at midnight. The CPAP was titrated to 14 cm H_2O, which abolished the hypopneas and oxyhemoglobin desaturations.

Despite these guidelines, portable sleep monitor utilization varies widely due to a number of factors, including local availability of in-laboratory PSG and the burgeoning number of insurers now mandating portable testing in lieu of PSG.[209] An algorithm for appropriate testing modalities for SDB can be seen in Figure 99-11.

In summary, in-laboratory PSG represents the gold standard for diagnosing sleep apnea. Technologic advancements in portable monitors and acceptance of out-of-center sleep testing by third party payers has led to increased access to diagnostic testing. However, excessive focus on the significance of absolute elevations in AHI can hamper the diagnosis and treatment of SDB. Patients may exhibit similar AHI, but experience dramatically different quality of sleep and outcomes. Important variables such as oxygen desaturation, number of arousals, and apnea/hypopnea length are not reflected by the AHI. Furthermore, it is not the AHI itself but the consequences (hypertension, myocardial infarction [MI], stroke, cardiac arrhythmias, excessive daytime sleepiness) of sleep apnea that are of paramount importance.

CONSEQUENCES OF OBSTRUCTIVE SLEEP APNEA

The number of recognized associations with sleep apnea has increased considerably. Figure 99-12 is a simplified representation of three principal disturbances associated with apnea during sleep, the proposed downstream pathophysiologic mechanisms, and reported clinical consequences. This is not a complete depiction of all that is known, and many factors operate in a complex interplay that can jointly augment health risk. Nevertheless, OSA sequelae can be broadly categorized by their neurocognitive, cardiovascular, and metabolic effects. OSA should be seen as a systemic disorder with effects on multiple organ systems.

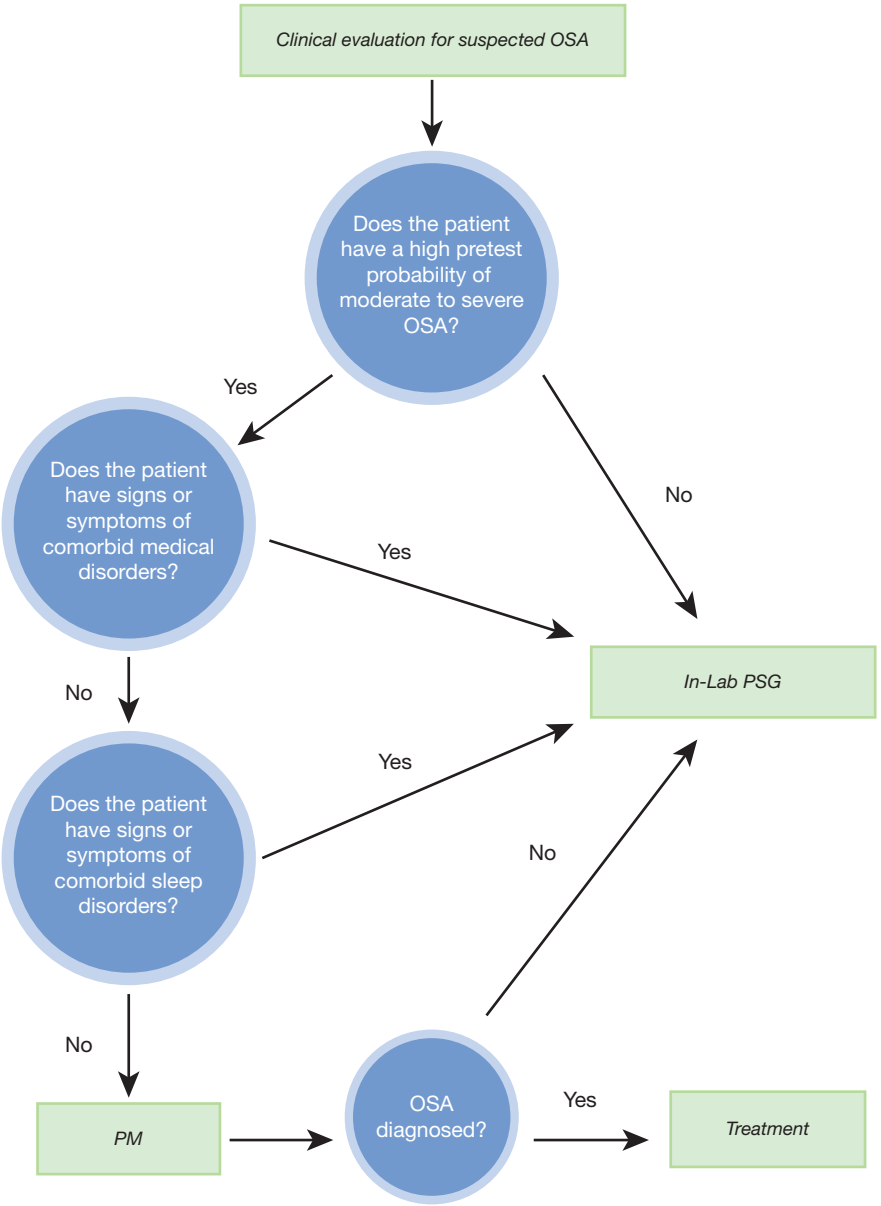

Figure 99-11 Out-of-center testing decision tree. Clinical guidelines for the use of unattended portable monitors in the diagnosis of obstructive sleep apnea in adult patients. J Clin Sleep Med. 2007;15:737–747.)*

■ NEUROCOGNITIVE CONSEQUENCES OF OSA

OSA-associated neurocognitive dysfunction may occur via a hypoxia/reperfusion injury mechanism whereby increased lipid peroxidation induces oxidative stress within neural tissue.[210,211] Neurovascular endothelial dysfunction has also been demonstrated in OSA patients, leading to an imbalance between vasodilation and vasoconstriction imbalance; lower nitric oxide levels in OSA patients appear to be a key mediator.[212] Dysregulated endothelium can also lead to hypercoagulability and atherosclerosis, potentially placing these patients at higher risk of vascular dementia.[213] Indeed, severe OSA has also been linked to increased risk of developing dementia in elderly patients.[214,215]

Excessive daytime sleepiness and sleep fragmentation associated with sleep apnea can lead to diminished cognitive function, affecting attention, memory, vigilance, and executive function.[216–219] While motor speed appears to be spared, fine motor coordination is impaired in OSA patients.[183,219,220] Despite these associations, recently published data from the Apnea Positive Pressure Long-term Efficacy Study (APPLES) failed to show correlation between AHI and neurocognitive performance after adjusting for ethnicity, educational level, and gender in a cross-sectional cohort.[221] Modest relationships between oxygen desaturation and neurocognitive performance were observed in this study and in the Sleep Heart Health Study.[222,223] Although the APPLES study's methodology has been questioned, these studies demonstrate inherent difficulties in establishing neurocognitive sequelae prevalence among OSA patients.[224]

OSA-related daytime sleepiness, attention lapses, and reduced vigilance are particularly salient when considering motor vehicle crashes. Several studies and a meta-analysis have shown these patients have at least a twofold increase in relative risk of automobile accidents; up to 20% of crashes are due to sleepiness, with OSA as the most common contributing medical cause.[180,225,226] When treated with CPAP, accident rates return to those of the general population.[227] This creates an intriguing medicolegal quandary for physicians treating nonadherent OSA patients who are known to drive drowsy. Practicing physicians should understand the relevant laws in their own state for guiding decisions regarding monitoring of drivers and reporting to appropriate agencies. The American Thoracic Society has published new guidelines regarding OSA and driving.[226] These support expedited diagnosis using PSG and/or out-of-center testing and rapid treatment

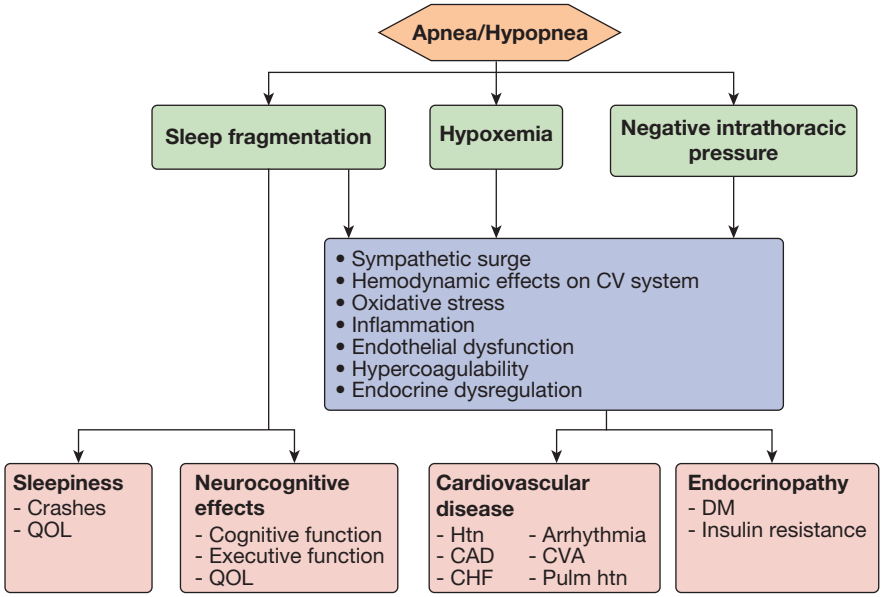

Figure 99-12 Flow chart of the proposed pathophysiologic mechanisms and consequences of obstructive sleep apnea. CV, cardiovascular; QOL, quality of life; Htn, hypertension; CHF, congestive heart failure; CVA, cerebrovascular accident; Pulm htn, pulmonary hypertension; DM, diabetes mellitus.

with PAP therapy. Clinicians should also consider implementation of a practice-based plan for patient education regarding drowsy driving risks and countermeasures.[226] Special consideration should be given to commercial drivers with OSA given the increased risk of fatality in large truck crashes.[228–231]

Untreated OSA has also been independently associated with depression.[188] SDB should be considered in anyone suffering from this mood disorder. Beyond depressive symptoms per se, OSA also impacts quality of life as measures by the Functional Outcomes of Sleepiness Questionnaire (FOSQ) and the Sleep Apnea Quality of Life Instrument (SAQLI).[232,233] CPAP therapy has been shown to improve these measures.[234]

■ CARDIOVASCULAR CONSEQUENCES OF OSA

A number of cardiovascular consequences of sleep apnea have been reported. While each is discussed individually, they share common and complex pathophysiology. Obstructive apneas result in recurrent hypoxia, repetitive arousals, and large swings in intrathoracic pressure.[235] These processes lead to an array of maladaptive mechanisms: Sympathetic surges, oxidative stress, inflammation, vascular endothelial dysfunction, metabolic dysregulation, hypercoagulability, and mechanical effects on the heart and vessels.[211,236–250] Each of these physiologic responses to apnea has been the focus of detailed research and requires further reading beyond the scope of this chapter. Overall, it is evident that sleep apnea induces physiologic processes conducive to the development of cardiovascular disease; results from a 10-year nonrandomized controlled observational study of patients with and without OSA showed untreated severe OSA patients had a 2.9-fold increased rate of fatal cardiovascular events after adjusting for confounding variables (Fig. 99-13).[200]

Hypertension

There are growing data that link OSA with systemic hypertension. About half of patients with known OSA have coexisting hypertension, and 30% to 40% of patients with hypertension have OSA.[251–253] The prevalence of OSA in patients with resistant hypertension is even higher; Logan et al.[254] studied subjects with hypertension who were all taking optimal doses of at least three antihypertensive agents and found an OSA (AHI ≥ 10 events/h) prevalence of 83% with a mean AHI of 25 events/h.

A canine model of sleep apnea demonstrated that recurrent occlusion of a tracheostomy each time when the animal fell asleep leads to the development of hypertension, both acutely during the sleeping period and subsequently chronically during the wake period even though the airway was no longer occluded.[255] In humans, OSA has ranked among the main causes of secondary hypertension, with several large cross-sectional studies demonstrating this relationship.[256] In the Sleep Heart Health Study, the odds ratio for the presence of hypertension in the highest category of AHI (≥30 events/h) was 1.37 compared with the lowest category AHI (<1.5 events/h).[257] The Wisconsin Sleep Cohort Study, a prospective population-based study, demonstrated an increased risk of incident hypertension in patients with even mild OSA (AHI = 5–15 events/h). Independent of BMI, the odds ratio was 2.0 for mild (AHI = 5–15 events/h) and 2.9 for moderate or severe sleep apnea (AHI ≥ 15 events/h) over a 4- to 8-year follow-up period.[258]

In several randomized trials, treatment of OSA with continuous positive airway pressure (CPAP) has been shown to reduce BP, particularly if OSA is severe.[259–261] In these studies, BP was significantly lowered not only in patients with resistant hypertension, but also in patients with relatively mild hypertension. One randomized controlled trial demonstrated that several weeks to months of CPAP resulted in a significant reduction in daytime BP up to 5.1 mm Hg compared to treatment with subtherapeutic CPAP.[262] A meta-analysis of 16 randomized trials comparing CPAP users to OSA-positive nonusers found a mean net decrease in systolic pressure of 2.46 mm Hg in the former group compared to the latter.[263] This effect may appear modest, but antihypertensive mediation literature shows a 41% decline in stroke and a 22% decline in coronary artery disease (CAD) from just a 5 mm Hg decline in diastolic BP; even a 2 mm Hg diastolic BP drop may decrease risk by 15% and 6%, respectively.[264,265]

CPAP appears to impact BP elevation most in patients with resistant hypertension. One study found a mean arterial pressure drop of 5.6 mm Hg in CPAP-adherent, resistant hypertension

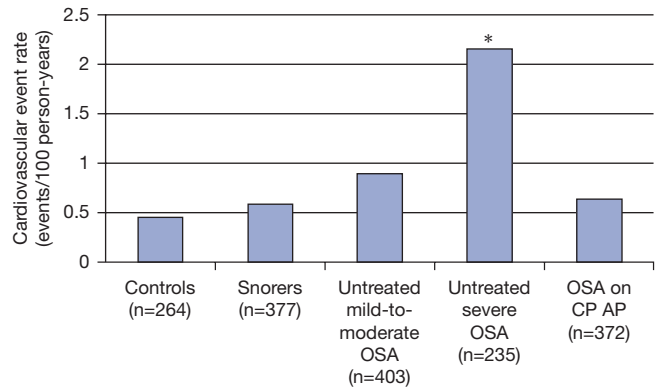

Figure 99-13 Cardiovascular event incidence during 10-year follow-up in healthy men (controls), snorers, and treated and untreated OSA patients. *p<0.0001 vs. healthy men. *(Data from Marin JM, Carrizo SJ, Vicente E, et al. Long-term cardiovascular outcomes in men with obstructive sleep apnoea-hypopnoea with or without treatment with continuous positive airway pressure: An observational study. Lancet. 2005;365:1046–1053.)*

patients versus a drop of 0.8 mm Hg in CPAP-adherent patients with controlled hypertension. Nearly 71% of these resistant hypertensive patients had their antihypertension regimen simplified after CPAP.[266] Other work has shown up to a 7.3 mm Hg drop in nocturnal systolic pressure in similar resistant hypertension patients using CPAP, with resumption of normal nocturnal BP dipping observed in 27% of their 33-person cohort.[267] These beneficial effects of CPAP on hypertension, however, should not detract from emphasis on conventional pharmacologic methods of lowering BP.

Myocardial and Cerebrovascular Events

OSA has been associated with MI and stroke in cross-sectional studies, with a large longitudinal follow-up study confirming increased rates of cardiovascular events and cardiovascular mortality in patients with untreated severe OSA (Fig. 99-13).[200,268,269] One study showed increased cardiovascular event rates even in patients with moderate OSA.[270]

Specifically considering the stroke literature, OSA prevalence among these patients ranges from 50% to 70%.[271] Therefore, all stroke patients should be screened for OSA. Recent results from the Sleep Heart Health Study reveal that men with moderately severe OSA have an almost threefold increased risk of ischemic stroke compared to men without OSA. In fact, risk of stroke in men increased 6% with every unit increase in AHI between 5 and 25 events/h. The effect does not seem as strong in women, with risk of stroke only significantly increased at AHI >25 events/h.[202]

OSA likely leads to MI and cerebrovascular events in a variety of ways. Hypoxic events during sleep may trigger them; individuals with OSA who suffered an MI are more likely to have had their acute event between the hours of midnight and 6:00 AM than OSA-free individuals.[272] Another contributor could be OSA-related oxidative stress and proinflammatory state, leading to atherosclerosis. This has been demonstrated in a mouse model.[273] In addition, research reveals that snoring is associated with plaques in the carotid arteries but not the femoral arteries, even in patients with few apneas.[274] Since rat tail vibration has been previously shown to induce blood vessel endothelial damage, snoring-related vibration may have a similar effect on the carotid arteries, increasing risk of stroke.[275] Should this concept be demonstrated in humans, treating any patient who snores – regardless of OSA status – could become the norm.

Other Cardiovascular Consequences of Sleep Apnea

OSA adversely impacts a number of other cardiovascular outcomes including CAD and CHF. The Sleep Heart Health Study studied men and women ≥40 years old who were free of CAD and CHF at baseline.[276] After a median 8.7-year follow-up and adjusting for multiple risk factors, they found OSA to be a significant predictor of CAD in men (but not women) ≤70 years of age. Men aged 40 to 70 were 68% more likely to develop CAD if they had severe OSA than no OSA. Men were also 58% more likely to develop incident CHF when comparing these two groups. Explanations for the observed sex differences are unclear, but may include less exposure to OSA in women due to their tendency to develop the disorder after menopause, and possible sex differences in physiologic response to OSA.[276]

There are several pathophysiologic explanations for higher rates of CHF in OSA patients.[277] Generation of negative intrathoracic pressure resulting from obstructive apneic events can increase the difference between extracardiac and intracardiac forces, increasing LV transmural pressure and leading to LV hypertrophy.[278] Apneic events can also distend the right ventricle, as increased filling (due to negative intrathoracic pressure) and pulmonary vasoconstriction (due to hypoxia) occur simultaneously. Leftward shifting of the intraventricular septum can occur, resulting in reduced LV filling and stroke volume.[279] OSA-associated hypoxia has also been shown to decrease systolic contractility directly while impairing diastolic relaxation.[280,281]

Cardiac arrhythmias have also been associated with OSA. Relatively benign arrhythmias (i.e., bradycardia/tachycardia [bradycardia during the apnea and tachycardia during the arousal], atrial premature contractions, and ventricular ectopy) have long been observed, but recent attention has focused on atrial fibrillation.[235] Data from the Sleep Heart Health Study have shown that atrial fibrillation is more common in patients with severe OSA than in those without OSA.[282] Patients with untreated OSA whose atrial fibrillation converts to sinus rhythm after cardioversion are more likely than other patients to relapse into atrial fibrillation.[283] In addition, OSA is felt to be a risk factor for recurrent atrial fibrillation after radiofrequency catheter ablation.[284–286]

METABOLIC CONSEQUENCES OF OSA

OSA has been proposed as an additional component of the metabolic syndrome, a multisystem disorder currently characterized by obesity, impaired fasting glucose, hypertriglyceridemia, and reduced high-density lipoprotein (HDL). In fact, OSA has been independently associated with each component of this syndrome; individuals with OSA (AHI ≥ 15 events/h) have about 5.9 to 9 times the likelihood of having the metabolic syndrome compared to individuals without it.[287–289] Specifically considering glucose tolerance, up to 86% of type 2 diabetes patients have at least mild OSA (AHI ≥ 5 events/h).[290] A recent study that followed diabetes-free men for 10 years showed that development of the disease was independently associated with presence of OSA at baseline.[291]

There is evidence of OSA as an independent risk factor for insulin resistance (controlling for obesity) in general population and sleep center cohort studies.[244,292] Results from intervention studies has been mixed, with CPAP therapy leading to improved glycemic control in one study, but having no significant impact in another.[293,294]

Assessing causality between OSA and the metabolic syndrome has been difficult, and there is likely synergy between the two disorders. Mechanisms underlying this link are likely complex and remain to be fully elucidated. Chronic intermittent hypoxia exposure and sleep fragmentation are key mediators that may trigger a systemic inflammatory response.[295] At a minimum, patients with OSA should be assessed for the presence of relevant metabolic disturbances and the metabolic syndrome. Obese patients with type 2 diabetes mellitus should be screened for OSA.

MORTALITY

Several cohort studies, including the Wisconsin Sleep Cohort, Busselton Health Study, and the Sleep Heart Health Study demonstrate an association between untreated OSA and increased mortality.[201,296,297] This relationship is strongest when considering cardiovascular mortality and individuals with severe OSA.[297] A recent study of patients with ischemic heart disease showed a dose–response relationship between OSA severity and mortality, reinforcing the importance of OSA screening in this population.[298] In addition, survival curves for patients with severe OSA are identical whether or not they complain of sleepiness, supporting treatment for nonsomnolent patients with OSA.[201,299]

The association between OSA and mortality is more questionable for individuals over the age of 65 years.[300] Indeed, Lavie et al. showed a survival *advantage* in elderly patients (≥65 years) with RDIs (similar to AHI) between 20 and 40 events/h; OSA may be protective in this group due to ischemic preconditioning, leading to increased vascular endothelial growth factor (VEGF) and collateral coronary vessels.[301,302] Nevertheless, a more recent study showed that mortality rates are significantly increased among elderly people with severe OSA (AHI ≥ 30 events/h), and that those rates return to normal with CPAP treatment.[303] Therefore, there is no consensus that modifying OSA evaluation and treatment for elderly patients leads to any mortality benefit.

ECONOMIC CONSEQUENCES OF OSA

Because it is so common, sleep apnea poses a sizeable economic burden on society. OSA subjects have been demonstrated to utilize healthcare resources at approximately 1.5 to 2 times the rate of controls as far back as 10 years prior to diagnosis.[304–307] Estimates of the total economic cost that sleep apnea confers upon society are sparse. However, the financial burden of moderate-to-severe OSA in the United States is $65 to $165 billion/y, which is greater than asthma, stroke, heart failure, and hypertensive disease ($20–$80 billion).[308,309]

Limited numbers of sleep laboratories, sleep physicians, and sleep technologists coupled with cost of equipment and reimbursement issues have created a "bottleneck" effect in which global demand for sleep medicine services exceeds capacity. Nevertheless, economic analyses have shown that addressing diagnosis and treatment of moderate-to-severe sleep apnea, particularly with CPAP, is economically attractive and supports the value to society relative to other accepted treatment for other common conditions such as hypertension control, breast cancer screening, and comprehensive diabetes care.[310–314]

TREATMENT OF OSA

The decision to treat OSA should be based on its severity, related symptoms, and medical comorbidities. Treating moderate-to-severe disease (defined as AHI ≥15), particularly with PAP therapy, reduces cardiovascular risk, improves neurobehavioral performance, and enhances quality of life.[315,316] The AASM currently considers PAP as *standard* therapy for this group regardless of symptoms or comorbidities.[317] The same Practice Guidelines suggest PAP as an *option* for mild OSA, given conflicting data on its medical, behavioral, and functional sequelae.[318] In addition to OSA severity, disease-related sleepiness (or lack thereof) has been identified as a treatment determinant. Only sleepy patients with mild-to-moderate OSA show functional improvement using PAP, though the effect may be small.[319,320] Moreover, nonsleepy patients may not experience significant BP or cardiovascular event rate reduction on PAP, regardless of OSA severity.[321,322]

Third party payers have utilized these data in creating treatment coverage structures. The Centers for Medicare and Medicaid Services cover at least the initial 12 weeks of PAP therapy in patients whose AHI or RDI is ≥15 events/h. Patients with indices ≥5 events/h but ≤14 events/h must have documented excessive daytime sleepiness, impaired cognition, mood disorders or insomnia, hypertension, ischemic heart disease, or history of stroke to qualify for PAP coverage.[323] Ultimately, provider expertise should dovetail with patient preference to guide treatment choice and modality.

Options for the treatment of OSA include PAP therapy, behavioral therapies, mandibular repositioning devices, surgical treatments, and adjunctive therapies.[199] First-line therapy for sleep apnea syndrome remains medical.

POSITIVE AIRWAY PRESSURE THERAPIES

Colin Sullivan et al.[10] first described the use of nasal CPAP to treat OSA in 1981 (see examples of subjects wearing CPAP in Fig. 99-14). Today, CPAP remains the mainstay of therapy for most patients with OSA. CPAP delivers a fixed pressure continuously throughout inspiration and expiration, providing a pneumatic splint for the airway that prevents airway collapse during sleep, when upper airway muscle dilator activity is reduced. CPAP therapy increases airway caliber in the retropalatal and retroglossal regions (Fig. 99-15); in particular, it increases the lateral dimensions of the airway and thins the lateral pharyngeal walls.[324]

CPAP usually reduces the number of apneic episodes during sleep to the normal range and has the advantage of being noninvasive. It clearly improves daytime sleepiness in patients with OSA in numerous studies including those in which patients were randomized to CPAP or sham (subtherapeutic) CPAP therapy, with greater improvements in daytime sleepiness among those with the highest AHIs.[320,325–330] A number of studies have demonstrated that CPAP use is associated with a modest reduction in BP among patients with hypertension and OSA.[259–261] In addition, drivers with OSA who are treated with CPAP have a reduced risk of motor vehicle crashes.[331]

CPAP therapy is indicated in all patients with moderate or severe sleep apnea (i.e., an AHI ≥15 events/h) and in those patients with mild OSA who have associated symptoms, as noted previously.[317] The optimal pressure can be determined during a titration polysomnogram or using out-of-laboratory treatment algorithms in conjunction with portable monitoring for OSA diagnosis.[332,333] Typically, pressures of 5 to 20 cm H_2O are needed to abolish apneic events, snoring, and oxyhemoglobin desaturation in all positions and during REM sleep.

CPAP can be delivered using a variety of interfaces (Fig. 99-14) including nasal masks, nasal inserts, or full-face masks (which cover the nose and mouth). It is important to ensure that the patient has a well-fitting interface with the CPAP machine absent of air leaks. Mouth leaks, which often result from mouth breathing while using a nasal mask, can render CPAP ineffective, since the positive pressure generated by the CPAP unit escapes. Use of heated humidity with CPAP therapy has been shown to successfully ameliorate some of the side effects listed in Table 99-6. Some but not all studies have demonstrated improvements in CPAP adherence with the use of heated humidification.[334–336]

Over the last two decades, CPAP machines and masks have become increasingly user friendly. CPAP masks have improved profoundly so the prospect of using CPAP has become much less daunting. Some institutions operate "mask clinics" concomitantly with sleep clinics so that patients with OSA can be fitted for a CPAP mask immediately after the sleep specialist consultation. CPAP units are also smaller, portable, and quieter, and they now nearly universally provide data

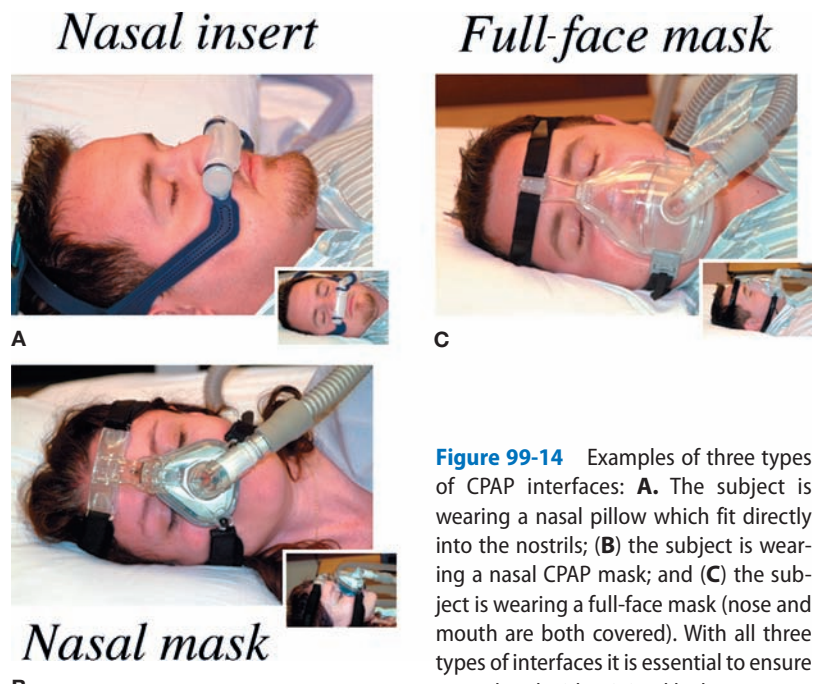

Figure 99-14 Examples of three types of CPAP interfaces: **A.** The subject is wearing a nasal pillow which fit directly into the nostrils; (**B**) the subject is wearing a nasal CPAP mask; and (**C**) the subject is wearing a full-face mask (nose and mouth are both covered). With all three types of interfaces it is essential to ensure a good seal with minimal leaks.

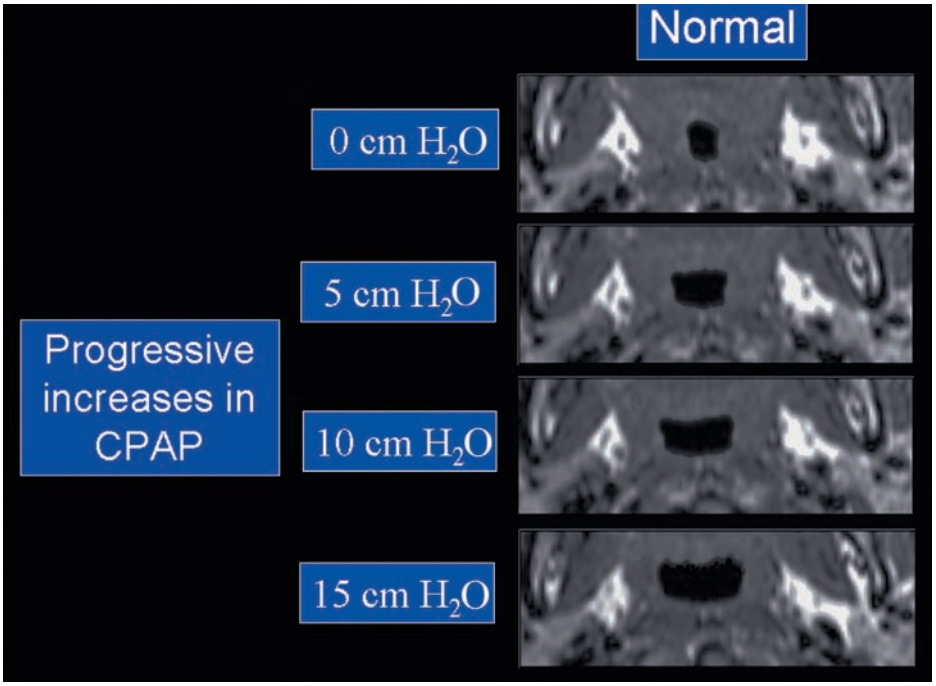

Figure 99-15 Axial retropalatal magnetic resonance imaging (MRI) in a normal individual with continuous positive airway pressure (CPAP) ranging from 0 to 15 cm H_2O. With increasing CPAP there is a progressive increase in the size of the upper airway, particularly in the lateral dimension (the anterior–posterior dimensions of the airway do not change significantly with CPAP). There is little movement of the parapharyngeal fat pads (*white structures* lateral to the airway) but progressive thinning of the lateral pharyngeal walls. *(Reproduced with permission from Schwab RJ, Pack AI, Gupta KB, et al. Upper airway and soft tissue structural changes induced by CPAP in normal subjects. Am J Respir Crit Care Med. 1996;154(4 Pt 1):1106–1116.)*

on patient adherence patterns, mask leaks, and the effectiveness of the delivered CPAP pressure (i.e., residual SDB events with use of CPAP). These data provide critical clinical information and are also being used by insurers to make coverage decisions (i.e., poor adherence to CPAP can lead to denials of equipment coverage). For instance, for continuing coverage, Medicare currently requires documentation of use of PAP ≥4 hours per night on 70% of nights during a consecutive 30-day period during the first 3 months of initial usage.[337]

CPAP use is associated with few serious side effects.[338–341] Common side effects are listed in Table 99-6. Nasal irritation and rhinitis are treated with heated humidification and consideration of a nasal steroid spray. Claustrophobia may be relieved in some cases by changing the type of mask. Aerophagia can be ameliorated by altering body position or mask type. Serious adverse effects are uncommon but include very rare reports of severe epistaxis, meningitis, and pneumocephalus.[342–344]

Adherence to CPAP therapy is variable and ranges in most studies from 60% to 85%.[345] Although estimates suggest that patients use CPAP treatment, on average, for only 4 to 5 hours per night, a dose–response relationship has been observed between longer durations of nightly use and greater likelihood of achieving normal daytime alertness and functional status.[346,347] Patterns of CPAP usage have been reported to declare themselves within the first weeks of therapy.[348,349] Groups of "consistent users" (CPAP >90% of nights per week) and "intermittent users" (skipped CPAP use one or more nights per week) remain stable at 1 to 3 months. Thus, initiatives to enhance CPAP adherence are likely to be more effective during the period immediately following initiation of CPAP therapy. Intervention studies have tested educational, technologic, psychosocial, pharmacologic, and multidimensional strategies.[345] Practices that may promote CPAP adherence include involving the bed partner, promoting positive initial experiences with CPAP, and anticipatory support for side effects and troubleshooting. Applications that allow OSA patients to access and track their own CPAP adherence data on computers and smartphones are also becoming available (e.g., SleepMapper from Respironics). Reported predictors of adherence to CPAP therapy include race/ethnicity, socioeconomic status, AHI, and Epworth Sleepiness Score.[341,345,350–353]

In addition to fixed CPAP, PAP can be delivered via bilevel systems and automatically titrating systems. Bilevel systems deliver higher pressures during inspiration and lower pressures during expiration, and may be used when patients report difficulty with exhaling against PAP. However, bilevel systems are more expensive and evidence is lacking in terms of better adherence and treatment outcomes when compared with CPAP.[354,355] Limited evidence suggests that patients with coexisting lung disease or respiratory acidosis demonstrate improved gas exchange with the use of bilevel PAP compared with CPAP.

Autotitrating CPAP, or auto-CPAP, adjusts CPAP during use by detecting airway flow, snoring, apneas, and inspiratory flow limitation (Fig. 99-16). The specific algorithm used depends on the individual device. Each auto-CPAP unit uses a different algorithm for abolishing apneas. These units can be utilized in several ways: For chronic treatment of OSA (e.g., for patients with difficulty tolerating fixed CPAP and evidence of variable positive pressure needs due to REM-related or positional sleep apnea); or for use in the laboratory or at home to determine the optimal setting for conventional fixed CPAP after a trial period.[356] Patient adherence does not appear to be significantly improved with chronic use of auto-CPAP compared to fixed CPAP therapy.[357] The use of auto-CPAP for OSA titration is associated with substantially lower costs compared to in-laboratory CPAP titration, and a number of studies have shown that auto-CPAP can be successfully incorporated into algorithms for diagnosis and treatment of OSA. Furthermore, with the greater implementation of out-of-laboratory treatment algorithms in which

TABLE 99-6 Complications Associated with CPAP

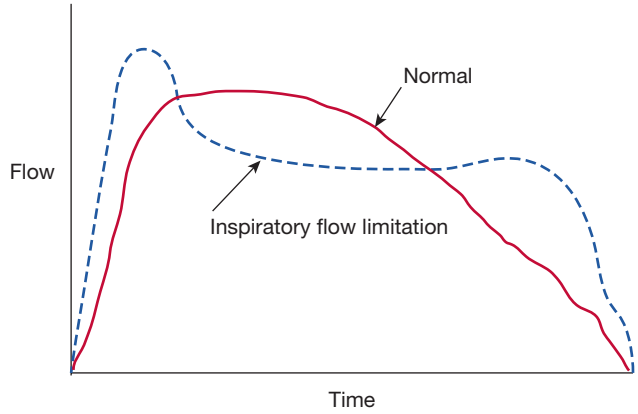

Figure 99-16 Schematic diagram showing the normal pattern of airflow during inspiration and that which occurs when there is inspiratory flow limitation. In the latter the flow quickly reaches a level that is maintained relatively constant throughout inspiration. This pattern of airflow can be detected by processors built into auto-CPAP units.

patients undergo portable monitoring for OSA diagnosis and are then started and maintained on auto-CPAP therapy, utilization of auto-CPAP has become increasingly common.[333,358,359] Studies to date have not demonstrated significant differences between the effects of auto-CPAP and fixed pressure CPAP on BP.[360–363]

GENERAL MEASURES

Patients with sleep apnea should avoid alcohol, sedative hypnotics, and opioids.[364] These commonly used substances are generally thought to reduce upper airway muscle tone and increase the severity of snoring and apneas.[365–370] They may also depress arousal mechanisms, thereby prolonging apneas and causing greater oxygen desaturations.[367,368,370]

Adherence to good sleep hygiene practices so as to maintain adequate sleep amounts also is important in sleep apnea patients. Sleep deprivation can reduce hypoxic and hypercapnic respiratory drive and prolong apnea duration.[371–374]

WEIGHT LOSS

Excess weight theoretically increases the propensity for upper airway collapse due to higher extraluminal pressures associated with excess soft tissue/fat and the encroachment of the tongue and soft palate.[42,375] Truncal obesity may also play a role by reducing chest compliance and functional residual capacity; this leads to increased oxygen demand.[376] Weight loss via dietary modification has been associated with significant reductions in SDB.[377,378] The extent of weight loss and degree of improvement are not always directly related, although it has been shown on average that a 1% change in weight is associated with a 3% change in AHI.[379] More specifically, weight loss in obese patients with type 2 diabetes mellitus is associated with a significant reduction in the AHI.[380] Interestingly, AHI changes associated with weight loss (or weight gain) are stronger in men than women.[381] Weight loss effects on OSA can be beneficial well into the weight maintenance phase.[382–384]

Over the past several years, there has been progressive interest in the use of bariatric surgery to treat extreme obesity. Interestingly, the effect of bariatric surgery as a treatment for OSA is unclear. In a recent randomized control trial, laparoscopic adjustable gastric bypass, although associated with major differences in weight loss over conventional therapy with dietary modification, was not associated with significantly greater reduction in SDB.[385] The Morbid Obesity treatment, Bariatric surgery versus Intensive Lifestyle intervention Study (MOBIL-study) demonstrated that patients undergoing Roux-en-Y gastric bypass had a greater reduction in the prevalence and severity of SDB compared to intensive lifestyle intervention. Of note, adjusting for degree of BMI change in this nonrandomized trial negated the effect on AHI.[386] These findings suggest that improvements in SDB are likely driven by weight loss more than the method of weight loss. Not surprisingly, short-term (30-day) complications were higher in individuals undergoing bariatric surgery (either Roux-en-Y or adjustable laparoscopic banding) who had a diagnosis of OSA as well as a history of thromboembolic disease and impaired functional status compared to those who were undergoing those surgeries without these comorbidities.[387] A recent meta-analysis demonstrated that bariatric surgery patients were unlikely to experience enough of a reduction in the AHI to obviate the need for continued treatment of OSA with CPAP despite significant surgical weight loss.[388] Given the available data, individuals who undergo bariatric surgery and experience a significant amount of weight loss should be formally reassessed for the presence of apnea after maximal weight loss has been achieved. The use of autoadjusting CPAP should be considered during the postoperative period to accommodate changes in SDB during this time. Of note, exercise appears to have a beneficial effect on the incidence of mild-to-moderate OSA; this effect appears to be related to changes in body habitus.[389] It should be noted that SDB can, in turn, promote obesity via several mechanisms including physical inactivity due to sleepiness, poor dietary habits related to abnormalities in leptin, a satiety hormone, insulin resistance, and systemic inflammation.[240,244,292,390–401] Given these findings, weight loss should be recommended in all overweight patients with OSA.

Of interest, a recent secondary analysis of data from the APPLES revealed that individuals using CPAP experienced modest weight gain compared to those using sham CPAP. Those who were the most adherent to CPAP (i.e., using CPAP for more than 4 hours for 70% of the nights) had the greatest amount of weight gain compared with nonadherent subjects.[402] While the reason for the weight gain is unclear, suggestions include a loss of increased sympathetic tone and/or a loss of a high energy cost of breathing overnight. Hypothetically, these lower energy states in conjunction with a continued level of caloric intake may lead to a net weight gain.

INTRAORAL DEVICES

Although CPAP represents the gold standard for treating OSA, adherence can be challenging for many patients.[339,341,348,403,404] Given this, increasing attention has focused on the intraoral devices, also known as oral appliances, as an alternative treatment to CPAP.

Oral devices aim to alter the position of the upper airway structures, thereby enlarging airway caliber or reducing airway collapsibility during sleep. The oral appliances have undergone considerable evolution in their design, comfort, and effect on airway structures in the past three decades. The tongue retaining device (TRD) developed in the 1980s by Samelson was designed to maintain the tongue in a forward position during sleep.[405] Two other types of devices are palatal lifting devices and mandibular advancing devices, the latter being the most studied (see example of mandibular advancing device, Fig. 99-17). The mandibular advancement devices produce downward rotation and advancement of the lower jaw during sleep.[406] These devices are fashioned out of a wide variety of materials and are available with various device features. Many mandibular advancement devices are custom-made for the client following a dental or maxillofacial surgery consultation. In choosing an oral device, attention to its adjustability (modifiability over time) and titratability (ability to alter jaw position by adjusting the appliance) are important. In addition, provisions for temporomandibular joint support, tooth coverage, and jaw mobility are important as side effects of the oral devices include excessive salivation, dry mouth, tooth or jaw discomfort, occlusive changes, and temporomandibular joint pain.[407]

A recent Cochrane review of the effect of oral appliances in the treatment of OSA in adults found that CPAP was more effective

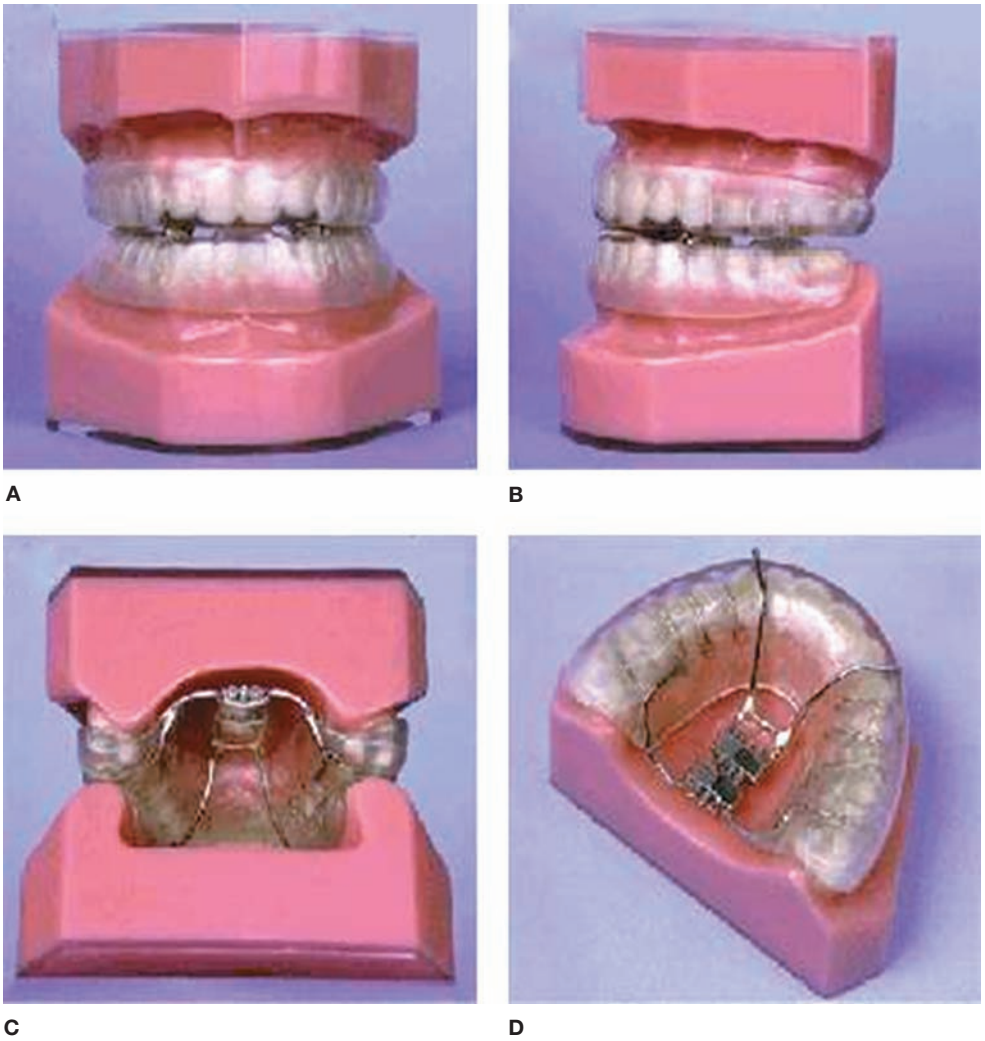

Figure 99-17 Anterior (**A**), lateral (**B**), posterior (**C**), and superior (**D**) views of an adjustable mandibular repositioning device (Klearway appliance, University of British Columbia, Vancouver, Canada). This device fits on the upper and lower teeth; it is worn during sleep and results in anterior motion of the mandible with consequent enlargement of the airway. The appliance is adjusted until the sleep-disordered breathing improves.

in reducing sleep disruption and AHI and was associated with an increase in the minimum oxygen saturation during sleep.[408] However, these benefits might be offset by increased patient adherence in those who used an oral appliance.[316] Based on randomized trials, the oral appliance is a reasonable alternative to CPAP, particularly for patients with mild-to-moderate OSA.[330,409–411]

At present, oral appliances/mandibular reposition devices are indicated for patients with primary snoring, or mild-to-moderate OSA who prefer them to CPAP or do not respond to, are not appropriate candidates for, or who fail treatment attempts with CPAP.[412] Patients with severe OSA should have a trial of CPAP first based on lower success rates with oral appliances.[317] Patients treated with an intraoral device are recommended to have follow-up PSG to verify efficacy, as some patients show no improvement. Importantly, the ability of oral appliances to reduce the severity of SDB to less than 10 events/h has been estimated to be approximately 50%.[407] Thus, there should be close monitoring by the treating physician to monitor for signs and symptoms of worsening OSA. In addition, regular follow-up with the dental specialist who fashioned the device is an important component of ongoing care in the patient who utilizes an oral appliance.

Recently, a novel treatment modality was introduced involving application of intraoral negative pressure via an oral interface connected to a vacuum pump in an attempt to stabilize upper airway tissue in patients with OSA.[413] A 4-week, multicenter, open-label, single-arm, randomized crossover trial was conducted on 63 subjects who used the oral pressure therapy (OPT device) and revealed improvement in the median AHI of 47% on the first treatment night and improvement in the 28-day median AHI of 43%. Thirty-one percent of the subjects saw a clinically significant response denoted as an AHI ≤10 events/h and ≤50% of control values. In addition, improvements in sleep quality (e.g., increased REM sleep and decreased arousals), sleepiness, and oxyhemoglobin desaturation index were noted. No significant adverse events were reported and nightly usage was high. Preliminary data suggest that OPT targets retropalatal collapse.[413] More studies including randomized controlled trials will be needed to determine the role OPT will play in the treatment of OSA.

■ POSITION THERAPY

It seems intuitive that body position during sleep would have an effect on respiratory mechanics.[414–416] Sleep in the supine position would seem to be more conducive to airway obstruction by virtue of gravity's effect on the tongue. Raising the head of bed angle to between 30 and 60 degrees has been studied; however, it is unclear if its effects reach beyond promoting airway stability to actually reducing AHI.[414,415,417] In 1984, Cartwright[418] defined positional-dependent sleep apnea as SDB in which the AHI while asleep in the supine position was at least twice as high as in the lateral position. The prevalence of position-dependent sleep apnea using this definition may be as high as 50% to 70% and may be of particular significance in patients with mild OSA.[419–423] For patients with position-dependent sleep apnea, symptoms may be alleviated by promoting sleep in the lateral decubitus position.[421,424–429] The lateral position is associated with increased maximum cross-sectional upper airway area and lower closing

pressure of the passive pharyngeal airway compared to the supine position.[416] Lateral positioning during sleep can be accomplished by sewing pockets for tennis balls to the back of sleep attire.[430] Devices to train people to sleep in the lateral position with the use of an alarm have been described.[424] Various other mechanisms have been suggested including a backpack and ball, a thoracic antisupine band, and a Zzoma positional sleeper.[421,431,432] Several studies have suggested that positional therapy is equivalent to CPAP in the treatment of positional-dependent sleep apnea.[421,432] However, a recent meta-analysis concluded that in terms of reducing the AHI and increasing oxyhemoglobin saturation, positional therapy was inferior to CPAP therapy.[433] In addition, long-term compliance for positional therapy appears to be mediocre at best; nonetheless it is better than adherence to CPAP therapy.[434] Interestingly, use of positional therapy in combination with other therapies for position-dependent OSA such as nasal expiratory PAP and mandibular repositioning devices may be associated with greater reductions in AHI.[435,436] Given all that is known about positional therapy, a relatively simple and inexpensive technique, consideration of its use to treat mild OSA with a positional component or as an additive measure to improve the efficacy of other treatment measures is warranted.

NASAL EXPIRATORY POSITIVE AIRWAY PRESSURE

Nasal expiratory positive airway pressure (EPAP) is delivered via a novel device with a one-way mechanical valve that provides high expiratory resistance in the setting of very low inspiratory resistance. The nasal EPAP device is applied to each nostril using adhesive and is designed for one-time use. Positive pressure resulting from the high expiratory resistance during exhalation stents open the upper airway, rendering it less likely to collapse on subsequent inhalation and increases end-expiratory lung volumes.[437,438] Nasal EPAP appears to reduce AHI and improve subjective sleepiness in patients with mild-to-moderate OSA.[439–441] Nasal EPAP has not yet been compared to CPAP directly in this population. A recent study assessing the utility of nasal EPAP as an alternative short-term therapy for patients with moderate-to-severe OSA already on therapeutic CPAP was unable to show a beneficial effect of nasal EPAP.[442] Given our current knowledge, nasal EPAP can be considered as an alternative therapy in individuals with mild-to-moderate SDB who are unable to tolerate CPAP therapy.

PHARYNGEAL MUSCLE STIMULATION

The genioglossus muscle is the largest airway dilator muscle. Electrical stimulation causes tongue protusion and stiffening of the anterior pharyngeal wall.[443] Attempts at muscle stimulation have enlarged upper airway diameter and reduced apneas and hypopneas during sleep in patients with SDB.[444–449] However, use of this technique has been limited by arousals associated with tongue protrusion.[449–451] An alternative strategy is to electrically stimulate the hypoglossal nerve to cause contraction of the genioglossus muscle, thereby increasing airway patency during sleep. The branches of the hypoglossal nerve that innervate the genioglossus consist mostly of efferent (motor) fibers that activate the genioglossus muscle with minimal sensory feedback.[443] Chronic stimulation of the hypoglossal nerve as a possible treatment for OSA was initially considered more than 20 years ago, but several technical limitations led to a 10-year hiatus before enthusiasm for hypoglossal nerve stimulation resurfaced.[443,452–455] Several recent open-label studies have demonstrated efficacy, including improved airflow, reduced AHI, and improved symptoms, as well as safety and compliance with the use of newer implantable hypoglossal nerve stimulators.[443,456–459] Preliminary data also suggest that there may be a beneficial residual effect after 1 year of therapy with hypoglossal nerve stimulation.[459] Although the recent data using new devices seem promising, more studies need to be performed with this modality.[460] A randomized clinical trial is presently underway that will hopefully provide additional information as to the role of hypoglossal nerve stimulation in patients with OSA.[461]

Genioglossus and hyoid advancement (GAHM)
Sliding genioplasty
Maxillomandibular advancement osteotomy
Tracheostomy

SURGICAL TREATMENT OF OSA

A variety of surgical options are available to correct abnormalities in the upper airway that lead to obstruction during sleep (Table 99-7). However, the success of these treatments, aside from tracheostomy, is less well established and generally less effective than PAP therapy.[298] The leading objective for presurgical evaluation is to identify the primary site(s) of obstruction. The level of obstructive site influences the type of surgical procedure to be performed. Fiberoptic laryngoscopy, drug-induced sleep endoscopy, or imaging can be used to classify the obstruction of the airway at the nasal, oropharyngeal, and/or hypopharyngeal level.[462,463] Surgeries aimed at reducing obstruction at the nasal, palatal, and lingual levels are referred to as Phase 1 surgeries. They are typically performed first with subsequent use of a Phase 2 surgery such as maxillomandibular advancement (MMA) if needed.[298]

Tracheostomy is virtually 100% effective in eliminating obstructive apneas.[464] Despite its high efficacy, it requires changes in lifestyle and is associated with negative impact on patients' quality of life. Tracheostomy is generally reserved for patients with severe OSA who have failed medical or surgical therapy and who manifest severe complications such as malignant arrhythmias without treatment.[465] Tonsillectomy and adenoidectomy is the primary therapy for children with OSA; however, it is not usually successful in adults.[466]

There is a paucity of high-level published data on the efficacy of the various surgical options for SDB.[467,468] When change in the AHI is used as the primary measure of efficacy, MMA emerges as a procedure with substantial reduction in AHI (87%).[468] The studies consisted of nine case series, which included 234 subjects.[469–477] All but two of the studies had a residual postoperative AHI <10 events/h.[468] Nevertheless, because of low-quality studies, the reliable reduction in AHI seen with PAP therapy and lack of data regarding the effect of MMA on sleepiness and quality of life, MMA should be considered only in patients with severe OSA in whom PAP therapy and oral appliance are ineffective.[465] In addition, a recent systematic review noted that uvulopalatopharyngoplasty (UPPP) with or without tonsillectomy as a sole surgical procedure does not have a consistent effect on the AHI, and therefore cannot be recommended as a stand-alone treatment for OSA.[468] However, there is some evidence to suggest that use of a multilevel surgical approach involving UPPP and MMA may be beneficial to some patients; additional research, including clinical trials, is much needed.[465]

The role of other Phase 1 therapies remains unclear. Currently, laser-assisted uvulopalatoplasty (LAUP), a procedure involving removal of the uvula and a part of the soft palate with a carbon dioxide laser, is not recommended as a treatment option for OSA

by the AASM.[465] Radiofrequency volumetric tissue reduction (i.e., radiofrequency ablation [RFA]), a minimally invasive technique, has been employed to treat turbinate hypertrophy and reduce the size of the base of the tongue. Palatal implants are intended to stiffen the soft palate and protect against upper airway collapse. Only modest improvements in symptoms and AHI were noted in one randomized controlled trial.[478] In part because of their relatively low surgical risk, RFA and soft palatal implants can be considered in individuals with mild-to-moderate OSA who have found CPAP and oral appliance therapy ineffective and/or undesirable.[465]

Genioglossus advancement with hyoid myotomy involves movement of the tongue forward without moving the mandible, with the leading aim of achieving a larger-caliber airway. The success of such combinations has been variable ranging from 23% to 77%.[479–482] Because of inconsistent results in the setting of increased surgical risks, genioglossus advancement and related surgeries are presently not recommended therapies for SDB.

The value of performing UPPP in combination with robot-assisted lingual tonsillectomy was assessed in a recent prospective, nonrandomized trial compared with historical controls.[483] In this case series of candidates who were selected via drug-induced sleep endoscopy, 20 patients underwent transoral robot-assisted lingual tonsillectomy with UPPP as well as pre- and postoperative PSG. The mean AHI of 56 events/h decreased by 57% to a mean AHI of 24 ($p < 0.001$). The minimal arterial oxygen saturation and subjective measure of sleepiness improved as well. Minimal surgical complications were noted.

Other procedures listed in Table 99-7 are designed to increase airway caliber or to improve CPAP compliance. Treatment of nasal obstruction by surgical means has proved helpful in some patients, especially by allowing the patient to better tolerate CPAP. The most common nasal surgical procedure is septoplasty and turbinate reduction. These procedures can lead to subjective improvement in nasal patency and a reduction in nasal CPAP pressure requirement.

Surgery represents a viable therapeutic option for carefully selected OSA patients who cannot tolerate PAP therapy or an oral appliance. Meticulous preoperative assessment by examination, nasopharyngoscopy, and radiologic imaging can help to identify the likely area of upper airway obstruction. If a surgical procedure is performed, close follow-up in the immediate postoperative period to assess treatment response as well as long-term follow-up to monitor for recurrence of disease are warranted.[465]

OXYGEN THERAPY

Oxygen may have a limited role in the treatment of sleep apnea syndrome. Chronic hypoxemia is associated with reduced hypoxic and hypercapnic ventilatory drives.[484] This may worsen the severity and duration of SDB events. Although oxygen desaturation may be mitigated by the delivery of oxygen, there is some evidence that administration of supplemental oxygen may delay the arousal threshold and thereby prolong apneic events.[485] In this same study of three patients, use of supplemental oxygen was also associated with worsening respiratory acidosis.[485] However, subsequent studies with larger numbers of subjects demonstrated that the use of supplemental oxygen reduced the degree of oxyhemoglobin desaturation and improved or did not worsen apnea frequency or duration.[484,486–489] Among patients with a relatively unstable ventilatory control system, supplemental oxygen may stabilize ventilation, thus reducing AHI.[490,491] The role of supplemental oxygen alone in the treatment of OSA remains unclear; at a minimum it improves nocturnal oxygen saturation during use without significant adverse consequences.

MEDICATIONS

Several pharmacologic agents have been investigated as possible therapies for primary treatment of OSA. Unfortunately, none have demonstrated significant effectiveness for treatment of OSA.[492] Specifically, selective serotonergic reuptake inhibitors, protriptyline, methylxanthine derivatives (e.g., theophylline), and estrogen therapy are not recommended.[199,493–495] Of notable exception, patients with hypothyroidism and acromegaly should be treated with thyroid replacement and somatostatin analogs, respectively, as such treatment can improve AHI.[199,493]

While short-acting nasal decongestants have no effect on airway patency in sleep apnea, topical nasal corticosteroids may be useful as adjunctive therapy to treat concurrent rhinitis.[199,494,495] Such treatment may be particularly helpful if rhinitis is exacerbated by PAP therapy despite the use of heated humidification. In addition, there are conflicting data regarding the use of sedative-hypnotics at the time of CPAP initiation.[496–499]

Stimulants, such as modafinil, can also be utilized as adjunctive therapy for residual sleepiness in patients who remain symptomatic despite adequate treatment for SDB.[494] Doses ranging from 200 to 400 mg daily have been shown to be effective in improving excessive daytime sleepiness in several randomized trials.[500–504] Treatment with modafinil should only be undertaken after a careful search for alternative causes of residual sleepiness has been performed.[199]

CENTRAL SLEEP APNEA SYNDROMES

CSA, in which repetitive episodes of breathing cessation occur in the absence of respiratory effort, is characterized by an altered ventilatory motor output (Fig. 99-18). CSA is much less common than OSA, with one study estimating the prevalence in the general population to be <1%. Even in the clinical sleep laboratory setting, CSA is relatively uncommon.[101,505] However, small disruptions within a number of complex feedback loops in the ventilatory control system can lead to and then sustain CSA. CSA has been described as a physiologic process in normal individuals in response to an arousal (especially children and the elderly), as a manifestation of breathing instability in a number of medical conditions (e.g., Cheyne–Stokes respiration [CSR] in CHF and high altitude), or in association with neurologic diseases such as Shy–Drager syndrome, stroke, myasthenia gravis, neuromuscular disease, bulbar poliomyelitis, brainstem infarction, and encephalitis.[506–510] It is often divided into hypocapnic and hypercapnic types.

The following discussion will focus on hypocapnic CSA, as the hypercapnic CSA syndromes (e.g., OHS and congenital central hypoventilation syndrome) are discussed elsewhere (Chapter 100). Note is made, however, of the fact that a majority of patients with OHS have concomitant OSA.[28,29] Characteristic findings observed with OHS include awake resting hypoxemia, hypersomnolence, signs of cor pulmonale (right-sided heart failure and lower extremity edema), and nocturnal hypoventilation. In general, the hypocapnic CSA syndromes are associated with increased chemoresponsiveness of the ventilatory control system and are seen most commonly in individuals with heart failure and at altitude.

During wakefulness, there is an endogenous drive to breathe that arises from the brainstem reticular formation and has been termed the wakefulness stimulus. With the onset of sleep, withdrawal of the wakefulness stimulus occurs and the chemical drive to breathe predominates.[511] Minute ventilation falls by 10% to 15% and P_{CO_2} levels rise approximately 2 to 6 Torr.[512–514] Central apneas occur if the arterial P_{CO_2} falls below the "apneic threshold," or P_{CO_2} level necessary to maintain rhythmic breathing, resulting in reduced ventilatory motor output.[515] Causes of hypocapnia include sleep-state changes, hypoxia, and fluctuations in minute ventilation related to heart failure.

Other features of the ventilatory control system can promote and sustain recurring central apneas. If the magnitude of the increase in ventilation that occurs in response to changes in P_{CO_2} is larger than is needed to achieve eupnea, self-sustaining oscillations in ventilation in which P_{CO_2} is repeatedly driven to the apneic threshold can occur and manifest as periodic breathing.[516–518] Such oscillations in ventilation can also occur when there is a lag between changes in

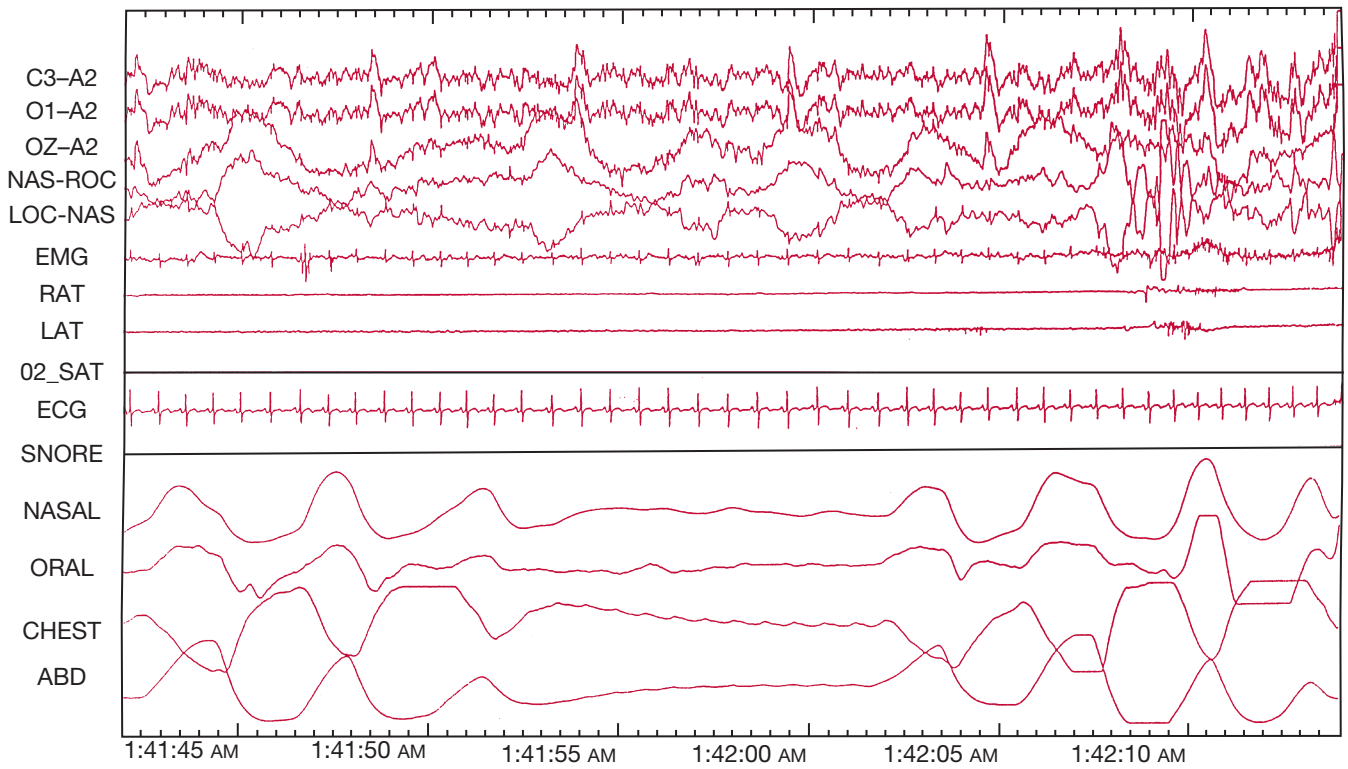

Figure 99-18 Example of central apneas. The polysomnography traces from the top down are as follows: Three EEG channels (C3, C4, O1); two EOG channels (ROC and LOC); submental electromyogram (EMG)); right and left anterior tibialis EMG (RAT and LAT), oxyhemoglobin saturation (SaO2); electrocardiogram (ECG); snoring channel (SNORE); nasal airflow (NASAL); oral thermistor (ORAL); and chest and abdominal motion (CHEST and ABD). During the apneic episodes, there is lack of airflow without rib cage or abdominal motion. At the end of each apneic episode there is a burst of EEG activity consistent with an arousal.

ventilation and detection of the ensuing effects on P_{CO_2} and P_{O_2} by the central and peripheral chemoreceptors, as occurs when arterial circulation time increases.[519] Recurrent arousals from sleep can also play an important role in initiating and maintaining central apneas as the state change from sleep to wakefulness re-engages the neurogenic drive to breathe.[515,520] This can provoke ventilatory overshoot as P_{CO_2} is driven to the lower P_{CO_2} set point of wakefulness, especially in the setting of continued sleep–wake instability.

■ HIGH ALTITUDE PERIODIC BREATHING

Periodic breathing with hypocapnic central apnea occurs in many healthy individuals at high altitude. At altitude, the peripheral chemoreceptors in the carotid body that sense hypoxia increase ventilatory drive.[521] As P_{CO_2} falls in response, the apneic threshold is reached, precipitating central apneas and creating a cycle of periodic breathing. Because the delay between changes in P_{O_2} and P_{CO_2} levels and detection by peripheral and central chemoreceptors is brief, the cycle time of periodic breathing at altitude tends to be short (12–34 seconds).[522] Poor sleep quality is a frequent complaint at altitude and is likely to be related to hypoxemia and periodic breathing with frequent arousals.[523,524] Although it seems intuitive that periodic breathing would resolve as individuals acclimate to altitude, observations of decreases, increases, and lack of change in periodic breathing have all been reported.[525–528] High altitude periodic breathing can be treated using acetazolamide, which increases the magnitude of the change in P_{CO_2} required to produce central apneas.[529] Use of supplemental oxygen improves high altitude periodic breathing and sleep quality and thus should also be considered.[530,531]

■ CHEYNE–STOKES RESPIRATION

CSR is most commonly seen in individuals with systolic heart failure and, especially when present during wakefulness, is a risk factor for higher mortality in this population.[532–534] CSR is also observed in individuals with encephalopathies, stroke, and other conditions.[535–537] Among individuals with systolic heart failure, male gender, age >65, atrial fibrillation, and hypocapnia all increase the risk for CSR.[538] Despite speculation that the prevalence of CSR has declined with the use of beta blockers for treatment of CHF in recent years, two recent studies indicate that the prevalence of SDB in general, and CSR in particular, remains high in this population.[539–541]

CSR is characterized by prolonged hyperpneas with a waxing and waning respiratory pattern and prolonged cycle duration (Fig. 99-19). Although CSR can occur during wakefulness, it is much more common during sleep, especially during non-REM sleep, when ventilation is predominantly under metabolic control and thus particularly sensitive to the apneic threshold and changes in P_{CO_2}.[542,543] Greater peripheral and central chemoresponsiveness among individuals with heart failure and CSR promotes hyperventilation and hypocapnia.[518,544] The timing and role of arousals associated with CSR, which tend to occur at the peak of ventilation, distinguish them from arousals associated with obstructive events, which occur at apnea termination. Thus, arousals during CSR provoke ventilatory overshoot and help to sustain oscillations in respiration, rather than fostering upper airway muscle activation and the resumption of airflow as occurs in obstructive apneas.[545] The cycle length in CSR generally ranges from 40 to 90 seconds, due at least in part to prolonged transit time between the lungs and chemoreceptors in the setting of reduced cardiac output and increased circulation time.[515]

The clinical presentation of patients with CSR is variable. Although some patients with heart failure and CSR complain of sleep fragmentation, daytime sleepiness, and poor nocturnal sleep, many do not.[546] The diagnosis of CSR is established by PSG demonstrating repetitive

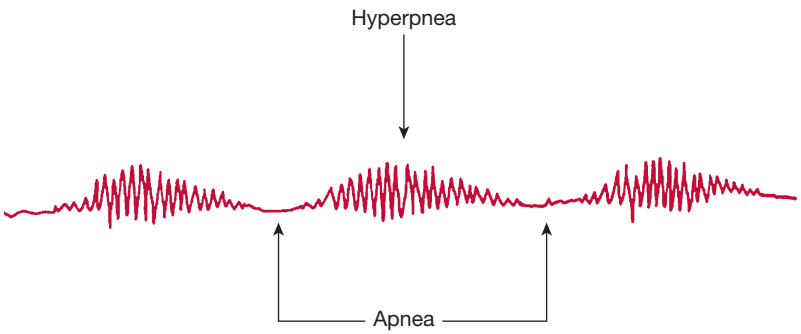

Figure 99-19 Example of Cheyne–Stokes respiration, a pattern of periodic breathing in which intervals of hyperpnea alternate with intervals of apnea. Respiration waxes and wanes in a crescendo–decrescendo pattern. Arousals during CSR tend to occur during the peak of ventilation, that is, during the hyperpneic phase rather than at the termination of the apnea. The duration of the hyperpneic phase of Cheyne–Stokes respiration correlates with the degree of circulatory delay.

apneas in the absence of thoracic–abdominal excursion.[14] Not infrequently, a combination of obstructive and mixed apneas may be seen; central SDB events must comprise >50% of total events to make the diagnosis of CSA.[545]

CSR can be treated in several ways. Aggressive pharmacologic management of heart failure, including beta blockade and angiotensin-converting enzyme inhibitors, improves heart failure status and may reduce CSA.[547,548] The use of supplemental oxygen can help to stabilize oscillations in ventilation but generally does not normalize the AHI.[549] Data demonstrating improved long-term outcomes with use of supplemental oxygen are lacking. However, given results from several recent trials demonstrating improvements in LV ejection fraction among patients with heart failure and CSA who received oxygen, supplemental oxygen has been recommended for this patient population.[550–553] Likewise, administering a small amount of CO_2 to patients with CSR dramatically reduces central apneas, though this intervention has not been implemented clinically.[554]

Although a number of initial reports demonstrated that CPAP therapy lowers AHI, reduces systolic BP, and improves LV systolic function, this treatment has proven disappointing.[533,555,556] A large, randomized trial in individuals with heart failure and CSA failed to demonstrate mortality benefit after use of CPAP for 2 years, despite improvements in the severity of CSA, nocturnal oxygenation, ejection fraction, and other physiologic measurements.[557] Furthermore, early survival was lower among those receiving CPAP, though ultimately, mortality was not significantly different between the groups. Post hoc analyses demonstrated that among those individuals receiving CPAP whose CSA was reduced to <15 events/h, survival was improved.[558] Whether these findings represent benefit from CPAP use in this subgroup, however, or whether the reduction in AHI to <15 events/h identified individuals with a better overall prognosis is unclear.

More recently, a mode of PAP therapy termed adaptive servo-ventilation has been developed for use in patients with CSR and other forms of hypocapnic CSA.[559] ASV provides bilevel PAP with a fixed expiratory pressure and variable inspiratory pressure that responds to changes in the ventilatory pattern while maintaining a target ventilation based on a continuous moving window of the patient's recent average ventilation. Thus, proportionate increases and decreases in inspiratory pressure occur that help to stabilize ventilation. To date, a number of randomized trials and other studies have shown that ASV improves CSA associated with CSR due to heart failure, as well as LV ejection fraction, sleep disruption, and exercise capacity.[560–565] While the ability of ASV to improve mortality in this population has not yet been demonstrated, a multinational, multicenter, randomized trial of ASV in patients with symptomatic chronic heart failure with depressed LV ejection fraction and predominant CSA is currently in progress and is expected to be completed in 2015.[566] After assessing the available current data, the AASM has recently recommended the use of CPAP, oxygen, or ASV for first-line treatment of CSR related to heart failure.[553]

IDIOPATHIC CENTRAL SLEEP APNEA

An idiopathic form of CSA similar to CSR has occasionally been described in individuals with normal cardiac function. Presenting symptoms can include snoring, witnessed apneas, insomnia, and excessive sleepiness.[567–569] These individuals have an increased ventilatory response to CO_2 during sleep and wakefulness. There is no standardized treatment. While CPAP therapy has proven effective for some patients, other reported treatments have included respiratory stimulants such as acetazolamide, and use of benzodiazepine and hypnotic medications to improve sleep continuity and reduce sleep state instability.[570–573]

COMPLEX SLEEP APNEA

In recent years, the term "complex sleep apnea" has been applied to the emergence of central apneas during CPAP titration for treatment of OSA.[505] The prevalence of complex sleep apnea has been estimated to be between 5% and 15% of patients undergoing CPAP titration.[505,574–577] Individuals who manifest CPAP-emergent central apneas have been described in some studies to be more likely to be male, to be more obese, and to be more likely to have a history of cardiac disease compared to individuals without complex sleep apnea.

The clinical relevance of complex sleep apnea has been vigorously debated, given evidence that CPAP-emergent central apneas may be associated primarily with CPAP initiation and are likely to resolve over time.[578,579] Two recent studies have observed that among patients who were initially diagnosed with complex sleep apnea, only 20% to 25% of patients who returned for PSG after using CPAP for 1 to 3 months had persistent central apneas >5/h.[574,577] Other explanations for CPAP-emergent central apneas include over- and undertitration of CPAP therapy, the presence of occult heart failure, and use of respiratory-depressant medications such as opioids and benzodiazepines.[579] Use of chronic opioid medications, which has become much more common in the past several decades, also places patients at risk for sustained complex apnea during sleep.[166,580,581]

The results of several studies that have examined the use of PAP devices for treatment of complex sleep apnea suggest that adaptive servo-ventilation appears to most effectively reduce AHI.[560,582,583] However, given evidence that complex apnea resolves in the majority of patients, it seems reasonable to initiate a trial of CPAP therapy and to reserve ASV for the relatively few individuals who exhibit persistent apnea.

EFFECT OF SLEEP IN PATIENTS WITH PULMONARY DISORDERS

Normal sleep is associated with hypoventilation and hypoxemia. This may occur via a variety of mechanisms. Sleep onset has been associated with a 2 to 6 mm Hg increase in the P_{CO_2} set point for ventilation.[584,585] Hypoxic ventilatory responses can be reduced such that normal subjects may experience a decrement in up to 10 mm Hg of Pa_{O_2} during sleep; this response may be more pronounced in men as compared to women.[113,586,587] Sleep is also associated with changes in respiratory mechanics, the most obvious of which is the posture adopted during sleep. The supine position, in particular, is associated with an additional

load on inspiratory muscles due to a shifting of abdominal contents.[588] REM sleep is associated with atonia, which spares the diaphragm, but not the accessory muscles of respiration and can reduce functional residual capacity.[589,590] Upper airway patency is dependent on muscle activity, which can be reduced or absent in NREM versus REM sleep and by an increase in supraglottic resistance.[591]

Pulmonary disorders can deteriorate during normal sleep and especially in patients with concomitant sleep apnea. SDB is associated with exaggeration of the normal circadian changes that elicit increases in bronchial hyperresponsiveness, vagal tone, and airway inflammation, which can contribute to asthma.[592–604] The sleep disruptions and hypoxia associated with SDB can also promote insulin resistance and glucose intolerance that, coupled with daytime sleepiness and reduction in general activity, ultimately lead to weight gain.[232,244,292,394,604–606] Obesity, in turn, is a significant risk factor for asthma.[604,607–613] Furthermore, snoring or apnea is likely to worsen gastroesophageal reflux, which in turn, is known to exacerbate asthma.[614–617] Studies addressing nocturnal asthma and OSA have shown symptom improvement with CPAP use.[618–621] Given these interactions, asthmatic patients who fail to improve with optimal medical therapy or who manifest primarily nocturnal asthma should be considered for evaluation of sleep apnea, particularly if snoring is present.[604,618]

In obstructive lung diseases such as COPD, those patients who exhibit daytime hypoxemia also experience profound declines in Pa_{O_2}, especially during REM sleep.[622,623] Hypoxemia is multifactorial, and mechanisms include exaggerated normal sleep respiratory physiology including reduced functional residual capacity (which decreases oxygen reserve), increased airway resistance, decreased respiratory muscle function, altered chemosensitivity, alveolar hypoventilation, and ventilation–perfusion mismatch.[624] The coexistence of COPD and OSA is relatively frequent because both disorders are so common.[625,626] In this so-called overlap syndrome, patients are at increased risk of pulmonary hypertension and respiratory failure related to progressive nocturnal hypoxemia.[569,626–628] Patients are also at increased risk of death and hospitalization due to COPD exacerbation.[629]

While oxygen is the therapy of choice in COPD patients with daytime hypoxia, its chronic use in patients with isolated nocturnal hypoxia without SDB is without clear benefit.[588,630–634] Oxygen therapy is unlikely to be sufficient in patients who suffer the overlap syndrome. In patients with COPD and chronic hypercapnia, the use of nocturnal noninvasive positive pressure ventilation is unlikely to be of added benefit.[635–637] Conversely, patients with the overlap syndrome (i.e., concomitant OSA and COPD) who are treated with CPAP have improved survival and decreased hospitalizations due to fewer COPD exacerbations.[629] Given this observation, screening of COPD patients for clinical features indicative of coexistent OSA is warranted.[629]

It is important to recognize that a wide variety of other lung diseases, including both parenchymal lung disease and neuromuscular disease, can place patients at risk for hypoxemia during sleep. This is related to operating on the steep segment of the sigmoid-shaped oxygen dissociation curve while awake.[634] As with patients with COPD, the benefit of oxygen therapy during sleep in patients with isolated nocturnal oxygen desaturations is not clearly established; clinical judgment should be exercised before instituting such therapy, and reassessment is advised.[634] Furthermore, it is likely that OSA is common in other types of lung diseases such as idiopathic pulmonary fibrosis and sickle cell disease.[638,639] The role of CPAP has yet to be defined in these non-COPD overlap syndromes.

CONCLUSION

The past several decades have brought major advances in our understanding of normal and disordered breathing during sleep. Results from a growing number of epidemiologic studies from around the world continue to illuminate our understanding of the consequences of OSA, which extend far beyond excessive daytime sleepiness to include cardiometabolic morbidity and increased mortality. Advances in basic and translational research are revealing that the effects of obesity on OSA risk may occur not only via anatomical and functional effects but also through effects on ventilation and neuromuscular control of the upper airway. Evidence that effective treatment of OSA can reduce morbidity and mortality continues to accumulate. And as we learn more about the genotypic and phenotypic expression of sleep apnea, we are likely to be able to better tailor individualized therapies for patients.

These advances are occurring against a backdrop of greater demand for sleep medicine services and reforms in health care that have generated growing pressure to streamline the diagnosis and management of sleep apnea patients with an emphasis on out-of-laboratory, portable testing. In response, new treatments for SDB continue to be developed and new technologies are helping providers to better understand and motivate adherence to PAP therapies. As algorithms for effective management within these systemic constraints are being developed and implemented, the intensifying focus within healthcare on patient-centered, outcomes-based care demands that these principles be incorporated into successful models of care for sleep disorders. Meeting this challenge is imperative to our ability to provide optimal patient care and to make continued advances in our understanding of SDB.

CHAPTER 100

Sleep-Related Hypoventilation Syndromes

Richard J. Schwab
Bernie Young Sunwoo

Sleep can have profound changes on the respiratory system (see Chapter 96) especially in patients with underlying cardiopulmonary disorders. Sleep-related hypoventilation syndromes are characterized by an abnormal increase in partial pressure of carbon dioxide (Pa_{CO_2}) and a decrease in Pa_{O_2} during sleep. In an attempt to standardize definitions and facilitate research, in 1999 the American Academy of Sleep Medicine (AASM) included an arterial Pa_{CO_2} >45 Torr during wakefulness and a greater than 10 Torr increase in Pa_{CO_2} during sleep from awake supine values in the definition of sleep hypoventilation syndromes.[1] Similarly, the 2005 International Classification of Sleep Disorders (ICSD-2) incorporated a Pa_{CO_2} during sleep greater than 45 mm Hg or disproportionately increased relative to levels during wakefulness in the diagnostic criteria for sleep-related hypoxemia/hypoventilation syndromes.[2] More recently, the AASM Sleep Apnea Definitions Task Force revised scoring of sleep hypoventilation in 2012 to include a Pa_{CO_2} increase >55 mm Hg for ≥10 minutes or a ≥10 mm Hg increase in Pa_{CO_2} during sleep in comparison to awake supine values to a value exceeding 50 mm Hg for ≥10 minutes.[3] While based on data that normal individuals rarely have a Pa_{CO_2} >55 mm Hg during sleep, the precise Pa_{CO_2} level demarcating the transition from physiologic hypercapnia to pathologic hypoventilation remains unclear. The duration of 10 minutes decided by the AASM Task Force was arbitrary and based on consensus with a lack of normative data on the amount of total sleep time at different Pa_{CO_2} values in sleeping adults.[3] Sleep is associated with stage-specific changes in ventilation covered in Chapter 96. Loss of the wakefulness drive to breathe, altered ventilatory response to hypoxia and hypercapnia and increased upper airway resistance result in a decrease in ventilation in both nonrapid eye movement (NREM) and rapid eye movement (REM) sleep when compared to wakefulness. Consequently there is a small normal physiologic increase in the Pa_{CO_2} of 4 to 6 mm Hg during sleep.

The small decrease in ventilation and increase in Pa_{CO_2} during sleep is usually of little clinical consequence in normal individuals but in patients with respiratory muscle weakness, altered respiratory mechanics, impaired gas exchange and/or abnormal ventilatory drive, sleep is a vulnerable time. Nocturnal hypoventilation often precedes chronic daytime hypoventilation but the extent to which sleep can elicit and exacerbate chronic hypoventilation is often under appreciated. A high index of clinical suspicion for nocturnal hypoventilation is necessary especially with the availability of effective treatment, and this chapter aims to review some of the common causes of sleep-related hypoventilation.

CAUSES OF SLEEP-RELATED HYPOVENTILATION

The Pa_{CO_2} is determined by CO_2 production divided by alveolar ventilation (minute ventilation [the product of tidal volume and respiratory rate] minus dead space ventilation). Hypercapnia results when alveolar ventilation is insufficient to meet metabolic needs and is caused by a decrease in minute ventilation, an increase in dead space ventilation, or rarely an increase in CO_2 production. The causes of sleep-related hypoventilation can be thought of as disorders of ventilatory drive, that is, "won't breathe," or disorders of respiratory mechanics and/or impaired gas exchange, that is, "can't breathe" (Table 100-1).[4] The ICSD-2 classified sleep-related hypoventilation/hypoxemic syndromes by etiology (Table 100-2).

DISORDERS OF VENTILATORY CONTROL

Disorders of ventilatory drive can result in central apnea and nocturnal hypoventilation. These disorders can be primary including congenital central hypoventilation syndrome (CCHS) and primary idiopathic alveolar hypoventilation where no other cause for central hypoventilation is found. Alternatively these disorders can be acquired, usually following neurologic disorders that affect the brain stem and spinal cord and opiate medications.

CONGENITAL CENTRAL ALVEOLAR HYPOVENTILATION SYNDROME

Congenital central hypoventilation syndrome (CCHS) is a rare cause of central hypoventilation first described in 1970 by Mellins et al.[5] CCHS is characterized by hypoventilation and diffuse autonomic nervous system dysregulation (ANSD) but the exact underlying mechanism is uncertain. Studies suggest abnormal brainstem integration of chemoreceptor afferent pathways for ventilation with demonstration of some, albeit blunted, physiologic response of both central and peripheral chemoreceptors. Abnormal central integration of chemoreceptor afferents is also thought to be responsible for the autonomic nervous system dysfunction seen in CCHS. Traditionally considered a disorder of infants and children, with advancements in knowledge and treatment, patients are now surviving into adulthood. Nonetheless, this lifelong disorder is rare. The exact incidence is unknown but a French CCHS registry reported a prevalence in 2005 of 1 in 200,000 live births.[6]

CCHS is caused by a mutation in the paired-like homeobox 2B (PHOX2B) gene.[7,8] The PHOX2B gene on chromosome 4p12 encodes for a transcription factor that plays a role in the development of the autonomic nervous system and regulation of neural crest cell migration. Approximately 90% of PHOX2B mutations involve polyalanine repeat expansion mutations (PARMs) producing genotypes of 20/24 to 20/33 whereas the normal genotype is

TABLE 100-1 The 2005 International Classification of Sleep Disorders

ISCD-2 Classification of Sleep-related Hypoventilation/Hypoxemic Syndrome

- Sleep-related hypoventilation/hypoxemic syndromes
  - Sleep-related nonobstructive alveolar hypoventilation, idiopathic
  - Congenital central alveolar hypoventilation syndrome
- Sleep-related hypoventilation/hypoxemia due to medical condition
  - Sleep-related hypoventilation/hypoxemia due to pulmonary parenchymal or vascular pathology
  - Sleep-related hypoventilation/hypoxemia due to lower airway obstruction
  - Sleep-related hypoventilation/hypoxemia due to neuromuscular and chest wall disorders

Source: Data from Medicine AAoS. The international classification of sleep disorders: diagnostic and coding manual. 2nd ed. Westchester, IL, 2005.

TABLE 100-2 Disorders Associated with Sleep-Related Hypoventilation

- Disorders of ventilatory control, i.e., "won't breathe": congenital central hypoventilation syndrome, brainstem injuries (stroke, infection, tumor), medications, idiopathic alveolar hypoventilation
- Disorders of respiratory mechanics and/or impaired gas exchange, i.e., "can't breathe"
  - Neuromuscular disorders: amyotrophic lateral sclerosis, spinal cord injury, poliomyelitis, Guillain–Barré syndrome, myasthenia gravis, spinal muscular atrophy, myotonic dystrophy, congenital myopathy, metabolic myopathies
  - Chest wall disorders: kyphoscoliosis, thorocoplasty, posttuberculosis, fibrothorax, obesity hypoventilation syndrome
  - Pulmonary disorders: chronic obstructive pulmonary disease, overlap syndrome, cystic fibrosis

20/20. The remaining 10% are heterozygous for nonpolyalanine repeat mutations (NPARMs) and include missense, nonsense, or frameshift mutations. Most expansion mutations occur de novo but in 5% to 10% parents will be mosaic for the PHOX2B mutation, with a 50% chance of transmitting the mutation in all.[9]

CCHS is a clinically heterogeneous disorder. Studies have demonstrated a relationship between the PHOX2B genotype and CCHS phenotype. A spectrum of hypoventilation severity is seen, and patients with 20/27 to 20/33 genotype and NPARMs typically require 24-hour continuous ventilatory support.[10] The syndrome is typically diagnosed in newborns with episodes of cyanosis and apnea usually requiring mechanical ventilation. After maturation of the respiratory and central nervous systems, many patients with CCHS eventually breathe adequately while awake but CCHS does not resolve spontaneously. Hypoventilation in CCHS is most apparent in NREM compared to REM sleep. This is unique from other sleep-related breathing disorders and is thought to be due to intrinsic REM-related ventilatory drive.[11] Moreover CCHS children lack perception of dyspnea, do not manifest signs of respiratory distress, and are unable to augment ventilation when faced with a respiratory challenge like an infection or anesthesia; therefore these patients can develop sudden decompensated respiratory failure. Unrecognized, children with CCHS present with complications of chronic hypoventilation including pulmonary hypertension, cor pulmonale, seizures, or developmental delay. While patients can present outside the newborn period with late-onset central hypoventilation syndrome (LO-CCHS), reported as late as 35 years,[12] careful review of the medical history typically reveals signs and symptoms compatible with hypoventilation and autonomic dysregulation from the newborn period. It is thought to reflect the variable penetrance of PHOX2B mutations and should be distinguished from rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD). ROHHAD is not associated with PHOX2B mutations. Patients typically present after the age of 2 years with hyperphagic obesity followed by hypothalamic and autonomic dysregulation, central hypoventilation and behavioral changes, and the syndrome is now considered distinct from CCHS.[9,13]

ANSD and disorders of neural crest origin are common in CCHS. Hirschsprung disease (a congenital malformation of the enteric nervous system) has been reported in approximately 16% of patients with CCHS and is often of greater severity than the general population with Hirschsprung disease while neural crest tumors including neuroblastoma or ganglioneuroma have been described in 5%.[14,15] Other symptoms of autonomic dysfunction described in CCHS patients include diminished pupillary light response, temperature instability, sporadic profuse sweating, altered perception of discomfort and anxiety, and esophageal dysmotility. Cardiac arrhythmias including decreased beat-to-beat heart rate variability, reduced respiratory sinus arrhythmia, and asystoles have been observed.[9,16] Children with CCHS may have a characteristic box-shaped facies that is shorter and flatter with a lip trait (Fig. 100-1).[17] PHOX2B genotype–CCHS phenotype relationships have also been demonstrated for the more severe CCHS phenotypes that manifest Hirschsprung disease, tumors of neural crest origin, cardiac asystole, ANSD, and facial dysmorphology.[9,10] For example, Hirschsprung disease has been reported in 87% to 100% of NPARMs compared to 13% to 30% of PARMs, while neural crest tumors have been described in 50% of NPARMs compared to 1% with PARMs.[9]

Diagnosis of CCHS relies on genetic testing after excluding other causes of central hypoventilation including pulmonary, neurologic, and metabolic etiologies. Genetic testing with PHOX2B Screening Test will identify mutations in 95% of cases. If the PHOX2B Screening Test is negative but there remains a high clinical suspicion the PHOX2B Sequencing Test can be performed to detect NPARM mutations. A sleep study with continuous monitoring of end-tidal CO_2 or transcutaneous P_{CO_2} is recommended to assess ventilatory requirements in all stages of sleep. Further diagnostic studies are guided by the clinical evaluation and include but are not limited to screening for other autonomic dysfunction including Hirschsprung with a barium enema or manometry, cardiac arrhythmias with 72-hour Holter monitoring, neural crest tumors with serial chest and abdominal imaging, pupillary function with a comprehensive ophthalmologic examination and neurocognitive testing.

Treatment for CCHS is directed at ensuring adequate ventilation both during sleep and wakefulness ideally with an experienced multidisciplinary team. Chronic ventilatory support is required and in 6% to 33% of patients ventilatory support during both wakefulness and sleep is needed.[14] Respiratory stimulants have not been shown to improve ventilatory drive in CCHS. Ventilatory support can be provided by various modalities including positive pressure ventilation via tracheostomy, bilevel positive airway pressure (BPAP) via nasal or full face mask, negative pressure ventilators, and diaphragmatic pacing. The mode of ventilatory support should be guided by the needs of the patient. In infants and younger children positive pressure ventilation via tracheostomy is preferred. When only nocturnal ventilatory support is required, BPAP via a mask interface is commonly used but in patients unable to generate adequate spontaneous breaths to trigger the ventilator, only the timed or spontaneous timed (setting a backup rate) modes guarantee breath delivery. Regardless of the mode of ventilatory support, close monitoring is necessary usually with continuous pulse oximeters and end-tidal CO_2 monitors. Apnea/bradycardia monitors will not detect hypoventilation or sinus pauses in CCHS and have no role. With early diagnosis, close monitoring and support, children with CCHS can be expected to function well in society and have a good quality of life but mortality rates of 8% to 38% have been reported.[14] Genetic counseling is essential for individuals diagnosed with CCHS.

OBESITY HYPOVENTILATION SYNDROME

The obesity hypoventilation syndrome (OHS) is defined by the presence of obesity (body mass index, BMI $\geq$30 kg/m^2), chronic alveolar hypoventilation with daytime hypercapnia (awake Pa_{CO_2} $\geq$45 mm Hg), and sleep-related breathing disorder in the absence of any other causes of hypoventilation. While first described in ancient Greek literature it was not until the 1950s following case descriptions by Auchincloss and later Burwell that the syndrome gained attention and the term, the "Pickwickian syndrome," from the character of Joe in The Posthumous Papers of the Pickwick Club by Charles Dickens emerged.[18–20]

The risk of OHS increases as BMI increases and in the United States it is now estimated that more than one-third of adults are

Figure 100-1 Photographs of representative congenital central hypoventilation syndrome (**A** and **C**) and control (**B** and **D**) subjects showing representative box-shaped facies of CCHS with decreases in the slope of the forehead, upper face height, upper facial inclination, nasolabial angle, upper and lower lip heights, and inferior inflection of the lateral vermillion border of the upper lip. *(Reproduced with permission from Todd ES, Weinberg SM, Berry-Kravis EM, et al. Facial phenotype in children and young adults with PHOX2B-determined congenital central hypoventilation syndrome: quantitative pattern of dysmorphology. Pediatr Res. 2006;59(1):39–45.)*

obese.[21] As obesity and in particular super obesity (BMI $\geq$50 kg/m^2) increases exponentially, OHS is emerging as a leading cause of sleep-related hypoventilation. A prevalence of 10% to 20% has been reported in obese patients with obstructive sleep apnea (OSA), almost 50% in hospitalized patients with a BMI $\geq$50 kg/m^2, while a conservative prevalence of 0.3% has been estimated in the general US adult population.[22–24]

■ PATHOPHYSIOLOGY

The precise mechanism by which obesity leads to hypoventilation remains incompletely understood. A complex interaction between (1) abnormal respiratory system mechanics and increased work of breathing due to obesity (reduced chest wall and respiratory system compliance, increased airway resistance, expiratory flow limitation, intrinsic positive end-expiratory pressure, reduced respiratory muscle efficiency); (2) sleep-related breathing disorder; and (3) blunted central hypercapnic and hypoxic ventilatory drive, including "resistance" to leptin (a protein produced mainly by adipose tissue that stimulates ventilation) likely exists (Fig. 100-2).[23]

In approximately 90% of OHS patients the sleep-related breathing disorder is OSA. In the remaining 10% the sleep-related breathing disorder is nonobstructive sleep hypoventilation characterized by sustained hypoxia and an increase in Pa_{CO_2} by 10 mm Hg above wakefulness in the absence of significant obstructive apneas or hypopneas.

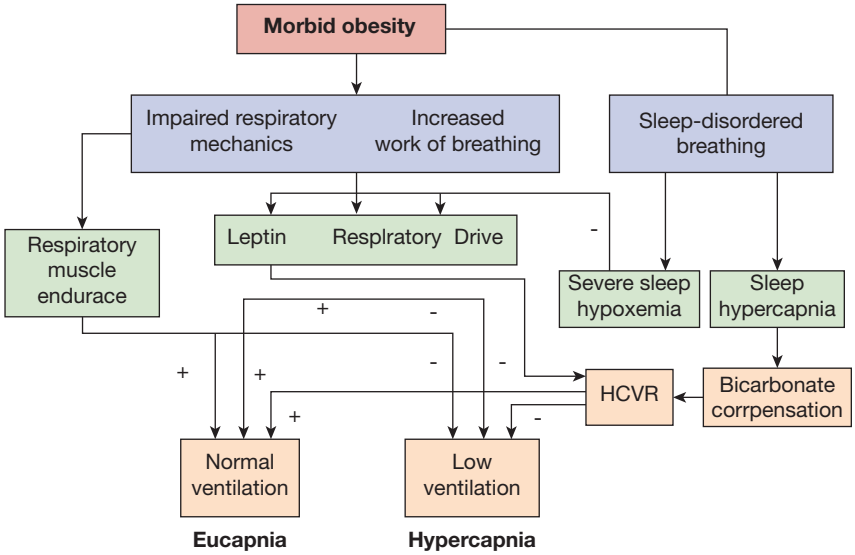

Figure 100-2 Interaction of the various pathophysiologic mechanisms implicated in the development of hypercapnia in the obesity hypoventilation syndrome. (+), positive influence on maintaining ventilation if normal or increased; (–), negative influence on maintaining ventilation if reduced or blunted; HCVR, hypercapnic ventilator response. *(Reproduced with permission from Piper AJ, Grunstein RR. Big breathing: the complex interaction of obesity, hypoventilation, weight loss, and respiratory function. J Appl Physiol. 2010;108(1):199–205.)*

More recently, OHS has been suggested to result from an inadequate compensatory ventilatory response to offload the CO_2 that accumulates during apneic and hypopneic events in sleep.[26] In addition, if the bicarbonate retained by the kidneys to buffer this transient decrease in pH is slowly eliminated, there is further blunting of the ventilatory responsiveness to CO_2, causing progressive hypercapnia (Fig. 100-3).[27]

CLINICAL PRESENTATION

OHS is associated with increased morbidity and mortality, higher rates of hospitalization and ICU admissions, increased healthcare utilization, and reduced quality of life.[22–24,28] Timely diagnosis is essential given higher rates of systemic hypertension, angina, congestive heart failure, and cor pulmonale reported in OHS compared to eucapnic obese individuals.[23,28] Yet despite the clinical consequences of OHS the diagnosis of OHS is often overlooked and a high index of clinical suspicion is required.[24]

Typical symptoms of OSA (see Chapter 97) are commonly reported by OHS patients but additional symptoms of hypercapnia including morning headaches may be present. Dyspnea is more frequently reported than eucapnic OSA patients. Pulmonary hypertension, cor pulmonale, and polycythemia are also more common in patients with OHS compared to patients with OSA alone. Not infrequently, OHS patients can present

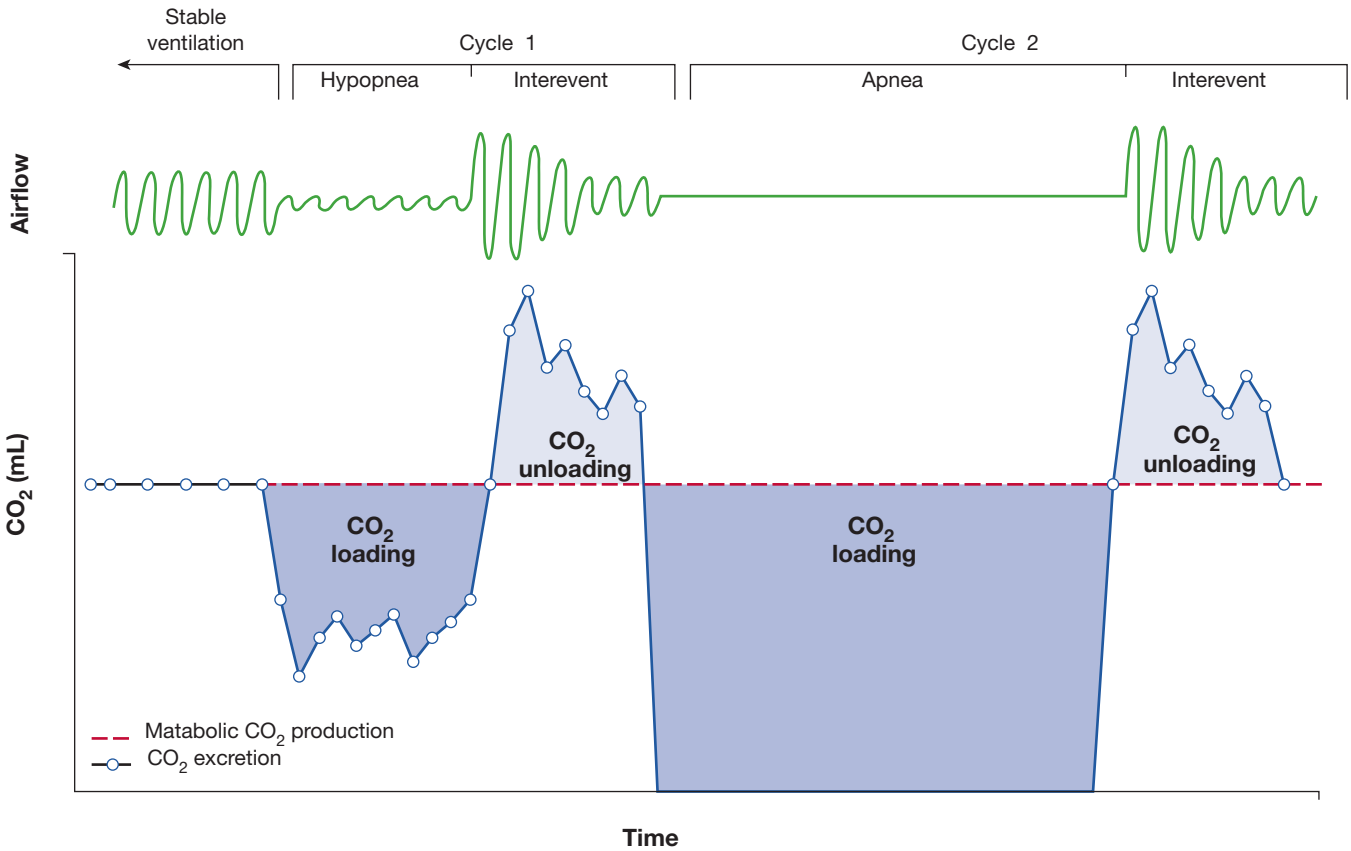

Figure 100-3 Schema depicting a proposed inadequate compensatory ventilatory response to CO_2 loading during obstructive respiratory events in the obesity hypoventilation syndrome. The dark-shaded areas depict CO_2 loading due to reduced CO_2 excretion during respiratory events while the light-shaded areas depict CO_2 unloading due to compensatory hyperventilation between respiratory events. *(Reproduced with permission from Berger KI, Goldring RM, Rapoport DM. Obesity hypoventilation syndrome. Semin Respir Crit Care Med. 2009;30(3):253–261.)*

decompensated in acute hypercapnic respiratory failure requiring the ICU.

Physical examination may reveal facial plethora, injected sclera, a prominent pulmonic component of the second heart sound and signs of right heart failure including lower extremity edema in addition to signs suggestive of OSA. Compared to eucapnic OSA patients, OHS patients commonly have awake hypoxemia typically with a Pa_{O_2} less than 70 mm Hg. Awake hypoxemia is uncommon in eucapnic OSA patients and a pulse oximetry recording of <94% should prompt consideration of an arterial blood gas measurement.[23]

DIAGNOSTIC APPROACH

The diagnosis of OHS relies on demonstration of awake hypercapnia and an arterial blood gas on room air is necessary. Chronic hypercapnia may be suggested by an elevated serum bicarbonate and a serum bicarbonate of 27 mEq/L or greater has been shown to be highly sensitive (92%) but not specific (50%) for hypercapnia.[23,29] Typically patients manifest a >10 Torr increase in their Pa_{CO_2} during sleep.

OHS is a diagnosis of exclusion. Other causes of chronic hypoventilation including significant pulmonary disease, chest wall disorders, neuromuscular disease, severe hypothyroidism, and central hypoventilation syndromes must be excluded, but in reality it is likely that the pathophysiologic mechanisms underlying OHS can coexist with these disorders. Further diagnostic testing should be guided by the clinical history and physical examination but should include pulmonary function testing, chest imaging, electrocardiography, thyroid function testing, and a sleep study, where a characteristic pattern is often seen including increased sleep time with Sp_{O_2} <90% as outlined in Figure 100-4.[23,30,31]

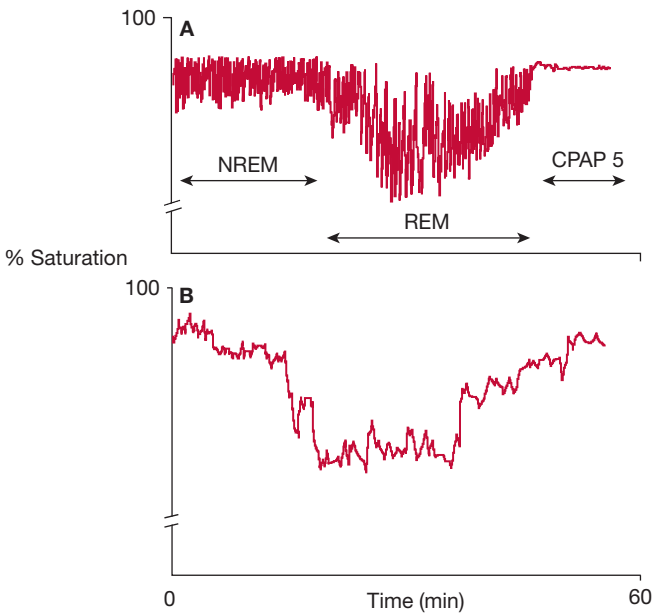

Figure 100-4 **A.** Nocturnal oximetry in a patient with severe obstructive sleep apnea demonstrating recurrent desaturations in nonrapid eye movement (NREM) and rapid eye movement (REM) sleep. Each apneic event results in an oxyhemoglobin desaturation that improves as the apnea is terminated. The degree of desaturation is greater in REM sleep and resolves when continuous positive airway pressure (CPAP) of 5 cm H_2O is applied. **B.** In contrast to **A**, this nocturnal oximetry demonstrates prolonged desaturation in a patient with obesity hypoventilation syndrome (OHS). The desaturation corresponds to periods of prolonged hypoventilation. Although not diagnostic, this pattern is highly suggestive of OHS.

TREATMENT

Nocturnal positive airway pressure (PAP) is currently the mainstay of treatment. PAP has been shown to improve hypercapnia and hypoxemia, symptoms, pulmonary hypertension, and quality of life.[22,32–35] Despite the widespread adoption of PAP the best modality remains unknown. Continuous positive airway pressure (CPAP) relieves upper airway obstruction and concomitant OSA. Since OSA is present in over 90% of OHS patients it is not surprising that CPAP alone has been shown to be effective in treating of the order of 60% to 80% of patients with OHS.[29,31,36] A sleep laboratory titration is recommended to determine optimal pressures to eliminate respiratory flow limitations and correct hypoxemia. While autoadjusting CPAP units are gaining increasing popularity, the technology as of yet does not recognize hypoventilation and cannot be routinely recommended. Serial ABG monitoring is suggested to ensure delivery of adequate ventilation. PAP adherence must be encouraged with the degree of improvement in hypercapnia shown to correlate with PAP adherence.[37]

Despite excellent adherence, hypercapnia and hypoxemia persist in 20% to 50% of OHS patients on CPAP.[23] BPAP is generally considered the next step but few studies to date have compared BPAP to CPAP, further complicated by the development of increasingly sophisticated home PAP units. Piper et al. randomized 36 OHS patients to either BPAP or CPAP and after 3 months observed no difference in CO_2 or O_2 levels or adherence between the two groups. The study, however, excluded 20% of subjects who had persistent hypoxemia defined arbitrarily as 10 continuous minutes of Sp_{O_2} <80% without apnea or an acute rise in transcutaneous carbon dioxide pressure during REM sleep (during a full night of CPAP titration), which limits the generalizability of the study.[36] In general, BPAP is recommended for decompensated acute hypercapnic respiratory failure, the small number of OHS patients without OSA, patients intolerant of CPAP especially at the higher pressures often required, and patients with persistent hypercapnia and hypoxemia despite 3 months of CPAP treatment. There are, however, no established guidelines regarding the optimal PAP modality in these patients.

Similarly no standard guidelines exist for BPAP titration in OHS. Frequently the expiratory positive airway pressure (EPAP) is increased until flow limitation is eliminated followed by the addition of inspiratory positive airway pressure (IPAP) to improve alveolar ventilation. Typically an EPAP of 6 to 10 cm H_2O, an IPAP of 16 to 20 cm H_2O, and a difference between IPAP and EPAP of at least 8 to 10 cm H_2O is required.[22,32,35,38] The role of a backup rate is unknown but should be used given the ventilatory control abnormalities in these patients. A newer hybrid mode of ventilator known as average volume assured pressure support (AVAPS) aims to maintain a target tidal volume by means of an algorithm estimating the patient's tidal volume over several breaths and adjusting IPAP to achieve that target tidal volume. For example, if patient effort and tidal volume decreases, AVAPS automatically increases IPAP to maintain the target tidal volume. Successful application of AVAPS in OHS has been described but few studies have compared it to more conventional BPAP modes.[39] In up to half of OHS patients, supplemental oxygen is needed in addition to PAP therapy to keep Sp_{O_2} >90%, although the need for supplemental oxygen may abate with continued PAP usage.[37] Oxygen therapy alone is inappropriate for OHS and may prolong apnea and worsen hypercapnia.[40] Oxygen should only be given in conjunction with PAP.

Weight loss should be encouraged in all patients but significant weight loss is often difficult to achieve and maintain medically. Bariatric surgery is an effective approach to sustained weight loss and should be considered in all patients with OHS. Hypercapnia can improve following bariatric surgery but a recent meta-analysis of 342 patients found 62% had residual OSA with a mean residual apnea–hypopnea index (AHI) of 16 events per hour following maximum weight loss after bariatric surgery.[41] Close clinical monitoring and a repeat sleep study are suggested following surgery. Worsening hypercapnia was reported

by Sugerman et al.[42] 1 to 5 years following surgery despite only a small increase in BMI, thought to be due to recurrence of sleep-related breathing disorder. While bariatric surgery is to be considered in all OHS patients it is important to recognize that the surgery is associated with postoperative risks with a reported perioperative mortality between 0.5% to 1.5%.[43,44] Tracheostomy was available long before PAP therapy but there are very few large studies evaluating long-term outcomes. A tracheostomy bypasses the upper airway and has been shown to improve OSA but correction of daytime hypercapnia is neither universal nor complete and ongoing monitoring is necessary.[45,46] Tracheostomy is now generally reserved for those who have failed all other PAP modalities, which is becoming increasingly uncommon with the technologic advances in PAP units and evolution of more comfortable and varied interfaces. In addition, tracheostomy is often challenging in this population given the excessive neck adipose tissue in most patients with OHS. If a tracheostomy is performed ventilation through the trachea will still be necessary to increase minute ventilation.

Finally, while there has been interest in the use of various pharmacologic respiratory stimulants including medroxyprogesterone and acetazolamide, a carbonic anhydrase inhibitor that induces metabolic acidosis thereby increasing minute ventilation, studies are few and small.[22] These medications should not be used in patients with OHS because of frequent side effects and a lack of demonstrated long-term benefits.

SLEEP-RELATED HYPOVENTILATION IN PULMONARY DISORDERS

Sleep-related hypoventilation occurring in chronic obstructive pulmonary disease and in the so-called "overlap syndrome" are discussed below.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients with chronic obstructive pulmonary disease (COPD) are particularly susceptible to nocturnal hypoventilation especially during REM sleep (Fig. 100-5).[47] Becker et al.[48] demonstrated an approximate 16% decrease in ventilation from wakefulness to NREM sleep and an almost 32% decrease during REM compared to wakefulness in COPD patients. The greater fall in minute ventilation in COPD patients during sleep is largely due to a decrease in tidal volume. Patients with COPD are often hyperinflated reducing diaphragmatic efficiency, which results in increased reliance on use of accessory muscles. During REM sleep there is muscle atonia with loss of this accessory muscle contribution such that ventilation is further reduced. Hypoventilation is further augmented by a decreased ventilatory responsiveness to CO_2 during sleep. Nocturnal hypoventilation results in nocturnal oxygen desaturation and nocturnal oxygen desaturation is a marker of increased mortality in COPD patients.[47,49] The oxygen desaturation nadir during sleep in patients with COPD has been shown to be greater than during exercise, with Sp_{O_2} falling an average of 12.9+10.5% during sleep compared to 4.5+3.7% during maximum treadmill exercise testing.[50]

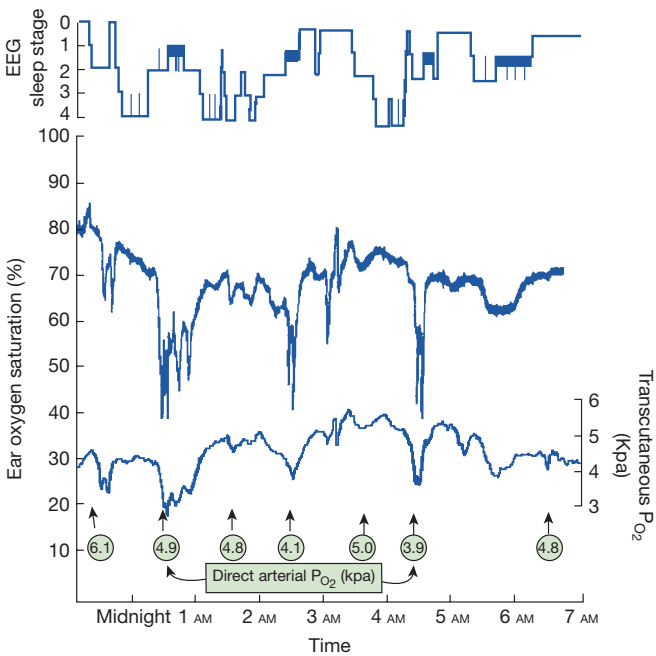

Figure 100-5 EEG sleep stage (*closed bars*, rapid eye movement [REM] sleep), ear oxygen saturation and transcutaneous P_{O_2} in a "blue bloater" during sleep on room air depicting susceptibility to nocturnal hypoventilation, particularly during REM sleep. 1 kPa = 7.501 Torr. *(Reproduced with permission from Flenley DC. Sleep in chronic obstructive lung disease. Clin Chest Med. 1985;6(4):651–661.)*

While alveolar hypoventilation likely accounts for most of the oxygen desaturation in COPD, changes in ventilation–perfusion matching and decreased end-expiratory lung volumes have also been described.[51,52] Ventilation–perfusion mismatching is suggested by discordance between a decreased Sa_{O_2} and a stable or slightly increased Pa_{CO_2}.[53] Changes in lung volumes including a reduction in functional residual capacity leading to closure of small airways have been suggested but studies are conflicting.[52] In addition, as patients with COPD typically have lower wakefulness Pa_{O_2} and lie closer to the steep portion of the oxyhemoglobin dissociation curve they are more susceptible to significant nocturnal oxygen desaturation. This is particularly relevant in the presence of coexisting OSA, as discussed below.

Nocturnal oxygen desaturation has been associated with pulmonary hypertension, cardiac arrhythmias, and impaired sleep quality.[51,53] Poor sleep has been both subjectively reported and objectively demonstrated in COPD patients with reduced sleep efficiency, delayed sleep onset, reduced total sleep time, sleep fragmentation, and a decrease in slow-wave and REM sleep.[54,55]

Long-term oxygen therapy worn ≥15 hours per day has been shown to improve mortality and quality of life in COPD patients with chronic resting hypoxemia.[56,57] However, correction of nocturnal hypoxemia in COPD patients with only nocturnal oxygen desaturation has not been shown to consistently improve outcomes.[12,58–60] There has been significant interest in the use of noninvasive ventilation (NIV) in stable hypercapnic COPD but studies are conflicting as to whether it is beneficial.[61–64] Currently the Centers for Medicare and Medicaid Services require a Pa_{CO_2} >52 mm Hg on an ABG drawn while awake (breathing the patient's prescribed FI_{O_2}) and sleep oximetry (performed while breathing supplemental oxygen at 2 L/min or the patient's usual prescribed FI_{O_2}) demonstrating an Sp_{O_2} <88% for >5 minutes for reimbursement of NIV in patients with stable COPD.[61]

THE OVERLAP SYNDROME

The term overlap syndrome was coined by Dr. David Flenley in 1985 to describe the coexistence of COPD and OSA although his original description alludes to a broader definition of coexisting hypoxemic lung disease and OSA.[51] It is of particular clinical relevance given its association with greater sleep-related hypoventilation than either COPD or OSA alone.

The prevalence of the overlap syndrome is estimated at 1% of adults but prevalence data varies with the definitions used for both COPD and OSA. There is a lack of a standardized definition for the overlap syndrome.[65] Using an OSA definition of AHI ≥5 events/h and a COPD definition of Global Initiative for Chronic Obstructive Lung Disease Stage I (FEV_1 >80%), a prevalence of 4% of males has been suggested based on an OSA prevalence of 24% of males in the Wisconsin Sleep Apnea Study and a COPD prevalence of 16.8% in

the National Health and Nutrition Examination Survey III (NHANES III).[65] Evidence suggests a similar prevalence of OSA in patients with COPD as in the general population with no increased association between at least mild COPD and OSA.[52,66,67]

Patients with the overlap syndrome have more significant nocturnal hypoventilation with greater hypoxemia and hypercapnia than COPD or OSA alone.[54,66,68,69] A decreased hypercapnic ventilatory response has been shown in these patients.[70] Pulmonary hypertension is more common and more severe than in either patients with COPD or OSA alone where typically severe pulmonary hypertension is uncommon.[71] Consequently, the overlap syndrome should be considered in patients with either COPD or OSA with significant hypoxemia, hypercapnia, or pulmonary hypertension disproportionate to the severity of their disease. What remains unclear, however, is if the degree of severity of the combined diseases has additive or synergistic clinical relevance. That is, it is unknown whether patients with severe COPD and mild OSA have the same clinical consequences as those with mild COPD and severe OSA.[52]

The diagnosis of the overlap syndrome is important given the increased morbidity and mortality compared to either COPD or OSA alone.[52] Marin et al.[72] in an observational study compared 213 patients with untreated overlap syndrome to 210 patients with COPD alone and demonstrated increased mortality (relative risk 1.79, confidence interval 1.16–2.77) in the overlap group over a median follow-up of 9.4 years. COPD has been shown to be a marker of increased mortality in OSA[73] and more recently there have been emerging data examining the potential overlap of systemic inflammation, oxidative stress, and leukocyte dysfunction implicated in both COPD and OSA and cardiovascular disease.[65]

Given the clinical implications of the overlap syndrome, the symptoms and signs suggestive of OSA should be included in the evaluation of all COPD patients. If there is any clinical suspicion a full in-laboratory sleep study should be performed. Unattended portable sleep studies have not yet been validated in the COPD population.[74] Similarly nocturnal oximetry alone cannot reliably discriminate nocturnal oxygen desaturation secondary to COPD alone, OSA or some combination of the two, and given differences in treatment based on the underlying pathophysiology it is not recommended currently for diagnosis.

Treatment of the overlap syndrome is directed at the constituent disorders. Recent studies have suggested a survival benefit in patients with the overlap syndrome with CPAP[72,75] but these studies were not randomized. Nevertheless, CPAP is currently the accepted standard for the treatment of the overlap syndrome. CPAP in addition to relieving upper airway obstruction has been suggested to off-load the respiratory muscles reducing hypoventilation, oxygen consumption or CO_2 production by respiratory muscles, and may offset intrinsic PEEP in severe COPD patients.[52] CPAP alone may not fully correct hypoxemia requiring addition of supplemental oxygen but oxygen alone is not recommended for the overlap syndrome because it can potentially worsen hypercapnia.[76] The role of BPAP in the treatment of the overlap syndrome has not yet been explored and it remains uncertain whether it offers additional benefits over CPAP. NIV may be beneficial in this population but further research on the long-term effects of NIV compared to CPAP with or without supplemental oxygen is required.[52]

SLEEP-RELATED HYPOVENTILATION IN NEUROMUSCULAR DISORDERS

Sleep-related hypoventilation is common in neuromuscular disorders[77] including but not limited to amyotrophic lateral sclerosis (ALS), spinal muscle atrophies, postpolio syndrome, muscular dystrophies, congenital muscular dystrophy, myotonic dystrophy, metabolic myopathies, Guillain–Barré syndrome, and myasthenia gravis. The effects of neuromuscular disorders on ventilation are covered in Chapter 84. Sleep-related breathing disorders generally precede daytime ventilatory failure and the full spectrum from obstructive and central respiratory events to hypoventilation are found.

The mechanisms for sleep-related hypoventilation in neuromuscular disorders are multifactorial. Respiratory muscle weakness plays a central role. The type and severity of sleep-related breathing disorders usually parallel the extent and distribution of respiratory muscle weakness. Sleep hypoventilation often develops when supine vital capacity is <60% of the predicted value or maximal inspiratory pressure not as negative than –34 cm H_2O.[78] Patients with diaphragmatic weakness depend on recruitment of accessory inspiratory muscles and expiratory abdominal muscles and are particularly susceptible to significant hypoventilation during REM sleep where there is relative atonia of these skeletal muscles.

Weakness of the upper airway musculature can cause obstructive events, further exacerbated by an imbalance between the inspiratory force generated by the inspiratory muscles and activity of the muscles responsible for stabilizing the upper airway.[79] With progressive respiratory muscle weakness the number of respiratory events and the AHI may decline in ALS.[80] This may reflect an inability of the inspiratory respiratory muscles to generate pressures above the closing pressure of the upper airway resulting in fewer recorded respiratory events. In addition, bulbar muscle dysfunction and aspiration risk have not been shown to be significantly associated with severity or type of sleep-related breathing disorders in ALS.[79,81,82]

Abnormalities of ventilatory control have been also described in certain neuromuscular disorders, including myotonic dystrophy and congenital myopathy.[79] The hypercapnia and bicarbonate retention caused by nocturnal hypoventilation can further depress respiratory drive exacerbating sleep-related hypoventilation. Consequently, sleep fragmentation with shorter total sleep time, frequent arousals, and a reduction in or complete suppression of REM sleep have been described in neuromuscular disorders.[83] This sleep fragmentation and sleep debt may further suppress the arousal response and worsen hypoventilation.

Given the pervasiveness of sleep-related hypoventilation in neuromuscular disorders a detailed sleep history is an essential component of any clinical evaluation. Early in-laboratory polysomnography with continuous CO_2 monitoring is indicated in this patient population as sleep-related hypoventilation may long precede diurnal hypoventilation. NIV has been shown to improve sleep quality, quality of life and mortality in various neuromuscular disorders, and management of neuromuscular respiratory muscle dysfunction is covered in Chapter 84.[62,63,83–85] However, the optimal criteria for initiation of NIV for sleep-related hypoventilation in neuromuscular disorders remain uncertain.

SLEEP-RELATED HYPOVENTILATION IN RESTRICTIVE CHEST WALL DISORDERS

Chest wall deformities, in particular scoliosis, often accompany neuromuscular disorders, and can contribute to sleep-related hypoventilation. Nonmuscular diseases of the chest wall are reviewed in Chapter 83.

Patients with scoliosis, a rotational deformity of the spine, have reduced chest wall and lung compliance, increased work of breathing, respiratory muscle weakness, ventilation–perfusion mismatching, and reduced respiratory drive. The degree of respiratory impairment is associated with severity of spinal deformity accordingly, and respiratory failure is uncommon if the Cobb angle (a radiographic measure of spinal curvature in the coronal plane, calculated from two lines drawn perpendicular to lines drawn through the middle of the two vertebrae at the top and bottom of the curved segment) is less than 100 degrees.[86] Sleep is a vulnerable period and as with neuromuscular disorders gas exchange is worst during REM sleep.[87–90] While central hypoventilation is more common,

airway obstruction can also occur. Patients with scoliosis breathe at low lung volumes and lower airway caliber is proportional to lung volumes. In addition, secondary cervical curvature can displace the intrathoracic trachea to cause significant upper airway obstruction. Therefore clinical evaluation for sleep-related hypoventilation is necessary in this population, followed by polysomnography when sleep-related breathing disorder is suspected. NIV has been shown in small studies to improve gas change in restrictive chest wall disorders including scoliosis and posttuberculosis but results on sleep architecture and sleep quality have been mixed.[90–94]

CONCLUSION

An understanding of normal sleep–associated changes in ventilation is essential in identifying sleep-related hypoventilation syndromes and appreciating the potential vulnerability of the sleep period for patients with underlying cardiopulmonary disorders, neuromuscular disease, and restrictive chest wall disorders. Consequently, a comprehensive sleep evaluation should be incorporated in the clinical evaluation of each of these high-risk patient populations. This is particularly relevant given the recent advances in NIV treatment.

CHAPTER 101

Changes in the Cardiorespiratory System During Sleep

Indira Gurubhagavatula

As outlined in Chapter 12, sleep occurs in distinct states classified broadly as non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. These occur in a temporally organized fashion across the sleep period, with NREM dominating during the early hours of sleep and REM during the final hours of sleep. Myocardial infarction and ischemic stroke occur at a higher frequency during early morning hours,[1–3] when REM sleep predominates. This temporal distribution of events may be explained at least in part by specific alterations in autonomic regulation during sleep. This chapter presents additional information on alterations in cardiopulmonary function during sleep.

CHANGES IN CARDIOVASCULAR CONTROL DURING SLEEP

During NREM sleep, heart rate slows by 5% to 10%,[4] and blood pressure drops by about 10%.[4] These changes are most prominent in the deepest stage of NREM sleep,[4] that is, stage 4 (now known as N3[5] or slow-wave sleep[4]). The mechanism for this decline was elucidated by the seminal studies of Somers et al.[4] using microneurography to record sympathetic bursts in the peroneal nerve in healthy humans during wake and in the different stages of sleep (Fig. 101-1). These studies confirmed a fall in sympathetic activity during NREM sleep, which is responsible for the drop in blood pressure, cardiac output, and systemic vascular resistance.[4] This fall is accompanied by an increase in parasympathetic (vagal nerve) activity that is believed to be responsible for the bradycardia of NREM sleep.[6] Thus, the balance of parasympathetic/sympathetic activity is altered during NREM sleep, with the parasympathetic being dominant. This also results in alteration in heart rate variability during sleep. The high-frequency component of this heart rate variability is said to reflect parasympathetic activity, while the low-frequency component is related to sympathetic activity.[4] Thus, during NREM sleep there is an increase in the high-frequency component compared with wakefulness and a quite marked reduction in the low-frequency component of heart rate variability.[4]

Changes in REM sleep differ from those that occur during NREM sleep. During REM sleep, which occurs at approximately 90-minute intervals, there is a return of sympathetic activity such that heart rate and blood pressure return to wakefulness levels.[4] This has been shown directly by recording sympathetic nerve activity (SNA) in humans (Figs. 101-1 and 101-2).[4] Thus, during REM sleep the high- and low-frequency components of heart rate variability are the same as in wakefulness.[4]

During REM sleep there is also phasic activity that occurs in bursts. These phasic bursts of activity result in REMs and hence the name for the state. Phasic bursts of activity can lead to both brief, sudden increases in heart rate and blood pressure that are mediated by increases in sympathetic activity,[4,6–8] which are similar to waking levels,[4] and by sudden, baroreflex-mediated periods of decrease.[6] These changes have pathophysiological significance. During surges of heart rate, there are also increases in coronary blood flow.[7,8] But these can be mismatched such that the increased delivery of blood flow is insufficient to meet the extra myocardial demands consequent to the increase in heart rate. Moreover, in animal models of severe coronary stenosis, phasic decreases in coronary arterial blood flow are found when heart rate increases.[7] Such changes may play a role in the known diurnal rhythm of timing of reported acute cardiac events in humans.[1–3]

Episodes of abrupt slowing of heart rate can also occur during REM sleep. In addition to baroreceptor-mediated decelerations, sudden slowing of the heart rate may be a result of reduction in central autonomic input to the heart, an increase in vagal tone, or both.[9] At the extreme, brief episodes of asystole in phasic REM sleep have been described in otherwise healthy adults.[10]

CHANGES IN VENTILATION AND ITS CONTROL WITH SLEEP

As with the cardiovascular system, there are important changes in ventilation during sleep.[11] These, too, are different in NREM and REM sleep.[11,12] During NREM sleep ventilation declines. The various studies in this area have been summarized by Krieger et al.[13] All studies have reported this decrease, although the magnitude of change varies from study to study (see summary in Fig. 101-3). In general, there is a decline in tidal volume while the change in respiratory rate is more variable (see Table 1 in Krieger J et al., 1990).[13] Ventilation in

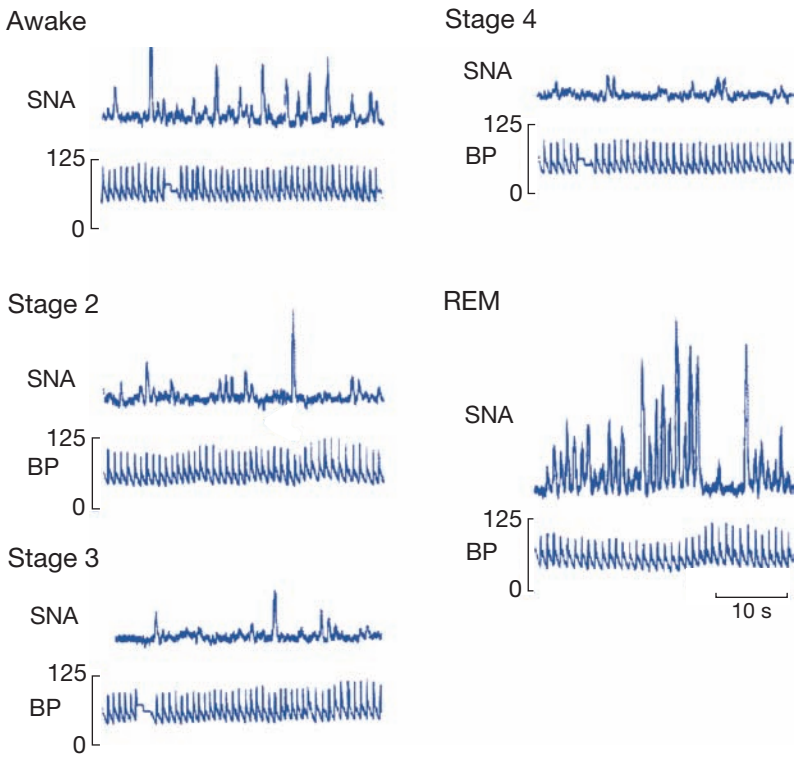

Figure 101-1 Alterations in recorded bursts of sympathetic nerve activity (SNA) and blood pressure in wakefulness, different stages of non-rapid eye movement sleep (NREM) (stages 2–4), and rapid eye movement (REM). With deepening of NREM sleep, there is progressive loss of sympathetic activity, which is virtually absent in slow-wave sleep (stage 4). Sympathetic activity returns in REM but is highly variable. *(Reproduced with permission from Somers VK, Dyken ME, Mark AL, et al. Sympathetic-nerve activity during sleep in normal subjects. N Engl J Med. 1993;328(5):303–307.)*

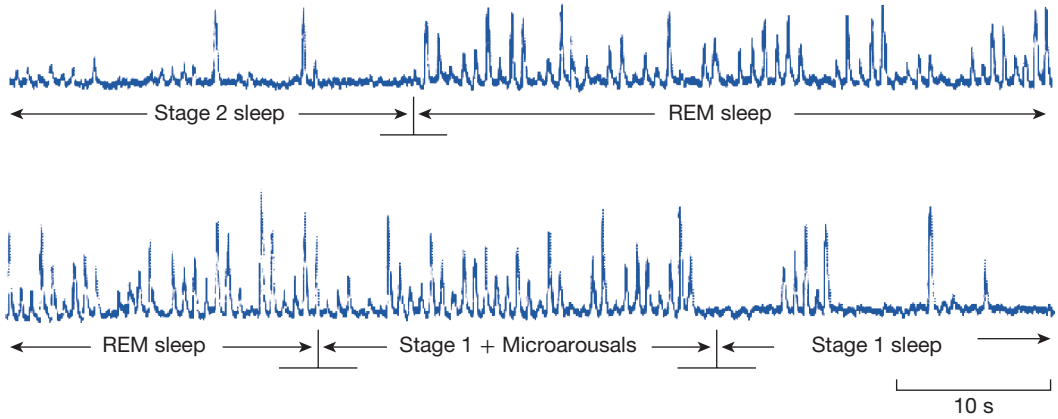

Figure 101-2 Changes in recorded sympathetic nerve bursts in a healthy human during transitions between different sleep stages. There are more bursts, that is, more sympathetic activity, in REM sleep compared with stage 2 NREM sleep (top panel) and more activity in stage 2 sleep when it is transitional with many microarousals than when fully established (bottom panel). *(Reproduced with permission from Somers VK, Dyken ME, Mark AL, et al. Sympathetic-nerve activity during sleep in normal subjects. N Engl J Med. 1993;328:303–307.)*

REM sleep is also consistently less than in wakefulness; some studies report a small increase in ventilation in REM compared with NREM sleep (0.9%–7.1%), whereas other studies report a further decrease (−1.1% to −10.8%).[13] This variability is likely related to the variability of ventilation in REM sleep itself. As in the cardiovascular system, there are changes in ventilation in association with the phasic events of REM sleep.[14] Both acceleration and slowing of respiratory rate are found as are declines in ventilation. These effects seem to vary between subjects (Fig. 101-4),[14] with some subjects showing large reductions in inspiratory flow and increased respiratory frequency during REMs and others showing only subtle changes.[14]

The changes in NREM sleep in normal humans are largely the result of increases in upper airway resistance.[15] This resistance progressively increases going from stage N1 to stage N3 NREM sleep (Fig. 101-5). This increase in resistance is associated with decrease in upper airway muscle activity in muscles such as the genioglossus[16–20] and tensor palatini[15] in the soft palate. During REM sleep, pharyngeal muscle activity is shut down via sleep-specific motor inhibition,[18] predisposing individuals to obstructive sleep apnea.

The neural control of upper airway motoneurons is complex and involves inputs from many premotor neurons originating in the forebrain, midbrain, pons, and medulla,[21] which communicate with upper airway motoneurons via a diverse group of neurotransmitters. It has always been the hope that identification of the neurochemical change that is responsible for reduced upper airway motor tone would elucidate promising pharmacologic targets for obstructive sleep apnea. It is now clear that neurochemical drive to upper airway motoneurons varies with behavioral state and in fact is quite distinct in NREM sleep relative to REM sleep. In NREM sleep, reduced noradrenergic input from the pons[16,19,20] contributes to reduced upper airway tone. Noradrenaline as a neuromodulator may play this role by potentiating glutamatergic excitation,[16] rather than via direct excitation, as measured by masseter muscle activity. Muscarinic inhibition of the hypoglossal motor pool prevents the inhibition of genioglossus activity throughout REM sleep.[18] During REM sleep, muscarinic receptors for acetylcholine linked to G-protein coupled, inwardly rectifying potassium (GIRK) channels have been shown to be important.[18] Thus, preventing apneas in both NREM and REM sleep will likely require modulation of both noradrenergic and cholinergic neurotransmitters as well as potentially specific GIRK channels.

Individuals without upper airway obstruction as well as those with sleep-disordered breathing demonstrate increased Pa_{CO_2} in sleep. These findings support the concept that central ventilatory drive is also altered by sleep state. Although an increase in upper airway resistance is the major mechanism, it is, however, not the only mechanism, since even in laryngotomized subjects with tracheostomies, which bypass the upper airway, P_{CO_2} increases in NREM sleep compared to wakefulness.[22] Of interest, the effects of sleep on ventilatory drive are in part gender-specific. The relative importance of the increase in upper airway resistance reflects different neural control of upper airway muscles[18–20,23,24] and the respiratory pump muscles such as the diaphragm. The former is much more coupled to state, that is, wake and sleep, while the latter, the diaphragm, is more affected by chemical control rather than variations in state (Fig. 101-6). This is why obstructive sleep apnea occurs commonly, whereas central sleep apnea is relatively rare. Sleep also alters the ventilatory response to hypoxia and hypercapnia. The ventilatory response to hypoxia declines in NREM sleep compared to wakefulness in men,[25,26] but appears to remain the same in wakefulness and NREM sleep in women.[27] This

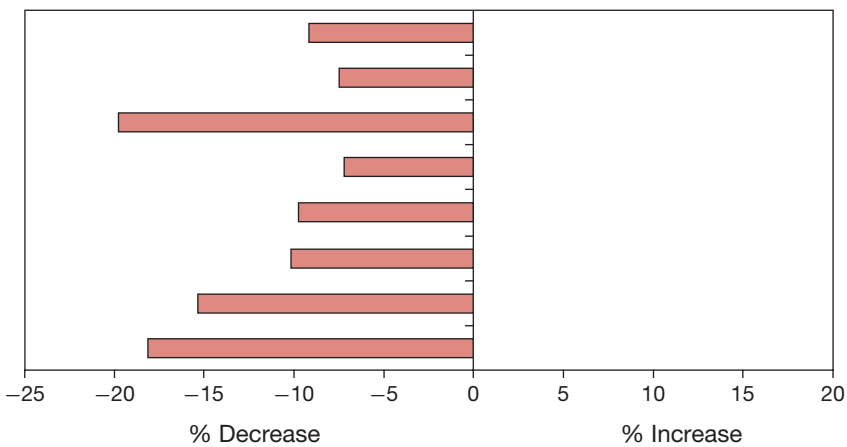

Figure 101-3 Percentage change in minute ventilation from wakefulness to NREM sleep in several different studies. There is some variation among studies in the magnitude of the drop in ventilation in NREM sleep, but all studies show a decline. *(Data from Krieger J, Maglasiu N, Sforza E, et al. Breathing during sleep in normal middle-aged subjects. Sleep. 1990;13:143–154.)*

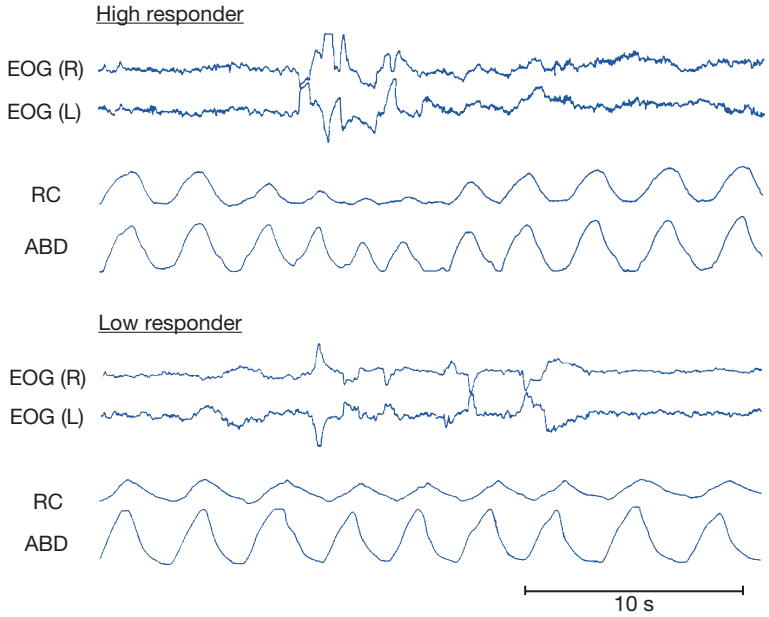

Figure 101-4 Changes in respiration during REM sleep. The data shown are for two normal healthy adults. The top traces are right and left electrooculogram [EOG(R) and EOG(L)] that show phasic eye movements during REM sleep. The bottom traces are ribcage (RC) and abdominal (ABD) motion. The subject in the top panel (labeled High Responder) has a marked fall in ribcage and to a lesser extent abdominal motion in association with the eye movements. The subject in the bottom panel (labeled Low Responder) has little alteration in ventilatory movements during these phasic eye movements. *(Reproduced with permission from Neilly JB, Gaipa EA, Maislin G, et al. Ventilation during early and late rapid-eye-movement sleep in normal humans. J Appl Physiol. 1991;71(4):1201–1215.)*

difference was attributed to higher rates of ventilation during wakefulness in men, with comparable rates in NREM sleep in men and women.[27] The ventilatory response to hypoxia is lower in REM sleep than NREM in both men and women.[25–27] Likewise, the slope of the ventilatory response to carbon dioxide is reduced in NREM sleep by as much as 50%,[28] compared to wakefulness and further reduced in REM sleep. However, there is no compelling evidence that there is alteration in central neural response to chemical stimuli since there is, as outlined, a change in upper airway resistance that will alter the increase in ventilation produced by increases in the neural output to the diaphragm.

As a consequence of these changes in ventilation and its control, Pa_{CO_2} rises typically from its normal value of 40 mm Hg by a few mm Hg in NREM sleep.[29] The magnitude of this increase in Pa_{CO_2} is a function of the responsiveness of the system to CO_2 during wakefulness; subjects with low ventilatory responses to CO_2 have larger increases in Pa_{CO_2} during NREM sleep than do subjects with high responsivity (Fig. 101-7).[29]

Parallel to this increase in Pa_{CO_2}, the Pa_{O_2} can fall in sleep. In healthy individuals living at sea level, the Pa_{O_2} does not fall to a level where significant desaturations occur. However, in persons with low Pa_{O_2} during wakefulness, who operate closer to the "knee" of the oxygen saturation curve, this fall in Pa_{O_2} during sleep may lead to a significant hypoxemia. For example, patients with chronic obstructive pulmonary disease may require supplemental oxygen during sleep but not during wakefulness. The severity of sleep-related hypoxemia will also vary with sleep-state–dependent functional residual capacity. When this is low as a consequence of obesity or intrinsic lung disease, the drops in Pa_{O_2} will be greater than expected for the increase in Pa_{CO_2}.

Another major change that occurs during NREM sleep is an increase in the CO_2 apnea threshold. This apnea threshold is the Pa_{CO_2} at which there is insufficient chemical drive and ventilation ceases. During wakefulness, Pa_{CO_2} can be reduced by assisted ventilation to values as low as 20 mm Hg and rhythmic ventilation will be maintained[12]; thus, the CO_2 apnea threshold during wakefulness is extremely low. In contrast, during NREM sleep, the Pa_{CO_2} needs be reduced only to values close to the normal awake Pa_{CO_2} (from 42–45 to 38–40 mm Hg) and ventilation will cease.[12] Indeed, the normal increase in Pa_{CO_2} that occurs during NREM sleep is often necessary to maintain rhythmic ventilation.

This NREM sleep–related increase in apnea threshold has profound implications. In situations in which ventilation is stimulated – for example, by hypoxia – Pa_{CO_2} may be reduced below the apnea threshold typical for normoxic conditions, creating a state of increased vulnerability to central apneas.[12,30] It is likely that unexplained central apnea during sleep occurs in association with hypocapnia.[30,31] This hypocapnia may be the result of chronic hyperventilation, which is probably related to augmented central and peripheral respiratory drive, which predisposes to respiratory control system instability.[30] If this is the mechanism for these apneas, increase in the Pa_{CO_2} should abolish them. This has been demonstrated in idiopathic central apnea.[12] Relative hypocapnia is also a risk factor for the development of Cheyne–Stokes respiration in patients with congestive heart failure.[30,31]

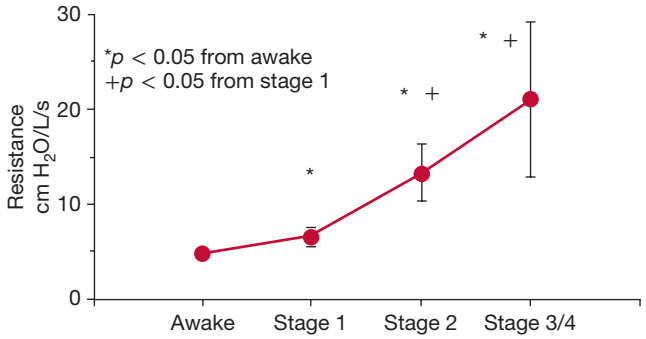

Figure 101-5 Upper airway resistance increases progressively on going from wakefulness to the deeper stages of NREM sleep. *(Data from Tangel DJ, Mezzanotte WS, White DP. Influence of sleep on tensor palatini EMG and upper airway resistance in normal men. J Appl Physiol. 1991;70:2574–2581.)*

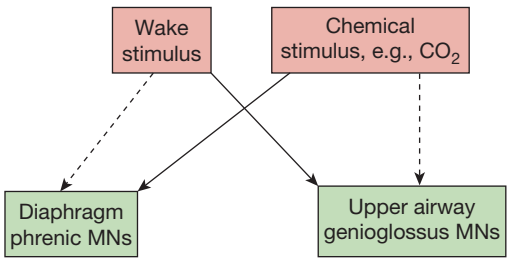

Figure 101-6 Schematic diagram illustrating the relative role of the "wakefulness drive" to breathe and that related to the chemical control system determined by Pa_{CO_2} and Pa_{O_2}. The diaphragm is only little affected by the wakefulness drive *(dashed line)* and is predominantly responding to chemical stimuli *(thick line)*. In contrast, upper airway motoneurons, such as genioglossus, are more affected by the "wakefulness stimulus" coupled to sleep state. MN, Motorneurons.

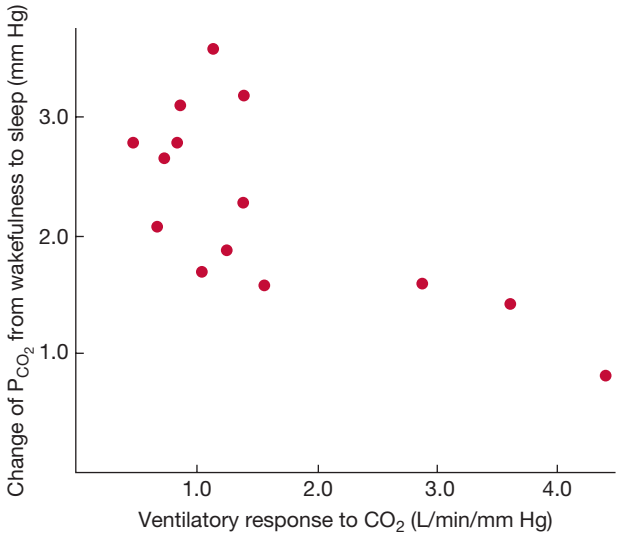

Figure 101-7 Relationship between the increase in Pa_{CO_2} that occurs in normal subjects in going from wakefulness to stages 1 and 2 NREM sleep and the CO_2 ventilatory response in wakefulness. Persons with the lowest ventilatory responses show the largest change in Pa_{CO_2} in going to sleep. *(Adapted with permission from Gothe B, Altose MD, Goldman MD, et al. Effect of quiet sleep on resting and CO_2-stimulated breathing in humans. J Appl Physiol Respir Environ Exerc Physiol. 1981;50(4):724–730.)*

The specific cellular and neurochemical mechanisms for this NREM sleep–related change in the apnea threshold are currently unknown. Conceptually, however, it may be considered within the same category as the so-called wakefulness stimulus for breathing. Brain stem neuronal groups, such as the locus coeruleus and raphe nuclei in which the major transmitters are norepinephrine and serotonin, respectively, decrease their activity with sleep.[32] Since both these transmitters have important excitatory effects at various levels of the central respiratory control system, these neuronal groups likely represent major components of the wakefulness stimulus.

AROUSAL DURING SLEEP

During sleep various sensory stimuli, including auditory and tactile,[33] can lead to a sudden change in sleep state to a lighter stage of sleep or complete wakefulness. Arousal can be detected with abrupt changes in the electroencephalogram.[34] Arousal also results in an increase in heart rate and blood pressure as well as an increase in ventilation,[35] a response that is independent of CO_2[36] and which decreases with age.[37] So-called subcortical or brain stem arousals can arise, including in patients with obstructive sleep apnea,[38] that is, when there is an abrupt change in cardiopulmonary variables but no change in the electroencephalogram. As would be anticipated from the discussion of the wakefulness stimulus, arousals produce much more marked increases in activity of the upper airway muscles than in the diaphragm,[39] but it is also critical to appreciate that an arousal response is akin to accentuated wakefulness and therefore can produce an overshoot.

Respiratory stimuli can also lead to arousal during sleep.[33,38] Such stimuli include airway occlusion, increased upper airway resistance, hypoxia, and hypercapnia.[33] Isocapnic hypoxia is, however, a poor stimulus to arousal. Subjects can remain asleep without interruption even with Sa_{O_2} values as low as 70%.[38] It appears that the major respiratory stimulus to arousal is the degree of respiratory effort.[38] Arousal occurs at a relatively constant increased respiratory neural output, that is, respiratory effort that is independent of the causes of this increased effort.[33,38]

PERIODICITIES OF VENTILATION IN LIGHT NREM SLEEP

Periodic (oscillatory) ventilation is more likely to occur during light NREM sleep (stages N1 and N2) than in slow-wave sleep (stage N3).[40–42] This is highly relevant to the problem of obstructive sleep apnea[42] (see further, Chapter 99); most apneas occur in stages N1 and N2 sleep.[42] If a subject with sleep apnea is able to enter stage N3 NREM sleep, regular ventilation resumes and apneas are less likely to occur.[42] Oscillatory ventilation is also typically observed during hypoxia, as in lung disease or at high altitude, and in certain cardiovascular diseases.[43]

Ventilation may be periodic because of particular dynamic properties of the chemical feedback system that controls respiration.[41,44,45] As in any feedback system, the critical determinants of this unstable (oscillatory) behavior are the overall response (gain) of the control system and the time delay (phase lag) between the plant and the controller. For the respiratory system, the plant is the gas exchange apparatus in the lung; the controllers are the chemoreceptors, peripheral and central; and the controlled variables are the arterial blood-gas tensions, Pa_{CO_2} and Pa_{O_2}. Thus, in the case of the respiratory control system, this time delay is that between the lung and the sensors, the peripheral and central chemoreceptors.[44]

The importance of this delay is illustrated in Figure 101-8 for a situation in which a disturbance to the ventilatory control system leads to a change in Pa_{CO_2}. If there is no delay, the control system responds immediately to this perturbation by adjusting ventilation to correct the change in Pa_{CO_2} (Fig. 101-8A). In contrast, if there is a delay in the feedback loop, the controller may act to sustain the cyclical disturbance (Fig. 101-8B); this is because during the time it takes the altered Pa_{CO_2} level to reach the sensor, the controller may make an inappropriate correction. For example, when the Pa_{CO_2} in the blood leaving the lung is low, the controller should respond by reducing ventilation, returning the Pa_{CO_2} to the regulated value. If, however, the delay is such that by the time the low Pa_{CO_2} signal reaches the sensor, the Pa_{CO_2} of the blood leaving the lung is already higher (e.g., due to the presence of an external perturbation or already existing oscillations, as in Fig. 101-8B), the controller will act incorrectly to reduce ventilation and further increase the Pa_{CO_2}. Such a situation promotes self-sustaining periodic ventilation. Thus, the time delay determines not only whether periodic ventilation will or will not occur, but also the period of this oscillation.

Periodic ventilation would not occur if the control system failed to respond, or responded weakly, to these perturbations. Thus, the gain of the response of the system is as important as the magnitude of the delay in determining whether unstable operation of the ventilatory control system will occur. This gain is usually defined as the product of the response of the controller (the change in ventilation per unit change in Pa_{CO_2}, i.e., CO_2 sensitivity) and the gain of the plant (the change in Pa_{CO_2} per unit change in ventilation, i.e., the plant gain). Overall loop gain is the product of these.[44]

Periodic breathing occurs in clinical situations, particularly in hypoxic subjects (e.g., patients with lung disease) and normal sojourners at high altitude.[46] Hypoxia increases the gain of the response of the controller, making the system more unstable. The period of the oscillations in ventilation induced by hypoxia is on the order of 20 seconds, that is, much shorter than those typically seen in patients with obstructive sleep apnea or in Cheyne–Stokes respiration. Abnormally increased circulatory time, which prolongs the delay between the lung and chemoreceptors, can also produce an unstable system and ventilatory periodicities. This mechanism is likely to be responsible, at least in part, for the ventilatory oscillations that occur during sleep in patients with severe congestive heart failure (Cheyne–Stokes respiration).[47,48]

In addition to these mechanisms that are related to instability of the chemical control system for ventilation, state instability can produce sleep-related oscillations in ventilation[12,14,25–28,44]; state

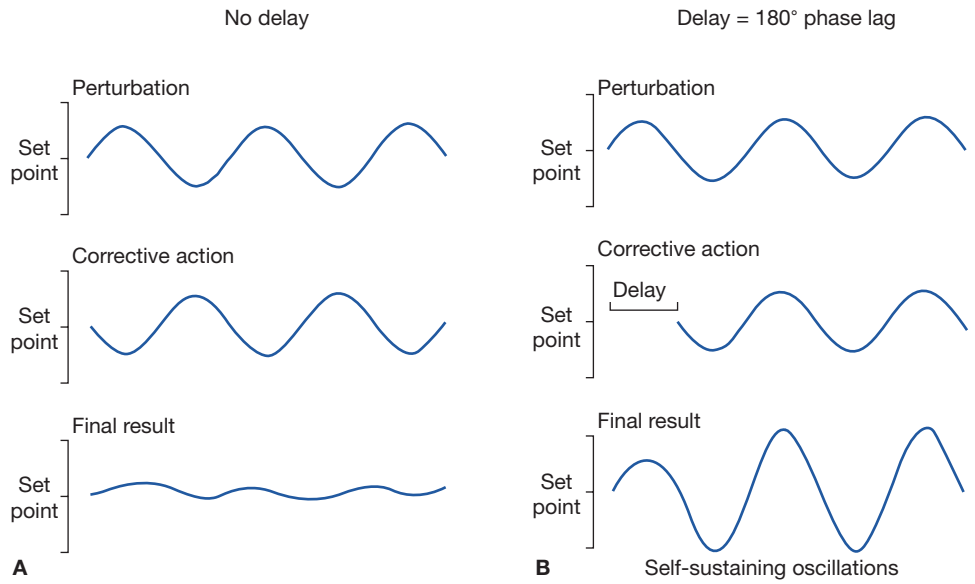

Figure 101-8 Implications for a control system with a delay between the plant and the control system. The left panel (**A**) shows how a control system will respond to a sinusoidal perturbation when there is no delay. The perturbation is essentially neutralized. The right panel (**B**) shows how a control system acts if it has a delay that results in the corrective action being 180 degrees out of phase with the perturbation. In this case, the controller's action acts to sustain, and not to neutralize, the original sinusoidal perturbation.

instability is defined as periodic changes in the stages of sleep that cause discrete and periodic changes in the level of the wakefulness stimulus to ventilation. As discussed in the preceding section, at the onset of sleep, there are decreases in ventilation[11,13,29] and increases in upper airway resistance[15] that cause an increase in Pa_{CO_2}; the increase in Pa_{CO_2} may, in turn, directly or indirectly interfere with the normal progression of the sleep cycle. For example, an abrupt change in sleep state may occur as a result of airflow limitation and increased respiratory effort, leading to an awakening to a lighter stage of sleep, that is, to an arousal. Upon arousal, ventilation increases, upper airway resistance decreases, and Pa_{CO_2} drops. The subject returns to sleep, and the whole cycle may repeat itself. This state instability is more likely to arise if the ventilatory response to CO_2 is low, since the Pa_{CO_2} increases more at sleep onset and is more apt to drive the level of respiratory effort to a point at which an arousal from sleep occurs. The period of ventilatory oscillation caused by this mechanism is longer than that seen with chemical instability, that is, around 60 to 90 seconds. This mechanism likely predominates in producing the sleep apnea syndrome and periodic breathing in patients with low ventilatory responses to CO_2 (e.g., patients with hypothyroidism, in whom central and obstructive apneas are common).[40,44]

CIRCADIAN CLOCKS IN THE CARDIOVASCULAR SYSTEM AND LUNG

While much is known about the physiology of cardiopulmonary changes during sleep, recently attention has turned to changes in molecular mechanisms. In the late 1990s the discovery of the molecular components that produce circadian clocks led to the study of expression of circadian clock genes in many different organs.[49] Surprisingly, functioning clocks were not only found where they were expected, that is, in the suprachiasmatic nucleus of the hypothalamus – the site of the master circadian clock – but also in many organs. In particular, functioning clocks have been demonstrated in the lung and cardiovascular system.[50,51] In cardiac myocytes and vascular smooth muscle cells, the clocks are intrinsic to these cells since they maintain a circadian rhythm even when the cells are isolated and in culture. This work has been described elsewhere.[51] Many other cell types have not been as extensively tested to date, but peripheral clocks including those in the liver, kidney, heart, and adipose tissue[52,53] have been described. These clocks likely alter the temporal pattern of expression of genes in the relevant organs. Microarray studies indicate that about 10% to 15% of all genes have a diurnal variation in their expression levels. In heart, there is, for example, diurnal variation of genes promoting fatty acid oxidation. Expression of these genes in rats peaks during the dark phase, that is, their active period.[51] Expression of genes for K+ channels also exhibits diurnal variation in the heart and likely contributes to the altered excitability of the cardiac myocyte across the day.[50]

These observations indicate that at a fundamental molecular level the heart and lung at night are not the same as during the day. Emerging data indicate that molecular processes in peripheral organs will also be affected by sleep and sleep deprivation,[54] and this is an area that is likely to be a fruitful area of inquiry. The molecular basis of circadian rhythms and molecular functions of sleep are discussed in more detail in Chapter 12.

CONCLUSION

In conclusion, there are major changes in cardiopulmonary function during sleep as compared with wakefulness. These changes are sleep-state specific, being different between NREM and REM sleep. The changes have important pathogenetic significance. This significance includes the following: the timing across the day of acute cardiovascular events; the periodic breathing that occurs during sleep at high altitude; the neuronal changes that lead to obstructive apnea during sleep; and the pathogenesis of Cheyne–Stokes respiration. Currently, a new window on changes in the cardiopulmonary system with sleep is opening, that is, changes at the molecular level. This is likely to lead to new insights that will also have implications for the pathogenesis of disease and treatment.

CHAPTER 102

Differential Diagnosis and Evaluation of Sleepiness

Mithu Sen
Meir H. Kryger

Excessive daytime sleepiness (EDS) is a common problem affecting large segments of the general population. Although estimates depend on how sleepiness is defined (i.e., sleeping too much vs. falling asleep in the daytime), about 16% of adults experience sleepiness that affects their daytime function, and there is increasing evidence that sleepiness plays a part in both industrial and road traffic accidents. The National Highway Traffic Safety Administration estimates that more than 100,000 automotive crashes per year are fatigue related. These sleepiness-related accidents contribute to 40,000 injuries and 1550 deaths per year.[1] Over the past two decades, research has provided increased understanding of obstructive sleep apnea (OSA), among other sleep disorders.[2]

The current prevalence estimates of moderate to severe sleep-disordered breathing with an apnea–hypopnea index, measured as events/h, ≥15 are thought to be higher, with contributing factors such as obesity increasing the prevalence. These estimated prevalence rates represent substantial increases over the last 20 years (relative increases of between 14% and 55% depending on the subgroup). Specifically, the prevalence is 10% (95% confidence interval [CI]: 7, 12) among 30- to 49-year-old men; 17% (95% CI: 15, 21) among 50- to 70-year-old men; 3% (95% CI: 2, 4) among 30- to 49-year-old women; and 9% (95% CI: 7, 11) among 50- to 70-year-old women.[3]

There is increasing awareness of sleep disorders by the general public and respiratory physicians, by necessity, are dealing more and more with sleep apnea and other sleep disorders. In recognition of the need for training pulmonary physicians in sleep disorders, in 1994 the American Thoracic Society (ATS) published recommendations for training in sleep medicine that has grown to include not only the ATS, but also the AASM, ACCP, AASM,[4] and ABIM.[5] There is also significant impact on future training in medicine and surgery based on the sleepiness of the learner. Restriction of duty hours has been reviewed in many countries including ACGME in the US and the RCPSC in Canada. The IOM Report Sleep Supervision and Safety reviewed the potential impact of sleep in training and recommendations made in 2008 were implemented by ACGME including:

The new ACGME standards require residency programs to:

1. Tailor supervision standards for different levels of training, particularly greater supervision for first-year residents.
2. Ensure competence in structured handover processes.
3. Incorporate clinical quality improvement and patient safety into resident learning.
4. Provide safe transportation and/or sleeping facilities for fatigued residents.
5. Adjust workload according to patient severity and resident training.
6. Improve oversight of compliance with duty hour limits.

Specific duty hour recommendations from the IOM include:

1. The maximum number of work hours remains at 80 hours per week, averaged over 4 weeks;
2. Moonlighting, now both internal and external, is counted against the 80-hour weekly limit; and
3. Duty periods are limited to 16 hours (although only for first-year residents by ACGME).

In Canada, the author (MS) was a member of the Medical Education Working Group and contributing author of Fatigue, Risk, Excellence: Towards a Pan-Canadian Consensus on Resident Duty Hours (June 2013). The recommendations from this report suggest each training program is unique and therefore deserves unique solutions for managing sleep schedules to optimize learning. The National Steering Committee published five recommendations for Canadian training programs:

1. Recognizing that there are many factors that contribute to resident fatigue, a comprehensive approach to minimize fatigue and fatigue-related risks should be developed and implemented in residency training in all jurisdictions in Canada.

2. Educational approaches should be redesigned to leverage innovations and new approaches, to ensure appropriate training and acquisition of competencies in an era of increasing resident duty hour regulations.
3. Accreditation standards must be adapted to support planned modifications of the content and duration of resident duty, through the enforcement of fatigue risk management activities.
4. An inventory of alternate models of scheduling and after-hours care provision should be created and disseminated to provide alternatives and benchmarks of scheduling and service delivery.
5. An independent, pan-Canadian consortium devoted to the evaluation of resident duty hours in Canada should be created.

These organizations are looking to guidance from physicians with sleep training to help mitigate sleepiness to optimize learning. There are many additional public health issues including patient safety that require physicians to understand sleepiness.[6] It is clear, therefore, that pulmonary physicians need to better understand and be able to treat EDS, regardless of the etiology.

THE PHENOMENON OF SLEEPINESS

Sleepiness is both a subjective and an objective phenomenon, a constellation of sensations and a physiological state with stereotypical behaviors. As such, it is sometimes difficult to define, and its measurement (see Section on Quantifying Sleepiness) depends on the circumstances. Sleepiness may be expressed as feeling sleepy, fatigued, or tired; sleeping too much; or fighting to maintain alertness. Sleepiness can be reflected by any or all of the following: heaviness of the eyelids, mild burning or itching of the eyes, difficulty keeping the eyes open, heaviness in the arms or legs, reluctance to move, loss of initiative, loss of interest in surroundings, and difficulty with concentration or memory. These sensations are accompanied by behavioral changes such as rubbing the eyes, yawning and stretching, and nodding the head, and by generally reduced motor functions such as speech, facial expression, and body movement. Literature shows that sleep-deprived healthy individuals demonstrate attenuated facial expressions to stimuli.[7]

Sleepiness may also be considered a physiological state like hunger or thirst. Just as hunger and thirst are physiological states that occur with fasting and are satisfied by eating and drinking, sleepiness in individuals without a specific sleep disorder is produced by sleep restriction or deprivation and is reversed or satisfied by sleep. However, a difference between sleep and other physiological factors is that food may satisfy hunger but the sleep quality along with quantity is necessary to satiate sleep loss. Sleep quality is impaired in individuals with specific sleep disorders such as sleep apnea. The factors that produce and influence sleepiness are detailed below; they include such obvious factors as time since last asleep, previous amount of sleep, continuity of sleep, and normal 24-hour circadian influences. Environmental stimuli influence this state and can determine, up to a point, whether or not this sleepy tendency will be manifested. For example, heavy meals, warm rooms, boring lectures, or monotonous tasks are usually considered soporific activities or situations. In these situations, a person might feel sleepy and, might fall asleep. Yet the environmental factors themselves do not cause the sleepiness; they only allow it to be expressed. Equally, the same degree of physiological sleep tendency might go unnoticed when environmental stimulation occurs in the form of a life-threatening situation. In other words, the degree to which sleepiness is experienced or evident in behavior is determined by the underlying physiological sleep tendency (or the need for sleep) and environmental factors, which interact to manifest the sleep tendency or sleep propensity.[8]

While it is accepted that sleepiness is a physiological state, the physiological substrates of this state have not been identified. Neurotransmitters such as serotonin, acetylcholine, histamine, and the catecholamines have been implicated in the sleep/wake mechanism along with a variety of other sleep-inducing substances, including adenosine through its inhibition of wakefulness-promoting neurons. While much research is ongoing, the understanding of the neurochemicals responsible for sleep, sleepiness, and loss of alertness are still far from clear.[9–13]

QUANTIFYING SLEEPINESS

The sensation of sleepiness is often difficult to quantify, as are other subjective symptoms, such as pain or shortness of breath. All of these subjective sensations may mean different things to different people, and are modified by factors including motivation, external stimulation, and competing needs. What constitutes extreme sleepiness for one person may be only mild sleepiness for another and depends on the situation in which it occurs. An approach is outlined in Table 102-1. Sleepiness has different dimensions with both feelings of perceived sleepiness as well as self-estimates of sleepy behavior, which are different in passive versus active situations. The notion of a sleepiness trait, a composite of sleep need and sleepability, which is the ability to transition into sleep.[14]

Other individual difference factors have been proposed to explain individual dissimilarities in sleepiness.[8] Sleep drive is an inherited trait.[15]

SUBJECTIVE MEASURES OF SLEEPINESS

Subjective reports may be used to quantify sleepiness, but statements such as "I feel sleepy" and "I feel very sleepy" often do not distinguish between feelings caused by a high physiological sleep tendency and those resulting from muscular fatigue, depressed mood, or a general lack of energy. Thus, several subjective sleepiness scales have been developed. The Stanford Sleepiness Scale (SSS), the first to receive widespread use, is a seven-point self-rating scale ranging from 1 (alert, wide awake) to 7 (almost in reverie, sleep onset soon).[16] It is brief, simple to use and measures current degree of sleepiness. It has been shown to correlate with the performance of mental tasks and demonstrate changes in sleepiness with sleep loss. However, there are no normative data and results often depend on the duration of prior sleepiness. For example, unlike normal persons who are experimentally sleep deprived, patients with more chronic sleep deprivation (i.e., sleep apnea) cannot be accurately tested with the SSS. Some patients who have an obvious overwhelming physiological sleep tendency may claim to be only mildly sleepy, yet fall asleep before your eyes. This was first observed in the early 1970s, and was a stimulus

for Stanford investigator group to develop more objective measures of sleepiness.[16] Studies have shown that with continued increases in lapses in performance over several days of sleep restriction but the self-reported sleepiness does not continue to get worse.[17]

It is clear that over a period of months or years, many sleep apnea patients lose their frame of reference with regard to normal alertness and cannot distinguish major changes in sleepiness. Thus, the subjective report of sleepiness (using the SSS) by people who are chronically and severely sleep deprived is not reliable.[16]

The Karolinska Sleepiness Scale (KSS) is a nine-point scale ranging from 1 (very alert) to 9 (very sleepy, fighting sleep, making an effort to keep awake), with verbal descriptions of every second point.[18] Like the SSS,[16] the KSS requires the subject to integrate and translate a number of sensations to a continuum that is fairly abstract despite the verbal description. Ratings obtained with these scales may be affected by the situation in which the scale is presented (at rest or during performing a task) and how the subject relates his or her perception to that particular time or place. These scales reflect current sleepiness. Nonetheless, both the SSS and KSS show high correlations with performance. The KSS was also found to be strongly related to EEG and electrooculographic signs of sleepiness.[18]

The Epworth Sleepiness Scale (ESS; Table 102-2) was designed to measure sleep propensity in a single, standardized way and is based on questions relating to eight situations, some known to be very soporific.[19] The ESS, in contrary to the KSS and SSS, assesses symptoms of chronic sleep deprivation. The questions are self-administered, and subjects are asked to rate on a 0 to 3 scale how likely they are to doze off in the situation based on their usual habits over recent weeks to months. The ESS tries to overcome the fact that people have different daily routines, some facilitating and others preventing daytime sleep. An ESS of 10 or below is considered normal. Scores above this are considered indicative of excessive sleepiness. ESS scores have shown significant correlations with mean sleep latency in the multiple sleep latency test (MSLT, see further below) and have distinguished groups of patients with disorders of excessive sleepiness such as narcolepsy, OSA, and idiopathic hypersomnolence. The ESS score has been validated against the MSLT in sleep disorder patient population, specifically narcolepsy patients, to show a 95% sensitivity and 73% specificity in comparison to the MSLT.[20] The ESS has high test–retest reliability and a high level of internal reliability in normals and patients with sleep apnea.[21] Further work examining the utility of measuring sleepiness in

TABLE 102-2 Epworth Sleepiness Scale

Epworth Sleepiness Scale

Name: _____ Today's date: _____

Your age (Yrs): _____ Your sex (Male = M, Female = F): _____

How likely are you to doze off or fall asleep in the following situations, in contrast to feeling just tired?

This refers to your usual way of life in recent times.

Even if you haven't done some of these things recently try to work out how they would have affected you.

Use the following scale to choose the **most appropriate number** for each situation:

0 = **would never** doze
1 = **slight chance** of dozing
2 = **moderate chance** of dozing
3 = **high chance** of dozing

It is important that you answer each question as best you can.

Situation	**Chance of Dozing (0-3)**
Sitting and reading	___
Watching TV	___
Sitting, inactive in a public place (e.g., a theatre or a meeting)	___
As a passenger in a car for an hour without a break	___
Lying down to rest in the afternoon when circumstances permit	___
Sitting and talking to someone	___
Sitting quietly after a lunch without alcohol	___
In a car, while stopped for a few minutes in the traffic	___

THANK YOU FOR YOUR COOPERATION

different situations using the ESS suggests that individual measurements of sleep propensity (i.e., sleepiness) entail three components of variation: a general characteristic of the subject (the average sleep propensity), a general characteristic of the situation in which the sleepiness or sleep propensity is measured (its soporific nature), and a third component that is specific for both subjects and situation.

OBJECTIVE MEASURES OF SLEEPINESS

MSLT[20] has been developed and standardized as an objective, reliable, and reproducible measure of physiological sleep tendency.[20] Performed at intervals throughout the day the MSLT measures the time to sleep onset, as determined by the EEG. This test is based on the assumption that, given the proper surroundings, physiological sleep tendency will be expressed; it has an intuitive appeal in that if one patient is more sleepy than the other, the sleepier patient should fall asleep more quickly. Patients are instrumented to record the EEG, electrooculogram (EOG), and electromyogram (EMG); they are put in a quiet, darkened, temperature-controlled room, and are asked to lie quietly, close their eyes, and try to fall asleep. Naps are scheduled at 2-hour intervals, with 20 minutes allowed for sleep to occur. If an individual initiates sleep, a mean sleep onset latency (SOL) can be measured and can support excessive daytime somnolence or a diagnosis of narcolepsy, as explained below. Thus, the average SOL of the naps represents the result of the MSLT. Both clinical and research protocols exist for conducting the MSLT.[20]

Since sleepiness follows a circadian rhythm (see Section on Circadian Rhythms), one nap is insufficient to document and quantify daytime sleepiness. Accordingly, a minimum of four and a maximum of six naps are recommended. The MSLT is a reliable, reproducible test that has been validated in a number of sleep deprivation experiments in normal subjects and a variety of clinical conditions with patients who have disorders such as narcolepsy and sleep apnea and may be useful for documenting treatment response to the sleep disorder, such as medications in narcolepsy or CPAP in sleep apnea.[20] An important advantage of the MSLT is that patient motivation cannot counteract the effects of previous sleep loss on sleep latency. That is, while most people can be motivated to compensate for reduced performance after sleep deprivation, motivation cannot overcome an increased pressure for sleep, particularly when the patient is in bed in a darkened room.

The Maintenance of Wakefulness Test (MWT) is an alternative to the MSLT. This is a variation on a theme in which subjects sit in a chair in a darkened room and are requested to remain awake for 20 (or 40) minutes. This test was developed on the assumption that the ability to fall asleep and the ability to stay awake are two separate phenomena. The MWT has undergone further tests of validity, but has been criticized for lack of a standardized protocol with 20-, 30-, and 40-minute tests being reported. Recent practice parameters suggest using a 20-minute four-trial protocol opportunities for the patient to initiate a nap.[20] The naps are separated by 2 hours.

This is a relevant question when assessing whether or not a patient can stay awake in a situation of personal or public safety. The physiological ability to fall asleep is measured by any naps initiated during the 20-minute period. Any sleep onset REM (SOREM) is closely observed as it can signify a diagnosis of narcolepsy.

While both MSLT and MWT require observer recognition of EEG changes, quantitative computerized analysis *of EEG* has been proposed as an alternate and perhaps more sensitive objective measure of sleepiness. Increased EEG delta activity with sleep deprivation and decreased alpha activity just before sleep onset are two possible metrics. However, these have yet to be translated into clinically useful tests. The Alpha Attenuation Test (AAT) has been validated in sleep-restricted normals and in patients with narcolepsy and correlates strongly with the MSLT.[20]

Oxford SLEep Resistance Test (OSLER test) was designed as a low-cost alternative designed to reproduce many of the features of the MWT, but without the labor-intensive, continuous technician monitoring of EEG.[22]

In the OSLER tests, subjects respond to a visual stimulus. A light-emitting diode mounted on the wall, which flashes for 1 second every 3 seconds in fixed intervals. If there is no response after seven consecutive stimuli, the subject is deemed to be asleep and the test is ended. The original study compared OSLER sleep latency with MWT latency in 10 OSA patients and 10 control subjects, done on separate days, and showed that OSLER could be validated against the MWT in this patient population. Two other studies involving small numbers of sleep disorders center patients and/or normal subjects before and after sleep deprivation have demonstrated excellent agreement between the two measures and suggest that the OSLER could be an alternative to measuring sleepiness.[23] In a study of heart failure patients receiving adaptive ventilation for treatment of Cheyne–Stokes respiration, improvement in OSLER scores followed improvement in nighttime sleep.[24] Despite these promising results, there are no large-scale studies using the OSLER, and the main limitation of this test is its dependence on patient cooperation.[25,26]

PERFORMANCE AND VIGILANCE TESTS

Measurements of performance after sleep loss reflect daytime sleepiness, since most people report decreased performance after a sleepless night. Previously it was felt that only performance tests that were prolonged and monotonous were sensitive to sleep loss. However, the work of Dinges et al. (using his Psychomotor Vigilance Task [PVT]) demonstrates that if the signal rate is high and the response measure sufficiently sensitive, repetitive tasks of only 10-minutes duration will expose the limits of performance in sleepy persons.[27,28] Performance decrements resulting from sleep deprivation (or sleep disorders such as sleep apnea) can be observed in such a task if results are analyzed over time. This time-on-task or vigilance decrement may be observed as evidence of fatigue even in well-motivated subjects with adequate prior sleep, and it manifests itself as a shallow decline in performance as time-on-task increases. When the subject is sleep deprived, it is impossible to sustain attention long enough to maintain peak performance throughout the entire task and lapses in performance occur. Sleep loss increases the rate of decline in performance. The number of interrupted episodes also contribute to performance decline. The Psychomotor Vigilance Test (PVT) has become the most widely used measure of neurobehavioral performance. It has been validated with the SSS and MSLT. Recent work using this test has demonstrated consistent individual differences in neurobehavioral deficits from sleep loss when repeated in the same subject, which indicate differential trait vulnerability to sleepiness.[29]

While the MSLT and MWT can provide helpful information, they require repeated testing every 2 hours and a whole day of tests. Data published recently suggest that a single administration of objective tests, in particular the PVT, can help assess sleepiness in controlled conditions that may be applied clinically.[30]

Other tests of sustained attention and performance have been developed, many to assess simulated driving performance. Using a divided attention task, where individuals are required to pay attention to more than one aspect of the task, such as a driving task, sleep apnea patients have been shown to perform poorly, and in some cases, equal to or worse than normals impaired by alcohol.[31] Nonetheless sleepiness as measured by MSLT accounts for less than 25% of the variance in tracking performance. Thus, while the effects of sleepiness on performance may occur in a dose-dependent fashion in normals, performance decrements in patients who are sleepy because of an underlying sleep disorder may be accounted for by factors other than sleepiness.

Mitigating subjective "sleepiness" in patients with mild to moderate OSA, untreated with CPAP, has been shown with modafinil. The effect size was clinically important as was the improvement on the driving simulator performance and reaction time.[32]

FACTORS AFFECTING SLEEPINESS

Sleepiness is determined by the quantity of sleep and the quality and type of sleep, interacting with circadian rhythms or drugs that patients may be taking.

SLEEP QUANTITY

The amount of nocturnal sleep has a strong relationship to the degree of daytime sleepiness. Partial or total sleep deprivation is followed by increased daytime sleepiness in normal persons. Furthermore, sleep restriction will become cumulative over time and lead to increasing daytime sleepiness.[28]

The effect of sleep restriction on SOL is shown in Figure 102-1. When the sleep of young adults was reduced by 2 hours a night on consecutive nights, sleepiness (as measured by the MSLT) progressively increased over 7 days. Even as little as 1 hour per night of sleep loss will accumulate over time and lead to daytime sleepiness—a fact generally not appreciated. Each person has a certain biological sleep need, and the specific amount varies from one subject to the next. Regardless of cultural or environmental factors, most adults sleep 7 to 8 hours per day, but the old adage that we must sleep 8 hours each night is not true for everyone. Some people require more than 8 hours, and others less. There may be many contributors to the amount of sleep an individual requires including a genetic contribution. Recent data support a genetic variant (hDEC2-P385R) contributing to individuals who only need a short sleep time.[33] Individual differences in required sleep time is also evident in conjoined twins who show an independence of sleep needs. In the absence of pathology, normal human sleep length varies between 6 and 9 hours, although some people require less. It would be ideal to require a minimum amount of sleep to allow maximum productivity in work and adequate time for social pursuits. Indeed, some investigators believe that Western society predisposes to sleep deprivation.[34] With economic and social constraints – the latter leading to voluntary sleep restriction – the sleep period is the time most encroached on, potentially leading to daytime sleepiness.[35] There has been progressive reduction in sleep duration over many age ranges that is more commonly found in the United States. There are multiple etiologies for this including work intruding into sleep period. Thus, there is a national agenda for 2020 (Healthy People 2020) in the United States to understand the implications and associations of this more comprehensively.[36] Overall, it appears short sleep duration is increasing in prevalence, which may be associated with adverse health outcomes, such as weight gain and associated morbidities of obesity.[37] In addition, the prevalence of short sleep (<6 hours) has increased in individuals who are employed full time.[38]

Voluntary sleep restriction or insufficient sleep causes daytime sleepiness. Among all prominent features differentiating this group of patients with insufficient sleep from those with narcolepsy is the report, obtained from the sleep history, of a disparity between the amount of sleep on weekdays and that on weekends. People with insufficient sleep typically have a much longer sleep period on weekends (by 2 hours or more).

Most patients consider their weekly sleep loss trivial and assume that it is recovered on weekends. However, while recovery from a single experimental sleep restriction occurs in a couple of nights, it is not likely that repeated episodes of sleep deprivation can be compensated for in just one night. A study of a large group of normal subjects without complaints of daytime sleepiness has shown that young subjects (particularly college students) had shorter sleep latencies than did older subjects. Within the group of 120 young subjects, 12 healthy, nonsmoking men aged 21 to 35 years, had a mean sleep latency of less than 6 minutes on MSLT testing, whereas another 12 had an MSLT of greater than 16 minutes.[20] These subjects had baseline testing and then extended their sleep period time from 8 to 10 hours over 6 days. Repeat testing on days 1, 3, and 6 showed stepwise increases in MSLT and performance testing for both subgroups. These data support the notion that chronic voluntary sleep restriction in real life produces objective sleepiness that may or may not be perceived by the subject.

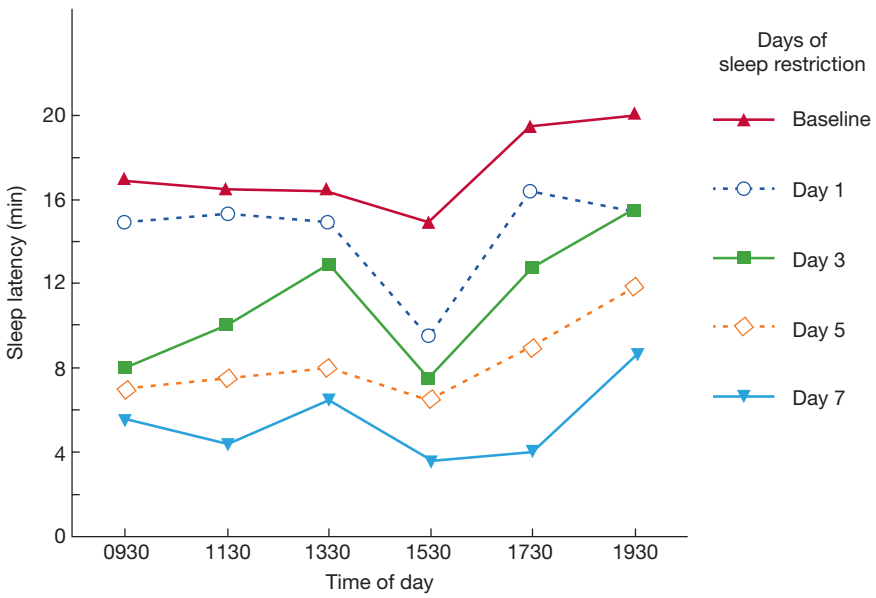

Figure 102-1 Average daily sleep latency test scores for young adults when nighttime sleep was reduced by 2 hours a night for 7 consecutive nights. *(Adapted with permission from Dement WC, Carskadon MA. An essay on sleepiness, in Boldy-Moulinier M (ed). Actualitiés en Médécine Expérimentale, en Hommage au Prof D Passouant. Montpellier, Euromed; 1981.)*

SLEEP QUALITY

Sleep quality is perceived to be abnormal when sleep is decreased or discontinuous. Disrupting sleep continuity – that is, causing arousal from sleep, either experimentally or by sleep disorders – affects the quality of sleep and results in increased physiological sleep tendency. An arousal can be defined as a brief (3–15 seconds) speeding up of the EEG, or as a burst of alpha activity occasionally accompanied by transient increases in skeletal muscle tone.[11,12] These typically do not result in awakening as defined by standard sleep staging criteria or behavioral indicators. Sleep studies can identify various causes of arousal, such as recurrent obstructive apnea, periodic leg movements, or chronic pain, in some but not all cases. A common exception is the patient with chronic obstructive pulmonary disease (COPD) who has frequent arousals from sleep in the absence of obstructive apnea or leg movements.[39] Patients with COPD often experience oxygen desaturation during sleep, and this is a potential stimulus for arousal. Nonetheless, compared with age-matched controls, COPD patients have discontinuous sleep and poor sleep efficiency (defined as percentage of time actually asleep in bed).

Auditory stimuli presented externally to normal subjects during sleep can produce arousal; repetitive presentation of such

stimuli can produce daytime sleepiness. Several studies have shown decreased performance and increased sleepiness the day after repetitive arousal, with the degree of daytime sleepiness related to the frequency of nocturnal sleep disruption. Not surprisingly, the shortest sleep latency occurred after the most fragmented nocturnal sleep. This increased sleepiness will result even if the stimulus is only sufficient to produce EEG signs of arousal, without full wakefulness. The importance of sleep disturbance from environmental noise has been reported by Basner et al.[40] There are both auditory effects such as EEG arousals, impaired daytime alertness from lack of sleep quality and quantity as well as quality of life and nonauditory effects, such as increased catecholamine release and association with cardiovascular disease. Environmental noise exposure, such as from airports and other urban environmental areas, can cause lasting damage resulting in hearing loss. Noise-induced hearing loss and tinnitus may not always be recognized in our society but the effects on the affected individuals' quality of life can be tremendous.[40]

CIRCADIAN RHYTHMS

If sleep latency is measured every 2 hours over a complete 24-hour day, a biphasic pattern of sleep tendency becomes obvious (Fig. 102-2). This demonstrates that there are two peaks and troughs of sleepiness over a 24-hour period. Not surprisingly, the times of increased sleepiness are during the nocturnal hours and during the daytime hours (in the midafternoon between 2 and 4 PM). This circadian rhythm of sleepiness is present in all age groups, although the time of the peak rhythm may vary. The circadian rhythm of sleepiness is similar to other circadian rhythms in that it possesses an endogenous periodicity that can be affected by environmental influences that fine tune or entrain the rhythm. Even in the absence of these environmental cues (i.e., awakening time, alarm clock, degree of light or darkness, food and stimulants, and social contact), rhythms show a persistent periodicity. The circadian rhythm of temperature is extremely stable. Temperatures fall in the late afternoon, are lowest during the middle of the sleep period, and rise before morning awakening. The temperature rhythm synchronizes most closely with sleepiness. Although the amplitude of body temperature and sleep latency rhythms differs considerably, no other biological rhythms correlate so well in time. Circadian rhythm is discussed more extensively in Chapter 12.

Two other examples of the influence of circadian rhythms on sleepiness are obvious. The first is that associated with shift work, and the second is due to transcontinental travel (jet lag). Workers with a normal nocturnal sleep period and a previously stable circadian sleepiness rhythm suddenly will have a trough of sleepiness during the middle of their night work period. They will attempt to stay awake, while the circadian influences will promote sleep.[27,41] Jet lag is similar, in that the body's circadian rhythm is out of synchrony with the destination clock time. As a result, performance may suffer.

MEDICATIONS

Drug effects on sleep can be significant and can either promote sleep and sleepiness or increase wakefulness and alertness. When assessing subjective or objective sleepiness, it is important to know whether the patient is taking a medication that may affect the degree of sleepiness, that is, sleepiness is a side effect of this medication.

Not surprisingly, sedative drugs increase sleepiness. Benzodiazepine hypnotics have been used to help people get to sleep at night however nonbenzodiazepine hypnotics are also used. Many objective studies confirm the ability of hypnotics to shorten sleep latency at bedtime through $GABA_A$ receptor stimulation. When given during the day, they will promote sleep. However, the daytime carryover effect of nocturnal sedation is not always recognized. This effect occurs most commonly with long-acting benzodiazepines, but it may occur with other medications as well. Recently, warnings have been issued from the FDA about potential sleepiness the morning after taking these medications, especially in women, and have recommended reduction in zolpidem dosages to half to increase patient safety. Second-generation antiepileptics (i.e., gabapentin, pregabalin, vigabatrin) also act as GABA agonists without interacting with the $GABA_A$ or $GABA_B$ receptors. Alcohol consistently shortens sleep onset and produces sedation, whether given at night or during the day. It, however, also alters sleep architecture by suppressing REM sleep and contributing to sleep fragmentation through the latter portions of the night.[42]

Drugs that produce sleepiness include antihistamines, which are used in allergy and pulmonary practice. Many of the early H_1 antihistamines, such as diphenhydramine and chlorpheniramine, have been shown to reduce the MSLT. Some newer antihistamines, such as terfenadine and astemizole, do not produce objective sleepiness. The more lipid-soluble drugs (i.e., diphenhydramine and chlorpheniramine) penetrate the central nervous system more easily and therefore are more likely than less lipid-soluble drugs to produce sedation. Other medications with high lipid solubility have been reported to produce daytime sedation; the most common of these are the beta-blocker drugs. There are no controlled, objective studies of sleep latency with this type of drug, and sleepiness from these medications is based on reports of side effects or subjective questionnaires, such as Pittsburg Sleep Quality Index (PSQI).[43]

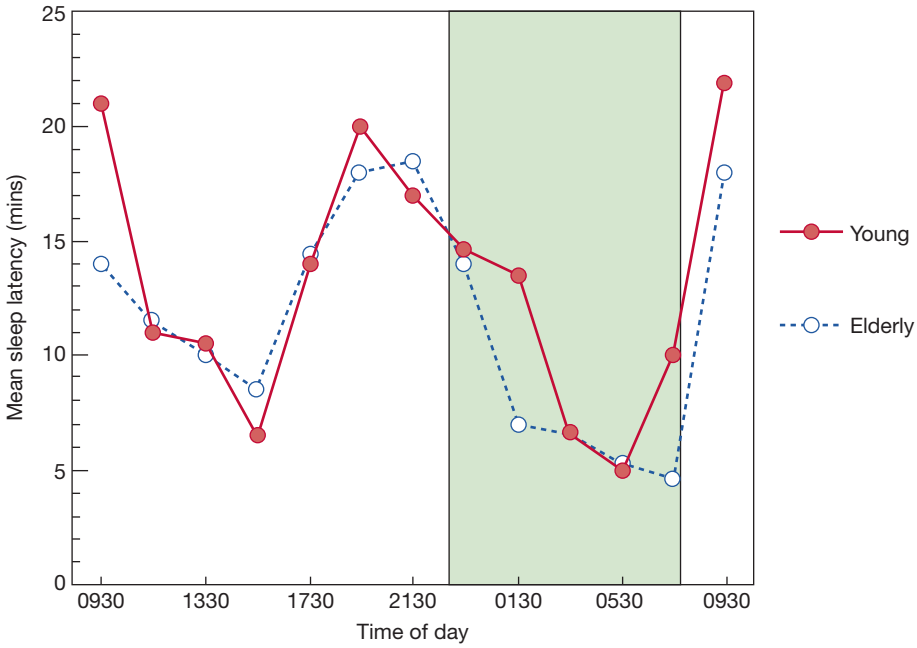

Figure 102-2 Sleep latency (mean) as a function of time of day for young subjects (*filled circles*) and elderly subjects (*open circles*). *Stippled area* denotes nighttime sleep period. *(Adapted with permission from Richardson GS, Carskadon MA, Orav EJ, et al. Circadian variation of sleep tendency in elderly and young adult subjects. Sleep. 1982;5(Suppl 2):S82–S94.)*

The effect of a particular drug in producing sleepiness also depends on the background level of sleepiness or alertness. When ethanol or caffeine is given to normal-sleeping young men in the morning, one might expect ethanol to produce daytime sleepiness and caffeine to increase sleep latency during the day. Subjects are consistently sleepier after ethanol than after caffeine ingestion, but fully rested subjects (those having spent 11 hours in bed) do not show sleepiness after taking ethanol. In other words, the sedative effects of drugs such as alcohol can be enhanced by increased background sleepiness. Thus, a driver who is sleepy to start with may be as vulnerable after just one or two drinks as a previously alert driver who has become legally intoxicated.[42]

Drugs that increase wakefulness or alertness include stimulants such as amphetamine, methylphenidate, modafinil, and armodafinil. These are most often used in the treatment of narcolepsy but may be used to stay awake for long periods of time. Caffeine, probably the most widely used stimulant, can reduce daytime sleepiness and transiently increase alertness. Excessive caffeine intake also paradoxically may cause a degree of daytime sleepiness. This occurs when caffeine levels persist into nocturnal hours and promote difficulties with sleep onset and increased awakenings during sleep.

In patients with narcolepsy, another agent, sodium oxybate (Xyrem) is used to treat EDS and cataplexy through action of $GABA_B$ and gamma-hydroxybutyrate (GHB) receptors.[44] While its mechanism of action is not completely clear, it has been shown to dramatically increase the amount and duration of slow-wave sleep in patients. While it is only given at night, due to its rapid onset of sedation, interestingly, the medication promotes alertness through the day shown in randomized trials.[45]

PREVALENCE OF EXCESSIVE DAYTIME SLEEPINESS

Prevalence rates for sleepiness depend greatly on the type of questions addressing sleepiness. Are you sleeping too much versus are you falling asleep during the daytime versus does your sense of sleepiness impair your daytime activities all result in widely different prevalence rates. Also men tend to report sleepy behavior whereas women report feelings of EDS, again contributing to variable prevalence. Prevalence of sleepiness also varies with the population examined.

There are many socioeconomic and demographic factors that may contribute to sleep disorders or poor sleep quality or quantity in the population. Specific associations with long SOL include being female, having black/African American heritage, lower education, lack of private health insurance, as well as food insecurity. The demographics were most associated, not only with prolonged SOL but with nonrestorative sleep as well as sleep maintenance difficulties, including early morning awakenings. EDS occurred more frequently in female gender and in divorced individuals.[46]

The Wisconsin Sleep Cohort study[47] was the first to formally determine the prevalence of sleepiness as a function of sleep apnea. This landmark study demonstrated that at least 2% of middle-aged women and 4% of middle-aged men had OSA and symptoms of EDS. More recent literature suggests 14% to 55% of the population has Obstructive Sleep Apnea Hypopnea Syndrome (OSAHS).[3] While there may have been other causes for the daytime sleepiness besides OSA, it is clear that sleep apnea is responsible for a great deal of the daytime sleepiness in North America.

EVALUATING THE SLEEPY PATIENT

Keeping in mind the factors that determine daytime sleepiness, the sleep history can be individualized and can be very helpful in narrowing the differential diagnosis (Table 102-3). One should always question the patient about his or her nocturnal sleep, looking specifically at sleep onset time, sleep period time, number of awakenings, and time of rising in the morning. One should also ask about when the change in sleep occurred as well as questions about sleep hygiene (i.e., when awake, reading book in dim light vs. playing games on an electronic device with bright light). Sleep onset phenomena such as sleep paralysis and hypnagogic hallucinations often suggest a diagnosis of narcolepsy although these sometimes occur in apneics who are severely sleep deprived.[48] A history of loud snoring or stopping breathing during sleep is suggestive of sleep apnea hypopnea syndrome, particularly if the snoring is "cyclical" rather than continuous, with periods of loud snoring or snorting alternating with quiet intervals. Since insufficient sleep may be the cause of sleepiness, it is important to ask if there is any difference in the amount of sleep required during the week compared with that on weekends. Equally important is whether the patient has any changes in subjective sleepiness on weekends or holidays compared with weekdays.

TABLE 102-3 Common Causes of Persistent Daytime Sleepiness

Obstructive sleep apnea and other sleep-disordered breathing conditions (e.g., neuromuscular weakness with nocturnal respiratory failure)
Narcolepsy/cataplexy syndrome
Sleep-related movement disorders (e.g., periodic limb movement disorder, bruxism, etc.)
Depression
Postviral fatigue
Head injury
Metabolic, toxic, and drug-induced hypersomnolence
Idiopathic hypersomnolence
Insufficient sleep
Circadian rhythm sleep disorders

In some instances, more information will be obtained from the spouse (or bed partner) or from a sleep/wake diary, since not all people are aware of the severity of their sleepiness. Moreover, patients may not understand the importance of good sleep hygiene; the diary can serve as a reminder for patients to be diligent about it.

In estimating the degree of daytime sleepiness, it is useful to ask when and during what activities the patient experiences sleepiness. Is the patient sleepy on awakening in the morning, or is it only by midday? Does the patient fall asleep while doing things or only when inactive? Driving to and from work are important times when sleepiness may become obvious, particularly while the person is waiting at a railroad crossing or stoplight. Episodes of automatic behavior, related to "microsleeps," often occur while one is driving. Do patients nap during the day, and if so, is the nap refreshing? Many patients with sleep apnea are still sleepy or foggy after a nap, whereas patients with narcolepsy most often feel refreshed immediately upon awakening.[26,29,49,50]

Since drugs can have a profound effect on sleep and sleepiness, a careful drug history is mandatory in the assessment of sleepiness. The clinician must remember to include queries not only about drugs that specifically affect sleep (hypnotics, sedatives, or other psychoactive medications) but also about substances that may not be considered to have any effect on sleep or waking. In particular, alcohol is a known precipitant or exaggerating factor for sleep apnea; patients will often report that they feel much worse the day after ingesting alcohol despite having had a nonintoxicating dose.[51]

It is important to remember that CNS pathology can independently contribute to EDS. While narcolepsy or idiopathic hypersomnia fall within the realm of sleep medicine, in other neurological

diseases (e.g., Parkinson disease) or neuromuscular diseases (e.g., myotonic dystrophy), EDS can be a presenting symptom that the pulmonologist should keep in the differential diagnosis. Apart from a general physical examination, one should pay particular attention to the size of the jaw, face, and upper airway, looking for obvious skeletal abnormalities—particularly retrognathia or micrognathia. One then carefully examines the upper airway, looking for nasal obstructions such as a deviated nasal septum or inflammatory allergic polyps; then, one examines the oropharynx, looking at the size of the tongue, the position of the soft palate, and the size of the uvula; finally one examines the larynx to rule out upper airway tumors or other obstructing lesions. While the typical sleep apnea patient will be the obese plethoric man with a thick neck, it is important to remember that examination of the awake, upright airway may bear no relationship to what happens when the patient is supine and asleep. Thus, the diagnosis of sleep apnea usually is confirmed by nocturnal polysomnography or a more limited home study (see further, Chapter 99).

The patient who has a history of snoring and daytime sleepiness but has no flow limitation, or sleep apnea or hypopnea during his or her nocturnal study must undergo an objective measure of daytime sleepiness, because some patients who claim to have substantial daytime somnolence are simply looking for compensation.[52] Also, some OSA patients will remain sleepy despite adequate treatment of their apnea and an additional sleep disorder may coexist. There may also be residual sleepiness in patients with mild to moderate OSA.[32] Again, daytime quantification of sleepiness will be necessary. The only disadvantage of the MSLT is that it is an inefficient test. Compared with objective measurements of airflow (i.e., an FEV_1), which take seconds to perform and interpret, the MSLT takes almost a whole day and provides only one piece of information. Until better tests are developed and validated, however, the MSLT will continue as a standard, albeit time-inefficient, objective measure of daytime sleepiness.

CONCLUSION

Sleep is important in health and wellness. Excessive sleepiness is a very common symptom. In patients with respiratory disease, a sleep disorder may be the presenting disease or may coexist with other disorders. Given the increasing prevalence of sleep disorders and their impact on health, it is imperative that there be a sound understanding of sleep medicine by practicing respirologists who are able to develop a relevant differential diagnosis for patients with excessive sleepiness and a management plan for their patients.

CHAPTER 103

Perioperative Respiratory Considerations in the Surgical Patient

Horace M. DeLisser
Michael A. Grippi

Postoperative pulmonary complications constitute a significant cause of morbidity and mortality following surgery. Managing patients at risk for postoperative pulmonary problems requires an understanding of the predictable changes in pulmonary physiology that occur with surgery and anesthesia, as well as knowledge of factors associated with development of postsurgical respiratory compromise. Despite the availability of several screening tests, a careful history and physical examination continue to be the cornerstone of preoperative pulmonary evaluation. Although a number of measures can be employed before and after surgery to minimize the risk of respiratory complications, close patient monitoring and early detection are essential.

This chapter focuses initially on changes in pulmonary function with surgery. Pulmonary risk factors before, during, and after surgery are reviewed prior to discussion of preoperative evaluation of the patient for surgery, including lung resectional surgery. Finally, recommendations are made regarding preoperative preparation and postoperative prophylactic measures. A more detailed discussion of the perioperative care of the patient undergoing resectional lung surgery is provided in Chapter 105 and development of acute respiratory failure in the surgical patient is addressed in Chapter 104.

CHANGES IN PULMONARY FUNCTION WITH SURGERY

Many postoperative respiratory complications relate to exaggerations of the expected postoperative changes in pulmonary function that occur as a result of the surgery itself, anesthesia, or various pharmacologic interventions.[1,2] Hence, an appreciation of normal postoperative pulmonary physiology is useful in understanding a number of pulmonary problems seen following surgery. Five principal categories of change in pulmonary function with surgery may be considered: (1) lung volumes, (2) diaphragm function, (3) gas exchange, (4) control of breathing, and (5) lung defense mechanisms (Table 103-1).

TABLE 103-1 Changes in Pulmonary Function with Surgery

Reduction in lung volumes
Diaphragm dysfunction
Impaired gas exchange
Respiratory depression due to residual effects of anesthesia or postoperative narcotics
Impaired cough and mucociliary clearance

LUNG VOLUMES

The pattern of pulmonary function abnormalities following thoracic and abdominal surgery is restrictive, characterized by moderate-to-severe reductions in vital capacity (VC) and smaller, but more important, reductions in functional residual capacity (FRC). The degree of impairment is similar after upper abdominal and thoracic surgery[3–5] and is less for laparoscopic procedures compared with open abdominal procedures.[6] Smaller changes in VC and FRC are noted with lower abdominal surgery; superficial or extremity surgery is usually not associated with any significant or persistent changes in lung volumes.[7,8] During the first 24 hours following upper abdominal surgery, VC and FRC may be reduced by more than 70% and 50%, respectively, and they may remain depressed for more than a week.[7–9] Consequently, it is not surprising that pulmonary complications are seen more often with thoracic and upper abdominal procedures than with surgery involving the lower abdomen or extremities (see discussion of intraoperative risk factors, below).

Reductions in other lung volumes, including total lung capacity (TLC), inspiratory capacity (IC), expiratory reserve volume (ERV), and residual volume (RV) have been noted. While the forced expiratory volume in 1 second (FEV_1) is decreased, the ratio of FEV_1 to the forced vital capacity (FEV_1/FVC%) remains unchanged, indicating that major airway obstruction does not occur.[4]

Since patients undergoing superficial or extremity surgery do not experience major changes in lung volumes, residual or carryover effects from general anesthesia do not appear to play a primary role in this regard. In fact, studies have shown that in many patients, FRC in the early postoperative period is unchanged from baseline. An alternative proposal for the reduction in FRC is that postsurgical pain and associated muscle splinting impair lung mechanics. However, while processes other than pain may be operative, based on the finding that effective pain control using epidural analgesia or intercostal nerve block fails to fully restore VC or FRC to preoperative levels,[10–12] this notion has been challenged.[13] The established consensus is that diaphragm dysfunction is an important contributing factor (see below).[2]

The postoperative reduction in FRC is of major physiologic significance. Its importance can be understood when the phenomenon of airway closure and the concept of closing capacity (CC) are considered.[4]

FRC is the lung volume at the end of a normal tidal expiration. CC is the lung volume at which small airways in the lung bases begin to close during expiration because of a reduction in airway radial traction. The relationship between the two is a key factor in the development of postoperative changes in lung function (Fig. 130-1). In a normal lung, FRC is always greater than CC, and the airways remain open throughout a tidal breath. However, when CC is greater than FRC, lung volume fails to increase sufficiently during tidal breathing to open all the airways and, consequently, some alveolar units remain closed during a breath. Such regions constitute areas of atelectasis. An intermediate state exists when CC exceeds lung volume for part of the time during each tidal breath. Under these circumstances, the airways open for only a portion of the respiratory cycle, creating areas of low ventilation relative to perfusion. In summary, any circumstance that reduces FRC below CC or that increases CC above FRC produces regions of reduced ventilation and atelectasis (Table 103-2).

DIAPHRAGM FUNCTION

Diaphragm dysfunction has been recognized as an important factor contributing to the postoperative reduction in lung volumes.[6,11–16] In patients undergoing cholecystectomy, the diaphragm's contribution

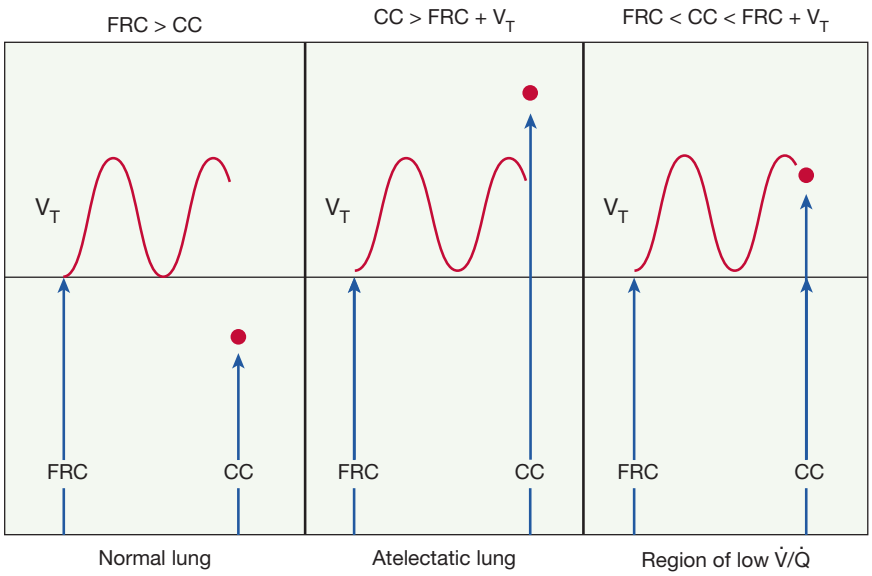

Figure 103-1 The relationship between functional residual capacity (FRC) and closing capacity (CC). V_T = Tidal volume. See text. *(Reproduced with permission from Goldmann DR, Brown FH, Guarnieri DM (eds). Perioperative Medicine. New York, McGraw-Hill; 1994.)*

to quiet tidal breathing after surgery is reduced.[14] Measurements of transdiaphragmatic pressure during maximal phrenic nerve stimulation following upper abdominal surgery indicate that decreased central nervous system output to the phrenic nerves, possibly as a result of inhibitory reflexes arising from sympathetic, vagal, or splanchnic receptors, may be the important etiologic factor.[15] Studies of the role of pain in this impairment have yielded conflicting results, pointing to either a limited[10–12] or significant[13] role for pain, depending on the procedures used for analgesia.

GAS EXCHANGE

Postoperative arterial hypoxemia occurs commonly, and two phases in its development may be described.[17,18]

The initial phase occurs in the first several hours following anesthesia and surgery. The underlying mechanisms are related largely to the residual effects of the anesthesia and include ventilation–perfusion mismatch, anesthetic-induced inhibition of hypoxic pulmonary vasoconstriction, right-to-left shunting, alveolar hypoventilation, depressed cardiac output, and increased oxygen consumption by peripheral muscles. This phase resolves within 24 hours following superficial surgery.

A second phase of hypoxemia, which may persist for several days or weeks, is seen after thoracic and upper abdominal surgery. This phase correlates with reductions in FRC and changes in the FRC–CC relationship. Although alterations in the FRC–CC relationship predominate, other processes may contribute to late postoperative hypoxemia: (1) alveolar hypoventilation (see discussion of control of breathing below); (2) increased dead space ventilation due to rapid, shallow breathing; and (3) decreased mixed venous oxygen tension due to increased oxygen consumption, impaired cardiac output, and reduced oxygen carrying capacity.

CONTROL OF BREATHING

Respiratory depression is a common feature of the postoperative period. Two factors are responsible. First, residual effects of preanesthetic or anesthetic agents inhibit respiratory drive and reduce the ventilatory response to hypercapnia, hypoxia, and acidosis.[19] Second, narcotics given for postoperative analgesia depress both hypercapnic and hypoxic ventilatory drives, resulting in decreased tidal volume, reduced minute ventilation, and increased Pa_{CO_2}.[20] Narcotics also alter the pattern of breathing, reducing the frequency of sighs or eliminating them entirely; in susceptible patients, narcotics may precipitate sleep apnea.

LUNG DEFENSE MECHANISMS

Several mechanisms protect the lung from environmental and infectious insults. Two of the most important – cough and mucociliary transport – are compromised after surgery, contributing to an increased risk of pulmonary infection.[4,21] Postoperative pain or excessive use of narcotics may inhibit coughing; in addition, altered lung mechanics decrease the expulsive force generated with each cough. Mucociliary clearance is impaired for up to a week following upper abdominal surgery. Although an ineffective cough reflex contributes significantly to reduced mucociliary clearance, several additional mechanisms are involved. These include (1) cilia damage from endotracheal intubation and inhalation of dry, hyperoxic gas mixtures; (2) reduced tracheal mucus velocity due to the presence of an endotracheal tube; (3) anesthetic-induced inhibition of mucociliary transport; and (4) atelectasis.

PULMONARY COMPLICATIONS

The criteria used for defining postoperative pulmonary morbidity have varied considerably in published reports,[22,23] although it is clear that, from a broad perspective, five major categories of complications may be considered: (1) atelectasis; (2) infection, including acute tracheobronchitis and pneumonia; (3) exacerbation of underlying chronic lung disease; (4) prolonged mechanical ventilation and respiratory failure; and (5) thromboembolic disease. With thoracic surgery, several additional problems may occur,[24–36] which are summarized in Table 103-3.

The variability in defining postoperative pulmonary complications has resulted in reported incidences that have ranged widely in the literature, depending on the patient population sampled and the procedures studied. In general, a healthy, young nonsmoker of normal weight has a very low risk of postoperative pulmonary complications (1% or less).[37] However, a number of factors have been identified that are associated with the development of postoperative pulmonary complications (Table 103-4).[22,23,38–41] They include preoperative factors (chronic lung disease, smoking, general state of health, age, obesity, nutritional status, and antecedent respiratory

TABLE 103-3 Pulmonary Complications Associated with Thoracic Surgery

Procedure	Complication	Incidence (%)	References
Coronary artery bypass grafting	Phrenic nerve damage[a]	10–20	24–26
	Pleural effusions (postpericardiotomy syndrome)	10–15	27
Lung resection surgery	Pleural space complications (bronchopleural fistula, prolonged air leaks, or empyema[b])	5–20	28–32
Median sternotomy	Sternal wound infection (mediastinitis or osteomyelitis)	1–4	33,34

tract infection), intraoperative factors (the emergent nature of the procedure, type and duration of anesthesia, location of surgical site, and type of surgical incision), and postoperative factors (inadequate pain control and immobilization). Tables 103-5 and 103-6 list, respectively, the relative strengths of preoperative and intraoperative factors associated with development of postoperative pulmonary complications based on odds ratios.[23,42]

PREOPERATIVE RISK FACTORS

A number of patient-related factors have been implicated in the development of postoperative respiratory complications.[23] They include the presence of chronic lung disease (particularly obstructive airway disease); the patient's overall state of health, age, and history of cigarette smoking; and the presence of comorbid conditions, including malnutrition, congestive heart failure, alcohol use, functional dependence, and impaired sensorium. The precise risk associated with recent respiratory viral infections is unknown. Obesity appears not to increase the risk for major postoperative pulmonary complications.

■ CHRONIC LUNG DISEASE

The following discussion focuses on the operative risks in patients who have one of four common categories of chronic lung disease: (1) chronic obstructive pulmonary disease (COPD), (2) restrictive lung diseases, (3) obstructive sleep apnea (OSA), and (4) pulmonary vascular diseases.

Chronic Obstructive Pulmonary Disease

Most studies addressing the impact of pre-existing lung disease on surgical risk have focused on COPD, which has been identified as a significant risk for development of postoperative pulmonary complications.[38,39,43–53] The reported incidence of postoperative pulmonary complications in patients with COPD varies from 10% to greater than 50% and is influenced by type of surgery, magnitude of pre-existing respiratory impairment, and criteria used to define complications. Although not precisely quantified in the literature, the risk for postoperative respiratory complications appears to increase significantly when the FEV_1 is below 65% of predicted. Evidence exists that the risk for postoperative respiratory complications in COPD may be raised further by the concomitant presence of resting hypoxemia.[54] Although an increased risk has been suggested for patients who are hypercapnic at rest,[43,55] whether hypercapnia is, in fact, an independent predictor of pulmonary complications after surgery is unclear.[56]

In patients with severe disease, an important issue is whether a critical level of lung function exists below which the risk of developing a major, potentially life-threatening pulmonary complication is so high as to make anesthesia and surgery too dangerous. In the past, such a prohibitive threshold or level was proposed. Subsequent studies, however, have failed to support this hypothesis.[57] Patients with an FEV_1 as low as 450 mL have been found to tolerate surgery safely.[55] Hence, patients should not be denied necessary operative procedures solely on the basis of marginal lung function. As with all medical interventions, the potential benefits of the operative procedure must be weighed against the operative risk.

TABLE 103-4 Factors Associated with Development of Postoperative Pulmonary Complications

Preoperative	Intraoperative	Postoperative
Chronic lung disease	Type of anesthesia	Immobilization
Smoking	Duration of anesthesia	Inadequate pain control
General state of health	Surgical site	
Age	Type of surgical incision	
Obesity		
Nutritional status	Emergent nature of the procedure	
Antecedent respiratory tract infection		

TABLE 103-5 Relative Strength of Preoperative Risk Factors Associated with the Development of Postoperative Pulmonary Complications

Factor	Odds Ratio
General state of health (ASA Class >II)	2.55–4.87
Congestive heart failure	2.93
Albumin <3.5 g/L	2.53
Age >60 y	2.09–3.04
COPD	1.79
Functional dependence	1.65–2.51
Weight loss	1.62
Impaired sensorium	1.39
Cigarette smoking	1.26
Alcohol use	1.21
Antecedent respiratory tract infection	Risk not known
Obesity	No increased risk for major morbidity

The increased incidence of postoperative pulmonary complications in patients with COPD is due, in part, to an increase in the CC, favoring development of areas of low ventilation-to-perfusion ratios and atelectasis. In addition, in patients who continue to smoke, impaired ciliary function and chronic tracheobronchitis may be contributing factors.

Restrictive Lung Diseases

The risk of pulmonary complications in patients with restrictive lung diseases who undergo surgery is unknown. Although some experience has been reported with patients having thoracic or corrective orthopedic surgery (see below), very little data exist with regard to abdominal and extremity surgery. One might expect a higher incidence of postoperative respiratory complications in these patients for two reasons: (1) FRC is reduced, favoring the formation of areas of poor ventilation and atelectasis; (2) coughing and the ability to clear respiratory secretions are impaired.

Experience with postoperative pulmonary complications has been reported in three relatively common situations for patients with restrictive disorders: (1) sarcoidosis complicated by aspergilloma and hemoptysis, (2) corrective surgery for kyphoscoliosis, and (3) myasthenia gravis with associated thymoma.

Sarcoidosis may progress to diffuse interstitial fibrosis and cavitary changes, primarily involving the upper lobes (see Chapter 55, Moller). The cavities are prone to infection with *Aspergillus* species and aspergilloma formation, with subsequent development of recurrent and, at times, life-threatening, hemoptysis. Affected patients generally have very poor lung function and, hence, are managed conservatively. However, if supportive medical therapy fails, patients may require thoracotomy and lung resection. These procedures can be done with low mortality, but they may be complicated by empyema, chylothorax, prolonged pulmonary parenchymal air leaks, or bronchopleural fistulae.[30–32]

Corrective surgery in patients with kyphoscoliosis may involve anterior or posterior spinal fusion procedures or a combination of the two.[58,59] In addition to correction of the primary orthopedic abnormality, an important indication for performing these procedures is progressive deterioration of pulmonary function. Postoperative respiratory complications have been reported in up to 20% of patients, including pleural space–related processes (e.g., pneumothorax, pleural effusion, bronchopleural fistula, and empyema) and lobar or total lung atelectasis.[59–61] Important risk factors include (1) nonidiopathic scoliosis, (2) open anterior spinal fusion procedures, (3) age greater than 20 years, (4) mental retardation, (5) preoperative hypoxemia, and (6) obstructive pulmonary function tests.[60] Thoracotomy has been associated with a significant decrease in pulmonary function for up to 2 years after surgery.[59,62] Video-assisted thoracoscopic surgery (VATS) has emerged as an alternative to open thoracotomy; the outcomes of anterior fusion via VATS and thoracotomy are similar.[63,64]

The majority of patients with myasthenia gravis will, during the course of their disease, undergo thymectomy, which appears to improve long-term outcomes.[65] Surgical options for thymectomy include the long-established method of transsternal resection, a transcervical approach, a combined transsternal–transcervical procedure, and, more recently, VATS.[66,67]

Historically, up to 30% of patients undergoing thymectomy required mechanical ventilation for more than 3 days following the transsternal approach.[68,69] Reported risk factors for postoperative pulmonary complications following transsternal resection include chronic myasthenia gravis (>6 years), severe bulbar weakness, preexisting respiratory illness, need for large doses of pyridostigmine, and reduced maximal static expiratory pressure (<50 cm H_2O or 66% of predicted).[68–70] Preoperative VC has not proved a consistent predictor of respiratory morbidity following thymectomy. More recent routine use of plasma exchange in patients with bulbar or generalized myasthenia gravis has significantly reduced the duration of postoperative ventilatory support and time in the intensive care unit following transsternal thymectomy.[66]

Video-assisted thoracoscopic thymectomy is an increasingly common approach, with outcomes equivalent or superior to more invasive procedures.[67]

Virtually all patients with myasthenia gravis are treated with anticholinesterases, which are usually discontinued prior to surgery to minimize tracheobronchial secretions. Controversy exists, however, regarding whether these agents should be restarted immediately after surgery or withheld for 24 to 48 hours following thymectomy.

Obstructive Sleep Apnea

OSA is common, with a prevalence of 5% or higher, depending on the population studied (see Chapter 99, Pien and Rosen). For many of these patients, the diagnosis of OSA is not established preoperatively.[71] Unrecognized OSA is significant, because both anesthesia and surgery affect sleep architecture; in addition, use of postoperative narcotics for analgesia may further blunt ventilatory chemosensitivity, suggesting that postoperative respiratory morbidity is likely higher in patients with OSA than in the general population. Although initial studies were consistent with this expectation,[72] subsequent reports have failed to show that OSA is significant risk factor for development of major postoperative pulmonary complications.[73–75] Thus, while it is prudent and in the patient's best interest to use the preoperative evaluation as an opportunity to screen for OSA, the value of preoperative screening for OSA as a means of decreasing postoperative pulmonary complications has not been established.

Pulmonary Vascular Diseases

The risk of postoperative pulmonary complications in patients with underlying pulmonary vascular disease and intact respiratory mechanics is not known. However, one might anticipate an exaggeration of, or prolongation in, the hypoxemia seen postoperatively

(see discussion of gas exchange, above). In addition, pulmonary reserve in these patients is usually reduced; hence, additional pulmonary insults are less likely to be tolerated.

SMOKING HISTORY

That smoking increases the risk of postoperative respiratory complications, even among those without COPD, has long been recognized.[44,76] Given the well-documented adverse effects of smoking on respiratory epithelium and pulmonary function, the magnitudes of which correlate with the degree of tobacco consumption, such an association is not surprising.

In individuals undergoing coronary artery bypass graft surgery, the risk of smoking becomes significant when tobacco use exceeds 20 pack-years.[77] A statistically significant reduction in complications occurs only when patients discontinue smoking for at least 8 weeks prior to surgery. This finding is consistent with studies showing that abnormalities in pulmonary function may persist up to several months after smoking cessation.[78,79] Although smoking cessation of more than 2 months is associated with a decreased risk of postoperative respiratory complications, early retrospective studies actually showed a paradoxical *increase* in pulmonary complications in patients who stopped smoking only a few weeks or days prior to surgery.[80] However, more recent studies[81] and analyses[82] have failed to demonstrate increased pulmonary complications in patients who quit smoking within 2 months of surgery.

GENERAL STATE OF HEALTH

Overall clinical status, as categorized by the American Society of Anesthesiologists' (ASA) classification (Table 103-7), correlates with development of postoperative pulmonary complications.[50,83–85] Specifically, an ASA classification of II or higher is a powerful predictor of increased risk for respiratory problems after surgery.[23]

AGE

Although increased age was previously thought to be a minor risk factor for postoperative respiratory complications,[86] more recent analyses indicate that increasing age is, in fact, a significant independent predictor, even after accounting for comorbid conditions associated with aging.[23] Advanced age, however, should not be the sole reason for withholding surgery, particularly lung resection.

In one important study, despite the finding of a higher 30-day postoperative mortality in patients over age 70 years who underwent resectional lung surgery, the incidence of postoperative pulmonary complications and hospital stay were not increased, and survival was not decreased, in the older group.[87] More recently, in a nested, case-control study of patients greater than age 70 years who underwent lung resection, no significant differences were found between the elderly and younger controls in length of stay, major morbidity, or operative mortality.[88] These findings, along with other published results,[89] indicate that treatment decisions should be individualized for each patient.

TABLE 103-7 American Society of Anesthesiologists' (ASA) Clinical Classification

ASA I	Otherwise healthy patient undergoing elective surgery
ASA II	Patient with single system or well-controlled disease that does not affect daily life
ASA III	Patient with multisystem or well-controlled major system disease that limits daily activity
ASA IV	Patient with severe, incapacitating disease that is poorly controlled or end stage
ASA V	Patient who is in imminent danger of death and is not expected to survive 24 h

OBESITY

A number of changes in respiratory mechanics and pulmonary function occur with obesity.[90–93] The accumulation of fat in the chest wall, diaphragm, and abdomen may reduce total respiratory compliance by more than 60%—a change that is amplified when the patient assumes the supine position.[94] The reduced compliance, in turn, increases the work of breathing.[90,91] Consequently, minute ventilation, oxygen consumption, and carbon dioxide production are further increased beyond baseline values, which are already elevated as a result of increased metabolic demands imposed by the obese state. In terms of gas exchange, modest effects at rest are observed only in morbidly obese individuals: lower than predicted Pa_{O_2}, higher than predicted alveolar-to-arterial oxygen pressure difference, normal blood oxygen saturation, and normal Pa_{CO_2}.[95]

Typically, spirometry in obese patients does not indicate airway obstruction. However, a reduction in ERV is found consistently. The magnitude of the reduction correlates with the degree of obesity. Areas of low ventilation relative to perfusion and atelectasis are seen (see discussion of lung volumes, above). In addition to these changes, obese patients appear to have a larger gastric volume and lower gastric pH than do nonobese patients and may be predisposed to aspiration.[96]

Morbidly obese patients may be at an increased risk for development of atelectasis, as noted on chest radiographs.[97,98] However, when bacterial pneumonia, acute respiratory failure, or prolonged mechanical ventilation are considered, and confounding factors are excluded, obese patients undergoing abdominal surgery do not show an increased incidence of clinically significant postoperative pulmonary complications compared with nonobese patients.[37,99–101] Major respiratory complications occur in only 4% to 7% of morbidly obese patients undergoing gastric bypass surgery; therefore, in the absence of concurrent cardiopulmonary disease, the risk of postoperative pulmonary complications associated with obesity appears not to be excessive.[102] However, as noted previously, obesity is clearly a risk factor for OSA syndrome, which may be unmasked or exacerbated because of use of postoperative analgesics or narcotics.[103]

NUTRITIONAL STATUS

The effects of malnutrition and severe starvation on the respiratory system include a reduced ventilatory response to hypoxia, decreased diaphragmatic muscle function, impaired cell-mediated and humoral immunity, and alterations in the elastic properties of the lung. Depending on the clinical metrics examined (e.g., weight loss >10% over the previous 6 months, BMI <20 kg/m^2), the screening procedures utilized (e.g., Mini Nutritional Assessment (MNA) score <17), and the laboratory tests employed (e.g., serum albumin <36 g/L), malnutrition may be found in 50% or more of hospitalized patients.[104,105] Evidence exists that these levels of malnutrition are associated with expiratory muscle weakness (despite preservation of pulmonary function)[106] and an increased incidence of postoperative respiratory complications.[38,99,107,108] However, aggressive preoperative nutritional support has not been shown to decrease postsurgical pulmonary morbidity.[109]

ANTECEDENT RESPIRATORY TRACT INFECTION

The effects of an antecedent respiratory tract infection on the incidence of respiratory complications following surgery are difficult to predict. With respiratory syncytial virus (RSV) infections, symptoms typically resolve in 7 to 10 days; viral shedding averages 10 to 13 days, but it may persist beyond 20 days.[110,111] Furthermore,

enhanced airway reactivity and increased airway resistance associated with this and other viral infections may persist for weeks beyond resolution of acute symptoms.[112,113] In addition, diaphragmatic function may be impaired during viral infections.[114]

In pediatric patients, perioperative, nonlife-threatening, adverse respiratory events are more common in patients with recent (within 4 weeks) upper respiratory tract infections compared with those without infections.[115,116] In an adult population, history of an acute respiratory infection in the month preceding surgery is an independent risk factor for development of a postoperative pulmonary complication.[41] Therefore, in the setting of an active or recent respiratory tract infection (in the previous 2 weeks), a 2- to 4-week delay in elective surgery is generally advised.

OTHER PATIENT-RELATED FACTORS

Other factors have been reported to be associated with an increased incidence of postoperative pulmonary complications.[23] These include congestive heart failure,[41,117,118] preoperative functional dependence, impaired sensorium (acute confusion or delirium), and active alcohol use (>2 drinks per day in the past 2 weeks).[38,39]

INTRAOPERATIVE RISK FACTORS

Several operative factors have been associated with development of pulmonary complications after surgery. These include whether the surgery is emergent or nonemergent, type of anesthesia used, length of the procedure (as determined by the duration of anesthesia), surgical site, and type of surgical incision.

EMERGENT NATURE OF THE PROCEDURE

Postoperative pulmonary complication rates are higher for surgeries done on an emergent basis.[38,39,41,47,48,117] The increased risk of emergency surgery may be significant[23] and may be related to loss of the ability to implement some of the preventative measures outlined subsequently or to deliberately plan the anesthetic strategy.

TYPE OF ANESTHESIA

The pulmonary effects of general anesthesia have been implicated in the development of postoperative pulmonary complications.[38,39,50,51] They include impairment of oxygenation and carbon dioxide elimination. These effects result from anesthetic-induced changes in the shape and motion of the chest wall and diaphragm, which, in turn, lead to increases in alveolar dead space, shunt fraction, and ventilation–perfusion mismatching. Alterations in lung function may contribute to pulmonary morbidity.

Because of the effects of general anesthesia on gas exchange, regional anesthesia (spinal or epidural anesthesia) or local anesthesia with monitored anesthesia care (MAC) has been used as alternatives, particularly in patients with underlying pulmonary disease. Indeed, epidural anesthesia to a T4 sensory level does not appear to alter FRC, VC, FEV_1, the alveolar–arterial oxygen gradient, shunt fraction, or cardiac output.[119] Overall, regional anesthesia, as compared to general anesthesia, decreases the risk of postoperative respiratory complications, particularly deep vein thrombosis.[120,121] These beneficial effects, however, appear to be most significant for abdominal and thoracic procedures[122,123] and less so for nonthoracoabdominal procedures, such as carotid endarterectomy[124,125] and hip fracture surgery.[126,127]

DURATION OF ANESTHESIA

The incidence of pulmonary complications increases significantly for procedures lasting longer than 2 to 4 hours.[41,44,45,69,84] Patients whose procedures last 4 hours or more are five times more likely to experience postoperative pneumonia than those whose procedures last less than 2 hours.[99]

SURGICAL SITE

Development of postoperative pulmonary complications has long been recognized to correlate strongly with the anatomic site of operation.[41,44,45,69,84] The complication rate (excluding thromboembolic disease) is less than 5% for gynecologic and urologic procedures, 5% to 10% for lower abdominal and head and neck surgeries, and 10% to 20% for upper abdominal surgeries. Abdominal aortic surgery is associated with a pulmonary complication rate of 25% or more.[23]

Reported postoperative complication rates for thoracic surgery involving lung resection vary from under 10% to 40% or higher.[128–133] Postoperative respiratory morbidity following lung resection surgery (in addition to all the factors cited earlier) also depends on a number of other issues, including (1) the presence of underlying lung disease, (2) the amount of functional lung removed, and (3) the extent to which the "bellows" function of the lung is impaired (see discussion of evaluation for lung resection below). Furthermore, the potentially higher incidence of postoperative respiratory complications after lung resection surgery relative to other procedures also reflects the occurrence of specific problems related to entering the pleural space or resection of lung tissue (e.g., development of pleural effusion, empyema, pneumothorax, or persistent pulmonary parenchymal air leak).

TYPE OF SURGICAL INCISION

For abdominal procedures, vertical laparotomy incisions may carry a higher incidence of postoperative complications than do horizontal incisions,[134] although this finding has been questioned.[135] Abdominal laparoscopic procedures and thoracoscopic lung resection have gained widespread acceptance because of reduced patient discomfort, shortened length of hospitalization, and faster patient return to full activity. Since the magnitude of incisional pain is usually less, and since patients typically ambulate sooner, the incidence of postoperative respiratory complications with these less invasive procedures is likely to be lower. Laparoscopic cholecystectomy, when compared with open cholecystectomy, demonstrates better preservation and faster recovery of lung volumes, higher arterial oxygen saturations, less postoperative pain and analgesia use, and a lower incidence of postoperative pulmonary complications.[136–138] Comparable findings have been noted for minimally invasive esophagectomies compared with open procedures, and for video-assisted thoracic surgery versus open thoracotomy.[29]

POSTOPERATIVE RISK FACTORS

Inadequate pain control, prolonged bed rest, and patient inactivity contribute to development of postoperative respiratory complications.

INADEQUATE POSTOPERATIVE ANALGESIA

Effective pain control is vital in the early postoperative period, since pain inhibits coughing and deep breathing and discourages early mobilization—factors that contribute to an increased risk of pulmonary complications. More importantly, there is evidence that effective analgesia after thoracic or abdominal surgery reduces the occurrences of postoperative pulmonary complications.[139–142] Obstacles to good postoperative analgesia include hesitancy of the patient to report pain for fear of being labeled a "bad" patient and anxiety of caregivers in administering narcotics because of side effects.

IMMOBILIZATION

Prolonged bed rest and inactivity following surgery impact the risk of postoperative respiratory complications in several ways. FRC decreases by 500 to 1000 mL in moving from the upright to the supine position, favoring development of atelectasis.[18] Increased ambulation is associated with better clearance of respiratory secretions. Postoperative immobilization is a major risk factor for development of deep venous thrombosis and pulmonary embolism.

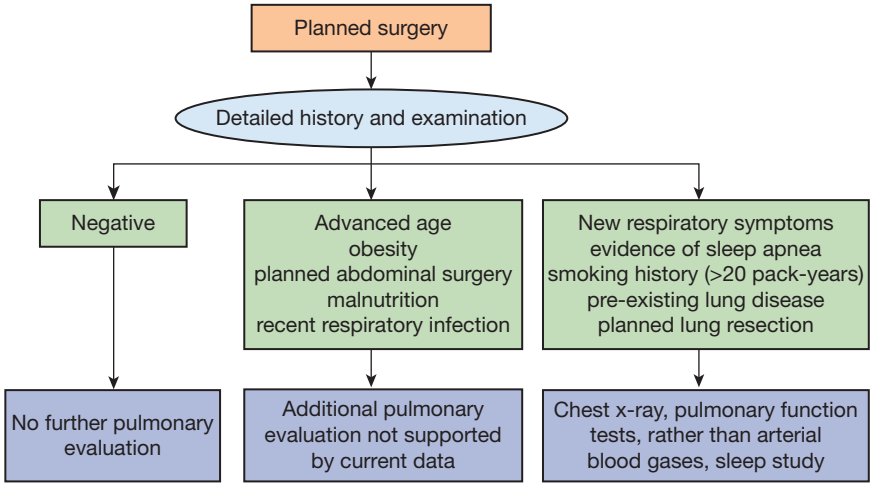

Figure 103-2 Algorithm for preoperative pulmonary evaluation. See text for discussion.

PREOPERATIVE EVALUATION

The principal elements in preoperative evaluation of the surgical patient are (1) the history and physical examination, (2) the chest radiograph, (3) arterial blood gas analysis, and (4) pulmonary function tests (Fig. 103-2).

HISTORY AND PHYSICAL EXAMINATION

A careful history is an essential component of preoperative evaluation. The following issues should be reviewed: (1) smoking history; (2) history of respiratory symptoms (e.g., cough, chest pain, dyspnea), including symptoms of sleep apnea; (3) extent of preexisting lung disease; and (4) history of recent respiratory tract infection. The physical examination is rarely helpful in identifying pulmonary risk factors. When the history is negative, the physical examination is typically unremarkable. However, the initial physical examination supplements the history and provides a baseline for future comparisons.

CHEST RADIOGRAPH

The preoperative chest radiograph is usually unrevealing if risk factors and abnormal physical findings are absent.[143,144] Although the admission or screening chest radiograph is more likely to show an abnormality in individuals with known cardiopulmonary disease, the study usually simply confirms the presence of previously known abnormalities; only occasionally does it result in an alteration in management. Thus, a preoperative chest radiograph is indicated when there are new or unexplained symptoms or signs, when there is a history of underlying lung disease and no recent chest radiograph, or when thoracic surgery is planned.

ARTERIAL BLOOD GAS ANALYSIS

Since an elevated Pa_{CO_2} is associated with an increased incidence of postoperative respiratory morbidity in patients with significant chronic lung disease, an arterial blood gas analysis should be done preoperatively in these patients.[54] Although supportive data are lacking, it is common practice to obtain an arterial blood gas sample in all patients undergoing lung resection surgery, even those without significant underlying lung disease. The determination serves as a basis for comparison with subsequent intra- and postoperative measurements. It is also recommended that an arterial blood gas specimen be obtained in patients who, by either history or physical examination, have a new significant pulmonary process. Data do not support the use of arterial blood gas analysis as a routine preoperative screening test.[145]

PULMONARY FUNCTION TESTS

An increased risk of postoperative respiratory complications has been demonstrated only with obstructive pulmonary disorders. Although theoretical reasons may prompt expectation of a higher incidence of postoperative respiratory problems in patients with restrictive lung diseases (see discussion of preoperative risk factors, above), currently, data demonstrating a correlation between the degree of restriction (as assessed by lung volumes) and postoperative pulmonary morbidity are lacking. Hence, although a complete battery of pulmonary function tests is useful in evaluating suspected restrictive lung disease, spirometry to evaluate for airway obstruction is all that is required to screen patients at risk for postoperative pulmonary complications.

Indications for preoperative pulmonary function testing include the presence of cough or unexplained dyspnea, a history of chronic lung disease, a history of cigarette smoking (>20 pack-years), or planned lung resection (see below). Current data do not support the routine use of these studies to evaluate the pulmonary risks of advanced age, obesity, malnutrition, or abdominal surgery.[146–149] Finally, normal pulmonary function tests obviously do not guarantee a complication-free postoperative course and do not lessen the need for diligent respiratory care following surgery.

EVALUATION FOR LUNG RESECTION

In evaluating patients for lung resection, the clinician must consider two broad issues: (1) What is the surgical morbidity and mortality for the patient with significant underlying chronic lung disease? (2) Will postoperative lung function be adequate to support a reasonable quality of life? Pulmonary function testing, supplemented by exercise testing in selected cases, provides the basis for answering these questions.[150,151]

PULMONARY FUNCTION TESTING

Studies dating back to the 1950s have shown that the risk of postoperative respiratory complications following pneumonectomy increases significantly when the FEV_1 is less than 2 L or 80% of predicted normal, or when the maximal voluntary ventilation (MVV) is less than 50% of predicted.[152] For a lobectomy, an FEV_1 of 1.5 L appears to be the critical threshold. The diffusion capacity for carbon monoxide (D_{LCO}) has also been identified as a predictor of postoperative complications.[153,154] Increased risk is associated with a D_{LCO} of less than 60% to 80% of predicted and appears to be independent from FEV_1 as a predictor of complications, morbidity, and death.[155–157] Therefore, predictive postoperative lung function should be estimated for patients with an FEV_1 or D_{LCO} less than 80% of predicted.[150,151]

PREDICTION OF POSTOPERATIVE FEV_1 OR D_{LCO}

Ventilation–perfusion lung scans measure the relative blood flow or ventilation to one lung or lung region and can be used to predict postoperative FEV_1 or D_{LCO} using the following equation:

$$\text{Predicted postoperative } FEV_1 \text{ or } D_{LCO} = \text{Preoperative } FEV_1 \text{ or } D_{LCO} \times (\text{lung function remaining after resection, as determined by radionuclide imaging}) \quad (1)$$

An alternative approach to estimating the predicted postoperative pulmonary function involves a calculation based on the number segments of the lung (10 on the right and nine on the left)[158] as follows:

Predicted postoperative FEV_1 or D_{LCO} = Preoperative FEV_1 or D_{LCO} × (lung function remaining after resection, as determined by radionuclide imaging) (2)

Studies comparing the radionuclide imaging-based technique versus the segment-based method suggest that perfusion imaging, overall, provides a better prediction of postoperative lung function, as the segment method underestimates lung function after pneumonectomy.[159,160]

In addition to the two methods noted earlier, other approaches have been employed to predict postresection lung function. However, procedures such as quantitative computed tomographic imaging,[161] have failed to gain wide acceptance, and oxygen-enhanced MRI,[162] although promising, awaits further development.

A number of studies have demonstrated that the perioperative risk for lung resection increases significantly when the predicted postoperative FEV_1 or D_{LCO} has <40% of predicted.[153,163–166] Therefore, a predicted postoperative FEV_1 or D_{LCO} ≥40% predicted has been proposed as useful criteria for undertaking "safe" pulmonary resection.[150,167] Finally, with recognition that most patients who undergo resectional lung surgery have lung cancer, and that this malignancy has virtually a 100% mortality without surgery (for nonsmall cell tumors), caution must be exercised in applying exclusionary criteria for surgery.

EXERCISE TESTING

A number of investigators have found measurement of maximal oxygen consumption (V_{O_2max}) during cardiopulmonary exercise testing to be useful in predicting postoperative morbidity and mortality.[168–172] Specifically, a $\dot{V}_{O_2\ max}$ of less than 15 to 20 mL/kg/min is associated with an increased incidence of postoperative complications. Cardiopulmonary exercise testing is, therefore, used to further assess the operability of patients of who would be at high risk for surgery based on determination of predicted postoperative pulmonary function.[150]

If cardiopulmonary exercise testing is unavailable, two technologically simpler approaches, stair climbing and a walking test, can be used to assess a patient's fitness for lung resection. Although standardization of the stair climbing test may be problematic, demonstration of a patient's ability to climb five flights of stairs predicts a $\dot{V}_{O_2\ max}$ >20 mL/kg/min; patients who are unable to climb one flight of stairs have a $\dot{V}_{O_2\ max}$ <10 mL/kg/min.[173] Furthermore, an ability to climb three flights of stairs reliably identifies patients who are likely to do well after a lobectomy, despite having a predicted postoperative FEV_1 or D_{LCO} that is <40% of predicted.[174,175]

The shuttle walk and 6-minute walk tests have also been investigated as alternatives to cardiopulmonary exercise testing. For the shuttle walk, the patient walks back and forth over a distance of 25 m at a progressively faster rate. Inability to complete 25 shuttles approximates a $\dot{V}_{O_2\ max}$ <10 mL/kg/min.[176,177] A 6-minute walk distance >1000 ft has been reported as predictive of successful surgical outcome.[164]

RECOMMENDED APPROACH

Summarized in Fig. 103-3 is a recommended sequence for evaluating patients for lung resection. The approach is adapted from

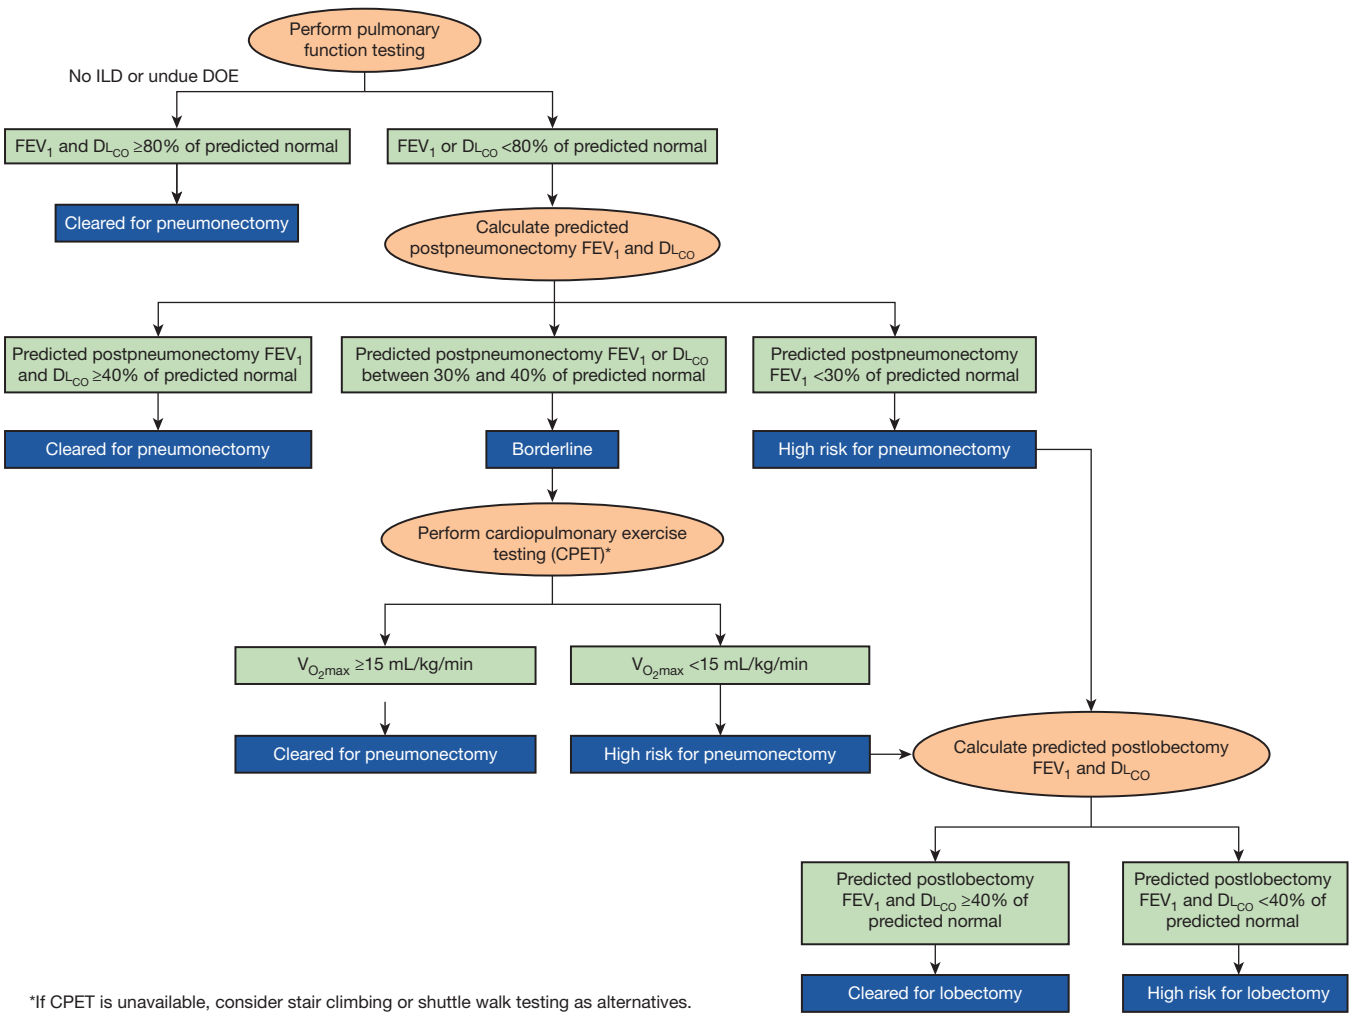

Figure 103-3 Algorithm for preoperative evaluation for lung resection. See text for discussion. ILD, interstitial lung disease; DOE, dyspnea on exertion.

recommendations of the American College of Chest Physicians (ACCP),[150] which, despite some differences, is also consistent with guidelines from several European professional societies.[151,167] The approach is predicated on determining the patient's operability for pneumonectomy, should this procedure be deemed necessary at the time of surgery (e.g., to permit complete removal of a tumor or to deal with an unanticipated intraoperative complication):

- If the preoperative FEV_1 and the D_{LCO} are ≥80% predicted normal and the patient has no dyspnea on exertion or interstitial lung disease, the patient is cleared for pneumonectomy; no further testing is required.
- If the preoperative FEV_1 or the D_{LCO} are <80% predicted normal, the predicted postpneumonectomy FEV_1 and D_{LCO} should be estimated.
- If the predicted postpneumonectomy FEV_1 and D_{LCO} are ≥40% of predicted normal, the patient is cleared for pneumonectomy and no further testing is required.
- If the predicted postpneumonectomy FEV_1 is <30% predicted normal, the patient is considered at high risk for a pneumonectomy.
- If the patient is considered at borderline risk for pneumonectomy (the predicted postoperative FEV_1 or D_{LCO} is <40% but ≥30 predicted normal), exercise testing should be done. Borderline patients with a $\dot{V}_{O_2\ max}$ ≥15 mL/kg/min are cleared for pneumonectomy (no further testing is required), while patients with $\dot{V}_{O_2\ max}$ <15 mL/kg/min are considered at high risk for a pneumonectomy.
- If the patient is determined to be at high risk for pneumonectomy, the predicted postlobectomy FEV_1 and D_{LCO} should be determined to inform conversations about the risks and benefits of more limited surgical resections or nonoperative treatment options.

For selected, high-risk patients with emphysema and potentially resectable lung cancer, consideration should be given for a segmental resection[178] or combined cancer resection and lung volume reduction.[179] The latter is particularly worth considering if the emphysema is heterogeneous and primarily involves the lobe to be resected.

PREOPERATIVE PREPARATION

Relatively few studies have specifically addressed the question of whether aggressive, preoperative pulmonary preparation decreases postoperative pulmonary morbidity and mortality.[180] Although data on preoperative preparation are limited, for patients with active obstructive airway disease, intensive preoperative respiratory therapy (bronchodilators, corticosteroids, antibiotics, and chest physiotherapy) does appear to reduce the incidence of postoperative respiratory complications by more than 50%.[84,181–183]

Several preoperative prophylactic measures should be considered in patients undergoing elective surgery (Table 103-8).

Pulmonary function in patients with obstructive airway disease should be optimized. Therapy may include any or all of the following: bronchodilators, corticosteroids, antibiotics (when there is evidence of infection), and chest physiotherapy (if excessive secretions are present). When possible, these interventions should be implemented 48 to 72 hours prior to surgery.

Ideally, for at least 8 weeks prior to surgery, smoking should be discontinued. As noted previously, recent data indicate that complication rates are not increased by shorter periods of abstinence; therefore, even when 8 weeks of abstinence is not possible, patients should still be advised to quit smoking prior to surgery.[81,82]

A program of inspiratory muscle training for at least 2 weeks prior to surgery may reduce the incidence of postoperative pulmonary complications in patients at high risk for their development.[184]

Finally, patient education on the importance of postoperative coughing and pain control, proper use of an incentive spirometer, and deep breathing exercises should take place preoperatively.

POSTOPERATIVE PROPHYLACTIC MEASURES

Several postoperative measures may be employed in an attempt to prevent respiratory complications (Table 103-9).

Early patient mobilization and ambulation should be encouraged. As noted previously, these measures are important postoperatively in reducing the incidence of atelectasis, in promoting the clearance of secretions, and in decreasing the risk of thromboembolic disease.

Prophylactic lung expansion maneuvers should be initiated.[185] Two equally effective measures are deep breathing exercises and incentive spirometry.[186,187] Intermittent positive pressure breathing (IPPB) is generally ineffective and costly and is associated with several adverse effects.[185] Reports of intermittent continuous positive airway pressure (CPAP) applied by face mask indicate that it is at least equivalent to deep breathing exercises and incentive spirometry in preventing atelectasis and pneumonia.[188]However, while CPAP may be useful in the patient who cannot cooperate with inspiratory maneuvers, its role in the management of patients capable of taking deep breaths is unclear.

Adequate analgesia should be provided, particularly for patients undergoing major, open surgery. Traditionally, parenteral narcotics have been used for postoperative analgesia, despite the risk of respiratory depression. Unfortunately, concerns over adverse respiratory effects may lead to inadequate dosing and inadequate pain relief. To overcome this problem, alternative approaches, including use of epidural analgesia, peripheral nerve blockade, paravertebral block, and wound catheter infiltration may be employed as alternatives to the use of systemic opioids.[189] These alternative techniques provide analgesia equivalent or superior to parenteral narcotics; however, whether they are effective in reducing postoperative pulmonary complications remains unclear.

Prophylaxis for thromboembolism is an important consideration,[190] and careful monitoring for other postoperative complications constitutes a key element in all surgical patients.

TABLE 103-8 Preoperative Pulmonary Preparation

Optimization of airway function in patients with obstructive lung disease (bronchodilators; corticosteroids, antibiotics, and chest physiotherapy, when indicated)
Smoking cessation (ideally, a minimum of 8 wk prior to surgery)
Patient education (deep breathing exercises, importance of coughing and pain control, use of incentive spirometry)
Consider inspiratory muscle training

Finally, several postoperative interventions have been shown to be ineffective, including chest physiotherapy in the absence of excessive secretions or sputum production,[191] and routine application of positive end-expiratory pressure in mechanically ventilated patients.[192]

CHAPTER 104

Acute Respiratory Failure in the Surgical Patient

Robert M. Kotloff

INTRODUCTION

Advances in surgical technique, anesthesia and analgesia, and postoperative supportive care have emboldened surgeons to consider an expanding spectrum of patients for surgical interventions. In most instances, the success or failure of the surgery is defined not in the operating room, but postoperatively, when the adverse effects of surgery may first become apparent and when intercurrent complications may jeopardize the patient's recovery. The respiratory system is particularly vulnerable to the effects of general anesthesia and surgery, and postoperative respiratory impairment is common. While generally mild and well tolerated in otherwise healthy, young patients, postoperative respiratory compromise may have serious consequences in the elderly and in patients with pre-existing lung disease. A number of postoperative complications, such as pneumonia, aspiration pneumonitis, and acute respiratory distress syndrome (ARDS) may lead to respiratory compromise independent of the patient's presurgical status.

This chapter focuses on the most serious consequence of perioperative respiratory compromise—acute respiratory failure. This complication is associated with a 30-day mortality rate in the range of 25% following major surgical procedures, compared to approximately 1% for unaffected patients.[1] In addition to its adverse impact on survival, respiratory failure prolongs intensive care and hospital stay, delays convalescence, and increases healthcare costs among survivors. Clinicians who provide preoperative evaluation and postoperative care must be able to identify high-risk patients who require a greater degree of vigilance, and to rapidly recognize and appropriately treat the complications that result in postoperative respiratory failure.

IDENTIFICATION OF THE HIGH-RISK PATIENT

There have been several published studies using large databases that have provided insight into the incidence of postoperative respiratory failure, its impact on survival, and factors associated with increased risk. In one of the earliest surveys involving over 7000 patients undergoing various gastrointestinal, urological, gynecological, and orthopedic procedures, respiratory failure requiring mechanical ventilation beyond 24 hours occurred in only 0.8%.[2] More recently, analysis of a database of 180,359 patients undergoing major general or vascular surgical procedures at 128 Veterans Affairs hospitals and 14 private sector hospitals documented a 3% incidence of postoperative respiratory failure (defined as mechanical ventilation beyond 48 hours after surgery or need for reintubation).[1] Thirty-day mortality was 27% for the group with respiratory failure compared to only 1.4% for those without. Twenty-eight variables were identified that were independently associated with increased risk. These included higher American Society of Anesthesiologists (ASA) class, preoperative sepsis, emergency as opposed to elective procedure, impaired preoperative renal function, history of smoking or COPD, and older age. The type of procedure also impacted risk (Table 104-1), with the greatest incidence of respiratory failure associated with upper aerodigestive tract surgery, thoracic or thoracoabdominal aneurysm repair, thoracic surgery, and gastrointestinal and hepatobiliary surgery. The investigators incorporated the 28 variables (Table 104-2) into a respiratory risk index (Table 104-3) to predict the likelihood that a patient will develop respiratory failure and validated it using a second patient cohort. Unfortunately, the complexity of the model renders it unwieldy and has limited its widespread acceptance.

In the largest study of this nature to date, investigators used the 2007 American College of Surgeons National Surgical Quality Improvement Program (NSQIP) database of over 210,000 patients who underwent a broad array of surgical procedures to identify risk factors and derive a predictive model for assessing risk of postoperative respiratory failure.[3] Respiratory failure developed in 3.1% of patients, with an associated 30-day mortality rate of 26% compared to 0.98% for patients not experiencing this complication. On multivariate logistic regression analysis, five preoperative predictors of postoperative respiratory failure were identified: type of surgery (highest risk with brain, abdominal, aortic surgery), emergency cases, poor preoperative functional status, preoperative sepsis, and higher ASA class. These variables were incorporated into a predictive model that was validated in a second cohort of over 250,000 patients from the 2008 NSQIP database. An interactive risk calculator, available online at http://www.surgicalriskcalculator.com/prf-risk-calculator, was then developed that estimates the likelihood of respiratory failure for a given patient.

Pulmonary consultants providing preoperative assessment are commonly asked to specifically comment on the risk posed by a patient's history of COPD. COPD has been identified as an

TABLE 104-1 Incidence of Respiratory Failure Following Various Surgical Procedures

Procedure	Incidence of Postoperative Respiratory Failure (%)
Mouth, palate, salivary glands, pharynx, adenoids, and esophagus	6.9
Thoracic and thoracoabdominal aneurysms, embolectomy/ thrombectomy, venous reconstruction, and endovascular repair	6.6
Stomach, intestines, appendix and mesentery, rectum and anus, liver, biliary tract, pancreas, abdomen, peritoneum, and omentum (nonhernia)	4.3
Respiratory system, hemic and lymphatic systems, mediastinum, and diaphragm	4.3
Aneurysm, blood vessel repair, thromboendarterectomy, angioscopy, angioplasty and atherectomy, bypass and composite grafts, other artery, and vein	4.2
Integumentary and musculoskeletal system	1.9
Hernioplasty, herniorrhaphy, herniotomy	0.4

TABLE 104-2 Scoring System for Estimating Risk of Postoperative Respiratory Failure: Parameters Used and Score Assigned

Parameter Set	Description	Score
1	ASA class 3	3
1	ASA class 4–5	5
2	Emergency	2
3	Work RVU 10–17	2
3	Work RVU >17	4
4	Preoperative albumin ≤3.5	1
5	Procedure: integumentary	1
5	Procedure: respiratory and hemic	3
5	Procedure: heart	2
5	Procedure: aneurysm	2
5	Procedure: mouth, palate	7
5	Procedure: stomach, intestines	2
5	Procedure: endocrine	2
6	Preoperative sepsis	2
7	Preoperative creatinine ≥1.5	2
8	History of severe COPD	2
9	Ascites	2
10	Dyspnea	1
11	Impaired sensorium	1
12	Preoperative bilirubin >1.0	1
13	>2 alcoholic drinks/d in 2 wk before admission	1
14	Bleeding disorders	1
15	Age >40 y	2
16	Preoperative white blood count <2.5 or >10	1
17	Preoperative serum sodium >145	2
18	Weight loss >10%	1
19	Preoperative acute renal failure	2
20	Male gender	1
21	Congestive heart failure <30 d before operation	1
22	Smoker	1
23	Preoperative platelet count ≤150	1
24	CVA/stroke with neurological deficit	1
25	Wound class (clean/contaminated)	1
25	Wound class (contaminated)	1
25	Wound class (infected)	1
26	Preoperative AST >40	1

independent predictor of postoperative respiratory failure in numerous studies.[1,4–7] The largest and most comprehensive study utilized the NSQIP database containing over 460,000 patients who underwent a variety of surgical procedures. COPD was independently associated with an increased risk of ventilator dependence for more than 48 hours following surgery (odds ratio 1.45) and reintubation (odds ratio 1.54). Notably, neither this study nor the others referenced earlier categorized patients according to preoperative pulmonary function parameters, precluding conclusions about the relationship between severity of COPD and risk of postoperative respiratory failure.

The use of preoperative pulmonary function testing to assess risk of postoperative respiratory failure in COPD patients has been most closely examined in the context of lung resection surgery for lung cancer. Studies of patients undergoing standard thoracotomy and either pneumonectomy or lobectomy have used preoperative spirometry in conjunction with quantitative ventilation/perfusion lung scans to estimate postresection FEV_1 and diffusing capacity. While the study populations are small, published case series suggest that a predicted postresection FEV_1 or diffusing capacity less than 40% of normal is associated with a high risk for postoperative respiratory failure and death.[8–11] In one study that examined the performance characteristics of these parameters, the probability of respiratory failure or death was 33% for those patients with an FEV_1 <40% while the probability of avoiding these complications was 90% for those with an FEV_1 ≥40%.[10] Coupling pulmonary function testing with cardiopulmonary exercise testing allows for more precise risk stratification. Those patient with peak oxygen consumption of ≥10 to 15 mL/kg/min despite predicted postresection FEV_1 or diffusing capacity <40% appear to have a low risk of respiratory failure and death following thoracotomy and definitive lung resection procedures.[9,12] The use of video-assisted thoracoscopic surgery (VATS) in combination with lobectomy, segmentectomy, or wedge resection appears to be well tolerated by patients with severe lung disease, with only a 4% incidence of respiratory failure and a 1% mortality rate documented in one study of 100 consecutive patients with an FEV_1 <35% predicted.[13]

TABLE 104-3 Scoring System for Estimating Risk of Postoperative Respiratory Failure: Respiratory Risk Index

Score Range	Risk Level	Predicted Probability of PRF (%)
<8	Low	0.2
8–12	Medium	1.0
>12	High	6.5

Studies using preoperative spirometry to assess severity of COPD in patients undergoing cardiac surgery have provided conflicting results with respect to the risk of respiratory failure. One study found that an FEV_1 <70% was an independent predictor of post-CABG respiratory failure but the rather broad nature of the spirometric threshold used limits the utility of this finding.[4] A study of 1412 patients found that the combined incidence of prolonged postoperative mechanical ventilation (>48 hours) and reintubation increased with increasing severity of COPD: 2.3% in patients without COPD compared to 0%, 13%, and 77% in patients with FEV_1 60% to 80%, 40% to 59%, and <40%, respectively. In contrast, the largest study to date utilizing a database of over 11,000 patients did not detect an association between COPD severity and risk of prolonged postoperative mechanical ventilation even among patients with the most severe disease (FEV_1 <50%), though there was an increased risk of early mortality in this group.[14]

Data related to the use of preoperative pulmonary function parameters to stratify risk of postoperative respiratory failure in relation to noncardiothoracic surgical procedures are scant and conflicting. These data are summarized in a recent guidelines statement issued by the American College of Physicians, which concludes that for noncardiothoracic surgery, "insufficient evidence supports preoperative spirometry as a tool to stratify risk."[15] The guideline authors caution that available studies do not define a spirometric threshold below which the risk for noncardiothoracic surgery is prohibitive.

MEASURES TO REDUCE RISK

A number of the factors associated with an increased risk of postoperative respiratory failure can potentially be addressed to mitigate the risk. In some cases, the surgical approach can be modified. For example, use of a transverse abdominal incision appears to carry less risk than a vertical midline incision. Cholecystectomy performed by laparoscopic technique is associated with significantly less compromise in postoperative FEV_1 and FVC and more rapid recovery of lung function compared with the conventional open approach.[16] For thoracic procedures, median sternotomy and muscle-sparing lateral thoracotomy are better tolerated than posterolateral thoracotomy. However, these approaches provide more limited access to the thorax than does the standard thoracotomy incision and they are generally inadequate for resection of the left lower lobe or for tumors involving the posterior chest wall, diaphragm, or superior sulcus. In addition, removal of bulky tumors via the muscle-sparing approach may be problematic. VATS offers a minimally invasive alternative that is associated with a less severe decrement in respiratory muscle strength and lung function in the immediate perioperative period compared to thoracotomy.[17] A propensity-matched analysis of patients undergoing lobectomy by means of VATS versus open thoracotomy demonstrated a significantly lower rate of postoperative reintubation in the VATS cohort (1.4% vs. 3.1%).

Patients with COPD scheduled for surgery should undergo a preparatory pulmonary regimen intended to optimize lung function and minimize airway secretions. This regimen should include smoking cessation, institution or intensification of inhaled bronchodilator and inhaled corticosteroid therapy, and use of oral antibiotics in the presence of purulent secretions or a "loose" cough. Patients should be instructed on the use of incentive spirometry or cough and deep breathing techniques prior to surgery. A short course of oral corticosteroids should be considered in patients who have a significant bronchospastic component to their disease. Other than the assurance of strict compliance with the regimen, there is no reason to believe that hospitalization is superior to outpatient preparation of the patient.

Smoking has been shown to be a risk factor for postoperative pulmonary complications in general and for prolonged ventilatory support in particular.[1] Smoking does not appear simply to be a surrogate marker of COPD; rather it poses risk that is independent of the magnitude of pulmonary impairment. Detrimental effects of smoking include bronchial irritation with resultant excessive airway secretions, impairment in mucociliary clearance, and elevation of carboxyhemoglobin levels with consequent impairment in oxygen uptake and tissue oxygen utilization. Observational studies suggest that preoperative smoking cessation is associated with a reduction in pulmonary complications but these studies do not address the specific question of whether abstinence reduces the risk of respiratory failure.[18] A prospective, randomized trial investigated the impact of a preoperative smoking cessation program (counseling and nicotine replacement patch) on a number of postoperative complications including respiratory failure, following elective hip and knee replacement. Complete abstinence from smoking was achieved in 60% of the patients in the intervention arm compared to only 7% in the control arm. Despite this marked difference, only one patient in each group experienced postoperative respiratory failure. The obvious limitation of this trial relates to the choice of a surgical population at minimal risk for the complication under investigation. Pending additional studies, it would appear prudent to initiate smoking cessation measures in preparing patients for surgery, though the full benefit with respect to global reduction in pulmonary complications may require a minimum of 8 weeks of abstinence.[19]

IMPACT OF ANESTHESIA AND POSTOPERATIVE ANALGESIA ON PULMONARY FUNCTION

The potential impact of anesthesia and postoperative analgesia on pulmonary function is related to the form of anesthesia or analgesia employed.

GENERAL ANESTHESIA

Use of general anesthetic agents is associated with a number of well-characterized alterations in pulmonary mechanics, gas exchange, and respiratory drive.[20,21] In the controlled environment of the operating room, these physiological derangements are clinically inconsequential and easily overcome by simple adjustments of the ventilator. However, lingering effects of general anesthesia after completion of surgery may impede efforts to extubate the patient or may precipitate respiratory failure in the recovery room.

Administration of general anesthesia, whether by the inhaled or intravenous route, results in an almost immediate loss of diaphragmatic and intercostal muscle tone, a cephalad shift of the diaphragm, and a decrease in the transverse thoracic diameter. These dimensional alterations in thoracic volume result in a 20% reduction in functional residual capacity (FRC) and in the development of compressive atelectasis. As demonstrated using computerized tomography during and after general anesthesia, patients develop crescent-shaped areas of atelectasis in dependent areas of lung within 10 minutes of induction.[22] Atelectatic areas comprise approximately 2% to 10% of total lung volume and disappear

with the application of positive end-expiratory pressure (PEEP). Dependent atelectasis develops after administration of either inhalational or intravenous anesthetics. A notable exception is ketamine, a drug that is unique in its maintenance of respiratory muscle tone. The degree of atelectasis appears unaffected by whether the patient is breathing spontaneously or is mechanically ventilated.

Areas of dependent atelectasis perturb the normal balance of ventilation and perfusion in the lung. Persistent perfusion of nonventilated atelectatic areas results in an increase in the shunt fraction, which may approach 15%. The magnitude of shunt correlates directly with the volume of atelectatic lung and may be further magnified by impairment of hypoxic pulmonary vasoconstriction induced by certain inhalational anesthetics. Elderly patients, those who are obese, and patients with underlying COPD are most likely to develop clinically apparent hypoxemia in response to general anesthesia; the effect may persist into the early postoperative period.

The inhaled anesthetic agents in common usage are respiratory depressants that blunt the response to both hypoxemia and hypercapnia. These agents depress the ventilatory response to CO_2 in a dose-dependent fashion. They have a negligible effect on the hypercapnic response at the low concentrations encountered during emergence from anesthesia. In contrast, hypoxemic drive is markedly attenuated even at very low, subanesthetic concentrations of the volatile agents. As a result of deposition of these agents in muscle and fat, concentrations sufficient to depress hypoxic drive persist for several hours after termination of anesthesia. This can result in significant postoperative respiratory depression in patients with chronic hypercapnia who are dependent on hypoxic ventilatory drive to breathe.

NEURAXIAL ANESTHESIA

It is common practice for those providing preoperative assessment of high-risk patients to recommend the use of neuraxial (i.e., spinal or epidural) anesthesia, predicated on the impression that this route of administration lessens the adverse impact of anesthesia on the respiratory system. Neuraxial anesthesia does possess a number of favorable physiological features. In contrast to the effects of general anesthesia, neuraxial anesthesia preserves diaphragmatic innervation and function. External intercostal muscle paralysis is induced by thoracic levels of neuraxial anesthesia, but the level is generally two dermatomes below the sensory level because of the lesser sensitivity of motor neurons to the effects of the anesthetic agent. Hypoxic pulmonary vasoconstriction is unaffected by neuraxial anesthesia, and the ventilatory response to CO_2 is unimpaired; indeed the CO_2 response may be heightened. A meta-analysis of trials comparing general to neuraxial anesthesia detected a significant reduction in 30-day mortality, venous thromboembolism, pneumonia, and respiratory depression.[23] Another meta-analysis restricted to patients undergoing hip fracture surgery also detected a reduction in 30-day mortality as well as a trend toward a lower incidence of postoperative hypoxemia associated with neuraxial anesthesia.[24] While these analyses suggest significant advantages associated with use of neuraxial anesthesia, they have been criticized because of the heterogeneous nature of the surgical populations and the use of older anesthetic techniques and older anesthetic agents.[25] Pending further studies, neuraxial anesthesia should not necessarily be viewed as the strategy of choice in more tenuous surgical candidates.

POSTOPERATIVE ANALGESIA

Postoperative analgesia is an essential component of the care of the surgical patient. Analgesia is important not only in ensuring patient comfort, but also in mitigating the adverse effects of pain on respiratory function and airway clearance. Inadequate pain relief can lead to splinting and patient reluctance to cough and deep breathe; the end result is promotion of retained secretions, atelectasis, hypoxemia, and, possibly, pneumonia. For major surgical procedures, particularly those involving the chest and upper abdomen, administration of opiates via the parenteral or epidural route has become the analgesic method of choice.

The use of narcotic analgesia in the postoperative period is associated with a small, but not insignificant, risk of precipitating respiratory depression. The reported incidence of respiratory depression varies based on the criteria employed. A meta-analysis of published studies revealed an incidence of 0.3% defined by the need to administer naloxone, 3.3% defined by the presence of hypercapnia, and 17% defined by oxygen desaturation.[26] The risk may be slightly lower in association with the epidural as opposed to parenteral route of administration. When administered epidurally, hydrophilic narcotics (e.g., morphine) have a greater tendency than lipophilic compounds (e.g., fentanyl) to remain in the cerebrospinal fluid and to spread rostrally to the respiratory center located in the floor of the fourth ventricle. Elderly patients are particularly susceptible to the respiratory depressant effects of opiates, likely reflecting an impaired ability to metabolize these agents. Respiratory depression in the postoperative patient is most likely to occur during the initial 24 hours following surgery. It is typically accompanied by a decreased level of consciousness and a slow respiratory rate. Treatment consists of administration of naloxone in 0.1 to 0.4 mg aliquots. Ventilation should be supported with a face mask and Ambu bag, reserving intubation for the failure of naloxone to swiftly rectify the problem.

Prospective, randomized trials examining pulmonary complications associated with epidural versus intravenous administration of perioperative analgesia following major abdominal surgical procedures have provided somewhat conflicting results. One study of 168 patients found no difference in rates of prolonged intubation or reintubation between groups receiving epidural versus intravenous postoperative analgesia.[27] A small trial involving 70 elderly patients reported no difference in duration of postoperative mechanical ventilation or major pulmonary complications (including reintubation).[28] In contrast, a larger study of 915 patients with at least one comorbidity defining them as "high-risk" surgical candidates found that epidural analgesia was associated with a significant reduction (23% with epidural vs. 30% with intravenous route) in postoperative respiratory failure, defined rather broadly as need for prolonged ventilation or reintubation or $Pa_{O_2} \leq 50$ mm Hg or $Pa_{CO_2} \geq 50$ mm Hg on room air.[29] Finally, a trial of over 1000 patients demonstrated a significant reduction in postoperative respiratory failure (defined as the need for intubation and mechanical ventilation for >24 hours postoperatively or reintubation) with the use of epidural analgesia in the subset of patients undergoing aortic surgery, but not those undergoing nonaortic abdominal surgery.[30]

IMPACT OF SURGERY ON POSTOPERATIVE PULMONARY FUNCTION

Surgery involving the upper abdomen and thorax results in a pronounced impairment in pulmonary function in the postoperative period. The impairment is more severe and prolonged than that due to administration of general anesthesia alone. Typically, upper abdominal and thoracic procedures are associated with a fall in lung volumes, development of atelectasis, and hypoxemia. These adverse effects commonly necessitate short-term administration of low-flow, supplemental oxygen, but when severe, or when accompanied by underlying lung disease, may precipitate respiratory failure.

UPPER ABDOMINAL SURGERY

Within 24 hours following upper abdominal surgery, vital capacity declines by 50%.[31] Although the vital capacity improves with time, marked impairment persists for as long as 7 days after the surgery. In contrast, vital capacity falls by only 25% following lower abdominal procedures; it returns to normal by the third postoperative day.[31]

Underlying these profound changes after upper abdominal surgery is the development of diaphragmatic dysfunction, as reflected in a reduction in transdiaphragmatic pressure with tidal respirations and in a shift from abdominal to rib cage breathing.[32,33]

Two main theories have been proposed to explain the observed impairment in diaphragmatic function. One theory is that there is a primary alteration in diaphragmatic contractility induced by local irritation, inflammation, surgical trauma, or pain. This theory has been rendered improbable with the demonstration that external stimulation of the phrenic nerves produces normal peak transdiaphragmatic pressure in patients recovering from upper abdominal surgery.[32] In other words, when maximally stimulated the diaphragm functions in a normal fashion.

The alternative, and currently favored, theory proposes that diaphragmatic dysfunction results from diminished phrenic nerve output. The basis for the attenuation in neural drive remains a matter of speculation, although several putative pathways can be rationally eliminated. For example, general anesthesia is known to depress output from the central respiratory centers, as well as to inhibit synaptic transmission. However, as noted previously, the effects of general anesthesia on diaphragmatic tone are transient and modest. In addition, the degree of dysfunction observed after upper abdominal procedures is not seen following general anesthesia for procedures on the lower abdomen and extremities. An inhibitory arc initiated by abdominal nociceptors for pain is unlikely, given that achievement of adequate pain control by epidural opiates fails to consistently improve pulmonary function or to normalize diaphragmatic performance. In contrast, the epidural administration of anesthetic agents such as bupivacaine does ameliorate diaphragmatic dysfunction following upper abdominal surgery. Since these agents produce sympathetic blockade in addition to pain control, it has been argued that visceral sympathetic afferents are responsible for providing an inhibitory signal that downgrades central neural drive and phrenic nerve activity, thereby leading to impaired diaphragmatic function. Supporting the notion of a reflex inhibitory arc mediated by visceral afferents is the demonstration in experimental animals that mechanical gall bladder stimulation strongly inhibits electromyographic activity and motion of the diaphragm.[34]

CARDIAC SURGERY

Although CABG – the most commonly performed cardiac surgical procedure – has been most intensively scrutinized with respect to its impact on the respiratory system, other related cardiac procedures (e.g., valve replacement) are likely to have similar effects. Lung volumes decrease by approximately 30% after CABG; the return to preoperative values may take several months.[35–37] Lung function may decline to a greater degree when internal mammary harvesting and grafting are employed.[35] Gas exchange is also impaired after CABG, as evident in the development of hypoxemia and significant widening of the alveolar–arterial oxygen gradient. In 125 patients who had daily room air arterial blood gas determinations prior to and following CABG, Pa_{O_2} fell from approximately 75 mm Hg preoperatively to a nadir of 55 mm Hg on postoperative day 2.[38] The Pa_{O_2} improved but remained below preoperative values at the end of the first postoperative week. A similar pattern and magnitude of decline in oxygenation have been demonstrated in other studies, with the development of hypoxemia associated with an increase in calculated shunt fraction from 3% preoperatively to a peak of 19% postoperatively.[37] The increase in shunt fraction is readily accounted for on the basis of atelectasis, which is invariably present postoperatively, especially on the left side.

A number of factors have been implicated in the development of post-CABG pulmonary dysfunction and atelectasis. Alterations in chest wall compliance and motion may result from division of the sternum, harvesting of the internal mammary artery, and traumatic injury to the costovertebral joints and first rib induced by retraction. Intraoperative lung retraction may directly injure the left lower lobe, leading to contusion and atelectasis, and, perhaps, accounting for the predilection for radiographic infiltrates on the left side. An alternative explanation for post-CABG left lower lobe atelectasis is intraoperative injury to the left phrenic nerve and consequent diaphragmatic paralysis or paresis. The phrenic nerve is vulnerable to stretch and ischemic injury during sternal retraction, dissection of the left internal mammary artery, or prolonged distention of the pericardium. In addition, thermal injury to the nerve may occur with the cardioplegic technique of instilling iced slush into the open pericardial sac. The actual incidence of phrenic nerve dysfunction after CABG is best defined in studies employing electrophysiological techniques, which have documented evidence of phrenic nerve injury in 10% to 16% of patients.[39–41] This suggests that phrenic nerve injury accounts for only a minority of the observed cases of left lower lobe atelectasis.

Finally, cardiopulmonary bypass (CPB) may contribute to pulmonary impairment after cardiac surgery. The duration of CPB has been linked to the severity of postoperative atelectasis; whether this relationship is causal is unclear.[40] It has been hypothesized that the use of CPB leads to abnormal surfactant production – possibly due to ischemic, thermal, or toxic injury to the alveolar epithelium – predisposing to the development of atelectasis. More clearly established is the ability of the bypass pump to induce a capillary leak syndrome, marked by extravasation of fluid into the alveolar interstitium and, rarely, into the airspaces. This process is thought to result from exposure of blood to nonendothelial surfaces, resultant activation of neutrophils, complement, and other inflammatory cascades, and sequestration of neutrophils within the microvasculature. While this rarely may lead to full-blown ARDS (see discussion below), the consequences are usually more subtle, manifesting as a widened arterial–alveolar oxygen gradient and diminished lung compliance. The recent introduction of "off-pump" CABG has permitted a greater appreciation of the adverse impact of CPB on postoperative lung function. For example, a recent large multicenter comparative analysis from the United Kingdom of CABG with or without CPB demonstrated significant reductions in the rates of prolonged mechanical ventilation (>24 hours), reintubation/tracheostomy, and ARDS/pulmonary edema/pneumonia among the group that underwent off-pump CABG.[42]

LUNG RESECTION

Unique to lung resection surgery is the immediate loss of lung function due to removal of lung parenchyma. The magnitude of the loss can be estimated reliably from preoperative quantitative lung scanning in conjunction with standard spirometry. The impact of lung resection on pulmonary function is further magnified in the perioperative period by other factors. For example, the standard posterolateral thoracotomy incision represents significant chest wall trauma, with rib retraction and resection, and transection of intercostal, latissimus dorsi, trapezius, and serratus anterior muscles. As a result, total respiratory compliance may fall by as much as 75%; work of breathing increases; and lung volumes decline dramatically, out of proportion to the surgical loss of functional lung. Following standard thoracotomy and lung resection (either lobectomy or wedge resection), FEV_1 and FVC fall to 25% of preoperative values at 1 hour, and to 30% at 24 hours. When a more limited, muscle-sparing incision is used, the impact on pulmonary function is markedly attenuated.[43] Lung resection via VATS is also associated with less severe impairment in lung function.[17]

As with cardiac and upper abdominal surgery, atelectasis is frequently present after lung surgery and results in impaired oxygenation. Phrenic nerve activity remains normal and diaphragmatic

TABLE 104-4 Causes of Postoperative Respiratory Failure

Factors extrinsic to the lung
• Depression of central respiratory drive (anesthetics, opioids, sedatives)
• Phrenic nerve injury/diaphragmatic dysfunction
• Obstructive sleep apnea
Factors intrinsic to the lung
• Atelectasis
• Pneumonia
• Aspiration of gastric contents
• Acute respiratory distress syndrome
• Volume overload/congestive heart failure
• Pulmonary embolism
• Bronchospasm/COPD

function during tidal breathing is preserved, although maximal diaphragmatic strength may be reduced.

CAUSES OF POSTOPERATIVE RESPIRATORY FAILURE

The development of acute respiratory failure in the surgical patient should prompt a systematic assessment of the likely causes (Table 104-4). In approaching this life-threatening problem, one must consider the nature and magnitude of pre-existing pulmonary disease, type of surgery performed, drugs administered intra- and postoperatively, and predominant derangement in gas exchange (i.e., hypoxemia or hypercapnia). In conjunction with important information derived from the physical examination and chest radiograph, the analysis should readily identify factors responsible for or contributing to respiratory failure. The following discussion focuses on the more common or unique causes of postoperative respiratory failure in the surgical setting.

■ ATELECTASIS

Atelectasis is the most common pulmonary complication encountered in the surgical patient, particularly following thoracic and upper abdominal procedures. As discussed previously, anesthesia and surgical manipulation act in concert to produce regional atelectasis through incompletely defined mechanisms, including diaphragmatic dysfunction and diminished surfactant activity. The atelectasis is typically basilar and segmental in distribution, obscuring the hemidiaphragms radiographically. A distinct and less common cause of postoperative atelectasis is plugging of central airways by retained secretions. This problem is encountered in the surgical patient whose efforts to clear secretions are compromised by depressed consciousness, inadequate pain control, or a weak, ineffective cough. When situated in a main stem bronchus, mucus plugs can result in collapse of an entire lung; more distal obstruction leads to lobar collapse. An abrupt termination of the proximal bronchial air shadow and the absence of air bronchograms within the atelectatic portion of lung are clues to the possible presence of mucus plugging.

While often clinically insignificant, postoperative atelectasis may lead to severe hypoxemia and respiratory distress. The magnitude of hypoxemia is dictated by the extent of atelectasis, the presence and severity of underlying lung disease, and the integrity of the hypoxemic pulmonary vasoconstrictive response. Impairment of hypoxemic pulmonary vasoconstriction by vasodilatory drugs, commonly administered to surgical patients for treatment of underlying hypertension or ischemic heart disease, prevents the compensatory diversion of blood flow away from nonventilated areas of lung and magnifies the shunt fraction.

Respiratory distress due to atelectasis usually evolves insidiously over the first several postoperative days. Supplemental oxygen requirements increase in association with worsening basilar infiltrates noted on the chest radiograph. The clinicoradiographic picture may be indistinguishable from that of pneumonia. While fever and leukocytosis suggest infection, these signs are common and nonspecific. When atelectasis is due to central airway occlusion by mucus plugs, hypoxemia and respiratory distress may develop quickly. A chest radiograph obtained immediately after the onset of symptoms may be surprisingly unrevealing if sufficient time has not passed to permit resorption of gas from the airspaces of the nonventilated lung. Careful examination of the patient, however, will reveal an absence of breath sounds over the involved lung, providing an important clue to the presence of central airway obstruction and obviating pursuit of other considerations, such as pulmonary embolism (PE).

Treatment of respiratory failure due to atelectasis is directed toward the combined goals of adequate oxygenation and re-expansion of lung segments. Supplemental oxygen should be titrated to achieve an arterial oxyhemoglobin saturation of at least 90%. Refractory hypoxemia, severe respiratory distress, progressive hypercapnia, or inability of the patient to clear copious airway secretions should prompt immediate intubation and mechanical ventilatory support. This lifesaving intervention permits more efficient delivery of oxygen, secures access for suctioning of the airways, and facilitates performance of bronchoscopy should it be necessary. Moreover, the positive pressure and large tidal volumes delivered by the ventilator are often effective in rapidly re-expanding collapsed lung segments. In less dire circumstances, noninvasive ventilation may be equally effective.

Fiberoptic bronchoscopy is commonly employed in the treatment of serious atelectasis but evidence suggests that it may be no more effective than standard chest physiotherapy. In the only randomized study directly comparing these strategies, immediate fiberoptic bronchoscopy did not result in more rapid or complete resolution of acute lobar atelectasis when compared with a regimen of deep breathing, coughing, suctioning of the intubated patient, aerosolized bronchodilator treatments, chest percussion, and postural drainage.[44] Resolution of atelectasis was dictated not by the treatment modality employed, but by radiographic evidence of central airway patency. In this regard, both chest physiotherapy and bronchoscopy were highly effective in the absence of an air bronchogram. In contrast, the presence of an air bronchogram, which indicates that the atelectasis is not due to proximal airway obstruction, was associated with minimal response to either modality. Based on this, standard respiratory therapy techniques applied to either the spontaneously or mechanically ventilated patient should be considered the mainstay of treatment for lobar atelectasis. Fiberoptic bronchoscopy should be reserved for those situations where chest physiotherapy is contraindicated (e.g., chest trauma, immobilized patient), poorly tolerated, or unsuccessful, or in the setting of life-threatening hypoxemia.

A number of other measures are commonly employed in the treatment of atelectasis. Judicious use of analgesia is an essential adjunct, permitting the patient to breathe deeply, cough forcefully, and comfortably participate in chest physiotherapy maneuvers. Care must be taken to avoid excessive sedation, which will offset the beneficial effects of pain control. In the setting of marked hypoxemia, attempts should be made to discontinue vasoactive drugs with the potential to influence the pulmonary vascular bed; examples include nitrates, nitroprusside, calcium channel blockers, angiotensin-converting enzyme inhibitors, and hydralazine. Mucolytics, such as N-acetyl cysteine, are commonly administered in an effort to promote clearance of tenacious secretions; however, their efficacy in this setting has not been well documented. Some clinicians and

respiratory therapists advocate the use of nasotracheal suctioning of the nonintubated patient with a weak and ineffective cough. However, this technique is associated with considerable discomfort and is an inefficient and highly transient means of clearing secretions from the tracheobronchial tree.

Maneuvers to promote periodic full lung expansion, including intermittent positive pressure breathing (IPPB), cough and deep breathing exercises, and incentive spirometry, have been developed in an attempt to prevent or mitigate the severity of atelectasis. Early trials suggested that all three techniques were equally efficacious and superior to no therapy in the prevention of postoperative pulmonary complications following abdominal surgery.[45] IPPB has largely been abandoned due to its expense, need for specially trained personnel and close patient supervision, and tendency to produce abdominal distention. While incentive spirometry is universally employed in the care of the postoperative patient, two recent Cochrane Reviews challenge the deeply ingrained view that this is an essential measure. These reviews, focusing on upper abdominal surgery[46] and CABG,[47] respectively, conclude that there is no evidence of benefit from incentive spirometry in reducing pulmonary complications and, in the case of CABG, in decreasing the negative effects on pulmonary function. Both reviews caution that there are extensive methodological shortcomings of available studies that limit their interpretation. Given that incentive spirometry is inexpensive and simple to perform, it seems prudent to continue this practice despite the absence of rigorous proof of efficacy.

PNEUMONIA

Pneumonia is the third most common postoperative infection and the most lethal, with an associated mortality rate of 20% to 50%.[48] Pneumonia represents a principal cause of postoperative respiratory compromise and may precipitate acute respiratory failure, as well as complicate respiratory failure in the patient who is ventilator-dependent for other reasons. The type of surgery heavily influences the risk of developing pneumonia in the postoperative period. In particular, the risk is greatest following abdominal aortic aneurysm repair, thoracic and upper abdominal procedures, head and neck surgery, and neurosurgical procedures.[48] Patient-specific risk factors that have been identified include advanced age, chronic steroid use, current or recent smoking, COPD, low serum albumin level, impaired sensorium, and dependent preoperative functional status.[48,49] The presence of a nasogastric tube and the use of gastric acid–suppressive medications, commonly employed interventions in postoperative patients, have been cited as risk factors for nosocomial pneumonia in general.[50] A multifactorial model, employing a number of these patient-related and procedure-related factors, has been developed and validated that predicts the risk of pneumonia in nonintubated patients following major noncardiac surgery.[48] Perhaps the most important risk factor, not addressed in this predictive model, is the need for postoperative mechanical ventilatory support. Overall, mechanically ventilated patients have a 6- to 21-fold increased risk of pneumonia compared with nonventilated patients.[51]

While organisms may reach the lower respiratory tract by several routes, microaspiration of oropharyngeal secretions appears to be the predominant mechanism in the pathogenesis of nosocomial pneumonia. A critical initiating event in this pathway is colonization of the oropharynx with gram-negative aerobic bacilli, a process that characteristically occurs in response to serious illness or surgical stress. Clinically occult aspiration of these virulent organisms is facilitated by a number of iatrogenic measures imposed upon the surgical patient. Paramount among these is the placement of an endotracheal tube, which impairs swallowing, stents open the glottis, and permits pooling of secretions above the tube cuff. The inflated cuff is an imperfect barrier and allows intermittent seepage of secretions into the lower airways. Prolonged intubation has also been associated with postextubation swallowing dysfunction. Depressed consciousness as a consequence of general anesthesia and postoperative analgesia further contributes to the risk of aspiration.

Recent attention has focused on the stomach as an additional source of bacteria in the development of nosocomial pneumonia. While the acidic milieu of the stomach normally inhibits bacterial growth, the common use of H2-blockers and antacids as stress ulcer prophylaxis overrides this natural barrier and promotes gastric colonization with gram-negative enteric organisms. Gastroesophageal reflux, a common feature of the critically ill patient, permits bacteria-laden gastric contents to enter the respiratory tract either directly or by first colonizing the oropharynx. This route of migration has been confirmed by recovery of technetium-99m-labeled gastric contents in endobronchial secretions and by the demonstration in some patients that organisms cultured from the airways first appeared in the stomach.[52] Perhaps the most compelling, albeit circumstantial, evidence derives from studies that have shown a higher incidence of nosocomial pneumonia in patients receiving H2-blockers or proton-pump inhibitors.[50]

The fate of organisms introduced into the lower respiratory tract is dependent upon the integrity of mechanical and immunological pulmonary defense mechanisms. Impairment of the mucociliary escalator (e.g., due to recent cigarette smoking or underlying COPD), weak and ineffective cough, and use of immunosuppressive medications (e.g., corticosteroids) favor the proliferation of organisms and the development of pneumonia. It is widely held that postoperative atelectasis predisposes to pneumonia by entrapping bacteria. However, studies demonstrating a lack of concordance between the degree of atelectasis and the subsequent risk of pneumonia challenge this contention.[53]

The constellation of fever, leukocytosis, purulent sputum, and radiographic infiltrates has traditionally defined the presence of pneumonia. While these diagnostic criteria are reasonably accurate in the previously healthy outpatient, they are notoriously nonspecific in the setting of recent surgery, particularly with prolonged use of mechanical ventilation. In one autopsy series, traditional clinical and radiographic criteria provided the correct antemortem diagnosis in only 70% of cases.[54] Alternative etiologies of radiographic infiltrates include atelectasis, pulmonary edema, infarction or hemorrhage due to pulmonary emboli, pulmonary contusion, and chemical pneumonitis. Cultures of sputum and tracheal aspirates are poorly reflective of the bacterial flora of the distal airways, since these specimens are contaminated by colonizing organisms in the oropharynx and upper respiratory tract. In an attempt to enhance diagnostic certainty, bronchoscopic sampling of the distal airways using a sterile sheathed brush or bronchoalveolar lavage has been advocated. While the absence of a "gold standard" for the diagnosis of pneumonia has complicated attempts to define the accuracy of these techniques, rates of false-positive and false-negative results have generally fallen in the range of 30%. It is questionable, therefore, whether the performance of bronchoscopy actually contributes significantly to a reduction in the degree of diagnostic uncertainty.

The most common organisms isolated in cases of postoperative pneumonia are gram-negative bacteria and *Staphylococcus aureus*.[55] Polymicrobial infections are common, occurring in approximately one-third of cases. The emergence of highly resistant organisms, such as methicillin-resistant *S. aureus* and multidrug resistant *Acinetobacter* species poses a particular challenge in selecting empiric antibiotics and in definitively treating these infections. In one large study of postoperative pneumonia, the initial antibiotic regimen had to be modified in 47% of cases because of antibiotic resistance or clinical failure.[55]

Preventative strategies intended to diminish the risk of pneumonia are an important consideration in the care of the surgical patient. Prevention begins in the preoperative phase with emphasis

on abstinence from cigarette smoking for a minimum of 8 weeks prior to elective surgery. Following surgery, nasogastric and endotracheal tubes should be removed as soon as possible. Postoperative analgesia must be titrated to permit the patient to comfortably and vigorously cough, but excessive sedation impairing protection of the airway and enhancing the risk of aspiration must be avoided. For the high-risk ventilator-dependent patient, maintenance of a semierect position has been shown to diminish the magnitude of clinically occult aspiration of gastric contents and the incidence of pneumonia. More controversial in this high-risk population is the use of selective digestive decontamination (SDD), intended to prevent or diminish the magnitude of gram-negative colonization of the aerodigestive tract. Regimens have varied among studies, but they typically consist of some combination of antibiotics applied topically to the oropharynx, instilled into the stomach as a slurry, and/or administered systemically. Several prospective randomized trials and meta-analyses demonstrated that SDD reduced the incidence of pneumonia among critically ill patients.[56,57] Despite the suggested efficacy of this approach, SDD is not widely utilized, in part because of lingering concerns that this strategy will lead to emergence of increasingly resistant bacterial strains.

■ ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is defined by the constellation of hypoxemic respiratory failure, diffuse pulmonary infiltrates, and the absence of clinical evidence of elevated left atrial pressure (see Chapter 141). The histological hallmark of ARDS is diffuse alveolar damage, a widespread injury to the alveolar–capillary membrane that leads to increased capillary permeability and development of noncardiogenic pulmonary edema. ARDS represents the end result of a variety of insults that either involve the lung directly (e.g., aspiration of gastric contents) or trigger pulmonary inflammation as part of a systemic process (e.g., sepsis). Many of the risk factors associated with development of ARDS are commonly encountered in surgical patients. In decreasing order of risk, these include sepsis, massive blood transfusion, pulmonary contusion, aspiration of gastric contents, and multiple fractures.[58] Causes of ARDS of particular relevance to the surgical patient, and, in some cases, unique to this population, are described in greater detail below.

■ ASPIRATION OF GASTRIC CONTENTS

Aspiration of gastric contents can rapidly lead to widespread acute lung injury and is an important cause of ARDS in the surgical patient. It is the third leading cause of anesthesia-related deaths, accounting for 10% to 30% of fatal outcomes. Aspiration typically occurs when the mechanisms of glottic closure and cough, which normally protect the airway, are compromised. In the surgical patient, the period of maximal vulnerability for aspiration spans from the induction of general anesthesia to full return of consciousness postoperatively. A number of factors combine to enhance the risk of aspiration during this period. Most important is the blunting of consciousness that accompanies induction and administration of general anesthesia. Insufflation of air into the stomach during induction may cause gastric distention and promote vomiting. Vomiting may also be provoked by noxious stimulation of the posterior oropharynx during intubation or extubation. Reflux of gastric contents is facilitated by medication-induced relaxation of the lower esophageal sphincter, placement of the patient in a supine position, and manipulation of the bowel during abdominal procedures. At the completion of surgery, extubation is commonly performed at a time when the patient, while able to ventilate adequately, may not yet be capable of fully protecting the airway. Indeed, upper airway reflexes remain significantly impaired for up to 2 hours after recovery from anesthesia, even at a time when mental alertness has returned. Moreover, translaryngeal intubation, even when brief, may cause residual glottic dysfunction for up to 8 hours following removal of the tube. While the risk of aspiration diminishes beyond the immediate perioperative period, it remains a concern in the patient receiving narcotic analgesia, which may not only induce vomiting, but also depress consciousness.

The risk of aspiration during the immediate perioperative period was delineated in a survey of over 215,000 general anesthetic procedures performed at the Mayo Clinic.[59] Aspiration was defined as the presence of bilious or particulate matter in the airways or the development of a new infiltrate on the immediate postoperative chest radiograph. The overall incidence of aspiration was only 0.03%, but the incidence was nearly fourfold higher (0.11%) in the setting of emergency surgery. In addition to the use of general anesthesia, other predisposing factors were present in over half of the patients who aspirated. These included gastrointestinal obstruction, swallowing dysfunction, altered sensorium, previous esophageal surgery, and a recent meal. The majority of events occurred during laryngoscopy (in preparation for insertion of the endotracheal tube) and during tracheal extubation. Twenty percent of patients who aspirated required postoperative mechanical ventilation in excess of 6 hours; 5% died as a direct result of this complication. The use of laryngeal mask airway devices does not appear to be associated with an increased risk of aspiration despite the fact that these devices do not isolate the larynx from the gastrointestinal tract.[60]

Acidic gastric contents introduced into the airways are rapidly disseminated throughout the bronchial tree and lung parenchyma, producing an almost instantaneous chemical burn. In addition, acid aspiration triggers a more delayed inflammatory response, with release of inflammatory cytokines and recruitment of neutrophils into the lung. The result is injury to the alveolar–capillary membrane, with flooding of the interstitium and airspaces by proteinaceous edema fluid. Surfactant levels drop precipitously due to both direct acid denaturation and diminished production, leading to alveolar instability and atelectasis. The magnitude of lung injury is directly related to the pH and volume of aspirated material. Initial studies in animals suggested that a pH of less than 2.5 and a volume in excess of 0.4 mL/kg are critical threshold values for the induction of lung injury.[61] While these values are now often quoted in the literature, their validity has been challenged by more recent studies demonstrating significant injury in association with lower volumes and higher pH. In particular, aspiration of bile is capable of inducing widespread injury even at a pH as high as 7.19. The presence of large food particles may further exacerbate the problem by causing airway obstruction and atelectasis. Notably, infection does not normally play a significant role in the initial lung injury from aspiration of acidic gastric contents, as the low pH serves to maintain relative sterility of the inoculum. However, gastric colonization with bacteria can occur in patients maintained on acid-suppressive agents, those receiving enteral feeds, and those with gastroparesis or small bowel obstruction.

The diagnosis of aspiration is most firmly established in the setting of witnessed vomiting or recovery of gastric contents from the airways. More often, the diagnosis is suspected circumstantially in a patient with risk factors and a compatible clinicoradiographic picture. Massive aspiration presents with fever, tachypnea, and diffuse rales developing within several hours of the event. Wheezing is appreciated in approximately one-third of patients and may be due either to obstruction of airways by particulate matter or, more commonly, to reflex bronchospasm. Hypoxemia is universally present with massive aspiration and is sufficiently severe in the majority of patients to mandate use of mechanical ventilation. The initial presence of apnea or shock is particularly ominous and portends a high risk of subsequent death. Initial radiographic patterns vary, depending upon the volume, causticity, and distribution of the aspirated material. However, three general patterns have been described:

(1) extensive bilateral consolidation resembling diffuse pulmonary edema; (2) widespread, but discrete, patchy infiltrates involving dependent areas of lung; and (3) focal consolidation usually localized to one or both lung bases.

The clinical course following massive aspiration is variable, but it typically diverges along one of several pathways. A minority of patients follow a fulminant course leading quickly to hypoxemic respiratory failure. More commonly, patients demonstrate progressive radiographic and clinical improvement over the first several days. Although most of these patients will go on to full recovery, a subset demonstrates secondary deterioration due to the development of nosocomial pneumonia. The overall mortality rate associated with massive aspiration is approximately 30% and exceeds 50% in those patients with initial shock or apnea, secondary pneumonia, or ARDS.

The treatment of respiratory failure secondary to aspiration is supportive and includes mechanical ventilatory strategies common to other forms of ARDS (Chapter 141). Bronchoscopy is indicated only when large airway obstruction by particulate matter is suspected on the basis of a localized wheeze or lobar atelectasis. Because acid is disseminated and endogenously neutralized within seconds, large-volume bronchoalveolar lavage is ineffective in attenuating the degree of injury and is not recommended. Studies of the administration of systemic corticosteroids in the treatment of aspiration pneumonitis have been inconclusive and do not currently justify their use. Similarly, use of prophylactic antibiotics is generally discouraged in the absence of supportive data and because of fear that this practice will preferentially select more highly resistant organisms. Some authors do advocate use of empiric antibiotics for that subset of patients at risk for gastric colonization with bacteria, as described above. In addition, up to 40% of patients will develop a superimposed bacterial pneumonia within several days of the aspiration event, often heralded by a new fever, new or progressive infiltrates, and purulent sputum. Broad-spectrum antibiotic therapy is indicated at that time.

The high morbidity and mortality associated with aspiration and the lack of effective therapy once the event has occurred have focused attention on measures to prevent this complication. The most straightforward and widely utilized measure is the convention of overnight fasting prior to elective surgery. However, despite prolonged fasting, up to one-third of patients will maintain a gastric volume in excess of 0.4 mL/kg (approximately 25–30 mL in the average adult), and up to three-quarters will have a gastric pH below 2.5. Administration of H2-blockers and proton-pump inhibitors can effectively raise the pH and reduce the volume of gastric contents, suggesting a potentially appealing strategy.[60] However, evidence suggesting that preoperative administration of these agents decreases the incidence or severity of aspiration is notably absent and their routine use in the preoperative setting is not currently recommended. In high-risk patients, rapid sequence induction of anesthesia should be employed to shorten the time between loss of consciousness and tracheal intubation. During induction, manual pressure should be applied to the cricoid cartilage (Sellick maneuver) and maintained until the endotracheal tube is in proper position and the cuff is inflated. Postoperatively, extubation should be performed only when consciousness and the gag reflex have returned to a level sufficient to permit adequate protection of the airway.

■ POSTPNEUMONECTOMY PULMONARY EDEMA

Postpneumonectomy pulmonary edema describes the development of diffuse pulmonary edema in the remaining lung, in the absence of identifiable causes. While some authors apply this term exclusively in the setting of pneumonectomy, others have reported similar cases following lobectomy. Demonstration of normal pulmonary artery occlusion pressures and of protein-rich edema fluid in a small number of patients suggests that an increase in vascular permeability rather than hydrostatic pressure underlies the edema formation.[62] However, the exact mechanism responsible for lung injury remains a matter of conjecture. Mechanisms that have been advanced include hyperinflation and volutrauma resulting from single lung ventilation, endothelial injury due to hyperperfusion of the remaining lung, disruption of lymphatic drainage, and ischemia-reperfusion injury.[63]

The incidence of postpneumonectomy pulmonary edema ranges between 4% and 7%, in part reflecting variable definitions.[63] For unclear reasons, the complication is encountered more frequently following right pneumonectomy. The majority of cases develop by postoperative day 3. The observed mortality rate is in the range of 50% to 100%. Treatment is supportive, centering on lung-protective ventilator strategies. A nonrandomized trial suggested that the intraoperative administration of Solu-Medrol was associated with a decreased incidence of postpneumonectomy pulmonary edema but this is not considered standard of care.[64]

■ CARDIOPULMONARY BYPASS

ARDS develops immediately following use of CPB in approximately 1% of cases.[65] While factors unrelated to the use of CPB may be at play, there is evidence from both animal models and clinical studies to suggest that CPB activates a number of inflammatory pathways that could lead to acute lung injury. It is well established, for example, that CPB results in neutrophil activation, likely through mechanical shear stress and exposure to the artificial surfaces of the bypass circuit. In addition, an increased expression of cell surface adhesion molecules has been demonstrated, which may promote neutrophil binding to pulmonary endothelium and release of proteolytic enzymes and reactive oxygen species. The central role played by neutrophils in causing acute lung injury following CPB is supported by several lines of evidence: (1) bronchoalveolar lavage fluid from patients undergoing CPB contains an increased number of neutrophils; (2) plasma levels of neutrophil elastase and myeloperoxidase are increased; and (3) inhibition of neutrophil activation with pentoxiphylline as well as neutrophil depletion attenuate the degree of pulmonary dysfunction. A number of other inflammatory mediators are released in association with CPB, including complement, proinflammatory cytokines, and prostaglandins. Perhaps the most compelling, albeit circumstantial, evidence implicating CPB as a cause of postoperative pulmonary dysfunction is the demonstration in multiple studies of a significant reduction in the incidence of prolonged postoperative ventilator dependence associated with CABG when performed off-pump.[42,66,67]

■ AMIODARONE

Amiodarone-induced pulmonary toxicity usually presents as a subacute illness characterized by cough, dyspnea, fever, and patchy pulmonary infiltrates. Less commonly, the use of amiodarone has been linked to the development of ARDS immediately following cardiac and thoracic surgery. In most of the reported cases, amiodarone was administered preoperatively for varying periods of time for control of arrhythmias.[68] The majority of patients had no evidence prior to surgery of the more indolent form of amiodarone pulmonary toxicity. Development of ARDS also has been described in patients whose only exposure to amiodarone occurred in the postoperative period, when the drug was initiated as prophylaxis or treatment for atrial arrhythmias. In one report, postoperative ARDS developed in 11% of patients receiving amiodarone and in only 1.8% of untreated patients.[69] The specific perioperative factors that act in concert with amiodarone to produce acute lung injury remain to be defined.

Some authors have suggested that exposure to high levels of supplemental oxygen may be a contributing factor. The diagnosis rests on exclusion of other causes rather than on specific diagnostic tests or histology. In addition to stopping the drug, high doses of corticosteroids are often given, though support for this is anecdotal at best.

TRANSFUSION-RELATED ACUTE LUNG INJURY

The transfusion of blood and blood products has been linked to the development of acute lung injury in two ways. An association between massive blood transfusion (>15 units/24 hours) and ARDS has been noted in epidemiological studies, but it remains unclear whether this link is truly causal or is indirect and reflective only of the critically ill nature of the patient requiring such massive transfusion support.[58] Acute lung injury can also be associated with the transfusion of a single unit of blood or blood components, an entity known as "transfusion-related acute lung injury" (TRALI). TRALI is operationally defined as the acute development of hypoxemia and bilateral radiographic opacities during or within 6 hours of a completed transfusion, in the absence of evidence of circulatory overload or alternative etiologies of acute lung injury.[70]

The mechanism underlying TRALI was initially determined to involve passive infusion via transfused blood products of donor-derived antibodies directed against recipient leukocytes. These antibodies are typically contained in blood products obtained from multiparous female donors, whose exposure to foreign human leukocyte antigen (HLA) or neutrophil antigens occurred during prior pregnancies. When transfused into a recipient with cognate antigens, these antibodies result in leukoagglutination and activation of recipient granulocytes or monocytes within the pulmonary microvasculature, triggering increased capillary permeability and the development of noncardiogenic pulmonary edema. Less commonly, the leukoagglutinating process can be triggered by an interaction between recipient anti-HLA or antineutrophil antibodies and donor-derived leukocytes contained in the transfused blood products.[71]

While ample clinical and animal model evidence exists to support the antibody hypothesis,[70,72] several lines of evidence suggest that other factors may also be involved. First, not all patients who receive blood products containing recipient-specific anti-HLA or antineutrophil antibodies develop TRALI. Second, in a significant minority of cases, leukoagglutinating antibodies cannot be detected in either the donor or recipient. This has prompted the proposal of an alternative "two hit" mechanism, whereby an initial event is required to prime recipient neutrophils and a second event leads to activation of primed neutrophils.[70,72] Priming events that have been associated with an increased risk of TRALI include recent surgery, active infection, sepsis, and chronic alcohol abuse.[73,74] The second event involves transfusion of substances that trigger neutrophil activation: either antileukocyte antibodies or biologically active lipids resulting from breakdown of stored blood products.

The true incidence of TRALI is difficult to determine due to underrecognition of the entity and a tendency to attribute the findings to other causes of acute lung injury. Although virtually all blood products have been implicated, the risk of TRALI is highest in association with fresh-frozen plasma and platelets.[71,72] Many cases are detected in surgical patients in the immediate postoperative period, a fact that likely reflects the frequent need for transfusions in this setting and the close monitoring of cardiopulmonary function in the postanesthesia recovery area.[75,76]

Clinically, TRALI is characterized by the abrupt onset of dyspnea and hypoxemia during or shortly following transfusion of blood products. Accompanying features include fever, chills, and hypotension. Respiratory distress and hypoxemia are of sufficient magnitude to require mechanical ventilatory support in up to 45% of cases.[71] The differential diagnosis includes volume overload, congestive heart failure, myocardial infarction, and aspiration. Although many cases are self-limited, with clearing of infiltrates and improved oxygenation over several days, mortality rates of 5% to 20% have been reported.[71]

When TRALI is suspected, the blood bank should be notified. Ideally, this should trigger testing of all donor specimens (typically retained by the blood bank) for the presence of anti-HLA and antineutrophil antibodies. However, the expense and time required often prevent blood banks from performing these studies.

ACUTE EXACERBATIONS OF PULMONARY FIBROSIS

Patients with idiopathic pulmonary fibrosis (IPF) can experience sudden and dramatic respiratory decompensation in the absence of identifiable precipitants. Referred to as an exacerbation of IPF, this phenomenon is characterized by acutely worsening hypoxemia in association with new bilateral ground-glass opacities or consolidation on chest CT.[77] The histological hallmark is diffuse alveolar damage, superimposed on underlying usual interstitial pneumonia. IPF exacerbation is a diagnosis of exclusion, established only after infection, heart failure, PE, and identifiable causes of acute lung injury have been ruled out.

The immediate postoperative period following lung surgery is one of the settings in which acute exacerbations of IPF have been reported to occur.[78–80] Most cases have occurred following either lung resection for lung cancer or lung biopsy for diagnosis of IPF. The reported incidence ranges from 2% to 7%. The mechanism by which surgical manipulation of the lung could cause an exacerbation is currently speculative. Mortality associated with postoperative acute exacerbations is high, ranging from 50% to 100%. Steroids and other immunosuppressive agents are commonly initiated but there is no compelling evidence for efficacy. Lung transplantation may be an option in selected cases.

PHRENIC NERVE INJURY AND DIAPHRAGMATIC DYSFUNCTION

Phrenic nerve injury is a well-described complication of CABG. In the past, this complication arose chiefly from the use of iced saline slush placed in the pericardium for topical cooling of the heart. Thermal injury causes both demyelination and axonal degeneration of the nerve, with slowing of conduction and impaired activation of the diaphragm. The use of topical cooling techniques has fallen out of favor largely because of this potential complication. However, the phrenic nerves can also be injured by traction, ischemia, use of diathermy, or transection during sternal retraction and harvesting of the internal mammary arteries. Unilateral phrenic nerve injury, typically involving the left phrenic, has been reported in approximately 10% of patients undergoing CABG.[41,81] Bilateral phrenic nerve injury was reported to occur in 1% to 3% of cases in the era of widespread topical cardioplegia usage but is now a rare event. Phrenic nerve injury is not restricted to CABG but is also seen in association with other cardiac procedures, thoracic surgery, neck surgery, and liver transplantation.

Although typically inconsequential in the otherwise healthy patient, unilateral diaphragmatic paralysis can lead to significant respiratory compromise in patients with underlying chronic lung disease or those who are otherwise marginal. In patients with COPD, for example, the duration of postoperative mechanical ventilation and the rate of reintubation are higher for those with versus without unilateral phrenic nerve injury following CABG.[82] Bilateral diaphragmatic paralysis results in marked impairment in pulmonary function and frequently leads to respiratory failure. In the proper setting, phrenic nerve injury should be suspected when attempts to wean a postoperative patient from mechanical

ventilation result in progressive hypercapnia or atelectasis. The spontaneously breathing patient will often complain of orthopnea, which may be misinterpreted by the unsuspecting clinician as indicative of congestive heart failure. However, orthopnea is actually due to further impairment in diaphragmatic function resulting from loss of gravitational assistance in the supine position. The detection of inspiratory thoracoabdominal paradox – an inward movement of the abdominal wall with simultaneous expansion of the thorax – is an important bedside clue to the presence of bilateral diaphragmatic paralysis and is best evoked in the supine position. The chest radiograph may also hold important clues, demonstrating either unilateral or bilateral elevation of the diaphragms and accompanying basilar atelectasis. However, these findings are not specific for phrenic nerve injury and may also be due to splinting or abdominal distention. A reduced maximum inspiratory pressure recorded at the mouth is another sensitive but nonspecific indication of significant diaphragmatic dysfunction.

Unilateral diaphragmatic paralysis can be readily diagnosed by fluoroscopic inspection, which reveals paradoxical upward movement of the affected hemidiaphragm with a maximal inspiratory effort ("sniff"). The situation is more problematic with bilateral diaphragmatic dysfunction. In this setting, patients often assume an altered breathing pattern marked by active contraction of the abdominal muscles during expiration, forcing the flaccid hemidiaphragms upward. With subsequent inspiration, the abdominal muscles relax and the hemidiaphragms descend briefly, potentially creating the false impression that they are functional. Because of this, fluoroscopy may not be confirmatory in these patients. Ultrasound has emerged as a simple bedside test for assessing diaphragmatic function. Thickening of the diaphragm with inspiration reflects diaphragmatic shortening and failure to observe this sign is indicative of diaphragmatic paralysis. Ultrasound can thus be used to diagnose both unilateral and bilateral paralysis and can be performed serially to assess for recovery of function.[83]

The gold standard for confirmation of phrenic nerve injury is electrophysiological testing, although even this methodology is occasionally flawed. The phrenic nerve is stimulated transcutaneously in the neck, and the diaphragmatic electromyogram (EMG) is recorded by surface electrodes placed in the seventh intercostal space at the costochondral junction. Demonstration of a prolonged latency between nerve stimulation and diaphragmatic action potential confirms a diagnosis of demyelinating injury. It is more difficult to interpret the significance of diminished amplitude or complete absence of the surface recording of the diaphragmatic EMG. This finding could represent either phrenic nerve injury/transection or failure to properly localize the diaphragm, which is typically shifted caudally in the postoperative patient and, therefore, away from the surface electrodes. Direct puncture of the diaphragm with a recording electrode may be employed to clarify this issue, but the technique requires a high level of expertise and carries a risk of pneumothorax.

Nontraumatic causes of phrenic nerve injury and diaphragmatic dysfunction can also lead to prolonged respiratory failure and delayed weaning in the surgical patient. Phrenic neuropathy can be a component of a more generalized polyneuropathy of critical illness, commonly encountered in the wake of an episode of severe sepsis or systemic inflammatory response syndrome. A critical illness myopathy affecting the diaphragms and other muscles of respiration can be encountered under the same circumstances. Finally, diaphragmatic dysfunction can arise as a component of a myopathy induced by the concurrent use of high-dose systemic corticosteroids and neuromuscular blocking agents.

Patients with diaphragmatic dysfunction are generally well suited for noninvasive positive pressure ventilatory support if they are awake and able to effectively handle respiratory secretions. Tracheostomy is indicated for patients with ineffective cough and those who cannot be weaned from conventional mechanical ventilation. The prognosis for patients with thermal or traction injury of the phrenic nerve is favorable; recovery is typically complete, but often protracted. In symptomatic patients with unilateral diaphragmatic paralysis due to transection of the phrenic nerve, surgical placation of the flaccid hemidiaphragm may lead to improved pulmonary function and successful liberation from mechanical ventilation.[84]

PULMONARY EMBOLISM

An increased risk of PE accompanies a number of surgical procedures, including upper abdominal, neurosurgical, cardiac, major urological, and lower extremity orthopedic procedures. Other, nonsurgical risk factors that predispose the patient to PE may also be present, including obesity, immobility, and underlying malignancy.

While alterations in gas exchange typify PE, frank hypoxemic respiratory failure is relatively uncommon and suggests massive clot burden. Lesser degrees of clot burden may produce equally devastating physiological impairment in patients with underlying pulmonary disease. In the presence of severe hypoxemia, there is little remaining cardiopulmonary reserve. Failure to establish a correct diagnosis and to swiftly and appropriately intervene can prove lethal.

Unfortunately, little information pointing specifically to a diagnosis of PE is easily gleaned at the bedside. The patient is often dyspneic, and tachypnea and tachycardia are observed on physical examination. However, these features are common in many postoperative patients because of pain and atelectasis. More informative, but infrequently detected, is evidence of acute cor pulmonale: distended neck veins, a parasternal heave, right-sided third heart sound, and accentuation of the pulmonic component of the second heart sound. An electrocardiogram may also demonstrate evidence of right heart strain, with an "S1Q3T3" pattern or new right bundle branch block. The chest radiograph is most suggestive of PE when it is normal in the face of severe hypoxemia. When abnormal, the greatest utility of the chest radiograph is in identifying other causes of hypoxemia such as pneumonia, pneumothorax, or ARDS. Echocardiography is commonly performed in the setting of hypotension; evidence of a dilated right ventricle in the face of a normal or underfilled left ventricle should raise suspicion for massive PE.

CT angiography has emerged as the imaging procedure of choice, assuming the patient is sufficiently stable to be safely transported for the study. The accuracy of CT angiography in diagnosing acute PE was most comprehensively assessed in the Prospective Investigation of Pulmonary Embolism Diagnosis II (PIOPED II) trial.[85] The positive predictive values of this technique were documented to be 96% and 92% when coupled with a high or intermediate clinical suspicion for PE, respectively, as assessed by use of the Wells Score. Conversely, the negative predictive value was 96% when coupled with a low clinical suspicion. Notably, discordance of radiographic results with clinical assessment significantly compromised the performance of CT angiography. For example, 42% of CT angiography readings were falsely positive among patients with a low clinical probability of PE. Conventional pulmonary angiography represents an alternative diagnostic modality in situations where CT angiography is not definitive.

While anticoagulation with heparin forms the mainstay of therapy for the otherwise stable patient, the presence of life-threatening hypoxemia and/or hemodynamic instability should prompt consideration of alternative or additional interventions. Since additional clot burden could be fatal, insertion of an inferior vena cava filter is generally advised in this setting and should be considered mandatory when anticoagulation is contraindicated. Thrombolytic therapy should also be considered in the critically ill patient, but its use in the postoperative period is limited by the risk of precipitating bleeding at the site of recent surgery. This risk appears to fall to an acceptable level beyond the seventh postoperative day; the exception is intracranial surgery, which contraindicates use of lytic agents for at least

2 months. Several interventional radiological techniques – thrombus fragmentation, suction embolectomy, and intraembolic infusion of low-dose thrombolytics – as well as surgical embolectomy are alternative considerations in the deteriorating patient for whom systemic thrombolytics are either contraindicated or unsuccessful.

OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea (OSA) is highly prevalent within surgical populations, affecting approximately 25% of adults undergoing elective general surgical procedures,[86] over 30% of neurosurgical patients,[87] and greater than 70% of morbidly obese patients undergoing bariatric surgery.[88] It is characterized by repetitive upper airway obstruction during sleep, resulting in arterial desaturation, hypercapnia, and arrhythmias. The perioperative period is a particularly precarious time for patients with this disorder. Because of alterations in oropharyngeal anatomy that commonly accompany obesity and OSA, orotracheal intubation at the time of induction may be difficult. The use of anesthetics, opioids, and sedatives diminishes the activity of the upper airway dilator musculature and concurrently dampens respiratory arousal mechanisms that can terminate obstructive apneas. These effects lead to an increase in the frequency and duration of obstructive apneas that, in turn, can place the surgical patient at significant risk for serious respiratory complications. A recent meta-analysis demonstrated that the incidence of postoperative respiratory failure was significantly higher among patients with OSA compared to those without.[87] Similarly, analysis of a national database of approximately 6 million surgical patients demonstrated that OSA increased the risk of postoperative intubation and mechanical ventilation fivefold after orthopedic procedures and twofold after general surgical procedures.[89]

As many as 80% of patients with OSA are undiagnosed at the time of surgery.[86] Identification of high-risk candidates with OSA prior to surgery is thus an essential strategy in minimizing the adverse impact of OSA on postoperative outcomes. Several easily administered screening tools have been developed and validated that can be incorporated into the preoperative assessment of surgical candidates. For example, the STOP-Bang tool uses a self-administered four-item questionnaire in conjunction with assessment of four patient characteristics (Table 104-5). It has positive predictive and negative predictive values of 52% and 90%, respectively, in identifying surgical candidates with moderate-to-severe OSA (apnea–hypopnea index >15).[90]

TABLE 104-5 STOP-Bang Scoring Model for Preoperative Assessment of OSA Risk[a]

Snoring: Do you snore loudly?
Tired: Do you often feel tired, fatigued, or sleepy during daytime?
Observed: Has anyone observed you stop breathing during your sleep?
Pressure: Do you have or are you being treated for high blood pressure?
BMI: BMI more than 35?
Age: Age over 50 y?
Neck circumference: Neck circumference greater than 40 cm?
Gender: Male?

[a]*High risk of OSA, answering yes to three or more items. Low risk of OSA, answering yes to less than three items.*

A number of measures can be employed in an attempt to reduce the risk of serious pulmonary complications in surgical patients with OSA.[88] The anesthesiologist should be made aware of the potential for a difficult intubation and emergency airway devices should be readily available. Ideally, shorter acting anesthetic agents should be employed. Intraoperative use of opioids should be minimized; if deemed necessary, use of ultrashort-acting agents such as remifentanil is preferable. Extubation following completion of surgery should be carried out only after the patient is fully awake. Application of continuous positive airway pressure (CPAP) immediately after extubation should be considered, particularly if apneic episodes are noted in the recovery area. Nonopioid analgesics should be used in an attempt to avoid or minimize use of opioids in the postoperative period.

USE OF NONINVASIVE POSITIVE PRESSURE VENTILATION

For patients with respiratory failure refractory to conservative measures, endotracheal intubation is the standard means to facilitate mechanical ventilatory support. However, in recent years, a greater appreciation for the untoward effects of endotracheal intubation has emerged. In addition to airway trauma, these include an increased risk of nosocomial pneumonia and sinusitis and the frequent need for heavy sedation that, while addressing patient discomfort, often prolongs the process of weaning and extubation. The desire to avoid endotracheal intubation has prompted interest in the use of noninvasive positive pressure ventilation (NIPPV), employing a tight-fitting nasal or full face mask as the interface between patient and ventilator.

There is ample evidence supporting the benefits of NIPPV in the treatment of a variety of causes of respiratory failure in the medical patient but only recently have data emerged confirming its safety and efficacy in the postoperative setting. The most compelling study randomized patients with hypoxic respiratory failure following lung resection surgery to standard therapy (supplemental oxygen, bronchodilators, chest physiotherapy) with or without NIPPV. Compared to the control group, the use of NIPPV was associated with a marked reduction in the need for endotracheal intubation (20.8% vs. 50%) and in mortality at 3 months (12.5% vs. 37.5%).[91] While there has been a concern about using NIPPV following esophageal or gastric surgery, recent experience suggests that this can be accomplished safely.[92] In this setting, care must be taken to avoid gastric distention, using a nasogastric tube for decompression if necessary, and the magnitude of positive pressure ventilation employed should be limited to <20 cm H_2O. Since NIPPV often requires a period of acclimation, it should not be used in unstable patients. Other contraindications to its use include depressed or agitated mental status, inability to protect the airway, compromised airway clearance due to copious secretions or weak cough.

CHAPTER 105

Perioperative Care of the Patient Undergoing Lung Resection

Robert J. Cerfolio
Ayesha S. Bryant

The postoperative care of any patient who undergoes pulmonary resection starts long before the incision is made and comprises three main areas. The first is patient selection, the second is the actual operation itself, and the third is postoperative care. This chapter briefly reviews some of the specifics that go into these three areas. In addition, it discusses the incidence, prevention, and treatment of some of the most common postoperative problems that continue to vex thoracic surgeons around the world.

PATIENT SELECTION

Perhaps the best way to minimize postoperative complications is to operate only on young healthy patients. Unfortunately, thoracic surgeons, like most other surgeons, are now presented with older and sicker patients with increasing comorbidities. The median age of our society has increased and so has obesity and patients with chronic pain syndromes. We are increasingly challenged with larger tumors in older patients with smaller pulmonary reserve. As the bar for the upper age limit has been raised, the threshold for the acceptable FEV_1% and D_{LCO} % has fallen. Currently there are few, if any, absolute contraindications to pulmonary resection based on chronological age or pulmonary function.

MORBIDITY AND MORTALITY

During the perioperative period, many factors contribute to pulmonary compromise. Estimates of the overall surgical mortality for pulmonary resection range in large series from 2% to 4%. The estimated mortality increases with the size of the resection—from less than 1% for a wedge resection of the lung, to 2% to 3% for a lobectomy, and 6% to 8% for a pneumonectomy.

The morbidity associated with elective pulmonary resection is also high. Complications have been reported to occur in 36% to 75% of patients undergoing pneumonectomy and 41% to 50% of patients after lobectomy. Most complications are minor and include air leak, atrial fibrillation, and atelectasis. However, a significant number are major; these most commonly include pneumonia, aspiration, respiratory failure, myocardial infarction, bronchopleural fistula (BPF), and pulmonary embolus.

PREOPERATIVE ASSESSMENT AND OPTIMIZATION

Preoperative evaluation focuses on assessment of pulmonary function and its optimization, evaluation of cardiac status, and careful consideration of issues related to quality of life.

LUNG FUNCTION

Assessment of the patient's risk for pulmonary resection starts preoperatively in the clinic. One important but difficult factor to quantify is the patient's desire to undergo the work required to recuperate from a thoracic surgical procedure. The importance of walking and

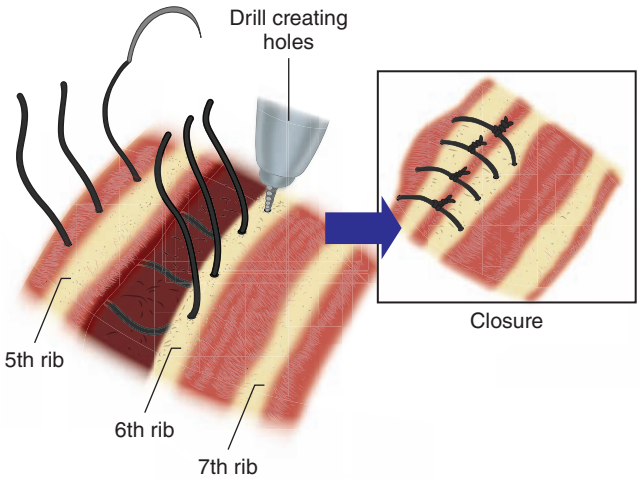

Figure 105-1 Drilling holes in the bottom rib, thus enabling sutures to be placed through it.

deep breathing after lung resection cannot be overstated. A study performed by the Lung Cancer Study Group suggested that the patient's attitude toward his or her malignancy was the best indicator of long-term survival.[1] A patient who appears to be unwilling to participate in his recovery should be allowed ample opportunity to explore reasonable alternative therapies, such as radiation. Moreover, if this attitude persists, it may be best not to operate at all.

A large number of studies have examined preoperative factors that predict postoperative risk to a patient. In a study of 476 patients operated on over 12 years, only 3 of 7 preoperative risk factors for morbidity and mortality were found to carry a significant association with mortality.[1] These risks were age older than 60 years, pneumonectomy, and the presence of ventricular premature contractions on the preoperative electrocardiogram. All risk factors analyzed together accounted for only 12% of the risk of mortality. At the time of the initial visit, an attempt to establish the amount and character of sputum production, the presence or absence of an effective cough, and a patient's ability to climb a flight of stairs of fixed height help provide an idea of a patient's ability to undergo surgery. Patients with preoperative arterial hypercapnia are apt to have pulmonary hypertension and are poor candidates for pneumonectomy, but they may be able to tolerate a lobectomy. Pulmonary function tests, in particular the FEV_1% and the D_{LCO} %, in combination with lobar perfusion scans, allow prediction of the postoperative predicted or postresectional FEV_1% (Fig. 105-1). A postresectional FEV_1% less than 40% of predicted is a cause for concern. A study of the D_{LCO} % in 165 patients who underwent lung resection identified it as the most important indicator of postoperative pulmonary complications or death.[2] Another study focused on the maximal oxygen consumption (MVO_2). An MVO_2 of 20 mL/kg/min was associated with the fewest chance of complications, whereas an MVO_2 less than 15 mL/kg/min was associated with a 75% postoperative morbidity rate.[3]

CARDIAC STRESS TEST

Since many patients are smokers and elderly, we prefer to perform a preoperative stress test in most patients prior to thoracotomy. Previously undiscovered or unsuspected coronary artery disease should be determined, anatomically identified, and corrected prior to elective thoracotomy.

QUALITY OF LIFE CONSIDERATIONS

Quality of life (QOL) is an important metric by which to assess all types of medical and surgical treatments. This is no different for patients who undergo pulmonary resection. In fact, QOL is becoming an increasingly important part of the preoperative conversation between patients and surgeons in planning out the procedure.[4] For this reason smaller resections such as segmentectomy are becoming more common especially for tumors that are less than 2 cm in size. Similarly, pneumonectomy is less commonly performed. Recently we evaluated the long-term QOL in 110 patients who underwent a pneumonectomy and found that their overall physical scores were quite low but their mental well-being scores were high.[5]

OPTIMIZATION OF PREOPERATIVE PULMONARY FUNCTION

A variety of medical therapies are designed to improve pulmonary function. Many patients who are to undergo elective pulmonary resection are current smokers. Optimization of pulmonary function begins first and foremost with smoking cessation. Even a short period of abstinence from cigarettes can improve the effectiveness of mucociliary transport. Heavy smokers also maintain high levels of carboxyhemoglobin that interfere with oxygen transport and delivery to peripheral tissues. However, the optimal time after smoking cessation for elective thoracotomy is still unknown. In patients with evidence of reversible airway obstruction on pulmonary function tests, or symptoms suggestive of airflow obstruction, nebulized albuterol appears to be of benefit. Mucostasis, if present, may warrant the addition of mucolytics such as N-acetylcysteine. However, this medication may also lead to certain side effects, such as increased mucus production and bronchoconstriction. Similarly, although the condition of patients with reversible airflow obstruction generally improves with corticosteroids, these agents should be added cautiously because of their adverse effects on wound healing and the increased risk of wound infection. If steroids are necessary, the dosage in the postoperative period should be minimized. Patients who produce purulent sputum should be treated with oral antibiotics directed at the organism identified and surgery delayed until the infection is eradicated.

PERIOPERATIVE FACTORS REDUCING CARDIOPULMONARY FUNCTION

Despite the wide variety of pathologies and types of operative procedures performed by thoracic surgeons, the postoperative course is often quite predictable. We have published the techniques and specific steps that enable patients to be "fast-tracked" after both elective pulmonary resection and esophageal resection.[6,7] These clinical pathways and/or computerized algorithms lead most importantly to safe results, high patient satisfaction, and only a 3- to 4-day length of stay after pulmonary resection. Early ambulation and aggressive pulmonary rehabilitation are cornerstones for successful fast-tracking. The physiological consequences of decreased activity and lack of changes in posture form a background for the pathophysiological processes caused by the underlying illness and the surgical procedure.

It is interesting that these changes might be less in patients with chronic pulmonary disease. Thus, in patients with chronic airflow obstruction, a decrease in FRC of only 3.5% accompanies a move from the upright to supine position and a decrease of only 1.9% accompanies the move from the supine to lateral decubitus position.[8] Finally, although arterial oxygen saturation decreases significantly in supine normal subjects, it does not do so in patients with significant airflow obstruction.

The degree to which the described changes affect gas exchange has been only partly studied. In normal young males after 10 days of bed rest, Pa_{O_2} decreased by 9 mm Hg and the alveolar–arterial difference in Po_2 by 10 mm Hg, without change in Pa_{CO_2}. Such changes, which would probably not be important in normal young people, might take on greater significance in a patient with chronic obstructive pulmonary disease (COPD).

BED REST AND CARDIAC FUNCTION

Upon standing, approximately 500 mL of blood shifts from the upper to the lower body. When lying down, the central venous

return increases, resulting in a decrease in heart rate, peripheral vasodilation, increased renal blood flow, and diuresis. Within an average of 24 hours the diuresis causes a 5% decrease in plasma volume, which continues to fall by 10% in 6 days and 20% in 14 days.

A wide variety of experimental subjects and protocols have been used to examine the cardiovascular effects of prolonged immobilization. Orthostatic intolerance is common after prolonged bed rest. This is attributable, at least in part, to the depletion in intravascular volume. This may be compounded by an increase in venous pooling in the lower extremities because of an increase in venous compliance after bed rest. Prolonged recumbency also blunts cardiac responsiveness to rapid changes in posture. Bed rest increases the resting heart rate by 4 to 15 beats per minute. After prolonged bed rest, the increase in heart rate during exercise is more pronounced. For example, normal volunteers experienced an increase in heart rate to approximately 129 beats per minute during submaximal exercise; after bed rest, the same exercise drove the heart rate to approximately 165 beats per minute.

■ ALTERATIONS IN LUNG FUNCTION SECONDARY TO SURGERY

In addition to the physiological consequences of inactivity described in the preceding section, the thoracic surgery patient also experiences major alterations in chest wall compliance. The pain and discomfort of deep breathing also lead to an increase in the work of breathing that is independent of the amount of resected lung. Manipulation of the lung and re-expansion of the lung lead to pulmonary "bruising." Microscopic or even macroscopic areas of atelectasis persist. Fluid or blood clots in the pleural cavity may compress the lung parenchyma. Inhalational anesthesia depresses mucociliary transport. Mechanical changes alter the work of breathing. Thoracotomy alone was found to decrease chest wall compliance to 47% of preoperative levels and to increase the work of breathing to 143% of preoperative levels.[9] As a result, vital capacity and oxygen saturation fall significantly in the first few postoperative days. Pain, among other factors, leads to diminished cough. Cough pressures were found to decrease to 29% of preoperative levels after surgery and to increase only to 50% of preoperative levels by the seventh postoperative day.

ROUTINE POSTOPERATIVE CARE

Routine post-operative care focuses on decisions regarding timing of extubation, use of supplemental oxygen, judicious use of antibiotics, and fluid and electrolyte management. Additionally, radiographic evaluation and decisions regarding use and removal of chest tubes are important considerations.

■ EXTUBATION AND POSTOPERATIVE SUPPLEMENTAL OXYGEN

Almost every patient undergoing lung resection should be extubated in the operating room and brought to the recovery room breathing spontaneously. Reintubation in the immediate postoperative period is rare. If prolonged intubation is anticipated, however, the double-lumen endotracheal tube should be replaced by a single-lumen endotracheal tube of sufficient size to permit the introduction of an adult bronchoscope. For extubation, standard criteria are followed: vital capacity more than 10 mL/kg, respiratory rate less than 30 breaths per minute, and acceptable arterial blood gases.

Supplemental oxygen is supplied in the postoperative period if the patient's arterial oxygen saturation, measured by pulse oximetry, is less than 90%, either at rest or during exercise. We prefer sending patients directly to the floor and have not used the intensive care unit after lobectomy for over a decade. Many centers have adopted a similar practice; however, patients must have 24-hour telemetry and pulse oximetry monitoring in these specialized units. Nurses need to have chest tube training. These types of floors allow the patient's family to stay in close proximity at all times. This offers significant psychological support to most patients; if the family is attentive and intelligent, they also can act as an invaluable part of the patient's care and add another level of patient protection.

■ PAIN CONTROL

Adequate pain control in the postoperative state is critically important. The choice of surgical procedure and analgesic strategy to be employed are discussed below.

Impact of Surgical Techniques on Postoperative Pain

A thoracotomy is a painful procedure, in part related to trauma and/or compression of the intercostal nerve. We have evaluated ways to reduce the pain of thoracotomy using prospective randomized studies. One study showed that drilling holes in the bottom rib, thus enabling sutures to be placed through it rather than around the ribs, helps avoid entrapment of the lower intercostal nerve (Fig. 105-1) and this simple technique reduces the pain compared with the standard pericostal sutures (Fig. 105-2).[10] Another study examined the use of an intercostal muscle flap.[11] This flap is harvested prior to rib retraction (Fig. 105-3) so as to avoid retractor injury to the intercostal nerve, which runs in the muscle flap. Both of these studies showed reduction in postoperative pain in the hospital and a lessening of a decrease in the tidal volume immediately postoperatively. In addition, there was less pain at 3 months, both early and up to 12 weeks postoperatively. Simple techniques such as these, as well as video-assisted procedures that help prevent or limit the amount of pain are important.

Postoperative pain is reduced through minimally invasive surgical approaches such as the use of video-assisted thoracoscopic surgery (VATS) and thoracic robotic surgery. Advantages of the robot in comparison to VATS include easier operations in the mediastinum, such as a thymectomy or a resection of an esophageal leiomyoma. Other potential advantages are improved lymph node resection and the dissection of enlarged or metastatic N1 lymph nodes off the pulmonary artery. However, there are significant limitations and concerns to the implementation of a robotic approach including the high cost, the lack of consistent platform availability, the lack of tactile feedback, the fact that several countries cannot afford the current robotic system, the need for the bedside assistant to fire the stapler on pulmonary vessels, and the lack of standardized credentials and training programs for the surgeons and technical assistants.

Analgesic Strategies

Postoperative pain that is not controlled early reduces the ability to breathe and cough and increases respiratory complications.

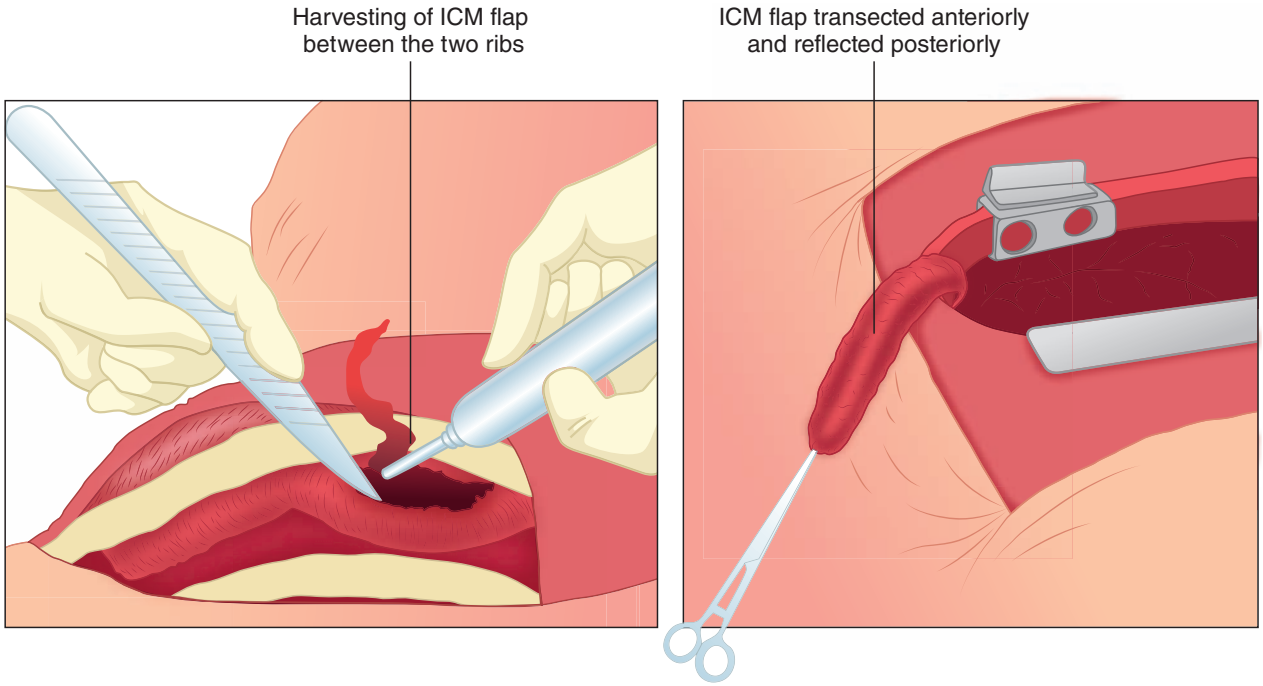

Figure 105-3 Muscle flap harvested prior to rib retraction.

Moreover, the best way to reduce late or chronic pain is to aggressively treat early pain. Most patients should receive a thoracic epidural prior to thoracotomy and/or a patient-controlled analgesic (PCA) intravenous device. Recently, some surgeons have tried subpleural catheter systems that infuse local anesthetics in the paravertebral area as well. The complications associated with epidural opiates are numerous and include pruritus, ileus, urinary retention, and respiratory depression. Epidural analgesia is most useful in the young patient with poor pulmonary function. We have avoided it in elderly patients, those who become somnolent, or those who have a rising carbon dioxide level on arterial blood gas. The use of nonsteroidal agents such as oral ketorolac in addition to narcotics is helpful as well and should be given immediately in the operating room and continued for a few days to help prevent pain. It should be avoided in those with marginal renal function. After postoperative day 2 or 3, the epidural should be removed and oral opioids should be added. Treating pain using a combination of different classes of agents is helpful.

■ ANTIBIOTICS

Wound infection following thoracotomy is rare. This may be due to the large amount of musculature contained in the chest wall. In addition, prophylactic antibiotics are often given in an attempt to reduce the incidence of wound infection. Currently, it is recommended that a broad-spectrum antibiotic, such as cefazolin, be administered within 1 hour of the skin incision. Subsequent antibiotic administration should be based on clinical factors such as fever, radiographic pulmonary infiltrates, leukocytosis, and sputum Gram stain and culture results. There is no need to provide antibiotic coverage simply because a chest tube is in place.

A study that examined the relationship between pulmonary flora and postoperative infections found that *Haemophilus influenzae* was the most common organism identified from sputum at the time of surgery and that the risk of pneumonia in culture-positive patients was 10-fold that of patients with culture-negative secretions.[12] However, the cultured organisms were sensitive to the antibiotic that was administered, suggesting that the administration of antibiotics may be less important than careful pulmonary toilet in preventing postoperative pneumonia.

■ FLUIDS, ELECTROLYTES, AND ORAL INTAKE

A routine lung resection is not associated with large fluid losses intraoperatively or sequestration of volume in the third space postoperatively. Most patients should leave the operating room relatively euvolemic. Administration of intravenous fluids consisting of 5% dextrose and 0.45% normal saline at 50 to 75 mL/h until the patient begins to take oral fluids is usually adequate to maintain intravascular fluid volume. Oral intake should be resumed as soon as the patient is able to take fluids by mouth, but strict aspiration precautions cannot be overemphasized. Urine output should be maintained at 0.5 to 1 mL/kg of body weight an hour to preserve renal function. Oliguria, which is often overtreated by surgical residents, should be tolerated in patients who have undergone elective pulmonary resection. Some surgeons practice aggressive diuresis with the goal of reducing secretions. However, it is not clear that a lower volume of thick, tenacious secretions is preferable to a higher volume of thin secretions that are more readily cleared. Ideally, diuresis should be guided by measurements of intravascular volume. Measurements of central venous pressure correlate poorly with intravascular volume. Many surgeons are reluctant to insert Swan–Ganz catheters into patients after lung resection, particularly after pneumonectomy, because of the possibility of disruption of a pulmonary artery closure. Even if a Swan–Ganz balloon-tipped catheter has been safely introduced into a patient postoperatively, the data should be interpreted with caution because the inflated balloon may have occluded a significant portion of the remaining pulmonary vascular bed, thereby artificially increasing right ventricular afterload and decreasing cardiac output. In our practice the measurement of central venous pressure is rarely if ever used and a Swan is reserved for a patient in the intensive care unit that is hypotensive, oliguric, and hypoxic.

Blood transfusion is not necessary unless the patient's hemodynamics and overall clinical scenario call for it. Some believe that a hematocrit less than 24% is an indication for transfusion, but we prefer to use the hemoglobin level, which is less affected by dilution. A decision should be made on each individual patient's situation and a knee-jerk reaction to any specific level should be avoided.

Transfusion of 250 mL of packed red blood cells increases the intravascular volume by 750 to 1000 mL, because of the movement of extravascular volume into the intravascular space due to plasma oncotic forces. The increase in intravascular volume may be more dangerous than low hemoglobin. Furthermore, the intraoperative administration of blood is probably immunosuppressive and may be associated with a decrease in frequency of 5-year disease-free intervals.

ROUTINE CHEST X-RAYS

We have studied the use of daily chest radiographs, which most surgeons perform to ensure the effective removal of air and fluid from the pleural space.[13] These films, which are labor intensive, costly, and wake the patient in the early morning hours, are not needed if the patient does not have an air leak or other clinical problems. If the postoperative chest roentgenogram in the recovery room after surgery has no significant pathology and the patient is not hypoxic, a daily chest X-ray is not needed. If a patient develops subcutaneous emphysema and hypoxemia and there is a pneumothorax, then suction should be added.

CHEST TUBES

Chest tubes are commonly placed after thoracotomy to drain blood, serum, and air from the pleural space. The ideal number, type, or size of a chest tube to place after elective pulmonary resection is controversial. There are little data to suggest that one practice is better than another; however, recently several prospective randomized studies have shown that one chest tube works as well as two.[14] After routine lobectomy we have changed our practice based on these studies and now only use one chest tube in patients who do not have a large untre atable air leak or a large fixed pleural space deficit after lobectomy. We use a 24-French soft catheter that is difficult to kink. The advantage of one tube is that it may cause less pain and morbidity, but this advantage is theoretical.

For resections other than pneumonectomy, chest tubes are removed when there is no air leak and fluid output has decreased. The maximum amount of drainage per day has not been studied. Many surgeon use less than 200 mL a day, but there are no data that higher volumes cannot be accepted. We currently remove tubes with 450 cc per day and this has been a safe cutoff value in more than 4000 thoracotomies. One needs to ensure there is no blood, chyle, or cerebrospinal fluid prior to removal of the tube. Removal is performed while the patient executes a Valsalva maneuver. Some argue that it may be best to remove the tube when the patient takes a deep breath out and holds it, as opposed to a deep breath in and holds it. An occlusive dressing is maintained over the site for 24 hours. Patients should be advised that it is not uncommon to have additional drainage after tube removal.

If the chest tube output in the first several hours after surgery is greater than 200 cc/h for more than a few hours or if clinically suspected, bleeding must be ruled out. Early surgical re-exploration, before the patient leaves the recovery room, is our preference if the patient's coagulogram (INR, PTT, and platelet count) is normal. Each individual patient's clinical scenario should be considered. Confirmation that the drainage is blood can be obtained by simple visual inspection of the effluent or, if needed, the effluent can be sent for a confirmatory hemoglobin and/or hematocrit level.

Postpneumonectomy space drainage is managed differently from postlobectomy drainage. After pneumonectomy, the position of the mediastinum is a major concern. Shift of the mediastinal structures either into the pneumonectomy cavity or toward the residual lung can lead to either hemodynamic or respiratory compromise. To allow "balancing" of the mediastinum after a pneumonectomy, most surgeons leave a single chest tube in the pleural cavity. This tube can be removed in the operating room after the patient has been returned to the supine position and is hemodynamically stable. We prefer to leave the tube in overnight attached to a special pneumonectomy-balanced drainage system. The tube can be removed the morning of postoperative day 1 if there is no bleeding.

COMPLICATIONS AFTER LUNG RESECTION

The spectrum of potential complications following lung resection is broad. Important examples are discussed below.

AIR LEAK

An alveolar pleural fistula (APF), more commonly known as an air leak, is probably the most common complication after elective pulmonary resection. It is defined as a communication between the pulmonary parenchyma distal to a segmental bronchus and the pleural space. Factors that increase the incidence of air leak include emphysema, steroids or other medical conditions that slow wound healing, bilobectomy compared with lobectomy, and poor chest tube placement. Operative techniques that help prevent air leaks include pleural tents, pericardial buttressed staple lines, fissure-less surgery, and checking for air leaks before closing.

Recently, a great deal of scientific research has been devoted to the best management of chest tubes after pulmonary resection. Until 1998 there were few if any objective data concerning the best setting (i.e., suction or water seal) for chest tubes after lung surgery and most practices were opinion driven rather than evidence based. We and others have studied this process using prospective randomized studies.[15–17] We have developed a classification system for air leaks so as to be able to study air leaks objectively with scientific rigor. The summary of our work is that we prefer to connect the tubes to suction for the night of surgery and then convert to water seal the next morning, especially in patients who have an air leak. If patients have no leak but have a pneumothorax, we prefer suction. In patients with an air leak, we prefer water seal unless there is a pneumothorax, in which case we prefer −10 cm H_2O of suction (instead of −20 cm H_2O). However, Brunelli, who has carefully and critically studied the problems of air leaks after the pulmonary resection process, prefers water seal during the day and some suction at night. Brunelli did not find a statistical advantage for water seal; however, he did identify a trend in patients who did not undergo pleural tenting favoring water seal over suction.[20] Marshall has corroborated our findings in a prospective randomized study of her own and found that air leaks are best treated by placing chest tubes on water seal instead of suction in the postoperative setting.[21] Thus, the best treatment of most air leaks appears to be water seal in most patients so long as they do not develop a pneumothorax or subcutaneous air on seal.

We have also studied the problem of air leaks in patients with a concomitant pneumothorax and found that the least amount of suction (usually −10 cm H_2O) needed to alleviate the pneumothorax or subcutaneous air is best. Other daily management techniques should include "stripping" the tubes in the attempt to remove clots, examining all connections to ensure their integrity, and maintaining appropriate water levels in all drainage bottles. If the leak continues after postoperative day 4, then the patient may be discharged home on a Heimlich valve or a similar device such as an Atrium Express (Atrium USA, Hudson, NH). The chest tube can be removed after 2 weeks even if the air leak remains. A discharge PA and lateral X-ray should be performed before leaving, which serves as an important baseline film for later comparisons.

Occasionally, massive subcutaneous emphysema may occur if either the loss of air from the lung into the pleural cavity exceeds the drainage capacities of the chest tube or the tube is positioned away from the site of the air leak (Fig. 105-4). The latter condition is much more common than the former. If this occurs, chest tubes should be examined for patency. Occasionally, a tube will be found to be clamped or twisted by the bed or IV pole, at the skin level or in the subcutaneous fat. If a tube is occluded because of a plug, the

Figure 105-4 Massive subcutaneous emphysema following a pulmonary resection.

tube should be stripped; if this fails to re-establish patency, the tube should be opened and suctioned, using sterile technique, with a nasotracheal suction catheter. Some surgeons irrigate an occluded tube with sterile saline, but because of the possibility of infectious contamination this should only be used as a last resort. If all methods fail to re-establish patency of a chest tube, the tube should be removed and a new one inserted.

Although uncomfortable and disfiguring, massive subcutaneous emphysema is rarely life threatening. However, two dangerous situations can arise. First, in patients with tracheostomies, the tube can be displaced into the subcutaneous tissues if the skin is elevated up and away from the tracheal opening. Second, circumferential massive lifting of the skin around the thorax can lead to restriction of normal outward excursions of the rib cage excursion, limiting tidal volume—as in the case of limitation imposed by circumferential eschar in a burn patient. Such emergency situations may require the placement of small skin incisions, usually in an infraclavicular location. This technique should be reserved for the scenario when the chest tube is in good position, on high (−40 cm H_2O) suction and patent, and the subcutaneous air is not decreasing.

Until recently air leaks have been reported using an analog system only. Recently a few companies have developed systems that quantify the air leaks digitally (in mL/min). Digital air leak meters allow clinicians to quantify the size of air leaks objectively. It almost eliminates the subjectivity to air leaks and may allow for more uniform chest tube management. This may shorten the length of stay as well as the number of patients that are discharged home with chest tubes. Some of the newer digital chest tube devices allow a recording of air leak history. Limitations include the high cost of these systems and training of the hospital personnel.[18,19]

■ HIGH-OUTPUT CHEST TUBE STATES (CHYLOTHORAX, SUBARACHNOID–PLEURAL FISTULA)

A chylothorax is diagnosed when milky white chylous drainage is observed from the chest tube in a patient after enteral intake. It consists of intestinal lymphatic fluid (lymphocytes, immunoglobulins, and enzymes) and fat (fat-soluble vitamins, chylomicrons, and triglycerides). Once the patient starts to eat, the diagnosis is obvious. However, the diagnosis should be suspected in a patient who is not eating, has a stable hemoglobin and hematocrit, and whose chest tube output is high but the cause is unexplained. The diagnosis is made by sending the effluent for analysis. A triglyceride level greater than 110 mg/dL or a positive Sudan fat stain helps secure the diagnosis, with the caveat that these studies can be negative if the patient is not eating. The incidence of a chylothorax has been reported to be about 1% to 2.4% after lobectomy, and 0.7% to 1% after pneumonectomy.

The treatment of a chylothorax depends on the level of the injury. Most commonly after pulmonary resection, a chylothorax occurs from engorged lymphatics in patients with positive mediastinal (N2) nodal disease who have undergone an aggressive nodal dissection. It is also seen in patients who have received neoadjuvant therapy for N2 nodal disease and have undergone a complete thoracic lymphadenectomy. The best treatment for most patients is to make them NPO and ensure the chest tube volume decreases. A medium-chain triglyceride (MCT) diet should then be instituted as well. In this situation reoperation is less helpful, even if fibrin glue is applied to the draining nodal basins, because the lymphatic channels are engorged with obstructed lymphatics from cancer. Radiation has been used successfully in this situation. The patient may be discharged home with the tube in place on the MCT diet for 2 weeks. Finally, we challenge the patient with fatty meals for 2 days. If chest tube output is decreased, the chest tube is removed. However, if the output volume remains high despite compliance on an MCT diet, then complete cessation of all oral intake is needed and total parental nutrient is required. Nutritional parameters should be tested and the white blood cell count monitored. Persistent chylothorax can lead to neutropenia, infection, and malnutrition. Surgical intervention is rarely needed.[20] Less frequently, a chylothorax following pulmonary resection occurs due to injury to the main thoracic duct. If there is an injury to the main thoracic duct (best determined from a lymphangiogram), then early reoperation with duct ligation and pleurodesis is best. Alternatively, percutaneous thoracic duct embolization performed by an interventional radiologist has been successful in addressing postoperative chylous effusions.

Subarachnoid–pleural fistulas are an unusual cause of high-output chest tube drainage. The incidence of a subarachnoid–pleural fistula after thoracic surgery is very low, but several cases have been reported. They occur most often after trauma but may also complicate thoracic surgical procedures if dissection in the costovertebral angle or excessive traction avulses a thoracic nerve root from its dural sleeve. The most common setting for this to occur is during resection of malignancies invading either the posterior chest wall or vertebral column. However, retraction of the ribs for exposure during a standard posterolateral thoracotomy may generate sufficient traction to avulse a nerve root. The presence of a communication between the subarachnoid and pleural spaces allows for the bidirectional movement of cerebrospinal fluid and pleural fluid: During inspiration, low intrathoracic pressure draws cerebrospinal fluid into the thorax; during expiration, the elevated thoracic pressure forces air and potentially contaminated material outward into the subarachnoid space. A chest tube placed next to the fistulous tract may increase loss of cerebrospinal fluid. As a result, patients may develop headaches, meningismus, paresis, seizures, hemorrhagic infarcts, and obtundation leading to death. Cerebrospinal fluid analysis may be bizarre, owing to the entry of serosanguineous fluid into the subarachnoid space.

The diagnosis of a communication between the subarachnoid and pleural spaces is suggested by visualization of a pneumocephalus on skull radiographs. More specifically, the fistulous communication may be delineated by contrast CT myelography. The time between thoracotomy and clinical diagnosis of the fistula ranges from 5 to 8 weeks. The unpredictable nature of the neurological sequelae mandates that surgical closure of the dura be carried out as soon as the diagnosis is confirmed via reoperation and application of glues and a muscle flap.

ATRIAL FIBRILLATION

Atrial fibrillation is another very common complication after pulmonary resection. The incidence varies due to inconsistent definitions. Its incidence ranged from 12% to 20% in several large series, with over 500 patients each, with a peak onset on postoperative day 2.

Risk factors for postoperative atrial fibrillation include advanced age (greatest for those older than 70 years old), amount of lung resected, clamshell incision, and history of congestive heart failure. The incidence is also dependent on the extent of pulmonary resection performed. Other identified risk factors for the development of postoperative atrial fibrillation include male gender, previous cardiac arrhythmia, and intraoperative blood transfusions.

The ideal treatment of atrial fibrillation is prevention. A prospective randomized trial from Sloan Kettering showed that prophylactic diltiazem reduced the overall incidence of atrial fibrillation after standard and intrapericardial pneumonectomy.[21] The treatment of postoperative atrial fibrillation depends on the patient's ventricular rate and hemodynamic status. If the patient is unstable, electrical cardioversion may be needed. However, the vast majority of patients are hemodynamically stable despite a rapid ventricular rate. These patients are best treated with a calcium channel blocker or beta blocker. Often a drip can be used while the blood pressure is carefully monitored. The use of digitalis has fallen out of favor, but this safe and time-tested drug slows the ventricular rate, although it may not restore normal sinus rhythm. More recently, amiodarone has been shown to be effective in the treatment of supraventricular arrhythmias; it is safe even in elderly patients and often restores normal sinus rhythm.

ATELECTASIS

Atelectasis is a common complication after pulmonary surgery. Fortunately, most atelectasis is plate-like, discoid, or linear and is subsegmental and has little clinical consequence in the patient with adequate pulmonary reserve. However, atelectasis that is segmental or greater may cause clinical deterioration and may require bronchoscopy. Risk factors for this type of atelectasis are poor cough, impaired pulmonary function, inadequate pain control, diaphragmatic dysfunction, chest wall instability, and sleeve resection. The clinical sequela of this type of atelectasis is ventilation–perfusion mismatch that leads to hypoxemia, impaired alveolar macrophage function, and often pneumonia.

Again, prevention is the best treatment. Chest physiotherapy with vibratory percussion, incentive spirometry, ambulation at least three to four times daily, and secretion control is the mainstay of prevention. Ambulation redirects pulmonary blood flow and helps improve areas of ventilation–perfusion mismatch. Respiratory treatments entail nebulized bronchodilators and chest percussion with postural drainage. Pain control allows for deep cough and facilitates adequate mobilization of secretions.

PNEUMONIA

Pneumonia remains a vexing problem following pulmonary resection. Although the incidence at our institution has been reported to be as low (2.2%) in one series, we have also seen much higher rates (7%–9%) reported in other series. When pneumonia occurs, it wreaks significant morbidity. Risk factors include longer preoperative hospital stay, immunocompromised state, procedure type (pneumonectomy > lobectomy), compromised pulmonary reserve, smoking, and atelectasis.

With the development of fever and a new infiltrate on chest X-ray, sputum cultures should be obtained and broad-spectrum antibiotics started. Although Tobin and Grenvik[22] showed that up to 30% of new infiltrates in the intensive care unit prove not to be pneumonia, a missed pneumonia in a postoperative patient has high morbidity. Once the culture results are available with a sensitivity panel, the antibiotics should be narrowed to treat the offending organism. Often there is no evidence of an infiltrate but the patient develops a productive cough, fever, and/or elevated white count. Since the radiological findings of an infiltrate often lag behind a clinical pneumonia, especially in the dehydrated patient, broad-spectrum antibiotics should be started. If all the cultures are negative, then the antibiotics can be stopped. However, if an infiltrate develops or worsens or if the patient's clinical course deteriorates, consideration should be given to performance of bronchoalveolar lavage to help identify the pathogen and direct antibiotic coverage.

POSTOPERATIVE SOMNOLENCE FROM EPIDURAL ANALGESIA

Epidural analgesia has been one of the most important advances in general thoracic surgery in the last several decades. It reduces respiratory complications by allowing patients to breathe deeper, walk sooner, and better mobilize secretions.

While beneficial, epidural analgesia is associated with a number of complications, including accidental entry into the subarachnoid space, hematoma, urinary retention, itching, nausea, and respiratory depression. A "wet tap" can occur when the needle or catheter accidentally enters the subarachnoid space. The former should be immediately recognized by the one placing the epidural. The latter is recognized when the test dose given after insertion results in numbness in the chest area. The most significant and common complication from epidural analgesia is the over-narcotized patient. This is not uncommon and needs to be swiftly recognized and treated. New-onset somnolence may have several etiologies (stoke, intracranial abnormalities, electrolyte imbalances, sundowning, etc.); however, the epidural should not be overlooked as a potential cause. Often, a patient's family members aggressively deliver the analgesia. Clinical staff should discourage this practice. If the patient cannot deliver his or her own pain medicines or does not understand how to use the machine, he or she is a poor candidate for PCA units and should not have one. In this case, traditional pain medicines should be delivered by the nursing staff.

If the patient is somnolent from excessive narcotic analgesia, we prefer to arouse her or him with external stimuli. A chest rub or aggressive bedside maneuvers can quickly wake a patient up, and this helps establish the diagnosis and can eliminate other potential causes. A reliable calm family member in the room can also be helpful, and often one-on-one nursing may be needed. If external stimulation fails, if the patient's oxygen saturations remain low or an arterial blood gas continues to show hypercapnia despite aggressive pulmonary toilet and incentive spirometry, then we prefer to give one-fourth amp of intravenous naloxone. A higher dose can result in too much rebound pain. If the patient does not awaken after this, a higher dose can be administered after other causes of the new-onset somnolence have been ruled out. This patient is best transferred to the intensive care unit. If the patient arouses with naloxone, the epidural basal rate should be eliminated and/or the catheter removed, depending on the situation and postoperative day.

ASPIRATION

Aspiration is a devastating complication after thoracic surgery. The incidence is often underestimated because pneumonia may be caused by silent (unsuspected) aspiration. Risk factors for an acute aspiration event include age (the incidence is greater in elderly patients), altered mental status, and weak and/or somnolent patients. It can also occur in a healthy patient who is preparing to go home following an uncomplicated postoperative course. In its most full-blown form, it can lead to sepsis syndrome, multiorgan

system failure, and death. Therefore, one's guard against aspiration can never be lowered; its occurrence must be aggressively avoided. Patients should be instructed to eat only when fully awake and sitting upright at 90 degrees in bed or a chair. Family members should be discouraged from "helping feed the patient to get him or her stronger," especially if the patient is sleepy.

Once aspiration occurs, patients quickly desaturate. Continuous pulse oximetry monitoring until discharge helps signal this event and leads to a quick diagnosis. The diagnosis can be made by history if the patient is still alert or by a family member if he or she was present at the time of the aspiration event. Treatment depends on the patient's clinical status. Most patients should have a nasogastric tube placed, a chest radiograph taken, an arterial blood gas drawn, and other laboratory work performed. If the patient is in extreme respiratory distress, immediate intubation should be performed. Broad-spectrum antibiotics should be employed if aspiration pneumonia rather than pneumonitis is suspected, hemodynamics maximized to help perfuse and protect end-organs, and the patient should be transferred to the intensive care unit.

PULMONARY EDEMA

Patients undergoing thoracic surgery do not typically require aggressive intravenous fluid resuscitation that many other postsurgical patients need. Pulmonary surgery does not cause large fluid shifts, as does intraperitoneal surgery. Moreover, expansion and deflation of the lung secondary to double-lumen tube anesthesia, intraoperative barotrauma and volutrauma to the alveoli, and surgical manipulation of the lung all lead to pulmonary damage and edema. Therefore, the guiding standard to treat pulmonary edema is the principle of prevention. The true incidence is difficult to gauge because of the different etiologies and definitions. The tendency to give the patient large volumes of fluids after the epidural placement because of hypotension from the sympathectomy effect must be avoided. This difficult task is only accomplished by continued communication among the surgeons; the rest of the surgical service; and the pain and anesthesia nurses and residents who continually rotate through these services. We prefer the use of alpha agonists such as phenylephrine if mean arterial blood pressure falls after epidural dosing in the patient who is to undergo pulmonary resection after one 250-cc bolus of fluids.

However, despite "running the patient dry," some patients still develop pulmonary edema. Obviously, one needs to ensure that the cause is not cardiac insufficiency. Diuretics remain the mainstay of treatment. Other factors that need to be considered include the patient's weight gain since surgery, the chloride level, and the urinary osmolarity if diuretics have not been given yet. The more commonly used central venous pressure and/or pulmonary capillary pressure are not needed in most patients unless they are "wet" on chest roentgenogram, hypoxic, hypotensive, and oliguric. If the patient continues to deteriorate, echocardiography should be performed to assess both right and left ventricular function and the patient should be transferred to the intensive care unit for placement of a Swan–Ganz catheter. Blood cultures and appropriate scans should be performed to rule out occult infection and noncardiogenic pulmonary edema from sepsis. If high-dose diuretics are not successful, the patient may have acute respiratory distress syndrome. Management of this complication is discussed elsewhere in this volume.

RIGHT VENTRICULAR FAILURE

Some patients with postoperative complications after lung resection experience an acute worsening of pulmonary arterial hypertension that leads to right ventricular failure and a decrease in cardiac output. Several reports suggest this possibility. One study, based on the use of thermodilution catheters, found that the right ventricular end-diastolic volume increased from 153 to 177 mL, and that the right ventricular ejection fraction decreased from 45% to 36% in the first few postoperative days.[23] Another, using echocardiography, found that patients who developed supraventricular arrhythmias after lung resection had a significant increase in the velocity of the tricuspid regurgitant jet, whereas those who underwent lung resection without arrhythmias did not.[24] A third study of patients undergoing pneumonectomy was unable to find any hemodynamic variable or pulmonary function test that augured early morbidity.[25] It did, however, indicate that a right ventricular ejection fraction of less than 35%, pulmonary vascular resistance greater than 200 dyne s/cm^5, and a pulmonary vascular resistance/right ventricular ejection fraction ratio equal to or greater than 5.0 indicated long-term cardiopulmonary disability. No studies have been reported of patients suffering severe complications, such as pneumonia, in the remaining lung after pneumonectomy to determine whether right ventricular failure is a component of cardiopulmonary dysfunction.

A better understanding of the alterations in right ventricular function might lead to modification in patient management. For example, the anesthetic technique might be altered. In a recent study concerning ventilation of one lung, the administration of propofol was associated with sustained decrease in right ventricular ejection fraction and mean cardiac output as compared with the administration of isoflurane.[26] The use of proper anesthetic agents might minimize the additive effects of hypoxic pulmonary vasoconstriction and surgical resection of the pulmonary vascular bed. In principle, numerous therapies are available to lessen the burden on the right ventricle in the postoperative period. Among the agents proposed are nitric oxide, adenosine, calcium channel blockers, dopamine, and mechanical devices. However, none of these has yet been put to the test.

EARLY BRONCHOPLEURAL FISTULA

BPF is defined as a communication between a lobar or segmental pulmonary bronchus and the pleural space. It is different from an APF. This difference is not just one of semantics, but also centers around treatment since an APF almost never requires a reoperation, whereas a BPF almost always does. A BPF can present as an early complication but more commonly is a late one. The incidence of a BPF has been reported to be 4.5% to 7% after a pneumonectomy (8.6% if right pneumonectomy and 2.3% if left pneumonectomy), about 1% after a lobectomy, and 0.3% after a segmentectomy.[27] However, a BPF after lobectomy that was performed for cancer is very rare. Risk factors for a BPF are divided into patient characteristics and intraoperative techniques. The former include infectious etiology, preoperative radiation, type of procedure (right pneumonectomies have the greatest incidence), immunocompromised state such as history of solid-organ transplant, and comorbidities such as diabetes. Intraoperative technique risk factors include surgeon inexperience, a long stump, leaving lymph nodes on the bronchus, and injuring the arterial blood supply to the bronchus.

When a BPF presents as an early complication, it is signaled by the development of a new large air leak.[28] It usually is a continuous leak as described by the RDC classification system of air leaks.[29] Immediate recognition is essential and requires a high index of suspicion any time the air leak suddenly increases. Usually the diagnosis can be confirmed with bronchoscopy; however, this test can be falsely negative, as a small BPF can be missed. If the diagnosis remains in question, a xenon ventilation scan can be performed, though this is difficult if the patient is intubated. The xenon gas can be seen escaping the airway, traversing the pleural space, and going into the chest tube and drainage system. This secures the diagnosis. Once diagnosed, the BPF should be treated with reoperation using muscle flaps or omentum.

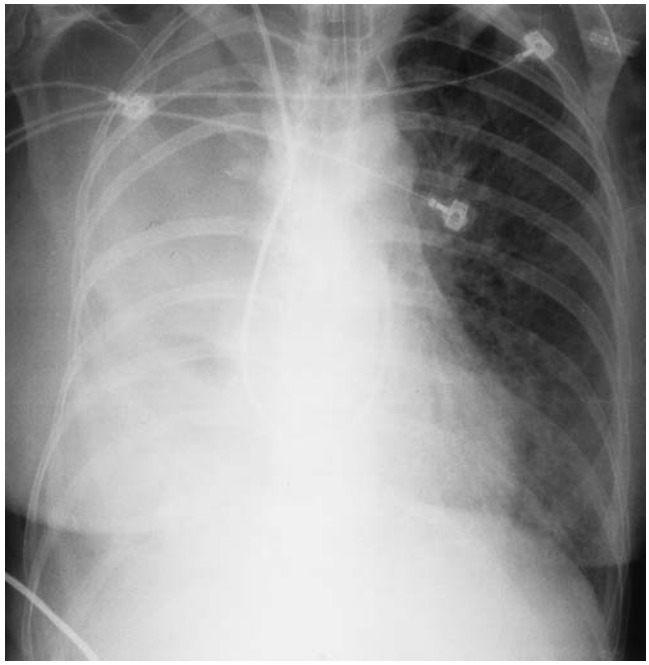

Figure 105-5 Postpneumonectomy pulmonary edema with onset 48 hours after extrapleural pneumonectomy. There is a diffuse interstitial infiltrate present that was heralded by the insidious development of hypoxemia in this otherwise healthy 60-year-old woman.

Figure 105-6 Marked shift of the mediastinum with hyperinflation of the left lung and tethering of the left mainstem bronchus over the vertebral column, characteristic of postpneumonectomy syndrome.

■ POSTPNEUMONECTOMY PULMONARY EDEMA

Postpneumonectomy pulmonary edema is a rare but potentially lethal complication of pneumonectomy. For several reasons, the patient who has undergone pneumonectomy is thought to be at increased risk of pulmonary edema. First, although the removal of one lung is well tolerated if the pulmonary vasculature is normal, if pre-existing pulmonary vascular disease is present, the reduced pulmonary vascular bed may be unable to accommodate the cardiac output without an inordinate increase in pulmonary arterial pressure. Second, disruption of lymphatics associated with mediastinal lymph node dissection may interfere significantly with the clearance of fluid from the lung. In the presence of these two predisposing factors, overzealous administration of fluid may lead to the formation of lethal pulmonary edema.

The clinical presentation of postpneumonectomy pulmonary edema is that of a relatively uneventful initial 24- to 48-hour postoperative period, followed by a relentlessly increasing need for respiratory support, usually culminating in death within 24 to 48 hours. The pulmonary edema progresses despite aggressive efforts to effect diuresis and other supportive measures (Fig. 105-5). Current therapy is directed at limiting the administration of fluids perioperatively and providing supportive measures if the complication should arise.

■ POSTPNEUMONECTOMY SYNDROME

Postpneumonectomy syndrome is a rare complication manifested by cough and dyspnea on exertion that usually follows right pneumonectomy. It is due to progressive mediastinal shift with compression of the left mainstem bronchus by the vertebral column. The underlying cause of this complication of pneumonectomy is herniation of the contralateral lung into the vacant pleural space, causing compression of the mainstem bronchus between the aorta, pulmonary artery, or vertebral column (Fig. 105-6). Repair is directed toward repositioning and stabilizing the mediastinum in the midline by a combined procedure of cardiopexy and placement of pliable, variable-volume tissue expanders into the empty pleural space. Cardiopexy alone probably provides insufficient protection against recurrence. Before surgical repositioning, it can be difficult to assess whether significant tracheomalacia is present in the compressed segment. Persistent airway narrowing and symptoms of obstruction following correction of mediastinal shift may require placement of an airway stent or reoperation for resection of the affected bronchial segment. Some surgeons have had success with minimally invasive repair of postpneumonectomy syndrome.[30]

■ EMPYEMA

Empyema is an uncommon complication after pulmonary resection; however, when it occurs, it is associated with high morbidity. It is most often seen in patients who have undergone pneumonectomy. It is estimated to occur in about 2% to 16% of postpneumonectomy patients. In a study by Varela et al.,[31] empyema was the most common cause of readmission after pulmonary resection, involving 18 of 727 patients (2.5%). The primary risk factor has been cited to be pneumonectomy with an associated BPF. Less commonly cited risk factors include anatomic extent of disease (no association with stage I cancer, some association with stages II and III cancer), degree of surgical manipulation, and an immunocompromised host.

The treatment centers on drainage of the pleural space. This can be established by chest tube placement, video-assisted thoracoscopic approach, or most commonly a redo thoracotomy with a muscle flap. If there is any question that an early BPF is the cause of the early empyema, then redo thoracotomy with muscle or omental harvesting is mandatory to not only drain the empyema and decorticate the lung, but to also buttress the open bronchus.

POSTOPERATIVE RESPIRATORY FAILURE

Despite preoperative tests and pulmonary preserving techniques, respiratory failure can still occur after pulmonary resection. The inability to extubate a patient immediately after the operation (which should be extremely rare) is a poor prognostic sign. The difficulty usually arises on postoperative day 2 or 3 secondary to pneumonia, poor cough effort, or pulmonary edema. The patient often begins to develop signs of respiratory distress even before an opacity appears on the chest radiograph. Sputum cultures should be obtained and broad-spectrum antibiotics should be started immediately. These should be tailored to the particular sensitivities of the organism reported later. Pulmonary mechanics must be maximized; this includes minimal intravenous fluids, aggressive chest physiotherapy, continuous respiratory treatments with bronchodilators, incentive spirometry, frequent ambulation with physical therapy, control of secretions, and nutritional support. If the patient cannot clear his or her own secretions, then nasal tracheal suction should be used to "encourage" coughing. Nasal tracheal suctioning via a nasal trumpet or even minitracheostomy affords the surgeon other methods to help clear the airway and avoid recurrent atelectasis and pneumonia. If the patient is somnolent, she or he needs to be aroused and treated as described in the preceding section "Postoperative solnolence from epidural analgesia". Arterial blood gases should be performed to rule out hypercapnia.

RENAL INSUFFICIENCY

It is not uncommon for patients to have an increase in their creatinine level after pulmonary resection. Most patients are elderly and thus have reduced renal reserve, and many are hypotensive due to effects of the epidural and the low amount of fluids administered. Thus, early recognition of this problem entails checking the creatinine level in all patients who produce less than 0.5 mg/kg per hour of urine. Treatment is early recognition, the removal of renal toxic agents, and the gentle rehydration of the patient.

POSTOPERATIVE HEMORRHAGE

The incidence of postoperative hemorrhage after elective general thoracic surgical procedures in a noncoagulopathic patient is extremely low. In our experience, re-exploration for bleeding occurred in 7 patients in our last 2400 thoracotomies (0.3%). In all cases, bleeding was from a small vessel (or the bronchial artery in one patient). The pulmonary artery should be handled with meticulous care, and it should be carefully dissected. We prefer double ligation or stapling. The vein can be safely handled with a stapler as well. Prior to chest closure, the major vascular structures in addition to all other sites of surgical dissection should also be re-examined to ensure hemostasis. The inferior pulmonary ligament, which usually contains a small artery, should be checked. We perform a complete lymph node resection in all patients with bronchogenic carcinoma; therefore, all lymph node stations are potential sites of postoperative bleeding. This is especially true of the #7, subcarinal area. There is a large artery that feeds the subcarinal lymph nodes that comes off the carina. It should be visualized and ligated. This is often difficult to do, especially on the left side. Excessive cauterization should be avoided, especially in the aorta–pulmonary window lymph node area on the left and the paratracheal area on the right, to avoid injury to the recurrent laryngeal nerves. Bleeding can also occur from the pulmonary parenchyma, especially after wedge resection. This area needs to be re-evaluated prior to chest closure. The surface of the undercut rib both anteriorly and posteriorly should be carefully examined also. Finally, the chest tube sites and pericostal sutures sites (if used instead of the preferred intracostal sutures) should be examined from inside the chest before closure. The branches of the bronchial artery that can spasm and later bleed should be identified and clipped or tied if dissected.

If a patient is having excessive postoperative bleeding of greater than 200 cc/h (i.e., blood loss alone; not chyle, cerebrospinal fluid, or transudative effusion) for 2 to 4 consecutive hours, INR, PTT, and platelet count should be checked. Any abnormalities should be corrected. If the mediastinum and/or pleural space do not have retained clots, and the coagulogram is abnormal, reoperation can be avoided if the underlying problem is corrected and the bleeding slows down. However, if there is residual clot in either space, this often leads to a local consumptive coagulopathy and the patient will continue to hemorrhage until the clot is fully evacuated, either via the chest tubes or usually by reoperation.

PULMONARY TORSION

During a pulmonary resection, an extensive dissection is usually performed around the hilum for division of the pulmonary vessels. In addition, after an upper lobectomy, the inferior pulmonary ligament is divided to allow the lower lobe to rise within the pleural space to obliterate the residual apical space and to remove the #9 inferior pulmonary ligament lymph node. Unfortunately, on rare occasions the increased mobility of these structures can lead to torsion of all or part of the residual lung, causing venous outflow obstruction and, possibly pulmonary gangrene. The right middle lobe is at greatest risk, especially after a right upper lobectomy, since the right middle lobe fissure-like connection to the right lower lobe is often diminutive. This complication is preventable by the surgeon. Some prefer to prevent it by tacking the middle to the lower lobe before closing the chest. However, we simply ensure that the right middle lobe inflates correctly without a twist after a right upper lobectomy has been performed and before closing the chest. We watch the middle and lower lobe inflated with the robotic camera, VATS camera, or under direct vision if a thoracotomy has been performed. However, it can still occur and any portion of residual lung can be affected (Fig. 105-7).

Pulmonary torsion may be suggested by the radiographic finding of consolidated lung, in association with fever, leukocytosis,

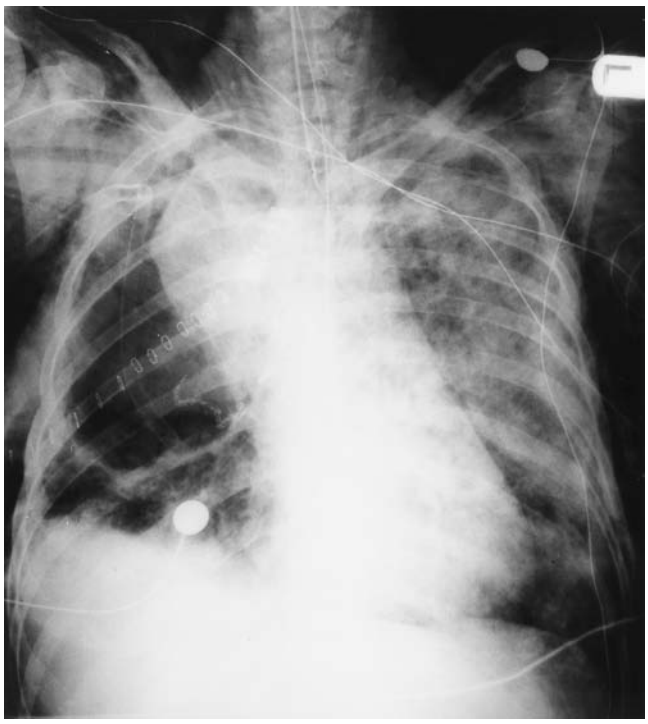

Figure 105-7 Consolidation of the right middle lobe caused by torsion following right upper lobectomy.

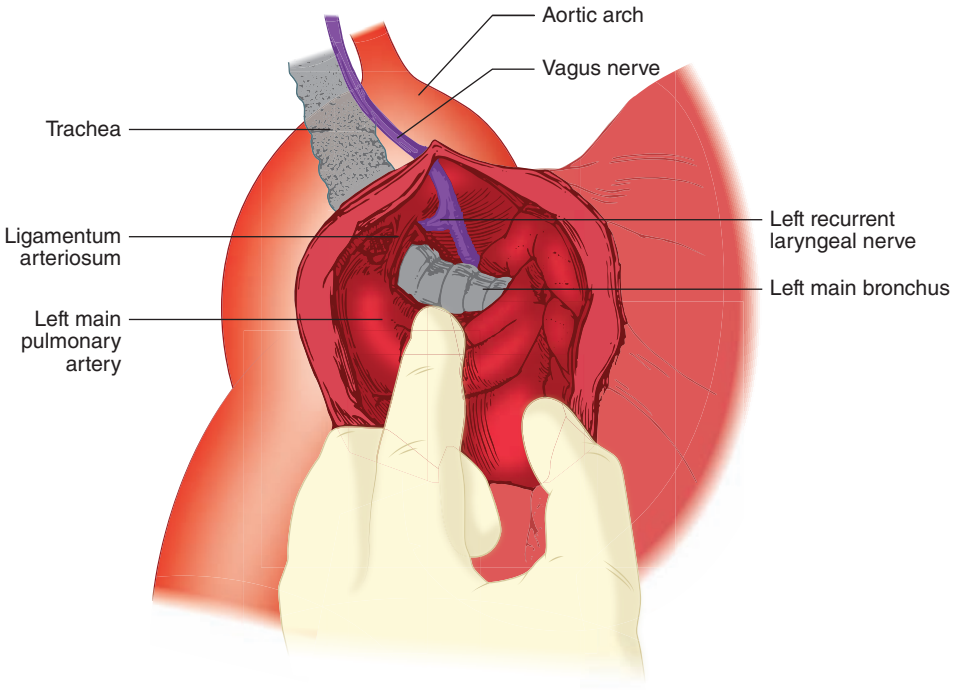

Figure 105-8 Location of the left recurrent laryngeal nerve as it takes its origin from the vagus nerve at the level of the aortic arch. Note its position relative to the ligamentum arteriosum.

and purulent, occasionally bloody, sputum. Bronchoscopy may be helpful if a twisted bronchus can be demonstrated. The treatment is immediate surgical exploration with rerotation of the affected lung, followed by fixation to surrounding structures. If the lung is not viable, lobectomy or complete pneumonectomy may be required. Sometimes if caught early, a bronchoscope can be used to untwist the right middle lobe bronchus and prevent the need for re-exploration, but this is uncommon.

RECURRENT LARYNGEAL NERVE INJURY

In a patient with lung cancer, the recurrent laryngeal nerves are vulnerable to injury because of either direct invasion by malignancy or injury during surgical dissection. The left vagus nerve is at greater risk than the right because of its course from the neck down into the left aspect of the mediastinum and across the aortic arch before giving off the left recurrent laryngeal nerve at the level of the inferior border of the aortic arch (Fig. 105-8). The nerve passes around the ligamentum arteriosum and "recurs" along the left tracheoesophageal groove. If either nerve is injured, unilateral vocal cord dysfunction results in hoarseness, an increased risk of aspiration, and marked decrease in the effectiveness of cough and the ability to clear secretions. Neurapraxia may resolve within weeks or last for 6 to 9 months. For the patient with limited pulmonary reserve who has undergone surgery with its attendant postoperative transient decrease in pulmonary function, vocal cord paralysis can be a devastating problem and may mean the difference between recovery and respiratory failure secondary to aspiration.

Surgical correction of unilateral vocal cord paralysis is becoming increasingly popular. Techniques include injection of Gelfoam for temporary medialization, Teflon for permanent medialization, or surgical placement of a hand-crafted silicone elastomer implant. The success rate, as measured by symptomatic improvement in dysphonia, aspiration, or incidence of pneumonia, exceeds 90%.

PULMONARY HERNIATION

Herniation of the lung outside of the chest is uncommon but can occur in immunocompromised thin patients. The patient complains of a bulge with coughing or sneezing and a CT scan demonstrates the pulmonary parenchyma in an extrathoracic position. Treatment is surgical reclosure and approximation of the ribs.

CONCLUSION

The key to the management of postoperative complications is thoughtful patient selection and meticulous intraoperative technique. Despite these caveats and hypervigilant postoperative care, many of the complications described earlier occur. Complications are a part of surgery. A full understanding of the cardiopulmonary physiological changes that occur after pulmonary resection, either after thoracotomy, video-assisted thoracoscopy, or a completely portal robotic approach is required for the proper management of complications. Early recognition secondary to a high index of suspicion along with prompt treatment leads to the minimization of the morbidity of these unwanted postoperative events.

ACKNOWLEDGMENT

The authors would like to thank Dr. Steve Goldberg for his contribution of the artwork in this chapter.

CHAPTER 106

Thoracic Trauma

Nathan T. Mowery
J. Wayne Meredith

EMERGENT INTERVENTIONS

Thoracic injuries are common, with up to one of five trauma patients presenting with injuries involving the chest. Thoracic injury and the ensuing complications are responsible for as much as 25% of the blunt trauma mortality.[1] Motor vehicle accidents (MVA) are the most common cause of blunt thoracic injuries, followed by falls, with injury resulting from the transmission of energy to the chest wall and underlying structures. The size and location of the chest make it vulnerable to penetrating mechanisms, such as gunshot and stab wounds. Early identification and intervention can lead to significant impact on mortality in the trauma population.

Many injuries to the thorax require immediate intervention during the primary survey to support cardiopulmonary function. Establishment of a secure airway and ventilatory assistance should occur immediately in patients with respiratory compromise. Evidence of reduced respiratory compliance measured on mechanical ventilation (i.e., elevated peak and plateau airway pressures) and decreased breath sounds may indicate a tension pneumothorax, which requires urgent intervention. External bleeding should be controlled with direct pressure while resuscitation with crystalloid solution and blood products is initiated. Hemodynamic instability may signal injuries that need to be addressed during the primary surgery such as tension pneumothorax requiring decompression, hypovolemia requiring hemorrhage control and resuscitation, or cardiac dysfunction secondary to pericardial tamponade. Evaluation for sources of bleeding should commence after addressing airway and breathing issues. This should include a chest X-ray as well as a bedside ultrasound looking for the presence of a pericardial effusion, especially in the setting of penetrating trauma. Based on these initial interventions, decisions regarding subsequent management such as immediate operation can be determined. In the event of cardiac arrest, especially in the setting of penetrating mechanisms, a resuscitative thoracotomy can be considered but carries with it an extremely high mortality. The chance of a salvageable patient is even less in blunt trauma and resuscitative thoracotomy should be reserved for circumstances where there is a witnessed cardiac arrest.

EVALUATION

Most thoracic injuries can be identified with a physical examination and plain chest radiography. Physical examination will reveal superficial injuries, including chest wall defects and penetrating wounds. Deviation of the trachea at the sternal notch may reveal intrathoracic tension on the side opposite the trachea. Distended neck veins indicate heart failure or impaired venous return, which requires further evaluation. Chest radiography is performed on all significantly injured patients at risk for thoracic injuries. This study can be obtained rapidly in the trauma bay, with the results quickly revealed. The chest radiograph identifies the presence of a pneumothorax or hemothorax, as well as rib and sternal fractures. The appearance of a widened mediastinum may suggest a thoracic aortic injury (Fig. 106-1). An ultrasound of the pericardium, which may reveal pericardial blood, is a component of the focused abdominal sonography for trauma (FAST) examination. In recent years, thoracic CT angiography has emerged as a valuable tool in the evaluation of blunt thoracic trauma. CT provides visualization of the chest wall and hemithoraces, allowing determination of rib fractures, pneumothoraces, and hemothoraces, and pulmonary contusion. Of great value has been the ability to evaluate the thoracic aorta for injury that historically required standard angiography when suggested by a chest radiograph. Chest CT angiography is able to identify transection of the aortic wall, as well as lower-grade injuries that involve only the aortic intima. Many thoracic surgeons have modified their approach and now proceed with operative intervention based on the chest CT alone, without formal angiography.

Penetrating injuries to the chest that cross the mediastinum or are in the vicinity of the heart and mediastinal structures require a methodical evaluation. Penetrating wounds in "the box," an area defined by the sternal notch superiorly, the costal margin inferiorly, and the nipples laterally, are in this group requiring further evaluation. This includes an assessment of the cardiovascular and aerodigestive structures of the mediastinum. Immediate ultrasound is performed to evaluate the pericardium for effusion. In the setting of an associated hemothorax, ultrasound may yield false-negative results due to decompression of a cardiac injury into the pleural cavity. In stable patients further evaluation has historically included an angiogram of the chest, which has now been replaced by CT angiography in most of the situations. The heart and great vessels are evaluated for injury, although this can be impeded by the presence of retained missile fragments that cause scatter on CT. In this setting, standard angiography may be necessary. Depending on the trajectory of the penetrating object, the trachea and proximal airways may require evaluation with bronchoscopy. If injury is suspected, the esophagus should be assessed with a combination of esophagoscopy and contrast esophagography. Frequently, thoracic CT will accurately identify the trajectory of the wound and thus guide the need for further evaluation.

MANAGEMENT

Up to 85% of all thoracic injuries can be managed with nothing more than a tube thoracostomy. In most cases, the placement of a chest tube is urgent but should still be performed in a controlled

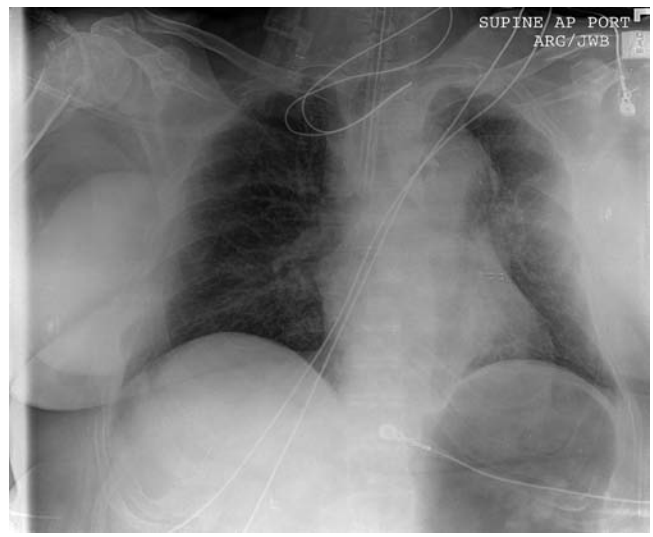

Figure 106-1 Widened mediastinum suspicious for thoracic aorta injury.

manner that includes strict sterile preparation and excellent surgical technique. This is very important given the morbidity associated with an empyema that can result from improper chest tube placement. The chest should be prepared appropriately with a formal skin preparation as well as wide draping to maintain the sterility of the field and the tube to be placed. The skin incision should be in the fourth to fifth intercostal space usually identified as the level of the nipple to stay superior enough to avoid the highest reach of the diaphragm. A tunnel is created in a superior direction and the chest is entered bluntly in an interspace above the skin incision. The lung is palpated to confirm chest entry and evaluate for intrathoracic adhesions. A tube large enough to drain blood (typically 32–36 Fr) is then advanced superiorly through the incision and posterior to the lung. Chest tubes that are being placed only for a pneumothorax can be positioned in the anterior hemithorax. The thoracostomy is then connected to an underwater drainage device providing 20 cm H_2O suction.

Tube thoracostomies that drain large amounts of blood on initial placement or demonstrate ongoing output may indicate active intrathoracic bleeding that requires thoracotomy. Other indications for immediate thoracotomy include a massive air leak with associated pneumothorax or drainage of esophageal or gastric contents from the chest tube. The choice of thoracic approach depends on the presumed injured structures. Access to the lungs, pulmonary vasculature, and hemidiaphragm is through a posterolateral thoracotomy that is best performed through the fifth interspace, with or without removal of the fifth rib. The decision of which side to approach the injury depends on the target organ and which portion of the organ needs to be exposed. A median sternotomy can be a highly versatile approach, allowing exposure of the right heart, ascending aorta, aortic arch with right-sided arch vessels, and pulmonary vasculature.

■ CHEST WALL AND PLEURAL SPACE INJURIES

During the trauma evaluation, chest wall injuries are commonly recognized. Chest wall tenderness and changes in chest wall motion are suggestive. Some patients require immediate intervention for chest injuries, but most will subsequently undergo further evaluation. Injuries involving the chest wall or pleural space can frequently be identified on chest radiographs (Fig. 106-2). Chest CT is a common part of the evaluation for thoracic injuries at many centers. CT identifies rib and sternal fractures, as well as pleural air and blood with high sensitivity.

Figure 106-2 Multiple left-sided rib fractures on a plain chest radiography.

Rib Fractures

Fractures of the ribs are the most common thoracic injury following blunt trauma, with almost 80% of patients with chest injuries sustaining one or more fractures. Rib fractures typically occur secondary to compression of the thoracic cage in an anteroposterior or lateral direction that often will dictate the location of the cortical disruption along the rib. Steering wheels and seatbelts are commonly identified as the impinging structure resulting in a fracture.

Rib fractures can vary greatly in severity, depending on the number present and patient characteristics. Associated pain can be severe and the resultant splinting can lead to the development of atelectasis and pneumonia. Aggressive analgesia should be provided to allow adequate pulmonary toilet and promote comfort. Adequate analgesia can be achieved with IV narcotics in mild cases but, in more severe cases, patients benefit greatly from the provision of epidural analgesia. Epidural analgesia after chest wall injuries has been associated with fewer ventilator days, shorter intensive care unit (ICU) length of stay, and fewer hospital days. Furthermore, one study demonstrated fewer pulmonary infections and decreased duration of mechanical ventilation with the use of epidural analgesia in patients with three or more rib fractures.[2] Nonsteroidal anti-inflammatory drugs (NSAIDs) are also beneficial in conjunction with narcotics. Aggressive pulmonary toilet, including deep breathing, frequent coughing, and incentive spirometry, should be highly encouraged. Chest physiotherapy and positive expiratory pressure exercises may also be beneficial. Severe chest wall injuries with respiratory failure may require mechanical ventilation.

There has been renewed interest in the operative fixation of rib fractures, although the optimal indications for these procedures and their associated benefit remain incompletely defined. Tanaka et al.[3] performed the only randomized, controlled study of operative fixation versus internal pneumatic stabilization. Groups were well matched in terms of injury severity, criteria for ventilatory support, and ventilator management. The incidence of pneumonia was lower in the surgical group (22% vs. 90%) as was the length of ventilation and length of ICU stay. The investigators reported improved lung volumes, decreased pain and dyspnea and higher return-to-work at 1 year with surgical fixation. The investigators concluded that surgical stabilization may be preferable for severe flail chest patients when prolonged ventilatory support would otherwise be expected. Other studies have yielded less supportive data. Ventilated patients who fail to demonstrate progress in moving toward extubation or patients with alternative indications for surgical intervention (e.g., retained hemothorax) should be strongly considered for chest wall stabilization.

Flail Chest

In its most severe form, large amounts of energy transferred to the chest wall can result in the creation of a flail segment, defined as two or more adjacent ribs that are each fractured in two or more locations. This results in a separation of a segment of the chest wall. Although pulmonary mechanics can be disrupted by the presence of a flail segment, the greatest physiologic insult is caused by the underlying pulmonary contusion that almost invariably occurs. As mentioned earlier, fixation of the chest wall is an attractive option but it does nothing to address the underlying contusion. Most current ongoing trials examining fixation exclude patients with large contusions, making further study of operative intervention in this population a challenge.

Pneumothorax

Simple pneumothorax is created when a tear in the pleura allows entry of air into the pleural space with resultant loss of negative intrathoracic pressure. If an injury to the lung parenchyma produces an air leak, the air accumulates in the pleural space with each breath, markedly increasing intrathoracic pressure and thereby shifting the

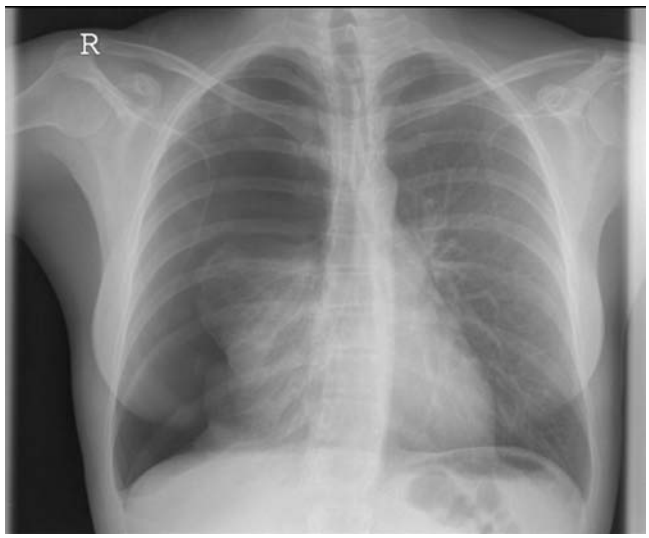

Figure 106-3 Tension pneumothorax on the right.

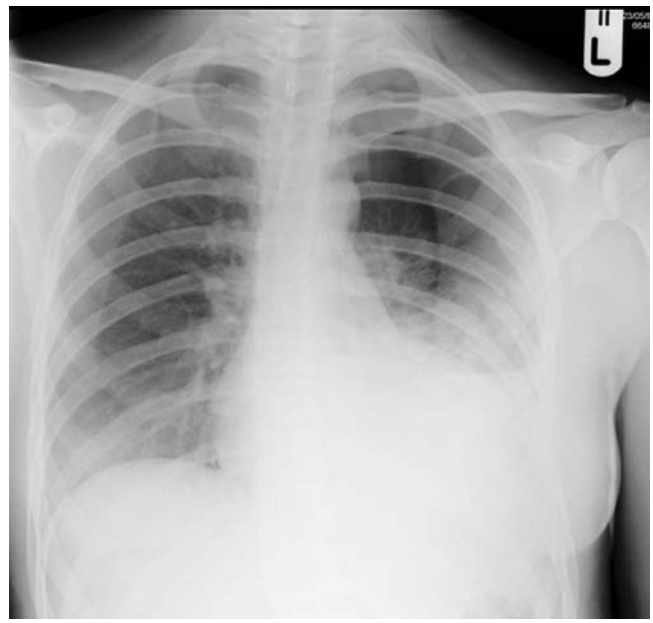

Figure 106-4 Left-sided hemothorax seen on plain chest radiography.

mediastinum toward the opposite hemithorax (Fig. 106-3). This so-called tension pneumothorax is immediately life-threatening because of the limitation of vena caval blood flow causing decreased venous return, which results in hypotension, tachycardia, and cardiac arrest. Once the diagnosis of tension pneumothorax is suspected, treatment should be initiated immediately without waiting for chest radiograph confirmation. This is most rapidly done by placing a large-bore needle into the second intercostal space. This is then followed by a formal tube thoracostomy under sterile precautions.

Pneumothorax that is visible on a chest radiograph requires performance of a tube thoracostomy. Chest tube drainage should continue until any pulmonary air leak has resolved and pleural fluid drainage is not excessive (<150 cc/d). As CT scan is being performed more commonly in the evaluation of trauma patients, many injuries are now identified that had previously not been detected. Occult pneumothorax, defined as a pneumothorax that is seen on chest CT but not on plain films, is being diagnosed more frequently.[4] Retrospective data in these cases suggests that placing a chest tube will lead to longer ICU and hospital stays.[5] Most occult pneumothoraces can be safely observed but enlargement of the pneumothorax on follow-up imaging necessitates a chest tube. Another key question has been the factor of positive pressure ventilation. Several investigators have tried to answer the effect that positive pressure has on occult pneumothorax, with conflicting results. In a prospective study, Enderson et al.[6] found that patients with pneumothoraces treated with observation who underwent positive pressure ventilation experienced an unacceptable rate of complications, with 3 of the 15 patients developing a tension pneumothorax. In contrast, in a prospective randomized study Brasel et al.[7] found no increase in complications regardless of whether chest tube or observation was chosen. Both studies suffered from low numbers but suggested that the majority of patients with occult pneumothoraces will not have progression regardless of the presence of positive pressure ventilation. Patients who demonstrate a large amount of subcutaneous air without significant pneumothorax should be followed closely, with a low threshold for placing a chest tube, because a pulmonary air leak may still be present.

Pneumothorax and Open Chest Wound When a pneumothorax is associated with an open chest wound after penetrating trauma, initial management is designed to restore a seal to the thoracic cavity. This is accomplished by applying a sterile occlusive dressing to the wound, taped on three sides. The dressing allows air to escape from the pleural space but does not allow air from the outside to enter. This should be immediately followed by placement of a chest tube at a different location.

Hemothorax

It is estimated that the occurrence of hemothorax related to trauma in the United States approaches 300,000 cases per year.[8] Hemothoraces should be drained if visible on plain films (Fig. 106-4) due to the concern that this quantity of blood in the pleural space could result in lung entrapment as the hematoma matures.[9,10] The presence of retained hemothorax after chest tube placement has been shown to be an independent predictor of the development of an empyema in 33% of patients.[10] Hemothoraces that do not resolve after insertion of a tube thoracostomy should be evaluated with a CT scan. Significant residual collections may benefit from drainage via video-assisted thoracoscopic surgery (VATS).[11] Surgical intervention is favored over placement of a second chest tube as it has been shown to decrease the duration of tube drainage, the length of hospital stay, and hospital cost.[12] The timing of VATS is also important. Early VATS (before day 3) results in statistically significant reduction in operative difficulty, contamination/infection of clot, and hospital length of stay, compared to those performed later.[13] There appears to be no absolute contraindication to attempting VATS in a delayed fashion as successful procedures have been performed as far out as 14 days.[14] The surgeon should anticipate that conversion to thoracotomy is more likely after 5 days, and should counsel the patient accordingly.[13,15]

Historically, immediate thoracotomy is indicated for more than 1500 mL of blood drained on chest tube insertion or more than 200 mL/h for 3 hours. These figures were based on Vietnam military data that suggested increased mortality in patients who reached these thresholds.[16] Although these values clearly may be associated with ongoing intrathoracic bleeding, the decision to operate should be carefully considered, especially with regard to the immediate output. In a hemodynamically stable patient, chest tubes that initially drain 1500 mL may indicate bleeding from a lung laceration that ceased with lung reexpansion and may not require or benefit from thoracotomy.

Sternal Fractures

Sternal fractures are managed similar to rib fractures, with emphasis on analgesia and pulmonary toilet. Occasionally, sternal fractures

result in the development of a mediastinal hematoma. Although these typically do not require specific treatment, the presence of active bleeding from the adjacent internal mammary artery may require angioembolization or open ligation in the setting of hemodynamic instability. The relationship of sternal fractures and cardiac contusions is weak enough that the injuries should be approached independently. In the absence of symptoms of cardiac contusion patients with a sternal fracture do not need an automatic evaluation for cardiac injury.

■ PULMONARY INJURIES

The lungs are susceptible to injury during blunt and penetrating mechanisms. Pulmonary contusion is the most common injury identified in the setting of blunt thoracic trauma, occurring in 30% to 70% of all cases. Pneumonia and acute respiratory distress syndrome are frequently encountered and mortality rates ranging from 10% to 25% have been reported. Pulmonary contusion results from energy transfer through the chest wall to the pulmonary parenchyma, resulting in tissue damage, as well as hemorrhage into the alveolar and interstitial spaces. The result is the development of physiologic shunt with hypoxemia. These injuries are also associated with a profound inflammatory response that can lead to further respiratory dysfunction and systemic inflammation.[17] Frequently, pulmonary contusion is identified in the presence of a flail segment and is the major cause of associated morbidity and mortality. Penetrating mechanisms can result in lung contusions or laceration of the pulmonary parenchyma.

Chest radiographs obtained shortly after patient arrival may demonstrate pneumothorax or hemothorax indicative of an underlying pulmonary injury. Lung contusions may be present on the initial chest radiograph but typically require time to become evident on plain film. Pulmonary contusions identified early on chest film are frequently severe and rapidly progressive to respiratory failure. A pulmonary contusion is easily identified by thoracic CT, although at times it can be challenging to differentiate contusion from atelectasis. A basic rule of thumb is that atelectasis does not cross pulmonary fissures, whereas contusions are not limited by anatomic segments (Fig. 106-5). Also, higher-density pulmonary tissue in the vicinity of chest wall injuries, especially when not in dependent areas, is highly suggestive of pulmonary contusion.

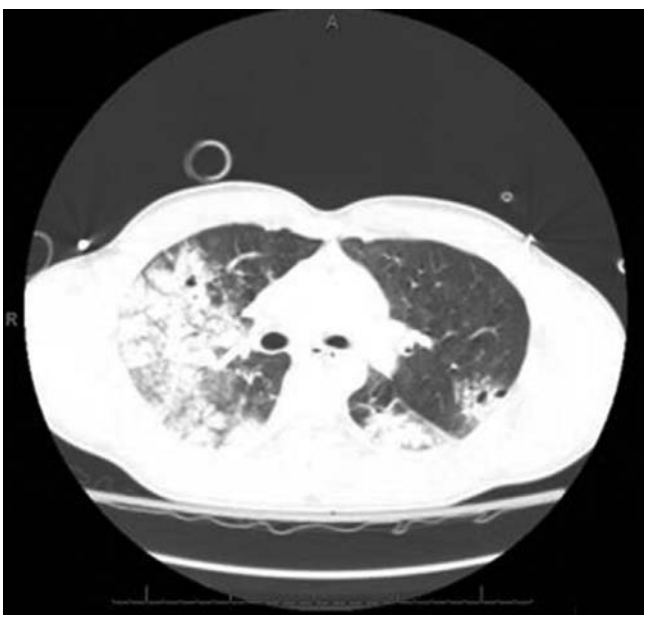

Figure 106-5 Pulmonary contusion crossing lobes of the right lung on axial CT scan.

The management of pulmonary contusion is largely supportive. Patients should be monitored for indications of respiratory decompensation such as hypoxemia, increased work of breathing, and agitation, which mandate intubation and mechanical ventilation. Pulmonary function is supported until the physiologic insult related to the contusion resolves. The mode of ventilation used does not impact overall outcome and the mode most familiar to the practitioner or most comfortable for the patient should be employed.[18] Efforts to prevent ventilator-associated pneumonia are valuable because of a significantly increased risk. Intubation should be guided by the patient's observed respiratory status and should not be performed prophylactically simply on recognition of pulmonary contusion. Similarly, the presence of a pulmonary contusion or flail chest does not require mandatory chest tube placement in the absence of a pneumothorax or hemothorax. It is a common misconception that patients with pulmonary contusion should be managed with fluid restriction.[19] Rather, appropriate resuscitation to maintain acceptable vital organ perfusion should be provided as for other severely injured patients. Excessive volume expansion should be avoided. Placement of a pulmonary artery catheter may be of value to guide fluid administration, especially when the respiratory status is tenuous and could suffer significantly from overvigorous fluid resuscitation. Aggressive pulmonary toilet can be beneficial, as well as adequate pain control, when concomitant chest wall injuries are present.

■ CARDIAC INJURIES

Sequelae from cardiac injuries range from the benign to catastrophic. It has been estimated that in the prehospital setting, 20% of traumatic deaths are caused by cardiac-related injuries.[20] These numbers likely underestimate the true incidence of cardiac injuries because many are immediately lethal and never present to a hospital.

Penetrating cardiac injuries will frequently be evident on initial examination. A significant number of patients will present in extremis with pericardial tamponade or bleeding into one of the hemithoraces. Diagnosis may then be made during resuscitative thoracotomy in agonal patients. In others, indicators of pericardial tamponade (Beck triad) may be present, including hypotension with distended neck veins and muffled heart sounds, although their presence can be highly variable. Ultrasound is a valuable tool for quickly assessing the pericardium for fluid and should be performed in all patients with hemodynamic instability. A subxiphoid pericardial window is a valuable means of evaluating for cardiac injury and should be used in cases for which ultrasound is not available or the results are inconclusive.

Rarely, blunt thoracic trauma can cause blunt cardiac injury (BCI) otherwise known as cardiac contusion, which is usually self-limited but can lead to arrhythmias. In rare cases, BCI can lead to more severe consequences such as septal defects, valvular damage, heart failure, or cardiogenic shock.

Diagnosis of BCI consists of recognizing a clinical pattern in the context of thoracic trauma. Since arrhythmias are the most common complication of BCI (up to 70% of the patients) documentation of their occurrence should prompt evaluation for BCI. Patients without EKG changes or arrhythmias on initial evaluation do not need further evaluation. Cardiac enzymes do not reliably predict which patients need intervention or will develop complications and are therefore of little clinical use in stable patients.[21,22] Most arrhythmias demonstrated on initial assessment do not require medical treatment and resolve quickly during the course of monitoring. Those with more severe electrocardiographic (EKG) changes or arrhythmias on admission require telemetry for 24 to 48 hours and therapy initiated for the specific electrical abnormality. The presence of hemodynamic instability with evidence of heart failure should prompt an echocardiogram (EKG) to assess cardiac wall and septal motion, as well as valvular function, which in rare cases can be compromised during blunt thoracic trauma. Heart failure may

require treatment with inotropic support and right ventricular afterload reduction, given the frequent involvement of the right heart. Patients who demonstrate structural abnormalities on echocardiography may require urgent operation to repair cardiac injuries.

THORACIC AORTIC INJURIES

Injuries to the thoracic aorta are life-threatening but fortunately not common. Only 0.3% of patients sustaining blunt trauma in the National Trauma Database sustained an aortic injury, although the associated mortality rate exceeded 47%.[23] As with cardiac injuries, this likely underestimates the true incidence because aortic transection is a common cause of immediate death in blunt trauma patients who never present to the emergency department. In 3.8% of cases, the aorta is involved in penetrating thoracic trauma; almost all these injuries are fatal (mortality = 86.1%).[24] Blunt aortic injuries have traditionally been believed to be a result of rapid deceleration, which tears the aortic wall in the vicinity of the ligamentum arteriosum, where it is fixed to the thorax. Lateral mechanisms may also contribute, during which the aortic arch acts as a lever and causes torque to develop at the aortic isthmus. These mechanisms can result in injuries that range from a tear in the aortic intima to full-thickness transection of the wall. Regardless of the degree of injury it must be a contained rupture for the patient to survive to presentation. A free rupture of a thoracic aorta would lead to death within moments.

Penetrating aortic injury may be discovered at the time of thoracotomy or sternotomy, performed because the patient was in extremis. Blunt aortic injury may be suggested by a chest radiograph that demonstrates a widened mediastinum, apical capping, loss of the aortic knob, or deviation of the left mainstem bronchus. Because of a high rate of missed injuries by plain radiograph, most patients involved in high-energy injury mechanisms undergo helical CT angiography of the chest to evaluate for aortic injury. Injuries to the thoracic aorta can be identified on CT as a disruption in the intima or as a pseudoaneurysm with a mediastinal hematoma, which appears as contrast contained outside the aortic lumen. Usually, this study alone is sufficient to plan operative repair, although standard angiography is necessary in some cases, usually at the discretion of the thoracic surgeon.

The treatment of patients who present with a contained blunt thoracic aortic rupture is evolving. Until recently, surgical repair was required in all of these cases because the natural history of these injuries is slow expansion, which ultimately culminates in free aortic rupture. To prevent that occurrence, medical therapy with beta antagonists aimed at controlling aortic wall stress is often initiated at the time of diagnosis. It has been recognized that there is usually a delay in progression of this injury that allows other more urgent issues, such as acute hemorrhage, to be addressed. Small penetrating injuries to the aorta can be closed primarily if exposed prior to exsanguination. Larger penetrating injuries and blunt transection require replacement of a segment of the aorta with a prosthetic graft. This is most commonly performed with the assistance of cardiopulmonary bypass, with full bypass through a femoral–femoral approach or with a centrifugal pump and left heart bypass. The use of cardiopulmonary bypass has been associated with a decreased incidence of paraplegia, which can result from cessation of aortic blood flow during the clamp and sew technique.[25]

More recently, there has been a great deal of interest in the use of endovascular stent grafts to repair the injured thoracic aorta. This is particularly appealing for those patients at high operative risk and with favorable vascular anatomy. In many centers, this approach is becoming a mainstay of treatment for managing these injuries. Described advantages associated with the endovascular repair of aortic injury include a reduction in the incidence of paraplegia and a potential improvement in mortality. Although rare, patients with an intimal tear only may be candidates for nonoperative management because many of these injuries will heal without intervention. Patients should be treated with beta blocker therapy and undergo follow-up imaging to ensure the absence of expansion and ultimately the resolution of the injury.

TRACHEOBRONCHIAL INJURIES

Injuries to the tracheobronchial tree are uncommon but are associated with significant morbidity and mortality. A mortality rate of 6% has been reported but it is believed that many patients with these injuries succumb prior to the arrival of prehospital personnel.[26] Approximately 50% of these injuries involved the right mainstem bronchus within 2 cm of the carina. It is thought that these injuries result from the application of a large amount of kinetic energy to the anterior chest, this force pulls the lungs laterally and avulses the bronchi from the fixed carina. Another proposed mechanism is a rupture caused by rapid compression of the lungs and airways against a closed glottis, which perforates the trachea along the membranous portion. Penetrating injuries, mainly secondary to gunshot wounds, can also result in injuries to the tracheobronchial tree.

Identification of tracheobronchial injuries depends somewhat on the location of airway disruption. Significant subcutaneous air may be present on physical examination. Injuries that involve the thoracic trachea and proximal bronchi may result in significant pneumomediastinum identified by chest radiography or chest CT. More distal airway injuries will typically cause a pneumothorax requiring insertion of a tube thoracostomy. A continuous air leak with persistent pneumothorax is highly suggestive of an injury to a bronchus. Diagnosis is made with fiberoptic bronchoscopy, which allows for the identification of the injury and a detailed characterization, such as the location and severity of the disruption.

Initial management of tracheobronchial injuries includes careful airway management. With the placement of any airway, avoiding any further disruption is vital and may benefit from bronchoscopic guidance under direct visualization. Injuries that occupy less than one-third of the luminal circumference may be considered for nonoperative management if any pneumothorax and associated air leak that were present resolve after insertion of a chest tube and the lung expands completely. Management includes antibiotics, humidified oxygen, careful suctioning, and close observation to be sure that infectious sequelae do not develop. Repair includes debridement of devitalized tissue or segmental resection with closure, using absorbable sutures. The repair then benefits from coverage with a tissue pedicle, such as a previously preserved intercostal muscle flap. Patients requiring ongoing ventilation may benefit from passage of the endotracheal tube distal to the repair to provide protection. Other options include dual-lung ventilation and extracorporeal life support during the immediate postoperative time period.

ESOPHAGEAL INJURIES

Injuries to the thoracic esophagus occur predominantly after penetrating trauma but remain uncommon from any cause. Most of these are caused by gunshot wounds, followed by stab wounds in fewer than 20% of cases. Penetrating esophageal injuries may be suggested by the trajectory of a missile or weapon. Injuries in the vicinity of the mediastinum require consideration of possible esophageal injury. The mortality associated with these injuries is significant (39%) because of the severe consequences of esophageal perforation and because the adjacent vital structures can also be injured along with the esophagus.[27] Blunt esophageal injury is exceedingly rare. Twenty-five percent of patients, with this injury die, largely because of the significant energy required to rupture the thoracic esophagus. Blunt esophageal injury is believed to be caused by a rapid elevation in intraluminal pressure during compression of the chest or abdomen. An impact to the upper abdomen can compress the distended stomach, leading to transmission of air and fluid up the esophagus and resulting in a perforation of the wall, usually in the distal segment.

The esophagus is best evaluated through a combination of contrast esophagography and esophagoscopy. Individually, these studies each have an approximate 20% false-negative rate, but their combined sensitivity approaches 100%.[28,29] Findings include extravasation of contrast from the esophageal lumen or a disruption of the mucosa visualized on endoscopy. These studies should also be used to determine the location of the injury along the esophagus to assist in operative planning. Chest CT may reveal air adjacent to the esophagus but outside the lumen, as well as surrounding soft tissue inflammation. At times, the defect itself can be visualized on CT. Esophageal injuries at the gastroesophageal junction may result in abdominal pain and tenderness.

The rapid identification and management of esophageal injuries are paramount because delays are associated with worse outcomes. Clinical evaluation and studies that reveal an esophageal injury should prompt immediate operative repair. Chest and mediastinal drains should be placed in the vicinity of the repair to control any leak that may develop. A gastrostomy and feeding jejunostomy are frequently advisable to allow gastric decompression and early nutritional support. Esophageal injuries that are identified late may not allow primary repair because of the massive amounts of inflammation that can develop. In some situations, esophagectomy is the only option to allow recovery from the associated inflammatory insult, followed by planned elective reconstruction.

DIAPHRAGMATIC INJURIES

Injuries to the diaphragm can be a diagnostic challenge. They are often first identified at the time of laparotomy for penetrating injury or late following blunt trauma. Approximately 3% of patients with trauma to the torso have a diaphragmatic injury identified, with approximately two-thirds of them secondary to penetrating trauma.[30,31] Mortality is secondary to injuries involving adjacent vital organs because diaphragmatic injuries themselves are usually of limited threat to life. Blunt diaphragmatic injuries are believed to be a result of a rapid increase in intra-abdominal pressure during an anterior impact that causes a blowout of the diaphragmatic tissue. Injuries are most commonly recognized on the left side, with only 25% occurring adjacent to the liver or in the central portion of the diaphragm. Because of the high energy required to create a blunt diaphragmatic rupture, there is a significant associated mortality, approximately 29%.[32]

Diagnosis requires a high index of suspicion when confronted with even the most subtle indicators of injury to the diaphragm. Frequently, penetrating diaphragmatic injuries are discovered on operative exploration of the chest or abdomen. Identifying the trajectory of the injury will usually allow recognition of the diaphragmatic defect. Blunt injuries can be more elusive. The chest radiograph may identify injuries to the diaphragm by demonstrating the presence of abdominal viscera, most commonly the stomach, within the chest (Fig. 106-6), although this finding may be absent in a significant number of injuries. Passage of a nasogastric tube can be of assistance if the tube is identified in the lower left hemithorax; the administration of gastric contrast may add to the detection. Chest and abdominal CT scans may demonstrate the presence of abdominal viscera in the chest or an abnormality of the diaphragm itself, such as discontinuity, thickening, or elevation. Given the challenge of diagnosis, operative exploration may be required when imaging is suggestive.

Repair of diaphragmatic injuries includes debridement of nonviable tissue and closure of the defect. Typically, the diaphragm exhibits enough redundancy to close all but the largest defects primarily. Large areas of tissue loss are rare in traumatic rupture but, when present, may require reconstruction with a prosthetic. When the diaphragm has been traumatically detached from the periphery, it may be reinserted to the chest wall one or two interspaces superior.

In cases where the diaphragmatic perforation was not initially recognized and repaired, the injury may only come to light months to years later. The natural history of these injuries includes progressive enlargement with herniation of abdominal viscera into the chest, which is commonly the identified abnormality on radiographic evaluation.

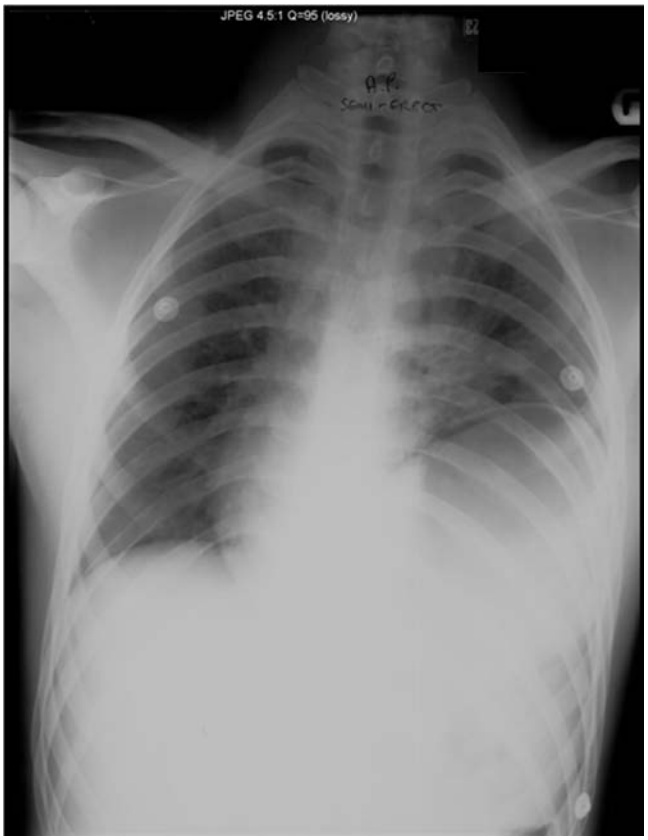

Figure 106-6 Left-sided diaphragmatic injury on a plain chest radiograph. The gas-filled stomach can be visualized in the left chest; this was caused by herniation through a large diaphragmatic laceration.

CHAPTER 107 Lung Transplantation

Allan R. Glanville

The last 30 years have seen the development and promulgation of lung transplantation as a robust therapy for advanced lung diseases for which no other medical therapy is effective. At best lung transplantation is immediately lifesaving and capable of offering selected recipients extended and good quality survival. However, there are many problems that beset the graft and may lead to chronic lung allograft dysfunction (CLAD). Principal among these is chronic rejection (CR), manifest as fibrotic luminal occlusion of small airways (bronchiolitis obliterans) for which the term bronchiolitis obliterans syndrome (BOS) was coined to allow a uniformity of description and grading of severity throughout the world.[1,2] As the field of lung transplantation has matured, a community of dedicated lung transplant clinicians and scientists has formed, working together to develop a number of position papers, guidelines and clinical trials to guide practice. Lung transplantation has expanded its reach in dramatic fashion, with the edge of the diaspora that commenced in the modern era at Stanford University Medical Center touching most nations and many conditions once thought unsuitable for transplantation. It has been used as a successful therapeutic intervention for a wide variety of end-stage pulmonary parenchymal and vascular diseases. There is no doubt that advances in recipient and donor selection, surgical technique, and postoperative management have improved early survival as documented in serial iterations of the annual registry of the International Society for Heart and Lung Transplantation (ISHLT); late survival is slowly improving as well.[4]

Novel areas of interest in the lung transplantation world include the use of so-called marginal donors to assist in overcoming the relative shortage of donor organs and the development of donation after circulatory death protocols that hold great promise to provide outcomes at least equivalent if not better than donation

after brain death.[5] *Ex vivo* lung perfusion may facilitate organ salvage and promote optimal outcomes.[6,7] So may our increasing understanding of antibody-mediated rejection (AMR), another area where knowledge is changing rapidly, generate superior outcomes in the future.[8,9]

HISTORY

Pioneering efforts in experimental lung transplantation were undertaken in the 1940s and 1950s. In Russia in 1946, Demikhov, working without the benefit of cardiopulmonary bypass, performed a variety of experiments involving transplantation of pulmonary lobes and heart–lung blocs in dogs.[10] These experiments demonstrated the technical feasibility of such procedures but warned of the physiologic challenges of the control of breathing reflexes. Dogs have a well-developed Hering–Breuer inflation inhibition reflex, so they fail to breathe adequately after reimplantation of the heart–lung bloc. Demikhov's first heart–lung transplant survived 2 hours and only 2 of the 67 transplants he performed over the next 5 years survived more than 5 days. Nakae subsequently demonstrated the fallacy of assuming the homogeneity of pulmonary neural control between species and showed how this reflex was developed differentially between species in an elegant series of experiments in cats, dogs, and monkeys.[11] This opened the way for further work on subhuman primates by Shumway and Reitz, who were able to demonstrate extended survival after heart–lung transplantation.[12] Subhuman primates were able to override the Hering–Breuer reflex and breathe so the hope of human lung transplantation was rekindled. This physiologic quirk excited a number of the early researchers who studied the physiology of the transplanted lung devoid of neural control mechanisms, cough reflexes, antegrade bronchial blood supply, and normal mucociliary clearance mechanisms.[13–20] In addition, an early observation was that in heart–lung transplantation, the heart and the lung individually pursued different functional courses, foreshadowing the differing rates of rejection of the heart and lungs that were seen in human combined heart–lung transplantation performed more than three decades later.[21]

Human lung transplantation was undertaken first by Hardy[22,23] in 1963. The procedure consisted of a left single-lung transplant performed for a carcinoma of the left lung that involved the hilum. The patient survived for 18 days, dying of renal failure and malnutrition. This effort demonstrated that a transplanted lung could function for the short term in a patient and stimulated further clinical and experimental efforts. Between 1963 and 1978, however, at least 38 attempts were made at isolated lung transplantation and only 1 patient survived to hospital discharge, succumbing to sepsis and CR 8 months after transplantation. The remaining patients in this 15-year experience all died postoperatively. The major cause of mortality beyond the first postoperative week in these patients was bronchial dehiscence. In addition, most of the patients were greatly debilitated at the time of the procedure, frequently ventilator dependent or in a state of multisystem and multiorgan failure, hindering their ability to survive. It was appreciated that in many of these patients, the available immunosuppressive regimens, which relied on high-dose corticosteroids, significantly compromised postoperative healing of the bronchus and further potentiated the adverse effects of preexisting conditions.

The problem of bronchial healing was related to the relative ischemia of the donor bronchus, which followed revascularization of the lung graft without reestablishment of the bronchial circulation. One technical approach to this problem was the development of a procedure for combined heart–lung transplantation, allowing for maintenance of collateral circulation from the coronary circulation to the tracheal anastomosis and mediastinal tissues as well as retrograde perfusion from the pulmonary arterial circulation. Although the operation was performed primarily for patients with end-stage cardiac failure due to pulmonary hypertension, the initial report of successful heart–lung transplantation demonstrated the feasibility of this approach in obtaining healing of the airway and confirmed the ability of the transplanted lung to provide long-term respiratory function. The world's first recipient of a combined heart–lung transplant died 5 years post transplant from trauma. Postmortem examination revealed no complications of rejection or infection in the transplanted heart or lungs. Subsequently, heart–lung transplantation has been performed for numerous pulmonary parenchymal diseases, including emphysema and bilateral septic lung disease, such as cystic fibrosis, but is now only performed for conditions that cannot be serviced by single- or bilateral-lung transplantation such as some forms of congenital heart disease.

An alternative technique for improving bronchial healing was to optimize the bronchial–pulmonary collateral circulation by limiting the length of the donor bronchus and by providing an alternative vascular supply by extrinsically wrapping the anastomosis with omentum. In addition to these technical measures, the avoidance of high-dose steroid immunosuppressive regimens, made possible by the use of cyclosporine, was shown to improve bronchial anastomotic healing. These advances, combined with the selection of well-conditioned recipients with pulmonary fibrosis, whose pathophysiology favored preferential perfusion and ventilation of the allograft, culminated in the initial clinical success of single-lung transplantation. Further efforts were made to perfect a technique for double-lung transplantation to expand this approach to patients with bilateral septic lung disease. The initial clinical success of an en bloc double-lung transplant procedure was tempered by a significant incidence of tracheal anastomotic complications. However, further modification of the technique, by either direct bronchial revascularization or performance of two sequential single-lung transplantations at the same operative sitting (i.e., bilateral sequential single-lung transplantation), has provided satisfactory results.

It has since been shown that despite initial concerns about the physiology of allograft ventilation, single-lung transplantation is also appropriate for patients with end-stage chronic obstructive pulmonary disease (COPD). Single- and bilateral-lung transplantation have also been successfully applied to patients with primary pulmonary hypertension or Eisenmenger syndrome (with correction of the congenital shunt), for whom combined heart–lung transplantation was initially devised. As the utility of lung transplantation for these pulmonary diseases has been demonstrated, the need for heart–lung transplantation has diminished. There are now relatively few surgeons who have extensive experience with combined heart–lung transplantation while experience with bilateral-lung transplantation continues to grow, driven by demonstrable superior outcomes for most indications.[4]

RECIPIENT SELECTION

Selection of appropriate candidates is critical to the success of lung transplantation. The numerous factors that are considered when selecting candidates are discussed in detail in the following sections.

GENERAL CONSIDERATIONS

Recipient selection is one area where a remarkable international consensus has been achieved among key societies dedicated to the investigation and management of advanced respiratory diseases.[24,25] The current published guidelines represent a conjoint effort of members of the ISHLT, American Thoracic Society, European Respiratory Society, American Society of Transplant Physicians, and

the Thoracic Society of Australia and New Zealand.[25] Published first in 1998 and revised in 2006, the guidelines are now under further revision as there have been major changes in acceptance of candidates, especially those needing advanced life support and those of more mature age.

In brief, the evaluation of a potential candidate for lung transplantation should include a complete assessment of cardiopulmonary function and the patient's general health in addition to a thorough evaluation of psychosocial status. A battery of screening tests is required, as well as evaluation by members of the transplant team, including pulmonologists, cardiologists, thoracic surgeons, psychiatrists, and social workers (Table 107-1). Contingent on the patient's status, this evaluation can be completed in many instances on an outpatient basis. A coordinated review of the results of these studies by the multidisciplinary transplant team serves to assure that the best candidates are accepted as potential transplant recipients. The so-called "best candidates" are those who are deemed to have a superior chance of obtaining both an immediate survival benefit and an enduring quality-of-life benefit. The introduction of the Lung Allocation Score (LAS) within the United States has been an attempt to provide potential lung transplant recipients with a uniform lung donor allocation system designed to achieve at least the first of these broad goals.[26] One iconoclastic action of the LAS has been to abolish the "time-accrued" principle of determining who received the next lung transplant. The "time-accrued" principle valued the serendipity of time of listing greater than the acuity of the disease and led directly to an excess mortality on the waiting list and indirectly to overly large waiting lists at some institutions. Within a month of introducing the LAS the number of patients waiting for lung transplantation within the United States halved due to the acknowledgment by transplant centers that many on the list were there simply to accrue time but were not in immediate need of transplantation.

INDICATIONS

Lung transplantation is a treatment of last resort. Potential recipients should be patients with end-stage pulmonary parenchymal, airways, or vascular disease who have a limited life expectancy and for whom no effective alternative therapy is available. Additional considerations include the degree of reduction in activities of daily living resulting from the disease and the patient's quality of life. The variable rates of progression of the diseases for which lung transplantation is performed and the variety of supportive therapies available dictate the use of disease-specific criteria in assessing the appropriate timing of listing a given patient.

Immunologic study of potential transplant candidates includes assessment of ABO status and preformed anti-HLA antibodies. All patients are currently matched to donors by ABO status, most commonly with ABO-identical donors and less commonly with ABO-compatible donors (this situation arises commonly for blood type AB candidates). Screening for sensitization to HLA antigens is now routine and will be further discussed under the section on AMR. Pregnancy, blood transfusion, or prior transplantation can lead to HLA sensitization.[27]

CONTRAINDICATIONS

There are few absolute contraindications to lung transplantation. Over the years the impetus has swung from focusing on which patients should be excluded to how to reasonably include patients after appropriate evaluation and management. With newer support technologies, a number of the original exclusion criteria have been relaxed. Absolute contraindications include bone marrow failure and hepatic cirrhosis, the latter to be distinguished from reversible hepatic dysfunction due to right heart failure, which resolves following lung transplantation (Table 107-2). In exceptional circumstances, combined liver and lung transplantation may be contemplated, and in experienced hands this procedure has acceptable long-term outcomes. Active malignancy precluding long-term survival is also an absolute contraindication. One consideration that impacts the determination of who may receive a transplant is the current limited supply of donor lungs. Hence, other significant life-limiting comorbidities also stand as a proscription against lung transplantation.

A host of additional factors may be considered relative contraindications to lung transplantation (Table 107-2). The age of the recipient may be a significant factor in view of the limited number of donor organs and the presumed subclinical organ dysfunction associated with the aging process that increases the potential for postoperative complications. As the latter factor is variable, a "physiologic age" rather than a strict chronologic criterion is appropriate. The type of transplant procedure also influences the significance of age as a contraindication. Many centers consider single-lung transplantation as more suitable for older patients because of its lower risk. Nevertheless, there is a definite creep toward offering transplantation to the well-chosen older recipient for whom it may be the best palliative option. In fact, according to the OPTN/SRTR 2011 report, the largest expansion in the waiting list population for lung transplantation in the United States was over the 65 age group.[28] Other contraindications are evidence of

TABLE 107-2 Absolute and Relative Contraindications for Lung Transplantation

Absolute Contraindications for Lung Transplantation	Relative Contraindications for Lung Transplantation
• Malignancy in the last 2 y, with the exception of cutaneous squamous and basal cell tumors. In general, a 5-y disease-free interval is prudent. The role of lung transplantation for localized bronchioalveolar cell carcinoma remains controversial • Untreatable advanced dysfunction of another major organ system (e.g., heart, liver, or kidney). Coronary artery disease not amenable to percutaneous intervention or bypass grafting, or associated with significant impairment of left ventricular function, is an absolute contraindication to lung transplantation, but heart–lung transplantation could be considered in highly selected cases • Noncurable chronic extrapulmonary infection including chronic active viral hepatitis B, hepatitis C, and human immunodeficiency virus • Significant chest wall/spinal deformity • Documented nonadherence or inability to follow through with medical therapy or office follow-up, or both • Untreatable psychiatric or psychologic condition associated with the inability to cooperate or comply with medical therapy • Absence of a consistent or reliable social support system • Substance addiction (e.g., alcohol, tobacco, or narcotics) that is either active or within the last 6 mo	• Age older than 65 y. Older patients have less optimal survival, likely due to comorbidities, and therefore, recipient age should be a factor in candidate selection. Although there cannot be endorsement of an upper age limit as an absolute contraindication (recognizing that advancing age alone in an otherwise acceptable candidate with few comorbidities does not necessarily compromise successful transplant outcomes), the presence of several relative contraindications can combine to increase the risks of transplantation above a safe threshold • Critical or unstable clinical condition (e.g., shock, mechanical ventilation or extracorporeal membrane oxygenation) • Severely limited functional status with poor rehabilitation potential • Colonization with highly resistant or highly virulent bacteria, fungi, or mycobacteria • Severe obesity defined as a body mass index (BMI) exceeding 30 kg/m^2 • Severe or symptomatic osteoporosis • Mechanical ventilation. Carefully selected candidates on mechanical ventilation without other acute or chronic organ dysfunction, who are able to actively participate in a meaningful rehabilitation program, may be successfully transplanted • Other medical conditions that have not resulted in end-stage organ damage, such as diabetes mellitus, systemic hypertension, peptic ulcer disease, or gastroesophageal reflux should be optimally treated before transplantation. Patients with coronary artery disease may undergo percutaneous intervention before transplantation or coronary artery bypass grafting concurrent with the procedure

psychosocial instability that would preclude compliance with the necessary posttransplant regimens and active use of tobacco products or other substances of addiction during the wait for transplantation. Obesity or cachexia can increase the risk for perioperative morbidity.[29–32] The same is true of the continued need for high doses of corticosteroid therapy (more than 20 mg of prednisone, or equivalent dose of another agent, per day).

Respiratory failure requiring mechanical ventilation before transplantation also increases the likelihood of complications.[33] Some centers will not consider a new patient for evaluation who is completely ventilator dependent or who has acutely deteriorated and become ventilator dependent. However, this stance is definitely changing and many centers, particularly those in Europe and Australia, have championed the use of a high-urgency status to allow successful transplantation of patients on extracorporeal membrane oxygenation (ECMO).[34] Patients who have a chronic need for partial ventilatory assistance or those who have been accepted as transplant candidates and require assisted ventilation because of progression of their native disease are often still considered potential recipients unless multiorgan failure intervenes.[35] Prolonged mechanical ventilation results in colonization of the lower respiratory tract with significant microbiologic pathogens and a degree of deconditioning and protein wasting that significantly increases the perioperative risk of transplantation. Nevertheless, despite these theoretical concerns recent outcomes have improved significantly for well-selected patients needing assisted ventilation.

Chronic kidney disease may affect eligibility for lung transplantation. The calcineurin inhibitors (CNIs) universally used as part of posttransplant immunosuppressive regimens are nephrotoxic and invariably cause some degree of renal insufficiency as a complication of therapy. As with irreversible hepatic dysfunction, combined renal and lung transplantation may be considered, but the potential risks of the procedure, particularly in the context of the shortage of donor lungs, require careful consideration. In most patients, severe pre-existing renal insufficiency is a contraindication for lung transplantation.

Severe peripheral vascular disease may be a limiting factor in selecting candidates for a number of reasons including the occasional need for cardiopulmonary support in the perioperative period by either partial cardiopulmonary bypass or ECMO via the femoral or subclavian routes. Peripheral vascular disease is also frequently associated with occult significant coronary or aortic disease, which may greatly increase the morbidity and mortality of the lung transplant procedure and limit quality long-term survival. Finally, transplantation is contraindicated in patients with gangrenous changes in the extremities due to peripheral vascular disease because of the potential for systemic spread of the infectious process during immunosuppression.

Careful consideration is required before patients with pre-existing osteoporosis are accepted for transplantation. In addition, chronic steroid immunosuppressive therapy causes bone loss in all patients and exacerbates the complications of prior osteoporosis. Post operative rib fractures or compression fractures of the vertebrae not only cause severe pain requiring the use of narcotic analgesia but limit cough, mobility, and rehabilitation and can lead directly to sputum retention, pneumonia, and death.

Infectious diseases have a profound effect on the morbidity and mortality of lung transplantation. Colonization of the respiratory tract with potential pathogens in patients with end-stage pulmonary disease requires careful assessment. Most bacterial flora in transplant candidates have a pattern of antibiotic sensitivity that can be identified preoperatively to select an appropriate perioperative antibiotic regimen. For example, lung transplant patients harboring gram-negative bacilli preoperatively were found to be at risk for posttransplant pneumonia, demonstrating the importance of preoperative identification and a plan for eradication of potential pathogens. However, *Burkholderia cenocepacia (BCC),* a pathogen found in up to 15% of patients with cystic fibrosis in some geographic regions, is often highly resistant to antimicrobials and is a relative contraindication to transplantation unless a suitable pattern of antibiotic sensitivity can be identified before transplantation. Irrespective of the precise genomovar, it is the biologic behavior of the organism within a particular host that determines outcome.[36,37] *Aspergillus fumigatus* and other *Aspergillus* species are also common pathogens in the sputum of patients with bronchiectasis, sarcoidosis, or COPD and, while not a contraindication to transplant, these organisms can occasionally lead to life-threatening posttransplant infections.[38–41] Other pathogens such as *Scedosporium species* may be associated with fatal dissemination post transplant.[38–41] *Scedosporium prolificans* in particular may be difficult to control and is hard to eradicate.[42,43] Lifelong therapy with voriconazole and terbinafine may be effective but carries the risk of accelerated development of skin cancers especially squamous cell cancer of the lip.[44] Interestingly, the presence of organisms in donor lungs is not always a predictor of post–lung transplant pneumonia, perhaps reflecting the efficacy of targeted antibiotic therapies or the successful eradication with removal of the diseased lungs.

Viral diseases in a potential lung transplant recipient can also have a significant impact on the outcome of transplantation. Active hepatitis B or C in the lung transplant candidate is associated with increased early and late mortality because of the effect of hepatic dysfunction on perioperative complications and the accelerated progression of these diseases in patients requiring chronic immunosuppression. However, successful lung transplantation has been reported in patients in whom therapy for hepatitis C has been effective.[45] Cytomegalovirus (CMV), a DNA-type virus that is incorporated into the host genome, can cause both systemic illness and pneumonitis in immunosuppressed patients. Therefore, the serologic CMV status of the recipient is an important determination to make before transplantation. An early publication in the preprophylaxis era found that CMV infection developed in 54% (32/59) of patients who underwent heart–lung or lung transplantation and survived for more than 30 days, and that CMV infection was more common in patients who had been CMV seropositive prior to transplant (95%) than those who had been seronegative preoperatively (38%).[46] While some centers still prefer to match CMV-negative recipients with CMV-negative donors as a strategy for reducing the chance of primary CMV infection, the widespread use of prophylactic ganciclovir and valganciclovir therapy has been shown to significantly reduce the risk of CMV disease in transplant patients. Extended prophylaxis with valganciclovir appears both safe and effective.[47–51] However, some strains of CMV are resistant to ganciclovir, hence ongoing surveillance for CMV using PCR assays and transbronchial lung biopsy is advised.[52]

SPECIFIC DISEASE STATES

In addition to general selection criteria, there are disease-specific considerations that impact decisions about candidate selection and timing of listing.

■ CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The rate of progression of the underlying disease is an important factor in the timing of the evaluation and selection of potential transplant recipients (Table 107-3). The most common indication for lung transplantation is obstructive lung disease, with COPD accounting for more than one-third of all lung transplants and emphysema due to α_1-antitrypsin deficiency accounting for 8% of all lung transplants. Patients with these diseases tend to remain relatively stable for long periods, albeit with a reduced quality of life. It is now apparent that lung transplantation not only provides marked symptomatic and functional palliation for these patients but improved survival as well, depending on the severity of disease at the time of transplant.[53] The recently devised BODE index (Table 107-4) that incorporates multiple factors (B, body mass index; O, obstruction as indicated by the FEV_1 as % predicted; D, degree of dyspnea; and E, exercise capacity) is a validated survival measure that is more accurate in predicting survival in individuals with COPD than the FEV_1 alone.[54–56] Accordingly, calculation of the BODE index is now included in the international guidelines for referral and transplantation for COPD (Table 107-3). Prior to the introduction of the LAS, death during the wait for transplantation was rare in these patients, occurring in less than 5% of cases. In addition to reflecting the slow progression of COPD, two additional factors may contribute to their low mortality: their participation in a graduated rehabilitation program while they await transplantation, which may maintain or even increase their functional capacity, and the institution of oxygen therapy, which improves survival in patients with obstructive lung disease.

■ INTERSTITIAL LUNG DISEASES

Interstitial lung diseases are the indication for lung transplantation in 24% of patients who undergo lung transplantation. The most common cause is idiopathic pulmonary fibrosis (IPF), whereas a variety of interstitial lung diseases including sarcoidosis, collagen vascular disease–associated interstitial lung disease, and drug-induced lung disease account for the remainder.

The end-stage fibrotic lung is characterized by severe destruction of gas exchange units, secondary distortion and dilatation of the airways with development of cystic lesions, and replacement of the lung with nondistensible fibrous tissue. The work of breathing in these patients may be increased five times above normal because of the increased elastic load. The vital capacity in patients with pulmonary fibrosis is severely reduced, as is the functional residual capacity and total lung capacity. Dead-space ventilation is increased, and may actually increase further during exercise. A marked reduction in diffusing capacity is invariably present. Although some degree of alveolar hyperventilation is common early in the course of disease, hypercapnia during exercise and later at rest is encountered in the advanced stages. Extensive intrapulmonary shunting of blood flow is seen, resulting in hypoxemia and, in later stages, pulmonary hypertension. Progression of the disease may be variable, but patients often deteriorate precipitously, developing progressive hypoxemia and pulmonary hypertension. Acute exacerbations of IPF are associated with mortality exceeding 50% irrespective of therapy. As a result, the mortality of these patients while they await transplantation is more than 20%. Criteria for considering IPF patients for transplantation include severe dyspnea, forced vital capacity less than 50% of predicted, resting arterial hypoxemia or hypercapnia, and pulmonary hypertension. However, a downhill clinical course is the best individual indication for transplantation. It must be emphasized that there is currently no proven therapy that reverses established IPF.[57–59]

Two other factors in patients with interstitial lung disease are also important. First, many of these diseases are systemic, and the effects

TABLE 107-3 Disease-Specific Considerations for Lung Transplantation

TABLE 107-4 The BODE Index for COPD

Variable	Points on BODE Index[a] 0	1	2	3
FEV_1(%) of predicted)[b]	≥65	50–64	36–49	≤35
Distance walked in 6 min (m)	≥350	250–349	150–249	≤149
MMRC dyspnea scale[c]	0–1	2	3	4
Body mass index[d]	>21	≤21		

[a]The cutoff values for the assignment of points are shown for each variable. The total possible values range from 0 to 10. FEV1 denotes forced expiratory volume in 1 second.
[b]The FEV_1 categories are based on stages identified by the American Thoracic Society.
[c]Scores on the modified Medical Research Council (MMRC) dyspnea scale can range from 0 to 4, with a score of 4 indicating that the patient is too breathless to leave the house or becomes breathless when dressing or undressing.
[d]The values for body mass index were 0 or 1 because of the inflection point in the inverse relation between survival and body mass index at a value of 21.
Source: Reproduced with permission from Celli BR, Cote CG, Marin JM, et al. The body-mass index, airflow obstruction, dyspnea, and exercise capacity index in chronic obstructive pulmonary disease. N Engl J Med. 2004;350(10):1005–1012.

of the disease on extrapulmonary organs may result in a sufficient number of relative contraindications to exclude the patient from consideration for transplantation. The presence of an underlying connective tissue disease should be investigated in appropriate cases, and an individual determination made about the possibility of an enduring benefit from lung transplantation. Second, a number of these diseases, including sarcoidosis and lymphangiomyomatosis, may recur in the lung graft, but typically do not impact posttransplant survival.

■ SEPTIC LUNG DISEASE

Septic lung disease, including cystic fibrosis and other types of bronchiectasis, accounts for approximately 20% of patients undergoing lung transplantation. Candidates with focal or unilateral disease can sometimes be managed with medical treatment or surgical resection of the affected area. In most patients, however, the disease is bilateral or systemic, and the natural history is one of recurrent infection and progressive respiratory failure. It is important to attempt to establish a cause of the bronchiectasis before transplant evaluation, because of the impact of systemic

diseases on management before and after transplantation. Cystic fibrosis can be diagnosed with a sweat test or from genotyping. Serum immunoglobulin levels should be measured and a careful assessment for evidence for a systemic illness – such as rheumatoid arthritis, ulcerative colitis, or immotile cilia syndrome – should be undertaken. Primary infectious causes, such as tuberculosis and allergic bronchopulmonary aspergillosis, should be identified and treated appropriately before consideration of the potential benefit of transplantation can be evaluated fully. Finally, any suggestion of aspiration as a primary or secondary factor demands further investigation, including a barium swallow and esophageal manometry testing to rule out gastroesophageal reflux.

Many of these patients demonstrate significant short-term improvement in response to optimum medical therapy, which includes postural drainage, intravenous and/or inhaled antibiotics, and nutritional supplementation. Once medical therapy has been optimized, however, a pattern of more frequent hospitalizations for exacerbations, continued weight loss, and progressive functional impairment is indicative of a patient who has a limited life span and should be given priority for transplantation. Cystic fibrosis patients with an FEV_1 under 30% of the predicted value, a Pa_{O_2} under 55 mm Hg, or a Pa_{CO_2} greater than 50 mm Hg have a 2-year mortality of 50%; the FEV_1 appears to be the most sensitive predictive factor. Any patient with septic lung disease who manifests these criteria should be further evaluated as a potential transplant recipient.

While the patient is awaiting transplantation, close medical follow-up is required, and all components of the patient's therapeutic regimen should be continued. Serial study of sputum microbiology is important for assessing changes in flora. Aerosolized broad-spectrum antibiotic therapy may reduce the colonizing bacterial load while minimizing the potential for renal toxicity and in some cases it may transiently improve functional capacity. In the event of progressive hemoptysis, bronchial artery embolization can provide adequate short-term control of the bleeding without significantly compromising technical aspects of the transplant procedure. Finally, institution of noninvasive positive pressure ventilation in the patient who is approaching respiratory failure has been shown to stabilize lung function without adversely affecting the outcome of transplantation. Because of the shortage of donor organs and the variability in the progression of the disease some programs had previously developed the approach of live donor lobar transplantation of the lung. This uses bilateral lobar transplants from two live donors, often parents or close relatives, particularly for small recipients with cystic fibrosis. It has proven to achieve outcomes comparable to cadaveric donor transplantation without donor mortality or significant morbidity.[60] The use of this procedure in the United States has largely been abandoned as the implementation of the LAS system has provided an alternative means of expediting transplantation for severely ill patients but the procedure has now gained popularity in Japan.[61–65]

■ PULMONARY VASCULAR DISEASE

Pulmonary vascular disease, either idiopathic pulmonary arterial hypertension (IPAH) or secondary pulmonary arterial hypertension due to Eisenmenger syndrome, accounts for 4% to 5% of patients requiring lung transplantation and approximately 25% of patients requiring heart–lung transplantation. The criteria for identifying patients who may require transplantation relate to the risks of death due to the underlying disease. On the basis of data from the National Heart, Lung, and Blood Institute registry, it is apparent that an NYHA class III or IV functional status, an elevated central venous pressure, a decreased cardiac index, and an elevated mean pulmonary artery pressure correlate with a poor prognosis. Episodes of near-syncope or syncope, which tend to occur later in the course of the disease, are also associated with mortality. The changing landscape of medical therapy for pulmonary arterial hypertension has had a major impact on the survival of these patient populations and the timing of referral and listing for lung transplantation. A wide variety of effective therapies are now available, including traditional therapies with anticoagulation and high-dose calcium channel blockers as well as newer vasodilator drugs such as sildenafil, endothelin receptor antagonists, and inhaled, subcutaneous and intravenous prostanoids.[66] These therapies may significantly modify the natural history of the disease. Therefore, symptomatic patients with pulmonary arterial hypertension who do not respond to medical therapy are the ones best considered for transplantation. Early referral before the development of end-stage organ system failure is critical to success. Although the vast majority of data concerning the natural history of patients with pulmonary arterial hypertension is derived from the IPAH population, similar clinical criteria are applied to those with Eisenmenger syndrome in deciding when to list for lung transplantation. Notably, however, many patients with Eisenmenger physiology are well compensated for many years and transplantation can often be delayed much longer than for patients with IPAH.

The decision as to what procedure a patient with pulmonary vascular disease should undergo has evolved over time. The relative shortage of suitable heart–lung donor blocs combined with a mortality of 20% to 25% among patients with significant pulmonary hypertension awaiting heart–lung transplantation, has led to a shift away from this procedure in favor of bilateral-lung transplantation. The results with bilateral-lung transplantation are similar to those with heart–lung transplantation for pulmonary vascular disease provided that there is no significant left ventricular dysfunction. Of interest, the presence of severe right ventricular systolic dysfunction does not appear to affect the results of lung transplantation; the severe tricuspid regurgitation and pulmonary valvular regurgitation that are present in virtually all patients preoperatively resolve almost immediately and right ventricular function normalizes over a period of weeks to months. Patients with Eisenmenger syndrome who have a shunt defect that can be corrected at the time of transplantation are also candidates for lung transplantation. Thus, heart–lung transplantation is primarily limited to patients with either significant biventricular dysfunction or uncorrectable congenital heart defects.

TRANSPLANT PROCEDURE SELECTION

Except for patients with bilateral septic lung disease or severe pulmonary arterial hypertension, single-lung transplantation is potentially suitable for the majority of end-stage pulmonary diseases that require transplantation (Table 107-5). However, there has been a very definite swing away from single-lung transplantation and toward bilateral-lung transplantation worldwide, based in part on the lower long-term survival outcomes associated with the former procedure, particularly when applied to the COPD population.[4,67] The argument that single-lung transplantation is associated with a shorter wait for donor lungs and a lower morbidity and mortality rate after transplantation than other lung transplant procedures performed for the same recipient diagnoses is no longer tenable given improvements in surgical experience and techniques combined with the ramifications of the LAS. The surgical mortality for single-lung transplantation ranges from 3% to 10%, relating to the specific transplant indication, the presence or absence of pulmonary hypertension, and the intraoperative need for cardiopulmonary bypass. The incidence of graft failure within the first 6 weeks following single-lung transplantation approximates 5%.[28]

TABLE 107-5 Indications for Lung Transplant Procedures

Single-lung transplantation
Obstructive lung disease
Restrictive lung disease
Idiopathic pulmonary arterial hypertension (rarely)
Eisenmenger syndrome with a correctable shunt defect (rarely)
Bilateral-lung transplantation
Obstructive lung disease (patient <60 y old)
Septic lung disease
Idiopathic pulmonary arterial hypertension
Eisenmenger syndrome with a correctable shunt defect
Combined heart–lung transplantation
Significant intrinsic left ventricular dysfunction (LVEF <45%)
Significant coronary artery disease, not amenable to nonsurgical interventions
Eisenmenger syndrome with an irreparable shunt defect

Bilateral-lung transplantation is the procedure of choice for patients with septic lung disease, such as cystic fibrosis, and for patients with severe pulmonary arterial hypertension from either primary or secondary causes. Many centers also favor bilateral-lung transplantation for patients with emphysema who are less than 60 to 65 years of age.[67] More controversial is the preferential use of bilateral-lung transplantation for patients with fibrotic lung disease in the absence of severe secondary pulmonary hypertension. As currently performed, each lung is sequentially resected and the donor lung implanted; that is, two single-lung transplants are performed sequentially at the same operative sitting. This is in distinction to the original double-lung transplant, which used a double-lung bloc and a tracheal anastomosis. Bilateral-lung transplantation is performed via a bilateral thoracosternotomy incision, median sternotomy, or bilateral anterior thoracotomy incisions. The latter has the decided advantage of avoiding transection of the sternum and thereby preventing any chance of sternal infection and dehiscence, a major complication that can be associated with significant morbidity and occasional mortality. Surgical mortality is now equivalent for bilateral- and single-lung transplantation. Similarly, at most large centers, perioperative rates of acute graft failure and bronchial dehiscence are similar.

Combined heart–lung transplantation has been used successfully for virtually all end-stage pulmonary diseases. However, with the perfection of the techniques of single and bilateral transplantation, and in light of the significant limitations in supply of donor organs, the use of heart–lung transplantation has focused on patients with significant intrinsic left ventricular dysfunction or Eisenmenger syndrome and surgically irreparable shunt defects. The surgical mortality for heart–lung transplantation at large centers is about 10%; typically, it is higher than the surgical mortality for single or bilateral transplantation for similar disease states. Notably, the number of procedures performed worldwide has fallen with the realization that most recipients can be well serviced with lung transplantation alone.

DONOR SELECTION

The most significant factor limiting wider application of lung transplantation is the supply of donor organs.[68] Unlike other solid organs used for transplantation, the lung is exposed before brain death to environmental contamination, including both microbiologic pathogens and toxic substances, which may significantly impair its functional capabilities. The microbiologic aspects of this exposure are accentuated by the endotracheal intubation that is a necessary aspect of donor management. In addition, aspiration of oropharyngeal or gastric contents is a common occurrence during the events preceding brain death. Nearly half of all comatose patients develop pneumonia within 1 week of intubation, probably owing to a combination of these factors. Brain death itself may also lead to neurogenic pulmonary edema. In cases of trauma that lead to brain death, significant injury to the thorax may occur, or the volume replacement required for the resuscitation of these patients may limit the suitability of the lungs for subsequent transplantation. In addition to these immediate insults, a history of significant cigarette smoking raises concerns about more chronic damage to donor lungs.

As a result of these factors, only about 25% of cadaveric organ donors have historically proven to be potential lung donors. In recent years concerted efforts to improve donor supply and optimize donor utilization worldwide have proved fruitful, pushing the lung recovery rate up to approximately 50% in some centers. In part, this has been facilitated by an increasing willingness to use donors that were formerly called "marginal donors," a practice that has proven to be safe in most circumstances. The advent of *ex vivo* lung perfusion to "recondition" lungs following recovery heralds a most exciting phase in the development of the science of lung transplantation and holds great promise of optimizing donor lungs and allowing salvage of lungs that formerly would not have been considered suitable for organ donation.[6,7,69,70]

Criteria for lung donation are meant to identify donors with evidence of acceptable gas exchange in the absence of infection of the airways or parenchyma (Table 107-6). A donor age of less than 60 years and a history of smoking for less than 20 to 30 pack-years are important. Both increasing age and prolonged tobacco use are known to correlate directly with anatomic alterations in the pulmonary parenchyma, which, despite preservation of gas exchange function in the donor, may result in impaired graft function in the recipient. Despite these theoretical considerations the ultimate decision to use or not use a particular donor often depends on the status of the potential recipient. It is argued that it is preferable to use a donor that has smoked than miss a transplant opportunity that may equate to a death on the waiting list.

The chest radiograph should reveal normal lung on the side(s) of the lung(s) considered for donation. Unilateral pneumonia or parenchymal trauma does not preclude use of the contralateral lung

TABLE 107-6 Traditional Characteristics of a Suitable Lung Donor

Age <60 y
Cigarette smoking <20-30 pack-years
No significant prior thoracic surgery on the side of the donor lung
Normal chest radiograph of the donor lung
Adequate gas exchange of the donor lung
Pa_{O_2} > 300 mm Hg on $F_{I_{O_2}}$ 1.0, PEEP ≥5 cm
Pv_{O_2} > 450 mm Hg on $F_{I_{O_2}}$ 1.0, PEEP ≥5 cm
Bronchoscopic evaluation demonstrating absence of mucosal inflammation or aspiration
No significant pulmonary trauma or anatomic abnormalities

for transplantation in most circumstances. No major thoracic surgery should have been performed on the side of proposed donation, not only because of potential technical limitations but also because such a history usually suggests either a major anatomic abnormality (e.g., prior lobectomy) or pathology (e.g., malignant neoplasm), which would preclude donation.

Finally, the size of the donor lungs, based on direct measurement or correlated to predicted total lung capacity – as estimated by donor height, age, and gender – is a useful parameter to use when selecting lungs for a particular recipient. The simple expediency of measuring lung heights (apex to base) and transthoracic diameter correlates well with predicted total lung capacity and is a time-honored method of determining lung size. Generally, the donor lungs should be within 25% of the *predicted* size of the recipient's lungs. Donor lungs larger than these measurements can be volume reduced at the time of transplantation, whereas donor lungs considerably smaller than these measurements usually should be avoided. As a rule of thumb, donor organs should be smaller than the actual size of the hyperinflated native lungs of the recipient with emphysema so that the optimal length–tension relationships of the respiratory muscles can be reestablished. Conversely the donor for a patient with restrictive physiology should be larger than the actual size of the recipient native lungs so that after remodeling of the chest cavity the new total lung capacity approximates normal.

Adequate oxygenation has been defined as a Pa_{O_2} greater than 300 mm Hg on mechanical ventilation, with an $F_{I_{O_2}}$ of 1.0 and positive end-expiratory pressure (PEEP) of at least 5 cm H_2O. However, this is both arbitrary and dynamic. It is the trend that is most important and lungs with initial poor gas exchange due to a host of factors such as edema or atelectasis may well be suitable. It is the challenge of the donor retrieval team to analyze closely the operational factors to determine how to maximize the function of any potential donor organ. A "low stretch" ventilator protocol (i.e., tidal volume 6 mL/kg) should be utilized and recruitment maneuvers should be employed to maximize oxygenation. If a unilateral pulmonary process is present, a lower Pa_{O_2} may be acceptable because of the possibility of mixing of venous blood from the two lungs at the level of the left atrium. In this circumstance, intraoperative evaluation of unilateral gas exchange by sampling from the ipsilateral pulmonary vein for determination of P_{O_2} can be used to determine that the prospective donor lung is satisfactory.

All lung donors have some evidence of colonization of the lower respiratory tract by potential pathogens owing to the requisite endotracheal intubation, which bypasses the defense mechanisms of the upper airway. A distal tracheitis is uniformly present after 72 hours of intubation. Therefore, a sputum Gram's stain revealing polymorphonuclear leukocytes or multiple bacterial forms does not necessarily imply invasive infection. For this reason, bronchoscopy is a critical step in the evaluation of any potential lung donor. Bronchoscopy allows inspection of the large airways for the presence of aspirated debris as well as assessment of the character of the secretions and status of the bronchial mucosa. A finding of diffuse bronchial mucosal inflammation is significant, even if only a limited amount of aspirated debris or secretions are present. However, purulent secretions without significant mucosal inflammation in the presence of a clear chest radiograph and preserved gas exchange generally indicate a suitable lung for donation. A potassium hydroxide smear for fungal organisms is also a part of the routine evaluation of the lung donor, although as with the Gram's stain, the mere presence of fungal organisms, particularly Candida species, does not preclude lung donation. In most cases, the presence of potential pathogens in the donor sputum by either Gram's stain or fungal smear requires preemptive modification of the recipient's antimicrobial regimen if such lungs are used for transplantation. At some centers, this treatment is begun by the administration of intravenous or aerosolized antimicrobial therapy to the donor before retrieval of the donor lungs. Prophylaxis for Candida and fungal organisms found in the donor swabs should be prolonged to prevent dehiscence of vascular and airway anastomoses.

The donor evaluation is completed by intraoperative inspection of the pleural space and lung. Occasionally, unsuspected parenchymal trauma is evident in the form of a bloody pleural effusion or pulmonary contusion. The donor lung also should be studied for evidence of unsuspected bullous disease or mass lesions. Excisional biopsy and intraoperative pathologic evaluation of any parenchymal mass lesion should be carried out. Finally, the anesthesiologist should be directed to maintain adequate tidal volumes and PEEP during intraoperative ventilation to preserve optimal function of the donor lung before its removal.

The appropriateness of a potential lung donor always should be interpreted in the context of the recipient's disease and clinical status. Older patients and patients with a sudden clinical deterioration, such as those who have recently been placed on mechanical ventilation, may all benefit from transplantation with a lung that does not fulfill all the criteria of an optimal donor lung. Most frequently, the criteria relating to cigarette smoking and Pa_{O_2} are breached in these circumstances. The results have generally been satisfactory in such recipients, suggesting that the use of "marginal" lung donors may partly address the problem of donor organ shortage.[71] It has also been shown that the effect of the functional status of the donor lung is most significant in the first 24 hours after transplantation, and that subsequent graft function depends primarily on factors related to the recipient. In addition, these studies have underscored that patients with pulmonary hypertension, who are the most difficult to manage postoperatively, are best served by transplantation with lungs from optimal donors.

LUNG PRESERVATION

The ideal method of pulmonary preservation has not yet been identified. With current techniques, however, satisfactory graft function can be obtained after ischemic intervals as long as 6 to 8 hours. As with other vascular solid organs used for transplantation, the lung consists of a heterogeneous population of cells, of which the vascular endothelial cell appears to be the most sensitive to ischemia. Ischemic injury to the pulmonary vascular endothelium increases its permeability and results in pulmonary edema, the common end point for assessment of injury in models of pulmonary preservation techniques. Hypothermia is the major method used clinically to limit ischemic injury to these cells. The lung also has some unique biologic and physical characteristics that distinguish it from other solid organ transplants. Although it has an absolute requirement for aerobic metabolism, the lung is capable of using ambient oxygen for the metabolism of glucose, even during the ischemic state. In addition, the effective size of the pulmonary vascular bed and thermal conductivity of the lung can be manipulated by the degree of lung inflation. Current clinical methods of lung preservation make use of these characteristics to optimize graft function following an ischemic interval.

Two techniques are currently being used for lung preservation, core cooling and hypothermic flush perfusion. *Extracorporeal core cooling* (ECC) is a technique that has been used primarily for procurement of heart–lung donor blocs, commonly in conjunction with multiorgan procurement at abdominal sites. ECC consists of systemic heparinization of the donor and institution of full cardiopulmonary bypass (CPB) by means of a transpericardial approach. The donor is cooled to 15°C (rectal temperature). Ventricular fibrillation typically develops during this maneuver, and the heart

is decompressed through the left ventricle. CPB is then discontinued, and the heart–lung bloc is harvested and transported in a cold ischemic state with the lungs inflated. No flush solutions are used, although the lungs are essentially being flushed by cooled autologous blood during the time of CPB. Safe ischemic times of 6 hours or more have been reported with adequate pulmonary function. It is of interest that while oxygenation in lungs preserved by ECC appears to be somewhat less optimal than in those preserved by hypothermic flush techniques, the pulmonary vascular resistance (PVR) upon reperfusion of the lungs following ECC is generally lower than that seen upon reperfusion of lungs obtained by flush techniques.

Hypothermic flush perfusion is the method most commonly used for pulmonary preservation in clinical practice. This technique consists of flushing the pulmonary vasculature with a cold solution after systemic heparinization of the donor, followed by extraction and transport of the lungs inflated with 100% oxygen. Flushing can be performed in antegrade fashion via the pulmonary artery or retrograde fashion via the left atrium or pulmonary veins. Many centers favor the retrograde technique as it appears to be more effective in flushing out clots from the pulmonary arterial circulation thereby improving gas exchange by enhancing ventilation and perfusion matching. A low-potassium dextran solution is used. The ideal pulmonary preservation solution is a topic of much debate.

The state of inflation of the lungs is important in obtaining optimal perfusion of the pulmonary vasculature by the flush solution, to achieve both rapid cooling and direct cellular preservation by the solution itself. Intraoperatively, maintaining a tidal volume similar to that used during the initial donor assessment is important. The addition of PEEP during the procurement procedure maintains functional residual capacity and the desired state of inflation of the donor lungs. PEEP also increases the intra-alveolar release of surfactant, minimizing pulmonary compliance abnormalities after implantation of the donor lungs. Ventilation is continued throughout the period of lung perfusion to maintain the effective size of the pulmonary vascular bed. Although it was once thought that the maintenance of an $F_{I_{O_2}}$ of 1.0 during the procurement was useful, particularly at the time of lung extraction, to provide an oxygen-rich ambient environment for metabolic activity of the lung during the ischemic interval, new information suggests that use of high $F_{I_{O_2}}$ is associated with a higher risk of primary graft dysfunction (PGD). The lungs are extracted and transported in a state of inflation that approximates end-tidal inspiration. Some consideration should be given to the fact that the donor lungs may be transported by aircraft, in which a fall in atmospheric pressure may result in further inflation of the lungs. Overinflation of the donor lungs is to be avoided, as this leads to increased capillary permeability and postimplantation pulmonary edema.

The administration of prostanoids, either prostaglandin E_1 (PgE_1) or prostacyclin, into the pulmonary circulation before flush perfusion has been shown to improve lung preservation. The mechanism of action of prostanoids includes dilation of the pulmonary vasculature, allowing for better distribution of the flush solution, and decreased leukocyte adhesiveness, which can abrogate the initial events of reperfusion injury. Most commonly in North America, PgE_1 is used as a bolus (500 μg) into the pulmonary circulation, with or without the addition of similar amounts of PgE_1 directly to the flush solution. The use of prostanoids in combination with intracellular flush solutions has been shown to provide pulmonary preservation equivalent, if not superior, to that with the use of extracellular-type flush solutions alone.

Most flush solutions are administered at a temperature of 4°C, while topical cooling is carried out by filling of the pleural cavity with iced crystalloid solution. After extraction, the lungs are immersed in crystalloid and packed in ice, resulting in a transport temperature of 1° to 4°C. Some studies have shown that lung preservation is superior when a more moderate hypothermia with a temperature of 10°C is used. However, because of the concerns regarding the deleterious effects of flush and storage temperatures greater than 10°C, and the difficulties in maintaining this temperature during the procurement procedure, clinical flush perfusion continues to be performed at the lower temperature ranges.

Experimental work has identified numerous adjuncts to the techniques currently used for pulmonary preservation that have the potential for prolonging ischemic intervals. A significant part of the lung injury seen after ischemia has been shown to be due to the phenomenon of reperfusion, which is initiated by leukocyte adhesion to endothelial cells and the production of oxygen-derived free radicals and peroxides. Measures that diminish this response, in addition to the use of prostanoids, include donor leukocyte depletion, the administration of antibodies to block adhesion molecules, the use of inhaled nitric oxide, and the inclusion of oxygen radical scavengers, such as superoxide dismutase or catalase, to the flush solution. In addition, methods of increasing the resistance of cells to ischemic injury, such as the induction of heat shock proteins, have been shown to be beneficial in other organs and may be of some use in lung preservation. Evidence of the effect of these manipulations on tolerable ischemic intervals in clinical lung transplantation awaits additional study.

TECHNIQUES OF LUNG TRANSPLANTATION

Technical aspects of lung transplantation include both anesthetic and surgical considerations. Single lung, bilateral lung, and heart-lung transplantation are the surgical options currently utilized.

ANESTHETIC MANAGEMENT

Proper perioperative management of the recipient is crucial to obtain the best outcome following lung transplantation.[72] Close cooperation and understanding between the anesthesiology and surgical teams are essential. An appreciation of the unique aspects of the physiology of the various types of lung transplant recipient is also important. Patients with COPD have reduced expiratory flow rates, air trapping, and increased lung volumes. Following endotracheal intubation, extreme care should be taken to allow adequate expiratory time for emptying of the lungs, avoiding the cardiovascular instability caused by "pulmonary tamponade" due to progressive air trapping in the lungs and reduction of ventricular filling. Tension pneumothorax due to rupture of bullae can also occur but is relatively uncommon. Pneumothorax is particularly difficult to diagnose in the supine patient and may be missed on fluoroscopy especially if there is an anterior air collection. Patients with restrictive lung disease have progressive fibrosis of the lung tissue, with secondary hypoxemia and progressive pulmonary hypertension. Patients with these diseases have an increased work of breathing and are oxygen dependent and extremely dyspneic before transplantation. Many of these patients have evidence of cor pulmonale at the time of transplantation and cannot tolerate occlusion of the pulmonary artery during implantation of the donor lung without the support of cardiopulmonary bypass. Careful and repeated assessment of filling pressures and cardiac output is required to allow prompt interventions in such patients. Patients with septic lung disease demonstrate primarily the abnormalities in pulmonary function seen in patients with obstructive airway disease. However, these recipients have excessive copious purulent secretions, which can exacerbate air trapping and also contribute to marked V/Q abnormalities – particularly during single-lung ventilation. Careful management

of double-lumen endotracheal tubes to avoid contamination of the contralateral lung graft and attention to bronchopulmonary hygiene to avoid obstruction of the lumens of these tubes are needed in these patients. Finally, recipients with pulmonary vascular disease who present for transplantation have marginally compensated cor pulmonale and are extremely dyspneic and anxious. Patients with IPAH become oxygen dependent late in the course of their disease, although oxygen is commonly administered to these patients to lessen the hypoxic contribution to their pulmonary hypertension. For this reason, oxygen therapy should be continued throughout the time of preoperative preparation and line placement to avoid abrupt right heart dysfunction. Because these patients have normal pulmonary mechanics, they generally tolerate mechanical ventilation well. Patients with Eisenmenger syndrome are well adapted to chronic hypoxemia. In these patients, supplemental oxygen does not reverse the hypoxemia and may even worsen arterial hypoxemia by eliciting systemic vasodilatation and increasing right-to-left shunting.

All lung transplant procedures should be performed with CPB available on standby, if not utilized by surgeon choice. There is an argument to avoid CPB in cases of septic lung disease or other situations where there are known extensive intrapleural adhesions, to avoid excessive bleeding complications, but as always it is a balance of experience and safety. No specific preoperative factors can be used to predict the need for CPB—with the exception of severe pulmonary arterial hypertension, for which CPB is requisite for the procedure. For other lung transplant recipients, assessment of the need for CPB is best made intraoperatively by trial clamping of the pulmonary artery, followed by assessment of hemodynamic parameters, oximetry, and if available, ventricular function testing by transesophageal echocardiography. Progressive deterioration in these parameters requires unclamping of the pulmonary artery and an attempt to optimize factors such as preload, inotropic support, Pa_{O_2}, Pa_{CO_2}, and PVR. If repeat trial clamping of the pulmonary artery is still not tolerated, plans for CPB are made. Typically, cannulation after systemic heparinization is via the femoral vessels for single-lung transplantation and via a transpericardial approach for patients undergoing bilateral-lung or heart–lung transplantation.

SINGLE-LUNG TRANSPLANTATION

The approach to single-lung transplantation requires an initial decision regarding the side of implantation. Most commonly, the native lung with the least pulmonary function based on preoperative V/Q scans is excised. In some patients, however, specific technical factors, such as a prior pleurodesis, may override this factor. When the function of the two lungs is equal or when the need for CPB is anticipated, the right side is preferred because of the greater ease of surgical exposure and the institution of CPB via the ascending aorta and right atrium. A right-sided approach also facilitates exposure for closure of intracardiac defects in patients with Eisenmenger syndrome. Despite the potential differences in size of the right and left hemithorax, there does not appear to be any long-term difference in outcome following right or left single-lung transplantation.

Most often, exposure for single-lung transplantation is via a generous posterolateral thoracotomy through the fifth intercostal space or the bed of the excised fifth rib. When elective CPB via the right hemithorax is planned, the use of a fourth interspace may facilitate placement of the cannulae. The ipsilateral groin is included in the surgical field in the event that cannulation of the femoral vessels is required for partial CPB. Although the use of femoral sites for cannulation requires repair of the vessels after removal of the cannulae, it does provide a site for additional venous drainage with use of intrathoracic cannulation sites. Femoral cannulation sites also provide access for conversion to ECMO support if acute graft failure occurs immediately after implantation. Occasionally, when the repair of an associated intracardiac defect requires an anterior approach, a median sternotomy may be used for right single-lung transplantation in patients with Eisenmenger syndrome (though single-lung transplantation is rarely used for this indication).

The donor lung is prepared for implantation and then wrapped in sponges soaked with cold crystalloid solution and placed into the hemithorax. The bronchial anastomosis is performed first. Although a variety of techniques have been described, the essential points are to minimize the length of both the donor and recipient bronchi to preserve collateral blood supply and achieve some degree of anastomotic overlap. An end-to-end anastomosis is preferred (Fig. 107-1). Occasionally, it is necessary to telescope the smaller bronchus, most commonly the donor bronchus, into the larger bronchus with either a technique of interrupted sutures or a combination of running sutures on the membranous wall and interrupted sutures on the anterior wall in a figure-eight or horizontal mattress fashion. Polyfilament absorbable suture (e.g., 4-0 polyglactin) or monofilament suture, either absorbable (e.g., polydioxanone) or nonabsorbable (e.g., polypropylene), may be used. The anastomosis is then covered by either local peribronchial tissue or local pedicled flaps of thymic tissue or pericardial fat.

The order of the vascular anastomoses can vary even though the pulmonary artery anastomosis is frequently the more technically difficult to perform. A continuous 5-0 polypropylene suture is used for each anastomosis, leaving the ends untied for deairing upon reperfusion of the lung. For the pulmonary artery anastomosis, the length of the donor and recipient vessels requires careful assessment to avoid kinking. For the left atrial anastomosis, the confluence of the recipient pulmonary veins is incised to create a left atrial cuff. Occasionally, dissection in the interatrial groove is required to allow more proximal placement of the vascular clamp on the recipient left atrium

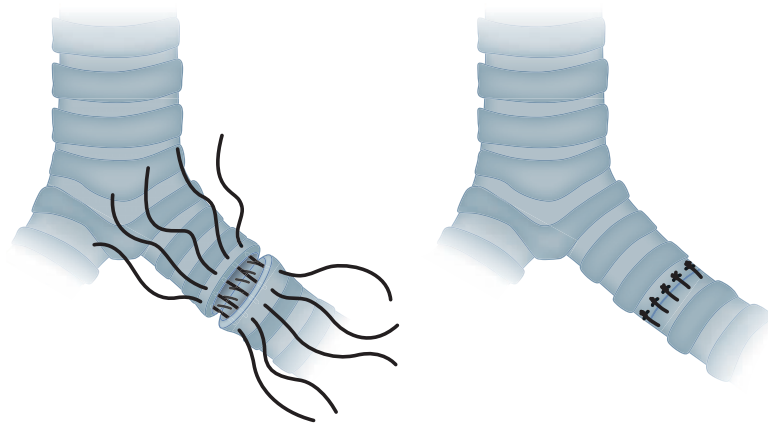

Figure 107-1 Bronchial anastomosis for lung transplantation. A technique of approximation using stay sutures at the junction of the cartilaginous and membranous walls is shown. If the donor and recipient bronchi are size matched a continuous monofilament suture can be utilized. If there is a significant size mismatch alternative techniques are employed to minimize puckering. A running suture is used for the membranous wall, followed by an interrupted suture technique of horizontal mattress sutures on the cartilaginous wall to achieve an end to end anastomosis. Additional anastomotic coverage may be obtained by approximation of peribronchial and mediastinal tissues about the site.

(Fig. 107-2). After completion of these anastomoses, the lung is gently reinflated. Perfusion of the lung graft is then reestablished, initially in an antegrade fashion, evacuating air via the left atrial suture line. The atrial clamp is removed, with the atrial suture line under a fluid level to prevent entrainment of air into the left heart. Ventilation of the donor lung is resumed, and after a few minutes to allow the vascular suture lines to adapt to the distention caused by increased flow, these suture lines are secured. Hemostasis is then obtained, two chest tubes are placed, and the chest is closed in a standard fashion. Following reintubation with a single-lumen tube, flexible bronchoscopy is completed to inspect the bronchial anastomosis and clear the airway of blood or residual secretions.

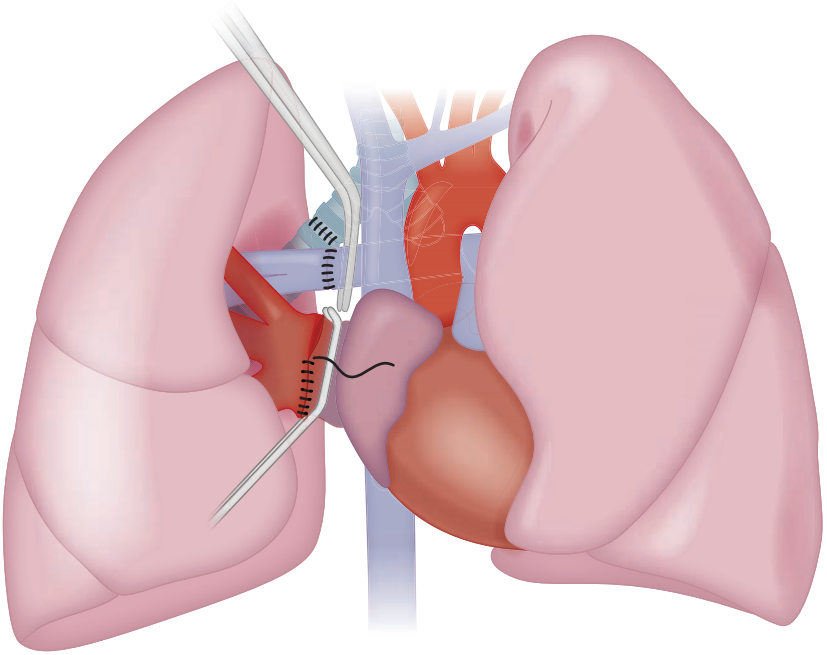

Figure 107-2 Implantation of the donor lung at the right hilum. The bronchial anastomosis is performed first, followed by the venous then arterial anastomoses. A clamp is placed on the left atrium within the pericardium. After excision of the pulmonary vein stumps, the confluence of the pulmonary veins is incised to create a cuff of left atrium. The atrial anastomosis is performed with a running monofilament suture following approximation with stay sutures superiorly and inferiorly. The pulmonary arterial anastomosis is performed last. A clamp is placed on the proximal pulmonary artery. Usually the anastomosis is proximal to the upper lobe pulmonary artery branch on the right side however if there is a size mismatch the anastomosis may be distal to this branch. On completion of the anastomosis, the sutures are left untied until lung reinflation and antegrade reperfusion is completed to evacuate air from the donor vasculature.

■ BILATERAL-LUNG TRANSPLANTATION

Although most commonly referred to as bilateral-lung transplantation in the medical literature, the most frequently performed bilateral procedure is more accurately described as bilateral sequential single-lung transplantation. This procedure has a significantly lower incidence of anastomotic complications than the en bloc double-lung procedure that it replaced, and is technically less difficult to perform than en bloc double lung with simultaneous bronchial artery revascularization. The exposure for bilateral-lung transplantation has traditionally been via bilateral anterolateral thoracotomies through the fourth or fifth intercostal space, connected by a transverse sternotomy—the so-called clamshell incision (Fig. 107-3). The incision provides adequate exposure for mobilization of intrapleural adhesions, even after previous pulmonary resections or pleurodesis, and also provides excellent access for institution of CPB and correction of intracardiac defects. In most patients, the entire incision is made at the beginning of the procedure, and both lungs are completely mobilized. For patients with emphysema who undergo bilateral-lung transplantation, however, the contralateral hemithorax may be left closed until after the first lung graft is implanted; this sequence minimizes the tendency to overinflation of the native lung that may occur during the initial implantation procedure. As mentioned above, a number of centers now prefer bilateral anterior thoracotomy incisions for bilateral-lung transplantation, which provides a superior cosmetic result as well as avoiding the risk of sternal dehiscence or infection. The mobilization and pneumonectomy of the native lung and the implantation of the lung graft are conducted in the same manner as described for single-lung transplantation. Thymic and anterior mediastinal tissue on a superiorly based vascular pedicle may be mobilized for coverage of the bronchial anastomoses. Finally, some centers utilize a median sternotomy approach.

Living-related lung transplantation is most commonly performed as a bilateral sequential transplant procedure using the clamshell incision. Cardiopulmonary bypass is instituted electively after the recipient native lungs are mobilized. Each of the donor lobes is implanted at the recipient hilum. Typically, there is little discrepancy in size between the lobar bronchus and pulmonary vein of the donor (usually an adult) and the main bronchus and left atrium of the typical pediatric recipient. The order of the anastomoses (bronchus first) and the technique are the same as for cadaveric single- and bilateral-lung transplantation. Overinflation of the lobar graft is more likely than with a cadaveric allograft and may contribute to postoperative pulmonary edema. A marked size discrepancy between the lobar allograft and the

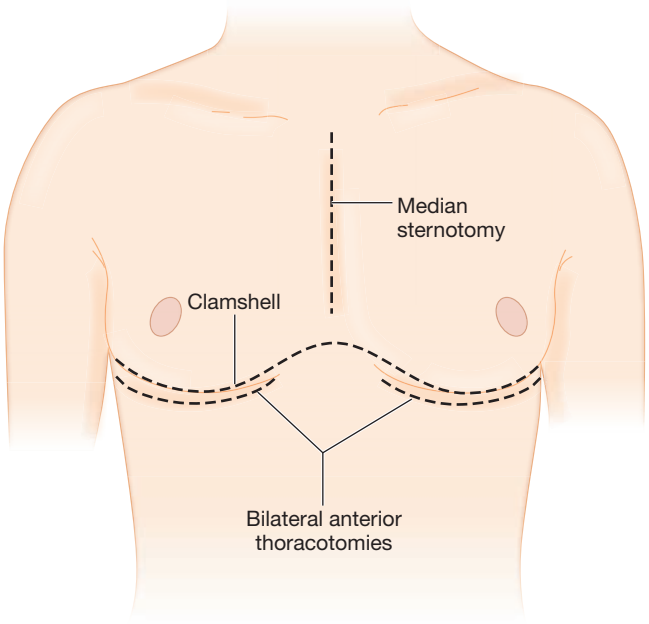

Figure 107-3 Approaches to bilateral lung transplantation. Bilateral anterior thoracotomy is now used commonly. Bilateral thoracosternotomy or "clam shell" incision is an alternative, consisting of bilateral anterior thoracotomy with transverse sternotomy, defined by the line of the inframammary crease. Entrance into the chest cavity is via either the fourth or fifth intercostal space, followed by placement of bilateral rib retractors. Occasionally a midline sternotomy is performed.

recipient hemithorax is uncommon; if present, the discrepancy should be treated conservatively (e.g., by avoiding chest tube suction rather than by aggressive surgical measures such as thoracoplasty). In all cases, sufficient remodeling of the thorax or hyperinflation of the lobar grafts will occur to obliterate any residual pleural space.

HEART–LUNG TRANSPLANTATION

Either a standard median sternotomy or a clamshell incision may be used for heart–lung transplantation. The latter provides better access for mobilization of intrapleural incisions and is particularly useful for recipients with septic lung disease or prior pulmonary procedures. Following institution of CPB, the lungs are removed by an extrapericardial approach using successive stapling of the bronchovascular structures at the pulmonary hila. The donor right atrium is incised from the inferior vena cava to the right atrial appendage. Inspection is made for the presence of an atrial septal defect and adequate closure of the superior vena cava. The donor bloc is positioned by passing the lungs into the pleural spaces via the retrophrenic pedicles. If a tracheal anastomosis is used, the posterior pericardium is incised between the ascending aorta and superior vena cava to expose the distal trachea and, after the donor and recipient tracheas have been trimmed, a distal tracheal anastomosis is performed. Some centers prefer bilateral bronchial anastomoses at the mediastinal pleural reflection, using the same technique employed for single-lung transplantation. This approach obviates dissection in the posterior mediastinum and may be associated with fewer anastomotic complications. The right atrial anastomosis is completed, followed by the aortic anastomosis. The aortic cross clamp is removed, and after reinflation of the lungs, the heart is deaired via the pulmonary artery and left ventricle. After defibrillation, the patient is weaned from CPB.

POSTOPERATIVE MANAGEMENT

Care of the lung transplant recipient in the immediate postoperative period is multifaceted and includes respiratory and hemodynamic management and initiation of antimicrobial prophylaxis and immunosuppressive agents.

VENTILATION

In most cases, ventilatory management follows standard criteria. The $F_{I_{O_2}}$ is adjusted to maintain a Pa_{O_2} greater than 65 mm Hg. Standard volume ventilation is used, and many centers are now using lower tidal volume of 6 mL/kg and PEEP of 5 to 7.5 cm H_2O. Transition from volume ventilation to pressure support ventilation is commonly performed once the patient is awake and spontaneously breathing. Appropriate management of postoperative pain is also helpful in weaning patients from the ventilator. Extubation is performed when the patient is awake and responsive to command and the patient has achieved a reasonable rate of ventilation and spontaneous tidal volume, typically 12 to 72 hours after the procedure. Maintaining good bronchopulmonary hygiene, with an early bronchoscopic inspection of the anastomoses and distal airways coupled with physiotherapy, is important in achieving and maintaining extubation in these patients.

Patients with emphysema who undergo single-lung transplantation are an exception to the guidelines mentioned earlier. These patients require particular attention to airway pressures and to the compliance difference between the allograft and the native lung. Hyperinflation of the native lung may not only result in compromise of cardiac filling but also interferes progressively with ventilation of the allograft. Efforts to control hyperinflation of the native lung include use of lower tidal volumes and respiratory rates and higher inspiratory flow rates to allow for more prolonged expiratory times. In rare circumstances, when significant edema has occurred in the allograft, independent lung ventilation using a double-lumen endotracheal tube may be needed.

In patients with significant pulmonary hypertension who undergo lung transplantation, the postoperative pulmonary hemodynamics are unique. In these patients, the right ventricle has been conditioned to generate peak systolic pressures against a markedly elevated PVR. Following lung transplantation, the PVR abruptly decreases to near-normal levels, accompanied by improved ventricular hemodynamics. Minimal catecholamine stimulation occurs when the patient awakens from anesthesia or is weaned from a ventilator, causing the right ventricle to respond by generating peak systolic pressures similar to those that existed preoperatively. The resultant abrupt increase in pulmonary artery pressure, in combination with increased capillary permeability due to ischemia and reperfusion injury and the absence of lymphatic continuity, causes fluid to accumulate rapidly in the donor lung. Typically, this pulmonary edema is very rapid in onset and results in hypoxia that elicits additional increase in pulmonary artery pressure. Preemptive treatment for this condition is necessary and requires maintenance of a high degree of sedation in the first 3 to 5 days after surgery. Following this period, patients can be awakened cautiously and weaned from the ventilator with standard methods while cardiac output, blood gases, and pulmonary artery pressures are closely monitored.

FLUID MANAGEMENT

The goal of fluid management after lung transplantation is to minimize the accumulation of edema fluid in the allograft(s) while maintaining optimal cardiac function. As previously noted, the effects of ischemia, reperfusion injury, and lymphatic discontinuity all contribute to a tendency to develop pulmonary edema in the lung graft. Pulmonary artery pressures and pulmonary capillary wedge pressures need to be kept as low as possible after surgery without compromising ventricular preload. For most patients, a reduction in PVR almost immediately after lung transplantation results in improved right ventricular and, secondarily, left ventricular performance. However, some inotropic support may be required in patients who have pre-existing right ventricular systolic dysfunction. Systolic vascular resistance may be low in the postoperative period, due to a systemic inflammatory response to surgery and to use of epidural analgesics, and this may necessitate the use of pressors to address hypotension.

ANTIMICROBIAL THERAPY

Bacterial prophylaxis entails the use of agents for prophylaxis against gram-positive, gram-negative, and anaerobic organisms in combination with targeted antibiotics to provide appropriate coverage for organisms identified preoperatively from the sputum of the recipient. Recipients who have been hospitalized recently, and therefore exposed to respiratory therapy equipment, or those with cystic fibrosis, require specific antibiotic coverage against *Pseudomonas* species, based on susceptibility data. Bear in mind that in vitro sensitivity does not always predict the in vivo response to antibiotics, which may show the effect of in vivo synergy and high-concentration gradients within the lung especially for quinolones and macrolides. For cystic fibrosis patients, ongoing surveillance of sputum flora and determination of antibiotic sensitivities are important in the waiting period before transplantation so that an appropriate multidrug antimicrobial regimen can be developed for perioperative use. The addition of antimicrobial inhalation therapy, using either tobramycin or Colistin, can have additive effects in reducing the colonizing load of organisms. Postoperative antibacterial coverage should be modified if pathogens not already covered by the recipient-specific regimen are found in the sputum or bronchoscopic specimens of the donor.

Routine prophylaxis for fungal organisms is useful when preoperative recipient sputum cultures have demonstrated the presence of *Aspergillus* species at any time before the transplant procedure or when there has been evidence of heavy overgrowth of yeast (e.g., *Candida*) in the donor sputum culture. In the case of *Aspergillus,*

most units employ prophylactic therapy with the use of either nebulized amphotericin B or azole therapy with voriconazole or itraconazole. Some centers employ a hybrid strategy of initial universal fungal prophylaxis with inhaled therapies followed by preemptive therapy for any organisms detected on surveillance cultures.

The occurrence of herpes simplex virus (HSV) infection, including mucosal ulceration, esophagitis, and pneumonitis, has been virtually eliminated by the routine use of antiviral prophylaxis after lung transplantation but significant infections can still occur and may impact both survival and quality of life.[73–75] Valganciclovir used to prevent CMV has cross reactivity for herpes simplex but it is important not to forget to institute prophylaxis in CMV donor-negative/CMV recipient–negative patients who may not be allocated valganciclovir.[47,51] In such cases, acyclovir or valacyclovir should be administered for a minimum of 6 months. CMV infection is still a significant problem following lung transplantation.[50,74–78] The incidence of CMV infection after lung transplantation is related to the preoperative CMV status of both the donor and the recipient. Recipients with prior exposure to CMV are at risk for reactivation of infection and, if they receive an organ from a CMV-positive donor, for reinfection. The greatest risk occurs when a CMV-negative recipient receives a lung from a CMV-positive donor; the primary infection of the recipient that can ensue tends to be more severe than either reactivation or reinfection. For this reason, some centers prefer to avoid mismatching a CMV-positive donor with a CMV-negative recipient. However, the use of antiviral prophylaxis with ganciclovir or valganciclovir prophylaxis has significantly reduced the incidence of primary disease.

The incidence of *Pneumocystis jiroveci* infection in lung transplant patients has also been significantly reduced by the routine use of trimethoprim–sulfamethoxazole.[79] If this drug is not tolerated alternatives such as dapsone (watch for Coombs-positive hemolytic anemia) or inhaled pentamidine should be entertained.

IMMUNOSUPPRESSION

The induction of a state of relatively nonspecific immune suppression by pharmacologic means has been the key to successful clinical lung transplantation. While the ideal method would be to achieve specific, permanent tolerance of the allograft without the need for chronic medication, this is not possible at present. As a result, although the current regimens lead to satisfactory control of most acute rejection (AR) processes, the combined side effects of these medications and their incomplete ability to control CR in the lung account for the major long-term morbidity and mortality associated with lung transplantation. It is always a balance of efficacy versus toxicity and the transplanted lung has one risk factor that no other solid organ faces, namely it is exposed to the ambient environment with every breath.[80,81]

The immunosuppressive regimens used for lung transplantation are based on the successful protocols that have evolved for renal and heart transplantation. Recent trials have supported similar regimes in lung transplantation.[82–89] Virtually all centers use a three-drug regimen for immunosuppression comprising a CNI, a cell-cycle inhibitor and a corticosteroid, with the hope of obtaining additive effects in terms of immune suppression while limiting drug toxicities. Most lung transplant programs use steroids as part of the regimen for the induction of immunosuppression. However, some centers have used cytolytic therapies such as daclizumab, basiliximab, alemtuzumab, OKT3, and antithymocyte globulin for this purpose. These therapies are typically initiated within 24 hours of transplantation, and are typically combined with the usual triple-drug regimen of steroids, a CNI, and a cell-cycle inhibitor.

Tacrolimus has now overtaken cyclosporine as the mainstay of immunosuppression for lung transplantation and there is a growing evidential base to support this policy.[4,89] Tacrolimus (FK-506) is a macrolide compound with a mechanism of action similar to that of cyclosporine mediated through an immunophilin protein called the FK-binding protein (FKBP). Toxicity is similar to that of cyclosporine and includes renal dysfunction, hypertension, and neurotoxicity. New-onset diabetes mellitus has also been reported. In contrast to cyclosporine, hirsuitism and gingival hyperplasia have not been seen with tacrolimus. In a randomized trial in lung-transplant patients of three-drug regimens containing either cyclosporine or tacrolimus, the incidence of postoperative fungal infections was higher in patients receiving tacrolimus. A large 3-year study recently reported a significant reduction in the rate of BOS at 3 years in the arm taking tacrolimus but this was not associated with a difference in 3-year mortality.[89]

Intravenous or sublingual administration of tacrolimus is usually begun before the graft is implanted and continued postoperatively, provided renal function remains satisfactory. Subsequent conversion to oral dosing is completed when gastrointestinal function is normal. Blood levels of both tacrolimus and cyclosporine correlate with immunosuppressive effects and toxicity but there is still some debate regarding the optimum method of performing therapeutic drug monitoring. For cyclosporine there is good evidence that the best single-point surrogate measure of the area under the time–concentration curve is the value taken at 2 hours post dose.[90–93] Less data are available for tacrolimus but it is clear that like cyclosporine, trough levels may both overestimate and underestimate total drug exposure, which may lead to risk of rejection and nephrotoxicity respectively. Nephrotoxicity, the major side effect of both cyclosporine and tacrolimus, results in part from vasoconstriction of the afferent glomerular arteriole and may be ameliorated by the concomitant use of diltiazem. However, chronic CNI toxicity is common and results in granular contracted kidneys with permanent renal failure.

Azathioprine, a purine analog, is converted to several purine metabolites, including 6-mercaptopurine, in red cells and hepatocytes. These purine metabolites have a variety of inhibitory effects on hematologic cell proliferation, with a somewhat greater effect on T cells than B cells. Azathioprine is begun at a dosage of 2 to 2.5 mg/kg per day and adjusted downward to maintain a white blood cell count of more than 4000 cells/mL. The dosage is the same for both the intravenous and oral routes. If necessary, azathioprine may be omitted for several days without significant compromise of its immunosuppressive effect.

Mycophenolate preparations subserve a similar role as cell-cycle inhibitors but despite demonstrable efficacy after heart transplantation in particular, trials after lung transplantation have not shown convincing evidence of superior efficacy or tolerability compared to azathioprine. The largest study to date was an open label study that may have been underpowered by the presentation of 1-year data that was favorable in the mycophenolate arm, perhaps leading to a large number of patients in the azathioprine arm switching to mycophenolate.[88] Mycophenolic acid inhibits de novo purine synthesis by inhibiting the conversion of inosine monophosphate to xanthine monophosphate. Since lymphocytes depend almost exclusively on de novo purine synthesis, mycophenolic acid selectively inhibits their replication, including the formation of cytotoxic lymphocytes and both primary and secondary antibody formation. Mycophenolic acid has been shown to reverse AR that is resistant to both corticosteroids and OKT3. Side effects include nausea, gastritis, ileus, and myelosuppression.[88]

Corticosteroids have a variety of effects on the immune response, mediated by the interaction of the steroid with a high-affinity cytoplasmic receptor. Steroids affect both inflammation and immunity, and modulate lymphocyte-, mononuclear phagocyte–, and antigen-presenting cell functions. Prednisone, prednisolone, and methylprednisolone are all synthetic derivatives of cortisol that are used clinically for transplant patients.[94] Intraoperatively, methylprednisolone is administered before reperfusion of the lung graft. Postoperatively, in the absence of cytolytic induction therapy,

moderate-dose corticosteroid therapy is used in combination with a CNI and cell-cycle inhibitor for induction immunosuppression. Oral corticosteroids (0.5–1.0 mg/kg/d) are usually begun after the postoperative intravenous steroids and when oral therapies are commenced. Although corticosteroids have profound inhibitory effects on wound healing, their use in this fashion in the immediate postoperative period has not adversely affected the outcomes of lung transplantation.

Various antilymphocyte antibody preparations, the so-called cytolytic therapies, have been used in clinical lung transplantation. Both polyclonal preparations, such as antilymphocyte globulin and antithymocyte globulin (ATG), and a murine monoclonal antibody to the CD3 complex of human lymphocytes (OKT3) have been used. Initially, it was believed that strict avoidance of corticosteroids was needed in the early postoperative period to assure satisfactory healing of the bronchial anastomosis. As a result, cytolytic therapy was thought to be necessary to induce immunosuppression before the initiation of steroid therapy in the second postoperative week. The subsequent demonstration that moderate-dose corticosteroid therapy was well tolerated immediately after lung transplantation, as described, as well as concerns regarding the risks of cytolytic therapy, resulted in many centers reserving the use of these agents for the treatment of refractory AR. However, data from the ISHLT Registry suggest the majority of centers now use some form of cytolytic induction based on the belief that the benefit of a reduced rate of BOS so engendered is worth the risk.[4]

The two most significant concerns regarding the use of cytolytic therapy have been the increased incidence of CMV disease and of posttransplant lymphoproliferative disorder (PTLD).[95–97]

The mammalian target of rapamycin inhibitors sirolimus (rapamycin) and everolimus inhibit the response of T lymphocytes to IL-2 and other cytokines but do not inhibit IL-2 production. Sirolimus has been shown to reverse rejection and prolong graft survival in animal models. However, sirolimus has been associated with lethal airway anastomotic dehiscence when used for immunosuppression early posttransplantation.[98] Recent reports also warn of an excess rate of venous thrombosis with sirolimus.[99] Concurrent cyclosporine administration increases the potency of rapamycin, suggesting that it may be used in combination with cyclosporine to lower the overall toxicity of a multidrug immunosuppressive regimen. Importantly, rapamycin increases the AUC of cyclosporine by more than 150%, which may lead to CNI-induced nephrotoxicity and possibly hemolytic uremic syndrome.[100]

COMPLICATIONS

Lung transplant recipients are at risk for a number of complications that can adversely impact allograft function as well as posttransplant survival. These include technical, infectious, immune-mediated, and neoplastic complications.

SURGICAL COMPLICATIONS

Major technical complications following lung transplantation have become increasingly rare with improvements in surgical technique and perioperative management. Postoperative hemorrhage requiring exploration is very uncommon with the use of the clamshell incision to improve operative exposure for patients requiring bilateral-lung transplantation or heart lung transplantation. Patients with extensive pleural adhesions from their underlying disease or from prior thoracic surgery or pleurodesis are at greatest risk for intraoperative and postoperative bleeding. Pulmonary artery obstruction can occur as a result of anastomotic stenosis, kinking, or extrinsic compression. In these patients, persistent pulmonary hypertension and unexplained hypoxemia may be evident. Attention to anatomic factors, such as the length of donor and recipient pulmonary arteries and division of the pericardial attachments surrounding the donor pulmonary artery, as well as awareness of the potential for a flap wrapping the bronchial anastomosis to compress the adjacent anastomosis, helps to avoid these problems. Pulmonary venous or left atrial anastomotic obstruction can also occur because of faulty anastomotic technique, kinking upon closure of the chest, or thrombus. This problem results in more severe abnormalities than pulmonary artery obstruction, including marked pulmonary hypertension and ipsilateral pulmonary edema. Diagnostic methods for these vascular anastomotic complications include routine intraoperative measurement of anastomotic gradients and transesophageal echocardiography, which is particularly helpful in assessing the left atrial anastomosis. Postoperatively, diagnostic measures include contrast angiography and ventilation/perfusion scanning. Urgent reoperation and correction of the anastomosis are indicated if clinical compromise is apparent, which is particularly likely if there is significant left atrial anastomotic obstruction. The clinical clue is a diffuse infiltrate within the transplanted lung with evidence of suffusion of the bronchial mucosa at bronchoscopy with or without blood-stained secretions, that may mimic frank pulmonary edema fluid.
