NPC may produce symptoms in patients of any age; and initial presentation may occur from neonatal to adult periods. Infants often have nonspecific symptoms that make exact diagnosis difficult. Along with liver disease, infants may present with often-fatal pulmonary failure due to impaired gas exchange due to lung infiltration with foam cells. Patients presenting in childhood or adolescence, or as adults, typically do not have pronounced pulmonary involvement.[30–32,35] Pulmonary alveolar proteinosis may occur in patients with NPC2 disease; possibly due to loss of normal NPC2 protein expression in alveolar macrophages and accumulation of functionally inactive cholesterol-rich surfactant.[33,34,36] Bronchoalveolar lavage has been reported to improve pulmonary symptoms in children with foam cell infiltrates.[37] Histologic features are similar to those seen in patients with NPA and NPB.

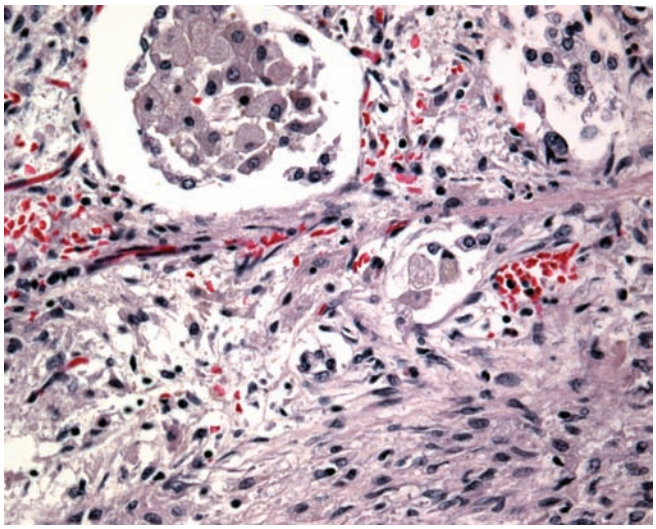

Figure 67-3 High power image of lung in long-standing Niemann–Pick disease showing developing pulmonary fibrosis.

GAUCHER DISEASE

Gaucher disease (GD), an autosomal recessive disease, is due to inadequate lysosomal enzyme glucosylceramidase activity, with the resulting accumulation of glucosylceramide, the enzyme's undegraded substrate, as well as other glycolipids.[12,15,38–40] The substrate arises primarily from the breakdown of red blood cells and other tissue cells. The undegraded substrate is then taken up by monocytes and macrophages. Central nervous system involvement with GD may be caused by membrane ganglioside turnover; however, neuron death may also play a role.[41]

GD encompasses three main clinical subtypes, as well as two additional subtypes, each with characteristic features. Type 1, 2, and 3 GD frequently show lung involvement. Type 1 GD is characterized clinically by bone disease, including osteonecrosis, lytic and sclerotic lesions, and osteopenia; anemia; thrombocytopenia; and hepatosplenomegaly; however, affected patients do not typically show central nervous system involvement. Type 2 and type 3 GD are both characterized by central nervous system involvement with disease; however, type 2 GD patients typically present with disease before age 2, exhibit poor psychomotor development, and rapidly deteriorate, with death occurring usually between ages 2 and 4. Patients with Type 3 GD, in contrast, typically present before age 2, but progress slowly, with some patients surviving to adulthood. There are also two additional subtypes, for which lung involvement is not characteristic. Cardiovascular GD shows mitral value and aortic valve calcification, corneal opacities, and supranuclear opthalmoplegia. Perinatal lethal GD shows nonimmune hydrops fetalis or skin abnormalities.

GD may be caused by mutations in Saposin C and acid-β-glucosidase.[42] Diagnosis of GD requires the demonstration of inadequate glucosylceramidase activity in peripheral blood leukocytes or other cells. Treatments include enzyme replacement therapy or substrate reduction therapy.[43–46]

Pulmonary involvement in patients with GD includes pulmonary hypertension, lobar consolidation, and interstitial lung disease.[1,12,15,38,47,48] Pulmonary hypertension is a typical finding in GD patients with hepatic disease, perhaps because of the patients' inability to detoxify gut-derived factors that affect pulmonary endothelium, with resultant pulmonary hypertension. Pulmonary hypertension may also occur in patients with GD without liver disease.[47] Some patients with type 1 GD without pulmonary disease may, nonetheless, exhibit rapid fatigability, possibly due to GD-caused circulatory impairment.[12,48,49]

Histologically, GD cells infiltrate liver, spleen, and bone marrow. Lung involvement is common in pediatric patients and less common in adults.[50] Lung involvement may be clinically significant in as many as one-third of patients.[51] GD cells most often involve septal capillaries; this is thought to be the cause of GD-associated pulmonary hypertension.[51] Infants and children may also demonstrate intra-alveolar involvement. GD cells have also been found to cause substantial septal thickening and patchy involvement in a lymphatic distribution.[51] The characteristic Gaucher cell has a "wrinkled paper" appearance (Fig. 67-4), highlighted with Periodic acid-Schiff (PAS) staining. Gaucher cells are CD68 negative, in contrast to alveolar macrophages, which show CD68 positivity.[52]

FABRY DISEASE

Fabry disease (FD) is an X-linked lysosomal storage disease caused by a deficiency of α-galactosidase A enzyme activity, resulting in globotriaosylceramide accumulation in a variety of tissues, including cardiomyocytes, smooth muscle cells, and endothelial cells.[53–55]

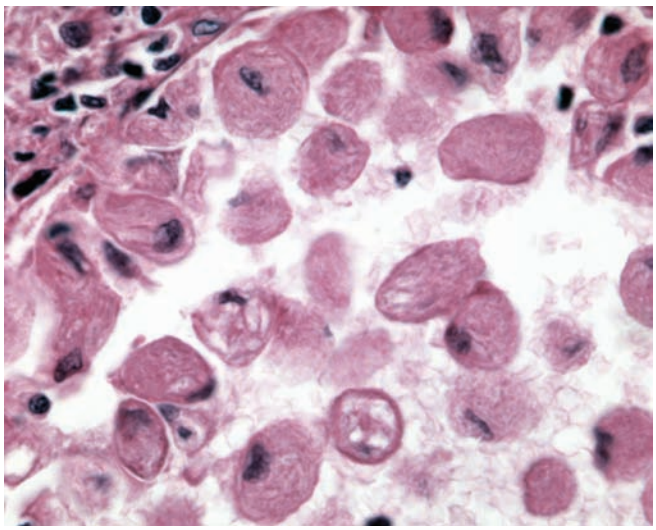

Figure 67-4 High power image of Gaucher cells within an alveolar space showing its characteristic "wrinkled paper" appearance.

Males with less than 1% enzyme activity develop the classic form of FD, which typically present in childhood or adolescence and is characterized by proteinuria, corneal and lenticular opacities, angiokeratomas, hypohidrosis, and periodic episodes of markedly painful extremities. By the third to fifth decades, gradually worsening renal function usually leads to end-stage renal disease. If an adult with FD survive their renal disease, they typically succumb to cerebrovascular or cardiovascular disorders. If men exhibit greater than 1% enzyme activity, however, they typically exhibit a renal variant, with resultant end-stage renal disease, but without extremity pain or skin lesions. Alternatively, they may exhibit a cardiac variant, which typically presents in men in their 50s to 70s. Findings include proteinuria, mitral value insufficiency, cardiomyopathy, and left ventricular hypertrophy; end-stage renal disease is absent.

Female patients with FD, who are heterozygous for the disease, often exhibit later onset of findings and milder symptoms than males; however, their presentations may range from essentially asymptomatic throughout life to symptoms mimicking their male counterparts with classic FD.

Diagnosis in males is made by showing α-galactosidase A enzyme deficiency in leukocytes, cultured cells, or plasma. Enzyme measurement is not a reliable test for females; some carriers have decreased enzyme activity, but others show normal activity. Enzyme testing for a mutation in *GLA*, the gene associated with FD, is necessary for diagnosis in female carriers. Males essentially always show a *GLA* mutation. Enzyme replacement therapy is typically used in male patients and symptomatic female carriers.[49,53,54]

Pulmonary involvement may occur in both males and females with FD.[12,56–58] Patients typically exhibit dyspnea, wheezing, and findings of chronic bronchitis; pulmonary function tests may show obstruction.[59] Radiologic changes may be minimal and do not correlate with the severity of pulmonary dysfunction. Histologic diagnosis of FD typically involves identification of laminated inclusions in type II pneumocytes and capillary endothelium.[58] Lamellar inclusions have been reportedly identified cytologically in alveolar macrophages, ciliated epithelial cells, and goblet cells by examination of induced sputum, bronchial brushings, and bronchoalveolar lavage specimens.[58,60,61]

HERMANSKY–PUDLAK SYNDROME

Hermansky–Pudlak syndrome (HPS), also termed oculocutaneous albinism syndrome, is a rare autosomal recessive multisystem disease involving disorders of intercellular trafficking. HPS is characterized by tyrosinase-positive oculocutaneous albinism, a platelet storage pool deficiency that causes bleeding diatheses, and, in some cases, pulmonary fibrosis.[62–71] Patients with HPS exhibit congenital nystagmus, decreased visual acuity, iris transillumination, and variable skin and hair hypopigmentation.[72] Approximately 15% of patients may also develop granulomatous colitis.[63–65,73] HPS is diagnosed based on clinical characteristics and ultrastructural absence of platelet-dense bodies.[74] Patients often exhibit easy bruising and prolonged bleeding.

HPS, including its subtypes, has been shown to be caused by mutations in several genes. These include *HPS1*, causing HPS-1; *AP3B1*, causing HPS-2, *HPS3*, causing HPS-3; *HPS4*, causing HPS-4; *HPS5*, causing HPS-5; *HPS6*, causing HPS-6; *DTNBP1*, causing HPS-7; *BLOC1 S3*, causing HPS-8; and *BLOC1 S*, causing HPS-9.[65,66,75]

Pulmonary involvement in patients with HPS generally presents clinically and radiologically as pulmonary fibrosis. Patients generally become symptomatic by the fourth decade; lung disease is progressive and restrictive in nature. Death may ensue within a few years following onset of pulmonary symptoms.[76] Pulmonary fibrosis is typically found in HPS1, HPS2, and HPS4; it is particularly prevalent in patients with HPS1 from Puerto Rico.[64,72,77–83] Pulmonary fibrosis is not characteristic of HPS3, HPS5, or HPS6. Lung transplantation may be appropriate for some patients with HPS.[84]

The basis for the pulmonary fibrosis is unknown; however, a postinflammatory response has been hypothesized as the causative factor.[85] Pirfenidone treatment has been attempted in patients with HPS with pulmonary function greater than 50% of normal, with some benefit.[77] Histologically, the pulmonary fibrosis may show a pattern of usual interstitial pneumonia or nonspecific interstitial pneumonia.[72,86] Ceroid–filled macrophages fill airspaces and the lung interstitium (Figs. 67-5–67-7) and may be identified with bronchoalveolar lavage.[86]

CHOLESTERYL ESTER STORAGE DISEASE

Cholesteryl ester storage disease (CESD), a rare autosomal recessive disease, is characterized by lysosomal acid lipase/cholesteryl ester hydrolase deficiency.[87] Most patients with CESD have some enzyme activity; individuals with complete enzyme deficiency are diagnosed as having Wolman disease.[88] In patients with CESD, there is deposition of cholesteryl ester generally in the liver, bone marrow, bowel, and spleen. Gastrointestinal bleeding, often occult, and hepatomegaly are frequently identified.[89] Patients usually survive well into adulthood, ultimately dying from chronic hepatic failure or premature atherosclerosis.[87]

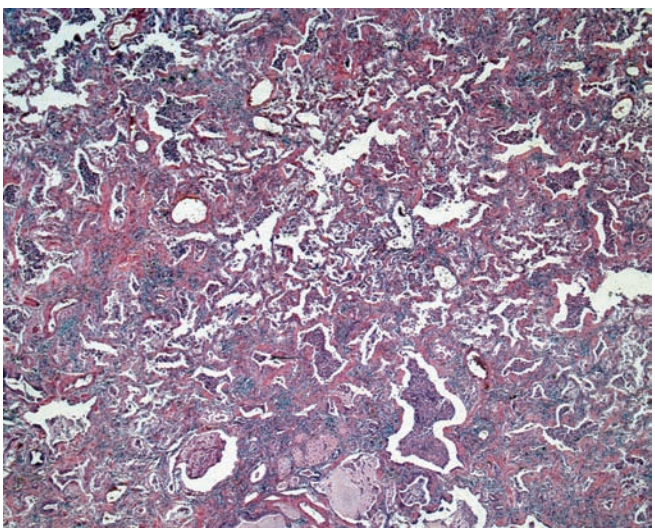

Figure 67-5 Lower power image of lung in Hermansky–Pudlak syndrome showing a nonspecific interstitial pneumonia-like pattern.

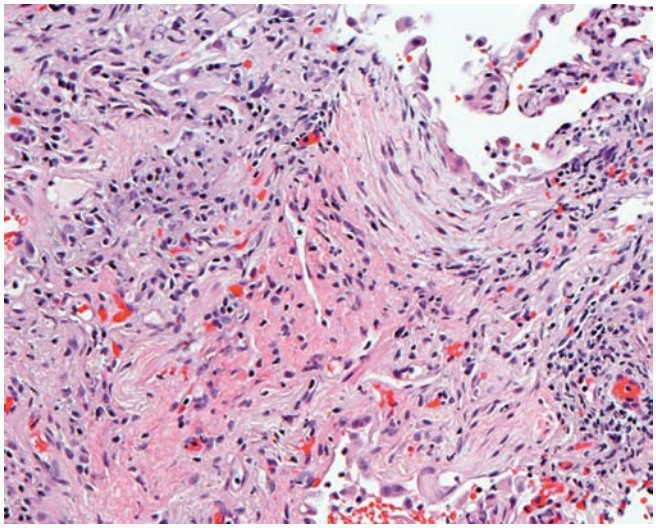

Figure 67-6 Medium power image of lung in Hermansky–Pudlak syndrome showing a usual interstitial pneumonia-like pattern.

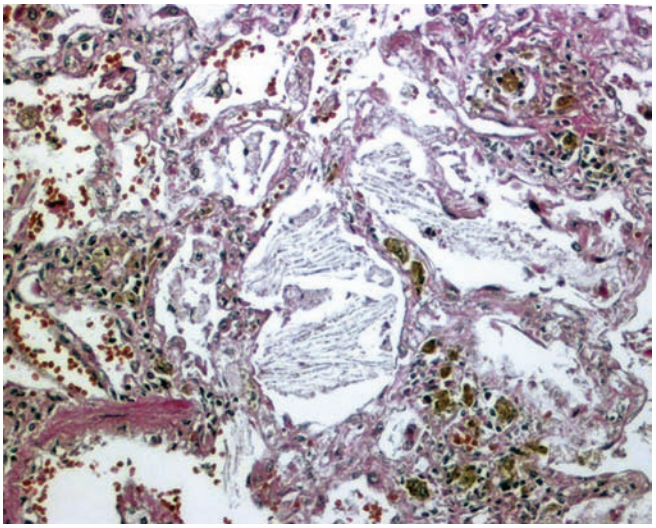

Figure 67-8 Medium power image of lung in cholesteryl ester storage disease showing cholesteryl ester accumulation within alveolar macrophages, and interstitial fibroblasts.

Pulmonary involvement in CESD is uncommon; however, it may occur due to accumulation of cholesteryl esters within alveolar macrophages and interstitial fibroblasts (Figs. 67-8 and 67-9). Pulmonary arteries may also develop from cell deposits within the intima, which may be complicated by associated reactive fibrosis.[90,91] Treatment of pulmonary involvement in patients with CESD is supportive; however, for most patients, pulmonary involvement is not life-threatening.[90]

MUCOPOLYSACCHARIDOSIS TYPE I

Mucopolysaccharidosis Type I (MPS1), an autosomal recessive disease, is a progressive multisystem disease due to a lysosomal storage disorder caused by deficiency of the enzyme α-L-iduronidase.[92,93] Patients with MPS1 show varying levels of severity. The diagnoses of Hurler syndrome, Hurler–Scheie syndrome, and Scheie syndrome have shown generally overlapping clinical features and no biochemical differences; therefore, currently, patients are clinically diagnosed as having either Severe MPS1 (formerly Hurler syndrome) or Attenuated MPS1 (formerly Hurler–Scheie syndrome and Scheie syndrome). The diagnosis of MPS1 is based on demonstration of insufficient α-L-iduronidase activity in plasma, in cultured fibroblasts, or peripheral blood leukocytes. Treatment may include enzyme replacement therapy and bone marrow transplantation.[92–95] Attenuated MPS1 patients may show pulmonary disease, including changes in forced vital capacity, and respiratory complications are often the cause of death.[96]

MUCOPOLYSACCHARIDOSIS TYPE II

Muopolysaccharidosis type II (MPSII), also termed Hunter syndrome, is inherited as an X-linked recessive disease. MPSII is a multisystem disease characterized by the pathologic lysosomal storage of glycosaminoglycans.[97–99] Most patients are males, with carrier females showing clinical features only rarely. Patients with MPSII typically show central nervous system involvement, predominantly a progressive deterioration of cognitive functions. Patients generally have macrocephaly, with or without communicating hydrocephalus, hoarseness, hearing loss, macroglossia, splenomegaly, hepatomegaly, short stature, dysostosis multiplex, and joint contractures.[98,99] Patients may also exhibit cardiac findings and progressive airway disease in severe cases. Patients frequently do not survive their second decade.

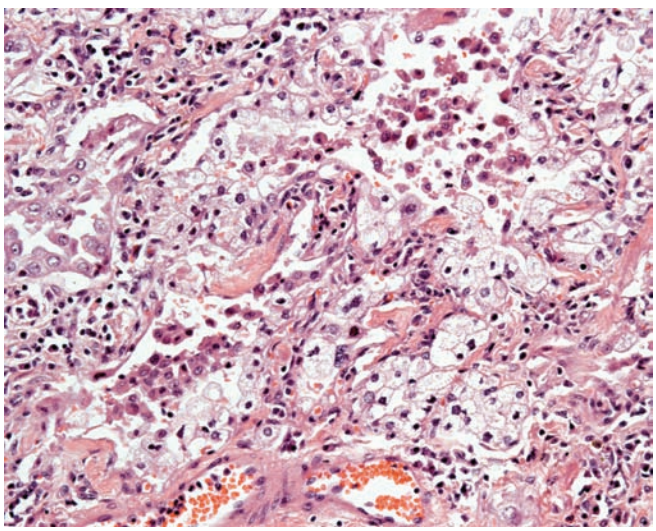

Figure 67-7 High power image of lung in Hermansky–Pudlak syndrome showing ceroid-filled histiocytes within alveolar spaces.

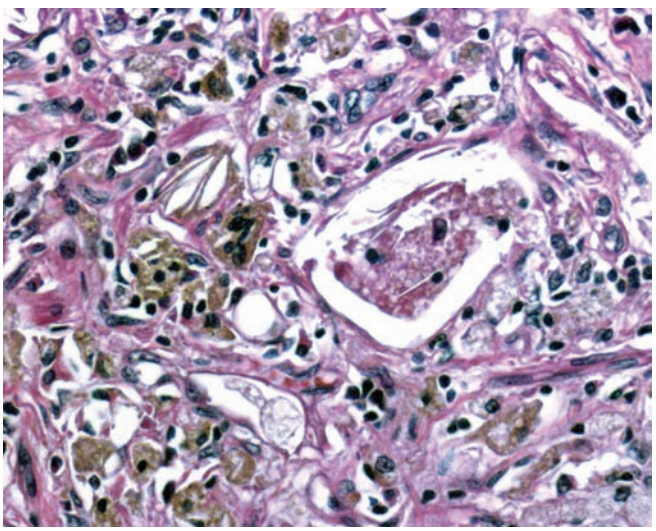

Figure 67-9 High power image of lung in cholesteryl ester storage disease showing alveolar macrophages containing cholesteryl esters.

Clinical manifestations and progression may vary significantly; severity should be considered to be on a continuum. Some patients with milder forms of disease show normal intelligence into early adulthood and survive into the sixth decade.[97,98]

To confirm clinical suspicion, testing for deficient iduronate sulfatase enzyme activity in plasma, fibroblasts, or white blood cells may be performed. Diagnosis may be confirmed by molecular testing of *IDS*, the gene associated with MPSII. Until recently, treatment has been supportive only.[97] Bone marrow transplantation has been attempted, but has not been successful.[100] Treatment with enzyme replacement therapy is currently being studied in patients with MPSII.[98,101–104]

Patients with MPSII often show frequent upper respiratory infections as an early feature of disease. Progressive airway narrowing due to accumulation of glycosaminoglycans in the tongue, upper airway, and trachea usually cause symptomatic airway obstruction.[97,99] Ultimately, progressive airway obstruction with associated sleep apnea requires tracheostomy. Along with airway obstruction, hepatomegaly and splenomegaly, thick pulmonary secretions, and chest wall stiffness.[98]

CHAPTER 68

Alveolar Hemorrhage Syndromes

Joseph P. Lynch
Michael C. Fishbein
Tisha Wang

Diffuse alveolar hemorrhage (DAH) is a potentially catastrophic complication of myriad immune and nonimmune disorders.[1–3] Clinical features are broad, but hemoptysis, infiltrates on chest radiographs, hypoxemia, and progressive respiratory insufficiency are common to diverse etiologies.[2] Nonimmune causes of alveolar hemorrhage include endobronchial tumors, arteriovenous malformations or aneurysms, ulcerative tracheobronchitis, hemorrhagic pneumonia, bronchiectasis, congestive heart failure, uremia, thrombocytopenia or coagulopathy, pulmonary venoocclusive disease, infections, and massive pulmonary embolism.[4,5] These nonimmune causes need to be excluded in patients with severe alveolar hemorrhage. Depending upon the clinical scenario, coagulation profiles and ancillary tests (e.g., echocardiogram, chest computed tomographic [CT] pulmonary angiography, fiberoptic bronchoscopy) may be required to establish a specific diagnosis. In addition, other causes of diffuse parenchymal infiltrates (but without severe alveolar hemorrhage) share features in common with DAH syndromes (e.g., cryptogenic organizing pneumonia, hypersensitivity pneumonia, pulmonary alveolar proteinosis, and diverse interstitial or alveolar lung disorders). A discussion of these disorders is beyond the scope of this chapter, which focuses primarily on immune-mediated causes of DAH.

AUTOIMMUNE CAUSES OF ALVEOLAR HEMORRHAGE: DIFFERENTIAL DIAGNOSIS

Autoimmune DAH results from diffuse injury to the pulmonary microvasculature (termed *capillaritis* or *endotheliitis*) (Table 68-1).[6,7] Systemic necrotizing vasculitides[8,9] (principally microscopic polyangiitis [MPA][10,11] and Wegener's granulomatosis [12] account for most cases of autoimmune DAH.* Other causes of autoimmune DAH include antiglomerular basement membrane (anti-GBM) antibody disease,[13–15] connective tissue disease (CTD) (principally systemic lupus erythematosus [SLE]),[16] exogenous agents or drugs.[17] In many of these disorders, rapidly progressive glomerulonephritis (RPGN) is present concomitantly.[18,19] In most patients with autoimmune DAH and glomerulonephritis (GN), anti-GBM antibody and immune complexes are lacking.[19] The term *pauci-immune glomerulonephritis* has been used to refer to this group of patients, who encompass a heterogeneous group of disorders.[20,21] (discussed in detail below).

Idiopathic pulmonary hemosiderosis (IPH), a rare cause of recurrent DAH with no renal or extrapulmonary component, occurs primarily in children[22–24] and remains a diagnosis of exclusion.

Differentiation of these diverse syndromes can usually be accomplished by serological studies and by kidney biopsy. In such cases, lung biopsy is not required. GN can be demonstrated in the great majority of patients with DAH complicating granulomatosis with polyangiitis (GPA)[12] or MPA.[7,10,11] By contrast, the kidneys may be spared in DAH associated with CTD,[16] bone marrow transplant recipients,[25,26] or immunocompromised patients.[27,28] Urinalysis (to look for microscopic hematuria, red cell casts, and proteinuria) and measurement of renal function should always be done in the diagnostic evaluation of DAH. Findings consistent with GN warrant a prompt and aggressive evaluation that should include percutaneous needle biopsy of the kidney.

CLINICAL FEATURES OF AUTOIMMUNE ALVEOLAR HEMORRHAGE

Irrespective of etiology, the clinical, radiographic, and histopathological features of DAH may be similar.[1,2,6] Classical findings are hemoptysis, diffuse alveolar infiltrates, hypoxemia, renal failure, and iron-deficiency anemia.[2,7] However, the clinical spectrum is wide, and many of these features may be subtle or absent. In this context, the diagnosis of DAH may be difficult, as signs and symptoms overlap with diverse etiologies of diffuse alveolar infiltrates. Prompt diagnosis and institution of therapy is vital to avert early mortality from DAH and late sequelae from end-stage renal failure. Chest radiographs typically reveal bilateral alveolar infiltrates, often with a batwing appearance. However, focal, and even unilateral, patterns indistinguishable from pneumonia may occur. Following cessation of bleeding, infiltrates markedly improve or normalize within 24 to 72 hours (Fig. 68-1). A presumptive diagnosis of DAH can often be made by a combination of clinical and serological findings and bronchoalveolar lavage (BAL) fluid. Grossly bloody BAL fluid (with progressively more blood with serial aliquots),[1,2,7] large numbers of hemosiderin-laden macrophages,[8,27] and the absence of purulent secretions or ancillary evidence for infection strongly support DAH as a cause of pulmonary infiltrates. Ancillary studies including serologies, renal function tests, and urinalysis may support the diagnosis.

TABLE 68-1 Etiology of Autoimmune Diffuse Alveolar Hemorrhage

Antiglomerular basement membrane antibody disease (Goodpasture's syndrome)
Antineutrophil cytoplasmic antibody (ANCA)-mediated vasculitis (e.g., granulomatosis with polyangiitis, microscopic polyangiitis, Churg–Strauss syndrome, pauci-immune glomerulonephritis)
Idiopathic rapidly progressive glomerulonephritis
Collagen vascular disease (e.g., systemic lupus erythematosus)
Immunocompromised status (e.g., bone marrow transplant, AIDS)
Exogenous agents or drugs (e.g., trimellitic anhydride, isocyanates, D-penicillamine, cocaine)
Idiopathic pulmonary hemosiderosis (pathogenesis unknown)

*The Boards of Directors of the American College of Rheumatology (ACR), American Society of Nephrology (ASN), and the European League Against Rheumatism (EULAR) have recommended a gradual shift from honorific eponyms to disease-descriptive or aetiology-based nomenclature. The leadership of these three organizations tasked an international group of senior academicians expert in the care of patients with vasculitis and engaged in research in the field to provide the medical community with proper descriptive terms instead of the names for Wegener's granulomatosis, Churg–Strauss syndrome, and Behçet syndrome. The move toward a vasculitis terminology based on pathology, rather than historical reference, was triggered by evidence that Dr Friedrich Wegener was a member of the Nazi party before and during World War II. DIAGNOSIS

THE ROLE OF LUNG BIOPSY

The role of lung biopsy in the diagnosis of DAH and the determination of its etiology is controversial. We believe the risks of open or thoracoscopic lung biopsy are excessive in patients with severe DAH and respiratory failure. Postoperative complications such as infection and air leaks may be exacerbated by the corticosteroid or immunosuppressive agents used to treat many of these immune-mediated DAH syndromes. Furthermore, histological features are usually nonspecific. Predominant findings are extensive intra-alveolar hemorrhage and necrotizing pulmonary capillaritis (endotheliitis) (Fig. 68-2).[6–8] Capillaritis is characterized by neutrophilic infiltration of capillaries, fragmented neutrophils (leukocytoclasis), and necrosis of the capillary walls (Fig. 68-3).[8] Loss of the integrity of the alveolar–capillary basement membrane results in leakage of red blood cells and neutrophils into the alveolar space.[2] Hemosiderin-laden macrophages (siderophages) accumulate within the alveolar spaces and interstitium; their presence is a clue to prior episodes of alveolar hemorrhage (Figs. 68-2B,C and 68-4).[8]

Capillaritis was initially described as a marker of systemic vasculitis, but may also be observed in myriad disorders associated with DAH (e.g., SLE,[16] CTD,[2] anti-GBM disease,[14] bone marrow[25,26] or lung[29] transplant recipients, and drug-induced DAH).[1,6,7] An associated venulitis and arteriolitis may sometimes be present, but larger vessels are spared.[8] Capillaritis is subtle and often overshadowed by DAH filling the alveolar spaces.

Pulmonary capillaritis can be diagnosed by transbronchial biopsy, but this diagnosis is made with greater confidence when larger biopsy specimens are obtained by video-assisted thoracoscopy or limited thoracotomy.[6] Additional pathological features may be seen in patients with underlying granulomatous vasculitis (e.g., granulomas, necrosis, or eosinophils).[6,8] Nongranulomatous inflammation in airways and lung interstitium, interstitial fibrosis, diffuse alveolar damage (DAD), fibrinous pleuritis, and organizing pneumonia have also been described in DAH associated with anti-neutrophil cytoplasmic antibody (ANCA) vasculitic syndromes.[8] It should be emphasized that histological findings of alveolar hemorrhage and capillaritis, although distinctive, are nonspecific.[7] Immunofluorescent (IF) stains (of lung or kidney) or serological markers (e.g., anti-GBM antibody or ANCA) are required to differentiate the various causes of autoimmune DAH (Table 68-2).[6–8] Linear deposits of immunoglobulin G (IgG) along alveolar septa is pathognomonic for anti-GBM disease.[13,14] A granular, or "lumpy-bumpy" pattern of immune complex deposits may be seen in SLE, systemic necrotizing vasculitis, or immune complex–mediated idiopathic RPGN.[6] In ANCA-associated capillaritis, immune complexes are usually lacking (hence the term *pauci-immune*).[10,11,30] When immune DAH is suspected, a portion of the lung biopsy can

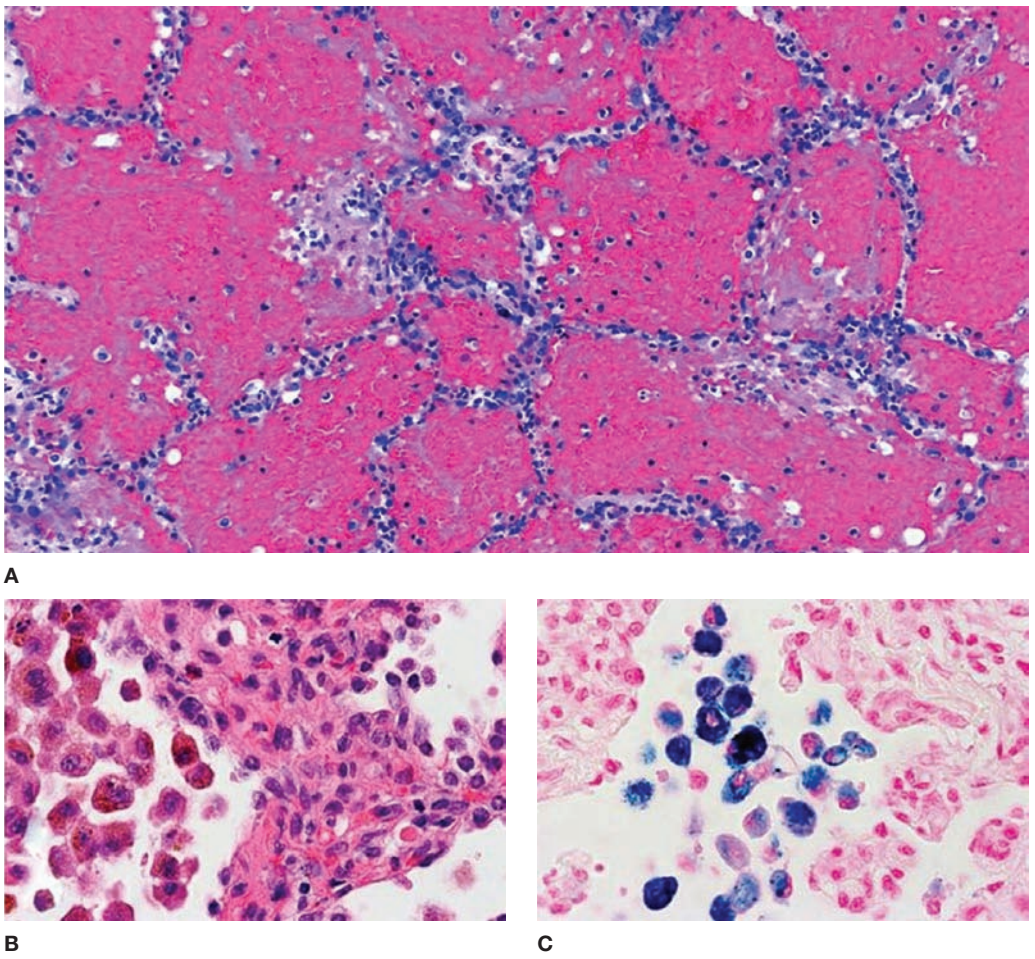

Figure 68-2 Alveolar hemorrhage. **A.** Acute hemorrhage with blood-filling alveolar spaces (H&E stain, ×40). **B.** Pigment-laden alveolar macrophages (H&E, ×200) shown in (**C**) to be full of iron (blue cytoplasm) indicative of prior hemorrhage (Prussian blue stain, ×200).

be frozen for IF stains, but IF stains of lung tissue are logistically difficult, and nonspecific background staining may lead to misinterpretation. When GN is present concomitantly, kidney IF stains are more sensitive and reliable.

Despite the greater accuracy of surgical lung biopsy in evaluating DAH, fiberoptic bronchoscopy with BAL is usually adequate to exclude infectious etiologies and support the diagnosis of DAH.[1] Bloody or serosanguinous BAL fluid (consistent with active or recent bleeding)[1,2,7] or hemosiderin-laden macrophages[8,27] (a clue to prior episodes of alveolar hemorrhage) may be sufficient to justify initiation of therapy provided clinical and serological features are consistent. Thoracoscopic lung biopsy may be useful in *noncritically ill* patients with suspected DAH when ancillary studies, kidney biopsy, and BAL are nondiagnostic.

■ THE ROLE OF PERCUTANEOUS KIDNEY BIOPSY

Necrotizing GN is a cardinal (albeit nonspecific) feature of most immune-mediated DAH syndromes.[19,31] The histological spectrum is varied, ranging from mild mesangial thickening to severe crescentic GN. Vasculitis of renal arterioles is rarely found, even in granulomatous vasculitides. Because of the strong association of autoimmune DAH and GN, percutaneous kidney biopsy should be performed in any patient with suspected DAH who has abnormalities on urinalysis or renal function tests. Conventional hematoxylin and eosin (H&E) stains are nonspecific, but the demonstration of glomerular inflammation with necrosis and crescents supports the diagnosis of an immune-mediated etiology (Fig. 68-5).[19,31,32] IF stains may clarify the nature of the underlying disorder. Bright linear IF staining along glomerular basement membranes (GBMs) is pathognomonic for anti-GBM disease (Fig. 68-6).[13,33] A lumpy-bumpy IF pattern, consistent with deposits of immune complexes, is found in some cases of CTD[16] and in idiopathic immune complex–mediated GN.[34] Negative IF stains are characteristic of the pauci-immune GN of necrotizing vasculitis.[19,30,35,36] Serologies are critically important in defining the underlying disorder responsible for DAH (particularly ANCA, anti-GBM antibody, and antinuclear antibodies). Recognizing the different pathogenetic mechanisms of these DAH syndromes is important, as the prognosis and treatment strategies differ.

■ THERAPY OF IMMUNE-MEDIATED ALVEOLAR HEMORRHAGE

Irrespective of etiology, the most immediate concern in patients with severe immune DAH is to control intrapulmonary bleeding, which may be fatal. Besides general supportive measures, corticosteroids are considered part of standard therapy for all immune-mediated DAH syndromes. For severe cases (e.g., severe hypoxemia, respiratory failure), high-dose "pulse" methylprednisolone (1000 mg daily for 3 days) should be given (irrespective of underlying etiology), even while pursuing a diagnostic workup.[1,7] Delaying pulse therapy in a critically ill patient for even a few hours may be catastrophic. Rapid resolution of bleeding can occur, often within 24 to 72 hours of initiation of therapy (Fig. 68-7). Following the 3-day pulse, corticosteroids (dose of methylprednisolone 60 to 120 mg per day or equivalent) should be continued for a few days, until control of the

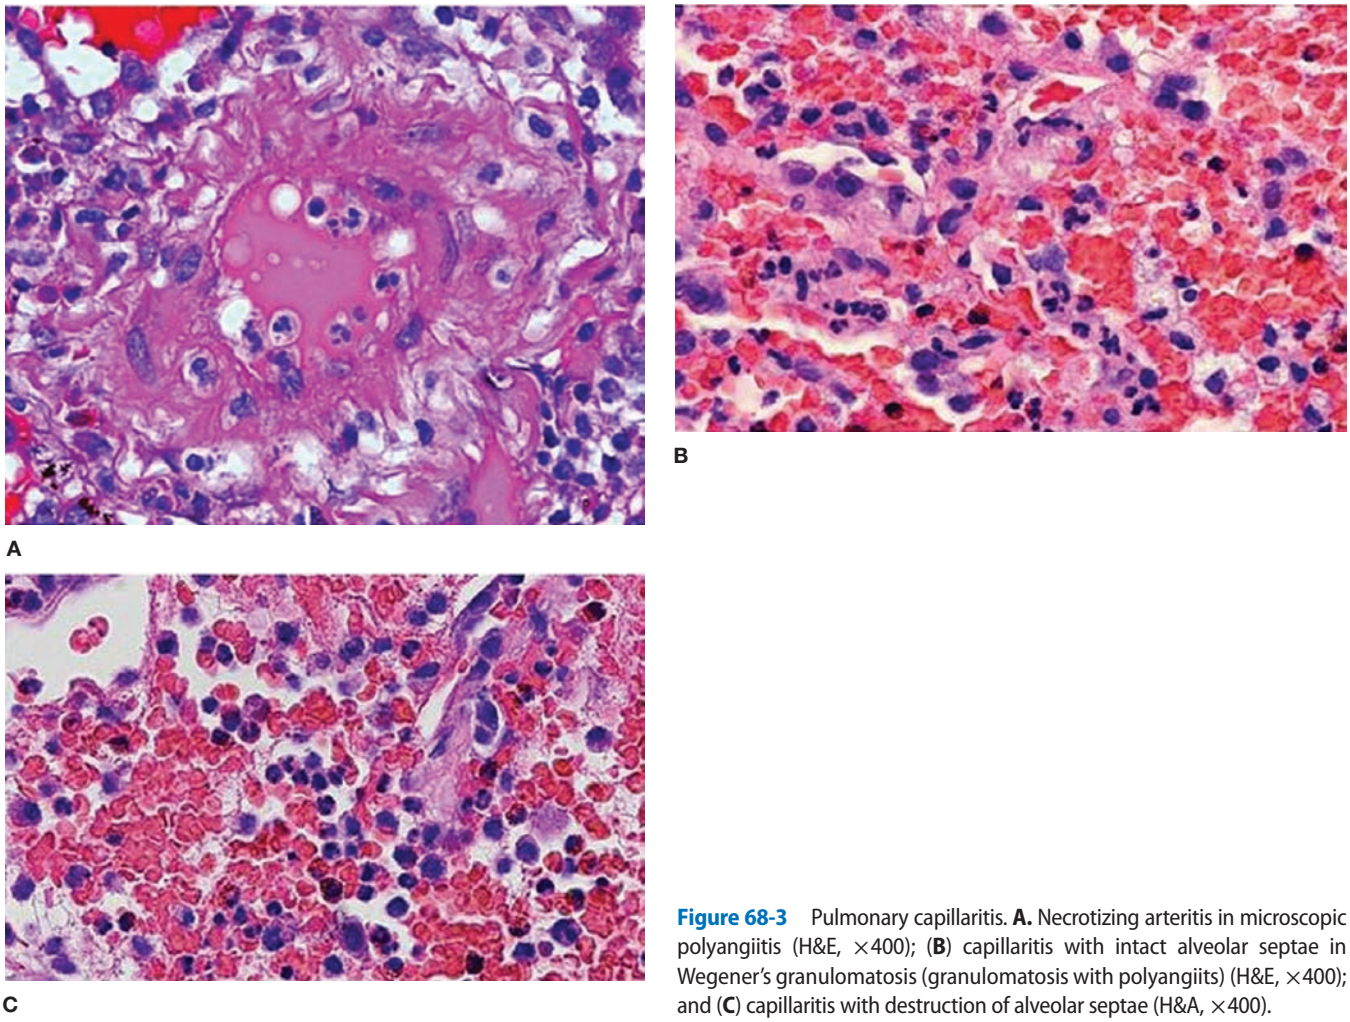

Figure 68-3 Pulmonary capillaritis. **A.** Necrotizing arteritis in microscopic polyangiitis (H&E, ×400); (**B**) capillaritis with intact alveolar septae in Wegener's granulomatosis (granulomatosis with polyangiits) (H&E, ×400); and (**C**) capillaritis with destruction of alveolar septae (H&A, ×400).

bleeding and extrapulmonary manifestations has been achieved. The subsequent dose and rate of corticosteroid taper need to be individualized, based upon clinical, radiographic, and serological response. The presence of renal involvement, vasculitis, or progression of DAH on corticosteroids is an indication for adding cyclophosphamide (CYC) (or occasionally other immunosuppressive agents).[1,18,37] Rituximab may be as effective, and possibly more effective than CYC for ANCA-associated vasculitis,[38,39] but data are limited for DAH.

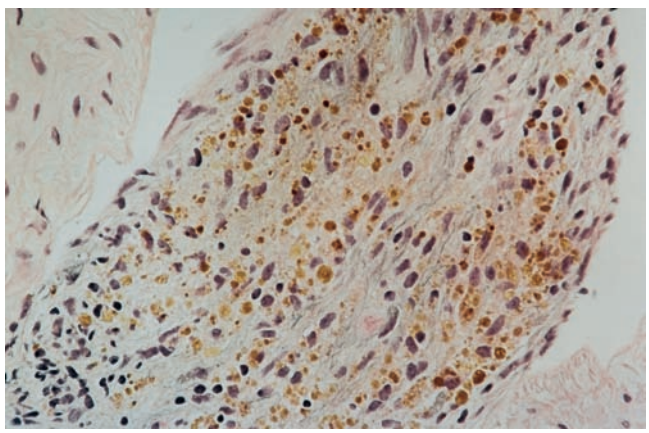

Figure 68-4 Hemosiderin-laden macrophages (siderophages) are prominent in the alveolar interstitium in a patient with recurrent alveolar hemorrhage (H&E). *(Used with permission of Joseph Fantone, MD.)*

Plasmapheresis is a central component of therapy for anti-GBM disease[13,14] but has no *routine* role for other disorders.[11,12,40,41] However, plasmapheresis may have an adjunctive role in patients with autoimmune DAH and severe renal insufficiency (i.e., serum creatinine >4 mg%)[41,42] and in patients with severe or progressive DAH refractory to corticosteroids or immunosuppressive agents.[43] Measures to ensure adequate oxygenation are also essential. Mechanical ventilatory support, often with positive end-expiratory pressure, may be necessary in fulminant cases of DAH, to prevent death due to refractory hypoxemia. Transfusion of red blood cells may be required to maintain an acceptable hematocrit (more than 25%) and adequate blood pressure. In the sections that follow, we discuss each of the autoimmune DAH syndromes individually.

SPECIFIC SYNDROMES

■ GOODPASTURE'S SYNDROME

Clinical Features

Anti-GBM disease (Goodpasture's syndrome), the prototype of pulmonary renal syndromes, accounts for 18% to 32% of immune-mediated DAH.[3,13,15,31,44] Classically, anti-GBM disease manifests as DAH and RPGN.[13,14,33,45] In 30% to 50% of patients with anti-GBM disease, GN occurs *without* DAH; DAH alone is rare (<5%).[14,15] Anti-GBM disease typically affects individuals between 20 and 45 years of age with a distinct male predominance.[14,45] The incidence has been estimated as 1 to 3 cases per million population per year.[46,47] The etiology is not known, but exposure to inhaled hydrocarbons,[46] cigarette smoke,[45] cocaine,[15] and antecedent viral

TABLE 68-2 Autoimmune Diffuse Alveolar Hemorrhage: Pathology and Serology

illnesses, particularly influenza, have been cited as risk factors.[14] The demonstration of anti-GBM antibodies in tissue (typically kidney)[33] or in serum[13,14] is the cornerstone of the diagnosis.

The clinical expression of anti-GBM disease is highly variable. Most patients present with progressive dyspnea, diffuse alveolar infiltrates, and hypoxemia; hemoptysis occurs in 45% to 94%.[13–15,48] GN is a cardinal feature.[33,47,49,50] Microscopic hematuria, red cell casts, or proteinuria are almost always present. Gross hematuria occurs in up to 41% of patients.[14] Azotemia is noted in 55% to 71% of patients at presentation.[13,48] Fatigue and weakness are common.[14] In the absence of therapy, progressive renal insufficiency ensues, often resulting in end-stage renal failure within days to weeks of the onset of symptoms.[13] Oliguria, severe renal failure, or greater than 50% crescents on renal biopsy are associated with a poor prognosis and low rate of recovery of renal function.[13,14,33,51] The course may be fulminant, with severe renal failure and explosive, life-threatening DAH.[13,14] Chest radiographs typically reveal dense bilateral alveolar infiltrates, often with air-bronchograms. With cessation of bleeding, infiltrates may resolve within 24 to 36 hours. Pleural effusions are rare and suggest an alternative diagnosis. Pulmonary function tests are rarely helpful in the acute setting of DAH.[14,15] Bloody or serosanguineous BAL fluid (that worsens with serial aliquots) suggests DAH but is nonspecific.[8] Anemia is present in more than 90% of cases and may be profound. Serum iron and ferritin levels are usually decreased, reflecting diminished iron stores. Factors associated with a higher incidence of DAH include cigarette smoking,[15] exposure to high concentrations of oxygen, upper respiratory tract infections, and increased hydrostatic (pulmonary capillary) pressures.[13,14]

Serological assays for anti-GBM antibody are invaluable in confirming the diagnosis and monitoring the adequacy of therapy.[14,47] Radioimmunoassays or enzyme-linked immunosorbent assays (ELISA) for anti-GBM antibody are highly sensitive (>95%) and specific (>97%)[13,14] but are performed in only a few laboratories. Results are usually not available for several days. Since delay in institution of therapy may preclude a favorable outcome, percutaneous renal biopsy is usually performed while awaiting the results of serum assays. Although disparate results have been reported, the height of serum anti-GBM antibody titer correlated with the prognosis of renal disease in some studies.[48,52] Further, changes in anti-GBM titer over time may be a guide to efficacy of therapy.[14] Treatment can be tapered and discontinued after the antibody has disappeared from the circulation (usually within 3–6 months).[15] Up to one-third of patients with circulating anti-GBM antibodies have concomitant ANCA (usually MPO).[13,32,53] Other serological studies are negative or nondiagnostic.

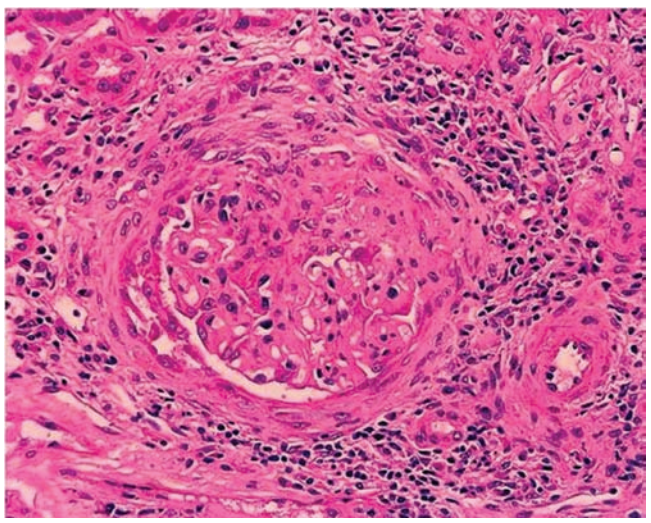

Figure 68-5 Segmental necrotizing and crescentic glomerulonephritis due to vasculitis (H&E).

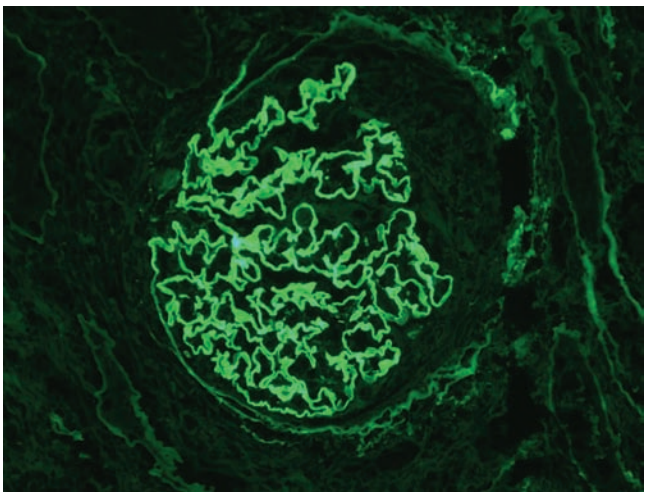

Figure 68-6 Linear immunofluorescent staining along glomeruli due to deposition of anti-glomerular basement membrane (anti-GBM) antibody.

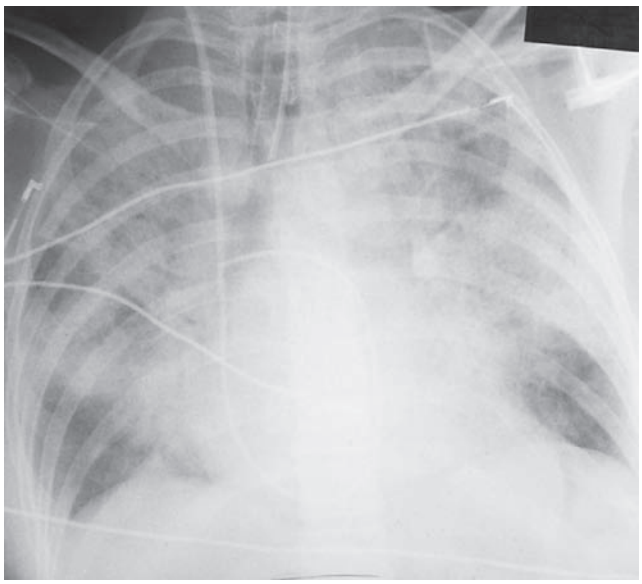
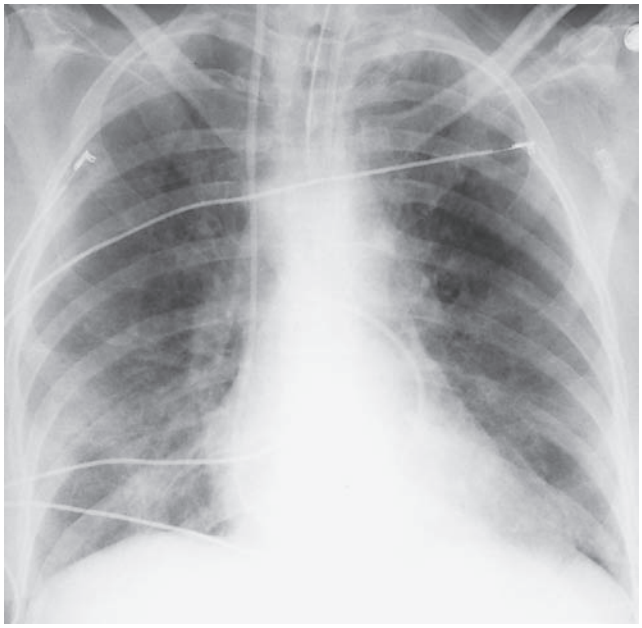


A



B

Figure 68-7 **A.** Alveolar hemorrhage due to microscopic polyarteritis (MPA). Posterior–anterior (PA) chest radiograph demonstrating massive alveolar infiltrates involving all lobes. Because of the severity of respiratory failure (requiring 16 cmH_2O of positive end-expiratory pressure to achieve acceptable oxygenation), no lung biopsy was performed. Urinalysis demonstrated numerous red cells and occasional red cell casts. Serum creatinine was 1.4 mg%. Pulse methylprednisolone (1 g daily × 3 days) was initiated, and renal biopsy was scheduled for the following morning. **B.** Alveolar hemorrhage due to MPA. PA chest radiograph from the same patient 12 hours following initiation of pulse methylprednisolone. Marked improvement in alveolar infiltrates is evident. Renal biopsy demonstrated glomerulonephritis and a necrotizing vasculitis involving renal arterioles; no granulomas were present. Cyclophosphamide (2 mg/kg per day) was instituted, and corticosteroids were continued. Within 5 days, the infiltrates had cleared completely and serum creatinine was 0.6 mg%.

HISTOPATHOLOGY

Percutaneous kidney biopsy is the preferred invasive procedure to substantiate the diagnosis of anti-GBM disease.[15] Light microscopy demonstrates a proliferative or necrotizing GN, often with cellular crescents.[14,33] Over time, the crescents may fibrose, and frank glomerulosclerosis, interstitial fibrosis, and tubular atrophy may be observed.[33] Although these microscopic features are nonspecific, IF stains are the cornerstone of the diagnosis. Bright linear deposits of IgG and complement (C3) along GBM are pathognomonic of anti-GBM disease (Fig. 68-6).[14,33] All four subclasses of IgG are represented, but IgG_1[54,55] and IgG_3[55] predominate in anti-GBM disease. Rare cases of linear deposits of IgM or IgA have been described.[15] Lung biopsies are rarely necessary,[14] as the histological features on renal biopsy are usually adequate to establish the diagnosis. When lung biopsy has been done, extensive hemorrhage predominates[6,8] with accumulation of hemosiderin-laden macrophages within the alveolar spaces.[14] Foci of DAD and capillaritis may also be found.[6] Interstitial or intra-alveolar inflammation is minimal or absent. Extensive necrosis or large-vessel vasculitis is not found. Similar histopathological features may be seen with a wide gamut of immune-mediated DAH syndromes.[6,8] IF stains of lung tissue may be diagnostic, provided a clear linear pattern of immunofluorescence is present. However, IF stains are technically difficult in lung tissue and autofluorescence may obscure the linear IgG deposits.

PATHOGENESIS

Antibodies are directed against the α3 chain of type IV collagen, an antigen highly expressed in both alveolar and GBMs.[13,15,54] Anti-GBM antibodies bind the GBM and activate complement, initiating an inflammatory pathway that elicits injury.[13] In addition to circulating antibodies, autoreactive T lymphocytes directed against the α3 antigen are key mediators for development of RPGN.[15,56] Immunoglobulin synthesis and deposits of IgG along the alveolar and glomerular capillary basement membranes then ensue. Anti-GBM disease is monophasic, and during the course of the disease, self-tolerance is restored.[13] Late relapses are rare.[13] This tolerance may be achieved by regulatory CD4+ and CD25+ T cells[15,57] or anti-idiotypic (blocking) antibodies,[54] but this remains speculative.

The pathogenesis of anti-GBM disease is unknown, but both genetic[15,58] and environmental factors[54] may play roles. Patients with anti-GBM disease preferentially express certain immunoglobulin Gm allotypes and links between anti-GBM disease and the HLA-DR2 histocompatibility antigen have been noted.[13,15] Exposure to cigarette smoke, hydrocarbon-containing solvents, hard-metal dust, influenza A2 virus, chlorine gas, and D-penicillamine have been associated with anti-GBM disease.[13–15] These exogenous factors may injure the basement membrane, resulting in increased capillary permeability, exposing the Goodpasture's antigen (α3 chain), which is then recognized as foreign, eliciting a T-helper cell response.[15,54]

TREATMENT

Before the availability of the current therapy and renal dialysis, mortality exceeded 90%.[13] Plasmapheresis was introduced as a therapeutic option for anti-GBM disease in the 1970s,[49] and was quickly adopted worldwide and incorporated in all clinical trials. Currently, with the combination of plasmapheresis, corticosteroids (CSs), and CYC, mortality has been reduced to less than 20%.[13–15] Because of the rarity of anti-GBM syndrome, only one small randomized trial compared immunosuppressive therapy with the *combination* of immunosuppressive therapy *plus* plasma exchange.[49] In that study, plasmapheresis plus immunosuppressive therapy was associated with more rapid disappearance of anti-GBM antibody and improved renal function than treatment with immunosuppressive agents *alone*.[49] The optimal extent and duration of plasma exchanges have not been defined. Most

investigators advocate plasma exchange daily or every other day for 2 to 3 weeks, until the clinical course has improved and serum anti-GBM antibodies are nondetectable.[13,41] Immunosuppressive therapy is required to inhibit antibody production and rebound hypersynthesis, which may occur following discontinuation of plasma exchange.[13] Treatment of acute, life-threatening DAH in Goodpasture's syndrome is similar to other autoimmune disorders. Pulse methylprednisolone (1 g daily for 3 days) is given, followed by a gradual corticosteroid taper.[14] Either CYC (oral or IV pulse) or azathioprine should be initiated once the diagnosis of anti-GBM disease is substantiated. Most investigators favor CYC over azathioprine,[13–15] but studies comparing these agents have not been done. CYC is maintained for the duration of therapy, unless complications such as leukopenia necessitate dose reduction. The corticosteroid dose is gradually tapered over several months. Immunosuppressive or cytotoxic therapy may be discontinued within 3 to 6 months provided a sustained remission has been achieved and anti-GBM antibodies have disappeared.[13,15] Circulating anti-GBM antibodies usually clear within 8 weeks, irrespective of the initial titer. Early relapse (within the first 2 months) may occur when circulating antibodies are still present. This typically manifests as DAH. Risk factors for relapse include infection, volume overload, and cigarette smoking.[15] Late recurrence, associated with renewed antibody synthesis following a remission, is rare.[14] In summary, aggressive therapy with plasmapheresis, corticosteroids, and immunosuppressive agents has dramatically improved prognosis.[14,15,51] With this approach, 5-year survival exceeds 80%, and fewer than 30% of patients require chronic dialysis.[14,15] Early recognition and treatment of this syndrome are critical, as the prognosis for recovery of renal function depends upon the initial extent of injury.[32,50] Recovery of renal function can be expected in patients with minor functional impairment. By contrast, patients manifesting initial serum creatinine greater than 4 mg/dL, oliguria, or greater than 50% crescents on renal biopsy rarely recover and usually progress to end-stage renal failure requiring chronic dialysis.[32,50] In one study of 71 patients with anti-GBM disease (all were treated with steroids, immunosuppressive agents, and plasmapheresis), renal survival was linked to extent of renal failure at presentation.[51] Renal survival rates at 1 year were as follows: 8% among 39 patients requiring dialysis at presentation; 82% among 13 patients with creatinine >5.7 but not requiring dialysis; 95% among 19 patients with initial serum creatinine <5.7 mg%. Renal transplantation has been successful in patients with irreversible renal failure, provided serum anti-GBM antibodies are undetectable.[59,60]

Systemic Vasculitis

DAH is a common complication of MPA[10,11] and granulomatosis with polyangiitis (GPA) (formerly called Wegener's syndrome)[12,61] and rarely complicates Churg–Strauss syndrome (CSS),[62,63] Behçet disease,[64] mixed cryoglobulinemia,[65] Henoch–Schöenlein purpura,[66] and other systemic necrotizing vasculitides.[1,37] Classic polyarteritis nodosa (PAN) rarely involves the lung.[8,67] Necrotizing small-vessel vasculitis accounts for the majority of autoimmune DAH syndromes.[1,8] RPGN is usually present in each of these DAH syndromes, but the disease is sometimes limited to the kidneys or lungs. Circulating antibodies directed against cytoplasmic components of neutrophils and monocytes (ANCA) have been detected in most patients with these "pulmonary–renal syndromes,"[7,34,37,68] suggesting a common pathogenesis and mechanism of lung injury in these diverse vasculitic disorders.

ANCA-Associated Vasculitides

Goodpasture's syndrome (anti-GBM disease) was the first of the pulmonary–renal syndromes to be immunologically characterized.[14,15] Subsequent studies documented immune complexes in serum or renal tissue in subsets of patients with pulmonary–renal syndromes, particularly SLE[16] and immune complex–mediated GN.[69] However, more than two-thirds of patients with pulmonary–renal syndromes are mediated by ANCA antibodies without anti-GBM or immune complexes (i.e., pauci-immune).[1,34,37] Depending upon clinicopathological features, some patients with pauci-immune GN and DAH may meet criteria for GPA or CSS, while others exhibit a multisystemic small-vessel vasculitis but lack granulomatous inflammation of the respiratory tract. In this context, the term *microscopic polyangiitis* is used.[10,11,70] The availability of serum assays for ANCAs has profoundly influenced the classification of immune DAH and GN. ANCA-positive patients with pauci-immune DAH and GN (*formerly* given a diagnosis of idiopathic RPGN and DAH) are now considered to have MPA.[11] The spectrum of ANCA-associated diseases is not limited to patients with pulmonary–renal syndromes but includes individuals with MPA limited to the lung (i.e., manifesting as DAH) or kidney (i.e., necrotizing GN).[11] To avoid further confusion, brief definitions of the major ANCA-associated vasculitides are outlined below.

■ GRANULOMATAOSIS WITH POLYANGIITIS, GPA (FORMERLY CALLED WEGENER'S GRANULOMATOSIS)

GPA, the most common of the pulmonary vasculitides, typically involves the upper respiratory tract (e.g., sinuses, ears, nasopharynx, oropharynx, trachea), lower respiratory tract (bronchi and lung), and kidney, with varying degrees of disseminated vasculitis (see Chapter 83).[12] The annual incidence of GPA has been estimated at 4 to 12 cases per million.[12,46,71,72] Alveolar hemorrhage is a rare complication of GPA, reflecting diffuse injury to the lung microvasculature (i.e., capillaritis) (Fig. 68-8).[1,6] In this context, RPGN is present in more than 90% of patients.[6,12] The salient histopathological features of GPA include small-vessel vasculitis (involving capillaries, arterioles, venules), geographic necrosis, hemorrhagic infarcts, a mixed inflammatory cellular infiltrate, and a granulomatous component.[6,8,12] Circulating c-ANCAs (PR3 epitope) have been detected in more than 90% of patients with active generalized GPA and in 40% to 70% with active regional GPA.[12,68,73–75] Oral CYC (2 mg/kg per day) plus prednisone has been the initial treatment of choice for GPA for more than 3 decades.[12,76,77] With this regimen, remissions are achieved in 70% to 93% of patients, with early mortality rates of less than 15%.[76–81]

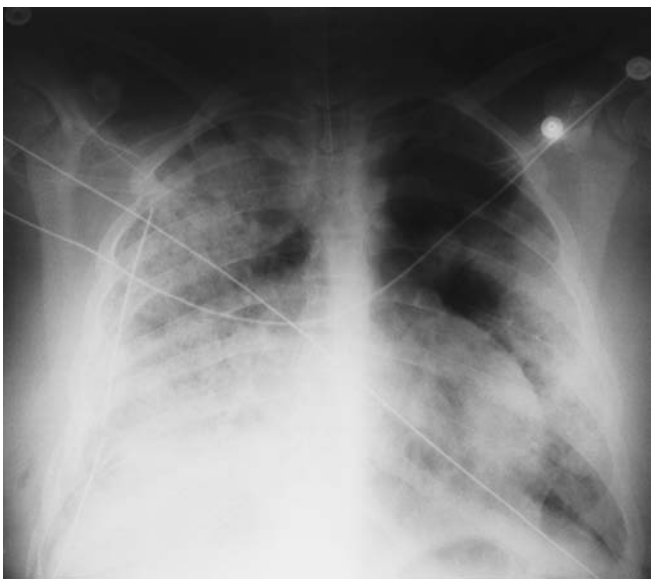


Figure 68-8 Granulomatosis with polyangiitis (GPA) (formerly called Wegener's granulomatosis. Posterior–anterior (PA) chest radiograph demonstrated bilateral alveolar infiltrates in a 13-year-old girl with hemoptysis and respiratory failure. A right chest tube is in place from an open lung biopsy performed 2 days earlier. Open lung biopsy demonstrated capillaritis and massive alveolar hemorrhage. Pulse methylprednisolone, followed by oral cyclophosphamide and prednisone, was associated with a complete remission.

By 3 to 6 months, assuming complete remissions are achieved, azathioprine[78,79] or methotrexate[79] can be substituted for CYC. Treatment should be continued for a minimum of 12 to 18 months (total duration).[12,77] Relapses can be treated with CYC and prednisone. Methotrexate may be used in patients with limited disease or those experiencing significant toxicity from CYC.[82,83] Rituximab may be as effective, and possibly more effective than CYC for GPA and AAV.[38,39,84–86] However, whether rituximab should be used with corticosteroids alone or corticosteroids combined with CYC has not been clarified. Further, the role for long-term maintenance therapy with rituximab has not been studied.[84–86] Additional studies are required to assess indications for rituximab, appropriate dosing and frequency of administration, role for concomitant therapy, and long-term side effects. Trimethoprim/sulfamethoxazole may have an adjunctive role (together with CYC and prednisone) to reduce relapse rates,[87] but should not be considered as primary therapy.

CHURG–STRAUSS SYNDROME (ALLERGIC ANGIITIS AND GRANULOMATOSIS)

CSS, also termed *allergic angiitis* and *granulomatosis,* is a rare, small-vessel vasculitis associated with a prominent allergic component, asthma, and eosinophils in blood or involved tissues (see Chapter 83).[63,88] CSS involves capillaries, venules, and arterioles.[63] Granulomas, eosinophils, and palisading histiocytes in extravascular tissues are hallmarks of the disorder[88,89] and distinguish CSS from other vasculitides.[8,63] The annual incidence of CSS has been estimated at 0.6 to 6.8 cases per million.[46,71,88,90] In the classic form of CSS, vasculitis develops after a several-year history of atopy or asthma.[89] Pulmonary involvement is nearly invariably present.[63,88,89] Asthma is present in 96% to 100%; focal infiltrates on chest radiographs, in 30% to 70% of cases.[63,88,89] DAH is a rare complication of CSS. In a French series of 112 patients with CSS, moderate DAH was observed in 3/43 ANCA-(+) patients and in 5/69 ANCA-negative patients.[91] DAH was cited in only 1/32 patients in a Spanish series,[92] and 1/19 in an Italian series.[93] Severe DAH has only rarely been reported in CSS.[94,95] Constitutional symptoms may herald the onset of vasculitis.[88] Extrapulmonary manifestations include mononeuritis multiplex (63%–93%); skin (50%–78%); cardiac (16%–56%); kidney (16%–49%); skin (50%–78%); gastrointestinal (GI) tract (17%–58%).[63,88] Factors associated with a worse prognosis include cardiac or GI tract involvement, renal insufficiency; age >65 years.[96]

The erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and blood eosinophil count are elevated in more than 80% of patients during the acute phase of vasculitis or exacerbations.[62,70,88,89] Circulating ANCAs (primarily p-ANCA) have been detected in 40% of patients with CSS.[88,91,97] Interestingly, the presence of ANCA was associated with a higher incidence of renal involvement and pulmonary hemorrhage, but a lower frequency of cardiac involvement.[97]

A variety of treatment regimens have been employed for CSS including corticosteroids, immunosuppressive or cytotoxic agents, and plasmapheresis (alone or in combination).[62,88,96] Corticosteroids achieve remissions in more than 80% of patients with CSS and are first-line therapy for mild to moderate cases of CSS.[88,98,99] Oral or pulse CYC (or other immunosuppressive agents such as azathioprine or mycophenolate mofetil) should be added for severe or multisystemic disease or corticosteroid-recalcitrant cases or when unfavorable prognostic factors are present.[40,62,88,96,98] Plasmapheresis should be considered as adjunctive therapy for ANCA-positive CSS patients with severe pulmonary–renal syndrome.[42]

MICROSCOPIC POLYANGIITIS

MPA (formerly termed *microscopic polyarteritis* or *polyangiitis overlap syndrome*) typically presents with GN and pulmonary capillaritis manifesting as DAH.[10,11] Clinical and serological features of MPA overlap with GPA and CSS.[11,70] MPA is rare, with an annual incidence of 2.1 to 17.5 cases per million.[46,71,90] As its name implies, MPA involves small vessels (arterioles, venules, or capillaries); extension to larger vessels occurs in a minority of cases.[100] Small vessels are always spared in classic PAN.[67,100] In contrast to GPA or CSS, neither granulomas nor eosinophils are prominent in MPA.[11,100] Circulating ANCAs are present in 50% to 90% of patients with MPA,[11,70,100] suggesting a relationship with other ANCA-associated vasculitides. By contrast, circulating ANCAs are present in fewer than 20% of patients with classic (macroscopic) PAN.[100] A necrotizing, crescentic pauci-immune GN is nearly invariably present in MPA[11,100] but is rare in classic PAN.[67] Alveolar hemorrhage, which is rarely observed in classic PAN, occurs in 30% to 50% of patients with MPA and is often the dominant and most life-threatening manifestation.[10,11,70]

Corticosteroids, CYC, and plasmapheresis, alone or in combination, have been used to treat MPA.[11,70,78] Response rates and long-term survival have generally been similar with the various regimens. Most investigators use oral CYC (2 mg/kg per day) plus prednisone (1 mg/kg per day, with gradual taper), similar to the regimen used for GPA. With this approach, favorable responses are achieved in more than 80% of patients; 10-year survival exceeds 70%.[11,70,78] By 3 to 6 months, once complete remissions have been achieved, azathioprine, methotrexate, or mycophenolate mofetil may be substituted for CYC.[11,78] As was discussed in the section on GPA, rituximab may be as efficacious as CYC-containing regimens for AAV,[38,39,84–86] but data are limited.

ANCA-ASSOCIATED PULMONARY RENAL SYNDROMES: CLINICAL FEATURES

The clinical and radiologic manifestations of ANCA-associated DAH are similar to other immune causes. Acute necrotizing GN is nearly always present, but the renal lesion is nonspecific.[34,35,101] Distinguishing the specific underlying disorder may be difficult. The pathological lesions in ANCA-associated diseases share characteristic features, regardless of the organ affected. The three key histopathological findings are a segmental (focal) distribution of vascular injury, infiltration with neutrophils, and fibrinoid necrosis.[11,70,100] The latter results from lysis of the vascular wall, allowing plasma coagulation factors to enter the interstitium and come into contact with thrombogenic substances, generating fibrin. Neutrophils that infiltrate vessel walls undergo disruption and karyorrhexis, leading to the typical leukocytoclastic pattern of injury in capillaries and venules.[100] ANCA-associated vascular injury is accompanied by few, if any, immune deposits (pauci-immune).[19] However, the presence of immune deposits may be associated with more severe renal injury.[34] The salient lesion of renal vasculitis is a segmental necrotizing GN, usually accompanied by extracapillary proliferation of Bowman capsule (crescents) (Fig. 68-5).[11] Depending on the duration and extent of renal injury, varying degrees of glomerular fibrosis and sclerosis may be seen.[19] Vasculitis affecting the kidney often involves only the glomerular capillaries; macroscopic arteritis is seldom apparent.[100] When the lung is involved, the histopathology is nonspecific, demonstrating only capillaritis and intra-alveolar hemorrhage.[7] Immune deposits are absent.

Clinical features of ANCA-associated DAH syndromes overlap. Striking elevations in the ESR and CRP may be observed in all the syndromes, particularly when disseminated vasculitis is present.[11,88] Anemia and leukocytosis are common. Marked eosinophilia is characteristic of CSS[89] but is not a feature of MPA[11] or GPA.[12] Extrapulmonary and extrarenal manifestations suggesting small-vessel vasculitis (e.g., palpable purpura, leukocytoclastic vasculitis, mononeuritis multiplex, arthralgias or arthritis, ocular disease, sinusitis) may direct biopsies at these sites. Histological features of granulomatous vasculitis are consistent with GPA or CSS whereas granulomas are lacking in MPA.[11,100] Radiographic features may discriminate granulomatous vasculitides from MPA. In GPA (and less

commonly in CSS), focal nodular or cavitary mass lesions may be seen.[12] These are not found in MPA.[11] The diagnosis of CSS can usually be readily established by a pronounced eosinophilic component in the blood or in extravascular sites.[67,89] However, discriminating GPA from MPA may be difficult or impossible as small-vessel vasculitis is common to both disorders. By definition, GPA is associated with concomitant granulomatous inflammation, typically, but not invariably involving the upper and lower respiratory tracts.[12] The latter may lead to the highly distinctive features attributed to GPA including sinusitis, otitis media, nasal or laryngotracheal ulcerations, subglottic stenosis, and cavitary pulmonary nodules.[12]

Characteristics of ANCA

The identification of circulating antibodies directed against cytoplasmic components of neutrophils and monocytes (i.e., ANCA) represented a major advance in the classification and understanding of vasculitis.[68,75] Using ethanol-fixed granulocytes incubated with patient serum, two distinct patterns of ANCA are identified by IF techniques: cytoplasmic (c-ANCA) and perinuclear (p-ANCA) (Fig. 68-9). The p-ANCA pattern is an artifact of fixation causing movement of the target antigens to a perinuclear location. These differing IF patterns reflect distinct antigenic specificities.

In both radioimmunoassays and ELISA, the antibody responsible for c-ANCA is directed against proteinase 3 (PR3).[68,75] The p-ANCA pattern is usually due to an antibody to myeloperoxidase (MPO).[68,75] MPO-ANCA is usually associated with small-vessel vasculitis, but multiple p-ANCA antibodies directed against a variety of antigens (e.g., cathepsin G, lactoferrin, and elastin) may be seen in nonvasculitic inflammatory disorders including CTD and inflammatory bowel or liver disease.[68,75] Therefore, while c-ANCA is more than 90% specific for small-vessel vasculitis, p-ANCA is nonspecific. In untreated GPA, circulating c-ANCA (PR3-ANCA) is detected in more than 70% of patients; the incidence is lower (40% to 65%) in patients with limited disease (e.g., involvement confined to the upper respiratory tract).[12] By contrast, p-ANCA (MPO-ANCA) is rarely found in GPA. Circulating ANCAs are present in more than 70% of patients with MPA[7,11,70] and 30% to 70% of patients with CSS.[62,67,88] In MPA either c-ANCA or MPO-ANCA may be present, but MPO is more common.[70] Circulating ANCAs have been found in fewer than 20% of patients with classic PAN.[67] When present, antibodies have shown MPO antigenic specificity. Individual patients almost never have both c-ANCA and p-ANCA. Most ANCAs are of the IgG class. However, IgM ANCAs associated with severe DAH have been described, either concomitant with IgG-ANCA or in the absence of IgG-ANCA.[102] It is unknown how often patients with ANCA-negative vasculitis would be ANCA-positive if reagents that detected IgM antibodies were used.

The antigenic specificities of ANCA (i.e., PR3 or MPO) may provide clues to the nature of the underlying disorder and may assist in categorizing the type of disease, but overlap exists.[68,75] Biopsies are important to differentiate the nature of the underlying vasculitic disorder. For example, patients with c-ANCA and small-vessel vasculitis may be misclassified as MPA if clinically inapparent areas of granulomatous inflammation are overlooked. For clinical purposes, distinguishing GPA from MPA is not critical, because therapy and management are similar.[78] Circulating p-ANCA (MPO) or c-ANCA (PR3) are present in more than 70% of patients with pauci-immune necrotizing GN (renal vasculitis).[30,68,75,103] ANCA-negative patients usually have disease limited to the kidney. Nearly all patients with concomitant DAH have circulating ANCA. Indeed, a negative ANCA provides strong evidence against vasculitis as the cause of DAH and GN. When applied to patients with RPGN, a positive ANCA almost invariably predicts pauci-immune necrotizing GN. In the setting of clinical, laboratory, and radiologic features that are highly suggestive of DAH and RPGN, a positive c-ANCA or MPO-ANCA, together with a negative anti-GBM and ANA assay, is virtually diagnostic of systemic vasculitis (e.g., GPA or MPA). Similarly, a positive ANCA (usually MPO-ANCA) is sufficient to diagnose lung-limited MPA, provided the clinical presentation is typical of DAH and nonimmune causes of DAH have been excluded. Most patients previously diagnosed as having idiopathic IPH likely had lung-limited MPA or ANCA-associated pulmonary capillaritis.

Problems with using serum ANCA to diagnose vasculitis arise when the clinical presentation is ambiguous. The low incidence of vasculitis in the general population dictates that the positive predictive value of ANCA will be low when applied indiscriminately. Routine assay of serum ANCA in patients with nonspecific respiratory complaints yields a high rate of false-positive results. Given the risks of immunosuppressive therapy, misinterpretation of ANCA may lead to devastating consequences. Accordingly, results of serum ANCA assays must be interpreted in light of the entire clinical picture.

Anti-GBM disease and vasculitis have traditionally been viewed as distinct clinicopathological entities. However, up to 30% of patients with anti-GBM disease (as evidenced by anti-GBM antibody in serum and linear deposits of IgG in kidney biopsy) also have serum MPO-ANCA.[7,32,15] The coexistence of ANCA and anti-GBM antibodies is almost certainly not a chance occurrence, given the rarity of both antibodies in the general population.[15] It is possible that ANCA initiates vascular injury, and anti-GBM antibody then forms in response to the damaged basement membrane.

The role of ANCA in the pathogenesis of vasculitis is uncertain, but these antibodies probably mediate vascular damage.[68,74,75,104] Sera from patients with either c-ANCA or MPO-ANCA induce neutrophils to undergo

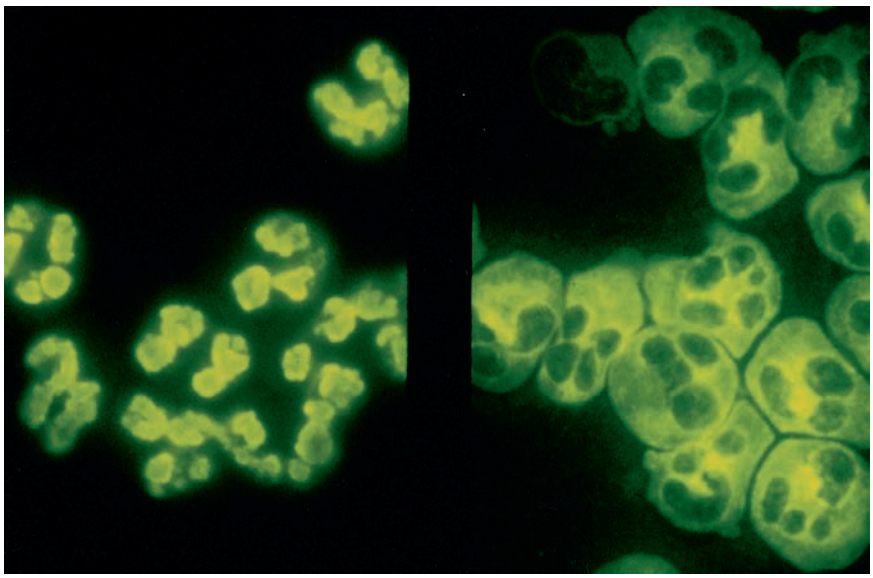

Figure 68-9 Indirect immunofluorescent stains demonstrating two distinct types of antineutrophil antibodies. On the left panel, note the perinuclear pattern of immunofluorescence characteristic of p-ANCA (myeloperoxidase epitope). On the right panel, a coarse granular pattern of immunofluorescence within the cytoplasm is evident, characteristic of c-ANCA (proteinase-3 epitope).

a respiratory burst with release of reactive oxygen species and proteolytic enzymes.[104] Cytokine-primed neutrophils are stimulated by ANCA to damage human endothelial cells in vitro.[104] These observations, together with correlations of ANCA titer with clinical disease in humans (although imperfect), suggest that ANCAs are not innocent markers of vasculitis but play a crucial role in mediating vessel injury.[68,75,104]

Therapy

Therapy of DAH due to ANCA-associated syndromes depends on the underlying disorder and the extent and severity of symptoms. Irrespective of etiology, the most immediate concern in patients with severe immune DAH is to control intrapulmonary bleeding, which may be fatal. Besides general supportive measures, high-dose "pulse" methylprednisolone (followed by a tapering regimen of corticosteroids) should be given. The presence of renal involvement *or* progression of DAH on corticosteroids is an indication for adding CYC (with or without empiric plasma exchange).[18] Plasma exchange has been used, with anecdotal successes, as therapy for ANCA-associated systemic vasculitis with severe renal insufficiency[43,105–109] or DAH.[43] Because ANCA may play a pivotal role in mediating tissue injury, plasmapheresis may be beneficial in selected patients (particularly those with DAH[43] or severe renal failure, i.e., serum creatinine >4 mg%[41,42] or dialysis-dependent).[105,107,109,110] When plasma exchange is used to treat ANCA-associated DAH, it may be preferable to use an apparatus that efficiently removes both IgM and IgG, because of the reported association of IgM-ANCA and DAH.[110] Protein A immunoadsorption has also been used to treat patients with DAH and GN,[111] in the hope of removing pathogenic antibodies without producing the side effects of plasma exchange. Additional strategies for patients resistant to conventional therapies include high-dose, intermittent intravenous immunoglobulin G (IVIG).[112] The mechanism of action is uncertain but may involve binding of ANCA idiotype by anti-idiotype antibodies in the intravenous IgG preparation.[112]

The role of serial ANCA determinations in following patients with vasculitis is controversial. We do not base therapeutic decisions on the ANCA titer alone. However, a rising titer should alert the clinician to the possibility of disease exacerbation and clinical follow-up should be intensified. Serial ANCA titers may help differentiate disease relapse from nonimmune causes of pulmonary infiltrates. However, ANCA titers do not obviate the need to aggressively evaluate patients with vasculitis presenting with a new pulmonary process while receiving immunosuppressive therapy.

CONNECTIVE TISSUE DISORDERS

■ SYSTEMIC LUPUS ERYTHEMATOSUS

Alveolar hemorrhage is a rare, but potentially catastrophic, complication of SLE, with mortality rates as high as 50%.[16,113–115] In one large tertiary care center, 19 episodes of DAH were observed among 15 patients with SLE, accounting for 3.7% of hospitalizations for complications of SLE.[16] Alveolar hemorrhage complicating SLE is almost invariably accompanied by other manifestations of active SLE.[16,113,114,116] Alveolar hemorrhage is rarely the sole or presenting feature of SLE.[16,116] Clinical and radiographic features of DAH complicating SLE are similar to other DAH syndromes. However, in SLE-associated DAH, GN is usually, but not uniformly, present.[16,113,114] Diffuse, bilateral alveolar infiltrates, dyspnea, and hypoxemia are characteristic (Fig. 68-10). Hemoptysis is noted in a minority of patients at presentation, obscuring the diagnosis.[16,114,116] The diffuse pulmonary infiltrates must be differentiated from other pulmonary complications of SLE[117] including lupus pneumonitis, opportunistic infections, congestive heart failure, uremia, or pulmonary embolism.

Lung biopsy may be needed to exclude alternative diagnoses and corroborate the diagnosis of DAH. However, the risk of lung biopsy may be substantial in critically ill patients with fulminant DAH and respiratory failure. In addition, as with other immune DAH syndromes, histopathological features of DAH complicating SLE are nonspecific. The dominant feature is intra-alveolar hemorrhage and capillaritis, without macroscopic necrosis.[16] The small-vessel necrotizing vasculitis rarely extends to arterioles and small muscular arteries in addition to capillaries. Granular deposits of IgG or C3 (consistent with immune complexes) have been found in up to 50% of cases of DAH complicating SLE.[16,118] Because of its potential morbidity, we rarely advise surgical lung biopsy to diagnose DAH. Provided clinical features are consistent, the diagnosis of DAH can often be established by fiberoptic bronchoscopy with BAL and transbronchial lung biopsies. Transbronchial biopsies may demonstrate foci of capillaritis with intra-alveolar hemorrhage, but due to sampling error, these features may be missed. However, the presence of gross blood in the airways or serosanguineous BAL fluid, large numbers of hemosiderin-laden macrophages, absence of purulent sputum, and lack of infectious organisms by appropriate stains strongly supports the diagnosis of autoimmune DAH and justifies institution of therapy. Transbronchial lung biopsies may be deferred in acutely ill patients with severe DAH and respiratory failure. In this context, BAL alone is adequate, primarily to exclude local or infectious causes of bleeding.

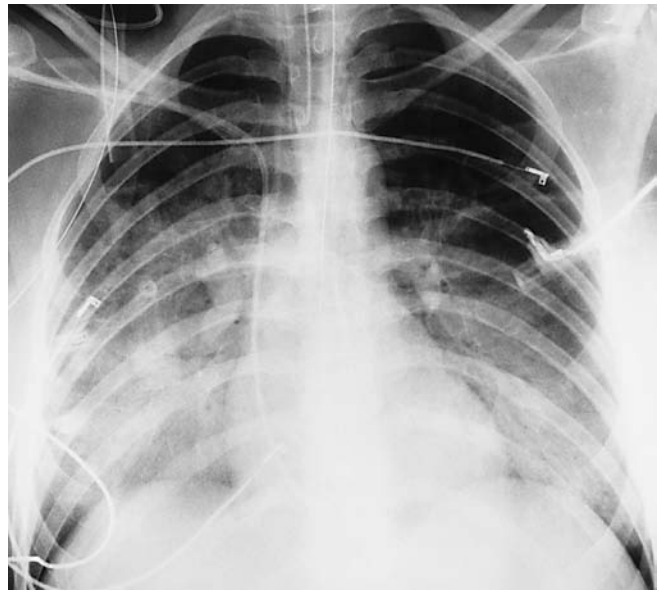

Figure 68-10 Systemic lupus erythematosus (SLE). Posterior–anterior (PA) chest radiograph reveals extensive bilateral alveolar infiltrates in a 22-year-old woman with SLE, hemoptysis, and anemia.

Due to the rarity of this syndrome, prospective, controlled trials evaluating therapy have not been performed. As with other causes of immune DAH, high-dose IV pulse methylprednisolone (1 g daily for 3 days), followed by gradual steroid taper is the mainstay of therapy.[16,115,116] Immunosuppressive or cytotoxic agents may be considered for DAH refractory to corticosteroids.[114–116,119] The role of plasmapheresis has not been elucidated, but anecdotal successes have been cited for severe DAH complicating SLE.[16,110,115,120] We reserve plasmapheresis for patients with severe DAH refractory to corticosteroids and/or cytotoxic agents. Rituximab was efficacious in anecdotal cases of SLE-associated DAH refractory to immunosuppressive agents.[119]

■ OTHER CONNECTIVE TISSUE DISORDERS

Anecdotal reports of DAH, with or without capillaritis, have been described in association with rheumatoid arthritis,[121] scleroderma,[122] mixed connective tissue disease,[121] polymyositis,[123]

antiphospholipid antibody syndrome,[124] Henoch–Schönlein syndrome,[125] and Behçet disease.[64] The clinical spectrum ranges from minimal hemoptysis to life-threatening respiratory failure. In addition to capillaritis and DAH, additional histopathological features on lung biopsies include vasculitis of small and medium muscular pulmonary arteries, DAD, and organizing pneumonia. In view of the rarity of DAH complicating these diverse CTDs, data regarding therapy are limited. High-dose (pulse) intravenous methylprednisolone is advised as initial treatment. In patients with fulminant or corticosteroid-recalcitrant disease, CYC, alone or combined with plasmapheresis,[110,122] should be added.

ALVEOLAR HEMORRHAGE IN IMMUNOCOMPROMISED HOSTS

Alveolar hemorrhage may occur in immunocompromised patients.[27,126] Alveolar hemorrhage may reflect injury to pulmonary endothelial or epithelial cells (secondary to chemotherapy or radiation toxicity), thrombocytopenia (secondary to bone marrow toxicity), pulmonary edema, pulmonary malignancies, and diverse infectious and nonspecific interstitial pneumonias.[126] The incidence of DAH in severely immunocompromised hosts with hematologic malignancies or bone marrow transplants has varied from 11% to 64%.[25,126] The variable frequency in large part is due to differing diagnostic criteria for the diagnosis of DAH. Subclinical alveolar hemorrhage (as evidenced by increased numbers of hemosiderin-laden macrophages in BAL) occurs in up to one-third of immunocompromised hosts with pulmonary infiltrates and may reflect pulmonary endothelial or epithelial injury from diverse causes.[27] Nonimmune causes of DAH in this patient population include coagulopathy, thrombocytopenia or platelet dysfunction, renal failure, congestive heart failure, bronchopulmonary Kaposi sarcoma, and diverse infections.[27,28]

ALVEOLAR HEMORRHAGE COMPLICATING BONE MARROW TRANSPLANTATION

DAH occurs in approximately 5% (range 2%–31%) of hematopoietic stem cell transplantation (HSCT) or bone marrow transplant (BMT) recipients receiving pre-BMT conditioning with high-dose chemotherapy or radiation therapy.[25,26,127–130] Opportunistic infections or thrombocytopenia account for some cases of DAH,[26,128,129] but a distinct syndrome of DAH in this population unrelated to infection is well accepted.[126,127] The incidence of DAH is similar among autologous and allogeneic HSCT recipients.[25,127,130] Risk factors for DAH include age >40 years,[128,130] myeloablative conditioning,[25,128,130] thoracic[131] or total body irradiation,[25,132] acute severe graft versus host disease (GVHD),[128,132] severe oral mucositis,[133] renal failure,[25,133] airway inflammation or increased proportions of bronchial neutrophils and eosinophils,[134] and leukocyte recovery.[25,134] Thrombocytopenia or coagulopathy do not predict DAH.[25,131,133] DAH usually develops within 10 to 40 days after BMT, but may develop earlier or later.[127,131,132] Case reports of DAH developing immediately following autologous bone marrow transfusion suggest that components within the transfusion (e.g., dimethylsulfoxide [DMSO] for cryopreservation of blood stem cells) may mediate acute lung injury in some cases.[135]

Progressive dyspnea, hypoxemia, and respiratory failure are typical.[25,128,130] Even with extensive DAH, hemoptysis is uncommon (<20%).[127,130,134] Chest radiographs *initially* demonstrate predominantly interstitial opacities, which evolve to diffuse alveolar opacities, with a confluent alveolar pattern involving all lobes. Serosanguineous or frankly bloody BAL fluid,[127,128,130] with negative stains for infectious organisms, support the diagnosis of DAH. Lung biopsies or necropsies typically reveal histological features of both DAD and DAH.[129,133,134,136] However, the risk of lung biopsy is excessive in critically ill patients, many of whom are thrombocytopenic.[130] Hence the diagnosis is made by clinical, radiographic, and BAL findings.[127,130]

The clinical course of DAH is variable, but severe respiratory failure requiring mechanical ventilation is common.[127,133] Mortality rates in patients with DAH are high (60-day mortality ranging from 48% to 84%).[26,127,128,133] In one study, hospital mortality was lower among autologous (28%) compared to allogeneic (70%) SCT recipients and early onset DAH (within 30 days of transplant) (32% mortality) compared to 70% for late-onset DAH.[127] Secondary infections are serious and potentially lethal.[26,126,128,129]

Multiple mechanisms may mediate alveolar hemorrhage in this patient population. Diffuse injury to the pulmonary microvasculature, secondary to chemotherapy or radiation therapy, coupled with a heightened inflammatory response in the airways, appear to be operative.[25] Bleeding may be amplified by a precipitating factor such as coagulopathy, pulmonary edema, GVHD, or infections. DAD, a pathological hallmark seen in toxic lung injury from chemotherapy, radiation therapy, or viral infections, is frequently observed in lung biopsies or necropsies in bone marrow recipients with DAH.[127] An association between microangiopathy and DAH in patients receiving BMT for hematologic malignancies was cited.[137] Neutrophils and other inflammatory cells likely play important roles in the pathogenesis of DAH. The onset of DAH frequently coincides with marrow recovery and reappearance of neutrophils within the circulation or BAL fluid. Influx of neutrophils may promote the lung injury by release of oxygen radicals, proteases, and other phlogistic mediators.[25,134] Hematopoietic growth factors (e.g., granulocyte colony–stimulating factor) may exacerbate alveolar damage and capillary leakage by increasing neutrophil influx into the lungs.[25]

High-dose pulse IV corticosteroids are considered standard of care for DAH,[25,26,127,129] but randomized, controlled studies are lacking and a survival benefit has not been established. Unfortunately, DAH or bloody BAL fluid may be seen in infectious causes of pneumonia (particularly due to cytomegalovirus [CMV] or *Aspergillus* spp.),[130] and high-dose corticosteroids could be disastrous under these circumstances. Infectious etiologies must be rigorously excluded. Among patients who respond favorably to corticosteroids, the dose can be gradually tapered over 2 to 6 weeks.[25,127] A more prolonged course is appropriate for patients with GVHD or other complications requiring long-term corticosteroid therapy. Anecdotal response to recombinant factor VIIa was cited in one allogeneic SCT recipient with DAH.[138]

ALVEOLAR HEMORRHAGE COMPLICATING HIV INFECTION

DAH can complicate human immunodeficiency virus (HIV) infection. The incidence and clinical significance of DAH is not clear, as additional pulmonary processes (e.g., opportunistic infections;[139] Kaposi sarcoma[140]) are usually present.[28] Subclinical episodes of alveolar hemorrhage are common, as studies in HIV-infected patients with pulmonary infiltrates detected more than 20% hemosiderin-laden macrophages in BAL fluid in 15% to 44% of patients.[27,28] In one study of 203 HIV-infected patients with pulmonary symptoms who underwent BAL, alveolar hemorrhage (AH) was detected in 73; however, AH was severe in only eight patients and AH did not affect survival.[28] Thrombocytopenia, coagulopathy, renal failure, hydrostatic pulmonary edema, CMV pneumonia, and Kaposi sarcoma were more frequent in patients with AH compared to HIV-infected controls without AH.[28] Pulmonary capillaritis has been cited in occasional patients, most of whom had concomitant opportunistic infections. CMV pneumonia has been implicated as a cause of DAH in HIV-infected patients.[139] CMV exhibits tropism for endothelial cells, and CMV may induce vascular injury or thrombotic microangiopathy. Antiviral therapy (e.g., ganciclovir) may be curative for CMV-associated DAH. Opportunistic pathogens[139] or endobronchial Kaposi sarcoma[140] account for most cases of DAH in HIV-infected individuals. The incidence and appropriate therapy of DAH of unknown etiology in the setting of acquired immunodeficiency syndrome (AIDS) has not been defined.

ALVEOLAR HEMORRHAGE DUE TO EXOGENOUS AGENTS

Certain exogenous agents or drugs[7,17] (e.g., trimellitic anhydride,[141] isocyanates,[142] D-penicillamine,[143] cocaine,[144] diphenylhydantoin,[145] propylthiouracil,[146] hydralazine,[147] sulfasalazine,[147] allopurinol,[1,147] all-*trans*-retinoic acid (ATRA),[148] minocycline[149] are rare causes of DAH. An exhaustive list of drugs capable of causing DAH is available on www.pneumotox.com. Circulating ANCAs, GN, and DAH have been linked with some agents (particularly d-penicillamine,[143] hydralazine,[150] propylthiouracil,[146] methimazole, and carbimazole[151]). Lung biopsies have rarely been performed in these cases of DAH. However, pulmonary capillaritis (without immune deposits) is the most common finding.[7,17]

ATRA, a therapeutic agent for acute promyelocytic leukemia, may be associated with "retinoic acid syndrome," characterized by fever, thrombosis, pulmonary infiltrates, and DAH.[148,152] The onset is 2 to 21 days after initiation of treatment. In this circumstance, ATRA is continued but high-dose IV corticosteroids should be administered.

Propylthiouracil can cause a systemic small-vessel vasculitis with necrotizing GN, leukocytoclastic vasculitis, ANCAs, and DAH secondary to pulmonary capillaritis.[146,147] Withdrawal of the drug may be associated with resolution of the disease, but corticosteroids or immunosuppressive agents are indicated in patients with severe DAH or renal failure.

A variety of chemotherapeutic agents (e.g., bischloroethyl nitrosourea [BCNU], carmustine, CYC, methotrexate, mitomycin C, bleomycin, or busulfan) may cause lung injury and fibrosis.[17,153] In some cases, DAH may result from epithelial injury and injury to the alveolar capillary basement membranes.[17] In this context, fatality rates are high (more than 50%).[17,153] High-dose corticosteroids are recommended, but efficacy is uncertain.

Trimellitic anhydride (TMA), a chemical used in manufacturing plastics and epoxy resins, may elicit pulmonary hemorrhage and anemia.[141,142] Most patients with DAH secondary to TMA exposure recover within a few days following removal from the offending environment. An immune mechanism is likely, as circulating IgG antibodies against trimellitic protein were found in some patients with DAH, suggesting TMA acts as a hapten.[142] TMA may cause asthma, rhinitis, and hemolytic anemia mediated by IgE antibodies directed against trimellitic protein. Animal models of TMA-induced lung disease have also been developed.[141] Induction of serum antibodies against epitopes of TMA produced acute lung injury in animals, mediated by at least two types of humoral antibodies. It is also possible that TMA may exert a direct toxic effect on alveolar endothelium. This syndrome is exceptionally rare, as only sporadic cases have been described. Exposure to isocyanates in spray paint has been linked to occupational asthma and (in a few cases) DAH.[154] The mechanism is likely mediated by high levels of IgE and IgG antibodies against diisocyanates.[142] Thus, exposure to TMA or isocyanates, and possibly other chemicals, can elicit hemorrhagic pneumonitis, likely mediated by circulating antibodies (IgG or IgE) and immune complexes.

Smoking, snorting, or intravenous "crack" cocaine has been associated with hemoptysis and varying degrees of DAH,[144,155] including rare fatalities. Histopathological features of cocaine-induced DAH are nonspecific, but include DAD, acute or chronic DAH, interstitial pneumonitis/fibrosis, and intra-alveolar edema.[156] The mechanism of DAH is not clear but may relate to direct toxic injury from cocaine or its contaminants, vasospasm, or a combination of both mechanisms. This syndrome typically reverses with cessation of exposure. The frequency of clinically significant DAH associated with inhaled or intravenous use of cocaine has not been established.

When drug- or hapten-induced DAH is suspected, immediate avoidance of the implicated agent or drug is essential. For acute or severe cases, a brief course of high-dose corticosteroids is warranted. Plasmapheresis or cytotoxic agents may be considered for fulminant cases refractory to corticosteroids, but data supporting their use are lacking.

Finally, coagulopathies, severe thrombocytopenia, or the use of anticoagulants, thrombolytic agents, or platelet inhibitors may rarely cause DAH.[157–159] In this context, the histology is "bland" without evidence for capillaritis or acute inflammation.

ALVEOLAR HEMORRHAGE DUE TO MOLDS

Acute, life-threatening DAH in infants identified fungal contamination as the etiology.[160,161] Exposure to *Stachybotrys chartarum* and other toxigenic fungi elicits the syndrome.[160] *Stachybotrys chartarum* produces several classes of toxins including hemolysins, proteinases, macrocyclic trichothecenes, phenylspirodrimanes, and others.[160] Acute respiratory distress, progressing to respiratory failure requiring mechanical ventilatory support, may occur.[160] High-dose IV corticosteroids are warranted for acute DAH. Long-term management mandates removal of infants from the residential environment to avoid relapse.[160,161] This syndrome has rarely been reported in adults, but must be considered in water-damaged homes or environs where mold/fungal contamination exists.[161]

IDIOPATHIC PULMONARY HEMOSIDEROSIS

IPH is an exceptionally rare cause of DAH that occurs primarily in infants and children.[23,162–164] The estimated incidence is 0.2 to 1.2 cases per million.[22,165] Many children with IPH have a history of milk or gluten sensitivity.[166] A subset of adults with celiac sprue manifest IPH,[167] which may respond to elimination of gluten from the diet.[168] Clinical features of IPH are similar to immune causes of DAH, but extrapulmonary or renal involvement is lacking.[23] Serum or tissue antibodies (including ANCA, immune complexes, anti-GBM antibody) are also absent. A diagnosis of IPH can be made *only* when other specific causes of DAH have been *reliably* excluded. Most early series of IPH, published in the 1960s and 1970s, antedated the availability of serologies and immunohistochemical assays (e.g., ANCA, anti-GBM antibody, etc.).[169,170] It is likely that most cases formerly diagnosed as IPH in adults had ANCA-associated vasculitis, MPA, or underlying CTD.

The onset of the disease is typically in infants and young children (<5 years old).[23,162] The clinical course of IPH is variable, but recurrent episodes of DAH over several years are characteristic.[23,164,171] Spontaneous remissions without long-term sequelae have been cited in up to 25% of cases.[164] Sequelae of recurrent episodes of DAH include pulmonary fibrosis, progressive respiratory failure, and cor pulmonale.[23,164,171] Early studies cited median survival rates of 3 to 6 years,[162,165] but more recent studies suggest a more favorable prognosis, with many patients surviving >10 to 15 years.[164,171] During acute episodes, chest radiographs demonstrate bilateral alveolar infiltrates. Following cessation of bleeding, chest radiographs may normalize within 1 to 2 weeks. Reticulonodular infiltrates may be observed as the process is resolving or with recurrent episodes (Fig. 68-11). CT reveals areas of ground-glass opacification, representing foci of alveolar hemorrhage. Thickening of interlobular septae and honeycombing may be observed in a subset of patients who progress to pulmonary fibrosis.[172] Hemoptysis may be absent, particularly in young children who may be unable to expectorate blood. Iron-deficiency anemia is characteristic and can be profound.[23,164,171,173] Iron deficiency may persist despite normal total body iron stores, because hemosiderin within alveolar macrophages is not available to developing erythrocytes. Siderophages may be found in sputum, BAL fluid, or tracheal or gastric aspirates in patients with recent episodes of DAH.[22,164,171] Lung biopsies may reveal fresh areas of alveolar hemorrhage or patchy interstitial fibrosis and aggregates of hemosiderin-laden macrophages from prior episodes of alveolar hemorrhage (Fig. 68-12).[23,164]

Figure 68-11 Idiopathic pulmonary hemosiderosis (IPH). Posterior–anterior (PA) chest radiograph demonstrates bilateral reticulonodular infiltrates in a 28-year-old woman with IPH confirmed 10 years earlier by open lung biopsy.

The pathogenesis of IPH is not known. In children, associations between IPH and cow's milk hypersensitivity, celiac disease,[173] IgA monoclonal gammopathy, autoimmune hemolytic anemia, and autoimmune thyrotoxicosis have been suggested,[164] but a pathogenetic link has not been substantiated. Resolution of pulmonary symptoms following elimination of milk products or gluten from diet[167,173] supports a role for exogenous factors in the pathogenesis in at least some cases. No genetic basis has been found, but clusters within families have been described.[170,174]

In view of the rarity of IPH, optimal therapy is not clear. Corticosteroids are considered the mainstay of therapy,[22–24,163] but controlled studies evaluating therapeutic regimens have not been done. Because IPH is life-threatening, most physicians treat acute episodes with daily corticosteroids and taper to the lowest dose that appears to control the disease. Long-term (and possibly indefinite) therapy may be required to prevent recurrences. Favorable responses have been cited with azathioprine,[175] CYC,[176] or other immunosuppressive agents[171] in patients failing corticosteroids. Chronic immunosuppressive agents may improve prognosis for patients with corticosteroid-recalcitrant disease or patients experiencing repetitive relapses of DAH.[171] In this context, we prefer azathioprine over CYC given the heightened risk of neoplasia and gonadal toxicities associated with the long-term use of CYC.[177]

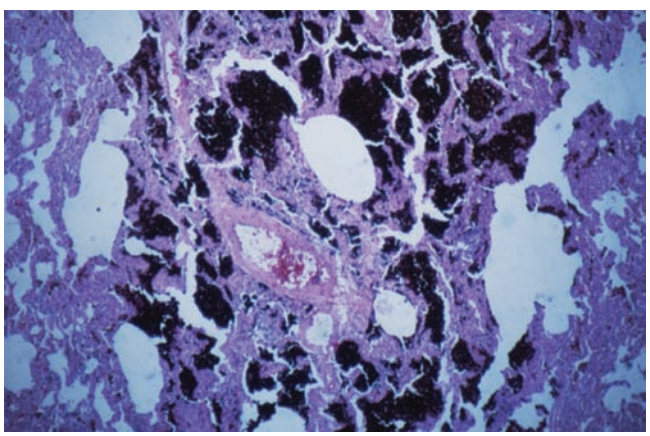

Figure 68-12 Idiopathic pulmonary hemosiderosis (IPH). Photomicrograph demonstrating extensive deposits of hemosiderin within alveolar interstitium (Prussian blue stain).

CHAPTER 69

Aspiration-Related Pulmonary Disorders

Paul E. Marik

Pneumonia—"Captain of the Men of Death"

—William Osler[1]

Aspiration is defined as the misdirection of oropharyngeal or gastric contents into the larynx and lower respiratory tract.[2] An assortment of pulmonary syndromes may occur following aspiration depending on the quantity and nature of the aspirated material, the chronicity of aspiration, as well as the nature of the host's defense mechanisms and the host's response to the aspirated material. The most important syndromes include "*aspiration pneumonitis*" or Mendelson's syndrome, which is a chemical pneumonitis caused by the aspiration of gastric contents, and "*aspiration pneumonia*," an infectious process caused by the aspiration of oropharyngeal secretions colonized by pathogenic bacteria.[2] While there is some overlap between these two syndromes they are distinct clinical entities. In addition, a variety of pulmonary conditions have been described from chronic recurrent occult aspiration, most notably "*diffuse aspiration bronchiolitis*."[3] Other aspiration syndromes include airway obstruction, lung abscess, exogenous lipoid pneumonia, chronic interstitial fibrosis, and *Mycobacterium fortuitum* pneumonia. This chapter will focus on the pathophysiology, clinical features and management of aspiration pneumonitis, aspiration pneumonia, and diffuse aspiration bronchiolitis.

ASPIRATION PNEUMONITIS

Aspiration pneumonitis is best defined as acute lung injury following the aspiration of regurgitated gastric contents.[2] This syndrome occurs in patients with a marked disturbance of consciousness such as drug overdose, seizures, coma due to acute neurologic insults, massive cerebrovascular accident, following head trauma and during anesthesia. It is important to emphasize that aspiration pneumonitis only occurs in patients who have a depressed level of consciousness with impairment of airway protective reflexes. In clinical practice, drug overdose is the most common cause of aspiration pneumonitis, occurring in approximately 10% of patients hospitalized following a drug overdosage. Adnet and Baud[4] demonstrated that the risk of aspiration increases with the degree of impairment in consciousness (as measured by the Glasgow Coma Scale). Historically, the syndrome most commonly associated with aspiration pneumonitis is Mendelson's syndrome, reported in 1946 in obstetric patients who aspirated while receiving general anesthesia.[5] Mendelson's original report consisted of 44,016 nonfasted obstetric patients whom he studied between 1932 and 1945, of whom more than half received an "operative intervention" with ether by mask without endotracheal intubation. He described aspiration in 66 patients (1:667). Although several of the patients were critically ill from their aspiration, recovery was usually complete within 24 to 36 hours and only two patients died (1:22,008).

Although aspiration is a widely feared complication of general anesthesia, clinically apparent aspiration in modern anesthesia practice is exceptionally rare, and in healthy patients the overall morbidity and mortality are low (see section below). The risk of aspiration is greatly increased in patients intubated emergently in the field, emergency room or in the ICU. In these patients every effort should be made to reduce the risk of aspiration; this includes removing dentures and clearing the airway and in certain circumstances placing a nasogastric tube to empty the stomach prior to intubation. If there is an immediate risk of airway compromise

endotracheal intubation should be performed prior to placement of a nasogastric tube. However, if the patient is likely to have a full stomach (upper GI bleed, small bowel obstruction, ileus, etc.) it may be prudent to place a nasogastric tube prior to endotracheal intubation. When intubating emergently, suction equipment must be immediately available and rapid-sequence induction using cricoid pressure should be performed.

PATHOPHYSIOLOGY

Mendelson emphasized the importance of acid when he showed that unneutralized gastric contents introduced into the lungs of rabbits caused severe pneumonitis indistinguishable from that caused by an equal amount of 0.1 N hydrochloric acid.[5–7] However, if the pH of the vomitus was neutralized before aspiration, the pulmonary injury was minimal. Experimental studies have demonstrated that the severity of lung injury increases significantly with the volume of the aspirate and inversely with its pH, with a pH of less than 2.5 being required to cause aspiration pneumonitis. However, the stomach contains a variety of other substance in addition to acid. Several experimental studies have revealed that aspiration of small, particulate food matter from the stomach may cause severe pulmonary damage, even if the pH of the aspirate is above 2.5.[8,9] These studies suggest that cell recruitment and expression of inflammatory mediators are most pronounced after injury with combined acid and small food particles. These data are supported by findings in patients where the most severe lung injury was observed in patients following aspiration with particulate food matter.[10,11]

Aspiration of gastric contents results in a chemical burn of the tracheobronchial tree and pulmonary parenchyma with an intense parenchymal inflammatory reaction. The proinflammatory cytokines including tumor necrosis factor-α and CXC chemokines are crucial to the development of aspiration pneumonitis by mediating neutrophil recruitment. Once localized to the lung, neutrophils play a key role in the development of lung injury through the release of oxygen radicals and proteases. Gastric acid prevents the growth of bacteria and therefore the contents of the stomach are normally sterile. Bacterial infection, therefore, does not play a significant role in the early stages of acute lung injury following aspiration of gastric contents. However, acid aspiration pneumonitis reduces host defenses against infection increasing the risk of superinfection.[12] The incidence of this complication has, however, not been well studied. Furthermore, experimental models suggest that acid aspiration pneumonitis "primes the lung" making secondary infection more severe.[12,13] Colonization of the gastric contents by potentially pathogenic organisms may occur when the gastric pH is increased by the use of antacids, histamine-2 (H2) receptor blockers, or proton pump inhibitors. In addition, gastric colonization by gram-negative bacteria occurs in patients receiving enteral feedings, as well as in patients with gastroparesis and small bowel obstruction. In these circumstances the pulmonary inflammatory response is likely to result from both bacterial infection and the inflammatory response of the gastric particulate matter.

ANESTHESIA AND ASPIRATION PNEUMONIA

Aspiration pneumonitis has traditionally been regarded as the major cause of serious anesthetic complications. However, with the recognition of the importance of this complication, and the fact that it is largely preventable, the risk of aspiration pneumonitis in modern anesthesia is very low. Nevertheless, aspiration pneumonitis is an important perioperative complication and remains the commonest cause of anesthesia-related death. The risk of aspiration with modern anesthesia is reported to be between 2.9 and 4.7 per 10,000 general anesthetics (about 1 in 3000 anesthetics) with a mortality of approximately 1:125,000, accounting for between 10% and 30% of all anesthetic deaths.[14,15] Warner et al.[7] published data from a study of 215,488 anesthetics and observed 67 episodes of aspiration in adults (3.1 per 10,000 patients) undergoing general anesthesia. In a recent study involving 99,441 patients undergoing nonobstetrical anesthesia, perioperative pulmonary aspiration occurred in 14 patients (1 in 7103 procedures).[16] All 14 patients has one or more risk factors for aspiration. The Thai Anesthesia Incident Monitoring Study prospectively recorded reports on aspiration from 51 hospitals across Thailand during a 6-month period in 2007.[17] Twenty-eight reports met the definition of pulmonary aspiration (denominator not reported). Most of the incidents occurred in American Society of Anesthesiology (ASA) class 1 to 2 patients (85.7%), during day time hours (64.3%), and when the anesthesiologists were in charge (67.9%). Eleven incidents (39.3%) occurred during induction, seven (25%) during maintenance, and seven (25%) during the emergence phase. All the incidents except one (96.4%) were considered human error and 25 (89.2%) were preventable. Thirteen patients (46.4%) had major physiologic changes and 10 (35.7%) of them required unplanned ICU admission. Ten patients (35.7%) needed prolonged ventilator support and two (7.14%) of them died.

The most definitive and extensive review on the risk of airway problems associated with intubation was reported by Cook et al.[18,19] who summarized the findings of the 4th National Audit Project of the Royal College of Anaesthetists. In this 1-year prospective audit, the authors examined the occurrence of serious airway complications in anesthesia, ICUs, and emergency departments of all the National Health Service hospitals in the United Kingdom. The authors found 184 cases that met the inclusion criteria: 133 from anesthesia, 36 from ICUs, and 15 from emergency departments. A concurrent national census of anesthesia activity over a 2-week period was performed to provide denominator data for anesthesia, which indicated 2.9 million anesthetic procedures annually, resulting in a nominal incidence (using the 133 anesthesia events) of one serious airway complication per 22,000 anesthetics. In total, 38 deaths were attributable to airway complications, and the death rate was 16 of 133 (12%) in anesthesia, 18 of 36 (50%) in the ICUs, and 4 of 16 (25%) in the emergency departments. Pulmonary aspiration of gastric contents was the commonest cause of death and brain damage. A supraglottic airway was the planned technique in more than 50% of death or brain damage cases. A statistical analysis of the reports suggested that as few as 25% of relevant incidents may have been reported. The authors therefore suggest that this audit provides an indication of the lower limit for the incidence of such complications.

Emergency surgery (particularly, trauma and abdominal surgery with delayed gastric emptying) procedures performed at night, inadequate anesthesia, obesity, elderly immobilized patients, and obstructive sleep apnea have been associated with a higher risk of aspiration.[15,20] Obtunded adults and children with known gastroesophageal reflux are more likely to aspirate even without narcotic or sedative impairment of airway reflexes. The factors increasing the risk for aspiration are listed in Table 69-1. Patients who are at risk before surgery are also at increased risk during the postoperative period when immobility, residual effects of anesthetic agents, and narcotics combine to decrease protective airway reflexes.[21–23]

The incidence of aspiration appears higher in obstetric patients as highlighted by the pioneering study of Mendelsohn.[5] A study from 1973 reported an incidence of 1 in 6000 obstetric patients receiving general anesthesia for vaginal deliveries and 1 in 430 for cesarean section patients.[24] In more recent studies, an aspiration incidence of 1 in 1547 and 1 in 1431, respectively, were described for cesarean section under general anesthesia,[21,23] and a recent audit showed an incidence of 1 in 900 women undergoing cesarean section.[22] The risk of pulmonary aspiration is, therefore, at least double or three times as high as in general surgical patients. Pregnant women are at increased risk of aspiration because of gastroesophageal reflux and delay in gastric emptying.[25,26]

TABLE 69-1 Factors Increasing the Risk of Perioperative Aspiration

Recent eating
Delayed gastric emptying
Diabetic neuropathy
Opioids
Paralytic ileus
Small bowel obstruction
Pregnancy
Emergency surgery
Obesity
Obstructive sleep apnea
Reflux esophagitis
Achalasia
Esophageal stricture
Previous gastric bypass surgery
Traumatic brain injury
Cerebral infarction/bleed

Gastroesophageal reflux is common in pregnancy and can be demonstrated even in the absence of symptoms. There is no difference in basal and evoked gastric acid secretion in pregnancy but there is a reduction in lower esophageal barrier pressure, which is likely to be a progesterone effect present from early pregnancy. The surgical procedure may itself increase aspiration risk through the adoption of lithotomy or Trendelenburg positions or the creation of a pneumoperitoneum.

The laryngeal mask airway (LMA) does not reliably protect the lungs from regurgitated stomach contents and should be avoided in patients at an increased risk for aspiration.[27,28] In a meta-analysis of 12,901 low-risk cases, where the standard contraindications to the use of the LMA were followed (e.g., absence of gastrointestinal pathology, obesity, history of reflux, or emergency surgery), only 3 cases of aspiration were identified, an incidence of 2.3 per 10,000.[29]

Inadequate reversal of neuromuscular blockage at the end of surgery is an important risk factor for aspiration. After the administration of nondepolarizing neuromuscular blocking agents, it is essential to ensure adequate return of normal neuromuscular function. Residual paralysis decreases upper esophageal tone, coordination of the esophageal musculature during swallowing, and the hypoxic ventilatory drive.[30] These factors significantly increase the risk for aspiration. Adequate recovery of postoperative neuromuscular function cannot be guaranteed without objective neuromuscular monitoring. Good evidence-based practice dictates that clinicians should always quantitate the extent of neuromuscular blockade by objective monitoring (train-of-four monitoring).[30] To exclude clinically significant residual neuromuscular blockade, the train-of-four ratio, when measured mechanically or by electromyography, must exceed 0.9. If sufficient recovery (i.e., train-of-four $\geq$0.9) has not been documented objectively at the end of the surgical procedure, the neuromuscular block should be antagonized.

Prevention of Aspiration During Anesthesia

In recent years more liberal preoperative fasting guidelines have been promoted. In healthy adults without an increased risk of regurgitation or aspiration solids should be avoided after midnight; however, a light meal such as dry toast may be considered up to 6 hours before anesthesia and clear liquids such as water, coffee without milk, or fruit juice can be given up to 2 hours before induction.[31,32] Meta-analyses of randomized controlled trials comparing fasting times of 2 to 4 hours *versus* more than 4 hours report smaller gastric volumes and higher gastric pH values in adult patients given clear liquids 2 to 4 hours before a procedure and this approach is currently endorsed by the ASA.[33]

Preoperative antacids, H2 receptor blockers, proton pump inhibitors, and prokinetic agents have been used to reduce the volume and/or acidity of the gastric contents. There is, however, a lack of data indicating that any of these drugs reduce the risk of aspiration pneumonitis.[34] The routine use of these drugs is not recommended by the ASA guidelines.[33] However, it is not unreasonable to use these drugs in patients at an increased risk of aspiration. It is however important to realize that it takes time for the clinical effects of the acid suppressive drugs to manifest and these drugs should therefore be dosed at least 2 hours prior to induction.[35]

Standard teaching suggests that rapid-sequence induction with cricoid pressure should be performed when intubating patients at an increased risk of aspiration. Cricoid pressure, known as the Sellick maneuver, is designed to occlude the cervical esophagus by compressing it between the cricoid cartilage and the vertebral bodies.[36] Passively regurgitated gastric contents are therefore prevented from entering the pharynx. Neither rapid-sequence induction nor cricoid pressure has been prospectively studied and proven to decrease the incidence of aspiration. Rapid-sequence induction shortens the time between the onset of unconsciousness and securing the airway, which may be of benefit if the aspiration risk is high. However, the use of cricoid pressure is controversial.[37] The esophagus cannot be reliably occluded between the cricoid cartilage and the vertebral bodies. Studies in volunteers (men and nonpregnant women) clearly show that the esophagus often does not lie in the midline or that cricoid pressure displaces the esophagus laterally without occluding it.[38] More recent data suggest that the hypopharynx posterior to the cricoid cartilage is in continuity with the esophageal inlet and this hypopharyngeal area is occluded with the Sellick maneuver.[39] Cricoid pressure is often applied incorrectly or without the appropriate amount of force and may reduce visualization of the vocal cords and impede intubation. Although not proven to reduce the risk of aspiration during emergent intubations, cricoid pressure is currently considered the standard of care in this situation.

CLINICAL PRESENTATION

Aspiration of gastric contents can present dramatically with a full-blown picture that includes gastric contents in the oropharynx, wheezing, coughing, shortness of breath, cyanosis, pulmonary edema, hypotension, and hypoxemia; this may progress rapidly to severe ARDS and death (see Fig. 69-1). However, many patients may not develop signs or symptoms associated with aspiration, while others may develop a cough or wheeze. In some patients aspiration may be clinically silent manifesting only as arterial desaturation with radiologic evidence of aspiration. Warner et al.[7] studied 67 patients who aspirated while undergoing anesthesia. Forty-two (64%) of these patients were totally asymptomatic, 13 required mechanical ventilatory support for more than 6 hours and 4 died.

MANAGEMENT OF ASPIRATION PNEUMONITIS

The upper airway should be suctioned following a witnessed aspiration. Endotracheal intubation should be considered in patients who are unable to protect their airway. While common practice, the prophylactic use of antibiotics in patients with suspected or witnessed aspiration is not recommended. Similarly, the use of antibiotics shortly after an aspiration episode in a patient who develops a fever, leukocytosis, and a pulmonary infiltrate is discouraged as it may select for more resistant organisms in a patient with an

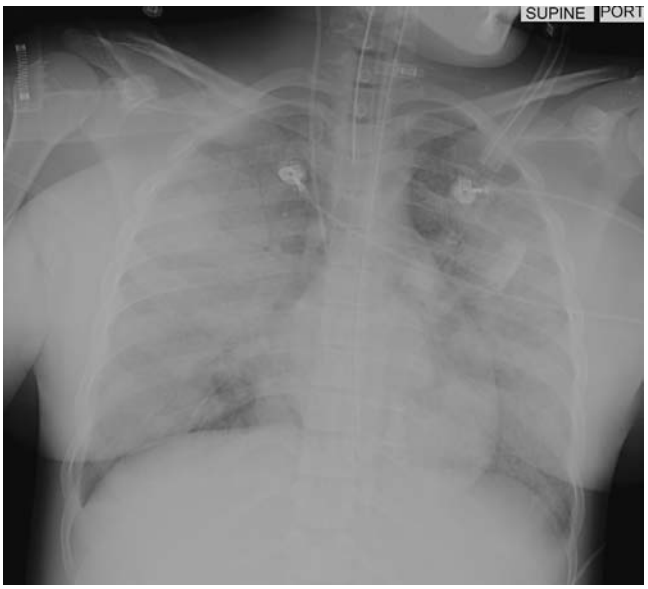

Figure 69-1 Anteroposterior chest radiograph demonstrating bilateral alveolar infiltrates following aspiration of gastric contents (aspiration pneumonitis).

uncomplicated chemical pneumonitis. However, empiric antimicrobial therapy is appropriate in patients who aspirate gastric contents in the setting of small bowel obstruction or in other circumstances associated with colonization of gastric contents (acid-suppressive therapy, tube feeds). Antimicrobial therapy should be considered in patients with an aspiration pneumonitis that fails to resolve within 48 hours. Empiric therapy with broad-spectrum agents is recommended. Antimicrobials with anaerobic activity are not routinely required. Recently serum procalcitonin has emerged as a biomarker that has been postulated to be able to discriminate bacterial infections from nonbacterial inflammatory disorders.[40] El-Solh et al.[41] investigated the predictive accuracy of serum procalcitonin in distinguishing aspiration with bacterial pneumonia from "sterile" aspiration pneumonitis. In this study serum procalcitonin levels had poor diagnostic value in separating bacterial pneumonia from aspiration pneumonitis based on quantitative bronchoalveolar lavage culture.

IMMUNOMODULATING AGENTS

Corticosteroids have been used in the management of aspiration pneumonitis since 1955.[42] However, limited data exist on which to evaluate the role of these agents, with only a single prospective, placebo-controlled study having been performed. In this study, Sukumaran et al.[43] randomized 60 patients with "aspiration pneumonitis" to methylprednisolone (15 mg/kg/day for 3 days) or placebo. The patients were subdivided into two groups; a younger group with drug overdose as the predominant diagnosis and an older group with neurologic disorders. Radiographic abnormalities improved more rapidly in the steroid group, as did oxygenation. The number of ventilator and ICU days was significantly shorter in the overdose patients who received corticosteroids; however, these variables were longer in the neurologic group receiving this therapy. There was no significant difference in the incidence of complications or mortality. The results of this study are somewhat difficult to interpret as it is likely that the patients in the overdose group had true "aspiration pneumonitis" while many patients in the neurologic group probably developed "aspiration pneumonia." Wolfe et al.[44] performed a case-controlled study of 43 patients with aspiration pneumonitis, of whom 25 received high-dose corticosteroids (approximately 600 mg prednisolone/day for 4 days). While there was no difference in mortality, secondary gram-negative pneumonia was reported to be more frequent in the steroid group (7/20 vs. 0/13); however, ventilator days tended to be less in this group (4.3 vs. 9.8 days). Based on this limited data it is not possible to make evidence-based recommendations on the use of corticosteroids in patients with aspiration pneumonitis.

In animal models, a number of pharmacologic interventions including inhaled B_2 agonists, pentoxifylline, antiplatelet drugs, and omega-3 fatty acids have been shown to attenuate the acute lung injury following acid aspiration.[45–50] The role of these interventions in patients remains to be tested; however, due to their inherent safety, these agents should be considered in patients with severe acid aspiration pneumonitis.

ASPIRATION PNEUMONIA

Aspiration pneumonia refers to the development of a radiographic infiltrate and clinical features consistent with pneumonia in a patient with risk factors for increased oropharyngeal aspiration (see Fig. 69-2). Approximately half of all healthy adults aspirate small amounts of oropharyngeal secretions during sleep. Presumably, the low virulent bacterial burden of normal pharyngeal secretions together with forceful coughing, active ciliary transport, and normal humoral and cellular immune mechanisms result in clearance of the inoculum, without sequelae. However, if the mechanical, humoral, or cellular mechanisms are impaired or if the aspirated inoculum is large enough, pneumonia may follow. Any condition that increases the volume and/or bacterial burden of oropharyngeal secretions in the setting of impaired host defense mechanism may lead to aspiration pneumonia. Indeed, in stroke patients undergoing swallow evaluation there is a strong correlation between the volume of the aspirate and the development of pneumonia.[51] Factors that increase oropharyngeal colonization with potentially pathogenic organisms and that increase the bacterial load may augment the

Figure 69-2 Anteroposterior chest radiograph demonstrating a left lower lobe aspiration pneumonia.

risk of aspiration pneumonia. The clinical setting in which pneumonia develops largely distinguishes aspiration pneumonia from other forms of pneumonia. However, there is much overlap. This is illustrated by the fact that otherwise healthy elderly patients with "community-acquired pneumonia" (CAP) have been demonstrated to have a significantly higher incidence of silent aspiration when compared with age-matched controls.[52]

EPIDEMIOLOGY

The lack of specific and sensitive markers of aspiration makes the epidemiologic study of aspiration syndromes difficult. Furthermore, most studies do not make the distinction between aspiration pneumonitis and aspiration pneumonia. Nevertheless, several studies list "aspiration pneumonia" as the cause of CAP in 5% to 15% of cases.[53,54] CAP is a major cause of morbidity and mortality in the elderly and it is likely that aspiration is the major cause of pneumonia in these patients. Epidemiologic studies have demonstrated that the incidence of pneumonia increases with aging, with the risk being almost six times higher in those over the age of 75, compared to those less than 60 years of age.[55,56] The attack rate for pneumonia is highest among those in nursing homes.[57]

DYSPHAGIA IN PATIENTS WITH ASPIRATION PNEUMONIA

Swallowing is a complex function, with both voluntary and reflexive components. Five cranial nerves and more than 50 muscles in the head and neck are involved in oropharyngeal swallowing. Both brainstem and cortical areas are involved in the neural processing of swallowing. The coordination of swallowing requires bilateral input from the sensorimotor cortex with descending input to the brainstem medullary swallowing center.[58] Functional and anatomic imaging studies have identified several sites that play an important role in swallowing, including the primary sensorimotor cortex, insula, anterior cingulate, internal capsule, basal ganglia, and thalamus. The swallowing process can be divided into oropharyngeal phase and esophageal phase.[59] The oropharyngeal phase includes biting and chewing in the oral cavity, and the transport of food into the pharynx. In simplified terms, this process is accompanied by elevation and anterior movement of the larynx to meet with the epiglottis for protection of the airway. It is followed by passage of the bolus through the upper esophageal sphincter into the esophagus (esophageal phase). During the esophageal phase, the lower esophageal sphincter relaxes and food is pushed into the stomach by peristalsis and gravity.

Dysphagia refers to the difficulty in swallowing. The severity of dysphagia varies from moderate difficulty to complete inability to swallow. Dysphagia is the major risk factor leading to aspiration pneumonia. In addition, dysphagia contributes significantly to protein-energy malnutrition and dehydration. Impairment in any component of the swallow mechanism including anatomical abnormities of the upper airway or esophagus can lead to dysphagia. Dysphagia has traditionally been associated with brainstem and bilateral cerebral infarction, though it has more recently been shown to occur in isolated cerebral infarctions as well. Furthermore, dysphagia is commonly associated with silent cerebral infarction.

Dysphagia is remarkably common in Westernized nations and is a major cause of morbidity and mortality. Indeed, aspiration pneumonia is probably the final common pathway by which most chronically ill patients die. It has been estimated that over 16 million senior citizens in the United States suffer from dysphagia.[60] Furthermore, an additional 300,000 to 600,000 patients develop dysphagia each year in the United States from neurologic disorders.[61] Dysphagia affects more than 30% of patients who have had a cerebrovascular accident; 52% to 82% of patients with Parkinson disease; 84% of patients with Alzheimer disease, up to 40% adults aged 65 years and older, and more than 60% of elderly institutionalized patients.[62] The efficiency of the swallow mechanism decreases with aging, increasing the risk of aspiration and pneumonia in the elderly. Kikuchi et al. evaluated the occurrence of silent aspiration in otherwise "healthy elderly patients" with CAP and age-matched control subjects using indium[111] chloride scanning.[52] Silent aspiration was demonstrated in 71% of patients with CAP compared to 10% in control subjects. The impaired swallow mechanism in the elderly can be attributed to diminished sensation, silent cerebral infarction, cerebral atrophy, a delay in the synapse conduction in the afferent inputs to the central nervous system, and lingual weakness (sarcopenia) caused by aging.[63,64]

RISK FACTOR FOR DYSPHAGIA

The major risk factors for dysphagia are listed in Table 69-2. In patients with an acute stroke the incidence of dysphagia ranges from 40% to 70%.[65] Dysphagic patients who aspirate are at an increased risk of developing pneumonia.[66,67] Although dysphagia improves in most patients following a stroke, in many the swallowing difficulties follow a fluctuating course with 10% to 30% continuing to have dysphagia with aspiration.[68,69]

The Cough Reflex in Patients with Aspiration Pneumonia

An intact cough reflex is an important respiratory defense mechanism. Sekizawa et al.[70] demonstrated a marked depression of the cough reflex in elderly patients with pneumonia. Furthermore, the greater the derangement of the cough reflex, the greater the risk of pneumonia.[71] Nakazawa et al.[72] demonstrated impairment of the swallow and the cough reflex in elderly patients with aspiration pneumonia but not in patients with dementia who had no prior history of aspiration pneumonia. Angiotensin-converting enzyme (ACE) modulates the cough reflex. Along with its effects that cleave angiotensin I to angiotensin II, ACE also metabolizes the protussive peptides, substance *P* and bradykinin. Substance P, which is released from vagal sensory nerves in the pharynx and upper airways, mediates the cough reflex. One study found that substance *P* levels in sputum were reduced substantially in elderly patients with pneumonia.[73] Bradykinin, an inflammatory peptide that mediates cough due

to ACE inhibitors, sensitizes airway sensory nerves and enhances the cough reflex. A number of reports indicate that the insertion/deletion (*I*/*D*) polymorphism of the ACE gene (ACE DD allele) is associated with an increased risk of pneumonia.[74,75] Furthermore, the use of ACE inhibitors is associated with a reduced risk of aspiration pneumonia (see the section that follows).

FACTORS THAT INCREASE THE RISK OF PNEUMONIA IN PATIENTS WHO ASPIRATE

While the presence of dysphagia and the volume of the aspirate are key factors that predispose patients to aspiration pneumonia, a number of other factors play an important role.[51] Colonization of the oropharynx is an important step in the pathogenesis of aspiration pneumonia. The elderly have increased oropharyngeal colonization with pathogens such as *Staphylococcus aureus* and aerobic gram-negative bacilli (e.g., *Klebsiella pneumoniae* and *Escherichia coli*). Although this increased colonization may be transient, it underlies the increased risk in the elderly of pneumonia with these pathogens. Furthermore, colonization of dental plaque may be an important risk factor for aspiration pneumonia.[76] The defects in host defenses that predispose to enhanced colonization with these organisms are uncertain; however, dysphagia with a decrease in salivary clearance and poor oral hygiene may be major risk factors.[77] Residents of long-term care facilities are prone to poor oral health due to lack of oral hygiene care as well as conditions of peridental and/or dental disease. Langmore et al.[78] reported that in elderly patients the number of decayed teeth and never or only occasionally brushing teeth were independent predictors of aspiration pneumonia. Similarly, Azarpazhooh and Leake [79] performed a systematic review that demonstrated that the presence of cariogenic and periodontal pathogens in dental plaque and saliva and decayed teeth were independent predictors of aspiration pneumonia. Awano et al.[80] demonstrated that persons with 10 or more periodontal pockets had an increased risk of death from pneumonia. Proton pump inhibitors increase gastric and oropharyngeal colonization with potentially pathogenic organisms. Gulmez et al.[81] reported that the concurrent use of proton pump inhibitors in patients over the age of 60 increased the risk for community-acquired (aspiration) pneumonia.

DIAGNOSIS AND MANAGEMENT OF ASPIRATION PNEUMONIA

There is no "gold standard" test to diagnose aspiration pneumonia. Furthermore, in patients with aspiration pneumonia, unlike the case of aspiration pneumonitis, the episode of aspiration is generally not witnessed. The diagnosis is therefore inferred when a patient with known risk factors for aspiration develops clinical features compatible with pneumonia (fever, shortness of breath, purulent sputum) with an infiltrate in a characteristic bronchopulmonary segment (see Fig. 69-2). In patients who aspirate in the recumbent position the commonest sites of involvement are the posterior segments of the upper lobes and the apical segments of the lower lobes. In patients who aspirate in the upright or semirecumbent position the basal segments of the lower lobes are favored. The usual picture is that of an acute pneumonic process, which runs a course similar to that of a typical CAP. Untreated, however, these patients appear to have a higher incidence of cavitation and lung abscess formation.[82]

Antimicrobial therapy is indicated in patients with aspiration pneumonia. The choice of antibiotics should depend on the setting in which the aspiration occurs as well as the patient's premorbid condition. This includes such factors as whether the aspiration occurred in the community or in a healthcare facility (healthcare-associated pneumonia [HCAP]) and patient characteristics such as alcoholism, oral hygiene, intravenous drug abuse, and the recent use of antibiotics or acid suppressive therapy.[83] In otherwise "healthy" outpatients a narrow-spectrum antibiotic which targets organisms such as *Streptococcus pneumoniae, S. aureus,* and *Haemophilus influenzae* is recommended. However, most patients with aspiration pneumonia have risk factors for colonization and infection with aerobic gram-negative organisms and require treatment with antimicrobials such as third generation cephalosporins, fluoroquinolones, piperacillin, or carbapenems.[83–86] In addition, vancomycin or linezolid should be considered in patients at risk of infection with methicillin-resistant *S. aureus* (MRSA). Although commonly prescribed (and often considered the standard of care) antimicrobials with specific anaerobic activity are not routinely warranted. The anaerobic bacteria that colonize the oropharynx are intrinsically of low virulence. In an experiment dating back to 1930, Smith introduced bacteria isolated from patients with Vincent angina into the lungs of rabbits.[87] Cultures of a single organism failed to produce pneumonia; only when multiple different organisms were instilled into the lungs did the animals develop pneumonia (synergistic anaerobic infection). In the most rigorous study to date, El-Sohl et al.[86] performed protected quantitative bronchial sampling in 95 patients with severe aspiration pneumonia. Out of the 67 pathogens identified, gram-negative enteric bacteria were the predominant organisms isolated (49%), followed by anaerobic bacteria (16%) and *S. aureus* (12%). A single anaerobic bacterium was isolated from 11 patients usually in association with a gram-negative pathogen. Although seven cases with anaerobic isolates received initially inadequate antimicrobial therapy, six had effective clinician response. Antimicrobials with specific anaerobic activity may only be indicated in patients with periodontal disease, patients expectorating putrid sputum and patients with a necrotizing pneumonia or lung abscess on chest radiograph.[2,83–85]

ASSESSMENT AND MANAGEMENT OF DYSPHAGIA

All elderly patients with CAP, as well as patients with a recent cerebrovascular accident and those with degenerative neurologic diseases should be referred to a speech and language pathologist (SLP) for a formal swallow evaluation (Video 69-1).[67,88] Those patients with dysphagia require the formulation and implementation of an individualized management strategy. A clinician's bedside assessment of the cough and gag reflex is unreliable in screening for patients at risk of aspiration. Because objective swallowing evaluation can be performed with a nasogastric tube or feeding tube in place, it is not necessary to remove the tube (and interrupt enteral feedings) to evaluate dysphagia. Similarly, there is no contraindication to leaving a nasogastric tube in place to supplement oral alimentation.[89]

The management of patients with dysphagia requires the coordinated expertise of a number of healthcare professionals, including the patient's primary care physician, pulmonologist, SLP, clinical dietician, occupational therapist, physiotherapist, nurse, oral

Video 69-1 An 82 year-old male admitted with PNA, required multiple intubations and eventual tracheostomy. Fiberoptic endoscopic evaluation of swallowing (FEES) completed with #5XLT proximal/cuffless tracheostomy (patient capped on room air) and Dobhoff feeding tube in place. FEES revealed a severe pharyngeal dysphagia. There is pooling of secretions throughout pharynx/larynx (valleculae and pyriform sinuses) with aspiration of secretions. With pureed texture there is residue throughout the pharynx suggestive of generalized reduced pharyngeal contraction. The residue in the valleculae is a result of reduced base of tongue retraction, epiglottis dysfunction, and poor hyoid elevation. The residue in the pyriform sinuses is a result of cricopharyngeus dysfunction/inadequate upper esophageal sphincter opening. There is a delayed pharyngeal swallow response with nectar consistency with bolus spilling to the pyriform sinuses resulting in + aspiration before/during/after the swallow response due to reduced arytenoid tilt and vocal fold adduction. *(Used with permission of Randy Dubin.) Access at www.fishmansonline.com*

hygienist, dentist, as well as the patient's primary caregivers. The goal is to optimize the safety, efficiency, and effectiveness of the oropharyngeal swallow to maintain adequate nutrition and hydration and to improve oral hygiene. Enhanced quality of life, wherever possible, should direct management and oral intake (when possible) is preferred over tube feeding. A fundamental principle of rehabilitation is that the best therapy for any activity is the activity itself; as swallowing may be considered the best therapy for swallowing disorders, rehabilitation should be aimed at identifying ways of ensuring safe and effective swallowing in individual patients. Current treatment for dysphagia includes prevention of aspiration in the form of diet and fluid modifications, compensatory maneuvers, position changes, and rehabilitation exercises.[90] Diet modification is a common treatment for dysphagia. Modifications in food consistency are individually determined by means of the clinical swallow and/or videofluoroscopic swallow evaluation. Reduction in bolus volume and enhancement of bolus viscosity significantly improve the safety of swallowing and reduce the risk of aspiration.[63] The SI physical unit of dynamic viscosity is the pascal-second (Pa·s). The prevalence of aspiration is maximal with water and thin fluids (20 Pa·s) and decreases with nectar (270 Pa·s) and pudding (3900 Pa·s) viscosity boluses.[63] By increasing the viscosity or thickness of the food or liquid bolus in patients with oral sensory or motor deficits, the material is less likely to escape from the oral cavity, fall into the laryngeal inlet, or penetrate the incompletely sealed larynx during the delay before pharyngeal swallowing starts. Videofluoroscopic studies have demonstrated that increasing viscosity of liquids to pudding viscosity significantly reduces the risk of aspiration.[91,92] In addition to changes in diet, maintenance of oral feeding often requires compensatory techniques to reduce aspiration or to improve pharyngeal clearance. A variety of behavioral techniques are used, including modifications in posture, head position and respiration, as well as specific swallowing maneuvers. The chin-down posture has been suggested to reduce the risk of aspiration.[92–94] Welch et al.[95] noted that the posterior shift of anterior pharyngeal structures with the chin-down posture improved airway protection. The preferred intervention in patients with dysphagia and the impact of these interventions on the risk of aspiration pneumonia is however unclear.[96]

Neuromuscular electrical stimulation (NMES) is a relatively new treatment for oropharyngeal dysphagia.[97–99] NMES for dysphagia entails applying electrodes to the muscles of the head and neck, and stimulating those muscles that are weakened or hemiparetic by means of electric pulses. This is generally combined with the subject swallowing food or fluids that are predetermined to represent the most appropriate consistency that the person can tolerate without aspiration. Further research on the effects of NMES is warranted before surface electrical stimulation can be recommended as treatment of dysphagia

Tube Feeding

Tube feeding is not essential in all patients who aspirate. Short-term tube feeding, however, may be indicated in elderly patients with severe dysphagia and aspiration in whom improvement of swallowing is likely to occur. Nakajoh et al.[71] demonstrated that the incidence of pneumonia was significantly higher in stroke patients with dysphagia who were fed orally compared to those who received tube feeding (54.3 vs. 13.2%, $p < 0.001$), despite the fact that the orally fed patients had a higher functional status (higher Barthel index). The *FOOD* trials consisted of two large randomized studies that enrolled dysphagic stroke patients.[100] In the first trial, patients enrolled within 7 days of admission were randomly allocated to early tube feeding or no tube feeding. Early tube feeding was associated with an absolute reduction in risk of death of 5.8%. The second trial allocated patients to early nasogastric feeding or early feeding via a percutaneous endoscopic gastrostomy (PEG) tube. PEG feeding was associated with an absolute increase in the risk of death of 1% and an increased risk of death or poor outcome of 7.8%. Patients with a PEG were less likely to be transitioned to oral feeding than the nasogastric group and were more likely to be living in an institution. This may in part explain the higher mortality of the PEG-fed patients. Furthermore, it was interesting to note that PEG-fed patients were more likely to develop pressure sores, suggesting that these patients may have been nursed differently. The results of the FOOD trials suggest that dysphagic stroke patients should be fed early via a nasogastric or feeding tube and transitioned to oral feeding as their dysphagia resolves. Those patients whose dysphagia does not resolve may be candidates for placement of a PEG tube.

Oral Hygiene

Dental plaque as well as "tongue coating" serves as a reservoir of potentially pathogenic organisms.[76] Occupants of residential homes have been shown to have poor oral hygiene and rarely receive treatment from dentists and oral hygienists.[101] An aggressive protocol of oral care will reduce colonization with potentially pathogenic organisms and decrease the bacterial load, measures that have been demonstrated to reduce the risk of aspiration pneumonia.[102–105] Oral care should not be overlooked in edentulous patients as "tongue cleaning" is associated with a decreased oropharyngeal bacterial load.[106,107]

Pharmacologic Management

The neurotransmitter, Substance P, is believed to play a major role in both the cough and swallow sensory pathways. ACE inhibitors prevent the breakdown of Substance P and may theoretically be useful in the management of patients with aspiration pneumonia. A number of studies have demonstrated a lower risk of aspiration pneumonia in stroke patients treated with an ACE inhibitor compared to other antihypertensive agents.[108,109] This observation was initially noted in Japanese patients and it has been suggested that this benefit was restricted to Asian populations.[110] Furthermore, it has been postulated that lipophilic ACE inhibitors may be more beneficial than hydrophilic ACE inhibitors.[111] However, a population-based case-control study from the United Kingdom demonstrated that the current prescription for an ACE inhibitor was associated with a reduction of the risk of pneumonia in the general population (OR 0.75, 95% CI 0.65–0.86).[112] Nicergoline (Sermion, Pfizer), an ergot alkaloid derivative, has been demonstrated to upregulate Substance P and improve dysphagia with an efficacy similar to that of ACE inhibitors.[113] Additional studies are required with this drug to determine its role in preventing aspiration pneumonia.

Sedative medication has been demonstrated to increase the risk of pneumonia in residents of long-term-care facilities and should, therefore, be avoided.[114] The prescription of phenothiazines and haloperidol should be very carefully considered, as they reduce oropharyngeal swallow coordination, causing dysphagia.[115,116] Medications that dry up secretions, including antihistamines and drugs with anticholinergic activity, make it more difficult for patients to swallow and should therefore also be avoided.[115,117]

DIFFUSE ASPIRATION BRONCHIOLITIS

Occult aspiration can result in lung damage with a variety of radiographic, clinical, and histologic manifestations. Occult aspiration in the elderly is usually associated with esophageal dysmotility, gastroesophageal reflux disease (GERD) as well as neurologic impairment (dysphagia) and frequently presents with acute onset of symptoms while sleeping.[118] Diffuse aspiration bronchiolitis is a distinct clinical entity that was first defined by Matsuse et al.[3] in 1996 as a syndrome characterized by chronic bronchiolar inflammation from recurrent aspiration of foreign matter (food). Their case series was based on autopsy findings and represented an elderly, chronically debilitated

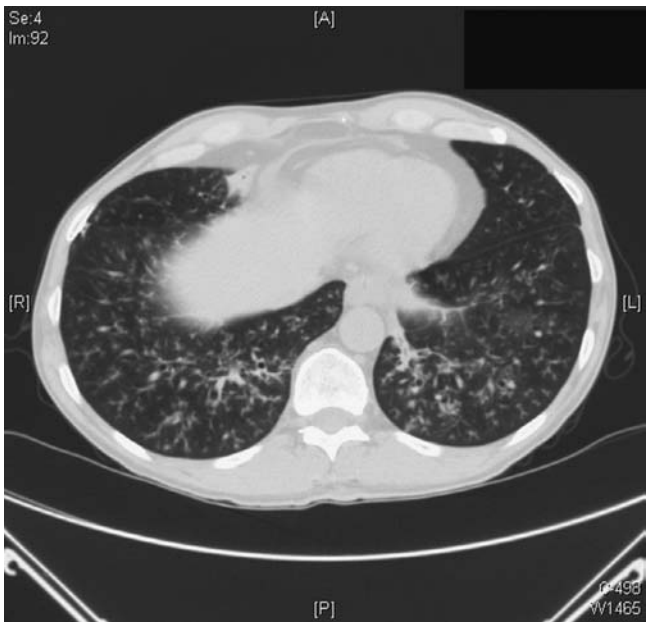

Figure 69-3 CT scan of patient with diffuse aspiration bronchiolitis.

population. Dysphagia was recorded in over half of the patients with two-thirds being bedridden. Diffuse aspiration bronchiolitis should be suspected in elderly patients with recurrent episodes of bronchorrhea, bronchospasm, and dyspnea. However, this syndrome has been reported in middle-aged patients (mean age 50 years) with "asymptomatic" GERD.[119] Typical findings on the chest radiograph include the presence of regional or disseminated small nodular shadows and hyperlucency. Airspace consolidation is relatively rare. Chest CT scans demonstrate diffuse centrilobular nodules with a tree-in-bud pattern (Fig. 69-3).[120] It is likely that this disease is underrecognized and therefore often inappropriately managed.

CONCLUSIONS

Aspiration pneumonitis and pneumonia are common clinical syndromes. Aspiration pneumonitis follows the aspiration of gastric contents, usually in patients with a marked decreased level of consciousness. Treatment of aspiration pneumonitis is essentially supportive, however, corticosteroids and other immunomodulating agents may have a role in these patients. Aspiration pneumonia occurs in patients with dysphagia and usually presents as a "CAP" with a focal infiltrate in a dependent bronchopulmonary segment. Patients with aspiration pneumonia require treatment with broad-spectrum antibiotics and management of the underlying dysphagia. Diffuse aspiration bronchiolitis presents with radiographic evidence of widespread centrilobular and tree-in-bud opacities; clinicians must be aware of the possibility of occult aspiration in order to make the correct diagnosis.

CHAPTER 70

Pulmonary Alveolar Proteinosis Syndrome

Bruce C. Trapnell
Takuji Suzuki

Pulmonary alveolar proteinosis (PAP) syndrome is characterized by the accumulation of surfactant in alveoli and terminal airways resulting in hypoxemic respiratory failure.[1] This fascinating syndrome continues to serve as a paradigm for disease discovery and development due to a globalized collaborative network, employment of diverse clinical, basic, and translational research approaches, and active patient involvement. While PAP occurs in many clinical settings including recently identified genetic etiologies, its molecular basis is now known in more than 90% of cases, and the molecular basis of the role of granulocyte macrophage colony–stimulating factor (GM-CSF) in surfactant homeostasis has been defined. Diseases associated with PAP can be grouped into primary PAP, secondary PAP, and congenital PAP based primarily on pathogenesis involved. Primary PAP is caused by impairment of GM-CSF–dependent surfactant clearance by alveolar macrophages and accounts for approximately 90% of all cases.[2] Secondary PAP occurs as a consequence of a comorbid condition that impair surfactant clearance by alveolar macrophages and accounts for about 5% of cases.[3] Congenital PAP is a clinically distinct and pathogenically heterogeneous group of genetic disorders associated with the production of abnormal surfactant and accounts for about 5% of cases.[4] Because of its increased frequency and greater research attention, primary PAP will be the focus of this chapter and data for secondary and congenital PAP will be provided where available.

PATHOGENESIS

In their initial description of PAP in 1958, Rosen et al.[5] established that the material accumulating within alveoli in PAP was composed of lipids, proteins, and a small amount of carbohydrate. Research over the past two decades has shown that in more than 90% of patients pathogenesis is driven by disruption of GM-CSF signaling, which blocks terminal differentiation of alveolar macrophages thereby

impairing their ability to clear surfactant.[2] GM-CSF is a 23-kDa cytokine produced by respiratory epithelium and other cells[6,7] initially identified by its ability to stimulate the formation of macrophage and granulocyte colonies from hematological progenitors and subsequently shown to stimulate functions in mature myeloid and other cells. GM-CSF is expressed similarly in humans and mice and its effects are mediated by binding to cell surface receptors composed of a GM-CSF–binding α-chain (CD116) and an affinity-enhancing β-chain (CD131). Ligand binding activates intracellular signaling via multiple pathways including signal transducer and activator of transcription 5 (STAT5) regulating diverse functions of myeloid cells including survival, differentiation, proliferation, and priming of specific host defense functions.[8,9] GM-CSF also has poorly understood effects of alveolar epithelium. In primary PAP, pathogenesis is caused by disruption of GM-CSF signaling by neutralizing GM-CSF autoantibodies in autoimmune PAP or by recessive mutations in *CSF2RA* or *CSF2RB* (encoding GM-CSF receptor α-chain [CD116] or β-chain [CD131], respectively) in hereditary PAP.[1,2,10–13]

■ SURFACTANT HOMEOSTASIS

Surfactant is vital to lung function and acts at the air–liquid–tissue interface to prevent alveolar wall collapse. It is composed of 90% lipids (largely phospholipids), 10% proteins (surfactant protein [SP]-A, -B, -C and -D), and less than 1% carbohydrate.[14] SP-B and SP-C are hydrophobic phosphoproteins that contribute significantly to the surface active properties of surfactant.[15] SP-A and SP-D are hydrophilic collectin family members that contribute to lung host defense.[16] Surfactant lipids and proteins are synthesized, stored, and secreted into the alveoli by type II alveolar epithelial cells. In the extracellular space, surfactant "large aggregates" contribute to formation of a film that lowers surface tension and stabilizes the alveolus.[17] Surfactant is expelled from the film as "small aggregates" that are internalized by type II cells and alveolar macrophages in roughly equal amounts (Fig. 70-1). Type II cells recycle and catabolize internalized surfactant equally via mechanisms that are poorly understood but do not appear to involve regulation by GM-CSF.[17–19] In contrast, alveolar macrophages exclusively catabolize internalized surfactant under the positive regulatory control of GM-CSF.[20,21]

■ ANIMAL MODELS OF PAP

The discovery that GM-CSF knockout ($GM\text{-}CSF^{KO}$) mice develop a pulmonary disease indistinguishable from primary PAP provided the first real pathogenic clue (Fig. 70-2).[22,23] In these mice, neither production of surfactant by type II cells, nor its uptake by alveolar macrophages was impaired.[22,24] Rather, surfactant clearance by alveolar macrophages was impaired.[25] Replacement of GM-CSF in the lungs by direct instillation or expression of its cDNA in airway epithelium corrected the lung disease.[26–28] Disruption of the GM-CSF receptor β gene (i.e., $Csf2rb^{KO}$ mice) caused a similar lung phenotype[29] that could be corrected by bone marrow transplantation, which indicated the critical cell type driving pathogenesis was myeloid (i.e., alveolar macrophages) not epithelial (i.e., type II cells) in origin.[30] Surfactant clearance in $GM\text{-}CSF^{KO}$ alveolar macrophages could be corrected by retroviral expression of PU.1, a transcription factor normally expressed in murine alveolar macrophages in vivo under tight regulatory control of pulmonary GM-CSF.[31] These studies established that GM-CSF, via PU.1, was required for surfactant clearance in alveolar macrophages (Fig. 70-3).[20] Recently, passive immunization with human PAP patient–derived neutralizing GM-CSF autoantibodies resulted in recapitulation of the cardinal pathological features

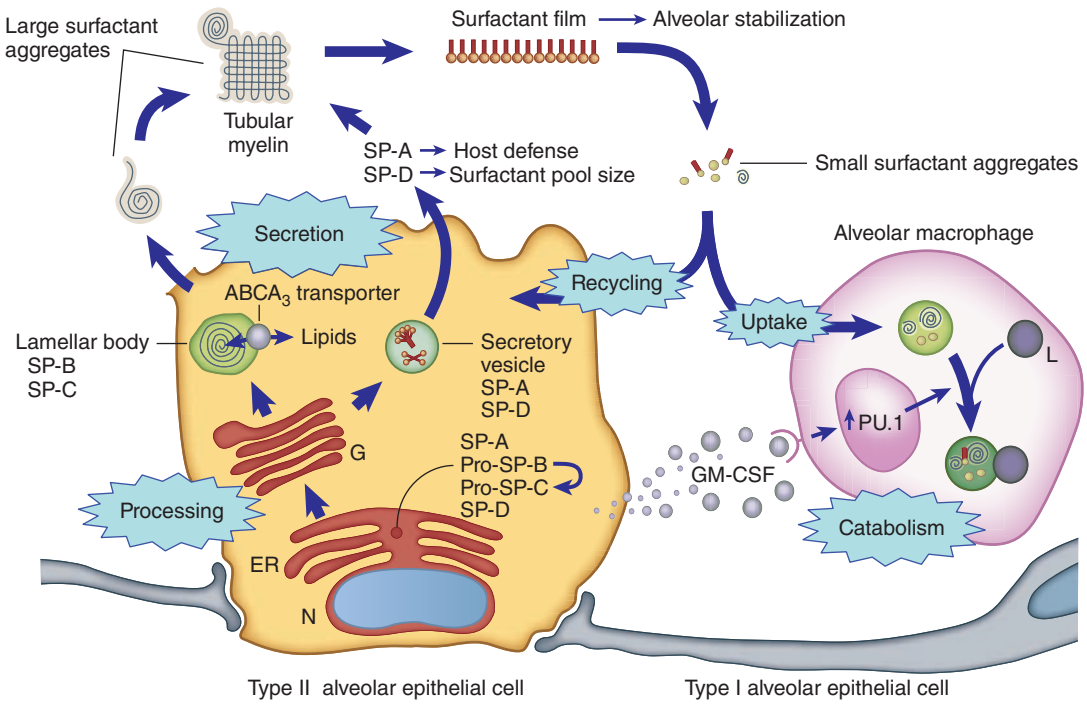

Figure 70-1 Schematic illustration depicting mechanisms of surfactant production, recycling, and catabolism. Surfactant phospholipids and proteins are synthesized in type II alveolar epithelial cells that line pulmonary alveoli. Surfactant B and C precursor proteins are processed, transported to lamellar bodies, and then secreted into the alveolar space where they interact with surfactant protein A to form tubular myelin. Surfactant monolayers and multilayers are formed from tubular myelin and function to reduce surface tension at the air–liquid–tissue interface, thus stabilizing the alveoli. Surfactant remnants are taken up and either catabolized or reutilized by type II alveolar epithelial cells. Alveolar macrophages play a critical role in surfactant homeostasis by taking up and catabolizing surfactant remnants. GM-CSF is required to maintain surfactant homeostasis and acts by stimulating catabolism of surfactant lipids and proteins in alveolar macrophages. *(Reproduced with permission from Whitsett JA, Wert SE, Trapnell BC. Genetic disorders influencing lung formation and function at birth. Hum Mol Genet. 2004;13[Spec No 2]:R207–R215.)*

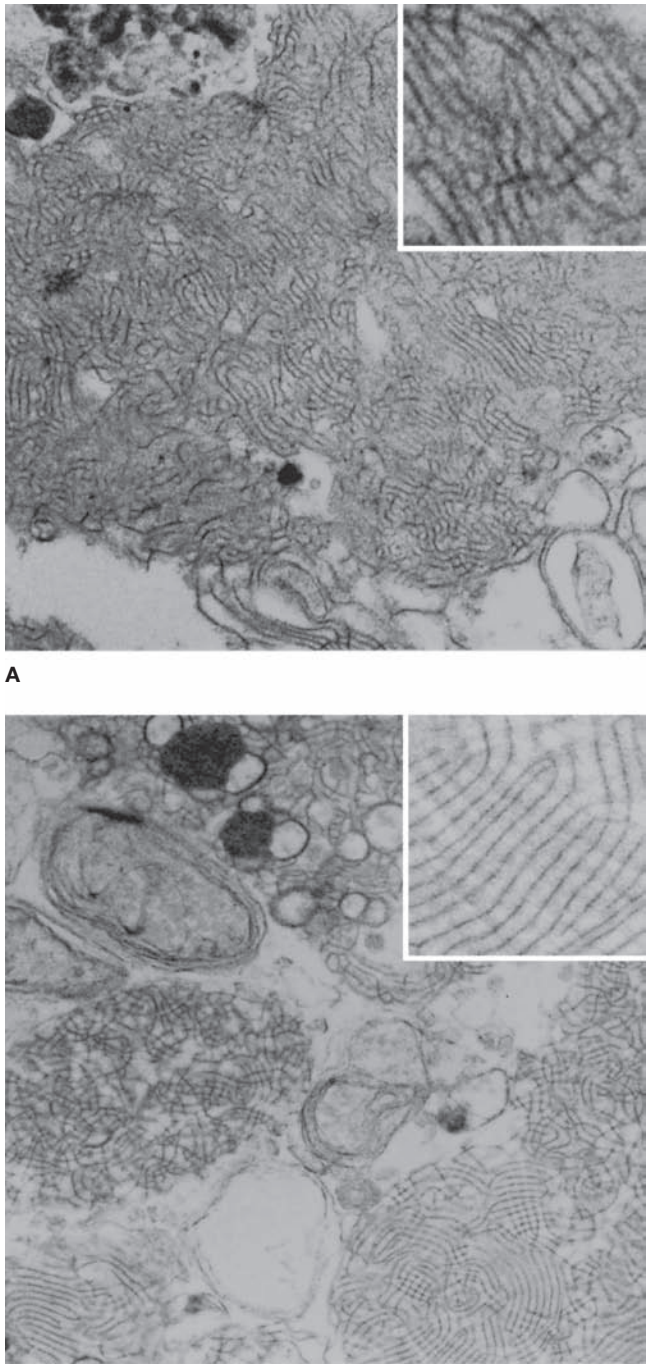

Figure 70-2 Ultrastructural appearance of the sediment from the lungs of a human patient with primary PAP (**A**) and a GM-CSF–deficient mouse (**B**). Note the presence of lamellated, fused membrane structures and amorphous debris (uranyl acetate, ×30,000).

of autoimmune PAP in nonhuman primates.[32,33] The abnormalities induced in alveolar macrophage included impaired GM-CSF signaling, GM-CSF–dependent gene expression (including PU.1), and surfactant clearance and increased neutral lipid accumulation resulting in foamy appearing alveolar macrophages. These animal models provide strong support for disruption of GM-CSF signaling as the critical driver of PAP pathogenesis. As a model of secondary PAP, depletion of alveolar macrophages has been shown to increase lung surfactant pool size in rats.[34] Congenital PAP models have been created in mice by disruption of the genes required for normal surfactant production *(Sftpb*, *Sftpc*, *Abca3)*.[35–37]

■ PRIMARY PAP

Autoimmune and hereditary forms of primary PAP are considered below.

Autoimmune PAP

In 1999, the Nakata group discovered that idiopathic PAP (also reported as acquired PAP) was specifically associated with high levels of neutralizing anti–GM-CSF autoantibodies (Fig. 70-4).[10] Subsequently, these autoantibodies were shown to be (1) polyclonal, primarily comprised of immunoglobulin G subclass 1 (IgG_1) and IgG_2 with smaller amounts of IgG_3 and IgG_4, (2) have a very high affinity for GM-CSF in the 3 to 20 pM range, and (3) capable of neutralizing GM-CSF, and (4) eliminating GM-CSF bioactivity in vivo.[38,39] Notwithstanding, several findings were difficult to reconcile. GM-CSF autoantibodies were also present in healthy individuals, albeit at lower levels,[39] and the antibody levels in PAP patients did not correlate with disease severity.[40] The recapitulation of PAP in healthy nonhuman primates by passive immunization with PAP patient–derived GM-CSF autoantibodies firmly established their critical role in pathogenesis.[32,33] The low autoantibody levels in healthy individuals and lack of correlation with disease severity in PAP patients was explained by a model in which constitutive in vivo stimulation of GM-CSF–dependent myeloid cell functions (including surfactant clearance) declined with increasing GM-CSF autoantibody level until a critical threshold was reached where function became zero.[39,41] The threshold level was identified and similar in humans and nonhuman primates.[33,39] These studies provide strong evidence that GM-CSF autoantibodies were pathogenic and led to a recommendation to change the name from "idiopathic PAP" to "autoimmune PAP."[41]

Hereditary PAP

While humans with GM-CSF deficiency have not been identified to date, in 2008, a GM-CSF autoantibody-negative child was found to have compound heterozygous mutations in *CSF2RA* (encoding GM-CSF receptor α) as the cause of familial PAP.[11] Additional patients were identified by exploiting use of a biomarker, increased serum GM-CSF, to screen sera from a repository including patients with PAP of unknown etiology, which identified a cohort of patients with PAP-causing *CSF2RA* mutations (Fig. 70-4).[42] Subsequently, *CSF2RB* mutations were identified as a cause of hereditary PAP.[12,43] Detailed characterization were done including molecular cloning and expression studies to recapitulate the receptor dysfunction established that the pathogenesis of hereditary PAP is caused by recessive or compound heterozygous mutations in the *CSF2RA* or *CSF2RB* genes.[11,12,42,43] A variety of mutation types were identified as the cause of hereditary PAP including missense mutations, nonsense mutations, small insertions and deletions, exon deletion, and gene deletion.[2] Together, these studies defined the clinical presentation, pathogenesis, diagnosis, and therapy of hereditary PAP.

■ SECONDARY PAP

Results from a national registry recently confirmed that secondary PAP occurs in association with a heterogeneous group of underlying diseases including hematological disorders, primarily myelodysplasia (76%–88% of cases), infectious diseases (2%–3%), other autoimmune diseases (7%), immunosuppression after organ transplantation (7%), and in nonhematological malignancies (5%).[44] Secondary PAP also occurs in association with (and presumably due to) heavy inhalation exposure to inorganic dusts (e.g., silica, titanium, aluminum) and other gasses and fumes, or as a consequence of systemic infections, for example, during human immunodeficiency virus (HIV) infection.[45] Secondary PAP appears to be caused by a reduction in the numbers or clearance capacity of alveolar macrophages, consistent with macrophage depletion studies in rats.[34]

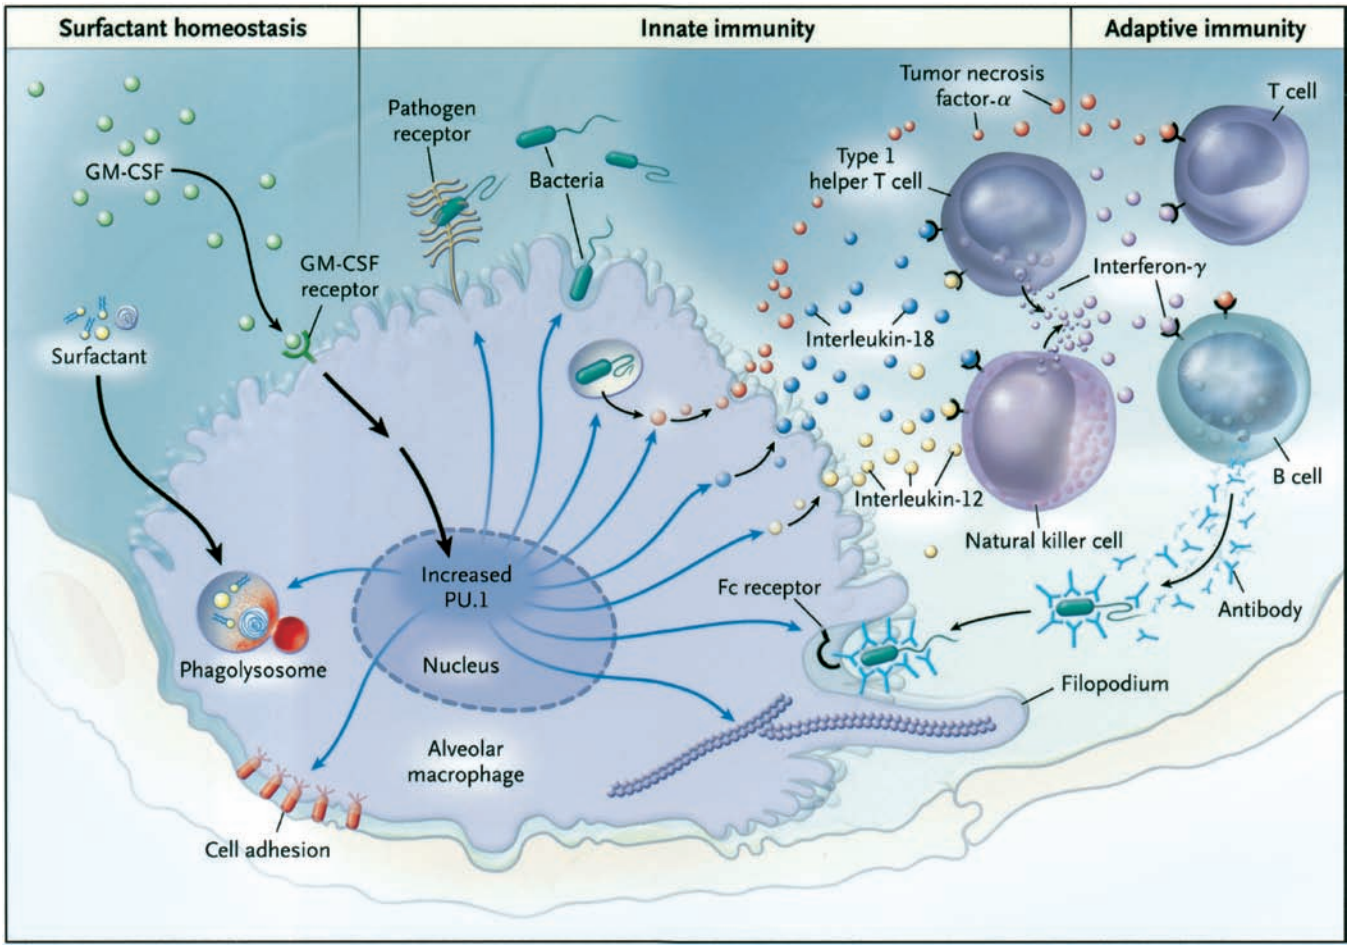

Figure 70-3 Role of GM-CSF in modulating the function of alveolar macrophages in mice. Pulmonary GM-CSF stimulates increased levels of the transcription factor PU.1 in alveolar macrophages in the lungs in vivo. Alveolar macrophages from mice deficient in GM-CSF have a number of functional defects including defects in cellular adhesion, catabolism of surfactant proteins and surfactant lipids, expression of pathogen-associated molecular pattern receptors (e.g., toll-like receptors and the mannose receptor), toll-like–receptor signaling, phagocytosis of pathogens, intracellular killing of bacteria (independent of uptake), pathogen-stimulated secretion of cytokines (tumor necrosis factor-α, interleukin [IL]-12, and IL-18), and Fc-receptor–mediated phagocytosis. Cytoskeletal organization is abnormal and may in part account for defects in phagocytosis. The ability of alveolar macrophages to release IL-12 and IL-18 severely impairs the interferon-γ response to pulmonary infection, thus impairing an important molecular connection between innate and adaptive immunity in the lung. Retroviral-mediated expression of PU.1 in alveolar macrophages from GM-CSF knockout mice corrects all these defects, suggesting that GM-CSF stimulates terminal differentiation of the macrophages primarily through the master transcription factor PU.1. The *blue arrows* represent the functions regulated by PU.1 that are affected by the absence of GM-CSF. *(Reproduced with permission from Trapnell BC, Whitsett JA, Nakata K. Pulmonary alveolar proteinosis. N Engl J Med. 2003;349(26):2527–2539.)*

■ CONGENITAL PAP

PAP occurs in neonates, infants, and children in association with various defects in the genes encoding SP-B, SP-C, ABCA3 – a lipid transporter expressed in type II alveolar epithelial cells, or TTF-1 – a transcription factor essential for lung development and surfactant expression.[4,46–49] In contrast to primary and secondary PAP that are caused by reduced surfactant clearance, these disorders result from production of abnormal surfactant. While surfactant accumulation does occur to varying degrees in surfactant production disorders, these disorders are clinically, histopathologically, and pathogenically distinct from primary and secondary PAP (see below).

■ THE EMERGING ROLE OF GM-CSF IN INNATE IMMUNITY

GM-CSF^{KO} mice have increased susceptibility to a broad range of microbial pathogens, increased mortality from spontaneous infections,[50,51] and numerous host defense defects in macrophages and neutrophils.[31,52] In macrophages, all these diverse defects could be corrected by forced expression of PU.1 (Fig. 70-3).[31] Similar defects are present in alveolar macrophages and neutrophils from humans and nonhuman primates with disruption of GM-CSF signaling.[2] GM-CSF^{KO} mice also have systemic immune and inflammatory abnormalities[51] including reduced severity in arthritis models,[53] an observation that has led to conduct the human trials of GM-CSF signaling disruption as therapy of rheumatoid arthritis.[54,55] These and other studies lead to an emerging understanding of the important roles that GM-CSF plays in the regulation of alveolar macrophage terminal differentiation, the basal functional capacity of circulating neutrophils, and in autoimmune and inflammatory diseases.[56]

EPIDEMIOLOGY

The epidemiology of PAP remains poorly defined. Results from a national registry study estimated the incidence and prevalence of autoimmune PAP in Japan to be approximately 0.49 and 6.2 per million in the general population, respectively.[57] In a subsequent report from the registry,[44] 40 cases of secondary PAP were identified premortem resulting in a prevalence estimate of approximately 0.3 per million. The incidence and prevalence of congenial PAP are unknown. In recent reports from specialized clinical centers, the

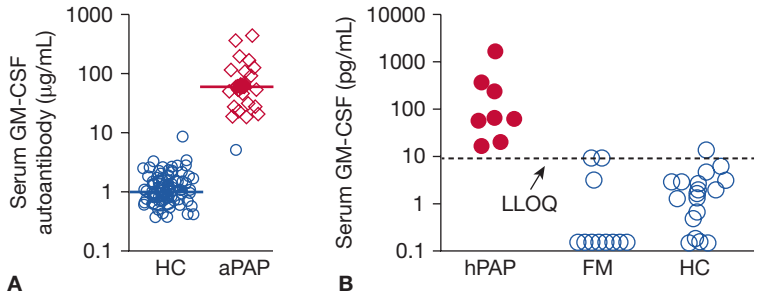

Figure 70-4 Biomarkers of use in identifying individuals with primary PAP. **A.** Serum GM-CSF autoantibody concentration. Shown are data for healthy controls (HCs) and patients with aPAP (autoimmune PAP). *(Reproduced with permission from Uchida K, Nakata K, Suzuki T, et al. GM-CSF autoantibodies and myeloid cell immune functions in healthy individuals. Blood. 2009;113(11):2547–2556.)* **B.** Serum GM-CSF concentration. Shown are data for children with hereditary PAP (hPAP) caused by recessive *CSF2RA* or *CSF2RB* mutations, members of their immediate family who were health (FM), or unrelated HCs. The lower limit of quantification (LLOQ) of the assay was 7.8 pg/mL *(dashed line)*. The serum levels of GM-CSF (median, interquartile range) in children with hPAP (52 pg/mL [28–101 pg/mL]) were increased compared with healthy family members (0.0 pg/mL [0.0–3 pg/mL]) and unrelated health controls (0.0 pg/mL [0.0–1.9 pg/mL]) ($n = 8, 11, 30$, respectively; $P < 0.001$; Kruskal–Wallis analysis of variance on ranks with comparisons using Dunn's method). *(Reproduced with permission from Suzuki T, Sakagami T, Young LR, et al. Hereditary pulmonary alveolar proteinosis: pathogenesis, presentation, diagnosis, and therapy. Am J Crit Care Med. 2010;182(10):1292–1304.)*

age at the time of diagnosis of autoimmune PAP in years (median/mean, number of patients, country) were 52 (248, Japan),[57] 42 (241, China),[58] 43 (70, Germany),[59] 40 (81, Italy),[60] although the diagnosis has been made in children as young as 3 years (unpublished). In these reports, the male/female ratio varied from 1.3 to 2.2 overall but was close to one in nonsmokers. Autoimmune PAP occurs in various ethnic backgrounds including Hispanic, Asian, Black, and white and in wide geographic distribution.

CLINICAL FEATURES

PRESENTATION

Autoimmune PAP typically presents as progressive dyspnea of insidious onset in previously healthy adults between the ages of 20 and 50 years, but has presented in children as young as 3 years old and in the elderly. In several series, dyspnea occurred in 67% to 94% of patients, followed by cough (23%–66%) and fatigue (49%) whereas fever (4%–11%) and sputum production (1%–4%) were less common.[57–60] In the Japanese registry study, one-third of patients were asymptomatic and identified only by mandatory health screening programs.[57] A history of diffuse pneumonia that is poorly responsive or unresponsive to antibiotic therapy is sometimes present and should raise the suspicion of PAP. The physical examination is often normal but commonly includes crackles especially in dependent areas and cyanosis is occasionally present in severe cases. Digital clubbing is typically absent. Hereditary PAP presents in remarkably similar fashion but at a mean age of 4.8 ± 1.6 years.[42] Secondary PAP has been reported to present at a median age of 49 years, most frequently accompanied by exertional dyspnea (40% of cases) followed by fever (38% of cases).[44] In patients with lung disease associated with abnormal surfactant production, dyspnea, crackles, and digital clubbing may be present.

RADIOGRAPHIC APPEARANCE

The chest radiograph in primary PAP usually reveals bilateral symmetrical alveolar opacities located centrally in mid- and lower-lung zones, often with a perihilar predominance resembling the "bat wing" appearance of pulmonary edema but without other signs of left-sided heart failure (Fig. 70-5A,C). The peripheral lung is commonly spared, resulting in lucency along the diaphragmatic, mediastinal, and peripheral borders. High-resolution computed tomography (HRCT) scanning reveals a characteristic geographical pattern of ground-glass opacification with superimposed interlobular septal and intralobular thickening, commonly referred to as "crazy paving" (Fig. 70-5B,D) that is characteristic of PAP but not diagnostic.

LABORATORY FINDINGS

In primary PAP, routine blood counts and chemistries are usually normal in primary PAP with the exception of serum lactate dehydrogenase (LDH), which is increased two- to threefold and correlates well with the degree of functional impairment as determined by physiological testing and arterial blood gas analysis. A number of biomarkers have been identified in autoimmune PAP including increased serum levels of GM-CSF autoantibody, SP-A, SP-B, SP-D, KL-6, CEA, Cyfra-21-1, cytokeratin 19, and others.[1,57,59–61] Many of these biomarkers are also increased in hereditary PAP.[11–13,42,43] Importantly, serum GM-CSF is specifically elevated in hereditary PAP but not in autoimmune PAP, which was important in identifying an initial cohort of patients for study (Fig. 70-4).[42] Biomarkers of secondary and congenital PAP have been less well studied.

LUNG FUNCTION

In primary PAP, spirometry and lung volume testing is usually normal or near normal but may show a restrictive pattern of impairment with modest reduction in the vital capacity and total lung capacity (TLC) and a disproportionate reduction of the carbon monoxide diffusing capacity (D_{LCO}). Arterial blood gas analysis in symptomatic patients reveals hypoxia caused by ventilation–perfusion inequality and intrapulmonary shunting, resulting in a widened alveolar–arterial diffusion gradient ($A\text{-}a_{DO_2}$).

BRONCHOSCOPIC FINDINGS

The bronchoscopic appearance of the airways in primary PAP is normal but white, frothy proteinosis material is occasionally seen.[42,59,60,62] The bronchoalveolar lavage (BAL) fluid is opaque and has a milky or waxy appearance and develops a thick layer of sediment upon standing overnight (Fig. 70-6). The sediment consists of large, acellular, eosinophilic bodies in a diffuse background of granular material that stains with periodic acid-Schiff (Fig. 70-7A). The cellular fraction contains large, foamy macrophages (Fig. 70-7B), smaller monocyte-like macrophages, and lymphocytes with relatively few neutrophils unless infection is also present. SP is increased and electron microscopy reveals the presence of lamellar bodies and tubular myelin that are characteristic of surfactant (Fig. 70-2).

LUNG PATHOLOGY

Macroscopically, the cut surface of the lung in autoimmune PAP reveals a patchwork of 2- to 3-cm grayish-yellow regions of firm consolidation that exudes fatty material. Microscopically, alveoli and terminal airspaces are filled with a fine eosinophilic material (Fig. 70-7C) that stains strongly for SPs (Fig. 70-7D).[1] In primary PAP, the alveolar wall and interstitial architecture are usually well preserved but occasionally, lymphocytosis and fibrosis can be seen. The vasculature appears normal. Electron microscopy reveals characteristic, concentrically laminated surfactant structures within the granular material and in alveolar macrophages. The gross and microscopic appearance of the lung in hereditary PAP

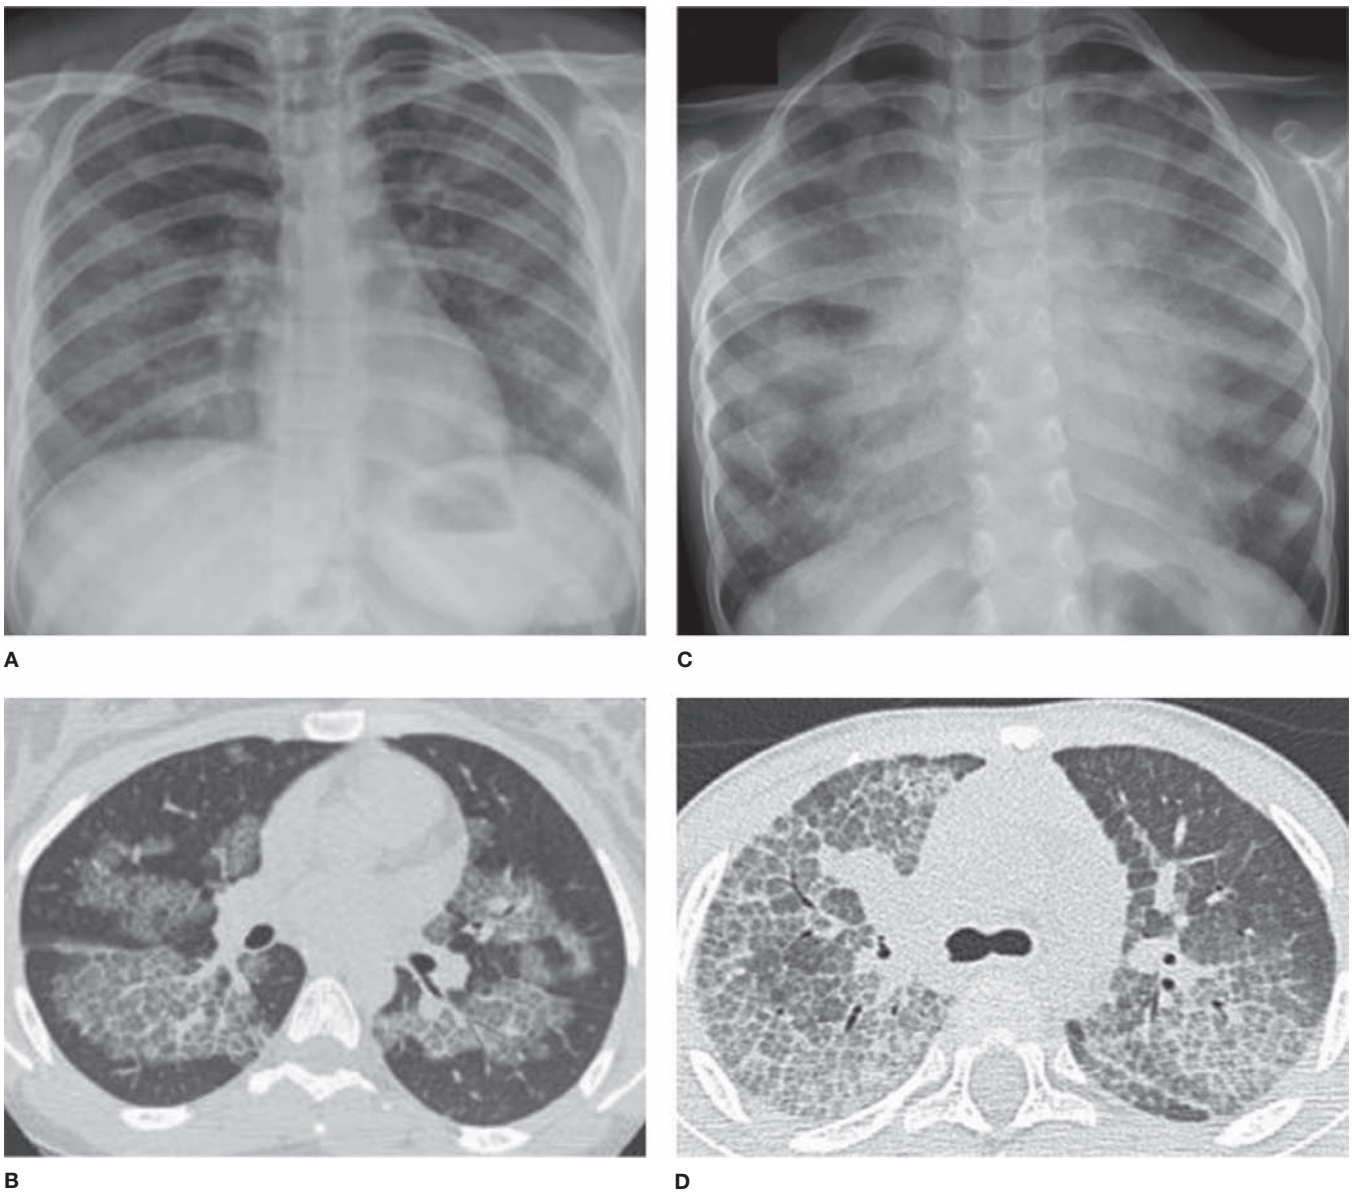

Figure 70-5 Radiographic appearance of primary PAP. **A.** Chest radiograph of a 25-year-old woman autoimmune PAP. **B.** Corresponding chest high-resolution computed tomographic (HRCT) scan. **C.** Chest radiograph of a 6-year-old girl with compound heterozygous *CSF2RA* mutations. **D.** HRCT of a 3-year-old girl with recessive null *CSF2RA* mutations.

is similar.[11–13,42,43] The lung pathology in secondary and congenital PAP varies significantly depending on the disease.

■ SECONDARY INFECTIONS

Individuals with autoimmune PAP have an increased risk of infections, which contribute significantly to increased morbidity and mortality.[1,61] Although pathogens commonly seen in community- and hospital-acquired lung infections are sometimes identified, opportunistic organisms are often responsible and can include Nocardia, Mycobacterium, Aspergillus, Cryptococcus, and others. Infections can occur at both pulmonary and extrapulmonary sites supporting the concept that a systemic defect in host defense is present secondary to defects in the antimicrobial functions of macrophages and neutrophils.[31,51,52,63]

DIAGNOSIS

While PAP syndrome can be suspected based on historical, physical, radiographic lung function findings, further studies are needed to exclude other conditions in the differential diagnosis such as hypersensitivity pneumonitis, pulmonary edema, pneumonia, and interstitial lung diseases. Traditionally, transbronchial or surgical lung biopsy have been considered necessary and are commonly used to identify the syndrome. However, none of these approaches *including lung biopsy* are capable of identifying the specific disease causing PAP. In contrast, the development and testing of several disease-specific and semi-specific biomarkers is particularly useful. The serum-based GM-CSF autoantibody ELISA initially established by Nakata[10] has been refined[38,39,52,62] and recently evaluated in a multinational validation study that demonstrated a sensitivity and specificity for a diagnosis of autoimmune PAP of 100%.[64] Similarly, an increase in serum GM-CSF appears to be both sensitive and specific for a diagnosis of hereditary PAP.[65] In both these diseases, the STAT5-phosphorylation index test can be helpful in establishing disruption of GM-CSF signaling.[66] Secondary PAP can usually be distinguished from primary PAP on the basis of the clinical context and histological or immunohistochemical evaluation of lung biopsy

Figure 70-6 Lavage fluid obtained during the whole lung lavage procedure of a patient with autoimmune PAP has a characteristic turbid appearance and a sediment that forms upon standing. The marked opacity and sediment of the fluid observed at the beginning (left bottle) shows progressive clearing by the end of the procedure (right bottle).

specimens. Further, disease mimics like *Pneumocystis pneumonia* can be distinguished by specific histological staining. That radiographic abnormalities are often increased out of proportion to the severity suspected on clinical grounds is of diagnostic utility but its practical application requires a high degree of clinical suspicion.

NATURAL HISTORY

Prospective, longitudinal studies of the natural history of PAP have not been done. However, experience from several large retrospective and cross-sectional PAP cohorts (number of patients) at tertiary referral centers in Japan (248), China (241), Germany (70), and Italy (81) have recently been reported.[57–60] The "time-to-diagnosis" ranged from 9 to 11 months similar to a prior report by Seymour.[57–61] Most patients had stable disease with mild, persistent symptoms while some had spontaneous remission or progressive disease. Spontaneous remissions occurred in 5% to 7% of 399 patients[57,59,60] confirming a previous estimate of 6% in 410 patients by Seymour.[61] In Seymour's study, the 5-year survival was 85% without therapy and 95% with whole lung lavage therapy.[61] Of the deaths attributable to PAP among 303 patients, 47 were due to respiratory failure from PAP, 12 were from infections, and 1 was from cardiac arrest during whole lung lavage (WLL) therapy (see below).[61] The prognosis of secondary PAP is worse than primary PAP due to linkage with the underlying disease with an estimated 5-year survival of between 20% to 40%.[44] The prognosis of congenital PAP varies, ranging widely from death at birth for SP-B deficiency and some ABCA3 mutations to respiratory insufficiency or failure from interstitial lung disease in adolescence or adulthood for SP-C mutations and some ABCA3 mutations.[4,48]

THERAPY

Therapy of PAP varies by disease. In autoimmune PAP, therapy is required by most but not all patients and is usually initiated when symptoms become limiting. In secondary PAP, treatment is aimed at the underlying clinical condition although WLL can be effective. In congenital PAP, therapy is generally limited to supportive care although SP-B deficiency has been treated successfully by lung transplantation.[67]

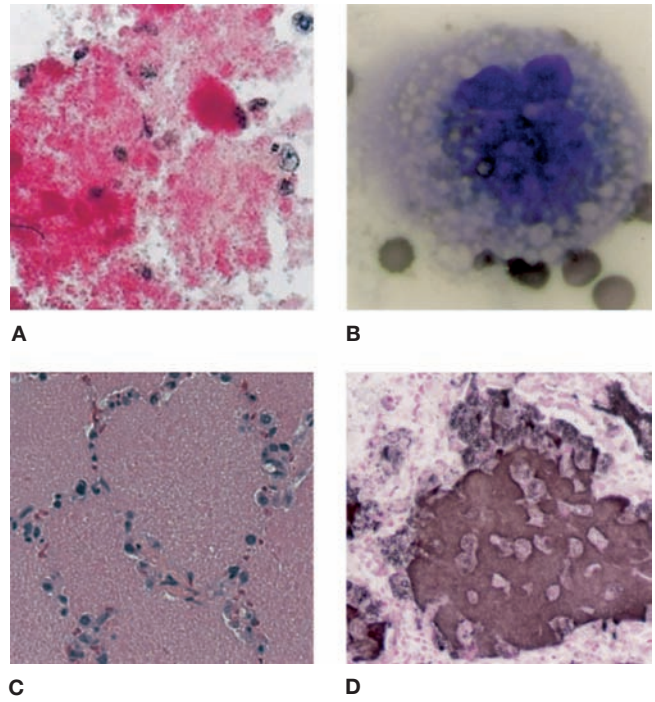

Figure 70-7 Cytological, pathological, and immunohistochemical appearance of the lipoproteinaceous material from patients with autoimmune alveolar proteinosis. **A.** Positive periodic acid-Schiff staining of the sediment from bronchoalveolar lavage (×100). **B.** Cytological appearance of a typical "foamy" alveolar macrophage. **C.** Histopathological appearance of the lung biopsy specimen from a 10-year-old child with primary PAP. Note the homogeneous staining pattern, normal alveolar wall architecture, and the absence of inflammatory cells (H&E, ×200). **D.** Immunohistochemical staining reveals the presence of abundant accumulation of surfactant protein A in a lung biopsy specimen (human anti–surfactant protein A immunostain, ×200).

■ WHOLE LUNG LAVAGE

WLL remains the most widely used therapy of primary PAP[57–61] and is still the recommended standard approach. It can be helpful in secondary PAP but has little to no utility in congenital PAP, likely due to the extensive parenchymal derangement present in these latter patients. In independent cohorts, WLL was used in 54% to 90% of a combined total of 899 patients.[51,57–60] While indications vary among centers, some of the recommendations include a histopathological diagnosis of PAP; Pa_{O_2} <60 mm Hg; A-a_{DO_2} gradient >40 mm Hg; shunt fraction >10% to 12%; or severe dyspnea at rest or with exercise. The WLL procedure itself also varies among centers. It requires general anesthesia, endotracheal intubation, and simultaneous mechanical ventilation of one lung while repeatedly filling and draining the other lung with warm saline with or without chest percussion to emulsify and physically remove the alveolar surfactant. Infusion volumes of up to 50 L per lung have been used in adults but may reach diminishing return above 20 L. Other variations include use of extracorporeal or hyperbaric oxygen. While specific therapeutic response criteria have not been defined, most patients experience clinical, physiological, and radiographic improvement following WLL.[68] Physiological parameters demonstrated to improve with lavage include increases in forced vital capacity (FVC), TLC, D_{LCO}, Pa_{O_2} at rest and with exercise, and a decrease in A-a_{DO_2} and shunt fraction. WLL improves the 5-year survival from 85±5% to 94±2%.[61] Two studies have reported a duration of response to WLL of 15 months.[60,61] Sequential lobar lavage has been used although its clinical utility is unclear.

EXPERIMENTAL APPROACHES

Our improved understanding of PAP as a disease driven by reduced GM-CSF–dependent surfactant clearance in alveolar macrophages has stimulated the development of specific pharmacological therapy. One such strategy is based on augmentation with recombinant human GM-CSF and several clinical studies have demonstrated therapeutic efficacy with this approach.[62,69–75] Both subcutaneous and inhaled administration have been used but the latter appears more efficacious. In 39 patients with unremitting/progressive autoimmune PAP, 62% of the patients receiving inhaled GM-CSF therapy had improvement in the A-a_{DO_2} gradient.[69] Radiographic improvement was also seen,[69] which in a separate study, was documented by quantitative densitometry of the chest HRCT.[75] Notwithstanding, GM-CSF therapy of autoimmune PAP is still in development and many questions remain unanswered including the optimal dosage, frequency of administration, duration of therapy. While no drug-emergent toxicities have been identified, formal safety studies of inhaled GM-CSF therapy have not been done but have been requested by the FDA and are currently underway with support from the National Institutes of Health Therapeutics for Rare and Neglected Diseases (TRND) program. Another approach aimed at GM-CSF autoantibodies is anti–B lymphocyte immunotherapy, which is used to deplete anti–GM-CSF autoantibody-producing cells.[76–78] While results are encouraging, the number of patients is small and results should be interpreted cautiously.

CHAPTER 71

The Eosinophilic Pneumonias

Carolyn L. Rochester

INTRODUCTION

The association between pulmonary infiltrates and eosinophilia was first identified by Loeffler in 1932. It is now recognized that the eosinophilic pneumonias are a heterogeneous group of disorders characterized by varying degrees of pulmonary parenchymal and/or blood eosinophilia.[1] The precise role that eosinophils play in the pathogenesis of the different eosinophilic pneumonias is not clear. Normally, less than 2% of the leukocyte cell differential in bronchoalveolar lavage (BAL) are eosinophils. The presence of increased BAL and/or tissue eosinophils, and our knowledge of the biology of eosinophils (see Chapter 22) does, however, suggest that they play a variety of roles, including initiation, perpetuation, and amplification of tissue inflammation and injury. These effector functions are no doubt the result of the ability of the eosinophils to release numerous soluble mediators, including granule-derived proteins, arachidonic acid metabolites, proinflammatory cytokines, superoxide anions, metalloproteases, and hydroxyl radicals. The different roles of eosinophils in these disorders can be appreciated when comparisons are made of parasitic infections and disorders such as asthma or allergic bronchopulmonary aspergillosis (ABPA). In the former, eosinophils play a crucial role in eradicating the infectious pathogen; in the latter, the eosinophils accumulate in the lung as a result of immune hypersensitivity and are prominent mediators of tissue injury.

The spectrum of diseases that can be primarily or secondarily associated with blood or pulmonary eosinophilia is shown in Table 71-1. It is beyond the scope of this chapter to discuss each of these disease entities in detail. Instead, discussion will focus on diseases of known or unknown causes in which eosinophilic infiltration of lung tissue is a characteristic feature, including acute eosinophilic pneumonias, tropical pulmonary eosinophilia (TPE), chronic eosinophilic pneumonia (CEP), ABPA, Churg–Strauss syndrome (now termed as eosinophilic granulomatosis with polyangiitis [EGPA]), and idiopathic hypereosinophilic syndrome (HES). Since eosinophilic granuloma of the lung is frequently seen in the absence of blood or tissue eosinophilia, it is considered separately (Chapter 74).

EOSINOPHILIC PNEUMONIAS WITH ACUTE PRESENTATIONS

Acute presentations of eosinophilic pneumonia center on several primary considerations, including Loeffler Syndrome, parasitic infections, drug- and toxin-related disorders, and idiopathic varieties. Each is discussed in the following sections.

LOEFFLER SYNDROME (SIMPLE PULMONARY EOSINOPHILIA)

In 1932, Loeffler first described a clinical syndrome characterized by mild respiratory symptoms, peripheral blood eosinophilia, and transient, migratory pulmonary infiltrates. The term *Loeffler syndrome,* or *simple pulmonary eosinophilia,* has been used to define the numerous similar cases reported subsequently. Immune hypersensitivity to *Ascaris lumbricoides* has been recognized as the likely cause of most of the earliest reported cases, although several other parasitic infections, including hookworms (*Ancylostoma duodenale, Necator Americanus, Necator Brasilensis*), *Strongyloides, Trichinella Spiralis, and Toxocara Canis*[2–4] and exposures to numerous drugs and other agents have also been recognized to induce a Loeffler-like syndrome (see below and Tables 71-2 and 71-3). An identifiable etiologic agent may be lacking in up to one-third of patients.

TABLE 71-1 Diseases Associated with Pulmonary Infiltrates and Eosinophilia

Pulmonary Eosinophilic Syndromes of Known Cause
Parasitic-induced eosinophilic pneumonias (including Loeffler syndrome)
Drug- or toxin-induced eosinophilic pneumonias
Tropical pulmonary eosinophilia
Allergic bronchopulmonary mycosis
Pulmonary Eosinophilic Syndromes of Unknown Cause
Idiopathic acute eosinophilic pneumonia
Chronic eosinophilic pneumonia
EGPA (allergic granulomatosis and angiitis)
Idiopathic hypereosinophilic syndrome
Other Lung Diseases Variably Associated with Eosinophilia
Asthma/allergy
Bronchocentric granulomatosis
Bronchiolitis obliterans–organizing pneumonia
Infections
Fungal (esp. coccidioidomycosis, *Aspergillus, Pneumocystis jirovecii*)
Tuberculosis
Viral
Interstitial lung disease
Idiopathic pulmonary fibrosis
Collagen vascular disease associated
Sarcoidosis
Hypersensitivity pneumonitis
Eosinophilic granuloma (pulmonary histiocytosis X)
Malignancy
Non–small-cell cancer of lung
Non-Hodgkin lymphoma
Myeloblastic leukemia
Metastatic disease
Miscellaneous (e.g., lung transplantation, lung allograft rejection, ulcerative colitis)

Loeffler syndrome affects people of all ages. It is characterized clinically by the presence of low-grade fever, nonproductive cough, dyspnea (mild to severe), chest discomfort with coughing or deep breathing, and, occasionally, hemoptysis.[3,5] The respiratory manifestations of Loeffler syndrome are usually self-limited, typically resolving in 1 to 2 weeks. Laboratory examination of peripheral

TABLE 71-2 Parasitic Infections Associated with Eosinophilic Pneumonia

Ancylostoma spp.	*Opisthorchis* spp.
Ascaris spp.	*Paragonimus westermani*
Brugia malayi	*Schistosoma* spp.
Clonorchis sinensis	*Strongyloides stercoralis*
Dirofilaria immitis	*Toxocara gondii*
Echinococcus spp.	*Trichinella spiralis*
Entamoeba histolytica	*Trichosporon terrestre*
Necator americanus	*Wuchereria bancrofti*

TABLE 71-3 Drugs and Other Exposures Causing Eosinophilic Pneumonia

Acetaminophen	Levofloxacin
Acetylsalicylic acid[a]	L-Tryptophan[a]
Aluminum	Maloprim
Amiodarone[a]	Mecamylamine
Amitriptyline[a]	Mephenesin carbamate
Ampicillin	Mesalazine
Angiotensin-converting enzyme inhibitors[a]	Methotrexate[a]
Azathioprine	Methylphenidate
Beclomethasone dipropionate	Minocycline[a]
Beryllium	Montelukast
β-Blockers	Naproxen
Bleomycin[a]	Nickel dust (inhalation)
Captopril[a]	Nilutamide[a]
Carbamazepine[a]	Nitrofurantoin[a]
Chloroquine	Nomifensine
Chlorpromazine	Oxaliplatin
Chlorpropamide	Para-aminosalicylic acid
Clarithromycin	Penicillamine[a]
Clofibrate	Penicillin
Cocaine (inhalation)	Pentamidine (inhaled)
Contrast agents	Phenytoin[a]
Cromolyn (inhalation)	Piroxicam
Dantrolene	Procarbazine
Dapsone	Progesterone
Daptomycin[a]	Prontosil
Desipramine	Propylthiouracil[a]
Diclofenac	Pyramethamine
D-penicillamine	Radiation exposure
Dust (inhalation), e.g., World Trade Center	Ranitidine
Ethambutol	Rapeseed oil
Fenbarbamate	Red spider antigens
Fenbufen	Salicylazosulfapyridine
Fludarabine	Scorpion stings
Glafenine	Sertraline
Gold salts[a]	Smoke exposure
Granulocyte macrophage colony–stimulating factor	Streptomycin
Heroin (inhalation)	Sulfa-containing antibiotics[a]
Hydrochlorothiazide	Sulfasalazine[a]
Ibuprofen	Sulindac
Imipramine	Tamoxifen
Indomethacin	Tetracycline
Infliximab	Thiazides
Interferon-alpha	Tolazamide
Interleukins	Tolfenamic acid
Iodinated contrast agents[a]	Trazodone
Isoniazid	Trichloroethane
	Venlafaxine

[a]*Drugs commonly or occasionally reported to cause pulmonary eosinophilia.*

blood from patients reveals moderate-to-extreme eosinophilia, which may be at peak levels as respiratory symptoms resolve and which resolves over several weeks.[4] Expectorated sputum, if present, frequently contains eosinophils and/or Charcot–Leyden crystals.[4,5] Transient, migratory, nonsegmental, bilateral, interstitial, and alveolar infiltrates (often peripheral or pleural based) are evident on the chest radiograph.[3] Infiltrates typically clear after several weeks. Pulmonary function evaluation typically reveals a mild-to-moderate restrictive ventilatory defect with a reduced diffusing capacity for carbon monoxide (D_{LCO}).

When Loeffler syndrome is due to *A. Lumbricoides*, hookworms or other parasites, the pulmonary manifestations are believed to result from a hypersensitivity reaction to the parasite larvae. Following ingestion of *Ascaris* ova, larvae hatch within the small intestine, then cross the intestinal wall to enter the splanchnic, and ultimately the pulmonary circulation. Subsequently, the larvae migrate across pulmonary capillaries into alveoli, mature into adult worms, ascend the large airways, and are swallowed into the gastrointestinal (GI) tract, where they complete their life cycle. The pulmonary manifestations of Loeffler syndrome begin approximately 9 to 14 days following ingestion and occur during the migration of larvae through the lung. *Ascaris suum,* a large roundworm endemic to pigs, can cause a nearly identical syndrome. Cutaneous penetration of larvae is the principal relevant mode of tissue entry for hookworms.

During the pneumonic stage of the illness, *Ascaris* or hookworm larvae may be identified in sputum or gastric aspirates.[4] In keeping with the life cycle of *Ascaris* or hookworms, stool examination for ova and parasites is typically negative until 8 weeks after the onset of the respiratory syndrome.[6] Histologic evaluation of lung tissue is not required for confirmation of the diagnosis. When tissue has been obtained, a characteristic and striking eosinophilic infiltration of interstitium and alveolar–capillary units has been noted. Increased numbers of macrophages have also been appreciated. Tissue necrosis and vasculitis are not features of the disorder. *Ascaris* or hookworm larvae may be identified in the tissue specimen.[4]

Since Loeffler syndrome may be induced by a variety of exposures, a search for an etiologic agent (e.g., parasitic infection or drug reaction) should be undertaken. Bronchodilators and rarely corticosteroids may be used for alleviation of pulmonary symptoms, although these are usually self-limited. In cases due to *Ascaris*, treatment with oral mebendazole (100 mg twice a day for 3 days or a single dose of 500 mg) should be given to prevent late GI manifestations of *Ascaris* infestation, which may include malnutrition, diarrhea, abdominal pain, and/or intestinal obstruction typically 8 weeks or more after onset of respiratory symptoms. Pyrantel pamoate, albendazole, or ivermectin are alternate treatment options.[4] Since stool specimens are negative for ova and parasites early in the illness, clinical follow-up over a 2- to 3-month period is indicated.

■ PARASITIC INFECTIONS

Infections with parasites other than *Ascaris* species are also commonly associated with pulmonary infiltrates and blood or pulmonary eosinophilia.[3–5] The parasites associated with the development of pulmonary eosinophilic syndromes are listed in Table 71-2. The prevalence of infection with each of these organisms varies with geographical location, socioeconomic status, and host immunity. Parasites may infect the lung via direct pulmonary invasion or via hematogenous seeding. In addition to *Ascaris* species, *Strongyloides stercoralis* (an intestinal nematode), *Ancylostoma brasiliensis* (cutaneous helminthiasis, "creeping eruption"), *Ancylostoma duodenale,* and *T. canis* (dog roundworm, "visceral larva migrans") are the parasitic agents most commonly associated with pulmonary eosinophilia in the United States.

Strongyloides is widely distributed in the tropical and subtropical regions.[3] Following initial transcutaneous infection, a Loeffler-like syndrome may occur as larvae migrate through the lungs. Chronic strongyloidiasis occurs as a result of autoinfection, whereby the noninfectious rhabditiform larvae transform within the GI tract into infectious filariform larvae, penetrate the colonic wall or perianal skin, and reinfect the host.[4,5] Chronic strongyloidiasis may be associated with recurrent asthma-like symptoms that may worsen with the administration of corticosteroids. The hyperinfection syndrome results from accelerated autoinfection, and usually occurs in persons with defects in cell-mediated immunity[3] (such as lymphoma, human immunodeficiency virus [HIV] or human-T lymphotropic virus type 1 [HTLV-1] infection, and with chronic corticosteroid use), as well as in persons with underlying GI disease, chronic lung disease, malnutrition, and use of H2 blockers or antacids.[7] It may also occur in healthy persons. Respiratory manifestations include cough, dyspnea, chronic bronchitis, wheezing, hemoptysis, and patchy pulmonary infiltrates, in association with blood eosinophilia. Rarely, acute respiratory distress syndrome (ARDS) has been reported in patients with hyperinfection. GI manifestations are also common, including abdominal pain, paralytic ileus, nausea and vomiting, bowel perforation, and secondary sepsis from gram-negative bacteria. Central nervous system (CNS) manifestations such as meningitis have also been noted.

The diagnosis of *Strongyloides* infection may be established by identification of larvae in sputum, BAL fluid, bronchial brushings, or transbronchial biopsy specimens, pleural fluid or stool. Several stool samples are often required to identify the pathogen.[5] Serologic testing, such as ELISA to detect IgG antibody to *Strongyloides stercoralis* can also be used to establish a diagnosis.[4] Patients at risk for *Strongyloides* hyperinfection syndrome should be screened for the parasite prior to initiation of immunosuppressive therapy.[3]

Thiabendazole (25 mg/kg twice a day for 2 days) or ivermectin (200 μg/kg given orally for 1–2 days) may be used for the treatment of uncomplicated or disseminated strongyloidias.[4] Ivermectin is generally better tolerated in terms of side effects.[5] Albendazole is an alternative agent. Higher dose and longer duration of thiabendizole treatment are needed to treat disseminated strongyloidiasis in immunocompromised persons.[5] The hyperinfection syndrome associated with *Strongyloides* can be difficult to cure. Therapy should be continued until the clinical syndrome resolves and larvae are no longer detectable in the GI tract.

Ancylostomiasis is a nematodal infection endemic to the southeastern coastal regions of the United States, Mexico, and Central and South America.[4,5] The organism is present in soil contaminated by stool from infected domestic animals. It penetrates human skin most commonly through the feet. This results in the development of the "creeping eruption" lesion – a raised, erythematous, serpiginous, tunnel-like, and often itchy lesion on areas of exposed skin.[8] A Loeffler-like syndrome occurs in up to 50% of cases of "creeping eruption." Specific treatment for pulmonary involvement is typically not required as illness is usually self-limited.

Infection with *T. canis* may occur throughout the world and leads to the clinical syndrome of "visceral larva migrans."[4] This syndrome is characterized by hepatomegaly, leukocytosis, fever, hypergammaglobulinemia, and persistent blood eosinophilia.[9] Because the disease most commonly affects young children, a high degree of clinical suspicion is necessary to establish the diagnosis in adults. Respiratory symptoms, including cough and severe wheezing, may occur after ingestion of substantial numbers of larvae. Laboratory evaluation reveals peripheral blood and BAL eosinophilia, elevated serum levels of immunoglobulin E (IgE), and poorly defined, diffuse nodular alveolar infiltrates on chest radiograph.[4] ELISA testing for larval antigens is diagnostic. Although the disease may be self-limited, treatment with thiabendazole, albendazole, mebendazole,

diethylcarbamazine, or corticosteroids may hasten recovery in patients who are severely ill.[3–5]

DRUG AND TOXIN-INDUCED PULMONARY EOSINOPHILIC SYNDROMES

A vast number of drugs and toxic exposures have been associated with the development of pulmonary infiltrates and blood or pulmonary eosinophilia.[1,10–13] A partial list of these medications and exposures is given in Table 71-3, and information regarding pulmonary drug toxicities may also be found on the Internet on the regularly updated web site, www.pneumotox.com. Of the medications implicated, many are commonly used antibiotics, nonsteroidal anti-inflammatory agents, anticonvulsants, cardiovascular medications, and antidepressants.

In addition to medications, a number of toxic exposures may also be associated with eosinophilic pneumonia.[10] For example, eosinophilic pneumonia has been described following radiation therapy for breast cancer, dust or smoke exposure,[14–17] exposure to iodinated contrast agents or 1,1,1-trichloroethane (Scotchguard),[18] and after inhalation of cocaine or heroin.[19–21]

Whereas most cases of drug- or toxin-induced pulmonary eosinophilia are sporadic, outbreaks of pulmonary eosinophilia have occurred following ingestion of rapeseed oil (contaminated with aniline derivatives)[22] or L-tryptophan.[23] The precise incidence of drug- or toxin-induced pulmonary eosinophilia is difficult to assess, since most of the literature pertaining to these syndromes is published in the form of case reports, rather than large series or controlled trials. For the same reason, the precise pathogenesis and the definition of the clinical syndromes associated with individual exposures are difficult to characterize.

In general, drug-induced pulmonary eosinophilic syndromes have an acute or subacute onset and are not always related to either the cumulative dose of drug used or the duration of treatment. Respiratory symptoms vary widely in severity, from a mild Loeffler-like illness with dyspnea, cough, and fever to severe fulminant respiratory failure. The DRESS syndrome consists of acute eosinophilic pneumonia with drug rash and systemic manifestations.[24] Wheezing may be present, but obstructive physiology is not common on pulmonary function testing. Although radiographic findings are not specific, interstitial or alveolar infiltrates are typically evident on chest radiograph (Fig. 71-1), and common high-resolution chest computed tomographic (CT) findings include bilateral consolidation and ground-glass opacities, both of which are frequently peripherally located.

A diagnosis of drug- or toxin-induced eosinophilic pneumonia is based upon a careful review of drug and other exposures (including nonprescription drugs, herbal preparations, street drugs, and environmental exposures). Other causes of eosinophilic lung disease must be excluded. A concurrent skin rash and pleural effusion can support the diagnosis of drug-induced eosinophilic pneumonia. In some cases, testing with lymphocyte proliferation assays may reveal T-cell sensitization to specific drugs. However, the utility of such assays is limited as negative tests do not rule out a drug-induced disorder, and these assays are not widely available for routine clinical use. The prognosis is favorable in most cases. Elimination of exposure to the drug or other toxin usually leads to resolution of symptoms, eosinophilia, pulmonary infiltrates, and normalization of lung function within a month. Supplemental therapy with corticosteroids is not universally required, but it may hasten recovery in patients who are severely ill.

IDIOPATHIC ACUTE EOSINOPHILIC PNEUMONIA

In contrast to the typically benign Loeffler syndrome, a more severe idiopathic form of eosinophilic pneumonia termed *acute eosinophilic pneumonia* (AEP) has been recognized as a distinct clinical entity.[25–28] Although seen in patients of both genders and any age group, AEP tends to occur in patients between the age of 20 and 40[26,29,30] and is more common in men.[25] AEP is usually idiopathic, occurs commonly in previously healthy persons, and may represent an acute hypersensitivity reaction to an inhaled agent.[28] Similar cases have been reported in persons with a history of chronic myelogenous leukemia, hematopoietic stem cell transplantation[31,32] or HIV infection.[33] Many cases have been reported in patients who have recently commenced smoking,[27,34–36] used flavored tobacco products,[37] or had other changes in smoking habits. The disease may recur when former smokers resume smoking.[35,38] Overall up to 70% of patients with AEP have a history of smoking.[26,39] In addition, cases have been reported in persons treated with venlafexine,[40] minocycline,[26] daptomycin,[11,41] and several other drugs.[26] It has also been reported among persons who have been involved in activities with unusual exposures (including exposure to dust from the World Trade Center collapse in New York City,[14] after military deployment in Iraq,[17] cave exploration, gasoline tank cleaning, plant repotting, woodpile moving, and indoor renovations).[26,42] AEP has also been seen following inhalation of cocaine or heroin[21,43] and in association with H1N1 influenza infection.[1,44] Although none of the patients in the original reported series had atopy or asthma, cases have since been described in persons with a history of atopy. No definite seasonal variation has been identified.

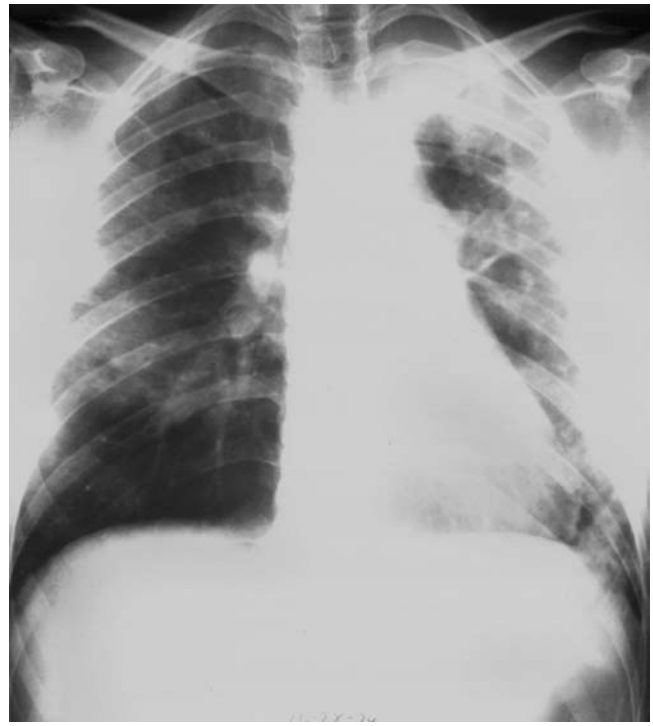

Figure 71-1 Chest radiograph of a 23-year-old woman with acute sulfasalazine-induced eosinophilic pneumonia. Bilateral interstitial and alveolar infiltrates are present.

Idiopathic AEP presents as an acute illness with dyspnea, fever, nonproductive cough, tachypnea, pleuritic chest pain, and hypoxemia (arterial Pa_{O_2} under 60 mm Hg) at times with myalgias.[25,26,39] Symptom duration is typically less than 7 days,[1] although longer courses of up to 30 days have been described. Patients usually have diffuse inspiratory crackles on chest auscultation, wheezing may be present, and rapid progression from mild dyspnea to overt respiratory failure requiring mechanical ventilation is common.[17,26,27] A moderate leukocytosis with left shift is typical,[27] but blood eosinophilia is usually absent at the onset of disease.[17,25,26] Early clinical features may be mistaken for community-acquired pneumonia. Blood eosinophilia may develop later in the course of the disease and may

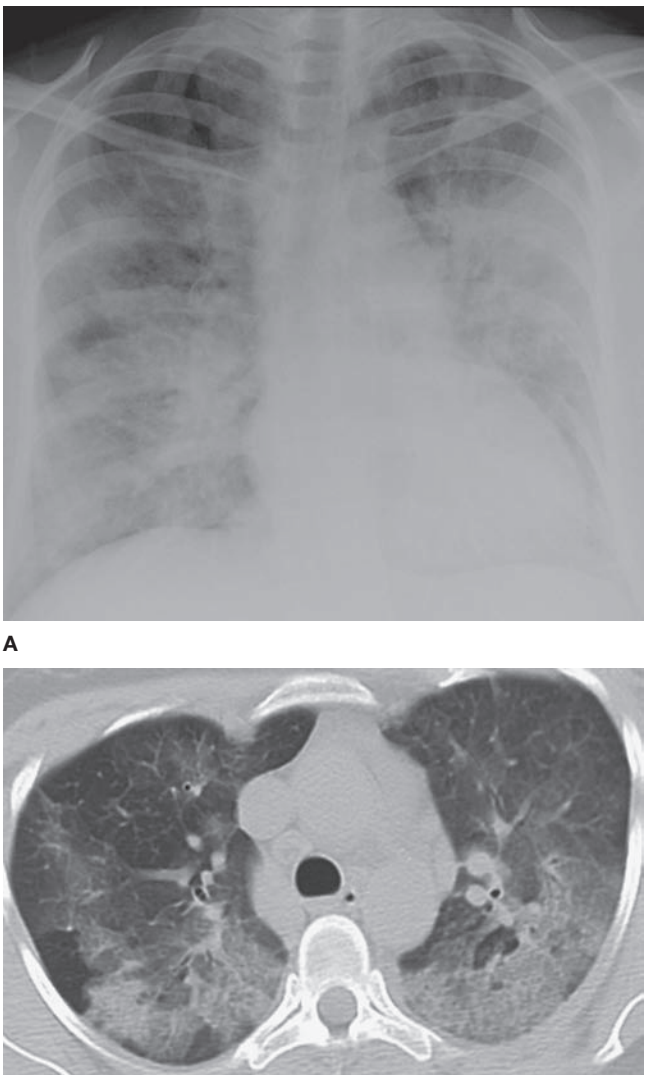

Figure 71-2 Radiographic apœpearance of idiopathic acute eosinophilic pneumonia (AEP). **A.** Diffuse bilateral alveolar and interstitial infiltrates apparent on chest radiograph. **B.** Diffuse parenchymal ground-glass opacity and consolidation evident on computed tomography scan.

provide a clue to the diagnosis.[27,45] Serum IgE levels may be moderately elevated.[26,46] The erythrocyte sedimentation rate (ESR) may be elevated as well. Serum levels of thymus and activation-regulated chemokine (TARC)/CCL17 (a ligand for CCR4 on Th2 lymphocytes) may be elevated and may help to distinguish AEP from other cause of acute lung injury(ALI).[47] Striking eosinophilia (25%–55%) is present in BAL fluid.[17,26,27,45,48] Increased numbers of lymphocytes (up to 20%) and neutrophils (up to 15%) are commonly also present in BAL fluid in AEP.[48] Pulmonary function tests reveal a restrictive ventilatory defect with a reduced D_{LCO} that typically normalize following treatment.[48]

Early in the course of illness, the chest radiograph reveals subtle, patchy infiltrates with Kerley B lines.[26,49] Diffuse, symmetric alveolar and interstitial infiltrates resembling ARDS with a ground-glass or micronodular or reticular appearance (Fig. 71-2A) develop within 48 hours.[50,51] Infiltrates are typically bilateral, although AEP with unilateral infiltrates has been described. Small-to-moderate bilateral pleural effusions are common (affecting up to 50%–70% of patients).[27] Fluid analysis typically reveals a high pH and marked eosinophilia.[51] CT scanning confirms the presence of diffuse parenchymal ground-glass attenuation, inerlobular septal thickening and/or consolidation (Fig. 71-2B), with prominence along bronchovascular bundles, with or without pleural effusion.[49,52] Lymphadenopathy may also be seen.

Light microscopic examination of lung tissue reveals prominent eosinophil infiltration in interstitium and/or alveolar spaces, and bronchial walls.[53] The pathologic pattern of diffuse alveolar damage with hyaline membranes and eosinophilic infiltrates should suggest the possibility of AEP. Lymphocytic infiltration of interstitium, type 2 pneumocyte hyperplasia, and intra-alveolar fibrinous exudate are also common. Granulomas, alveolar hemmorhage, and nonnecrotic perivascular inflammation have been reported.[53] Basal lamina damage is unusual.[49] Extrapulmonary involvement is rare.

The pathogenesis of idiopathic AEP is poorly understood.[26,39] The occurrence of cases following unusual environmental exposures (as noted earlier) suggests these exposures as possible disease-inciting events, perhaps as triggers for a hypersensitivity reaction to an unidentified antigen in susceptible persons. Of note, elevated levels of the fungal cell wall component β-D-glucan have been described in the BAL fluid of some patients with AEP, suggesting a possible association between exposure to fungus and development of disease.

However, the roles of lymphocytes and eosinophils in this disorder have not been fully elucidated. Elevated levels of interleukin (IL)-5, a Th2 lymphocyte–derived cytokine involved in activation and recruitment of eosinophils, have been described in the BAL of patients with AEP.[54] Levels of vascular endothelial growth factor (VEGF), a cytokine induced by IL-5, have also been shown to be elevated in BAL and to correlate with number of eosinophils and levels of IL-5.[55] Elevated BAL levels of IL-18, a cytokine capable of inducing several cytokines known to induce or enhance eosinophilia, have also been identified among patients with acute (and other) forms of eosinophilic pneumonia.[26] Collectively, these findings suggest a role for Th2 lymphocytes and eosinophils in disease pathogenesis. It remains unknown, however, whether the eosinophils initiate the disease process or are a secondary manifestation of the disorder. Alveolar macrophage–derived cytokines may also play a role in the development of AEP.[56]

Idiopathic AEP is a diagnosis of exclusion[51] and should be considered in a patient who presents with an acute febrile illness less than 1 week in duration, apparent ALI or ARDS without a typical antecedent illness. A careful search must be undertaken for other causes of pulmonary infiltrates, especially fungal or other infection, and drug or other exposures. Specimens of blood, sputum, stool, BAL, and often transbronchial biopsy specimens should be obtained for stain and culture as well as serologic testing to rule out viral, bacterial, mycobacterial, fungal, and parasitic infection.[26,39] BAL cell differential should be performed. Elevated blood levels of TARC/CCL17 may distinguish AEP from other causes of ALI, even in the early phase of disease before blood esoinophilia is present.[47] In contrast, levels of KL-6, a marker for alveolar cell damage, tend to be lower in AEP than in other forms of ALI.[47] An elevated fraction of exhaled nitric oxide (FeNO; e.g., levels >23.5 ppb) may also help to distinguish AEP from non-AEP disorders[57] and FeNO levels decreased following corticosteroid treatment. Lower serum IgG levels have also been reported in AEP as compared with other causes of pulmonary eosinophilia.[58]

Idiopathic AEP generally carries an excellent prognosis. Although fatalities have been reported, most patients demonstrate rapid dramatic responses to corticosteroid therapy,[25,26,59] with abatement of fever and respiratory symptoms within 12 to 48 hours and complete resolution of infiltrates, pleural effusion, and pulmonary function impairment usually within 1 month.[27,48] The optimal steroid regimen for the treatment of AEP has not been determined. However, initial doses of methylprednisolone typically used range from 60 to 125 mg administered every 6 hours. After resolution of respiratory failure, oral prednisone (in doses of 40–60 mg per day) may

be continued for 2 to 4 weeks with a subsequent slow taper over the next several weeks.[26,51] Despite the apparent clinical success of steroid treatment, there is no definitive proof that steroids alter the natural history of the disease. Spontaneous disease regression has been reported,[27] and in contrast to idiopathic CEP, absence of clinical relapse is characteristic. Follow-up pulmonary function testing is generally normal, although a small number of patients may demonstrate mild reductions in D_{LCO} or lung volumes.

TROPICAL PULMONARY EOSINOPHILIA

TPE was first described in the early 1940s[60] as a syndrome characterized by fevers, malaise, anorexia, weight loss, paroxysmal dry cough with dyspnea or wheezing, marked peripheral blood eosinophilia, and spontaneous resolution over several weeks' time. In the 1950s and 1960s, filarial infections were recognized as the cause of this disorder.[61] TPE is most prominent in India, Africa, and Southeast Asia, but it may be seen worldwide in filarial-endemic regions.[3,4,62] Disease may also present in nonendemic regions among immigrants or travelers.[62,63] A rare manifestation of parasitic infection, TPE occurs in less than 1% of patients infected with lymphatic filariae (usually introduced by mosquito bite) and results from a hypersensitivity reaction to microfilariae from *Wuchereria bancrofti* and *Brugia malayi*.[5,62,64] Illnesses resembling TPE have also been reported following infection with other parasites. Approximately four times more common in men, most patients with TPE manifest the disease between the age of 25 and 40 years,[4,62] although children and older adults may also be affected. There is no known seasonal or genetic propensity to this disease, and it remains unclear why only such a small percentage of patients with filarial infection develop TPE.

Clinical manifestations of TPE develop months to years after the infection.[4] The most common distinguishing symptom of TPE is spasmodic cough that usually occurs at night.[62] Other typical early symptoms include low-grade fevers, weight loss, fatigue, and malaise. Dyspnea and wheezing, which can be severe, are common, and the clinical presentation may resemble status asthmaticus. Chest pain, muscle tenderness, and cardiac, pericardial, and CNS involvement have also been reported. Rarely, patients remain asymptomatic. Physical examination of patients with TPE is notable for coarse rales or rhonchi and wheezing,[62] although no abnormalities are found in approximately 20% of patients. Generalized lymphadenopathy and hepatosplenomegaly, pericarditis, musculoskeletal or CNS manifestations may be present,[4,62] but they are less common in adults than in children.

Laboratory findings in TPE include extreme peripheral blood eosinophilia[4,5,62] (usually more than 3000 eosinophils per cubic millimeter and up to 90% of the leukocyte differential) that persists for several weeks, although the degree of eosinophilia generally does not correlate well with clinical disease severity or radiographic findings. Blood eosinophils appear degranulated and contain cytoplasmic vacuoles.[62] Total serum IgE is usually elevated (more than 1000 U/mL), and the presence of high titers of filarial-specific IgE and IgG, measured by complement fixation or hemagglutination techniques, confirms the diagnosis.[3,5] Hypergammaglobulinemia results from polyclonal activation of B cells.[4] The ESR, circulating immune complexes, serum IgG, IgM and IgA, and complement (CH50) may be moderately elevated,[4,5] and patients may also have an abnormal electrocardiogram (ECG). Eosinophils may be identified in the sputum,[4,62] and, in those with active disease, BAL typically reveals intense eosinophilia (upto 50% of the differential), elevated levels of total IgE, and filarial-specific IgE, IgM, IgG and fibronectin.[4,5,62] BAL may also contain IgE antibodies to *B. Malayi* BM 23–25 antigen[4,62,65] as well as eosinophil-derived neurotoxin.[5] Pleural fluid, when present, is eosinophilic and also contains elevated IgE.[4] Serum α1-antitrypsin levels are reduced and return to normal with treatment.[4,66] Microfilariae are not found in blood or sputum,[4] and examination of stool or urine for ova and parasites is negative (although patients from endemic countries may be simultaneously infected with other parasites). In contrast, microfilariae have been identified in lung and lymph node tissue, especially when lymphadenopathy is present.

Pulmonary function test findings vary with the duration of disease: They reveal an obstructive ventilatory defect in up to 30% of patients, particularly when symptoms have been present less than 1 month. A restrictive ventilatory defect and reduced D_{LCO}, with or without a concomitant obstructive defect, are typical of long-standing disease.[3–5] Mild arterial hypoxemia may be present.[62] Ill-defined, diffuse reticulonodular infiltrates with a mottled appearance primarily affecting the mid to lower lung fields are characteristic radiographic findings in TPE.[3,4,62] Bronchovascular markings may be prominent and hilar adenopathy and pleural effusions have occasionally been reported.[4,62] The chest radiograph may be normal at the time of presentation in as many as 20% of patients.[62] In rare cases where *Dirofilaria* is the causative agent, the chest radiograph may reveal solitary or multiple nodules thought to represent infarcts caused by parasitic emboli. CT scanning may show mediastinal adenopathy, bronchiectasis, and areas of calcification.[67]

The histopathologic findings in TPE depend on the tissue examined, as well as the stage and duration of the disease.[62] Studies of lung pathology have shown that the early stage of the disease (within the first 2 weeks) is characterized by histiocytic inflammation in the alveolar, interstitial, peribronchial, and perivascular spaces, with preservation of lung architecture.[4] Tiny nodules may be palpable within the lung tissue. One to three months after symptom onset, eosinophilic infiltration with eosinophilic bronchopneumonia and microabscesses is present in lungs of untreated patients. Degenerating microfilariae may be present within the center of the microabscesses, and some destruction of alveolar walls may be evident. Local bronchial walls are also edematous and inflamed, with evidence of epithelial disruption. Long-standing untreated disease is associated with the presence of chronic mixed-cell inflammation (histiocytes, eosinophils, and lymphocytes) in a nodular pattern and the development of pulmonary fibrosis.[4,62] Foreign body–type granulomatous lesions are often present. Lymph node biopsies may reveal degenerating microfilariae or adult worms, surrounded by aggregates of eosinophils, their granule products, and giant cells.

The clinical features of TPE are believed to result from an intense hypersensitivity reaction to microfilarial antigens of *W. bancrofti* and *Brugia malayi*. Although a broad spectrum of clinical disease may be caused by filaria, patients with TPE rarely have other systemic features of filariasis. Canine filarial forms (e.g., *Dirofilaria immitis*) are rarely transmitted to humans but also may be recovered from lung and lymph node specimens. Disease occurs when larvae introduced into the body via insect bites develop into mature filariae.[4] The adult worms, dwelling within the lymphatics, produce microfilariae, which are then trapped in the pulmonary vasculature. The release of antigens from degenerating microfilariae leads to an intense local and systemic inflammatory response. A striking antibody and eosinophilic response, similar to that seen in peripheral blood, is also present within the lung.[4,5,62] Although little is known about the precise mechanisms by which filariae are cleared in patients with TPE, both antibody-dependent mechanisms and eosinophils probably play a role.[4,62] In vitro, both granulocytes and macrophages can bind microfilariae in the presence of IgG, IgE, or complement leading to the death of the organism. The finding of an intense lymphocytic- and plasma-cell infiltrate around microfilariae in tissues suggests that lymphocytes may be important for clearance of the organism. In vitro lymphocyte transformation in response to stimulation with microfilarial antigens can be demonstrated in some cases. The transcription factor NFkB[68]

and oxidants[69] are also reported to play an important role in the inflammatory response to TPE. The precise mechanisms by which eosinophils accumulate in the lung and contribute to tissue inflammation in patients with TPE are incompletely understood. Lung (as well as blood) eosinophils appear degranulated by microscopy.[62,70] Elevated levels of eosinophil-derived neurotoxin, an RNase capable of damaging the lung epithelium, have been observed in the BAL fluid of patients with TPE. IgE and eosinophil-, lymphocyte-, mast cell-, or basophil-derived products may contribute to the wheezing and airway hyperresponsiveness that can occur in this disorder.

The diagnosis of TPE is usually established on the basis of the clinical and laboratory findings described earlier including pertinent exposure history. Lung or other tissue biopsies are not typically required. The diagnostic criteria for TPE are summarized in Table 71-4.[62] Biopsy of enlarged lymph nodes (e.g., scalene) may assist in establishing the diagnosis in some cases. A rapid treatment response may provide confirmatory evidence that the correct diagnosis has been made. The differential diagnosis includes Loeffler syndrome, CEP, ABPA, drug reactions, other parasitic infections, HES, and lymphangitic spread of carcinoma. In nonendemic areas, the disease may also masquerade as asthma, atypical pneumonia, sarcoidosis, EGPA, granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis, WG), or tuberculosis (TB). Diagnosis in nonendemic regions is often delayed, and a careful review of travel history and a high index of suspicion are necessary to prompt the diagnosis.

Diethylcarbamazine, a piperazine derivative used widely in the treatment of filarial infections, is the therapy of choice for TPE, typically at a dose of 6 mg/kg/d for 14 to 21 days.[4,5,62] Diethylcarbamazine acts by both direct and indirect mechanisms. It is directly filaricidal to both adult worms and microfilariae. It can also enhance the binding of granulocytes, macrophages, antibodies, and complement to the surface of microfilariae. A marked clinical improvement and decrease in eosinophil count usually occurs in the first 7 to 14 days of therapy. Clinical improvement following diethylcarbamazine treatment has been correlated temporally with the resolution of eosinophilic alveolitis. In addition, improvement in pulmonary function, reduction in BAL eosinophilia, a decrease in total and filarial-specific IgE and IgG, increase in serum α1-antitrypsin levels, and radiographic clearing generally occur within 1 to 4 weeks of treatment.[4,62]

The course and prognosis of the acute disease in patients treated with diethylcarbamazine are generally benign, and 3 weeks of diethylcarbamazine therapy is curative in most patients. However, acute relapses related to reinfection or release of microfilaria from existing adult worms do occur in up to 20% of patients.[4] Persons whose α1-antitrypsin levels remain low after initial treatment may be at greater risk of relapse .[4,66] Patients who experience acute relapses often respond to additional treatment with diethylcarbamazine at higher doses of 2 to 4 mg/kg three times a day for 21 to 30 days. Alternatively, mild, chronic inflammation may persist, causing chronic interstitial lung disease, with persistent respiratory symptoms, radiographic findings, and hematologic and serologic abnormalities.[62] Persistent clinical symptoms have been reported over 2- to 5-year follow-up periods in up to 13% of patients with TPE treated with a standard course of therapy. BAL in these patients reveals a mild, persistent eosinophilia. Persons with symptoms of longer duration are less likely to have a favorable treatment response. Alternative antifilarial drugs (e.g., ivermectin) or a trial of corticosteroids may be useful therapies for the chronic variant of the disease,[4,62] although controlled studies of these agents are lacking. A subset of patients with apparent TPE may fail to respond to diethylcarbamazine; whether these patients have diethylcarbamazine-resistant TPE or disease due to other parasites is unclear, as current serologic testing does not distinguish between human lymphatic filarial antigens and antigens on certain other parasites.

Untreated disease usually persists for weeks to months. Untreated TPE may remit spontaneously, but it commonly recurs within months to years. It is important to treat TPE early in the course of the disease, since although seldom fatal, untreated TPE often leads to the development of irreversible pulmonary fibrosis.[63,71]

CHRONIC EOSINOPHILIC PNEUMONIA

CEP was first described as a clinical entity by Carrington et al.[72] in 1969. Although CEP may develop in people of any age, the peak incidence occurs in persons 30 to 45 years of age.[1,73,74] Women are affected approximately twice as often as men, and CEP has been reported during pregnancy and following radiation therapy for breast cancer.[75] The female predominance is less obvious among patients whose disease begins after the age of 60. Most cases occur in Caucasians. Up to two-thirds have adult-onset asthma preceding (by several weeks to years) or arising concurrently with the occurrence of CEP.[1,74,76,77] The asthma is often severe and may lead to fixed airflow obstruction (approximately 10% of patients) despite medical therapy.[76] Most patients with CEP are nonsmokers. In addition, approximately one-third to one-half of patients have antecedent atopy, allergic rhinitis, nasal polyps, or urticaria.[1]

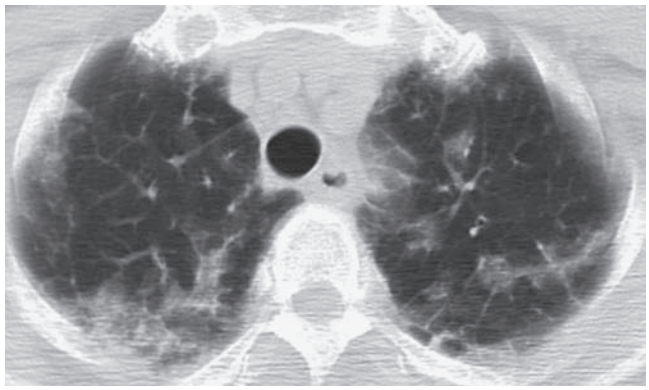
In contrast to idiopathic AEP, CEP typically has a subacute presentation, with symptoms present for weeks to several months before diagnosis.[1,74] Common presenting complaints include dyspnea, low-grade fevers, malaise, drenching night sweats, and moderate (10 to 50 lb) weight loss.[74,77] Cough, often dry initially and later productive of small amounts of mucoid sputum, is a virtually universal finding.[74] Rhinitis or sinusitis may be present. Two of the nine patients described in Carrington's original series had minor hemoptysis. Patients ultimately develop progressive dyspnea, which may be associated with wheezing in those with adult-onset asthma. Very rarely, patients with CEP may also have severe acute respiratory failure or ARDS, with severe hypoxemia requiring mechanical ventilation. There are no major extrapulmonary manifestations of CEP. Rarely, arthralgias, skin rash, diarrhea or colitis, mononeuritis, hepatitis, pericarditis or unexplained heart failure have been described, raising suspicion that there may be a continuum between CEP and EGPA.[74] Indeed, cases have been reported wherein patients initially diagnosed with CEP later developed EGPA.[78,79]

Patients with CEP frequently manifest a moderate leukocytosis. The majority (66%–95%) have peripheral blood eosinophilia (usually $>1000/mm^3$),[74] with eosinophils constituting more than 6%, and typically up to 20% to 30% of their leukocyte differential.[73,80] Leukocyte differentials with up to 90% eosinophils have been noted in this disorder. However, a lack of peripheral blood eosinophilia does not rule out the diagnosis, since eosinophilia may be absent in 10% to 30% of cases.[73,77] Normochromic, normocytic anemia and thrombocytosis may be present. The C-reactive protein levels and the

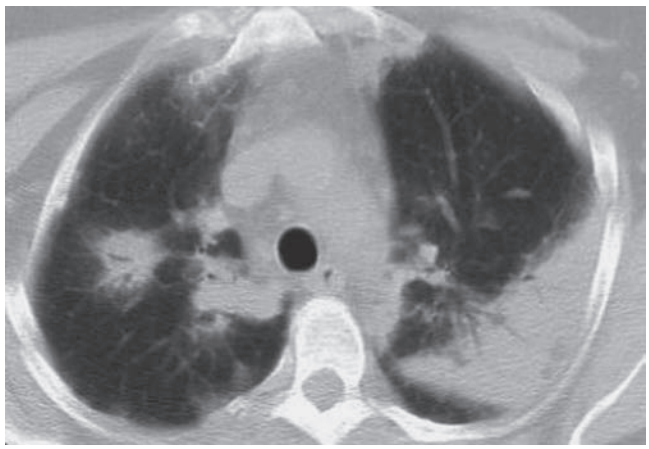
ESR are typically elevated (greater than 20 mm per hour),[74] and IgE levels are elevated in up to one-half of cases. Analysis of BAL fluid reveals increased eosinophils, typically accounting for 40% or more of the white blood cell (WBC) differential, with a range from 12% to 95% reported.[1,74,77,81] Urinary eosinophil-derived neurotoxin levels are also elevated.[82] Blood and sputum cultures routinely fail to identify an infectious etiology in these patients.

The severity of pulmonary function abnormalities depends on the stage and severity of the disease. In the initial stage prior to treatment with corticosteroids, testing may reveal restrictive, obstructive, or normal physiology.[74] Obstructive ventilatory defects, while more common in patients with a history of asthma, are also encountered in patients without pre-existing asthma. Restrictive physiology may result from changes in lung compliance due to acute eosinophilic infiltration of lung parenchyma. Diffusing capacity may be reduced and the alveolar–arterial oxygen gradient may be mildly elevated.[74,77]

In the original series, Carrington et al. described three radiographic features that are characteristic for CEP: (1) peripherally based, progressive dense infiltrates; (2) rapid resolution of infiltrates following corticosteroid treatment, with recurrences in identical locations; and (3) the appearance of infiltrates as the "photographic negative of pulmonary edema."[72,83,84] The pulmonary infiltrates associated with CEP are typically dense and patchy areas of airspace consolidation with ill-defined margins usually affecting the outer two-thirds of the lung fields (Fig. 71-3). Infiltrates are most commonly bilateral, tend to be located in the mid to upper lung zones, and may mimic loculated pleural fluid. They are frequently nonsegmental, subsegmental, or lobar in distribution. The characteristic "photographic negative of pulmonary edema" appearance (which occurs in <50% of cases) results if extensive infiltrates surround major portions of or the entire lung. Pleural effusions and cavitation are rare.[73,85,86] The infiltrates may be migratory in up to 25% of cases. Occasionally, the chest radiograph can be normal.



A



B

Figure 71-3 Radiographic appearance of chronic eosinophilic pneumonia (CEP). Variable computed tomography appearance of infiltrates in two patients with chronic eosinophilic pneumonia. Peripheral upper lobe–predominant infiltrates may have a ground-glass appearance (**A**) or may appear as regions of dense consolidation or nodular opacity (**B**).

Common CT scan findings include ground-glass opacities and areas of consolidation involving the middle and/or upper lung zones in peripheral regions of the lung.[73,87–90] In addition, apparent unilateral or isolated lower lung zone involvement noted on chest radiography may prove to be bilateral and diffuse on CT scanning. Mediastinal adenopathy, which may be evident on conventional chest radiograph, may also be identified on CT scan.[90] Less typical radiographic findings include nodular infiltrates, linear oblique or vertical densities, bronchial wall thickening, pleural effusion, and areas of fibrosis unassociated with anatomic divisions. Findings on CT scan may vary depending on the timing of the CT relative to the onset of symptoms. Typical areas of dense, peripherally located airspace consolidation are found in most cases within the first several weeks of disease onset. Streaky bandlike opacities may appear when symptoms have been present for more than 2 months.

The pulmonary lesions of CEP are characterized histopathologically by varying degrees of leukocytic infiltration of the alveolar airspaces and alveolar septae. These infiltrates are predominantly eosinophilic,[49,72,77] with some associated macrophages, a small-to-moderate number of lymphocytes, occasional plasma cells, multinucleated giant cells, and an associated fibrinous exudate. Unlike AEP, the basal lamina may be disrupted[49] but frank alveolar necrosis is absent. Eosinophilic microabscesses can be found. Focal edema of the capillary endothelium, focal type II epithelial cell hyperplasia, proteinaceous and fibrinous alveolar exudates can also be appreciated. Histologic evidence of proliferative bronchiolitis obliterans or bronchiolitis obliterans–organizing pneumonia may occur in up to one-third of cases, and a mild, nonnecrotizing microangiitis affecting predominantly the small venules may be seen. Biopsy specimens of lymph nodes from patients with intrathoracic lymphadenopathy reveal lymphoid hyperplasia and eosinophil infiltration.

The cause of CEP is unknown. No specific genetic predisposition for the disease has been identified, although CEP has been reported in identical twins, raising the question of a familial tendency toward the disease. An association has been reported between rheumatoid arthritis and CEP[91] but no clear causal relationship has been identified.[92] Although the precise immunopathogenesis of CEP is unknown, evidence suggests that Th2 helper T cells likely have a role in disease pathogenesis. Levels of the cytokines TARC-CCL17 and macrophage-derived cytokine 22 (MDC-22) and macrophage inflammatory protein 1-beta (MIP-1β/CCL14), which help recruit Th2 T cells are increased in CEP.[74,84] Increased levels of the T-cell–derived eosinophil chemoattractant cytokines IL-5, eotaxin, and RANTES (CCL-5) are also elevated in BAL fluid of patients with CEP.[74] Thus Th2 cells likely recruit and attract eosinophils to the lung.[84] The number of regulatory (CD4+CD25+) T-cells is also increased in peripheral blood and BAL in CEP.[93] The potential role of blood and lung tissue lymphocytes in the pathogenesis of CEP requires further study.

Several lines of evidence suggest that eosinophils also play a primary pathogenetic role in the pulmonary tissue damage seen in this disorder. Increased numbers of eosinophils appear in the peripheral blood and bone marrow before the onset of clinical disease, and eosinophilia is the predominant abnormality in BAL fluid. These eosinophils appear to be activated, since they show evidence of degranulation on electron microscopy,[94] eosinophil-derived granule proteins (EDGPs) have been identified microscopically within the

pulmonary parenchyma and microvasculature, increased concentrations of EDGP are identified in BAL fluid from patients with CEP compared to controls, and BAL-derived eosinophils express activation markers including class II major histocompatibility (MHC) antigens.[95] Also, eosinophil-derived neurotoxin[82] and leukotriene E4[96] are identified in the urine of patients with CEP, and inducible nitric oxide synthase (iNOS) is expressed on lung eosinophils.[97] The processes that regulate eosinophil activation and degranulation in CEP are not clear. Evidence showing that class II MHC and other activation markers are expressed by BAL- but not blood-derived eosinophils suggests the presence of an immune inflammatory response compartmentalized within the lung. Data also suggest that eosinophils from the BAL fluid are more resistant to apoptosis than peripheral blood eosinophils in subjects with CEP.[98]

Of interest are the findings that immunoglobulins can augment eosinophil chemotaxis and degranulation in vitro, and that circulating immune complexes and elevated titers of IgE are noted in the context of clinical flares of the disease. To date, however, no clear causal relationship has been established between immunoglobulins and eosinophil activation in CEP. An association between CEP and diffuse pulmonary neuroendocrine cell hyperplasia has also been reported.[99]

The diagnosis of CEP is based on the presence of compatible clinical, radiographic, and BAL findings, and on the inability to document pulmonary or systemic infection or other known causes of eosinophilic lung disease. The clinical signs and symptoms of CEP are nonspecific, however, and blood eosinophilia and typical radiographic features may be absent in some cases. In most reported series, open lung biopsy has been required only rarely to establish the diagnosis. Transbronchial biopsy, usually performed to rule out other diagnostic entities, may reveal eosinophil and mononuclear cell infiltrates. Because of the rapid and dramatic responsiveness of CEP to steroid treatment, a therapeutic trial of steroids is often useful in establishing the diagnosis. Failure to document rapid clinical improvement should alert the clinician to consider other diagnoses. The differential diagnosis of CEP includes drug-induced eosinophilic pneumonia, infection (especially TB, fungal diseases such as cryptococcosis and parasitic disease), sarcoidosis, Loeffler syndrome, desquamative interstitial pneumonitis, cryptogenic organizing pneumonia, ABPA, chronic hypersensitivity pneumonitis, acute idiopathic eosinophilic pneumonia, EGPA, and eosinophilic granuloma.

CEP rarely resolves without therapy and if left untreated may result in pulmonary fibrosis.[100] Corticosteroids are the mainstay of therapy for CEP. Dramatic clinical, radiographic, and physiologic improvements have been documented following steroid treatment in all series reported.[1,74,87] Even patients presenting with severe respiratory failure may respond well to steroid treatment. In most cases, treatment with steroids leads to defervescence within 6 hours, reduced dyspnea, cough, and blood eosinophilia within 24 to 48 hours, resolution of hypoxia in 2 to 3 days, radiographic improvement within 1 to 2 weeks, complete resolution of symptoms within 2 to 3 weeks, and normalization of the chest radiograph within 2 months.[1,73,77] No comparative studies exist to determine optimum treatment doses or duration of steroids, but one recommended regimen is prednisone 0.5 mg/kg/d (40–60 mg a day) continued until 2 weeks after resolution of symptoms and radiographic abnormalities, generally for 4 to 6 weeks. The dose of prednisone can then be tapered slowly by 0.25 mg/kg/d and then continued for the subsequent 8 weeks. Treatment is usually maintained for at least 3 months and optimally for 6 to 9 months; during this phase prednisone dosing can be decreased by 5 mg every 4 weeks. Shorter courses of prednisone may also be effective.[74]

The prognosis of CEP is generally favorable.[101] In steroid-treated patients, morbidity and mortality directly related to CEP are low. Patients may require 1 to 3 years of initial steroid treatment to control the disease,[1] and up to 50% may require long-term maintenance treatment (2.5–10 mg prednisone a day) to remain disease-free.[74] The lowest possible dose of steroid that suppresses disease activity should be used. Some patients may respond to high doses (e.g., 1000–1500 µg/24 h) of inhaled corticosteroids, allowing discontinuation of oral steroids, although inhaled steroids alone as initial therapy are inadequate.

Clinical, hematologic, or radiographic evidence of relapses are common, occurring in 50% to 80% of cases when steroids are tapered or discontinued.[1,73,74,77] Relapses may involve radiographic infiltrates in the same or different anatomic distribution compared to the original disease. Relapsing CEP must be distinguished from the development of new or worsening asthma. No obvious factors exist to identify persons who are likely to relapse or require long-term steroids, although relapses are more common in persons treated initially with a short course (<6 months) of steroids. Regular long-term treatment of patients with CEP and asthma with inhaled corticosteroids may reduce the risk of CEP relapses.[76] Multiple recurrences may occur in anyone. Relapses should be managed by increasing the prednisone dose to ≥40 mg per day until 2 weeks after symptom control has been achieved, with gradual taper thereafter. The reinstitution of steroids generally leads to improvement, and relapses do not appear to indicate a worse prognosis, increased likelihood of treatment failure, or increased morbidity. The anti–IL-5 monoclonal antibody omalizumab has also been used successfully as a steroid-sparing agent in the treatment of CEP.[102]

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS (MYCOSIS)

ABPA is a disorder caused by a complex hypersensitivity response to inhaled fungal antigens.[103–110] Since the disease is most commonly induced by *Aspergillus* species, it is usually known as ABPA. When induced by non-*Aspergillus* species, the syndrome is called allergic bronchopulmonary mycosis. A comprehensive discussion of ABPA is provided in Chapter 48. Highlights of the disorder are discussed here.

ABPA occurs most commonly in immunocompetent patients and complicates 1% to 2% of cases of persistent asthma and 7% to 14% of cases of chronic steroid-dependent asthma,[111] most often among patients in their third to fourth decade. It also complicates up to 15% of patients with cystic fibrosis (CF), most often during the teen years.[105,112] Rare cases lacking a history of asthma but meeting the other major diagnostic criteria (summarized in Table 71-5) have

TABLE 71-5 Diagnostic Criteria for Allergic Bronchopulmonary Aspergillosis

Major[a]
Asthma (ABPA is also common in persons with cystic fibrosis)
Positive immediate hypersensitivity skin-prick test to *Aspergillus*
Precipitating antibodies against *Aspergillus*
Elevated total IgE
Elevated serum *Aspergillus*–specific IgE, IgG
History of pulmonary infiltrates
Peripheral blood eosinophilia
± Central bronchiectasis
Minor
Expectoration of thick brown mucus plugs
Aspergillus in sputum
Dual cutaneous reaction to *Aspergillus*

[a]*The presence of 6 of eight major criteria strongly suggests the diagnosis.*

been reported.[113] The diagnosis of ABPA is based on appropriate clinical features in combination with supporting serologic and radiologic findings.[104]

Patterson and Greenberger[114] proposed five minimal essential criteria needed to establish the diagnosis, including (1) asthma, (2) positive immediate hypersensitivity skin test to *Aspergillus,* (3) total IgE greater than 1000 ng/mL (or >417 IU/mL), (4) elevated serum anti-AF IgE and IgG (more than twofold greater than for asthmatic controls), and (5) serum precipitins to *Aspergillus fumigatus* (AF) or other relevant fungus. These features, as well as a history of current or previous pulmonary infiltrates and/or central bronchiectasis evident on high-resolution CT scan (HRCT) and peripheral blood eosinophils (~10,000 cells/mL), comprise the major diagnostic criteria of ABPA.[103,106,115–118] Expectoration of brown mucus plugs, identification of *Aspergillus* (or other relevant fungus) in the sputum, and dual (immediate and delayed) cutaneous reactions to challenge with *Aspergillus* are also common clinical features of ABPA.

Five clinical stages of ABPA have been recognized: acute illness (stage 1); remission (stage II); exacerbation (stage III); steroid-dependent asthma (stage IV); and fibrotic lung disease (stage V).[104,105,114] The clinical features of these stages are shown in Table 71-6. Two variants of ABPA have been recognized: seropositive ABPA (ABPA-S), wherein the preceding essential criteria are met and there is no evidence of central bronchiectasis; and ABPA with central bronchiectasis (ABPA-CB), wherein the above criteria are met and CB is present.[105,119] It is unclear whether ABPA-S is an earlier stage of disease that precedes ABPA-CB or whether it is perhaps a milder form of the disease.

TABLE 71-6 Clinical Stages of Allergic Bronchopulmonary Aspergillosis

Stage I: Acute
Acute asthma symptoms ± constitutional symptoms
Elevated serum IgE (typically >1000 ng/mL)
Elevated *Aspergillus*-specific IgE and IgG
Infiltrate on chest radiograph
Peripheral blood eosinophilia
Immediate skin reactivity to *Aspergillus*
Positive precipitating antibodies to *Aspergillus fumigatus*
Stage II: Remission
Resolution of symptoms (concurrent decrease in total IgE needed to confirm remission)
Radiographic clearing
Reduction or stabilization of IgE levels (normalization rare)
Stage III: Exacerbation
Recurrence of elevated IgE levels (greater than twofold over baseline)
± Development of a new pulmonary infiltrate on chest radiograph
± Escalation of asthma symptoms
Stage IV: Steroid-dependent Asthma
Difficult to control, steroid-dependent asthma
Persistently elevated total IgE, *Aspergillus* precipitins and *Aspergillus*-specific IgE and IgG despite corticosteroid therapy
± Transient infiltrates and/or bronchiectasis on chest radiograph or CT
Stage V: Fibrotic lung disease
Persistent steroid-dependent asthma
Fibrotic lung disease with gas exchange disturbances
Chronic sputum production and frequent infections common

Typical radiographic manifestations of ABPA include transient, irregular pulmonary infiltrates with a predilection for the upper lobes (Fig. 71-4).[88,120] Other common radiographic features include "finger-in-glove opacities," "tramline shadows," "parallel lines," "toothpaste shadows," "ring shadows," and lobar consolidation (Fig. 71-4). These findings result from bronchial and bronchiolar wall inflammation, edema, and remodeling, and from mucoid impaction of the bronchi with or without parenchymal involvement. As noted, central (proximal) bronchiectasis, another characteristic radiographic manifestation of ABPA, occurs in many, although not all, patients. The presence of high attenuation mucus on HRCT may be a marker for disease severity.[121] ABPA is not typically diagnosed by tissue sampling. Nevertheless, histopathologic findings of ABPA include intense bronchocentric inflammation with eosinophils, lymphocytes, plasma cells, and monocytes, bronchocentric granulomatosis, as well as mucoid impaction of bronchi.[112,116] Fungal hyphae are typically present in mucus plugs without bronchial tissue invasion. The histologic findings may vary in differing parts of the lung and in different stages of the disease.

The features of ABPA are believed to result from a complex immunologic reaction to chronic airway colonization by *Aspergillus* (or other relevant fungal species) that includes features of type I, type III, and type IV immune responses.[104] T-helper lymphocytes, neutrophils, eosinophils, genetic susceptibility factors, and the fungus itself all also likely contribute to the pathogenesis of the disease.[103,122]

Typical symptoms include wheeze, cough, dyspnea, and sputum production, at times with expectoration of brownish/black mucus plugs. Other symptoms may include malaise, myalgias, low-grade fever, chest pain, weight loss, or hemoptysis. Respiratory symptoms may at times be absent despite serologic and radiologic evidence of active disease. The diagnosis of ABPA should be considered in any patient with asthma or CF who experiences frequent and/or recurrent exacerbations of respiratory symptoms, and/or the combination of asthma and eosinophilia. Worsening of lung function and/or steroid dependence or failure to improve clinically following antibiotic therapy for a suspected bacterial infection may also suggest the diagnosis in patients with CF.[112,123] The differential diagnosis of ABPA is broad, and in addition to other pulmonary eosinophilic disorders, includes asthma with fungal sensitization without ABPA, refractory asthma without fungal sensitization, aspergillus bronchitis, and other nonfungal infectious bronchitis or pneumonia. ABPA often goes unrecognized, due to overlap of clinical features with these disorders. ABPA may also be challenging to recognize due to the varying clinical presentations at different stages of disease.

Goals of treatment are to control symptoms, preserve normal lung function, and prevent exacerbations and disease progression. Early recognition and aggressive treatment are essential to prevent development of permanent airway remodeling, bronchiectasis, and pulmonary fibrosis.[105] Systemic corticosteroids, with careful patient monitoring of clinical symptoms, IgE levels, and chest radiograph, are the mainstay of therapy.[124–126] Corticosteroid doses that reduce IgE levels by at least half of acute stage levels within 6 to 8 weeks and induce clearing of radiographic infiltrates must be used to control the disease. These doses are typically higher than those needed to control symptoms alone.

The recommended initial prednisone dose is 0.5 mg/kg/d for 2 weeks followed by every other day dosing for 6 to 12 weeks, followed by a gradual taper of 5 to 10 mg every 2 weeks over 3 to 6 months.[105] Children with CF may require higher doses and/or longer duration of treatment. Total serum IgE levels should be measured at the time of diagnosis, at 4 and 8 weeks, and every 2 months thereafter for 1 year.

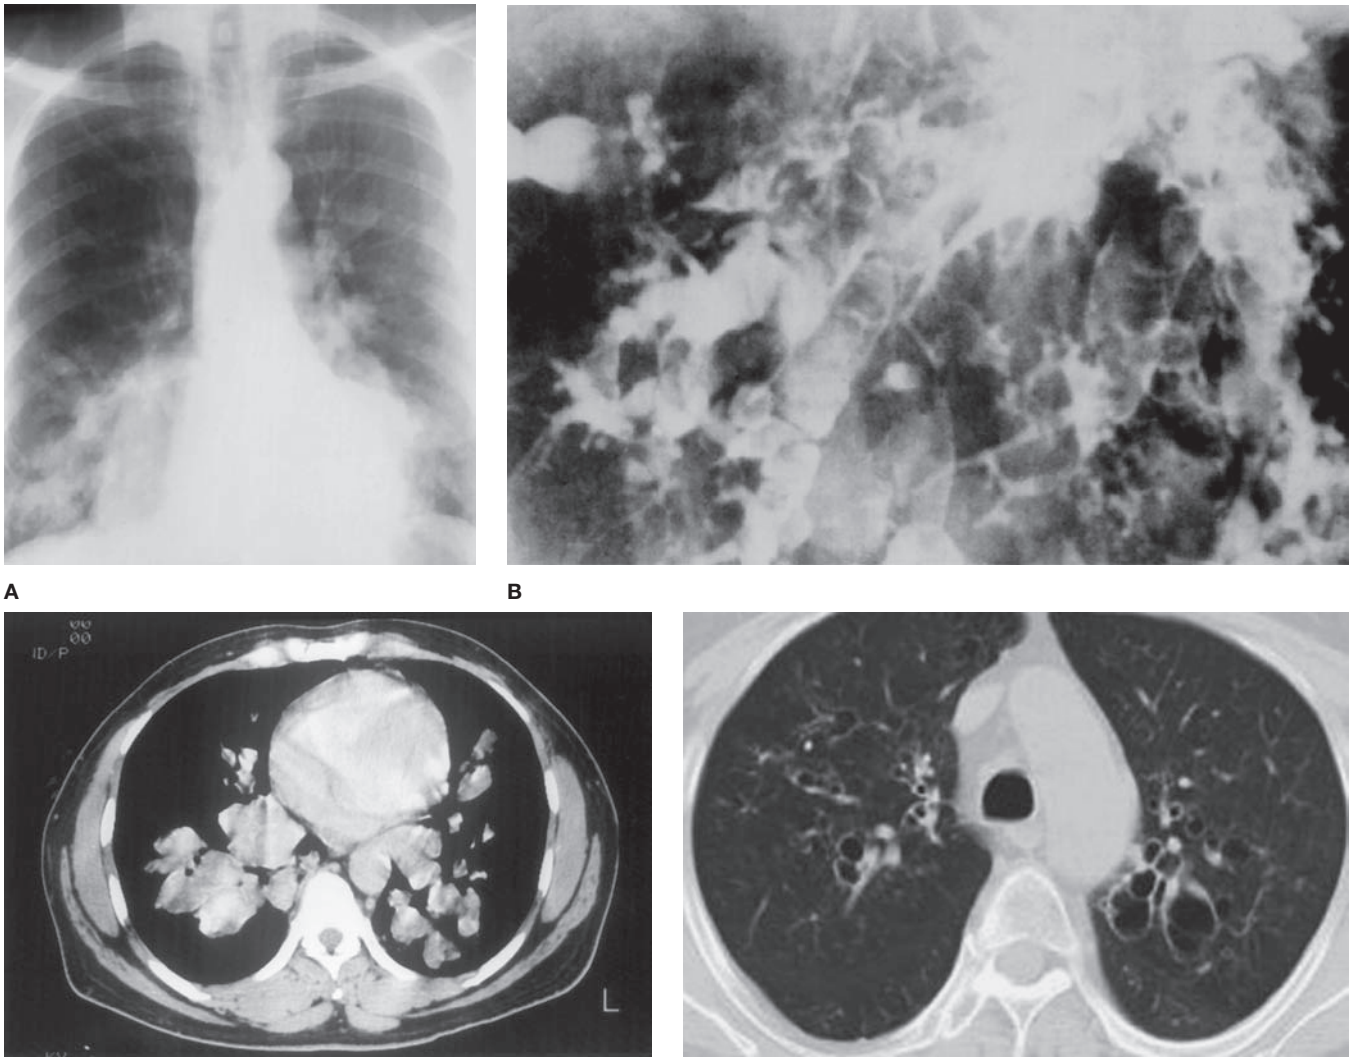


Figure 71-4 Radiographic appearance of allergic bronchopulmonary aspergillosis (ABPA). Extensive infiltrates with tubular configuration and "gloved finger" appearance are present, in this case predominantly in the lower lobes (**A**), the bronchogram (**B**), and computed tomography (CT) of the chest (**C**) reveal extensive proximal bronchiectasis. Extensive mucoid impaction of the bronchi is evident on CT scan (**C**). Central bronchiectasis and tram-track shadows in a patient with ABPA may also be present without mucoid impaction (**D**).

Treatment with the antifungal agent itraconazole can also help control the symptoms and immunologic features and exacerbations of the disease[127–129] and may enable reduction of the systemic corticosteroid dose.[130,131] Voriconazole may be a suitable alernate antifungal agent.[132,133] In case series, the anti-IgE antibody omalizumab has helped to control the disease in steroid-dependent patients with ABPA who have failed itraconazole treatment.[134–137] Bronchodilators and antibiotics help control bronchospasm and secondary respiratory infections. Inhaled corticosteroids alone are inadequate to prevent or treat acute episodes of ABPA. Yearly spirometry should be performed and patients should be monitored for concurrent gastroesophageal reflux, rhinosinusitis, or environmental mold exposures.[105]

CHURG–STRAUSS SYNDROME (EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS)

In 1939, Rackemann and Greene reported a subgroup of patients with polyarteritis nodosa and concomitant allergic disease. Similar findings were reported in the early 1940s by Harkavy. The histopathology and clinical features associated with this disease entity were first described in 1951 by Churg and Strauss, who reported a form of necrotizing vasculitis in several organs, associated with eosinophilic tissue inflammation and extravascular granulomas, occurring in asthmatics, with associated fever and peripheral hypereosinophilia (Churg–Strauss syndrome).[138] This disease entity, now termed eosinophilic granulomatosis with polyangiitis (EGPA), is an uncommon systemic disease.[139–141] An overall prevalence of 10.7 to 13 cases per million inhabitants is estimated among the general population,[142] and up to 64 cases per million persons per year is estimated among patients with a history of asthma. The mean annual incidence has been estimated at 0.5 to 6.8 per million population across various countries.[142]

Approximately 10% of all patients with vasculitis prove ultimately to have EGPA (see also Chapter 74). Nevertheless, the precise incidence of EGPA is unknown due to uncertainties regarding diagnosis and variable clinical presentation. The true incidence of EGPA may be higher than is generally recognized, since the syndrome has many clinical, radiographic, and histologic features in common with other vasculitic, eosinophilic, and granulomatous disease states. The diagnosis of EGPA may be missed if not carefully entertained.

EGPA may occur in patients of any age, but it develops most commonly in patients between the ages of 38 and 50.[1,143,144] It is rare

in persons older than age 65, as well as children and adolescents. However, among affected children, it tends to follow a more aggressive clinical course.[145] There is no clear gender predominance.[142,144] Among women, disease onset has been reported during pregnancy. The MHC complex DRB4 allele may confer genetic risk for the disease.[146,147]

EGPA tends to follow a subacute course, with symptoms ranging over months to years. Historically, three distinct clinical phases of the disease have been recognized: the prodromal phase, the eosinophilic phase, and the vasculitic phase.[148,149] The *prodromal phase* has been characterized by "late-onset" (in the second or third decade) allergic rhinitis and atopy in persons often lacking a family history of atopy. Severe allergic rhinitis, sinusitis, and drug sensitivity are usually present for 8 to 10 years, and up to 30 years before EGPA disease recognition. Asthma is a feature of EGPA in all cases. It typically precedes the onset of vasculitis by 3 to 6 years.[148] The *eosinophilic phase* is typified by the development of marked peripheral blood eosinophilia and eosinophilic tissue infiltration, most commonly of the lung, GI tract, and skin. The *vasculitic phase* is characterized by vasculitis of the small and medium vessels with vascular and extravascular granulomas. The onset of the vasculitic phase is often heralded by development of constitutional symptoms, including fever, malaise, weight loss, arthralgias, myalgias, and increased allergic or asthmatic symptoms. Although the vasculitis tends to occur several years after the onset of allergic manifestations of the disease, in some cases it develops within months of, or concomitant with, the onset of asthma. A short duration between the onset of asthma and vasculitis has been associated with increased severity of vasculitis. During the vasculitic stage, the asthma symptoms may persist and worsen, or they may diminish. When asthma dissipates, it often flares later in the course of illness and may require prolonged steroid treatment. Importantly, not all patients progress sequentially through these phases, and overlap of clinical features between phases is often present. Although EGPA typically affects multiple organ systems, limited forms of disease have also been described.[142,150] Manifestations in the lungs, heart, skin, and nervous system are most common.

Lung involvement occurs in nearly all patients with EGPA.[142] Most of the respiratory manifestations of EGPA occur in the prodromal and eosinophilic phases of the disease. As noted earlier, all patients have asthma at some point in the illness. Upper airway allergic disease, including sinusitis, rhinitis, and polyposis, is seen in 75% to 85% of patients and may be the presenting symptom.[1,142] Unlike granulomatosis with polyangiitis, necrotizing granulomas involving the upper airway are unusual in EGPA. The asthma and upper airway disease usually are long-standing, severe, and often require steroid therapy (systemic or inhaled) to maintain control of symptoms.[142] Spirometry may reveal an obstructive ventilatory defect.[151] A Loeffler-like syndrome with eosinophilic infiltration of the lung parenchyma is seen in 50% to 70% of patients. These patients may develop dyspnea, cough, and wheezing. Their chest radiographs have transient, migratory, patchy, nonlobar, nonsegmental, often peripheral pulmonary infiltrates, with no regional predilection.[152–154] Nodular lesions, reticular opacities, bronchial wall thickening, bronchiectasis, and hilar adenopathy are less common findings. In contrast to granulomatosis with polyangiitis, the allergic granulomas cavitate more rarely. Up to 50% of patients develop unilateral or bilateral pleural effusions,[154] which may be associated with pleuritic chest pain. The chest radiograph may occasionally be normal. HRCT scanning has demonstrated bronchial wall thickening, pulmonary artery enlargement (in comparison to the corresponding bronchi), irregular stellate configuration of some vessels, adenopathy, areas of interlobular septal thickening, and scattered patchy parenchymal opacities with ground-glass, nodular, consolidated, or tree-in bud appearance.[1] Nodules may be present within areas of ground glass.[90,154,155] These findings have been reported to correlate with pathologic findings evident on open lung biopsy such as eosinophilic pneumonia, alveolar hemorrhage, eosinophilic infiltration of the bronchial wall, and septum.[153] Further studies are necessary to determine whether high-resolution CT is useful to stage the disease or establish the diagnosis without tissue biopsy.

Cardiac manifestations generally are not evident on initial presentation of EGPA. However, they typically occur during the vasculitic phase of the disease and are a major source of morbidity and the principal cause of death (in up to 50% of cases) from the disorder.[142,143,156] Patients may be asymptomatic. Progressive congestive heart failure (CHF) occurs in up to 47% of cases because of endomyocardial infiltration by eosinophils[1,157] or ischemic cardiomyopathy resulting from necrotizing vasculitis of the coronary arteries.[158] This coronary vasculitis is fatal up to 60% of the time. Acute pericarditis is present in approximately one-third of cases, and cardiac tamponade has been reported. Constrictive pericarditis may develop over time. Cardiac involvement is more common in persons with EGPA who lack serum ANCA (see below).[159,160]

A wide array of neurologic manifestations may develop in EGPA. Mono- or polyneuropathy (most notably mononeuritis multiplex) is present in 69% to 75% of cases. The common peroneal, ulnar, and internal popliteal nerves are most frequently affected.[142] CNS manifestations occur more rarely and include cranial nerve impairment (especially optic neuritis), seizure, subarachnoid hemorrhage, and cerebral infarction. Skin, GI, renal, and other systemic alterations have been well described in EGPA. Skin findings are present in 40% to 70% of cases and may develop in localized crops. They can manifest as nonthrombocytopenic purpura (particularly on the lower extremities), urticaria, a maculopapular rash, petechiae, ecchymoses, or livedo reticularis. Skin biopsies typically demonstrate eosinophilic infiltration and leukocytoclastic vasculitis.[161] Tender cutaneous or subcutaneous nodules (which may ulcerate) containing extravascular granulomas may preferentially involve the fingers, scalp, and extensor surface of the elbow.[142] GI manifestations of EGPA are present in up to 60% of cases. They can include eosinophilic gastroenteritis or vasculitis that can lead to diarrhea, abdominal pain, intestinal obstruction, cholecystitis, pancreatitis, bleeding, liver function test abnormalities, and bowel perforation.[142] GI disease also carries a poor prognosis[142] and is the second leading cause of death in patients with EGPA. A degree of renal insufficiency occurs in 25% to 50% of patients with EGPA. Eosinophilic interstitial nephritis with necrotizing features is the most common histopathologic finding, but focal segmental glomerulosclerosis, hematuria, and proteinuria also occur.[143,162,163] Severe, difficult-to-control hypertension is also a major sequela of EGPA (in 25%–75% of cases) and may be due to recurrent renal infarction. In contrast to granulomatosis with polyangiitis, overt renal failure is not commonly seen in EGPA.[143] Mild lymphadenopathy (in 30%–40%), rheumatologic manifestations (migratory polyarthralgias, myalgias, temporal arteritis), urologic disease (ureteral, urethral, prostatic), and ocular manifestations (scleritis, uveitis, optic neuropathy, conjunctival nodules)[142] have also been described.

The diagnosis of EGPA is based on clinical features with corroborating laboratory and/or histologic findings. There is no single laboratory test specific for a diagnosis of EGPA. A majority of patients with EGPA have a striking but fluctuating degree of peripheral blood eosinophilia (mean values between 5 and 20,000/mm^3; 20% to 90% of the WBC differential) at diagnosis,[1,142] generally greater than that seen with asthma alone. The

degree of eosinophilia tends to parallel the vasculitis activity[1] and may be suppressed by corticosteroid treatment of asthma. Serum C-reactive protein levels and total IgE levels are elevated (range, 500–1000 U/mL) in 75% of patients. Elevated exhaled breath condensate and BAL fluid concentrations of the eicosanoid 12-HETE can help distinguish EGPA from asthma without EGPA.[164] Elevated blood levels of the Th2 T lymphocyte cytokines IL-4, IL-5, and IL-13[165] as well as serum IgG4,[166] TARC/CCL17,[167] urinary eosinophil–derived neurotoxin,[168] and serum eotaxin-3 levels[169,170] also correlate with disease activity. BAL fluid of patients with active EGPA also contains increased levels of the Th2 cytokines IL-4, IL-5, and IL-10 as compared with inactive EGPA.[171,172] Most patients have a normochromic, normocytic anemia, and moderate elevation of their ESR. Rheumatoid factor titers may be positive, but antinuclear antibodies are usually negative.[142] Hypergammaglobulinemia and circulating immune complexes may also be seen.

Approximately 40% to 60% of patients have positive antinuclear cytoplasmic antibody with a perinuclear staining pattern (pANCA).[159,160,173] The majority of these are directed against myeloperoxidase (MPO-ANCA) and a minority against proteinase 3 (PR3-ANCA). The absence of ANCA does not exclude the diagnosis. Indeed, recent case series suggest that persons positive for ANCA have different clinical features than those without.[174] Persons with positive ANCA (the "vasculitic phenotype") tend to manifest evidence of biopsy-proven vasculitis, purpura, ENT manifestations, peripheral neuropathy, and renal disease but have less cardiac involvement.[159,160,175] In contrast, those without ANCA (the "eosinophilic tissue infiltration phenotype") manifest predominantly with fever, eosinophilic pneumonia, and eosinophilic myocarditis.[159,160,176]

Laboratory examination of pleural fluid, if present, reveals an eosinophil-predominant exudate with low glucose levels.[142] Pleural biopsy shows chronic pleuritis with eosinophilic infiltration. BAL reveals an increased percentage of eosinophils,[177] the magnitude of which is generally less than that seen with CEP or idiopathic HES. However, patients have been described whose BAL fluid leukocyte differential contained 81% eosinophils. Electrocardiogram, echocardiography, N-terminal pro-brain natriuretic peptide and tropinin-1 levels, and/or cardiac MRI are recommended to evaluate patients with suspected EGPA for the presence of cardiac involvement.[142,178,179] ^{18}FDG/^{13}N ammonia positron emission tomography (PET) imaging may also be useful to identify cardiac involvement in EGPA. Magnetic resonance imaging may show T2-weighted signals in subcortical matter suggestive of CNS vasculitis.[142]

Although lung biopsy is rarely required for diagnosis, the histopathologic hallmarks of EGPA vary depending on the stage of illness but include tissue (interstitial, blood vessel, and alveolar) infiltration by eosinophils, eosinophilic necrotizing giant cell vasculitis of small arteries, arterioles, and, to a lesser extent, small veins, venules, and capillaries and perivascular and interstitial eosinophilic granulomas (typically microscopic).[180–182] Both pulmonary and systemic vessels may be affected. The precise histopathology of vascular impairment depends on the stage of the lesion. Early lesions demonstrate eosinophilic infiltration of the vessels and perivascular region (Fig. 71-5). Later lesions are characterized by necrotizing arteritis or vessel obliteration and scarring. The extent of vascular impairment varies from mild, eosinophilic perivascular cuffing to severe transmural inflammation with necrotization. Lesions may be sparse or widespread. In the lung the allergic granulomas may have central necrosis with eosinophilic infammation, may involve interlobular septae and extend along the pleura. Diffuse capillaritis and alveolar hemmorhage has been reported. Eosinophilic lymphadenopathy may also be present. Biopsies of skin, nerve, or muscle may also confirm the diagnosis.[156]

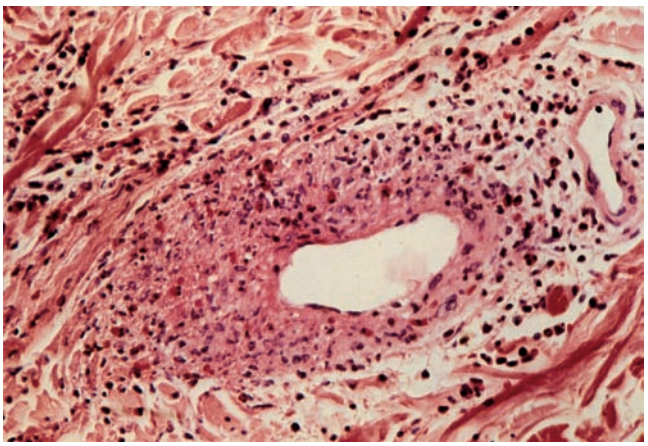

Figure 71-5 Pathologic appearance of small arteriole in Churg–Strauss vasculitis. Intense perivascular inflammation with eosinophilia is present.

The pathogenesis of EGPA remains poorly understood. A possible pathogenic role of antineutrophil cytoplasmic antibody (ANCA) is suggested by the finding of ANCA in 40% to 60% of patients with EGPA.[144] ANCA may contribute to tissue inflammation and injury by activation of inflammatory cells, release of proteolytic enzymes, and generation of oxidative stress[142] but its presence may be a consequence rather than a cause of the tissue injury. As noted previously, the clinical features of EGPA differ between persons with versus without ANCA.[159,160] The strong association with allergy, atopy, eosinophilia, and elevated blood levels of Th2 T lymphocyte-derived cytokines and IgE (especially during the vasculitic phase of the disease) has raised the likelihood of augmented Th2 immunity.[142,172,183–185]

Reductions in T regulatory cells[183,186] and augmented Th1 immunity[187] have also been demonstrated. Eosinophils likely also contribute significantly to the tissue injury[188] since blood, BAL, and urine specimens contain eosinophil-derived cytotoxic granule proteins.[142] Based on these collective findings, it has been proposed that repeated antigenic stimulation in patients with a heightened T-cell and eosinophil response may be important in the development of the disorder. Heightened humoral immunity with immune complex disease may also play a role. Genetic factors including polymorphisms in the IL-10 gene[189] and HLA-DRB107 and HLA-DRB4[146] may be important in predilection to develop EGPA.

The relationship between the pathophysiology of asthma in EGPA to that of asthma without EGPA also remains uncertain. CEP with asthma may precede EGPA in up to 50% of cases. A decrease in the number of blood regulatory T cells (Treg) occurs in persons who develop EGPA following CEP, but not in those with CEP who do not later develop EGPA or in persons with asthma without EGPA.[186,190] This suggests that maintenance of normal numbers of Treg cells may protect against the development of EGPA. Also, a strong association has been noted between the use of leukotriene receptor antagonists (LTRA) and 5-lipoxygenase inhibitors,[172,191–194] as well as other asthma therapies including inhaled glucocorticoids[195,196] and omalizumab[197] and the development of EGPA. These findings raise question as to whether these agents may serve as triggers for the disease. The appearance of EGPA following reduction in systemic corticosteroid dosing in many of these reports raises the likelihood that pre-existing, underlying EGPA that was being treated with corticosteroids is unmasked by the administration of these agents and the reduction in corticosteroid dose. Thus, it remains uncertain whether any of these agents may be causally related to the onset of EGPA. Patients with steroid-dependent asthma, in whom the diagnosis of EGPA has not been demonstrated or entertained, should be monitored closely for evidence of EGPA when steroid doses are

tapered, or when symptoms escalate despite systemic corticosteroid treatment and require intensification of medical therapy. EGPA has also been reported following inhalational use of cocaine,[198] following exposure to other medications, birds, vaccinations, and various infectious pathogens.[13,142]

The diagnosis of EGPA is generally based on clinical features. Various diagnostic criteria have been reported.[148,182] In 1990, the American College of Rheumatology published diagnostic criteria for EGPA,[182] based on assessments of the sensitivity and specificity of the diagnostic criteria used previously. The presence of at least four out of six of the following criteria yielded 85% sensitivity and 99.7% specificity in establishing the diagnosis: (1) asthma, (2) peripheral eosinophilia greater than 10%, (3) mono- or polyarthropathy, (4) migratory or transient pulmonary infiltrates, (5) paranasal sinus abnormality, and (6) extravascular eosinophils in a blood vessel on a biopsy specimen. The presence of asthma or allergy as well as more than 10% eosinophilia was 95% sensitive and 99% specific in distinguishing EGPA among a subgroup of patients with well-documented systemic vasculitis. Subsequently, the Chapel Hill Consensus Conference recommended that diagnostic criteria for EGPA include[1] appropriate clinical setting and histopathology and[2] eosinophil-rich and granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small and medium vessels with associated asthma and eosinophilia.[199] However, these criteria require tissue biopsy and are less sensitive for EGPA than others that have been proposed; hence, they may be less useful to assist diagnosis in the routine clinical setting. Open lung biopsy is the gold standard for tissue biopsy but is rarely necessary. Transbronchial biopsy may reveal the diagnosis if there is alveolar involvement, but is often nondiagnostic. Biopsy of other sites (e.g., skin, pericardium, muscle, nerve, gut), with or without immunostaining, may assist in establishing the diagnosis in selected cases, although demonstration of characteristic histopathologic changes are not essential for establishing the diagnosis. The diagnosis may be elusive since EGPA may be suppressed by corticosteroid treatment for asthma.

The differential diagnosis of EGPA includes polyarteritis nodosa, microscopic angiitis, granulomatosis with polyangiitis, CEP, ABPA, idiopathic HES, Loeffler syndrome, asthma, fungal or parasitic infection, drug-induced vasculitis, sarcoidosis, and Hodgkin lymphoma. EGPA can be distinguished from granulomatosis with polyangiitis since compared with the latter, patients with EGPA have nasal polyps and allergic rhinitis but lack significant necrotizing upper airway lesions and cavitation of lung nodules, and are more likely to have pANCA (in contrast to the c-ANCA seen in granulomatosis with polyangiitis). Also, patients with EGPA are less likely to develop renal failure, and vasculitic neuropathy and asthma/eosinophilia are not typical features of granulomatosis with polyangiitis. EGPA can be distinguished from MPO-ANCA–positive microscopic angiitis since patients with the latter syndrome have leukocytoclastic vasculitis without granulomas and do not have upper airway involvement, asthma, and eosinophilia. Further, unlike EGPA, cardiac involvement is rare in MPO-ANCA–positive vasculitis. EGPA may be difficult to distinguish from idiopathic HES among persons who lack ANCA and/or neuropathy without overt vasculitis.[200] EGPA is more likely among those with lower eosinophil counts who later develop vasculitis.

Patients in whom EGPA goes untreated have a poor prognosis; up to 50% die within 3 months after the onset of vasculitis. As such, efforts at early recognition and treatment are important.

Two randomized controlled trials of therapy for EGPA have been conducted recently.[201,202] The choice of treatment depends in part on the clinical features at the time of diagnosis, since the presence of some features portends a worse prognosis and requires a more aggressive treatment approach.[201–203] Poor prognostic features include age >65 years, cardiac, GI, CNS, and renal involvement (with serum creatinine >150 μmol/L) and absence of ENT involvement.[175,203] In persons *without* poor prognostic features, corticosteroids are the mainstay of treatment and generally lead to dramatic clinical improvement, with disease stabilization or cure. Prednisone, 1 to 1.5 mg/kg/d (or 60 mg per day in adults) is given for 3 to 12 weeks, aiming to eliminate constitutional symptoms and cardiac, renal, neurologic, or other vasculitic manifestations. Higher doses (e.g., 15 mg/kg/d methylprednisolone) are occasionally required for control of life-threatening symptoms. Severe hypertension and mononeuritis multiplex often require prolonged steroid treatment and may be difficult to eliminate. Once the vasculitic phase is controlled, steroids may be tapered, with doses titrated to maintain disease control. Low-dose prednisone (e.g., 5–10 mg) is often given every day or every other day for up to 1 year. Although relapses are uncommon, patients should be followed closely for evidence of clinical deterioration, and should have periodic screening of total WBC and differential, ESR, and IgE levels. Most reports suggest the pANCA is not useful to monitor disease activity or direct therapeutic intervention, but one recent case series demonstrated that ANCA-positive persons had more frequent relapses and lower 5-year relapse-free survival rates than ANCA-negative persons.[175] Treatment with cytotoxic immunosuppressive agents, such as cyclophosphamide or azathioprine, should be administered in patients whose condition fails to improve or have relapses despite steroid treatment.

Persons who have poor prognostic features at the time of disease presentation,[142,204] or who have severe systemic involvement should receive high-dose intravenous methylprednisolone or oral prednisone for 3 days plus induction therapy with cyclophosphamide (2 mg/kg/d orally or 0.6–0.7 g/m^2 intravenously day 1, 15, and 30 and then every 3 to 4 weeks theareafter).[205] Patients treated with cyclophosphamide should be monitored closely for hemorrhagic cystitis, renal insufficiency, bone marrow suppression, bladder fibrosis, and urologic malignancies. Patients with severe disease treated with corticosteroids and cyclophosphamide have better survival than those treated with corticosteroids alone. Azathioprine maintenance therapy (2 mg/kg/d) for 18 to 24 months may be beneficial once remission of disease has been achieved.[142,143,202]

Intravenous immunoglobulin (IvIg) may be beneficial for use in pregnant women and for reducing symptoms and organ involvement and improving long-term disease control among persons with severe organ involvement. The number of blood Treg cells was increased among persons with EGPA treated with IV Ig and conventional therapy.[206] The anti-IL5 antibody mepolizumab has also demonstrated efficacy as a steroid-sparing agent in small uncontrolled case series.[207,208] The immunoregulatory cytokine interferon-α (IFN-α) has led to improved pulmonary function tests, reduction in corticosteroid dose, and decreased WBC count and may be considered as another alternative treatment in persons with refractory disease[209] but may be of limited efficacy and can cause cardiac toxicity. Plasma exchange may also be a successful adjunct treatment in some patients,[142,210] particularly those with ANCA positivity and glomerulonephritis. Finally, rituximab may be effective as an alternate therapeutic agent but further studies are needed to clarify benefits of treatment in EGPA as compared with other forms of ANCA-positive vasculitis.[211] β-Blockers should be avoided in the management of EGPA-related hypertension, owing to the risk of bronchospasm and CHF. Persons undergoing immunosuppressive treatment for EGPA should receive prophylactic treatment to prevent infection with pneumocystis jirovecii.

Prolonged treatment may be necessary to maintain disease control. Long-term overall remission can be achieved in approximately 81% to 92% of patients[142,156]; relapses occur in 25% of cases and are most common within 1 year.[142] In a series of 30 patients collected over the period 1950 to 1974, a median survival of more than 9 years was reported in patients treated with steroids; 1-year survival was 90%, 3-year survival was 76%, and 62% survival was noted at 5 years. More recent studies suggest 85% to 100% survival at 5 years.[1,175,205]

IDIOPATHIC HYPEREOSINOPHILIC SYNDROME

Idiopathic HES is a rare disorder first described in 1968 by Hardy and Anderson. Over the ensuing years, many case reports of severe peripheral eosinophilia and diffuse organ infiltration with eosinophils were described. Several names – including *eosinophilic leukemia, Loeffler fibroplastic endocarditis,* and *disseminated eosinophilic cardiovascular disease* – were used to describe this disease entity. In 1975, Chusid et al. [212] revised the definition of HES to include only cases in which no other underlying cause of hypereosinophilia could be found. HES is now recognized as a clinically heterogeneous syndrome with a wide range of disease severity. Whereas some patients experience a mild, limited form of the disease with minimal involvement of noncritical organs (e.g., skin), others have life-threatening multiorgan dysfunction. Emerging evidence suggests that HES may indeed represent several diseases of distinct etiology that share several features in common.[213–215]

Current consensus defines hypereosinophilia as blood eosinophils $>1.5 \times 10^9$/L on two examinations separated by ≥1 month and/or tissue eosinophilia (defined as >20% of cells in a bone marrow specimen, tissue infiltration defined by a pathologist, and/or marked deposition of EDGP in tissue).[216] The term HES is defined as the presence of hypereosinophilia together with eosinophilic tissue infiltration and organ damage (in the absence of other identifiable cause). HES is a rare disorder. Although persons of any age may be affected, disease onset is most common between 20 and 50 years of age.[217,218] When it occurs in children it often heralds a clonal hematologic disturbance.[218] There is no known racial or ethnic predisposition. Familial cases with autosomal dominant transmission have been reported.

Clinical features and symptoms vary according to the organ system(s) affected. Presenting complaints are often nonspecific and include weakness, fatigue, low-grade fevers, myalgias, cough, angioedema, rash, retinal lesions, and dyspnea. Involvement of virtually every organ system has been described.

Several distinct clinical variants of HES have been recognized.[216,219] Three of the most common are:

1. The myeloproliferative variant (primary/neoplastic HES): In this variant there is clonal expansion of eosinophils related to stem cell, myeloid, or eosinophil neoplasms. Clinical features inlcude anemia, thrombocytopenia, hepatosplenomegaly, elevated leukocyte alkaline phosphatase, circulating immature leukocytes, and elevated B_{12} levels.[220] The most common chromosomal abnormality noted is deletion on 4q12, leading to fusion of genes for and constitutive activation of the tyrosine kinase fusion protein FIP1L1-PDGFRA.[221] Other chromosomal abnormalities have also been reported.
2. The lymphocytic variant (secondary, reactive HES, ~30% of cases): This variant is related to clonal expansion of Th2 T cells with an abnormal surface antigen phenotype (CD3−/CD4+) and increased production of IL-5.[222,223] Increased amounts of IL-4, IL-13, GMCSF, and hypergammaglobulinemia may be present.[224] Skin and soft tissue involvement are the predominant clinical features of this variant.
3. The idiopathic variant (~50% of cases): The disturbances present in the previously noted variants are lacking, but end-organ damage is present.[215]

The respiratory system is affected in an estimated 63% of patients with HES.[225] The most common symptoms include a predominantly nocturnal cough, which is either nonproductive or productive of small quantities of nonpurulent sputum, wheezing, and dyspnea (without evidence of airflow obstruction on spirometric examination). In general, respiratory manifestations are mild.[225] Pulmonary hypertension, ARDS, and pleural effusions (which may be due to CHF) have been reported but are rare. In patients with pulmonary manifestations, the chest radiograph or CT may reveal transient focal consolidation, ground glass opacities or diffuse pulmonary infiltrates (with no predilection for any particular distribution), small nodules, pleural effusion(s), adenopathy, or pulmonary emboli.[212,225] Histopathologic examination of affected lung specimens most commonly reveals intense interstitial infiltration with eosinophils. Less commonly, necrotic areas of parenchyma are found. These are believed to be due to pulmonary microemboli. In contrast to EGPA, significant vasculitis is not present.

Cardiac disease is the major cause of morbidity and mortality in patients with HES.[217,226] The most common cardiac manifestations are relentlessly progressive CHF due to eosinophilic myocarditis and endocarditis, intracardiac thrombi, and endocardial fibrosis.[217] Cardiac involvement in HES, which may be clinically silent, is believed to progress from an initial acute necrosis stage, followed by endocardial thrombus formation and eventually development of fibrosis, which may lead to restrictive cardiomyopathy or valvular dysfunction such as mitral regurgitation.[217] Intracardiac thrombus formation can lead to ischemic embolic events. Bacterial endocarditis has also been noted. The cardiac damage is believed to be mediated at least in part by EDGP . Elevation in serum troponin level can provide a clue to the presence of cardiac involvement in HES.[227] Disturbingly, cardiac involvement correlates poorly with the peripheral blood eosinophilia, hence echocardiographic follow-up at 6-month intervals is recommended. Cardiac MRI also detects eosinophil-mediated cardiac injury[228] or intracardiac thrombus.

Involvement of the central or peripheral nervous system, which occurs in up to 60% of patients, is also a major cause of morbidity.[229] Neurologic manifestations of HES include encephalopathy with neuropsychiatric dysfunction, memory loss, gait disturbances with or without signs of upper motor neuron injury, visual changes, and sequelae of thromboembolic events, including hemiparesis. Peripheral neuropathy with sensory and/or motor axonal loss (no vasculitic or eosinophilic infiltration) is extremely common in HES.

The bone marrow is universally affected with a striking eosinophilia (up to 25%–75% of the differential). Other hematologic manifestations are venous and arterial thromboembolism,[230] anemia, thrombocytopenia, elevated vitamin B_{12} levels, hepatosplenomegaly, and lymphadenopathy (in 12%–20%).

Cutaneous manifestations may include eczema, uritcaria, angioedema, nodular or papular lesions, skin thickening, erythroderma or dermatographia.[217,231] Mucosal ulcerations may develop. As noted, cutaneous manifestations are more likely seen among persons with the lymphocyte HES variant.[223] Urticaria or angioedema generally portend a benign prognosis. Persons with papules are likely to have the FIP1L1-PDGFRA variant.[232] GI (20–30% of patients), renal (10–20%), musculoskeletal, ocular, and endocrine manifestations are all also well described.

Laboratory findings associated with HES include peripheral blood eosinophilia >1.5 × 10^9/L,[212] an elevated total serum IgE (25%–38%), hypergammaglobulinemia, circulating immune complexes (32%–50%), and an ESR above 15 mm/h (68%). Anemia is likely in patients with the myeloproliferative variant.[233] Elevated serum B_{12} and leukocyte alkaline phosphatase levels are also noted. Fungal and parasitic serologies, as well as aspirates of body fluids for ova and parasites, are negative. Of interest is that whereas blood and BAL eosinophilia are both prominent in persons with pulmonary involvement, blood eosinophilia is present and BAL eosinophilia is absent in persons lacking pulmonary manifestations of the disease. This finding has raised the question whether BAL eosinophilia may serve as a marker for the development of pulmonary disease associated with HES.

The organ damage in HES is believed to be due to both eosinophilic infiltration of tissues[234,235] and tissue injury caused by thromboembolic events. Eosinophils probably contribute to tissue damage via antibody-mediated cytotoxicity and the release of toxic granule products such as major basic protein and eosinophil cationic protein. Elevated serum levels of eosinophil cationic protein and major basic protein have been reported, but they do not correlate universally with clinical disease severity. The precise events inciting the extreme eosinophilia in HES are unknown, but several mechanisms have been proposed, including overproduction or abnormal activity of cytokines leading to eosinophilia, and defects in cytokine signaling or signal transduction.

The diagnosis of HES is established by demonstrating multiorgan dysfunction, severe peripheral blood eosinophilia (>1.5 × 10^9/L) on two separate occasions in the absence of any other known causes of peripheral blood eosinophilia. Occasionally, the disease presents with the incidental finding of blood eosinophilia before development of other complications. The total peripheral leukocyte count is typically elevated to above 10,000 (typical range, 10,000 to 30,000), with a preponderance of eosinophils (up to 70%). The leukocytosis may be progressive. Eosinophilic blast transformation was reported to occur at some time during the course of the disease in 28% of 51 patients in one series. Tests recommended to assess for end-organ damage also include serum chemistries, liver function tests, CPK, troponin, EKG, echocardiogram, chest x-ray and/or CT, pulmonary function tests, abdominal CT scan, and tissue biopsy as indicated. Serum tryptase, vitamin B_{12} and Ig levels may also support the diagnosis.[236] In addition, patients with suspected HES should undergo bone marrow aspirate and biopsy, FIP1L1/PDGFRA mutation analysis, and T lymphocyte phenotyping by flow cytometry or karyotype analysis to evaluate for the HES subtypes noted earlier. Proper diagnosis of the HES subtypes has implications for choosing therapy for the disease.

The differential diagnosis of HES includes parasitic infection, acute eosinophilic leukemia, drug-induced hypersensitivity, EGPA, episodic angioedema with eosinophilia, tuberculous or fungal infection, allergic or autoimmune disease, other acute or CEPs, TPE, other lymphoproliferative disorders, and paraneoplastic syndromes. Patients with eosinophilic leukemia have immature eosinophils or blasts in the bone marrow and/or blood, whereas patients with HES typically do not. Patients with HES do not have asthma or vasculitis characteristically associated with EGPA, and patients with episodic angioedema typically lack the multiorgan involvement associated with HES.

Before the discovery of an effective therapy, the prognosis of HES was poor. In one early series, 81% of 48 patients died within 1 year of diagnosis. Overall, without therapy, average survival was 9 months, and 3- to 4-year survival was estimated at 10% to 12%.[212] The greatest mortality occurs within the first year after diagnosis. Death may occur from refractory CHF, azotemia, hepatic failure, venous thromboembolism, a perforated abdominal viscus, or infection. Persons with the myeloproliferative variant of HES (especially those with FIP1L1/PDGFRA positive disease) tend to have an aggressive course with high mortality without treatment. The advent of effective therapy for HES has led to a marked improvement in median survival to more than 10 years.

Patients with the incidental finding of peripheral eosinophilia but without evidence of end-organ dysfunction can be followed closely at 3- to 6-month intervals without specific treatment, as they tend to follow a benign course. Patients should be monitored routinely at 6-month intervals with chemistries, EKG, echocardiogram, and pulmonary function tests as well as monitored for clinical signs of thrombotic complications. Additional monitoring and testing should be done as indicated depending on symptoms and other known organ involvement.

The tyrosine kinase inhibitor imatinib mesylate (initial dose 400 mg per day) is the first line therapy for all patients with the PDGFRA-positive variant of HES.[214,221,237,238] Persons with cardiac involvement should receive concomitant systemic corticosteroid therapy, to avoid further cardiac damage potentially induced by imatinib.[239] Case reports have suggested other tyrosine kinase inhibitors, nilotinib and sorafenib, can be effective alternate therapies in cases of resistance to imatinib therapy.[240,241]

A mainstay of therapy for persons with HES and organ involvement who lack FIP1L1/PDGFRA fusion or other imatinib responsive mutation includes corticosteroids such as prednisone at 1 mg/kg/d for several weeks, with taper of dose attempted to an every-other-day regimen once eosinophil levels are reduced. The mechanisms by which steroids are effective in this disorder are not fully clear. If the disease stabilizes or resolves (e.g., if blood eosinophilia and symptoms are controlled), corticosteroids can be tapered gradually to alternate-day dosing, and should be continued for approximately 1 year at the minimal dose that effectively controls disease activity.[214]

IFN-α, a mediator that suppresses eosinophil function in vitro, has been beneficial in management of HES, perhaps by inhibiting eosinophil proliferation and differentiation. IFN-α should be tried as a second-line agent among patients with HES who fail to respond to corticosteroid treatment or as a steroid-sparing agent for persons requiring high-dose corticosteroids.[214] IFN-α monotherapy should be avoided among persons with lymphocyte-variant disease.[242] Pegylated interferon may be an effective alternate therapy in selected cases.[243] Existing data suggest that another anti-eosinophil strategy, the anti–IL-5 antibody mepolizumab, may reduce symptoms and eosinophilic organ involvement associated with HES, and may be particularly helpful as a steroid-sparing agent in patients with high IL-5 levels (e.g., persons with lymphocyte variant HES lacking the FIP1L1/PDGFRA fusion gene).[244,245] Case reports have also demonstrated efficacy of the anti–CD-52 antibody alemtuzumab that targets eosinophils and T cells in the lymphocyte variant of HES.[246–248]

Hydroxyurea (0.5–1.5 g per day) may be added to the regimen if there is evidence of further disease progression or steroid toxicity,[214] with the aim of reducing the peripheral leukocyte count to the range of 5000 to 10,000. Vincristine may be used as a chemotherapeutic inducing agent in patients with extremely high peripheral WBC counts. Etoposide, chlorambucil, and other chemotherapeutic agents may be effective alternative agents for cases that prove refractory to standard treatment with corticosteroids. Cyclosporine may also be of benefit in controlling the disease, especially when used in combination with corticosteroids.

Allogeneic bone marrow transplantation has also been reported anecdotally to be successful in selected severe cases of HES in which end-organ damage is potentially reversible.[249]

Leukapheresis affords no clear benefit unless there is elevated blood viscosity with associated coagulation. Antiparasitic agents and radiation therapy are ineffective. Anticoaguation with warfarin and/or antiplatelet agents may be needed for management of thromboembolic events.

Favorable prognostic features include a rapid clinical response to treatment with reduction in blood eosinophilia, the presence of angioedema, an elevated IgE, and absence of findings associated with myeloproliferative disorder.[217,236,250,251] Factors associated with a poor prognosis include presence of total blood WBC greater than 100,000/mm^3, myeloblasts in the peripheral blood, refractory CHF, basophilia above 3%, identifiable chromosomal abnormalities in bone marrow cells, and elevated serum B_{12} levels. The mechanisms by which these features are associated with a given prognosis are largely unknown.

APPROACH TO THE EVALUATION OF EOSINOPHILIC PNEUMONIAS

In approaching the patient with pulmonary infiltrates and eosinophilia, one must first establish whether the patient has one of the eosinophilic disorders described in this chapter or a disease process that is secondarily associated with eosinophilia (Table 71-1). A useful algorithmic approach to the evaluation of patients with pulmonary infiltrates and eosinophilia (blood or lung) is shown in Figure 71-6. A careful search for the cause of the disease should be undertaken. A comprehensive medical history should be elicited, with particular attention paid to any antecedent illness (e.g., atopy, rhinitis, asthma, steroid use, immunosuppression), disease exposures, travel, and the duration and nature of the patient's symptoms. One should take special notice of the sequence and timing of events during the course of the illness. In addition to a careful chest examination, a search should be undertaken for physical findings suggestive of extrapulmonary disease (e.g., skin lesions, CHF, hypertension, neurologic abnormalities, musculoskeletal disorders, or GI illness). The nature, distribution, and duration of infiltrates on chest radiograph should be noted. CT scanning of the chest can also provide additional information that may not be apparent on the chest radiograph.

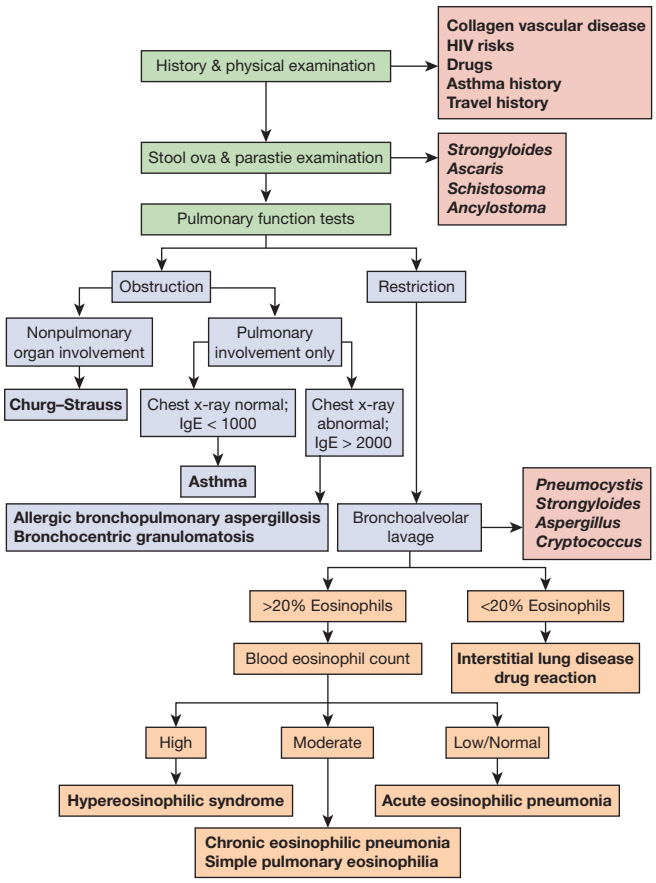

Figure 71-6 Algorithmic approach to evaluation of patients with pulmonary infiltrate and eosinophilia. *(Data from Allen JN, Davis WB. Eosinophilic lung diseases. Am J Respir Crit Care Med. 1994;150: 1423–1438.)*

The workup should include the following additional laboratory data: complete blood count (CBC) with differential, ESR, IgE level, ECG, blood urea nitrogen (BUN), creatinine, liver function tests, urinalysis, sputum cultures, and, when appropriate, sputum cytology. Serologies (e.g., *Aspergillus* precipitins, ANCA, antiparasitic antibodies) are indicated in selected cases. Bronchoscopy with BAL or transbronchial biopsy is important in the evaluation of pulmonary eosinophilic syndromes. The advent of BAL has allowed diagnosis of most cases of eosinophilic pneumonia without open lung biopsy. Normally, BAL fluid contains less than 2% eosinophils. In contrast to diseases associated secondarily with eosinophilia, all the primary pulmonary eosinophilic syndromes are characterized by prominent BAL eosinophilia (more than 20% of the BAL leukocyte differential). The finding of more than 20% BAL eosinophils, viewed in combination with appropriate clinical and radiographic features, is strongly suggestive of the diagnosis of one of these syndromes. BAL and transbronchial biopsy are also useful in ruling out infections (bacterial, fungal, tuberculous, and parasitic), malignancies, and other causes of eosinophil-associated disease. It must be kept in mind that in the context of the overall list of pulmonary diseases associated with more than 5% BAL eosinophilia, the true pulmonary eosinophilic syndromes are rare.

The pulmonary eosinophilic syndromes are at times difficult to distinguish from one another, owing to the substantial amount of overlap among their clinical, radiographic, and histologic features, as well as variable features at different stages of disease. The comparative features of the eosinophilic pneumonias described in this chapter, with regard to several key features, are shown in Table 71-7. The clinical presentation may be acute, subacute, or chronic. Disease may range from mild and self-limited to severe and life-threatening illness. To varying degrees in all the pulmonary eosinophilic syndromes, dyspnea, malaise, low-grade fever, cough, and wheezing are common presenting complaints. Of the diseases considered in detail in this chapter, only EGPA and HES are consistently associated with significant extrapulmonary manifestations. Radiographic infiltrates may be transient in Loeffler syndrome, TPE, EGPA, ABPA, and HES. Blood eosinophilia is present in all the diseases discussed except idiopathic AEP and in a minority of cases of CEP. Variable degrees of elevation of serum IgE are also present. Pulmonary function abnormalities are not specific for these disorders. Except for the diseases caused by parasites, corticosteroids are the mainstay of therapy.

Although the eosinophilic pneumonias can, at times, pose diagnostic difficulties, it is crucial to establish an accurate diagnosis whenever possible. An accurate diagnosis is important because the dose and duration of steroid treatment, prognosis, and follow-up measures for each of these diseases vary widely, and initiation of other specific therapeutic interventions improves outcomes in selected situations. Furthermore, chronic fibrotic lung disease may result from failure to accurately diagnose and treat some of these disorders in a timely fashion, and misdiagnosis with resultant inappropriate therapy (e.g., high-dose steroid treatment of invasive fungal infection masquerading as CEP) may be catastrophic.

TABLE 71-7 Comparative Features of the Pulmonary Eosinophilic Syndromes

	Loeffler's	AEP	TPE	CEP	ABPA	EGPA	HES
Clinical course	Acute	Acute	Acute, subacute, chronic	Subacute	Acute, subacute, chronic	Acute, subacute, chronic	Subacute, chronic
Respiratory Symptoms	Self-limited, mild	Severe	Severe	Mod.–severe	Mod.—severe	Mod.–severe	Mild
H/o allergic disease/asthma	—	±	—	+(30–60%)	Nearly 100%	100%	—
Blood eosinophilia	Mod. to extreme, transient	Absent (delayed)	Extreme	Moderate in most	Typical	Extreme, fluctuating	Extreme, persistent
Sputum/BAL eosinophilia	Prominent	Striking	Prominent	Striking	In some	Prominent	Striking
Elevated serum IgE	±	Moderate elev. in some	High elev.	Mod.–elev. in 50%	Marked elev., fluctuates w/disease	Mod.–elev.	Mod.–elev. in some
Etiologic agent	*Ascaris* spp. *Ancylostoma*, *Strongyloides*, drugs	Unknown	Filarial infection	Unknown	*Aspergillus* (or other fungus)	Unknown	Unknown
Radiographic findings (CXR, CT)	Patchy, often peripheral unilateral or bilateral consolidation and GGO; usually transient, migratory, nonsegmental	Diffuse, alveolar and interstitial GGO and airspace opacities, interlobular septal thickening, pleural effusion	Diffuse, reticulonodular	Predominately, peripheral consolidation and GGO; "photographic negative of pulmonary edema"	Upper lobe–predominant proximal bronchiectasis	Transient, migratory peripheral, rarely diffuse; patchy peribronchial and septal thickening, patchy parenchymal GGO or consolidation, pleural effusion	Transient, focal or diffuse GGO or consolidation
PFTs	± Mild RVD	RVD	OVD early, RVD late, or mixed pattern	Normal, OVD, or RVD	OVD ± RVD	OVD ± RVD	Mild RVD in some
Characteristic diagnostic findings	*Ascaris* larvae in sputum, BAL, gastric aspirate	None	Filaria-specific IgE, IgG, microfilaria in LN/lung	None	See Table 71-5	Histopathology plus appropriate clinical setting	Extreme persistent eosinophilia and multiorgan dysfunction (no other evident cause)
Vasculitis	None	None	None	Occasionally mild, nonnecrotic	None	Characteristic (see text)	None
Extrapulmonary manifestations	GI late, if untreated	None	Cardiac, CNS rare	Very rarely reported	None	Typical of vasculitic phase	Cardiac, neurologic, GI, hematologic, other
Therapy	Mebendazole, if *Ascaris* or hookworm; removal of drug or toxin exposure ± steroids	Corticosteroids	Diethylcarbamazine, Ivermectin	Corticosteroids	Corticosteroids, bronchodilators, antibiotics, antifungals	Corticosteroids, other immunosuppressives (see text)	Depends on disease variant (see text)
Chronic/recurrent disease	None	None	May occur	Common	Typical	May occur (~25%)	Chronicity typical

+, yes or present; −, no or not present; BAL, bronchoalveolar lavage; CT, computed tomography; elev., elevated; GGO, ground-glass opacity; GI, gastrointestinal; h/o, history of; LN, lymph node; mod., moderately; OVD, obstructive ventilatory defect; CXR, chest x-ray (radiograph); PFTs, pulmonary function tests; RVD, restrictive ventilatory defect.

CHAPTER 72

Pulmonary Arterial Hypertension

Darren B. Taichman
Jess Mandel
Kimberly A. Smith
Jason X.-J. Yuan

Pulmonary arterial hypertension (PAH) is a progressive disease of the pulmonary vasculature in which an ever increasing resistance to circulatory flow imposes a mounting afterload for the right heart to overcome. Without therapy, and frequently despite it, patients with PAH suffer progressive and inexorable right heart failure, functional decline, and ultimately die. Although rapid progress has resulted in the availability of therapy that can improve the outlook for many patients, long delays in disease recognition are common, exposing patients to prolonged suffering and potentially irreversible harm.

PAH is one of several possible causes of pulmonary hypertension. Pulmonary hypertension is defined as a mean pulmonary artery pressure greater than or equal to 25 mm Hg at rest. It can be due to diseases primarily isolated to the pulmonary vasculature itself, as in PAH, or can be a complication of other diseases, including hypoxemic lung disorders (e.g., chronic obstructive pulmonary disease [COPD]), left heart disease (e.g., systolic, diastolic, or valvular dysfunctions), or thromboembolism.[1,2] Identification of its cause is essential, as appropriate therapy for pulmonary hypertension is aimed at its underlying cause—be that repair of a stenotic mitral valve, bronchodilators for obstructive lung disease or, in the case of PAH, the use of advanced therapies targeted at the pulmonary vasculature.

CLASSIFICATION OF THE PULMONARY HYPERTENSIVE DISEASES

A "sclerosis of the pulmonary arteries" ("Uber Sklerose der Lungen Arterie") without identifiable cause was first described by Ernst von Romberg in 1891.[3] Exclusively descriptive reports of pathologic findings continued until the 1950s when the development of catheterization techniques allowed for hemodynamic evaluation. Using such methods, Dresdale and colleagues described a hypertensive vasculopathy of the pulmonary circulation involving vasoconstriction, elevation of pulmonary arterial pressures (PAPs), and a measurable response to the injection of the nonselective alpha adrenergic antagonist tolazoline.[4] No cause could be identified for the pulmonary arteriopathy and the term primary pulmonary hypertension (PPH) was introduced.[5]

Subsequent classification schemes for diseases-causing pulmonary hypertension have been adopted by international consensus panels. These have evolved from systems based primarily on histopathologic findings to a current model that emphasizes the grouping of entities according to similarities in hemodynamic and clinical characteristics (Table 72-1).[6] Importantly, accurate classification of pulmonary hypertension is essential to guide the rational and appropriate use of medications.

It is important to note the specific nomenclature purposefully adopted in the current classification scheme. The group of patients with PAH is identified as distinct from those patients with other causes of pulmonary hypertension (e.g., due to chronic left heart or respiratory disease). This grouping recognizes similarities in the histologic and many clinical features of patients with identifiable genetic causes of PAH (i.e., those with heritable PAH), collagen vascular or other diseases known to be associated with PAH (Associated PAH), and patients in whom no known associated entity or genetic cause has

TABLE 72-1 Updated Classification of Pulmonary Hypertension[a]

1.	Pulmonary arterial hypertension
1.1	Idiopathic PAH
1.2	Heritable PAH
1.2.1	BMPR2
1.2.2	ALK-1, ENG, SMADS, CAV1, KCNK3
1.2.3	Unknown
1.3	Drug and toxin induced
1.4	Associated with:
1.4.1	Connective tissue disease
1.4.2	HIV infection
1.4.3	Portal hypertension
1.4.4	Congenital heart diseases
1.4.5	Schistosomiasis
1′	Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis
1″.	Persistent pulmonary hypertension of the newborn (PPHN)
2.	Pulmonary hypertension due to left heart disease
2.1	Left ventricular systolic dysfunction
2.2	Left ventricular diastolic dysfunction
2.3	Valvular disease
2.4	Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
3.	Pulmonary hypertension due to lung diseases and/or hypoxia
3.1	Chronic obstructive pulmonary disease
3.2	Interstitial lung disease
3.3	Other pulmonary diseases with mixed restrictive and obstructive pattern
3.4	Sleep-disordered breathing
3.5	Alveolar hypoventilation disorders
3.6	Chronic exposure to high altitude
3.7	Developmental lung diseases
4.	Chronic thromboembolic pulmonary hypertension (CTEPH)
5.	Pulmonary hypertension with unclear multifactorial mechanisms
5.1	Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy
5.2	Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis
5.3	Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
5.4	Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure, segmental PH

[a]5th WSPH Nice 2013. Main modifications to the previous Dana Point classification are in bold.
BMPR2, bone morphogenetic protein receptor type II; CAV1, caveolin 1; ENG, endogin; HIV, human immunodeficiency virus; PAH, pulmonary arterial hypertension.

been found. This last group is referred to as having idiopathic PAH (IPAH). IPAH replaces the previously (and often loosely) used term "PPH." Abandonment of the term "primary" also is important as a means of discouraging the use of the confusing and clinically inappropriate term "secondary" pulmonary hypertension. Use of such "primary" and "secondary" groupings may inappropriately suggest clinical similarities among the many very different diseases previously referred to as "secondary" pulmonary hypertension (e.g., patients with COPD and those with congenital heart disease). It may also promote a failure to recognize important similarities in clinical features (including appropriate treatment) between what was previously called "primary" pulmonary hypertension and entities inappropriately labeled "secondary" (e.g., patients with Eisenmenger syndrome or HIV infection).

DETERMINANTS OF PULMONARY ARTERY PRESSURE AND PULMONARY VASCULAR RESISTANCE

The pulmonary circulation normally is a high-flow, low-resistance, low-pressure system that carries blood into the pulmonary microcirculation where the blood takes up oxygen and unloads excess carbon dioxide. From early childhood to the fifth decade of life, the mean PAP is approximately 20 mm Hg.[7] PAP is the product of cardiac output (CO) and pulmonary vascular resistance (PVR) as shown in equation 1 (Eq. 1), where PVR is the vascular resistance of the entire lung, including the pulmonary arteries, capillaries, and veins.

$$PAP = CO \times [PVR_{arteries} + PVR_{capillaries} + PVR_{veins}] \quad \text{(Eq. 1)}$$

From this equation, it is clear that PAP can be raised by an increase in CO or an increase in arterial, capillary, or venous resistance. It would be expected then, that during periods of increased CO, such as during strenuous exercise, there would be a significant increase in PAP. However, in a normal healthy individual, the PAP is only slightly increased during periods of increased CO due to the compensatory increase in the cross-sectional area of the pulmonary vascular bed (due to recruitment of previously unperfused vessels and distension of vessels) resulting in a decreased PVR. Arterial distension and optimal recruitment are dependent upon the compliance of the blood vessel walls. Loss of this compliance due to vascular remodeling leads to pulmonary hypertension. As demonstrated in Eq. 1, an increase in PVR of any of the three components of the pulmonary vasculature can lead to an increase in PAP.[8]

Eq. 1 demonstrates the physical laws that govern blood flow in the lungs. To further understand and use this equation, we must know its physical and anatomical foundations. When a liquid (e.g., blood) flows through a cylindrical tubular structure (e.g., a blood vessel), the resistance (e.g., PVR) is inversely proportional to the fourth power of the radius of the lumen of the tube. This is demonstrated by the Poiseuille equation (Eq. 2), where L is the length of the tube (or vessel), r is the inner radius of the tube, and η is the coefficient of viscosity of the liquid (blood). Therefore, even small changes in the radius of a vessel can significantly change the PVR.[8]

$$PVR = (8L\eta)/\pi \times 1/r^4 \quad \text{(Eq. 2)}$$

PULMONARY VASCULAR STRUCTURAL AND FUNCTIONAL CHANGES IN PULMONARY HYPERTENSION

Regardless of the initial genetic or pathogenic trigger, the increased PVR seen in pulmonary hypertension can be attributed to the collective effects of sustained vasoconstriction, vascular remodeling, in situ thrombosis, and increased arterial wall stiffness (Fig. 72-1).[8–13] A rise in cytosolic free Ca^{2+} concentration ($[Ca^{2+}]_{cyt}$)

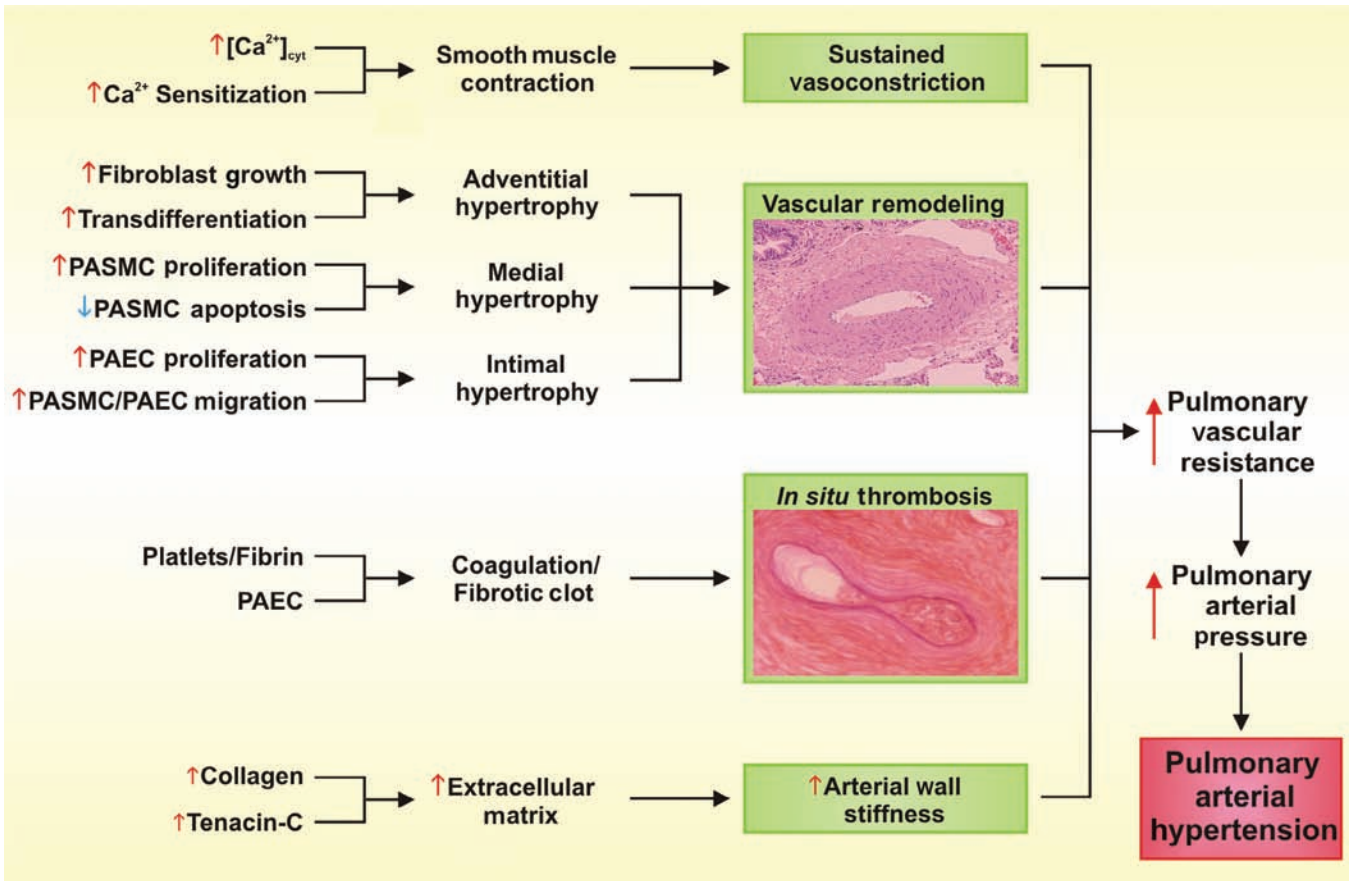

Figure 72-1 Schematic illustration of pathophysiologic components contributing to the development of increased pulmonary vascular resistance, pulmonary arterial pressure, and pulmonary arterial hypertension. *(In situ thrombosis figure reproduced with permission from Zwicke D. PAH and pregnancy: Physiological changes, challenges, and outcomes. Advances in Pulmonary Hypertension. Fall; 2011;10(3).)*

in pulmonary arterial smooth muscle cells is a major trigger for vasoconstriction and a key stimulus for pulmonary arterial smooth muscle cell proliferation and migration, which contributes to vascular remodeling.

SUSTAINED VASOCONSTRICTION

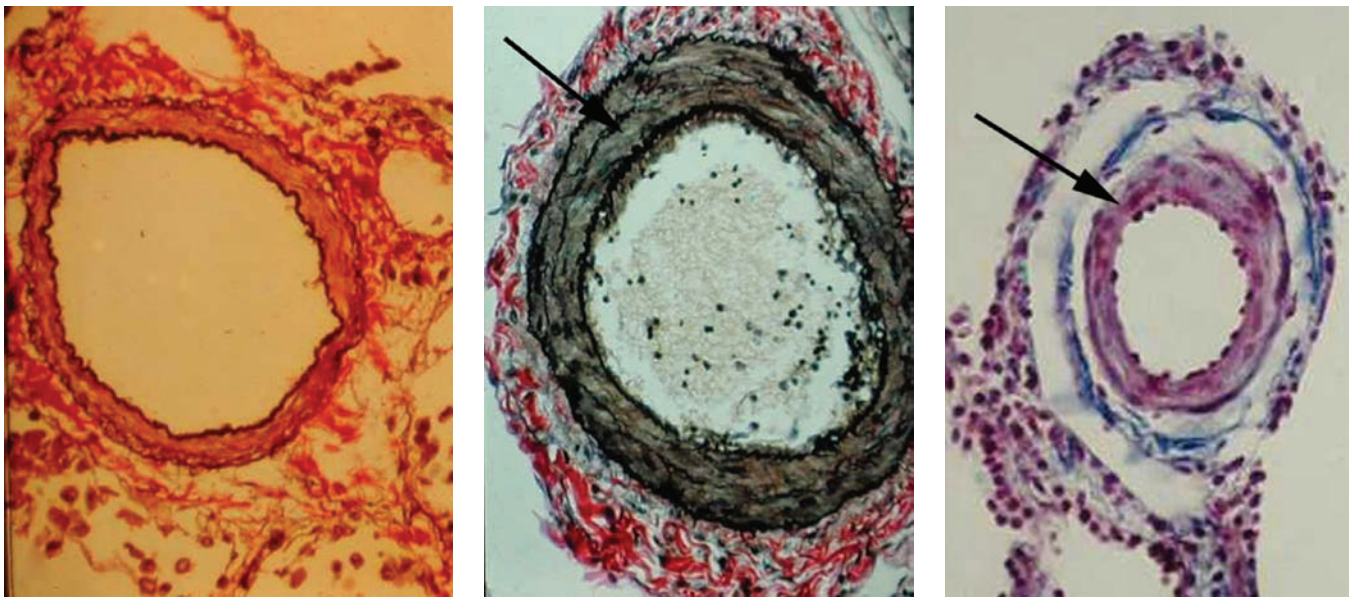
Pulmonary vasoconstriction can be a major contributor to increased PVR and hence PAP. Vasoconstrictive lesions include medial hypertrophy involving an increase in the number and size of pulmonary arterial smooth muscle cells. The elevated PAP and sustained vasoconstriction in PAH can, in turn, enhance pulmonary arterial smooth muscle cell hypertrophy and hyperplasia.[14] Marked smooth muscle hypertrophy can eventually cause medial atrophy, fibrosis, and the subsequent thinning of the media and dilation of the vessel lumen. Extension of pulmonary arterial smooth muscle cells into vessels normally only partially muscularized or nonmuscularized is a common and often prominent feature of precapillary vessels (Fig. 72-2).[15]

Hypoxic pulmonary vasoconstriction is an adaptive mechanism important for redirecting blood flow away from poorly ventilated areas of the lung and into the better ventilated areas to maximize the ventilation–perfusion matching and optimize oxygenation of blood.[16–19] Hypoxia induces vasoconstriction in isolated pulmonary arteries without the endothelium and also induces contraction in a single isolated pulmonary arterial smooth muscle cell model, indicating that hypoxic pulmonary vasoconstriction is an intrinsic property of pulmonary arterial smooth muscle cells. In chronic hypoxia, two factors contribute to increased PAP: vascular remodeling due to pulmonary arterial smooth muscle cell proliferation and sustained vasoconstriction and structural changes that develop within a matter of weeks.[20,21] This remodeling is characterized by thickening of the media of the small pulmonary arteries and arterioles, and by peripheral extension of muscle into minute pulmonary vessels that are normally devoid of muscle (Fig. 72-2).[22] Although the precise mechanism by which hypoxia induces pulmonary vasoconstriction is still somewhat unclear, the signaling pathways initiated in response to acute and chronic hypoxia seem to relate, at least in part, to disrupted Ca^{2+} homeostasis.[8,23]

VASCULAR REMODELING

The thickness and tissue mass of the pulmonary arterial walls are maintained at an appropriate level by a fine balance between proliferation and apoptosis of fibroblasts, pulmonary arterial smooth muscle cells, and pulmonary arterial endothelial cells. Thickening of the wall and luminal narrowing and eventual obliteration can occur if the balance is tipped in favor of cell proliferation. These structural changes that lead to hypertrophy and/or luminal occlusion are referred to as pulmonary vascular remodeling.[24–26] The precise cellular and molecular mechanisms contributing to vascular remodeling are extremely complex. However, vasoconstriction and cellular proliferation share a common pathway. Increased proliferation and hypertrophy of pulmonary arterial smooth muscle cells have been implicated in the development of PAH and these processes, like vasoconstriction, relate in part to disturbed Ca^{2+} homeostasis.[7] Resting $[Ca^{2+}]_{cyt}$ is increased in proliferating pulmonary artery smooth muscle cells compared to growth-arrested cells, demonstrating a role for enhanced Ca^{2+} in both proliferation and vasoconstriction.[27,28] In addition to increased proliferation, decreased apoptosis has been implicated in the development and maintenance of severe pulmonary hypertension,[29] and induction of apoptosis has been shown to promote the regression of hypertrophied pulmonary vascular walls in animal experiments.[30] Hypoxia can induce proliferation of pulmonary arterial adventitial fibroblasts, and in pulmonary hypertension patients, hypoxia induces the appearance of α-smooth muscle actin in the proliferative and matrix-producing fibroblasts, suggesting these cells have transdifferentiated into myofibroblasts.[31] Therefore, fibroblasts may play an important role in vascular remodeling due to hypoxia.

Complex lesions such as plexiform lesions also contribute to vascular remodeling. Plexiform lesions are aneurysmatic dilations of a muscular artery that can occur in very small arteries and arterioles.[8,32] These lesions are often found in patients with IPAH, but they



A B C

Figure 72-2 Vascular remodeling. As compared with a normal vessel (**A**), hypertrophy of smooth muscle cells *(arrow)* is seen in the pulmonary artery of a patient with pulmonary arterial hypertension (**B**). Extension of muscle *(arrow)* into normally nonmuscularized small intra-acinar pulmonary vessels is another prominent feature of pulmonary arterial hypertension (**C**). *(Reproduced with permission from Taichman DB, Snow JL, Pietra GG. Histopathology of pulmonary arterial hypertension. In: Pulmonary Vascular Disease, Mandel J, Taichman DB. Philadelphia: WB. Saunders; 2006.)*

also occur in the lungs of patients with severe PAH associated with left-to-right cardiac shunts, HIV infection, liver cirrhosis, and scleroderma. Although not pathognomonic, the plexiform lesion has been the focus of many studies of the cellular and molecular pathogenesis of PAH.[33–36] They contain collections of proliferating endothelial and smooth muscle cells, together with myofibroblasts and matrix proteins that can partially or completely occlude the vessel lumen. Narrowing or complete obliteration of the parent vessel by intimal thickening is a frequent associated finding, as is destruction of its media. Plexiform lesions often coexist with other obliterative vascular changes such as concentric laminar intimal thickening.[37]

The origin of plexiform lesions is complex and somewhat controversial. Originally, plexiform lesions were considered a congenital malformation.[38] Currently, there are investigators who believe that plexiform lesions develop due to the proliferation of pulmonary arterial smooth muscle cells that transform into myofibroblasts.[39–41] Other investigators propose that, in IPAH patients, plexiform lesions develop due to an endothelial-initiated response to cytokines, growth factors, or vascular injury.[39,41,42] Endothelial cells isolated from the plexiform lesions of IPAH patients proliferate in a monoclonal fashion. However, plexiform lesions from patients with forms of pulmonary hypertension other than IPAH develop from a polyclonal cell population, suggesting different mechanisms contribute to plexiform lesion development in different forms of PAH.[8,43]

IN SITU THROMBOSIS

Monoclonal proliferation of pulmonary arterial endothelial cells, pulmonary arterial smooth muscle cell migration, and accumulation of circulating inflammatory cells, platelets, and progenitor cells can result in occlusion of smaller vessels.[11,42] Thrombosis is frequently seen within the small vessels of patients with PAH. This occurs without evidence of a remote (embolic) source of the thrombus,[44–47] suggesting a local imbalance of pro- and anticoagulant forces. Activation and altered function of the endothelium leading to a shift from anti- to procoagulant activities might be due to the effects of shear stress associated with elevated pressure and/or flow. In addition to altered endothelial cell activity, platelets also promote thrombus formation by releasing vasoactive and mitogenic factors such as thromboxane metabolites and serotonin.[48] These, as well as other platelet-derived products (e.g., platelet-derived growth factor [PGDF], transforming growth factor-beta (TGFβ), and vascular endothelial growth factor [VEGF]) likely also contribute to the remodeling of vessel walls seen in PAH.

INCREASED ARTERIAL WALL STIFFNESS

Increased arterial wall stiffness can also contribute to increased PVR.[49,50] The normal turnover of extracellular matrix proteins is accelerated with remodeling of the vasculature in PAH patients.[51,52] The expression of tenascin-C, for example, is increased in experimental pulmonary hypertension induced by either monocrotaline in rats or increased blood flow in swine.[53–55] Indeed, inhibition of tenascin-C expression by antisense RNA ameliorates monocrotaline-induced pulmonary vascular lesions.[56] Elevated levels of this extracellular matrix protein are also seen on pulmonary arteries of patients with PAH.[57,58] Decreased vascular compliance resulting in the inability to recruit previously unperfused vessels due to increased parenchymal stiffness can also contribute to the development of PAH.[11,42] As a result, there is little capacity for distention and modest increases in pulmonary blood flow can elicit disproportionate elevations in PAPs. This situation is in marked contrast to that of the normal pulmonary circulation, in which an amputation of considerable lung parenchyma rarely suffices, per se, to raise PAPs to pulmonary hypertensive levels, as the remaining vessels retain their normal high capacitance. In some interstitial lung diseases, such as progressive systemic sclerosis, the parenchymal disease and the pulmonary vascular disease can evolve independently. In other connective tissue disorders, such as systemic lupus erythematosis, combinations of interstitial disease and intrinsic vascular abnormalities can contribute to pulmonary hypertension. While there are many structural changes in the pulmonary vasculature that lead to the development of PAH, vasoconstriction and vascular remodeling characterized by intimal, medial, and adventitial hypertrophy are the major structural changes that contribute to the increased PVR/PAP seen in PAH patients.

No single histologic feature distinguishes between the clinical PAH diagnoses. Each of the changes described can be seen in varying proportions in all clinical forms of PAH. For example, the vascular remodeling seen in chronic hypoxia-induced pulmonary hypertension is virtually indistinguishable from that seen in IPAH.[8] The predominant causes of the increased PVR in patients with PAH are sustained vasoconstriction, vascular remodeling, in situ thrombosis, and increased arterial wall stiffness. Persistent pulmonary hypertension, regardless of the cause, can ultimately lead to the development of cor pulmonale with hypertrophy of the right ventricle, its eventual dilation, and ultimately its failure (Fig. 72-3).

PATHOGENIC MECHANISMS OF PULMONARY HYPERTENSION

The pathogenic mechanisms leading to pulmonary hypertension have been conceptualized in six categories (Table 72-2): (1) *passive,* due to obstruction to pulmonary venous outflow (e.g., fibrosing mediastinitis, mitral stenosis, or left heart failure); (2) *hyperkinetic,* due to abnormally high pulmonary blood flow (e.g., left-to-right shunts); (3) *obstructive,* due to pulmonary thromboembolic disease; (4) *obliterative,* due to destruction of the pulmonary vascular bed by parenchymal proliferative disease; (5) *vasoconstrictive,* due to hypoxic vasoconstriction; and (6) *idiopathic* (i.e., without discernible cause).[59] Each mechanism leads to pulmonary vascular remodeling discussed previously, though the progression and reversibility may vary between entities. Other anatomic alterations can be seen in several categories and, over time, distinctions between categories tend to become blurred (e.g., thrombosis may complicate obliterative vascular disease). Also, by the time pulmonary hypertension becomes manifest clinically, the pulmonary arterial tree has undergone considerable remodeling that limits its area and distensibility.

These mechanisms share commonality with the clinical classification of pulmonary hypertension, though overlap of mechanisms occur. The most clearly linked is chronic thromboembolic pulmonary hypertension (CTEPH) with the obstructive mechanism. The most common form of pulmonary hypertension, that related to left heart failure, can also closely be tied to its passive mechanism along with fibrosing mediastinitis, which is classified in group 5 with unclear multifactorial mechanisms. Pulmonary hypertension owing to lung diseases and/or hypoxia, group 3, can be understood as having two primary pathogenic mechanisms, vasoconstrictive in the chronic hypoxic subset and obliterative in the parenchymal disease/fibrosis subset, though these two often overlap. Group 5, pulmonary hypertension with unclear multifactorial mechanisms by definition contains multiple pathogenic mechanisms. Group 1 remains the most diverse and difficult to equate to a particular mechanism as hyperkinetic, vasoconstrictive, obliterative, and other idiopathic mechanisms all contribute to disease pathophysiology.

GENETIC, CELLULAR, AND MOLECULAR MECHANISMS OF PULMONARY ARTERIAL HYPERTENSION

The development of PAH involves increased PVR due to sustained vasoconstriction, vascular remodeling, in situ thrombosis, and increased atrial wall stiffness (Fig. 72-1). Abnormalities in the expression of numerous vasoactive mediators, vasoconstriction mediators, growth factors, and cytokines cause, or result from

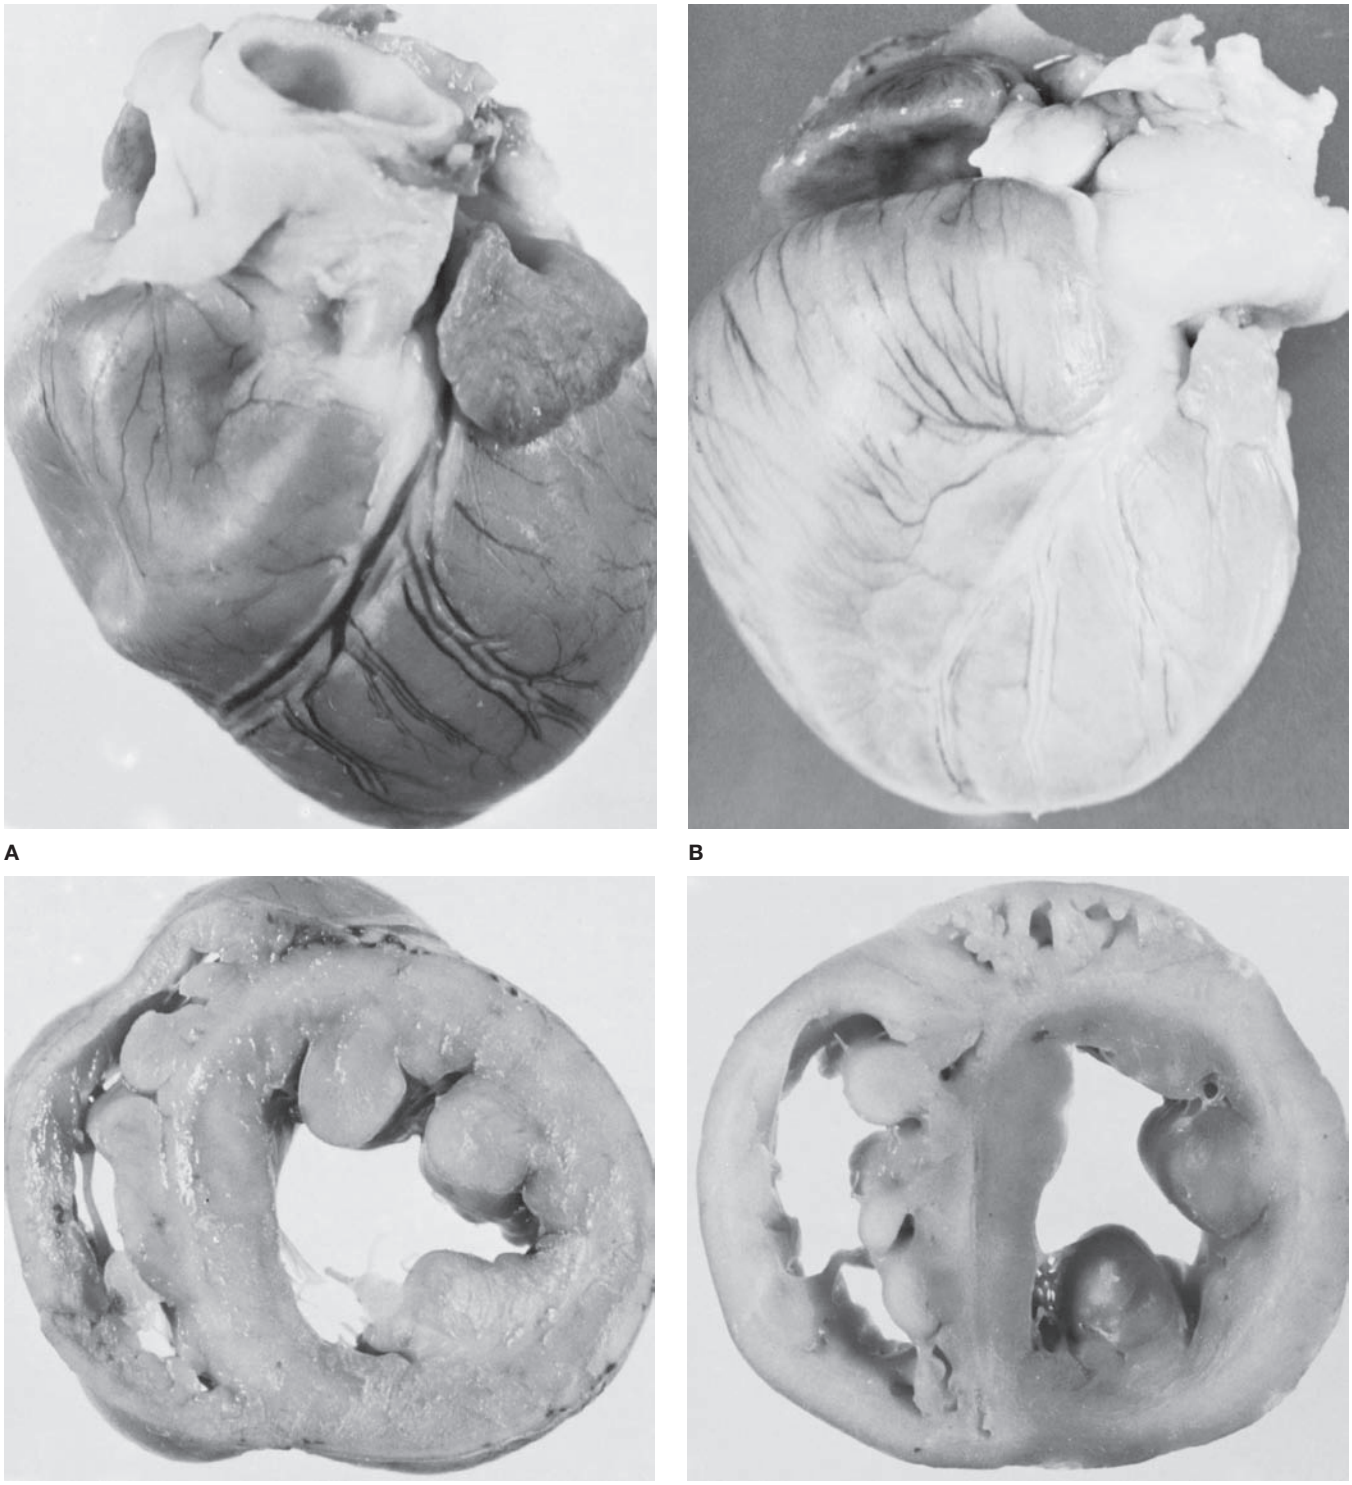


Figure 72-3 Cor pulmonale in experimental pulmonary arterial hypertension in the dog. **A.** Normal heart. **B.** Chronic cor pulmonale secondary to severe pulmonary arterial hypertension. **C.** Cross section of normal heart to show thin wall of the right ventricular cavity. **D.** Cross section of heart with chronic cor pulmonale to show hypertrophy of the right ventricular myocardium and enlargement of the right ventricular cavity. *(Used with permission of Dr. B. Atkinson.)*

changes in pulmonary arterial endothelial cells, pulmonary arterial smooth muscle cells, and platelet function and together result in a thickened vessel wall and markedly narrowed or even completely obliterated lumen. Some of the mechanisms for this combination of uncontrolled vasoconstriction, cell proliferation, and thrombosis are highlighted here.

■ IMBALANCE OF VASOACTIVE MEDIATORS

Relative deficiencies of factors with vasodilatory properties and a simultaneous excess in those promoting vasoconstriction have been noted in both animal models and patients with PAH. In addition to vasoconstriction/dilation, these same factors influence cell proliferation and thrombosis. Deficiencies in the production

TABLE 72-2 Pathogenetic Mechanisms of Pulmonary Hypertension

	Mechanism	Examples
Passive	Pulmonary venous hypertension	Mitral stenosis, left atrial myxoma, fibrosing mediastinitis, pulmonary venoocclusive disease
Hyperkinetic	Increased pulmonary blood flow[a]	Left-to-right intracardiac shunts
Obstructive	Thromboembolic pulmonary vascular disease	High grade obstruction of large pulmonary arteries by organized thromboemboli, multiple pulmonary emboli
Obliterative	Inflammatory and/or proliferative pulmonary vascular disease	Interstitial lung disease, pulmonary arterial hypertension, schistosomiasis
Venoconstrictive	Hypoxia	High altitude, chronic bronchitis and emphysema (COPD)
Idiopathic	Unknown	Drug-associated pulmonary hypertension, portopulmonary hypertension, HIV infection

[a]Most categories overlap to some extent. For example, increased pulmonary blood flow is usually coupled with anatomic changes in the resistance vessels to produce pulmonary hypertension.

of the potent vasodilators nitric oxide (NO) and prostacyclin have each been observed, and indeed both substances have been used as a basis for effective therapies for PAH. Normally produced by vascular endothelial cells, each promotes the formation of cyclic nucleotides (cGMP and cAMP) by pulmonary arterial smooth muscle cells resulting in their relaxation and vasodilation. In addition, both prostacyclin and NO inhibit pulmonary arterial smooth muscle cell proliferation and platelet aggregation. In patients with PAH, the chronic administration of prostacyclin analogs improves hemodynamics, exercise capacity, and survival. The overexpression of NO synthase (NOS) by transgenic animals protects against the development of hypoxia-induced pulmonary hypertension, whereas mice lacking the gene for this enzyme develop severe pulmonary hypertension upon exposure to mild hypoxia.[60–62] In rats, monocrotaline-induced pulmonary hypertension can be prevented, or even reversed, with the administration of endothelial progenitor cells overexpressing human endothelial NOS (eNOS).[63] Inhaled NO has been proposed for the treatment of PAH and persistent pulmonary hypertension of the newborn,[64] however, inhaled NO has limitations regarding dose and duration of the exposure.[65] The inorganic anion nitrite (NO_2^-) is an oxidative product of NO metabolism and can function as an intravascular reservoir of NO bioactivity that can be converted to NO under physiologic and pathologic conditions.[65] Studies have shown that inhaled nebulized nitrite can prevent and reverse established pulmonary hypertension in the monocrotaline-induced rat pulmonary hypertension model.[66,67]

Vasoactive intestinal protein (VIP) also promotes vasodilation and inhibits smooth muscle proliferation and platelet aggregation. VIP levels are reduced in patients with PAH. In a preliminary study of 8 patients with IPAH, treatment with inhaled VIP improved hemodynamics and exercise capacity.[68] The acute effect of inhaled VIP was confirmed in a subsequent study that included patients with multiple etiologies of pulmonary hypertension including IPAH, congenital heart disease, CTEPH, and pulmonary hypertension related to parenchymal lung disease, although the modest effect on hemodynamics had questionable clinical relevance.[69]

INCREASE IN VASOCONSTRICTION MEDIATORS

In addition to deficiencies in vasodilators, excesses of other mediators capable of promoting vasoconstriction, smooth muscle proliferation, or platelet aggregation have been noted in patients with PAH. Thromboxane, an arachidonic acid metabolite produced by endothelial cells and platelets, causes vasoconstriction, platelet aggregation, and is a smooth muscle mitogen. Increased thromboxane metabolites have been documented in the urine of patients with PAH.[48] Attention was focused on the effects of serotonin (5-HT) on the pulmonary circulation by the epidemic of PAH in patients who ingested the appetite suppressants aminorex and fenfluramine.[70] These agents increase plasma 5-HT levels by inducing the release of 5-HT from platelets and interfering with its reuptake.[71] The 5-HT hypothesis was supported by the occurrence of pulmonary hypertension in fawn-hooded rats with an inherited defect in the platelet storage of 5-HT, and by an increase in circulating 5-HT in a patient with platelet storage disease and PAH.[72] 5-HT causes vasoconstriction and is a smooth muscle mitogen (Fig. 72-4). A key regulator of 5-HT action is the 5-HT transporter (5-HTT) whose expression is increased above normal in platelets and the pulmonary arteries of patients with IPAH. The overexpression of the 5-HTT gene in recombinant mice results in worsened hypoxia-induced pulmonary hypertension[73] whereas loss of the gene's function is protective against hypoxia or monocrotaline-induced disease.[74,75] A polymorphism in the 5-HTT gene that increases its activity may confer an increased susceptibility to the development of pulmonary hypertension in patients with COPD.[76] While some studies have suggested a similar role in IPAH,[77] larger data sets have not found such an association.[78] Blockade of the 5-HT receptor has successfully prevented the development and progression of experimental pulmonary hypertension in rats, yet a human trial was not able to show significant decreases in PVR.[79,80]

Endothelin-1 (ET-1) is one of the most potent endogenous vasoconstrictors known. Its expression is increased in the blood and tissues of patients with idiopathic and other forms of PAH and correlates with disease severity.[81–83] In addition to its vasoconstricting properties, ET-1 is mitogenic for both pulmonary arterial smooth muscle cells and fibroblasts (Fig. 72-4).[84,85] ET-1 administration or overexpression in animal models has been shown to result in fibrosis, inflammation, and platelet aggregation.[86,87] ET-1 binds endothelin A (ET_A) and B (ET_B) receptors on the surface of pulmonary arterial smooth muscle cells, resulting in potent vasoconstriction. ET_B receptors on pulmonary arterial endothelial cells increase the production of nitric oxide, resulting in vasodilatation. ET_B receptors are also active in the clearance of endothelin. The net effect of endothelin's vasoconstricting or dilating actions may be both site and context dependent, as both the distribution and relative expression of the ET_A and ET_B receptors differ according to vessel location in normal lung tissue, and are altered in patients with IPAH.[88,89] Indeed, both selective ET_A and dual ET_A/ET_B inhibition improve the hemodynamic derangements and clinical outcome of patients with PAH.[90–92]

INCREASED EXPRESSION OF GROWTH FACTORS

Growth factors that promote the maturation and stabilization of the developing vasculature have also been implicated in the

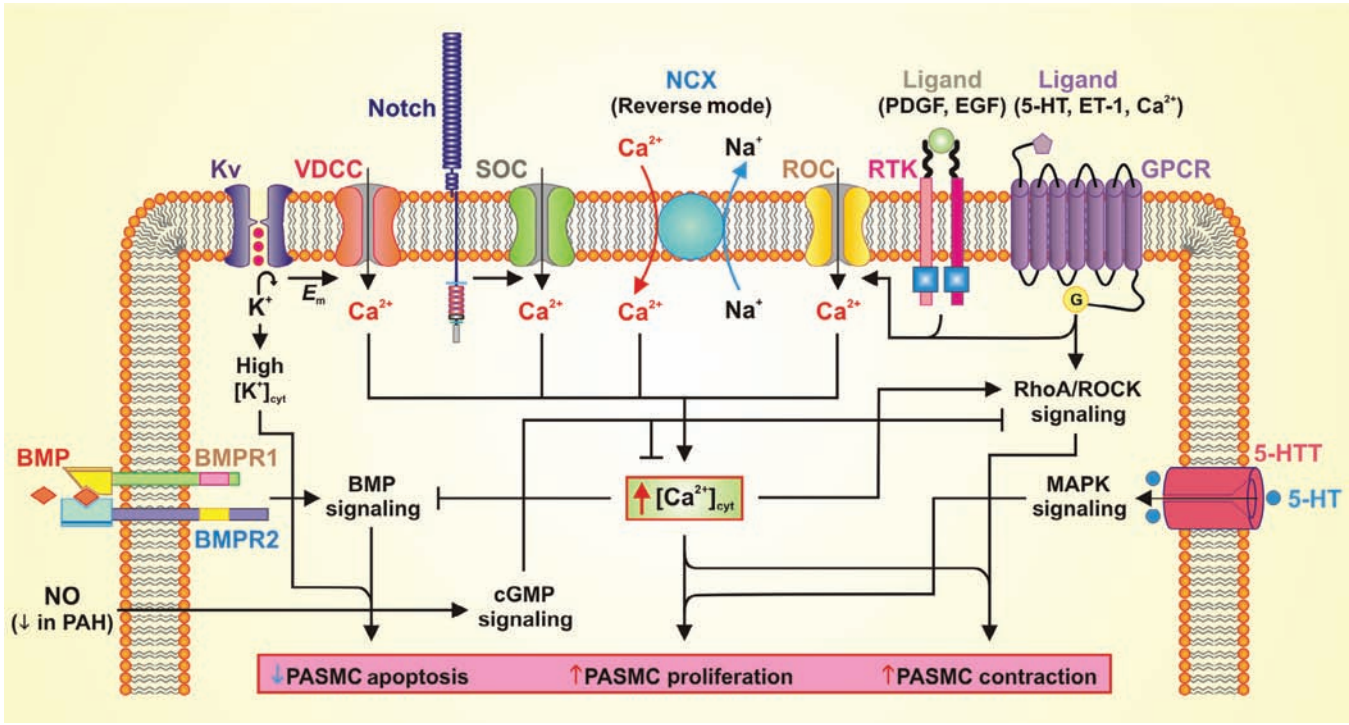

Figure 72-4 Potential mechanisms involved in the development of pulmonary arterial hypertension. BMP, bone morphogenic protein; BMPR, bone morphogenic protein receptor; cGMP, cyclic guanosine monophosphate; E_m, membrane potential; ET-1, endothelin 1; EGF, epidermal growth factor; GPCR, G-protein–coupled receptor; 5-HT, hydroxytryptamine (serotonin); 5-HTT, hydroxytryptamine (serotonin) transporter; Kv, voltage-gated K^+ channel; MAPK, mitogen-activated protein kinase; NO, nitric oxide; NCX, Na^+/Ca^{2+} exchanger; PAH, pulmonary arterial hypertension; PASMC, pulmonary arterial smooth muscle cell; PDGF, platelet-derived growth factor; ROC, receptor-operated Ca^{2+} channel; RTK, receptor tyrosine kinase; SOC, store-operated Ca^{2+} channel; VDCC, voltage-dependent Ca^{2+} channel.

pathogenesis of PAH. Elevations in angiopoietin 1 and its ligand TIE2 correlate with disease severity in patients with multiple forms of PAH.[93] Angiopoietin 1 is overexpressed in most forms of nonfamilial PAH,[93,94] however, how angiopoietin becomes elevated in these patients is not clear. Several lines of evidence suggest that angiopoietin 1 regulates pulmonary arterial smooth muscle cell hyperplasia in PAH.[9] Interestingly, in an animal model of PAH induced by monocrotaline, the overexpression of angiopoietin is actually protective.[95] Whether this discrepancy represents differences in human versus animal tissues or the differing insults to the vasculature involved is not clear. Another modulator of development, VEGF and its target, tyrosine kinase receptor, are increased in the pulmonary vasculature of patients with PAH. Increased VEGF expression has been reported specifically within plexiform lesions[34,96] where its proangiogenic properties are hypothesized to mediate disordered endothelial cell proliferation.[97] Whether such changes are primary, secondary, or indeed detrimental is not entirely clear. Like elevations in angiopoietin, increases in the expression of VEGF thought to be deleterious in some situations might be beneficial in others that promote the development of pulmonary hypertension. In animal models of hypoxia, the inhibition of VEGF signaling results in proliferative vascular abnormalities[98] and promotion of VEGF signaling is protective against the development of monocrotaline-induced PH.[99]

PDGF along with its receptor, tyrosine kinase, are also found to be increased in the pulmonary vasculature of patients with PAH (Fig. 72-4).[100] PDGF has been implicated in smooth muscle cell proliferation and migration, which is thought to contribute to PAH pathogenesis. The tyrosine kinase inhibitor imatinib has a particular affinity for the PDGF receptor and several small studies have identified a potential benefit in PAH patients.[101] Early human trials have also shown improvements in hemodynamic measurements after treatment.[102]

Cellular microparticles recently have been implicated as vasoactive mediators in PAH. Microparticles represent vesicle fragments of the cell membrane containing various proteins and antigens that are involved in cellular communication.[103] These small particles are released during cell activation or apoptosis and can be derived from multiple cell lines including endothelial cells, platelets, leukocytes, red blood cells, and fibroblasts. Circulating levels of endothelial microparticles are increased in PAH, which may represent endothelial dysfunction and has also been correlated with disease survival.[104] Microparticles, when isolated from rats with hypoxia-induced pulmonary hypertension, have been shown to impair endothelium-dependent vasorelaxation in pulmonary arteries and decrease NO production.[105] Circulating microparticles have also been linked to inflammatory signaling in the lung.[106]

■ INCREASED CYTOKINES AND INFLAMMATION

The close association of systemic inflammatory disorders to IPAH has implicated inflammation as an important factor in vascular remodeling. Numerous cytokines have been implicated in the pathogenesis of PAH including tumor necrosis factor alpha, and interleukins 1b, 2, 4, 6, 8, 10, and 12p70. Early data showed increased levels of IL-1β and IL-6 in IPAH patients[107] and higher IL-6 levels were later found to be associated with mortality.[108] The chemokine fractalkine (CX3CL1) is elevated in CD4 and CD8 T-cells of PAH patients and further studies have shown that CX3CL1 may promote proliferation in pulmonary arterial smooth muscle cells.[109,110] Monocyte chemotactant protein (MCP)-1 is also elevated in serum and lung samples from IPAH patients and may influence monocyte and T-cell recruitment to the diseased lung.[111] Increased expression of Regulated upon Activation, Normal T cell Expressed and Secreted (RANTES) has been found in lung

samples from PAH patients.[112] As a chemoattractant for monocytes and T-cells, RANTES is thought to promote inflammation, but may also play a role in the synthesis of endothelin-1, a potent vasoconstrictor.

FUNCTIONAL CHANGES IN MEMBRANE RECEPTORS AND ION CHANNELS

Important functional changes in membrane receptors and ion channels in IPAH are discussed below.

Ca^{2+} CHANNELS IN IPAH

Sustained vasoconstriction and vascular remodeling are both directly mediated by pulmonary arterial smooth muscle cell contraction and proliferation. A rise in $[Ca^{2+}]_{cyt}$ due to Ca^{2+} influx through various Ca^{2+}-permeable channels in the plasma membrane is a major trigger for pulmonary arterial smooth muscle cell contraction and a key stimulus for pulmonary arterial smooth muscle cell proliferation.[113] Therefore, understanding how the regulation of Ca^{2+} homeostasis is disrupted in IPAH is important to understanding how IPAH develops. Pulmonary arterial smooth muscle cells isolated from IPAH patients have an elevated $[Ca^{2+}]_{cyt}$.[114–117] Ca^{2+} influx through the plasma membrane in pulmonary arterial smooth muscle cells involves multiple Ca^{2+}-permeable channels including (a) voltage-dependent Ca^{2+} channels (VDCC) regulated by changes in membrane potential,[118] (b) receptor-operated Ca^{2+} channels (ROC) activated by interaction of agonist with membrane receptors, and (c) store-operated Ca^{2+} channels (SOC) activated by depletion of Ca^{2+} from the intracellular stores (Fig. 72-4).[8] Decreased expression and/or function of K^+ channels leads to sustained membrane depolarization, activation of VDCC, and increased $[Ca^{2+}]_{cyt}$. Ca^{2+} influx through ROC, termed receptor-operated Ca^{2+} entry (ROCE), and through SOC, referred to as store-operated Ca^{2+} entry (SOCE) is enhanced in IPAH-associated pulmonary arterial smooth muscle cells compared to those from normal controls.[114–117] Several experimental studies have demonstrated increased expression of several proteins involved in ROCE/SOCE such as, TRPC3, TRPC6, STIM2, and Orai2, in pulmonary arterial smooth muscle cells from IPAH patients.[114–117,119,120] In addition, a single-nucleotide polymorphism (SNP) has been identified in IPAH patients that results in enhanced expression and function of TRPC6.[115]

K^+CHANNELS IN IPAH

Vascular tone might also be altered in IPAH by changes in the expression of voltage-gated K^+ (Kv) channels as well as other types of K^+ channels (Fig. 72-4). Their activation normally allows an efflux of K^+ and resultant changes in intracellular Ca^{2+} that promote vasodilation.[121] Gene expression of Kv channel family members is downregulated by hypoxia-induced pulmonary hypertension in rats,[122,123] whereas induction of their expression can reverse the hemodynamic effects of hypoxia.[122,124] The expression of specific Kv channels is also decreased in the lungs of patients with IPAH[125–127] possibly contributing to heightened vasoconstriction resulting from a more depolarized membrane leading to increased $[Ca^{2+}]_{cyt}$ due to activation of VDCC. Kv channels may also mediate the effects of certain drugs. The anorexigens dexfenfluramine and aminorex inhibit smooth muscle Kv channel activity, thus causing pulmonary vasoconstriction.[128] In contrast, enhanced activity of Kv channels may be one mechanism by which sildenafil promotes vasodilation in addition to its activity as an inhibitor of phosphodiesterase-5.[122] One final way in which decreased activity of Kv channels might promote the development of PAH is by inhibiting apoptosis, thus enabling unchecked pulmonary arterial smooth muscle cell proliferation. Apoptosis requires a loss in cell volume as well as the function of specific caspases, both of which require appropriate K^+ movement via Kv channels.[129,130]

G-PROTEIN–COUPLED RECEPTORS IN IPAH

The Ca^{2+}-sensing receptor is a G-protein–coupled receptor in the plasma membrane that can be activated by extracellular Ca^{2+} (and Mg^{2+}), polyamines (e.g., spermine), amino acids and neomycin.[131–134] Activation of the Ca^{2+}-sensing receptor results in activation of intracellular Ca^{2+} signaling pathways that lead to pulmonary arterial smooth muscle cell contraction, proliferation, and migration (Fig. 72-4).[135,136] Like some G-protein–coupled receptors coupled to Gq (e.g., endothelin receptors), Ca^{2+}-sensing receptor activation increases the synthesis of inositol 1,4,5 triphosphate (IP_3) and diacylglycerol via phospholipase C. IP_3 binds to the IP_3 receptor on the sarcoplasmic reticulum (SR) membrane and releases Ca^{2+} from the SR to the cytosol. Depletion of Ca^{2+} from the SR induces Ca^{2+} entry via SOCE, and diacylglycerol directly activates ROCE. In addition to increasing $[Ca^{2+}]_{cyt}$ via ROCE and SOCE, the extracellular Ca^{2+}-induced activation of CaSR also activates other signal transduction pathways (e.g., Akt/mTOR and MAPK/ERK) to induce cellular proliferation.[137–139] A recent study[135] indicates that the extracellular Ca^{2+}-induced increase in $[Ca^{2+}]_{cyt}$ by activation of the Ca^{2+}-sensing receptor is enhanced and the Ca^{2+}-sensing receptor protein expression is upregulated in IPAH-pulmonary arterial smooth muscle cells compared to normal pulmonary arterial smooth muscle cells. These observations suggest that upregulated expression and enhanced function of Ca^{2+}-sensing receptor in pulmonary arterial smooth muscle cells are involved in the development of sustained pulmonary vasoconstriction and pulmonary vascular remodeling in patients with IPAH and animals with experimental pulmonary hypertension. In addition to Ca^{2+}-sensing receptor, many other G-protein–coupled receptors are reported to be involved in PAH such as endothelin receptor, prostacyclin receptor, and serotonin receptor.[48,140,141]

Na^+/Ca^{2+} EXCHANGER IN IPAH

The Na^+/Ca^{2+} exchanger (NCX) is a ubiquitously expressed protein that transports Ca^{2+} across the plasma membrane along the electrochemical gradient of Na^+ and Ca^{2+}.[142] The NCX can operate in either forward mode, transporting 3 Na^+ ions into the cell and 1 Ca^{2+} ion out of the cell, or the reverse mode, transporting 1 Ca^{2+} ion into the cell and 3 Na^+ ions out of the cell, based on the Na^+ and Ca^{2+} concentration gradients and membrane potential. Due to the reverse mode of the NCX, a small increase in the cytosolic Na^+ concentration ($[Na^+]_{cyt}$) can greatly increase $[Ca^{2+}]_{cyt}$. The canonical transient receptor potential (TRPC) channels, such as TRPC6, which is overexpressed in IPAH patients, are permeable to both Na^+ and Ca^{2+}, and for many TRPC channels, the permeability to Na^+ is greater than the permeability to Ca^{2+}. The reverse mode of the NCX has been shown to couple to TRPC6 and localized increases in $[Na^+]_{cyt}$ result in transport of Ca^{2+} into the cell resulting in increased $[Ca^{2+}]_{cyt}$ in pulmonary arterial smooth muscle cells.[143] The NCX is overexpressed in PASMC isolated from patients with IPAH, and is found localized in caveolae along with other G-protein–coupled receptors, ROC, and SOC resulting in a functional coupling of these receptors and contributing to increased $[Ca^{2+}]_{cyt}$, resulting in increased proliferation and contraction of PASCM in patients with IPAH.[116,144]

ALTERED SIGNALING PATHWAYS IN IPAH

Alterations in signaling pathways have been observed in IPAH and are discussed below.

CYCLIC GUANOSINE MONOPHOSPHATE IN IPAH

IPAH is associated with abnormally low levels of the potent pulmonary arterial smooth muscle cell relaxant NO. In pulmonary arterial endothelial cells, NO produced by eNOS freely diffuses across the

cell membrane to pulmonary arterial smooth muscle cells and activates intracellular soluble guanylate cyclase (sGC), which catalyzes the conversion of guanosine 5′-triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). cGMP then activates cGMP-dependent kinases, which can reduce $[Ca^{2+}]_{cyt}$, inhibit Rho signaling, and inhibit phosphorylation of myosin-binding protein, all of which lead to smooth muscle relaxation.[145,146] In the lung, metabolism of cGMP is controlled by phosphodiesterase 5 (PDE-5). PDE-5 inhibitors block the breakdown of cGMP, leading to vasodilation due to an accumulation of cGMP in the tissue.[147] In 2005, following several clinical studies, sildenafil was approved for the treatment of PAH.[148] Tadalafil was approved for the treatment of PAH in 2009.[149] Both sildenafil and tadalafil share structural similarities with cGMP and inhibit PDE-5 by competitively binding to the catalytic site.[147]

PDGF AND Akt/mTOR SIGNALING IN IPAH

PDGF and its receptor PDGFR have been implicated in the pathogenesis of IPAH. Previous studies have indicated that PDGF increases SOCE in rat and human pulmonary arterial smooth muscle cells, thereby promoting cell proliferation (Fig. 72-4).[119,150] Binding of PDGF to PDGFR leads to activation of phosphatidylinositol 3-kinase (PI3K),[151] which activates Akt. Akt promotes cell growth through the downstream mediator mammalian target of rapamycin (mTOR) or by directly phosphorylating proteins involved in cell cycle regulation and apoptosis.[152] The Akt/mTOR pathway has been shown to be important for pulmonary arterial smooth muscle cell proliferation[150,153] and the development of PAH.[154] Inhibition of mTOR and Akt by rapamycin and Akt inhibitor VIII, respectively, abrogated the PDGF-induced increased SOCE and Ca^{2+} channel expression in normal and PAH-pulmonary arterial smooth muscle cells,[150,155] suggesting that the PDGF-mediated increase in SOCE occurs via the Akt/mTOR pathway. Clinical trials have shown some benefit to the use of imatinib, an orally active PDGFR inhibitor, in patients with severe PAH.[102]

RhoA/ROCK SIGNALING IN IPAH

The RhoA/ROCK signaling pathway is a major mediator of Ca^{2+}-sensitization/desensitization and a key regulator of vascular tone (Fig. 72-4).[156,157] RhoA is a GTP-binding protein that is activated following activation of G-protein–coupled receptors by vasodilators. In addition, RhoA can be activated by serotonin, which enters the cell through its transporter 5-HTT, and by an increase in $[Ca^{2+}]_{cyt}$.[158] Activation of RhoA leads to activation of Rho kinase (ROCK), which increases the Ca^{2+} sensitivity of contraction in pulmonary arterial smooth muscle cells by inhibiting myosin light chain phosphatase and increasing the phosphorylation of myosin light chain kinase, leading to increased contraction of pulmonary arterial smooth muscle cells.[20,21] Recent studies have indicated that the RhoA/ROCK signaling pathway is enhanced in patients with IPAH.[159,160] Small clinical studies have demonstrated that inhibition of the RhoA/ROCK signaling pathway with fasudil, a selective ROCK inhibitor, results in acutely improved pulmonary hemodynamic variables in patients with IPAH.[161,162]

NOTCH SIGNALING IN IPAH

Notch signaling is involved in vascular development and has been implicated in the development of IPAH (Fig. 72-4).[163,164] Both Notch receptors (Notch1-Notch4) and their ligands, Jagged (Jag1 and Jag2) and Delta-like (Dll1, Dll3, and Dll4), are single-transmembrane–spanning proteins that restrict Notch signaling to adjacent cells. After ligand binding, Notch undergoes a series of proteolytic cleavages resulting in the release of the Notch intracellular domain, which translocates to the nucleus where it interacts with recombination signal binding protein for immunoglobulin kappa j region (RBPjκ) to function as a transcription factor resulting in activation of transcription of Notch target genes.[163,165–167] The most commonly induced Notch target genes are the basic helix–loop–helix transcriptional repressors of the *Hes* (*Hairy/Enhancers of Split*) and *Hrt* (*Hes-related transcription factor*) gene families. In addition, Notch signaling has been shown to upregulate expression of PDGFR-β,[168] which is known to be upregulated in IPAH.[155,169] Notch3 signaling has recently been implicated in PAH. Lung tissue from IPAH patients displays increased Notch3 and Notch3 intracellular domain (N3ICD) expression when compared to normotensive patients.[164] In addition, Notch3 and N3ICD expression is increased in two animal models of pulmonary hypertension, hypoxic-induced pulmonary hypertension in mice and monocrotaline-induced pulmonary hypertension in rats.[164] This suggests that the Notch signaling pathway may be an important pathway to target for the development of new drugs for the treatment of IPAH.

GENETIC ALTERATIONS RELATED TO IDIOPATHIC AND FAMILIAL PAH

Identification of bone morphogenetic protein receptor II (BMPR2) gene mutations has led to increasing interest in genetic susceptibility to pulmonary hypertension. As a receptor for the TGFβ super family, BMPR2 is involved in diverse cell growth and differentiation processes in multiple systems. Engagement of a BMP receptor with its ligand normally results in the activation of intracellular mediators (Smads) and their translocation to the cell nucleus and regulation of the transcription of target genes. The resulting activation of some genes and the inhibition of others varies according to the BMP pathway and tissue involved. BMP signaling is essential to both normal vascular development and the maintenance of the normal adult pulmonary vasculature, likely by regulating the growth and apoptosis of endothelial and smooth muscle cells (Fig. 72-4). Loss of such regulation gives rise to pulmonary hypertension.[170] Normally found primarily on endothelium and to a lesser extent smooth muscle cells, the expression of BMPR2 is reduced and its function abnormal in patients with various types of PAH, most notably those with mutations of the *BMPR2* gene.[171] The ability of BMP to inhibit smooth muscle proliferation and induce apoptosis is suppressed in cells isolated specifically from smaller pulmonary vessels in patients with IPAH (e.g., 1 to 2 mm, where occlusive vascular pathologic changes predominate).[29,172,173] Germline mutations in *BMPR2* have been identified in up to 70% of patients with familial PAH, and in 20% of patients with IPAH,[174–180] as well as disease associated with anorexigens,[181] congenital heart disease,[182] and pulmonary venoocclusive disease (PVOD).[183] Nearly 300 different mutations of BMPR2 have been identified.[177]

Further work has identified other genetic alterations in the TGFβ pathway including activin receptor kinase-like 1 (*ALK1*), endoglin (*Eng*), and Smad 8.[184] ALK1 is a receptor for TGFβ and endoglin is its coreceptor; while Smad 8 is a downstream second messenger of BMPR2. Mutations in *ALK1* and *Eng* have been shown to confer susceptibility to the development of PAH in patients with hereditary hemorrhagic telangiectasia.[185,186] In addition, concomitant Thrombospondin-1 gene mutation (*THBS1*) has been detected in a small subset of familial PAH patients with BMPR2 mutations; this mutation has been proposed to further promote pulmonary hypertension development and increase genetic penetrance.[187]

CLINICAL EVALUATION OF PULMONARY HYPERTENSION

The symptoms and signs of PAH are nonspecific, overlapping with many more common entities. As a result, patients experience problematic delays between the time of symptom onset and appropriate diagnosis.[188,189] The problem is usually first suggested by findings suggestive of pulmonary hypertension on an echocardiogram. The evaluation of PAH is predominantly,

TABLE 72-3 Presenting Symptom(s) Attributable to PAH

Symptom	Percentage of Patients at Presentation
Abdominal distention	4%
Chest pain/discomfort	2%
Cough	14%
Dizziness/lightheadedness	15%
Dyspnea at rest	11%
Dyspnea on exertion	86%
Edema	21%
Fatigue	27%
Presyncope/syncope	17%
Palpitations	13%

Source: Data from Brown LM, Chen H, Halpern S, et al. Delay in recognition of pulmonary arterial hypertension: factors identified from the REVEAL registry. Chest. 2011;140(1):19–26 and represent percentage of patients with each indicated symptom at the time of initial presentation, from among 2493 patient enrolled in a multicenter United States national registry of patients with pulmonary hypertension (Registry to Evaluate Early and Long-term PAH Disease Management).

TABLE 72-4 World Health Organization Functional Classification of Patients with Pulmonary Hypertension

Class I: Patients with PH but without resulting limitation of physical activity. Ordinary physical activity does not cause undue dyspnea or fatigue, chest pain, or near syncope.
Class II: Patients with PH resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity causes undue dyspnea or fatigue, chest pain, or near syncope.
Class III: Patients with PH resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary activity causes undue dyspnea or fatigue, chest pain, or near syncope.
Class IV: Patients with PH with inability to carry out any physical activity without symptoms. These patients manifest signs of right heart failure. Dyspnea and/or fatigue may even be present at rest. Discomfort is increased by any physical activity.

therefore, the evaluation of pulmonary hypertension more generically: a step-wise process to establishing whether pulmonary hypertension is likely present, and if so confirmation and careful evaluation of the specific cause and classification so as to guide rational therapy.

■ PATIENT HISTORY IN PULMONARY HYPERTENSION

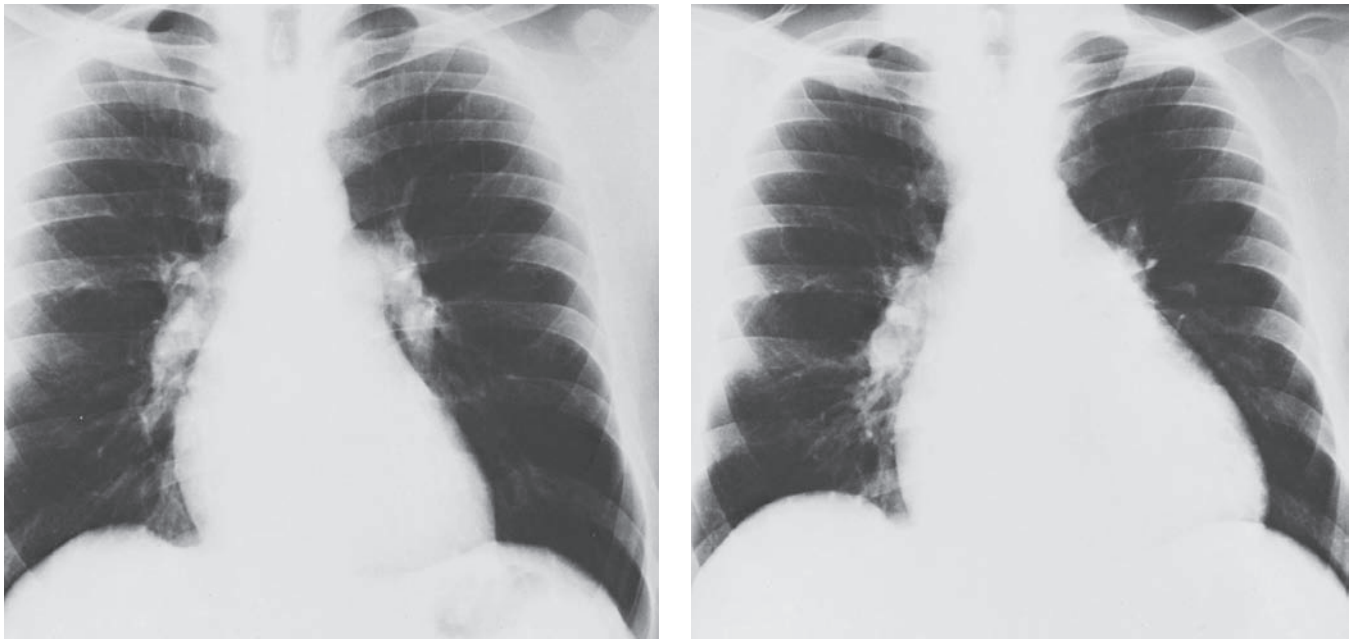
Except for mild breathlessness – often attributed to being "out of shape" – PAH is generally asymptomatic until severe. Because of the nonspecific nature of the symptoms (Table 72-3), underrecognition of the disease by healthcare providers, and its confusion with other conditions, a significant delay between the onset of symptoms and the diagnosis of PAH is common. The mean time from symptom onset until PAH diagnosis was over 2 years in a National Institutes of Health (NIH) registry assembled in the 1980s.[190] Twenty years later, registries in China, France, Germany, and the United States each found that similarly disappointing delays of over 2 years persist.[189,191–193] As a result, diagnosis is delayed until most patients have severe functional impairment, with more than one-half reporting World Health Organization (WHO) functional class III or IV symptoms (Table 72-4).

Symptoms due to pulmonary hypertension are generally difficult to dissociate from symptoms of underlying pulmonary or cardiac disease. In IPAH, the first symptoms generally occur during exertion, usually as dyspnea and, less often, chest pain, dizziness, or syncope.[194] Dyspnea on exertion is by far the most common presenting complaint. Often, because of the lack of other signs or symptoms, it is attributed to physical deconditioning or anxiety. Other initial complaints, particularly easy fatigability and chest discomfort, are often similarly dismissed. Angina-like or nonspecific chest pain is common in patients with severe pulmonary hypertension and generally attributed to right ventricular overload and myocardial ischemia. Chest pain might also occur due to the extrinsic compression of the left main coronary artery by an enlarged pulmonary artery.[195]

In time, in the absence of amelioration of the pulmonary hypertension, right-sided heart failure evolves. Syncope, or light-headedness on exertion, are less common but more ominous complications of pulmonary hypertension. They occur in patients with severe pulmonary hypertension and a fixed low CO. The cause is inadequate cerebral blood flow due to a combination of failure to increase the CO, along with diversion of systemic blood flow toward the exercising muscles. Syncope may also occur at rest in association with the onset of bradycardia, presumably vagal in origin. Hoarseness, due to paralysis of the left recurrent laryngeal nerve, may result from trapping of the nerve between the aorta and the dilated left pulmonary artery (a form of Ortner syndrome). If the right ventricle should fail, lower extremity swelling is common, as are abdominal signs and symptoms including a sensation of "bloating," early satiety, tender hepatomegaly, ascites, and abdominal pain. Symptoms of right ventricular failure and the presence of syncopal events are associated with a worse prognosis. Hemoptysis in the setting of pulmonary hypertension is most often due to pulmonary venous congestion but when mitral stenosis is present, it is generally attributed to bleeding from bronchial veins. Occasionally, hemoptysis occurs in other forms of pulmonary hypertension and may originate in alveolar capillaries, precapillaries, or elsewhere in the pulmonary arterial tree.

Not infrequently, the suspicion of pulmonary hypertension is raised by the presence of a known risk for pulmonary hypertension (e.g., systemic sclerosis) or by serendipitous discovery of right ventricular enlargement by an electrocardiogram or chest radiograph taken for other reasons (Figs. 72-5 and 72-6). Initial recognition of the presence of pulmonary hypertension also frequently occurs in the absence of reported symptoms when an echocardiogram is performed for the evaluation of a murmur. Alternatively, echocardiographic evidence of pulmonary hypertension may be found unsuspectedly when the study is obtained as "routine" evaluation of a patient complaining of any of a number of chest symptoms, including dyspnea. Patients with severe pulmonary hypertension are prone to sudden death and its occurrence may be the first (and last) indication of disease. Death has occurred unexpectedly during normal activities, cardiac catheterization, and surgical procedures, and after the administration of sedatives or anesthetic agents. In a few instances, bradycardia leading to cardiac arrest has preceded sudden death.

An important hint to the presence of pulmonary hypertension is a history of long-standing dyspnea that has not responded to treatment for other more common disorders. Patients have often seen several clinicians before an appropriate diagnosis is made.



A B

Figure 72-5 Radiographic changes in idiopathic pulmonary arterial hypertension. As compared to a chest radiograph 14 months earlier (**A**) enlargement of the cardiac silhouette has occurred in a 30-year-old man in association with increasing dyspnea (**B**). Decrease in the cardiac silhouette occurred in response to chronic pulmonary vasodilator therapy.

Younger patients have frequently been told their symptoms are due to asthma, yet failed to improve significantly with aggressive anti-inflammatory and bronchodilator therapies. In older patients, dyspnea or exercise limitation may have been blamed on COPD, often despite a trivial history of tobacco use. Unfortunately, a further clue in such patients is learning that these "diagnostic" labels were never investigated with pulmonary function testing. Patients should be asked about important symptoms or risk factors that might suggest the presence and cause of pulmonary hypertension. These include symptoms of collagen vascular disease (e.g., dysphagia, skin or joint changes, Raynaud's phenomenon), sleep apnea (e.g., witnessed apneic events, daytime hypersomnolence), history of risks for thromboembolism, HIV infection, liver disease, or anorectic agent use. A history of tobacco use and chronic sputum production, or a known history of asthma with poor control might be important clues to the presence of obstructive airway disease and hypoxia as the cause of pulmonary hypertension. A prior history of interstitial lung disease or any cause of chronic hypoxia must be noted. A careful family history should be taken including inquiring about relatives who suffer(ed) poorly understood cardiopulmonary conditions.

■ PHYSICAL EXAMINATION

A careful physical examination is necessary to recognize the presence of pulmonary hypertension and begin elucidating its cause (Table 72-5). In mild-to-moderate pulmonary hypertension, the physical examination is apt to be unrevealing unless suspicion has been aroused that pulmonary hypertension may be present. Right ventricular enlargement is an important clue but notoriously difficult to detect in its early stages on physical examination. Evidence of pulmonary hypertension, such as prominent closure of the pulmonary valve, is apt to be overlooked or discounted, especially in younger people; recognition of tricuspid insufficiency or a right ventricular gallop is often delayed until pulmonary hypertension becomes severe and has led to heart failure.

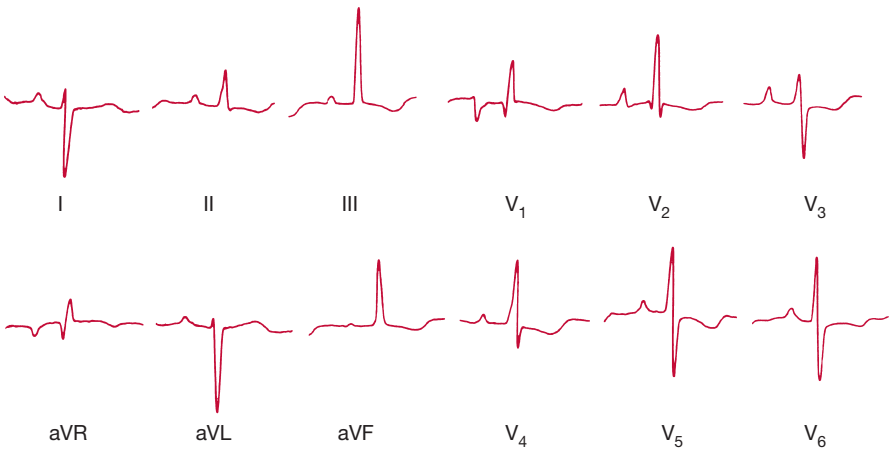


Figure 72-6 Twenty-six-year-old woman in whom the first evidence of primary pulmonary hypertension was by electrocardiography. The record shows marked right axis deviation and dominant R waves over the right precordium consistent with right ventricular hypertrophy.

TABLE 72-5 Physical Examination Findings in Pulmonary Hypertension

Physical Signs that Reflect Severity of PH	
Sign	**Implication**
Accentuated pulmonary component of S2 (audible at apex in over 90%)	High pulmonary pressure increases force of pulmonic valve closure
Early systolic click	Sudden interruption of opening of pulmonary valve into high-pressure artery
Midsystolic ejection murmur	Turbulent transvalvular pulmonary outflow
Left parasternal lift	High right ventricular pressure and hypertrophy present
Right ventricular S4 (in 38%)	High right ventricular pressure and hypertrophy present
Increased jugular "a" wave	Poor right ventricular compliance
Physical Signs that Suggest Moderate-to-Severe PH	
Sign	**Implication**
Moderate-to-severe PH	Tricuspid regurgitation
Holosystolic murmur that increases with inspiration tricuspid regurgitation	
Increased jugular v waves	
Pulsatile liver	
Diastolic murmur	Pulmonary regurgitation
Hepatojugular reflux	High central venous pressure
Advanced PH with right ventricular failure	
Right ventricular S3 (in 23%)	Right ventricular dysfunction
Distention of jugular veins	Right ventricular dysfunction or tricuspid regurgitation or both
Hepatomegaly	
Peripheral edema (in 32%)	
Ascites	
Low blood pressure, diminished pulse pressure, cool extremities	Reduced cardiac output, peripheral vasoconstriction
Physical Signs that Suggest Possible Underlying Cause or Associations of PH	
Sign	**Implication**
Central cyanosis	Abnormal V/Q, intrapulmonary shunt, hypoxemia, pulmonary-to-systemic shunt
Clubbing	Congenital heart disease, pulmonary venoocclusive disease
Cardiac systolic murmurs, diastolic murmurs, opening snap, and gallop	Congenital or acquired heart or valvular disease
Crackles, dullness, or decreased breath sounds	Pulmonary congestion or effusion or both
Crackles, accessory muscle use, wheezing, protracted expiration, productive cough	Pulmonary parenchymal disease
Obesity, kyphoscoliosis, enlarged tonsils, narrowed pharyngeal opening, macroglossia	Disordered ventilation, sleep apnea
Sclerodactyly, arthritis, telangiectasia, Raynaud phenomenon, rash	Connective tissue disorder
Peripheral venous insufficiency or obstruction	Possible venous thrombosis
Venous stasis ulcers	Possible sickle cell disease
Pulmonary vascular bruits	Chronic thromboembolic PH
Splenomegaly, spider angiomata, palmary erythema, icterus, caput medusa, ascites	Portal hypertension

ACCF/AHA 2009 expert consensus document on pulmonary hypertension a report of the American College of Cardiology Foundation task force on expert consensus documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc.; and the Pulmonary Hypertension Association. J Am Coll Cardiol. 2009;53(17):1573–1619.

Once pulmonary hypertension is suspected, the physical examination can offer important signs. When symptoms first become manifest, a large *a* wave generally can be detected in the jugular venous pulse. Auscultation usually discloses splitting of the second heart sound with accentuation of the pulmonic component. A sharp systolic ejection click over the region of the pulmonary artery is usually heard. As pulmonary hypertension persists, enlargement of the right ventricle becomes evident as a palpable cardiac impulse near the left sternal border and in the hypogastrium. An important sign of cor pulmonale is a right-sided (ventricular) diastolic (S_3) gallop; it is accentuated by inspiration. Less helpful is the right atrial gallop (S_4), which occurs immediately before the first heart sound and suggests an increase in the filling pressure of the right side of the heart.

In time, tricuspid insufficiency develops. It is manifested by a holosystolic murmur, best heard in the fourth interspace to the left of the sternum; the murmur characteristically increases in intensity during inspiration (as do the third and fourth heart sounds). A prominent *v* wave appears in the jugular pulse, and distended neck veins pulsate with each heartbeat. The onset of right ventricular failure is often marked by discomfort in the right upper quadrant due to hepatic engorgement as well as edema in the lower extremities. The liver often also shows expansive pulsations that are synchronous with the heartbeat. Hydrothorax and ascites are uncommon, even after right ventricular failure has progressed to the stage of hepatomegaly and pedal edema. Systemic arterial hypoxemia is often present. Assessment of oxyhemoglobin desaturation with activity is an important component of the patient evaluation; if desaturation is noted, formal exercise testing to titrate oxygen therapy should be pursued promptly. Late in the disease, many patients develop peripheral cyanosis secondary to a reduced CO and peripheral vasoconstriction; central cyanosis also occurs preterminally in some patients because of right-to-left shunting through a patent foramen ovale.

The physical examination should be focused on the presence of additional signs to indicate a possible cause of pulmonary hypertension. Systemic hypertension, a risk factor for coronary artery disease or diastolic dysfunction, may suggest left-sided heart disease. Abnormal lung sounds might include wheezing suggesting airway obstruction, or crackles suggesting either pulmonary edema or interstitial disease. Additional findings suggestive of lung disease include hyperresonance to percussion or hyperinflation of the thorax (barrel chest) suggestive of COPD or kyphoscoliosis causing a restrictive pattern. Skin changes such as rash or telangiectasias are clues to the presence of collagen vascular disease, as are digital ulcers in patients with the CREST variant of systemic sclerosis. The presence of digital clubbing should also be noted as it may indicate congenital heart disease, certain forms of chronic hypoxic lung disease (e.g., cystic fibrosis or certain interstitial lung diseases) or PVOD.[196] Narrowing of the posterior oropharynx, macroglossia, and a large neck size may suggest obstructive sleep apnea.

DIAGNOSTIC STUDIES

Diagnostic testing is used to confirm the presence of pulmonary hypertension, identify the etiology, assess severity and prognosis, and to help guide appropriate therapy. Table 72-6 lists tests that are essential in the evaluation of pulmonary hypertension.[197] Table 72-7 lists the criteria required for a diagnosis of PAH.

Following a detailed history and physical examination, an electrocardiogram, chest radiograph, and echocardiogram are indicated if there is suspicion of pulmonary hypertension, and often as logical tests to evaluate symptoms such as dyspnea even if concern for pulmonary hypertension has not been raised.

Chest Radiograph and Electrocardiogram

Early in the evolution of pulmonary hypertension, the chest radiograph appears normal. In time, the central pulmonary arteries become increasingly prominent as the peripheral vessels become attenuated, and the cardiac silhouette enlarges (Fig. 72-7). The chest radiograph (together with pulmonary function tests) may also suggest the presence of underlying lung disease. An electrocardiogram should be obtained and may indicate signs of ischemic heart disease or conduction abnormalities. Findings suggestive of the presence of pulmonary hypertension include right axis deviation, right atrial enlargement, and right

TABLE 72-6 Evaluation of Patients with Pulmonary Hypertension

Detection of pulmonary hypertension	Detailed history and physical examination	Suspicion of pulmonary hypertension and possible causes/associations
	Electrocardiogram	Exclude other causes of cardiopulmonary symptoms
	Chest radiograph	
	Echocardiogram (at rest, to consider repeat with exertion)	Evaluate for presence of pulmonary hypertension, assess chamber sizes and function, valvular abnormalities, contrast (bubble) study to evaluate possible shunt
Essential testing	Pulmonary function testing	Exclude intrinsic lung disease
	Overnight oximetry	Screen for sleep-disordered breathing
	Lung (V/Q) scan	Exclude thromboembolism
	Blood serologies (e.g., CBC, liver function, renal function, HIV, ANA, antiphospholipid antibodies)	Exclude collagen vascular disease, liver disease, infection, and other possible causes of pulmonary hypertension
	Oxygen desaturation study	Assess need for supplemental oxygen (rest and exertion)
	6-Minute walk test	Establish baseline
	Right cardiac catheterization	Confirm diagnosis, assess other cardiac causes (shunt); consider left heart catheterization
Contingent testing	Transesophageal echocardiogram	Assess patent foramen ovale (PFO)
		Characterize valvular function
	Computed tomogram of chest	Assess interstitial lung disease, adenopathy
	Polysomnogram	Diagnosis and treatment of sleep-disordered breathing
	Pulmonary angiogram	Assess presence and location of organized thromboemboli and suitability for pulmonary thromboendarterectomy
	Blood studies (BNP, clotting studies, genetic testing)	
	Lung biopsy	Exclude subtle interstitial lung disease vasculitis and other uncommon diseases (PVOD, PCH) to assist planning

TABLE 72-7 Requirements for the Diagnosis of Pulmonary Arterial Hypertension

Required Testing	Rationale
Cardiac catheterization: • A mean pulmonary artery pressure ≥25 mm Hg • Pulmonary artery wedge or left ventricular end diastolic pressure ≤15 mm Hg • Pulmonary vascular resistance >3 Wood units[a]	Confirm presence of pulmonary hypertension Exclude left heart disease as the cause of pulmonary hypertension (pulmonary venous hypertension) (Group 2 PH)
PFTs, chest imaging without evidence of more than mild lung disease	Exclude chronic hypoxemic lung disease as cause of PH (Group 3 PH)
Ventilation–perfusion scan without evidence of unmatched perfusion defects	Exclude chronic thromboembolic pulmonary hypertension (Group 4 PH)

[a]*An elevated pulmonary vascular resistance is not included in all published criteria for the diagnosis of PAH.*

ventricular hypertrophy (Fig. 72-6). Arrhythmias are uncommon until late in the course of the disease, when they may contribute to syncopal episodes.

Echocardiogram

When there is suspicion, the echocardiogram is the appropriate first test to assess if pulmonary hypertension is present.[194,198] Indeed, as noted earlier, the unsuspected finding of pulmonary hypertension on an echocardiogram often first brings the issue to attention. A carefully performed Doppler examination is able to quantify the tricuspid regurgitant jet in the majority of cases.[199] A modified Bernoulli equation is used to estimate right ventricular systolic (RVSP = $4v^2$ + right atrial pressure; v = tricuspid jet velocity in meters per second) and is assumed equal to the pulmonary artery systolic pressure when the pulmonic valve is normal. Normal RVSP has been reported as 28 ± 5 mm Hg. Echocardiographic evaluation with exercise is an additional consideration when estimates of RVSP at rest are normal and there is a high suspicion of pulmonary hypertension (e.g., dyspnea in a patient with systemic sclerosis and no other obvious cause).

Figure 72-7 Chronic thromboembolic pulmonary hypertension. Prominent central pulmonary arteries in conjunction with the marked pruning of the peripheral tree reflect marked pulmonary hypertension in a patient with a history of multiple pulmonary thromboemboli.

Echocardiographic measurements taken at peak exercise may reveal undue elevations, perhaps signaling the presence of earlier disease. However, normative echocardiographic values of RVSP with exercise have not been well established and whether patients with "exercise-induced" pulmonary hypertension require or benefit from therapies useful for patients with resting pulmonary hypertension is debated.

The echocardiogram also reveals important anatomical and functional information that may assist in identifying the cause of pulmonary hypertension (Table 72-8). Evaluation for a patent foramen ovale and intracardiac or intrapulmonary shunting of blood should be performed (e.g., using "bubble" contrast). Echocardiography can help to rule out related anatomic abnormalities, such as acquired or congenital mitral valve disease or left atrial myxoma. Left ventricular hypertrophy, signs of diastolic noncompliance, decreased systolic function or focal hypokinesis as well as mitral or aortic valvular

TABLE 72-8 Potential Causes of Pulmonary Hypertension that may be Identified by Echocardiography

Conditions that Predispose to Pulmonary Hypertension
Congenital or acquired valvular disease (MR, MS, AS, prosthetic valve dysfunction)
Left ventricular systolic dysfunction
Impaired left ventricular diastolic function (hypertensive heart disease, HCM, Fabry disease, infiltrative cardiomyopathies)
Other obstructive lesions (aortic coarctation, supravalvular AS, subaortic membrane, cor triatriatum)
Congenital disease with shunt (ASD, VSD, coronary fistula, patent ductus arteriosus, anomalous pulmonary venous return)
Pulmonary embolus (thrombus in IVC, right-sided cardiac chamber, or PA; tricuspid or pulmonic valve vegetation)
Pulmonary vein thrombosis/stenosis
Findings that Suggest Specific Disease Entity
Left-sided valve changes (SLE, anorexigen use)
Intrapulmonary shunts (hereditary hemorrhagic telangiectasia)
Pericardial effusion (IPAH, SLE, systemic sclerosis)

ACCF/AHA 2009 expert consensus document on pulmonary hypertension: a report of the American College of Cardiology Foundation task force on expert consensus documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc. and the Pulmonary Hypertension Association. J Am Coll Cardiol. 2009;53(17):1573–1619.

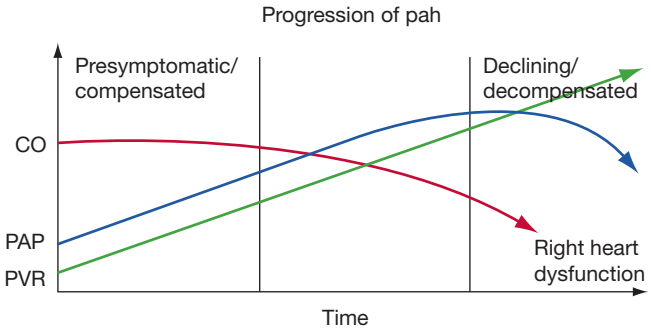

Figure 72-8 Hemodynamic changes during the progression of pulmonary arterial hypertension. With progressive increase in the pulmonary vascular resistance (PVR), the pulmonary artery pressure (PAP) initially increase until a failing right heart can no longer generate the required pressures to maintain cardiac output (CO). At this late stage both the cardiac output and pulmonary pressures may fall. *(Reproduced with permission from Friedman EB, Palevsky HI, Taichman DB. Classification and prognosis of pulmonary arterial hypertension. In: Pulmonary Vascular Disease, Taichman DB. Philadelphia: WB. Saunders; 2006.)*

defects all are vital observations when evaluating the likely cause of pulmonary hypertension. Assessment of right ventricular size and function is essential, as the symptoms caused by pulmonary hypertension and the prognosis of patients with PAH are determined in large measure by the status of the right heart (Fig. 72-8). Indeed, unexplained echocardiographic findings of RV dilation and/or decreased function warrant further investigation regardless of whether pulmonary hypertension appears to be present by echocardiographic estimate. The degree of RV function is often evaluated subjectively, but more quantitative approaches to assessment are becoming more commonly reported, have variably been shown to predict right ventricular output and patient prognosis, and may provide better means of assessing change with disease progression or in response to therapy. Such approaches include evaluation of the tricuspid annular plane systolic excursion, tissue Doppler imaging, and myocardial performance index (Tei-Doppler index).[200] The presence and greater size of a pericardial effusion are also poor prognostic signs.[201–204] Flattening of the intraventricular septum is seen with advanced right heart dilation and failure, and the leftward movement of the septum may impair left ventricular filling (Videos 72-1 and 72-2).

Video 72-1 Short-axis view of an echocardiogram of a patient with pulmonary hypertension demonstrating flattening of the interventricular septum with bowing toward the left ventricle during diastole. The right ventricle is hypocontractile. A small pericardial effusion is demonstrated as well. *(Used with permission of Drs. Lissa Sugeng and Wassim Fares, Yale School of Medicine.)* **Video 1, still shot 1**: An echocardiogram performed during diastole in the short-axis view demonstrates an enlarged right ventricle (RV), a flattened interventricular septum (IVS) with bowing toward the left ventricle (LV), and a small pericardial effusion (PE). *(Used with permission of Drs. Lissa Sugeng and Wassim Fares, Yale School of Medicine.)* **Video 1, still shot 2**: An echocardiogram performed during systole in the short-axis view demonstrates an enlarged right ventricle (RV), a flattened interventricular septum (IVS), and a small pericardial effusion (PE). Impaired filling of the left ventricle (LV) during diastole compromises stroke volume. *(Used with permission of Drs. Lissa Sugeng and Wassim Fares, Yale School of Medicine.) Access at www.fishmansonline.com*

Video 72-2 A four-chamber view of an echocardiogram in a patient with pulmonary hypertension. The right ventricle (RV) is enlarged, dilated, and hypocontractile. The right atrium (RA) is enlarged. The interventricular septum (IS) moves paradoxically toward the left ventricle (LV) during diastole, impairing LV filling. A small pericardial effusion (PE) is demonstrated. *(Used with permission of Drs. Lissa Sugeng and Wassim Fares, Yale School of Medicine.)* **Video 2, still shot 1**: An echocardiogram in the four-chamber view demonstrating an enlarged, dilated RV and RA, as well as a relatively underfilled left ventricle LV and a small PE. The moderator band (MB) of the right ventricle is well visualized. *(Used with permission of Drs. Lissa Sugeng and Wassim Fares, Yale School of Medicine.) Access at www.fishmansonline.com*

While the correlation between echocardiographic estimates of pulmonary arterial systolic pressure and measurements taken at right heart catheterization is generally good, there is significant variability and confirmation by catheterization is absolutely required when the presence of pulmonary hypertension will influence the approach to treatment. For example, in the setting of some patients with severe COPD in whom an echocardiogram reveals evidence of pulmonary hypertension, confirmation by right heart catheterization might not impact medical therapy. If, on the other hand, there is consideration of surgical interventions for the COPD (e.g., transplantation or volume reduction), confirmation of the presence of pulmonary hypertension with catheterization may be important. When the diagnosis might be PAH, diagnostic catheterization is absolutely required to confirm the diagnosis and to guide appropriate therapy. Cardiac catheterization in the evaluation of pulmonary hypertension is described in the following section.

Pulmonary Function Testing, Ventilation–Perfusion Scanning, Sleep Studies

Once echocardiographic evidence of pulmonary hypertension has been established, testing for possible causes is in order. Pulmonary function tests, a radionuclide ventilation–perfusion scan, and overnight oximetry are essential to screen for possible underlying obstructive/restrictive lung disease, occult thromboembolism, and sleep-disordered breathing, respectively. Although computed tomographic angiography may reveal the presence of organized thrombus and is frequently useful for evaluation of other possible causes of the patient's symptoms, it is not established to be sufficiently sensitive to exclude CTEPH. Since a diagnosis of CTEPH as a cause of pulmonary hypertension will markedly alter therapeutic approach, its exclusion with a ventilation–perfusion scan remains an essential test (Fig. 72-9). A history or examination findings suggestive of sleep-disordered breathing should prompt performance of overnight oximetry and/or polysomnography. Treatment of significant sleep apnea may be all that is required to treat mild pulmonary hypertension in some patients with preserved right ventricular function who are followed closely for compliance and resolution of pulmonary hypertension.

■ LABORATORY TESTING

Blood tests including HIV antibody, rheumatologic serologies (e.g., ANA), liver function tests, and a complete blood count are essential. Dyspnea due to PAH may the presenting symptom leading to the initial diagnosis of systemic sclerosis or HIV infection, and the presence of either would alter required therapeutic plans. Abnormal liver function should prompt further evaluation for possible portal hypertension as an explanation for PAH.

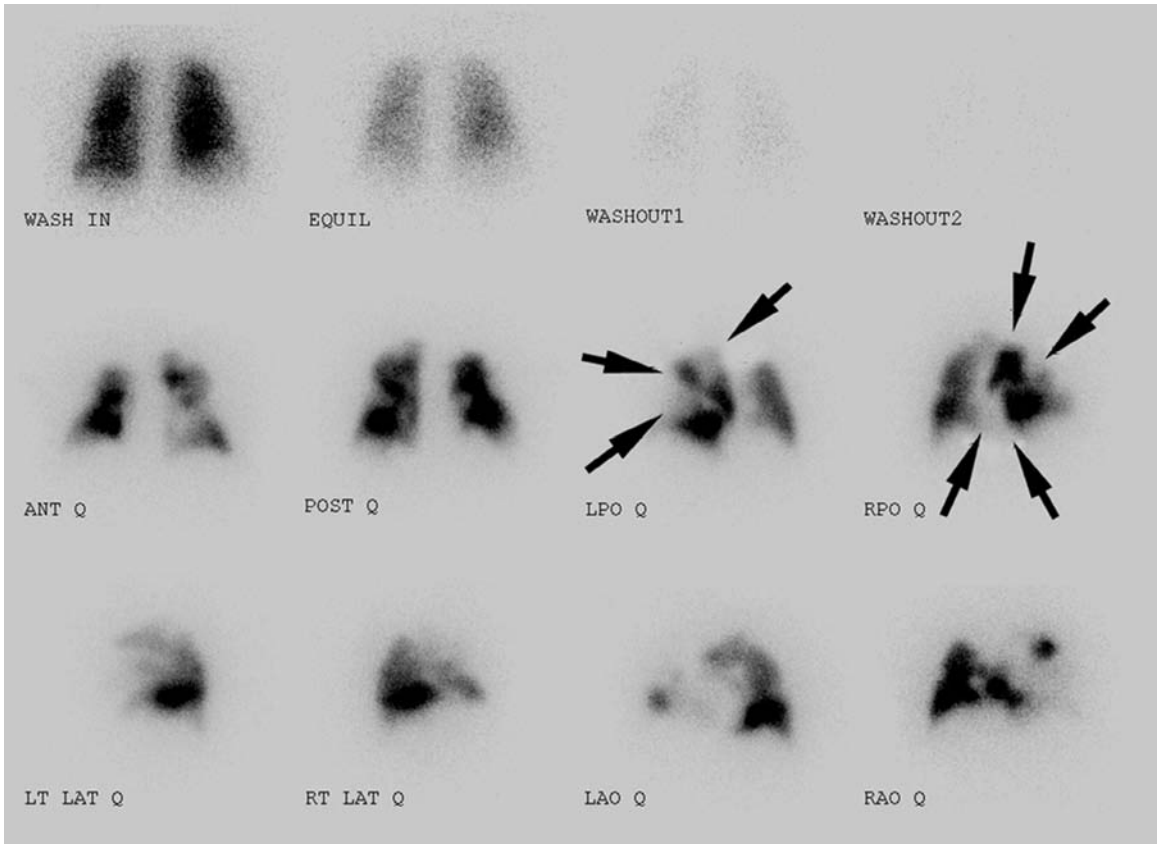

Figure 72-9 Ventilation–perfusion scan in chronic thromboembolic pulmonary hypertension. The top row of images shows normal ventilation; images in the following two rows reveal multiple unmatched perfusion defects, indicated by arrows in the posterior oblique views. *(Image used with permission of Kim Kerr, MD.)*

EXERCISE TESTING AND ASSESSMENT OF OXYHEMOGLOBIN SATURATION

Baseline testing should also include assessments of exercise tolerance and a determination of whether supplemental oxygen is required. A 6-minute walk test is a useful means of assessing exercise capacity and prognosis. It may be useful when choosing initial therapy and serial testing can be helpful in evaluating the response to therapy. Measurements of arterial oxyhemoglobin saturation both at rest and with exertion are important to ensure adequate levels are maintained, and to titrate supplemental oxygen appropriately.

CARDIAC CATHETERIZATION

Right heart cardiac catheterization is required to confirm the diagnosis of pulmonary hypertension, test for important cardiac causes, and in appropriate patients perform vasodilator trials to determine an initial approach to therapy. Both to ensure appropriate interpretation and avoid the need to subject the patient to repeated invasive testing when initial testing is inadequately performed, cardiac catheterization should be performed under the direction of expert operators sufficiently familiar with the evaluation of pulmonary hypertension. Except in those considered to be at very low risk of coronary artery disease, many expert centers also perform a left heart catheterization in all patients. In addition to coronary angiography, measurement of the left ventricular end diastolic pressure (LVEDP) is important to exclude left atrial hypertension (e.g., as seen in diastolic dysfunction) as an important cause of pulmonary hypertension (pulmonary venous hypertension). Although pulmonary artery wedge pressure (PAWP) is routinely obtained during right heart catheterization, it does not always provide an accurate estimate of LVEDP. To maximize the chance of an accurate measurement, PAWP should be made at end expiration and not on the basis of digitally computed "mean" PAWP.[205,206] The PAWP should be measured with equipment leveled at the midchest position (halfway between the table surface and skin surface at the sternum). Discrepant readings between the PAWP and the LVEDP may occur frequently, and so the need for left heart catheterization to directly measure left-sided pressures should be carefully considered given the therapeutic implications of the findings.[207]

During right heart catheterization, serial measurements of blood oxygen saturation should be performed for evidence of a "step up" in oxyhemoglobin saturation suggesting the presence of left to right shunting of blood as an etiology of PAH. Attention should also be paid to the right atrial pressure as significant elevation has been associated with a poorer prognosis. When suspicion of pulmonary hypertension is high and resting pressures are normal, some centers assess values with exercise (e.g., with serial leg lifts, arm raising with weights, or with a stationary bicycle). As noted previously, however, normative values for pressures with exercise have not been well established and whether exercise-induced PAH represents an early stage of disease or alone warrants treatment remains debated.

A diagnosis of PAH requires a mean pulmonary artery pressure greater than or equal to 25 mm Hg, an adequately measured PAWP or a directly recorded LVEDP of less than or equal to 15 mm Hg; an elevated PVR >3 Wood units is also seen and required in some published diagnostic criteria for PAH. The CO is obtained by either thermodilution or use of measured arterial and venous hemoglobin saturations and the Fick principle; the latter is likely more accurate when either significant tricuspid or pulmonary regurgitation is present or the CO is very low. The PVR is calculated as (mean

PA pressure – PCWP)/CO. A normal PVR may be seen if pulmonary hypertension is due to pulmonary venous hypertension, or abnormally high CO (as may occur, for example, in patients with hyperthyroidism, thiamine deficiency, Paget disease of the bone, or arteriovenous fistulae in hereditary hemorrhagic telangiectasia). PH with an elevated CO and normal PVR may also be found in some patients with liver disease (which is to be distinguished from those with PAH associated with liver disease, termed portopulmonary hypertension (POPH) and characterized by an elevated PVR, PH, and a variable CO). It must also be noted that although the hemodynamic profile of patients with PAH (an elevated mean PA with a normal PAWP) may be seen in patients with pulmonary hypertension and pulmonary parenchymal disease (Group 3) but pulmonary function testing and chest imaging distinguish these patients from those with PAH.

In patients with PAH, vasodilator testing is often performed at the time of right heart catheterization to identify those few patients in whom a trial of treatment with oral calcium channel antagonists is appropriate (discussed below). Agents commonly used for acute vasodilator testing include inhaled nitric oxide, intravenous adenosine, or epoprostenol administered by either route.[208–214] Although the definition has varied, a decrease in the mPAP of at least 10 mm Hg to a value less than 40 mm Hg, together with a CO that is unchanged or increased (but not decreased) is generally considered a "positive" acute vasodilator response.[194,215]

Acute vasodilator testing carries significant risk and deaths have been reported.[216] It should not be performed when PVOD is suspected, as the inability of the venous system to accommodate an acute increase in flow may precipitate pulmonary edema.[217] Acute vasodilator testing should be performed only at experienced centers and when the results will influence therapy. Patients who do not demonstrate acute vasoreactivity at the time of right heart catheterization should not receive calcium channel antagonist therapy.

EPIDEMIOLOGY OF PAH

Estimates of the incidence of PAH in studies from France, Scotland, Spain, and the United States range between 2.4 and 7.6 cases per million people. Prevalence estimates range between 15 and 26 cases per million people.[189,191,218–221] Overall, PAH appears to occur more frequently among women (around 2:1) and at a mean age of approximately 50. IPAH and PAH associated with connective tissue diseases appear to be the most commonly recognized in published studies, although limited studies suggest that the burden of schistosomiasis-related disease is likely large.

In the largest such study to date, the mean (±SD) age of patients enrolled in a multicenter US-based national registry of 2525 patients with PAH was 50.1 ± 14.4 years and 79.5% were female. Nearly half of the patients were diagnosed with idiopathic disease (Fig. 72-10). It is important to note that 86% of these were prevalent patients, with a mean of almost 3 years from the time of initial PAH diagnosis until enrollment in the study, thus limiting the ability to extrapolate these data to incident disease.[191]

The prognosis of patients with PAH is worse when hemodynamic variables indicate right heart dysfunction (e.g., elevated right atrial pressure or a depressed CO), and varies according to the specific diagnosis, with PAH associated with scleroderma and portal hypertension portending a worse prognosis than other forms of PAH. Although the outlook appears to have improved with advances in disease management and the availability of multiple drug classes for therapy, many patients continue to require consideration of lung transplantation, and many continue to die. Several risk prediction tools have been recently developed, derived using data from both incident and prevalent patients managed with currently available therapies.[222] One such tool derived and validated with patients in a large US-based cohort is shown in Figure 72-11. This, as well as other risk prediction models, have been validated in populations from other countries.[222–225]

SPECIFIC PAH DISEASE SUBTYPES

In the sections to follow, the various PAH disease subtypes will be discussed in detail.

■ IDIOPATHIC PULMONARY ARTERIAL HYPERTENSION

IPAH is a rare disease with an estimated incidence of 1 to 2 cases per million in industrialized countries.[226–228] The paucity of numbers of patients with IPAH and the likelihood that diverse causes and pathogenetic mechanisms can produce the same clinical syndrome have complicated descriptions of its natural history. In the past, certain stereotypes were regarded as the norm: young women with Raynaud's syndrome, with acute onset of dyspnea and fatigue, and death within 3 years. Now it is appreciated that even though there

World Health Organization (WHO) Group I pulmonary arterial hypertension classification of REVEAL patients at enrollment. **A.** WHO Group I PAH classification. **B.** Breakdown of associated PAH subgroup. APAH, associated PAH; CHD, congenital heart disease; CVT/CTD, collagen vascular disease/connective tissue disease; FPAH, familial PAH; PAH, pulmonary arterial hypertension; PCH, pulmonary capillary hemangiomatosis; PPHN, persistent pulmonary hypertension of the newborn; PVOD, pulmonary venoocclusive disease; REVEAL, Registry to Evaluate Early And Long-term PAH Disease Management.

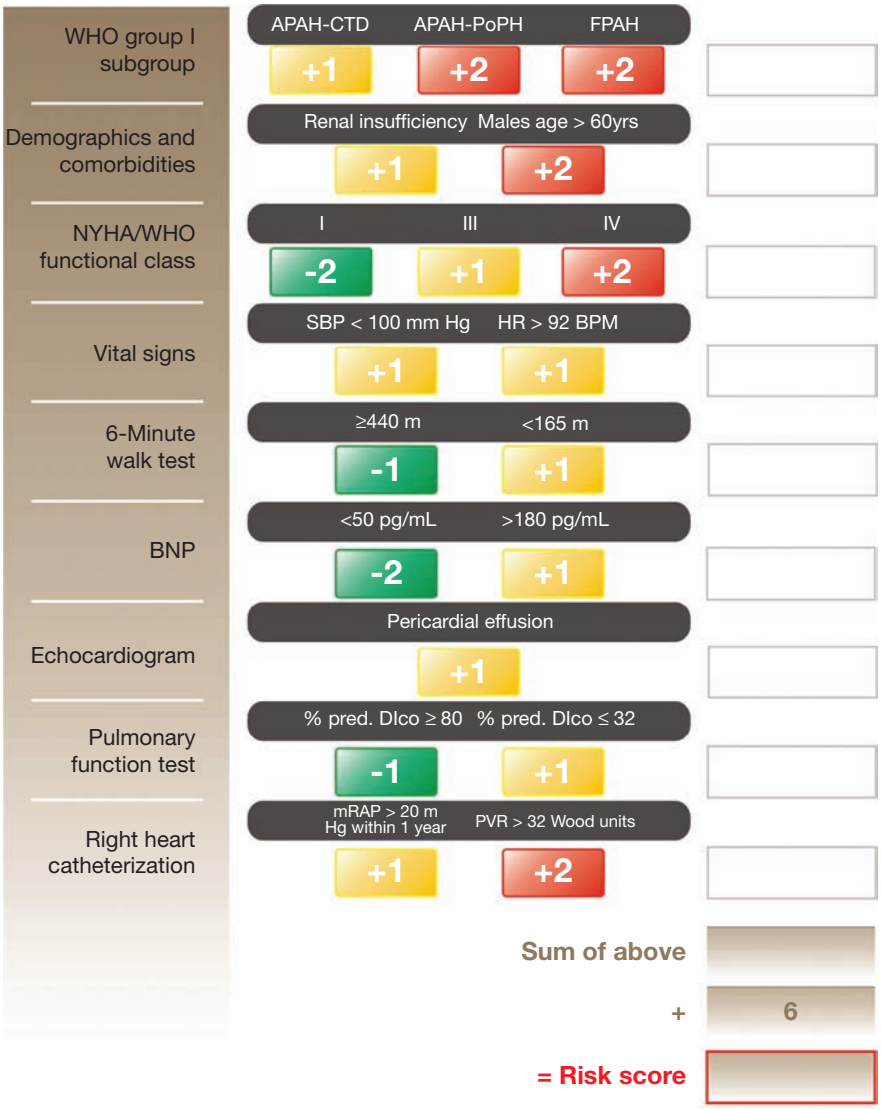

Figure 72-11 REVEAL Registry PAH Risk Score Calculator. Calculated risk scores can range from 0 (lowest risk) to 22 (highest risk). In the REVEAL cohort, the average predicted 1-year survival was 95% to 100% in the low-risk group (score <7), 90% to <95% in the average-risk group (score 8), 85% to <90% in the moderately high-risk group (score 9), 70% to <85% in the high-risk group (score 10–11), and <70% in the very high-risk group (score >12). If N-terminal proBNP is available and BNP is not, listed cut points are replaced with <300 pg/mL and >1500 pg/mL. APAH, associated pulmonary arterial hypertension; BNP, brain natriuretic peptide; BPM, beats per minute; CTD, connective tissue disease; $D_{L_{CO}}$, diffusing capacity of lung for carbon monoxide; FPAH, familial pulmonary arterial hypertension; HR, heart rate; mRAP, mean right atrial pressure; NYHA, New York Heart Association; PAH, pulmonary arterial hypertension; PoPH, portopulmonary hypertension; PVR, pulmonary vascular resistance; REVEAL Registry, Registry to Evaluate Early and Long-term Pulmonary Arterial Hypertension Disease Management; SBP 5 systolic BP; WHO, World Health Organization. *(Reproduced with permission from Benza RL, Gomberg-Maitland M, Miller DP, et al. The REVEAL Registry risk score calculator in patients newly diagnosed with pulmonary arterial hypertension. Chest. 2012;141(2):354–362.)*

is such a subset, prolonged survival in response to medical therapy is not unusual and the disease may affect all ages, both sexes, and different ethnic groups.[229,230]

To overcome the limitations of sporadic reports, the NIH established a nationwide registry in 1981 to collect and analyze data on IPAH (then called PPH). Criteria for entry of a patient into the national registry included normal pulmonary function tests (except for a moderate reduction in diffusing capacity); a right heart catheterization to exclude congenital or left heart disease; perfusion scans and, if inconclusive, pulmonary angiography to exclude CTEPH; and serologic testing to rule out collagen vascular disease. Included in the registry were certain associated diseases, such as hepatic cirrhosis, because the reason for the association was unclear and because of the suspicion that the association might provide a clue to etiology.

By the close of the registry in 1987, data were available on 187 patients.[231] The mean age was 36.4 years and similar for women and men, although the female-to-male ratio was 1.7:1. Few patients were older than 60 years, although race and ethnicity of the cohort was similar to that of the general population. Similar demographic trends have been reported in series from France, Israel, Japan, and Mexico.[228,232,233] Dyspnea was the most common initial symptom and the mean time to diagnosis among patients in the NIH registry was 2 years.

Prognosis of IPAH

Without effective therapy the prognosis of IPAH is very poor. The median survival of patients in the NIH registry was 2.8 years; estimated survival at 1, 3, and 5 years was 68%, 48%, and 34%, respectively.[231] Similar or even poorer figures have been reported absent

effective treatment in other series from various countries.[46,234] Most patients die of right heart failure.

The outlook is worse with more advanced symptoms. NIH registry patients with WHO functional classes III and IV symptoms had a median survival of only 31.5 months, as compared with 58.6 months in patients with milder impairment (Class I or II; Table 72-4). Although the figures have improved, functional status remains a significant indicator of prognosis even with effective advanced therapy.[228,235–238] Functional assessment with a 6-minute walk test, for example, is a useful means of following response to therapy and independently predicts prognosis.[237,239–241] Maximal oxygen consumption has also been used to assess response to therapy and can correlate with survival.[241]

On echocardiogram, an enlargement of the right atrium, the presence of a pericardial effusion and its severity are each associated with an increased risk of death.[201–204] A relative increase in the isovolumetric contraction and relaxation times of the RV as compared to RV ejection time is indicative of RV dysfunction and a significantly poorer prognosis.[242]

Levels of endothelin, catecholamines, and atrial natriuretic peptide have been correlated with disease severity, whereas elevations of uric acid, von Willebrand factor, D-dimer, troponin-T, and brain natriuretic peptide have each been associated with a poorer survival in patients with IPAH.[243–249] More recently, a low serum albumin has been associated with an increased risk of death, independent other measures that would reflect passive hepatic congestion or right heart dysfunction.[204] None of these putative prognostic markers is currently incorporated into clinical decision making.

Hemodynamic variables reflecting the development of right heart failure (an increased right atrial pressure and decreased cardiac index) are associated with a poorer prognosis.[228,233,250,251] Worsened survival has been seen in association with both increasing and decreasing mean pulmonary artery pressures (mPAPs). These observations are not necessarily contradictory. Rather, they reflect the natural history of right heart failure in PAH: mPAP rises initially as the vascular derangements worsen only to fall later as the right heart fails and is no longer able to generate an increased pressure (Figs. 72-8 and 72-12.)

A regression equation based on hemodynamic data from the NIH registry has been used to predict survival.[233,252] Because of the dismal prognosis expected, long-term "control" groups without treatment in clinical trials are unethical and assessments of survival with new therapies have been compared with outcome as predicted by the NIH equation. Such comparisons have suggested improved survival with epoprostenol and endothelin receptor antagonists. These improvements are addressed in the discussion of individual therapies in the following sections. As a growing number of effective drugs are now routinely employed, the relevance of survival estimates based on data from an era lacking effective treatment is questionable. The NIH registry equation may no longer be sufficient for predicting survival given current standards of care and background therapies. Indeed, when applied to a more recent cohort of patients treated with current agents, the NIH equation underestimated survival.[204]

It is not surprising that the prognosis of patients with IPAH who have suffered cardiac arrest is dismal even when resuscitative efforts are initiated promptly. In a retrospective review of the records of over 3000 patients, 132 episodes of attempted cardiopulmonary resuscitation (CPR) following cardiac arrest were identified. Survival at 90 days following CPR was only 6%.[253]

HERITABLE PULMONARY ARTERIAL HYPERTENSION

A family of patients with what was then termed "PPH" was first described by Dresdale in 1951.[4] Thereafter additional families were reported, and Loyd and Newman identified an autosomal dominant

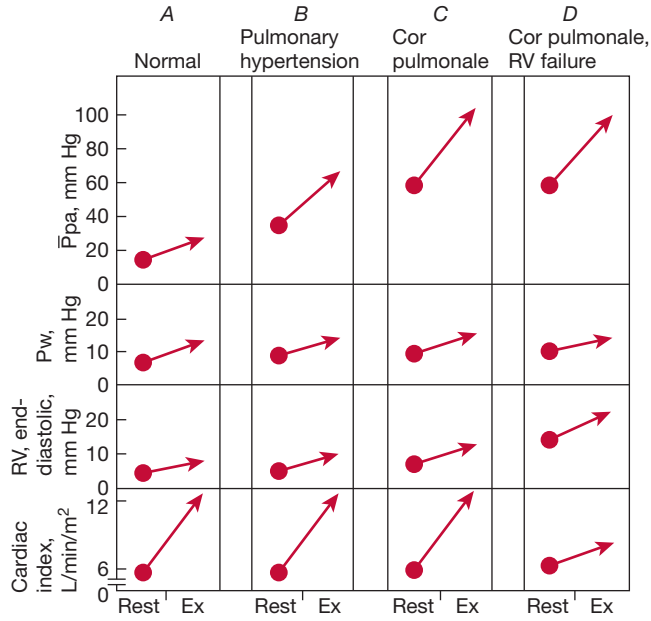

Figure 72-12 Schematic representation of evolution of chronic cor pulmonale. Hemodynamic studies at rest and during exercise in a normal subject (**A**). The stage of pulmonary arterial hypertension (**B**) is succeeded by cor pulmonale (**C**), in which the right ventricle performs normally despite pulmonary arterial hypertension but is known to be enlarged because of radiographic and electrocardiographic findings. Once right ventricular failure supervenes (**D**), cardiac output fails to increase normally during exercise, despite an increase of right ventricular filling pressure (end-diastolic) to abnormally high levels.

pattern of inheritance, a greater tendency for female carriers to manifest clinical disease, and an earlier onset in successive generations (genetic anticipation).[254,255] Linkage analysis led to a marker at chromosome 2q31–32, and mutations in the gene for a member of the TGFβ family of receptors, bone morphogenetic protein receptor II (BMPRII), were identified as the cause of heritable PAH.[175,176,256,257] Mutations in another member of the TGFβ family, ALK1 predispose patients with hereditary hemorrhagic telangiectasia to develop PAH.[185,186,258,259]

TGFβ receptors control an array of cell growth and differentiation systems. BMP signaling is involved in the control of normal vascular development as well as the homeostasis of the adult pulmonary vasculature, likely by regulating the growth and apoptosis of endothelial and smooth muscle cells.[170] In an assessment of mutations from the coding sequence of *BMPRII* in 210 patients, over 140 distinct mutations were identified, the majority predicting premature truncation of the gene transcript. Disease is believed to result from haploinsufficiency, where inadequate quantities of BMPR2 protein are produced for normal function.[177] In addition, the low penetrance observed in heritable PAH suggests that additional environmental factors likely contribute to disease development in genetically susceptible individuals.[260] Up to 70% of patients with heritable PAH have germline mutations in a *BMPRII* allele as do some patients with idiopathic and other associated forms of PAH.[175,176,178–183] Clinically asymptomatic carriers may have evidence of mild pulmonary hypertension on echocardiogram.[261] Common ancestries have been identified that link previously assumed "sporadic" cases of IPAH. Failure to recognize heritable cases of PAH may arise due to incomplete family history taking or reporting, and low disease penetrance, particularly in smaller families.[179,262]

There are no established differences in the approach to treating patients with heritable PAH as compared with IPAH. At present, the clinical evaluation of patients remains the same. Genetic testing of family members should be considered to assess the risk of developing PAH. As a rough guide, there is a one in five chance of PAH developing in a first-order relative who carries a disease-causing *BMPRII* mutation. If genetic testing has not been performed, the risk of disease developing in the first-order relative of a patient with known heritable PAH is approximately one in ten. In the absence of a disease-causing *BMPRII* mutation, the risk of disease is the same as in the general population (estimated at one in a million).[260] Because of the potential interpersonal, psychological, and economic implications of identifying an at-risk genotype, genetic testing should only be performed in conjunction with professional genetic counseling.

■ PULMONARY ARTERIAL HYPERTENSION ASSOCIATED WITH SPECIFIC CONDITIONS

Pulmonary arterial hypertension has been reported in a wide variety of disorders, as discussed below.

Collagen Vascular Diseases

The lungs and the pleura are commonly affected in patients with collagen vascular diseases. Although the incidence in each of the collagen vascular diseases varies, interstitial lung disease is more common than isolated involvement of the pulmonary vasculature. When present, however, PAH is frequently a more rapidly lethal development than interstitial lung disease. It is important in this population to differentiate between pulmonary hypertension associated with interstitial lung disease and the true development of PAH that occurs in the absence of significant interstitial changes. Pulmonary hypertension may also develop due to left heart ischemia or diastolic dysfunction, or to thromboembolic complications of collagen vascular disease.[263] Unfortunately, both interstitial lung disease and true PAH coexist in many patients. Most clinical studies of PAH therapy have excluded patients with collagen vascular diseases and evidence of "significant" restriction (usually defined as an FVC of <70% of predicted values) or interstitial changes on radiographs. Drugs that are efficacious in PAH have not proven effective in the treatment of pulmonary hypertension that accompanies interstitial lung disease. Among patients with systemic sclerosis, PAH occurs most commonly in those with limited disease or the CREST syndrome. Prevalence estimates have ranged significantly, but when investigated with right heart catheterization, PAH has been found in between 7% and 12% of patients.[264,265] The prognosis of patients with scleroderma is worse when their disease is complicated by PAH than by pulmonary fibrosis, even when the latter is severe. Nearly one-half of patients with PAH in the context of scleroderma die within 1 year, compared with a 3-year 50% mortality when the lung is affected by fibrosis alone.[266,267] Even with the use of equivalent therapies, the outcome of patients with PAH associated with systemic sclerosis is less favorable than for IPAH (Fig. 72-13).[90,236,266,268,269]

When estimated by echocardiography, pulmonary hypertension has been identified in approximately 4% to 10% of patients with systemic lupus erythematosis, but as many as 43% when patients are followed prospectively.[270–275] Estimates of prevalence are variable and most were obtained without confirmation by catheterization in patients with mixed connective tissue disease. Regardless of frequency, however, when it is present, PAH appears to be a significant cause of death in these patients. PAH occurs in numerous other rheumatologic disorders, including Sjögren's syndrome and rheumatoid arthritis although firm data on incidence or impact on survival are lacking.

Human Immunodeficiency Virus

Patients infected with the human immunodeficiency virus (HIV) are at increased risk of developing PAH. The mechanism by which HIV predisposes to the development of PAH is not known, but it does not appear to be due to direct viral infection of pulmonary vascular endothelial cells.[276] Infection may cause elevations in local concentrations of growth factors or other mediators such as endothelin to indirectly result in the development of PAH.[277–279]

The estimated annual incidence of PAH among HIV-infected patients is approximately 0.5%, significantly higher than the estimated annual incidence of 1.7 per million in the general population.[226,280] The annual incidence of pulmonary hypertension in a large Swiss cohort of HIV-positive patients appears to be declining, having peaked at 0.24% in 1993 as compared with 0.02% in 2001; this decline was hypothesized to relate to the introduction of highly effective antiretroviral therapies.[281] However, no such change was seen in a French study population, comparing rates of HIV-associated PAH between the early 1990s and 2008.[282] It is unclear, therefore, if better control of HIV infection alters the risk of developing PAH.

Symptoms, hemodynamic findings, and survival of PAH associated with HIV appear to be similar to IPAH.[283] Like IPAH, the prognosis is worse with more advanced symptoms (e.g., WHO functional class III or IV as compared with either I or II). A CD4 lymphocyte count below 212 cells/mm^3 has also been associated with a poorer prognosis.[284] Mortality is more often directly attributable to PAH and right heart failure than to infectious complications.[283,284]

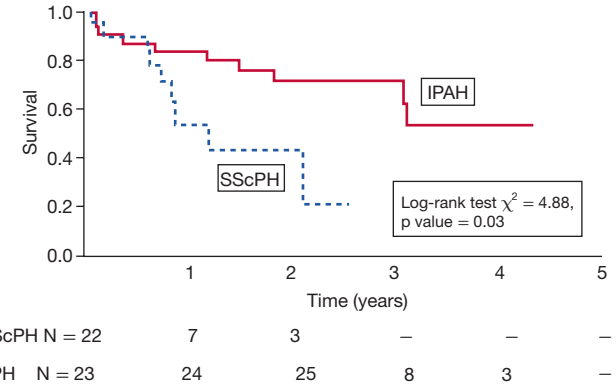

Figure 72-13 Survival of patients with systemic sclerosis–associated pulmonary arterial hypertension is worse than that of patients with idiopathic pulmonary arterial hypertension despite equivalent therapies. *(Reproduced with permission from Kawut SM, Taichman DB, Archer-Chicko CL, et al. Hemodynamics and survival in patients with pulmonary arterial hypertension related to systemic sclerosis. Chest. 2003;123(2):344–350.)*

Portal Hypertension

The lung may be affected by chronic liver disease in several ways, including the hepatopulmonary syndrome with the development of vascular dilatations and resultant hypoxemia, the development of pleural effusions (hepatic hydrothorax), and pulmonary hypertension. Liver disease is frequently characterized by a low systemic vascular resistance and high CO; the accompanying increased flow and blood volume result in pulmonary hypertension although the PVR is normal or even decreased. Vascular changes resulting in an elevated PVR, on the other hand, are seen with the development of PAH associated with portal hypertension, also termed POPH. Evaluation of pulmonary hypertension in these patients may be difficult as the high CO state of liver disease may precede or accompany the developmental POPH. Thus, as compared with patients with IPAH, patients with similar degrees of clinical impairment and POPH may display numerically smaller elevations in PVR or decrements in CO.[285]

The pathologic changes seen in POPH are similar to those described in other forms of PAH: vasoconstrictive, proliferative, and obliterative changes including both plexiform and thrombotic lesions.[286,287] The pathogenesis is not well understood and may involve abnormal proliferative (or other) vascular responses, but inducing triggers are not well defined. Portal hypertension might alter the vasoactive mediators to which the pulmonary circulation is exposed because of blood bypassing the liver via portosystemic shunts and returning to the systemic circulation.[288] As in other forms of PAH, altered levels of vasodilators and vasoconstrictors have been observed in patients with POPH.[289,290] Women with portal hypertension appear to be at greater risk for the development of POPH than men, as do patients with autoimmune hepatitis. The severity of portal hypertension does not appear to influence the risk of POPH.[291,292] Predisposing, likely genetic, factors are also believed to determine why only some patients with liver disease develop POPH.[293] The degree to which mutations in *BMPRII* are involved in the development of POPH remains unclear.

The prevalence of PAH in patients with liver disease has not been established. Estimates of up to 16% have been reported in studies screening patients with advanced liver disease.[289,294] In one series of patients evaluated for liver transplantation, the prevalence of POPH was 8.5%.[286] Incidence has not been evaluated. Without effective treatment the prognosis of POPH is poor, with a mean survival of only 15 months reported in one retrospective series of 78 patients.[295] Survival with current therapies is worse for patients with POPH than IPAH. In the REVEAL cohort, despite less severe hemodynamic derangements at the time of enrollment, 5-year survival of 174 patients with POPH was significantly worse than of 1478 patients with IPAH/HPAH (40% vs. 64%, respectively), although the initiation of therapy appeared to have been delayed in POPH as compared to IPAH.[285]

The symptoms and findings on physical examination of POPH reflect the presence of both PAH and of chronic liver disease. While shortness of breath may be overshadowed by abdominal complaints and fatigue, dyspnea becomes prominent as POPH progresses. Differentiating between the contributions of PAH-related cor pulmonale and cirrhosis as the cause of fatigue, edema, and abdominal complaints such as satiety, bloating, and ascites can be difficult.

Compared with IPAH, relatively little is known regarding effective treatments for POPH, due to the small number of patients with POPH and their exclusion from clinical trials. Mild disease usually does not require specific treatment; whether early therapy will prevent progression is unknown. Treatment for more severe disease differs from that of other patients with PAH in that some experts have advised against the use of calcium channel antagonists even if acute vasoreactivity is documented during cardiac catheterization. This concern is based upon the potential worsening of intrahepatic venous gradients by calcium channel antagonists.[296–299] Diuretics are particularly important in POPH due to the frequent presence of both cor pulmonale and cirrhosis causing fluid retention, edema, and ascites. Anticoagulation is less frequently employed due to pre-existing coagulopathy related to underlying hepatic synthetic deficiencies or the presence of splenomegaly and significant thrombocytopenia.

The experience with inhaled or parenteral prostenoids or oral endothelin antagonists or phosphodiesterase-5 inhibitors in the treatment of POPH has been reported in small case series.[300–309] Given the significant incidence of liver function abnormalities associated with endothelin antagonist treatment, there has been concern for their use in patients with POPH. However, bosentan was successfully used in a nonrandomized study of 11 patients with POPH and Child Class A resulting in improvements in hemodynamic values, exercise capacity, and no significant liver toxicity.[310] The potentially more favorable liver toxicity profile of ambrisentan may permit therapy in additional patients with POPH, and the safe use of the drug in this setting has been reported.[311,312]

Many patients with advanced hepatic dysfunction require liver transplantation. The perioperative mortality is significantly increased by the presence of severe PAH, however, and therefore a mean PA pressure above 50 mm Hg is considered a contraindication to transplantation at most centers.[313,314] Effective treatment to lower PAPs has been used in some patients who subsequently underwent orthotopic liver transplantation successfully.[300–303,307,315] It is therefore essential that POPH be recognized in patients being considered for liver transplantation prior to surgery. All potential liver transplant patients should be assessed by echocardiography, and cardiac catheterization should be undertaken when the estimated right ventricular systolic pressure approaches 50 mm Hg. Serial monitoring for the development of pulmonary hypertension should be performed in patients listed for liver transplantation.[316] Unlike the hepatopulmonary syndrome in which liver transplantation results in resolution of the pulmonary vascular abnormality, liver transplantation is not reliably curative of POPH. While some cases of reversal have been reported, POPH has progressed in other patients following transplantation.[296]

Drugs and Toxins

The term "dietary pulmonary hypertension" refers to the fact that substances taken by mouth can damage the pulmonary circulation. In animals, ingestion of *Crotalaria spectabilis*, an annual shrub, causes multiorgan injury, including damage to the lungs. In humans, certain appetite suppressant drugs exert similar effects.

Anorectic Agents—Aminorex and Fenfluramine Derivative

Between 1966 and 1968, an epidemic of PAH erupted in Switzerland, Austria, and Germany where the incidence increased 20-fold.[317] The epidemic followed the introduction in these countries of an appetite-depressant agent, aminorex (2-amino-5-phenyl-2-oxazoline), in November 1965. Although only 2% of those exposed to the drug developed PAH, the relative risk compared to unexposed individuals was 52:1.[318] Aminorex resembles epinephrine and amphetamine in chemical structure; both of these agents release endogenous stores of catecholamines. Aminorex was banned in 1968, and the epidemic subsided. After stopping the drug, the level of pulmonary hypertension decreased or stabilized at a tolerable level in some patients and completely reversed in others. However, in many patients, the disease continued inexorably from pulmonary hypertension to cor pulmonale and death despite discontinuation of the drug. The pathology produced by aminorex in humans was identical with that of IPAH, including plexiform lesions and intimal fibrosis. Unfortunately, attempts to produce pulmonary hypertension by administering aminorex to experimental animals were consistently unsuccessful.

This outbreak had several important epidemiologic implications: (1) A medication taken by mouth could damage pulmonary arteries and arterioles; (2) because only few of the many individuals who used the agent developed pulmonary hypertension, the possibility was raised of genetic susceptibility to injury by aminorex; (3) other anorectic medications that resemble the catecholamines and amphetamines in structure might have similar effects in predisposed individuals (this possibility was reinforced by experience with phenformin, an antidiabetic agent that resembles the amphetamines in structure); and (4) pulmonary hypertension can be reversible, particularly when detected early in its course and before pressures reach systemic levels.

After the aminorex epidemic, a variety of appetite-suppressant medications were used with little heed to the possibility that these agents might cause PAH. Then, in the early 1990s, Brenot et al.[319] called attention to possible association in Europe of PAH and the

use of fenfluramine derivatives for weight reduction, prompting the establishment of an international registry in Europe to assess the incidence and risks of IPAH. Among the 95 patients enrolled in the registry, anorectic agent use was clearly associated with an increased risk of PAH, especially when taken longer than 3 months (odds ratio 23.8). In 1996, Abenheim sounded the alarm that an epidemic might be in the making: the Food and Drug Administration in the United States had approved the use of dexfenfluramine, a fenfluramine derivative, for the long-term treatment of obesity even though experience with long-term use was extremely sparse.[226]

Approval of dexfenfluramine by the FDA was followed by a tremendous increase in sales of this and other anorectic agents. A registry of idiopathic and anorectic agent associated PAH in the United States revealed that use of fenfluramine was strongly associated with the development of PAH (odds ratio 7.5 with greater than 6 months use). A high prevalence of anorectic agent use in patients with other forms of PAH was also seen, suggesting these agents might also precipitate disease in the presence of other risks such as a collagen vascular disease.[320]

Several points were illustrated: (1) Although aminorex and the fenfluramines differ in their pharmacologic characteristics, the pulmonary vascular lesions in the patients who die of pulmonary hypertension after taking either drug are identical; (2) the longer the anorectic agent is used, the more likely pulmonary hypertension is to develop; and (3) the occurrence of pulmonary hypertension in users of anorectic agents likely is related to other determinants of susceptibility, perhaps genetic.

Aminorex and fenfluramine derivatives may cause PAH by altering blood levels of serotonin (5-HT). These agents cause the release of serotonin from storage in platelets and inhibit its reuptake,[71] and serotonin is a potent vasoconstrictor and induces the aggregation of platelets. An additional mechanism by which aminorex and fenfluramine derivatives might contribute to pulmonary vasoconstriction is via the inhibition of potassium channels that mediate vasodilation.[128] An inductive role of anorexigens in promoting the development of PAH in genetically susceptible individuals has also been hypothesized. Genotyping for the presence of mutations in *BMPRII* (with familial PAH) has not revealed a significant number of abnormalities among patients with anorexigen-associated PAH.[181,321]

In one series of 62 patients with fenfluramine-associated PAH evaluated over a 10-year period at a single center in France, the interval from drug exposure to the development of dyspnea was approximately 4 years. Hemodynamic values at the time of diagnosis were similar to a control group of patients with IPAH, although the anorectic agent–exposed patients were less likely to demonstrate acute vasoreactivity and thus be treated with calcium channel antagonists.[322] The approach to therapy for PAH associated with anorectic agent use, however, is similar as for IPAH.

Relatively little is known regarding the prognosis of anorectic agent–associated disease. Data conflict regarding prognosis as compared with IPAH. In one retrospective study of 104 patients with aminorex-associated PAH and 69 with IPAH, survival was better in both groups for patients treated with warfarin, and better overall for the anorectic-agent associated disease patients.[323] With the use of advanced therapies, survival in fenfluramine-exposed patients with PAH appears similar to that of IPAH patients.[322] When matched according to treatments and disease severity, however, a separate study of IPAH and fenfluramine-exposed patients found poorer survival in the anorectic agent group.[324]

Toxic Oil Syndrome

Another episode of dietary pulmonary hypertension unfolded with the occurrence of the "toxic oil syndrome." In May and June 1981, rapeseed oil adulterated with aniline was sold door to door as olive oil in Spain and caused an outbreak of noncardiogenic pulmonary edema.[325] Twenty thousand persons were affected, and approximately 375 died. About 2000 individuals experienced sequelae. As a consequence of close surveillance, the features of three stages of the disease were categorized as early (first 6 months), intermediate (6 months to 2 years), and chronic (persisting years). From the outset, it was clear that the damage was widespread (affecting lungs, liver, skin, nervous system, immune system, muscle, and fat) and that pervasive endothelial injury featured prominently in the pathogenesis of the clinical syndromes.

The early stage was characterized by noncardiogenic pulmonary edema, eosinophilia, and pulmonary hypertension in a subset of patients; these findings resolved within 6 months. The intermediate stage was marked by thromboembolic events, weight loss, and neuromuscular dystrophies; PAH developed in some but often resolved. The chronic stage (particularly 4 and 5 years after the oil was ingested) involved progressive PAH and cor pulmonale. Increasingly evident were vascular lesions of intimal fibrosis and proliferation in association with organized pulmonary thromboemboli. Plexiform lesions were also seen.

Unfortunately, the exact chemical ingredients in the toxic oil responsible for the syndrome remain enigmatic and are unlikely to be identified, since the bootleggers could provide no recipe for the adulterated cooking oil. Nonetheless, the outbreak did show that material taken by mouth – often in small quantities – could cause widespread endothelial injury in the lungs. It also underscored the spontaneous reversibility of the pulmonary hypertension (as well as the ineffectiveness of vasodilators tried at different stages in the disease).

Hemoglobinopathies

Patients with sickle cell anemia and other hemoglobinopathies are at increased risk for the development of pulmonary hypertension. Pulmonary hypertension in this setting has been variably categorized as WHO Group 1 (PAH) or as WHO Group 5 disease. Multiple factors likely contribute to the pathogenesis of pulmonary hypertension in patients with hemolytic states, including recurrent thromboembolism, recurrent infectious or hemolytic crises causing lung damage and hypoxia, asplenia, and the microvascular effects of intravascular hemolysis itself. Hemolysis contributes to the development of pulmonary hypertension by reducing the bioavailability of NO. Hemoglobin is released into the plasma from destroyed red blood cells where it can bind and sequester NO. There is also destruction of the substrate for NO production, L-arginine, by increased levels the enzyme arginase, also released into plasma by hemolysis. Further effects of hemolysis include an increase in the expression of vascular adhesion molecules, platelet activation, the production of free radicals, and elevated levels of endothelin, all of which might contribute to the vasculopathy.[326–328]

The reported prevalence of pulmonary hypertension in patients with sickle cell anemia has ranged from 0% to 40%. Factors influencing this wide range include the age of patients examined, whether the study involved asymptomatic or symptomatic patients, and whether testing involved echocardiography or cardiac catheterization. In one prospective study of 195 adult patients with sickle cell anemia, 32% of patients had echocardiographic evidence of pulmonary hypertension, of which over 90% had the SS phenotype.[329] Pulmonary hypertension is associated with a poorer prognosis in patients with sickle cell anemia.[326,329] Pulmonary hypertension has also been noted in patients with other chronic hemolytic disorders, including thalassemias, hereditary spherocytosis, and paroxysmal nocturnal hemoglobinuria.[330–335]

The hemodynamic findings of pulmonary hypertension associated with sickle cell anemia differ from those seen in patients with idiopathic or other forms of associated PAH. Specifically, the mean PAP tends to be lower and CO higher in patients with sickle cell anemia diagnosed

with pulmonary hypertension than in patients with IPAH. In addition, many patients with hemoglobinopathy and pulmonary hypertension demonstrate a combination of intrinsic pulmonary vascular disease suggested by an elevated vascular resistance together with left heart diastolic dysfunction with an elevated PAWP.[336] As an example, in 20 patients with pulmonary hypertension associated with sickle cell anemia the mean PAP was 36 mm Hg, CO 8.6 L/min, and PCWP 16 mm Hg; one-half of the patients had PAWP values above 15 mm Hg.[337]

The optimal treatment of patients with pulmonary hypertension associated with a hemoglobinopathy has not been established. As markers of ongoing hemolysis correlate with the severity of pulmonary hypertension as well as survival in patients with sickle cell disease, maximizing treatment of the hemolytic anemia is likely an important therapeutic consideration.[326,329] Treatment includes the use of hydroxyurea or transfusions to minimize anemia and ongoing hemolysis. Intravenous prostacyclin can acutely decrease the mean PAP and PVR in patients with PAH associated with sickle cell anemia, but its long-term benefits have not been established.[337] Oral sildenafil has been shown to acutely improve the mPAP, PVR and cardiac index; however, conflicting effects on 6-minute walk distance have been reported.[338,339] Safety concerns such as headache, priapism, and increased hospitalization rates for pain remain incompletely resolved. Improvement with sildenafil has also been reported in a small, uncontrolled series of patients with other hemoglobinopathies but large trials are lacking.[340] Supplemental oxygen to prevent hypoxia should be used as in other forms of pulmonary hypertension. While not studied in patients with hemoglobinopathy for treatment of pulmonary hypertension itself, anticoagulation to prevent thromboembolic complications of sickle cell anemia is also a consideration.

PULMONARY VENOOCCLUSIVE DISEASE

PVOD is a rare form of PAH in which there is even less understanding of mechanisms and less experience with therapy.[217,341] Some combination of pathologic changes on both the arterial and venous sides of the pulmonary circulation is found in all forms of PAH, but arterial changes tend to predominate in most cases. There is patchy occlusion of pulmonary veins by fibrous tissue, intimal thickening, and large numbers of hemosiderin-laden macrophages. Lymphatic dilation in the lung and pleura are additional features, likely related to pulmonary capillary hypertension and consequent chronically increased hydrostatic movement of fluid from the capillaries into the interstitium.

The incidence and prevalence of PVOD are unknown owing at least in part to frequent misdiagnosis as IPAH. Thirteen percent of cases in the NIH registry had histologic changes of PVOD.[37] In a pooling of IPAH patient series in which cases meeting criteria for a diagnosis of PVOD were reported, an incidence of 0.1 to 0.2 cases per million persons in the general population has been estimated.[217] Prospective studies have not been performed, however, and this figure likely underestimates the true incidence of PVOD, as some cases are likely misclassified as either interstitial lung disease or heart failure because of similarities in radiographic appearance.[341] There is no apparent predilection for women (as is seen in IPAH) and patients have been diagnosed from infancy to the seventh decade of life.[342]

The risk factors for PVOD are not well known. As familial cases of this apparently rare disease have been reported, a genetic predisposition has been postulated. Indeed, mutations in *BMPRII* have been identified in several patients with PVOD.[183,342] Case reports of PVOD complicating treatment of cancer with various chemotherapeutic agents (notably mitomycin, bleomycin, carmustine, and gemcitabine) or following bone marrow transplantation suggest that toxic exposures might elicit pathologic vascular responses.[343–356] Other case reports have noted the development of PVOD in association with various thrombophilic states, autoimmune disorders, or following bacterial or viral infection, including HIV.[357–364] More recently, abnormal circulating cytotoxic lymphocyte subpopulations and epigenetic dysregulation within the GNLY gene have been reported in individuals with PVOD, although the significance of such observations remains unclear.[365]

Patients with PVOD usually present with dyspnea and fatigue; symptoms less typical of other forms of PAH such as cough, orthopnea, and hemoptysis have also been observed.[196,366–370] The presence of basilar inspiratory crackles on physical examination favors a diagnosis of PVOD over other forms of PAH although these are clearly nonspecific. Decreased basilar breath sounds might suggest the presence of pleural effusions, which tend to occur more commonly in PVOD.[371,372]

The diagnosis of PVOD is suggested by the triad of pulmonary hypertension, radiographic evidence of pulmonary edema, and a normal PCWP. Unfortunately, all three are not universally present in cases of PVOD and the diagnosis frequently is delayed because of confusing findings during evaluation. As an example, "high probability" findings on ventilation–perfusion scanning, a frequent finding in PVOD, may lead to an erroneous diagnosis of CTEPH.[373] Findings on plain radiographs and CT scans in PVOD include enlargement of the central pulmonary arteries, peribronchial cuffing, Kerley B lines, interstitial infiltrates, and pleural effusions that in other circumstances might suggest left heart failure.[196,374]

In the appropriately placed pulmonary artery catheter with its balloon inflated, there is a static column of blood from the catheter tip to the left atrium and the pressure transduced is reflective of left heart chamber filling pressures (which should be normal in patients with PVOD).[375,376] Obtaining an adequate tracing, however, can be difficult and may require positioning the catheter in multiple areas. Of note, there may be a marked rise in measured pressure and a subsequent slow decline back to normal when saline is flushed through the wedged catheter; this is presumed due to impaired run-off of fluid through the restricted pulmonary venous vessels.

The antemortem diagnosis of PVOD often requires surgical biopsy but this frequently is avoided due to increased operative and anesthetic risk in the setting of severe pulmonary hypertension, particularly given the questionable impact on therapy that establishing the diagnosis produces. However, establishing a diagnosis does provide prognostic information to the patient, may influence the urgency of evaluation for lung transplantation, and may be helpful in avoiding needless and possibly harmful therapies.

The features atypical of other forms of PAH (e.g., radiographic abnormalities "normally" consistent with left heart failure) should prompt caution when considering acute vasodilator testing.[196,374] Acute pulmonary edema, at times life-threatening, has been precipitated by the administration of vasodilators to patients with PVOD.

There are no established therapies for PVOD. Controlled studies have not been performed and only anecdotal reports are available. These describe both positive and negative responses to various agents. Some patients have experienced benefit while others have died with the use of calcium channel antagonists, intravenous epoprostenol, or other advanced therapies.[196,377–382] Glucocorticoids and other immunosuppressive agents have been attempted but experience has been anecdotal, with mixed results, and their use is not generally recommended except in rare cases where a concomitant inflammatory condition exists.[341,383,384] As in other forms of PAH, diuretics and supplemental oxygen should be employed as indicated. Lung transplantation is the only therapeutic option for many patients. The prognosis of patients with PVOD is poor, with most dying within 2 years of diagnosis.

PULMONARY CAPILLARY HEMANGIOMATOSIS

Pulmonary capillary hemangiomatosis is another rare form of PAH with predominant involvement of the pulmonary veins. Pathologically, the findings are those of "pulmonary microvasculopathy" marked by angioproliferative capillary lesions that appear to invade the pulmonary vessels, interstitium, and in some cases the airways.[385,386] The etiology is unknown. Descriptive studies have reported the presence of vascular growth factors as well as markers of altered endothelial cell

proliferation; altered expression of nitric oxide synthase has also been noted.[387–389] A heritable form has been reported to have occurred in three siblings but specific genetic linkage has not been established.[390]

Epidemiologic features of the disease are unknown, as only scattered case reports are available for evaluation. Pulmonary capillary hemangiomatosis may present with dyspnea and episodes of hemoptysis, and cases both with and without associated pulmonary hypertension have been reported. The radiographic findings are described as diffuse bilateral reticulonodular infiltrates, often associated with enlargement of the central pulmonary arteries.[391,392] The prognosis is poor, with most cases reported as fatal, often rapidly. Attempts at treatment with intravenous epoprostenol have resulted in pulmonary edema.[393–395] Successful treatment of several patients has been described with α-interferon; another patient with superimposed endotheliomatosis was stabilized with doxycycline.[396,397] Urgent evaluation for lung transplantation is recommended.

■ SCHISTOSOMIASIS

Schistosomiasis, also referred to as bilharzia or snail fever, is caused by infection with any of several species of the trematode flatworm fluke *Schistosoma.* Typically, humans contract schistosomiasis by contact with shallow water that contains snails that are intermediate hosts of the *Schistosoma* pathogen. Cercariae, the life-cycle stage released from infected snails, may penetrate human skin and after a conformational change to become schistosomulae, reach the lungs.[398] Lung involvement tends to develop after extensive chronic liver involvement and there is debate about the relative contributions of POPH, periovular granulomas in the lungs, and host immunologic changes in producing PAH-like pathologic changes in up to 9% of patients.[399] It is estimated that up to 300 million individuals worldwide have schistosomiasis and as such it is likely to be one of the most numerically important causes of PAH. Patients generally present clinically with dyspnea on exertion and other features similar to PAH due to other causes. Diagnosis requires documentation of PAH via hemodynamic assessments along with clinical and serologic evidence of *Schistosoma* infection.

Much remains unknown regarding the prognosis and optimal approach to therapy. One series of 54 patients in Brazil suggested a more benign course than IPAH patients at the same institution.[400] Treatment with prostenoids, endothelin antagonists, and phosphodiesterase-5 inhibitors appears efficacious in improving hemodynamics and 6-minute walk distance although large randomized trials are lacking.[401] The antischistosomal agent, praziquantel, can reverse pulmonary hypertension and vascular remodeling in murine schistosomiasis although its efficacy in human disease is not documented.[402]

THERAPY FOR PULMONARY ARTERIAL HYPERTENSION

The many facets and challenges in treating pulmonary arterial hypertension are presented below.

■ A CAUTIONARY NOTE: NON-PAH FORMS OF PULMONARY HYPERTENSION

Therapy must be driven by an appropriately established diagnosis.[403] As is noted previously, PAH is but one form of pulmonary hypertension and overall less common than pulmonary hypertension due to parenchymal lung or left heart disorders. Appropriate therapy for pulmonary hypertension due to left heart disease or parenchymal lung disease centers on optimal management of the underlying left heart disorder or lung disease, respectively. Far too often focus on the presence of pulmonary hypertension distracts clinicians' attention from the underlying cause. This not only leads to inappropriate use of drugs that are of established benefit only among patients with PAH, but may be accompanied by a failure to pursue appropriate therapies more likely to relieve a patient's symptoms (such as appropriate fluid management for left heart failure, interventions for coronary artery disease, correction of a mitral or aortic valvular dysfunction, bronchodilators and other inhaled medications for obstructive lung disease, or control of systemic hypertension). Other times, when underlying lung or left heart disorders have been maximally treated and symptoms remain, frustrated clinicians and patients may be driven to "blame" persistent problems on the presence of pulmonary hypertension. They may try drugs approved for treatment of PAH reasoning, "there is nothing else to do," or that, "it couldn't hurt." Unfortunately, such an approach is currently ill-informed and potentially harmful. The use of drugs approved for treatment of PAH in patients with other forms of pulmonary hypertension has not been found to be beneficial and is associated with known harms including exposure to well-established side effects. For example, randomized trials of patients with decreased left ventricular systolic function have raised concerns for worsened heart failure with the use of endothelin receptor antagonists, and have resulted in an increased risk for death with epoprostenol infusion.[404,405] Another randomized trial of patients with COPD and echocardiographic evidence of pulmonary hypertension found use of bosentan worsened hypoxemia and quality of life, and failed to improve exercise capacity.[406] Despite suggestion of improved exercise capacity among patients with left heart dysfunction and pulmonary hypertension treated with sildenafil in a preliminary study, a larger randomized trial found no improvement, and there were more adverse events among the participants who received sildenafil.[407,408] Finally, the high expense of these drugs often must be borne by the patient as well as the healthcare system.

■ GENERAL MANAGEMENT

A variety of pharmacologic and nonpharmacologic interventions are used in treatment of pulmonary arterial hypertension. PAH-specific pharmacotherapy is discussed in a separate section, below.

Exercise and the Avoidance of Deconditioning

Regardless of the cause, patients with pulmonary hypertension and cor pulmonale should be encouraged to maintain as active a lifestyle as possible. Recommendations that the patient minimize exertion for fear of further raising pulmonary pressures generally result only in deconditioning of the muscles and an increase in fatigue and breathlessness when an activity is attempted. Regular, steady aerobic exercise should be encouraged, and is often best initiated under guidance of a pulmonary or cardiac rehabilitation program. Indeed, randomized trials of exercise rehabilitation in patients with PAH or CTEPH have demonstrated not only the safety of exercise in these patients, but improvements in exercise capacity (e.g., 6-minute walk distance) greater than that observed in randomized clinical trails of currently available pharmacologic treatments for PAH. Clinically significant improvements in exercise capacity as well as health-related quality of life occurred in both an intensive exercise regimen beginning with inpatient therapy, as well as a 10-week outpatient program of treadmill walking similar in intensity to that commonly used in pulmonary and cardiac rehabilitation programs.[409,410] In addition to improving strength and endurance, the benefits of a supervised rehabilitation program may include a decrease in the fear many patients with dyspnea experience when initiating exercise programs. Many rehabilitation programs teach techniques to cope with dyspnea when it occurs, allowing exercise to continue. Importantly, activities that cause patients to experience lightheadedness or syncope should be avoided, including hot showers or baths and bending over to lift heavy objects.

Oxygen Therapy

Although controlled studies analogous to those performed in the treatment of COPD have not been conducted,[411] it is recommended that patients with pulmonary hypertension avoid acute hypoxia, as hypoxic pulmonary vasoconstriction will add to the burden on the right ventricle. Oxygen relieves hypoxic pulmonary vasoconstriction, thus decreasing vascular resistance and improving CO.

It also lessens renal vasoconstriction, improving urinary sodium excretion, and alleviates tissue hypoxia by improving oxygen delivery. Measurements of arterial oxyhemoglobin saturation should be performed at rest, with exertion, and with sleep. Levels of arterial oxygen saturation below 90% should prompt supplemental oxygen. Maintenance of adequate oxygen saturation may be difficult in patients with severe pulmonary hypertension in whom a patient foramen ovale allows right-to-left shunting.

Air travel is a particular concern because of the threat of hypoxic pulmonary vasoconstriction. Measurements made during commercial airline flights lasting a mean of 3.6 hours in a series of patients with PAH or CTEPH found that oxyhemoglobin desaturation below 85% occurred in 26% of participants, at a mean cabin pressure of 1971 ± 73 m (6467 ± 240 ft) with the lowest occurring at 1829 m (6000 ft).[412] Over one-third of patients developed symptoms during flight. Although more definitive studies have not been performed, it seems prudent to evaluate pulmonary hypertension patients who plan air travel that will last more than a few hours for in-flight oxygen use, particularly among patients with prior need of supplemental oxygen (including with sleep only). Many pulmonary function laboratories can simulate conditions of high altitude with an inspired oxygen concentration of 15% to determine whether the patient requires supplemental oxygen to maintain adequate oxyhemoglobin saturation. Patients should contact airlines in advance of travel as requirements differ, as do costs (which regrettably may not be covered by insurance). An attractive alternative to stored oxygen systems are portable concentrators, which most airlines will permit patients to carry on board without special arrangements.

Immunizations

Immunizations against influenza and pneumococcal pneumonia are important preventive measures in all patients with pulmonary hypertension and cor pulmonale. Influenza vaccination should occur annually, and administration of the 23-valent polysaccharide pneumococcal vaccine should occur once at the time PH is diagnosed and again when the patient turns 65.

Fluid Management and Diuretics

Careful attention to avoid fluid overload is central to the management of cor pulmonale of any cause. Patients must be educated regarding appropriate dietary habits and to restrict sodium intake to minimize fluid retention and the development of right heart failure. Patients should weigh themselves daily so that any trend toward fluid retention can be reversed before progressive right ventricular overload results in failure that may then be more difficult to reverse and require inpatient treatment.

Management of right heart failure relies heavily on diuretic therapy. Spironolactone is often used to manage mild fluid retention. It may also have beneficial effects in heart failure by modulating neurohormones. Loop diuretics are often required to prevent more significant fluid retention and right heart failure. Indeed, high doses and combinations of diuretics are often required to maintain appropriate fluid balance, but must be used cautiously to avoid electrolyte imbalances and volume depletion.

Digitalis

It is unsettled whether cardiac glycosides should play a role in treating right heart failure. In one series of 17 patients with PAH and right ventricular failure, the intravenous administration of 1 mg of digoxin resulted in a modest increase in CO after 2 hours[413] but longer-term data are lacking. Approximately 25% of patients in the REVEAL registry were using digoxin, [191] but many physicians avoid use of this agent even when right-sided heart failure is evident on account of a lack of sufficient evidence regarding its use in PAH and the potential for toxicity.

Anticoagulation

In the absence of contraindications, anticoagulation with warfarin is recommended for patients with significant IPAH.[191,197] This is reasoned to be of benefit on the basis of autopsy studies revealing in situ thrombosis in both venous and arterial vessels without evidence of an embolic source in a significant proportion of patients with PAH.[44–46] Anticoagulation is also justified on the basis of the increased risk of venous thromboembolic disease in patients with severe heart failure and immobility, and their expected poor tolerance of embolic events. The efficacy of anticoagulant therapy in patients with PAH has never been studied in randomized controlled trials. Uncontrolled observational reports, however, have demonstrated an association between warfarin use and increased survival. In a study of 64 IPAH patients randomized to treatment with calcium channel antagonists or placebo, survival after 5 years was greater among those patients in either group who at their provider's discretion had received warfarin.[414] In a retrospective evaluation of 173 patients with either idiopathic or anorexigen-associated PAH, anticoagulation was associated with a statistically greater survival among the anorexigen agent patients and a trend toward improvement after 5 years of therapy in patients with idiopathic disease.[323] Extrapolating from such studies, warfarin is often prescribed to patients with other forms of PAH but disease-specific data supporting this practice is nonexistent.

The generally recommended target international normalized ratio (INR) for warfarin therapy in patients with PAH is 1.5 to 2.5.[415] The severity of disease (e.g., threshold mean PAP or PVR) at which anticoagulation should be initiated has not been determined. A role for newer, non-warfarin oral anticoagulants (e.g., rivaroxaban, dabigatran, apixaban) has not been defined in patients with PAH.

Contraception and Pregnancy

Pregnancy in women with IPAH is associated with a high mortality, on the order of 30% to 50%.[416–418] Expert consensus is that pregnancy should be avoided, and early termination recommended on account of the high maternal mortality.[191,197] Effective contraception should be ensured; if hormonal contraception is chosen, anticoagulation may be advisable to reduce the risk of venous thromboembolism. Although the successful management of pregnancy has been reported,[419] single and multicenter series continue to report high rates of maternal death despite the use of aggressive treatments including intravenous prostenoids.[420–422]

Other Considerations

Patients should be queried about the concomitant use of medications and herbs. Warfarin is particularly apt to be associated with drug–drug interactions. The use of vasoconstrictor or serotonergic medications for unrelated illnesses, such as migraine, should also be undertaken cautiously. Patients taking bosentan are at risk of interaction with such medications as cyclosporine and azole-type antimicrobial agents, and care must be taken to avoid glyburide-containing diabetic therapies. Surgical procedures may entail considerable operative and postoperative risk in patients with hemodynamic compromise from PAH.

Vulnerability of patients with severe PAH to vasovagal events has to be kept in mind. An attack can be precipitated by pain, nausea, vomiting, or straining (Fig. 72-14). The induction of anesthesia and intubation may be a particularly troublesome time. The combination of bradycardia and systemic vasodilation can lead to a precipitous drop in systemic blood pressure. Atropine or a similar agent should be kept at hand during invasive procedures.

■ PAH-SPECIFIC PHARMACOTHERAPY

Treatment of PAH aims to decrease PVR, thereby improving CO. Acute improvements occur in some patients with certain vasodilators. Used chronically, some agents also appear to have cellular

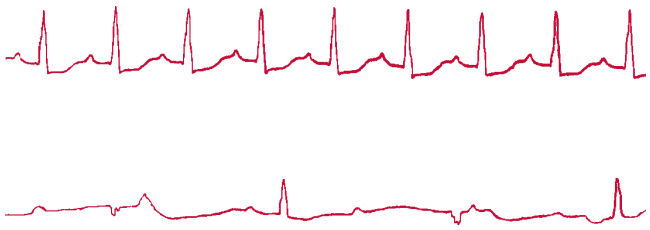

Figure 72-14 Idiopathic pulmonary arterial hypertension. Bradycardia and prolongation of atrioventricular conduction progressed to atrioventricular dissociation while patient was on bedpan. Associated with syncope.

effects that may ameliorate some of the vascular derangements seen in untreated disease. Remarkable progress in the treatment of IPAH has resulted in the availability of multiple therapies and a significantly improved outlook, with many long-term survivors. No currently available medical treatment, however, is curative and despite clinical improvement in many patients that is durable in some, histopathologic changes of vasculopathy remain.[423] Lung transplantation remains an option for some failing medical therapy.

The majority of subjects studied in controlled clinical trials of treatment with calcium channel antagonists, prostenoids, endothelin receptor antagonists, or phosphodiesterase inhibitors have been patients with either IPAH or PAH associated with scleroderma. Since most of these studies compared a single agent to placebo, our knowledge regarding the relative efficacy of available agents is limited by the lack of head-to-head comparisons. In addition, patients treated in earlier studies with epoprostenol were generally sicker than those treated in more recent studies of oral therapies. Finally, only small numbers of patients with heritable or various other forms of PAH have been studied, limiting our ability to draw firm conclusions about efficacy in these less common disorders.

Care must be taken in comparing and applying the results of clinical trials of different pharmacologic agents. Most clinical trials have enrolled patients and assessed response at least in part on the basis of a WHO modification of the New York Heart Association functional assessment of patients with heart failure (Table 72-4), and there appears to be substantial variability in even expert clinicians' judgments of functional class.[424] The 6-minute walk distance has been the most commonly used primary end point in trials of PAH drugs currently available, and with several exceptions improvements in this parameter have been the basis for their approval by the US Food and Drug Administration. The minimal clinically meaningful change in 6-minute walk distance in patients with PAH has been estimated to be between 33 and 42 meters.[425,426] These estimates, however, have been made using data from trials of predominantly treatment naïve patients, and may not be applicable when additional therapies are added.[427,428] Further, trials have mostly been of short duration (12–16 weeks). Additional endpoints such as threshold levels of exercise capacity, indications of clinical deterioration and long-term morbidity or even mortality may emerge as more important metrics to assess individual and combinations of drugs. Assessments of clinical deterioration have been reported as endpoints in several trials of PAH-specific therapy, including, for example, the time until PAH-related hospitalization, death, need for transplantation, or escalation of therapy, but the definitions used have varied.

In addition, the results of long-term follow-up studies (discussed below) must be interpreted with caution. In addition to being open-label (nonblinded) therapy, the selection of patients for therapy was determined at the physician's discretion (nonrandomized) and nonprotocol changes in other therapies occurred. Thus, confident assessments of the benefit or adverse effects of a given agent, comparison to others, and generalization of the findings are not possible. These results are, however, the best descriptions currently available regarding long-term use of these agents.

In general, the choice of initial therapy depends upon an assessment of disease severity and the patient's prognosis and risk for further, rapid deterioration. This judgment involves an assessment of a combination of variables, including hemodynamic and echocardiographic findings, exercise capacity, functional classification, and recent clinical stability of deterioration (Table 72-9). Although more or less "aggressive" approaches have not been compared directly in randomized studies, in general, patients thought to be at lower risk are first treated with an oral agent, whereas

TABLE 72-9 Assessment of Risk in PAH[a]

Determinants of Risk	Lower Risk (Good Prognosis)	Higher Risk (Poor Prognosis)
Clinical evidence of RV failure	No	Yes
Progression of symptoms	Gradual	Rapid
WHO class[b]	II, III	IV
6MW distance[c]	Longer (>400 m)	Shorter (<300 m)
CPET	Peak $\dot{V}_{O_2}$ greater than 10.4 mL/kg/min	Peak $\dot{V}_{O_2}$ less than 10.4 mL/kg/min
Echocardiography	Minimal RV dysfunction	Pericardial effusion, significant RV enlargement/dysfunction, right atrial enlargement
Hemodynamics	RAP less than 10 mm Hg, CI greater than 2.5 L/min/m^2	RAP greater than 20 mm Hg, CI less than 2.0 L/min/m^2
BNP[d]	Minimally elevated	Significantly elevated

[a]*Most data available pertains to IPAH. Little data is available for other forms of PAH. One should not rely on any single factor to make risk predictions.*
[b]*WHO class is the functional classification for PAH and is a modification of the New York Heart Association functional class.*
[c]*6MW distance is also influenced by age, gender and height.*
[d]*As there is currently limited data regarding the influence of BNP on prognosis, and many factors including renal function, weight, age, and gender may influence BNP, absolute numbers are not given for this variable.*
natriuretic peptide. CI, cardiac index; CPET, cardiopulmonary exercise testing; peak $\dot{V}_{O_2}$, average peak oxygen uptake during exercise; RAP, right atrial pressure; RV, right ventricle; WHO, World Health Organization.

ACCF/AHA 2009 expert consensus document on pulmonary hypertension a report of the American College of Cardiology Foundation task force on expert consensus documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc. and the Pulmonary Hypertension Association. J Am Coll Cardiol. 2009;53(17):1573–1619.

higher-risk patients are started on parenteral therapy. No single variable determines the choice of therapy. For example, a WHO functional class III patient without rapid recent clinical change and a cardiac index above 2.5 L/min/m^2 might be appropriately treated initially with oral therapy. A WHO class III patient who is either rapidly declining clinically or who has a more severely depressed cardiac index (e.g., below 2 L/min/m^2), however, might be more appropriately managed initially with intravenous prostenoid therapy. Personal preferences often influence a patient's willingness to undertake intravenous therapy. In addition, psychosocial issues, cognitive abilities, and other determinants of patient compliance may make certain therapies unsafe even if otherwise medically indicated.[429]

How best to follow patients treated for PAH, and to adjust medications, also are not well established. In addition to the clinical evaluation, most expert referral centers monitor patients with varying combinations of 6-minute walk distance measurements, echocardiograms, and serum NT-BNP. Some practitioners will repeat the right heart catheterization at regular intervals, while others do so only when a change in clinical status requires repeat diagnostic evaluation to guide further treatment. Which tests and frequencies are best at improving outcomes have not been studied in an organized manner, nor has the relative cost effectiveness of different approaches.

Note that additional therapies approved for the treatment of PAH by the FDA since the completion of this volume include an endothelin receptor antagonist (macitentan), an oral prostenoid (treprostinil) and a soluble guanylate cyclase inhibitor (riociguat). In addition, an up-dated guideline to pharmacotherapy for PAH has been released.[430]

Calcium Channel Antagonists

The calcium channel antagonists diminish vascular tone by preventing an increase in cytosolic calcium concentration through inhibition of both the influx of extracellular calcium and the release of calcium from intracellular stores. The long-term prognosis is good for some IPAH patients who respond acutely to the administration of short-acting pulmonary vasodilators and are treated subsequently with calcium channel antagonists. In one study, the survival rate of acutely vasoresponsive patients treated chronically with oral calcium antagonists was maintained at 94% when measured at 1, 3, and 5 years.[414] Unfortunately, relatively few patients demonstrate acute vasoreactivity (~10% by recent estimates) and of these only about one-half experience a sustained clinical response.[431] Oral calcium antagonists should not be used as vasodilator therapy in the absence of documented acute vasoreactivity. Those failing to demonstrate acute vasoreactivity not only fail to benefit from calcium channel antagonist therapy, but are also prone to adverse side effects including systemic hypotension, decreased CO because of a negative inotropic effects, arrhythmias, salt and water retention, syncope, and death. Acute vasodilator testing as described earlier is therefore required to determine whether a clinical trial of calcium channel antagonist therapy is appropriate.

Patients who do manifest a significant acute pulmonary vasodilator response to short-acting agents should undergo monitored trials of oral calcium channel antagonists while the pulmonary artery catheter is still in place. Increasing doses of nifedipine or diltiazem are usually administered until pulmonary hemodynamics are improved (i.e., there is a significant decrease in PVR and PAP and, ideally, an increase in CO). Agents such as verapamil, which exert negative inotropic effects, should be avoided. Testing is stopped if systemic hypotension or a trend of worsening hemodynamic values is seen. Relatively high doses of calcium channel antagonists are required to promote sufficient pulmonary vasodilation. In some instances, the required daily doses of nifedipine and diltiazem have exceeded 200 mg and 700 mg, respectively.[432] The total daily dose should be divided and administered in two or three doses of long-acting formulations to minimize peak and trough drug effects throughout the day. Patients treated with oral calcium antagonists must be monitored for the development of side effects including systemic hypotension or peripheral edema, as well as for evidence of continued benefit.

Endothelin Receptor Antagonists

Endothelin-1 (ET-1) is a member of the endothelin family of peptides secreted by endothelial cells that promote vasoconstriction and modulate the proliferation of vascular smooth muscle and endothelial cells. ET-1 is overexpressed in the vasculature of patients with various forms of PAH and antagonists of its interaction with its receptors (ET_A and ET_B) have been developed for oral use. A dual ET_A/ET_B and a relatively ET_A-selective antagonist are available.

Bosentan is a dual ET_A/ET_B antagonist that improves hemodynamics, exercise capacity, WHO functional class, and the time to clinical worsening (defined as death, PAH-related hospitalization, need for altered therapy or lung transplantation).[90,433] In a double-blind, randomized, placebo-controlled trial of patients with IPAH and PAH associated with collagen vascular disease (predominantly systemic sclerosis), bosentan improved the 6-minute walk distance by 44 m as compared with placebo at 16 weeks. Exercise capacity improved in IPAH patients, while stabilization or a slowing in the rate of deterioration was observed in patients with systemic sclerosis.[90] The beneficial effects of bosentan on exercise capacity and functional class persist at 1 year with open-label use.[434] In a double-blind, randomized placebo-controlled trial of PAH patients with less severe symptoms (WHO functional class II), bosentan treatment for 6 months improved hemodynamics and 6-minute walk distance as compared to placebo.[435] Survival of IPAH patients treated with bosentan in these trials and their open-label extensions was 96% at 1 year and 89% at 2 years as compared with "expected" survival of 69% and 57%, respectively, as predicted by the NIH registry equation.[92]

Improved hemodynamics and exercise capacity have also been demonstrated with bosentan use in a 16-week randomized controlled trial of patients with Eisenmenger syndrome, with persistent effects seen during a 24-week open-label extension.[436,437] Nonrandomized reports have suggested a benefit of bosentan in other specific PAH populations. A prospective open-label study of 16 patients with PAH associated with HIV infection reported improved hemodynamics, exercise capacity, and quality of life after 16 weeks.[438] Retrospective observational studies have reported the successful use of bosentan in pediatric patients with PAH.[439–442]

Ambrisentan is a relatively ET_A-selective antagonist. In concurrent double-blind, placebo-controlled studies of patients with PAH, 5 and 10 mg daily of ambrisentan for 12 weeks resulted in placebo-corrected improvements in 6-minute walk distance of 31 and 51 m, respectively, in one trial, and 32 and 59 m with 2.5 and 5 mg treatments, respectively, in the other trial. A delay in the time to clinical worsening was seen in one of the trials, and health-related quality of life improved in both.[443] In open-label extension studies, ambrisentan therapy was accompanied by improved hemodynamic values at a median duration of over 1 year and persistent improvements in exercise capacity at 2 years.[444,445]

Bosentan therapy is initiated at 62.5 mg orally twice daily and, if liver function remains normal, increased after 1 month to 125 mg twice daily. Liver function must be monitored monthly as significant elevations may occur; severe elevations (transaminase levels greater than eight times normal) require discontinuation of therapy. Lower rates of elevated transaminases are observed with ambrisentan than bosentan and the FDA-label requirement for monthly liver function monitoring has been removed for ambrisentan, although experts continue to recommend intermittent evaluations. Notable

side effects include peripheral edema (usually readily responsive to diuretics), anemia, and nasal congestion. Bosentan is contraindicated with either cyclosporine or glyburide. Both ambrisentan and bosentan are teratogenic and contraception and pregnancy testing are required for use in women with childbearing potential.

Phosphodiesterase Inhibitors

The relative deficiency of NO-mediated vasodilation and modulation of cell growth in patients with PAH has led to attempts to augment its effects therapeutically. NO acts through the second messenger cGMP, which is metabolized in the lung predominantly by phosphodiesterase 5. Specific inhibitors of phosphodiesterase type 5 (e.g., sildenafil, vardenafil, and tadalafil) can promote acute pulmonary vasodilation.[446]

In a double-blind, randomized placebo-controlled trial of 267 patients predominantly with IPAH but also some with congenital heart or collagen vascular disease, sildenafil administered orally at 20, 40, or 80 mg three times daily improved hemodynamics, exercise capacity, and functional class.[148] Although the time to clinical worsening was not affected in this single trial, the improvement in exercise capacity (51 m as compared with baseline) was maintained over 1 year among the subset of patients continuing open-label use of sildenafil at 80 mg three times daily. No statistically significant dose response was seen in the primary end point, exercise capacity, of this trial and the FDA-approved dosage for treatment of PAH is 20 mg by mouth three times daily. In open-label follow-up of a subset of patients up to 3 years following 12 weeks of randomized therapy with sildenafil, 46% demonstrated continued improvement over baseline exercise capacity, although additional therapies had been added to sildenafil during this period. In a posthoc analysis of patients in this randomized trial who had PAH associated with connective tissue disease (predominantly scleroderma and lupus erythematosis), improvements in exercise capacity, functional class, and hemodynamics were seen. An initial 12-week, double-blind, placebo-controlled trial of sildenafil for treatment of PAH in children aged 1 to 18 years demonstrated efficacy in improving exercise capacity and hemodynamics at some doses, although the optimal regimen requires further study.[447]

A 12-week, double-blind, placebo-controlled trial of four different doses of tadalafil found an overall placebo-corrected increase in 6-minute walk distance of 33 m (although statistically significant only for the highest dose group, 40 mg daily). The time to clinical worsening and quality of life also improved.[149] The trial included both treatment naïve patients with PAH, as well as those already receiving bosentan treatment. The mean improvement in 6-minute walk distance was greater among the treatment naïve participants (44 m) than those already receiving bosentan (23 m). During open-label extension for up to 1 year, improvements in 6-minute walk distance in patients receiving either 20 or 40 mg daily of tadalafil appeared to be maintained.[448] In a 12-week, double-blind, placebo-controlled trial of an additional phosphodiesterase type 5 inhibitor, vardenafil, improved 6-minute walk distance and hemodynamic values.[449]

Common side effects of phosphodiesterase type 5 inhibitors when used to treat PAH are headache, flushing, diarrhea, epistaxis, and myalgias. Systemic hypotension has also occurred, particularly with concomitant nitrate use, and this combination should be avoided.

Prostenoid Therapies

Prostacyclin analogs have played a key role in the management of idiopathic and other forms of PAH. Prostacyclin is a powerful vasodilator (both pulmonary and systemic) as well as an inhibitor of smooth muscle proliferation and platelet aggregation. It is a product of arachidonic acid metabolism and acts, at least in part, by stimulating the intracellular production of cAMP. Its major source is the vascular endothelial cell and deficiencies are noted in patients with PAH. Several synthetic prostacyclin analogs are currently available in the United States for the long-term treatment of PAH, including formulations administered by continuous intravenous infusion (epoprostenol and treprostinil), subcutaneous infusion (treprostinil), and via inhalation (treprostinil and iloprost).

Prostenoid infusion therapy requires a relatively highly functional and compliant patient for safe administration, preferably in conjunction with a strong social support system at home. Intensive patient and family education is required for safe initiation of therapy and, particularly for intravenous infusions, is often performed with the patient hospitalized until appropriate understanding and proficiency in self-care is demonstrated. While appropriate expertise in the management of PAH is required for nonparenteral treatments, parenteral prostenoid therapy in particular requires the support of a dedicated team of nurses and physicians at a program with sufficient expertise, typically with the additional assistance of nurses from specialty pharmacies.[450]

Intravenous Prostenoid Therapy (Epoprostenol, Iloprost, and Treprostinil) The first prostenoid therapy shown in randomized clinical trials to be beneficial in the treatment of PAH was epoprostenol. Because of its short half-life (on the order of only minutes) it requires continuous intravenous infusion. In an initial study, 81 patients with IPAH were randomized to receive epoprostenol infusion or treatment considered "standard" at the time (oral vasodilators, diuretics, cardiac glycosides, and anticoagulants).[451] After 12 weeks of treatment, hemodynamic values were improved in the epoprostenol group (e.g., a 21% decrease in PVR as compared with an increase in control patients) as was the 6-minute walk distance (increased by 31 m compared with a decrease of 29 m). None of the patients treated with epoprostenol died during the study, as compared to a 20% mortality by 12 weeks with conventional therapy. Intravenous epoprostenol therapy for IPAH was approved by the FDA in 1995.

Additional reports have confirmed and extended these observations. Indeed, originally conceived as a "bridge" to lung transplantation in patients with severe PAH, the long-term use of epoprostenol and other treatments was followed by a decrease in the demand for lung transplantation for this indication.[452] In a cohort of 162 IPAH patients treated with intravenous epoprostenol at a center in the United States, the observed 1- and 3-year survival rates were 88% and 62%, compared to rates of 59% and 35% predicted by the NIH registry equation.[238] Remarkably similar results were observed in a cohort in France of 178 epoprostenol-treated patients with IPAH at 1 and 3 years, and somewhat lower survival rates in a cohort of 91 patients at a second United States center. In each case survival was improved over that predicted by the NIH registry equation.[236,237] Unfortunately, however, one-third of patients with IPAH died within 3 years and nearly half by 5 years (Fig. 72-15).[234]

Epoprostenol infusion therapy has also been used in other forms of PAH. A randomized multicenter trial in patients with systemic sclerosis associated PAH (without significant interstitial lung disease) showed improvements in both hemodynamics and exercise capacity.[453] Favorable results of epoprostenol treatment have also been reported in uncontrolled series of patients with systemic lupus erythematosis,[454] congenital left-to-right shunts,[455] anorectic agent use,[322] patients with HIV, POPH,[300] and inoperable CTEPH.[456] Epoprostenol has been used successfully in isolated reports of patients with PVOD. The use of epoprostenol in patient with PVOD must be approached with extreme caution, however, as its use in patients with impeded venous blood flow might precipitate pulmonary edema.[217] Isolated attempts at treating patients with pulmonary capillary hemangiomatosis (also characterized by predominant involvement of the pulmonary veins) have resulted in death.[397] In a single randomized trial of patients with left ventricular dysfunction, the use of epoprostenol was associated with a trend toward increased mortality.

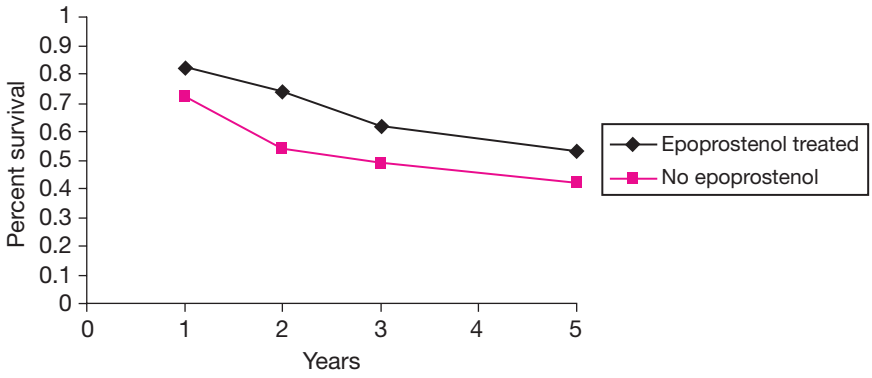

Figure 72-15 The effect of chronically infused epoprostenol therapy on survival in patients ($n = 431$) from multiple series with idiopathic pulmonary arterial hypertension. Survival in the absence of epoprostenol was estimated using a prediction equation derived from observation in the NIH registry of primary pulmonary hypertension at which time effective therapy was not available. *(Reproduced with permission from McLaughlin V V, Presberg KW, Doyle RL, et al. Prognosis of pulmonary arterial hypertension: ACCP evidence-based clinical practice guidelines, Chest. 2004;126(1 Suppl):78S–92S.)*

A longer half-life (3 hours) and stability at room temperature prompted the development of treprostinil as an alternative prostenoid analog for intravenous therapy. Treprostinil appears to have acute hemodynamic effects similar to those of epoprostenol.[457] In an uncontrolled 12-week, open-label study of 16 PAH (8 with IPAH and 6 and 2 associated with connective tissue and congenital heart disease, respectively) intravenous treprostinil infusion resulted in an 82-m improvement in 6-minute walk distance as well as improvements in hemodynamic values.[458] In a subsequent 12-week placebo-controlled randomized trial of 44 PAH patients continuously infused treprostinil resulted in an 83-m placebo-corrected increase in 6-minute walk distance and improvements in functional class.[459] Importantly, this randomized study involved the placement of central venous catheters for placebo infusions (that indeed were associated with harm, including a death). This has raised ethical concerns and questions that must be addressed as investigators of therapy in this rare disease face difficulties with recruitment and aim to extend their reach.[460,461]

Intravenously administered iloprost, another prostanoid, is available in some European countries, but not in the United States. In uncontrolled trials it has been used in patients with IPAH, collagen vascular disease associated PAH, and CTEPH.[462–464] The acute hemodynamic effects are similar to those of epoprostenol, but no controlled trials of its efficacy are available. In a retrospective analysis of 50 patients with PAH treated at multiple centers in Germany with intravenous iloprost following insufficient or deteriorating clinical status after the use of oral therapy with endothelin receptor or phosphodiesterase type 5 inhibitors, only approximately 25% had an improved functional class at 3 months, and more than 50% of patients died or required lung transplantation within 1 year.[465]

Epoprostenol therapy is initiated at 1 to 4 ng/kg/min and progressively increased in 0.5 to 1 ng/kg/min increments at intervals dictated by patient response and side effects. Treprostinil is initiated at 0.625 or 1.25 ng/kg/min and similarly increased as dictated by clinical response, typically in increments of 1.25 ng/kg/min. Induced metabolism mandates a need for continuous increases in dosage to maintain improvements in symptoms. Increases are usually required at more frequent intervals initially to relieve symptoms due to PAH (e.g., dyspnea and lightheadedness) although many patients will reach a more stable dosing with less frequently required increases after several weeks to months. Such titration must be closely monitored for prostenoid side effects (nausea, tachycardia, diarrhea, masticatory jaw pain).[450] Even patients lacking an acute vasodilator response (e.g., to infused epoprostenol) have shown improved hemodynamics and exercise capacity after sustained treatment, suggesting that the beneficial effects are not mediated merely through acute vasodilation, but also by altering cell growth.

Intravenous treatment with epoprostenol or treprostinil requires a tunneled venous catheter and thus is associated with a significant risk of bacterial infection. In an evaluation of 1146 patients who received intravenous prostenoid therapy during over 3 years of the multicenter observational US-based REVEAL cohort, an approximate threefold increase in blood stream infections of any type and over sixfold increase in those due to gram-negative organisms was observed among patients receiving intravenous treprostinil as compared with intravenous epoprostenol.[466] A retrospective study by the US Center for Disease Control of data from seven PAH treatment centers also concluded that rates of bloodstream infection were higher with continuous intravenous infusions of treprostinil than epoprostenol. The higher rate of infection did not appear to be due to intrinsic drug contamination,[467] but may have been related to the neutral pH of the treprostinil diluent, as substitution with the basic pH epoprostenol diluent appeared to eliminate the increase in infection rates with treprostinil at one institution.[468]

Prostenoid infusion requires the use of a battery-powered portable infusion pump that must be carried at all times. A back-up medication cassette and pump must also be immediately available as an interruption of only minutes can result in hemodynamic compromise. In theory, the risk with interrupted treprostinil infusion is somewhat lower on account of its longer half-life. The originally available formulation of epoprostenol is unstable at room temperature and must be mixed daily and kept cool with ice packs. Like treprostinil, a more recently approved formulation of epoprostenol has greater stability at room temperature and does not require continuous cooling with ice packs.[469] Treprostinil may be administered with the same infusion pump used for epoprostenol therapy but smaller equipment is available that may potentially allow for more convenient therapy. Preliminary experience suggests that a higher dosage of treprostinil is required than epoprostenol to maintain an improvement in symptoms. Further observation is required to establish whether survival is similarly improved with treprostinil as with epoprostenol. Experience and established duration of benefit is greatest with epoprostenol infusion and it remains an important treatment for severe PAH, and a benchmark against which other therapies are often compared.

Subcutaneous Prostenoid Therapy (Treprostinil) Treprostinil is also available for subcutaneous administration. In a large randomized double-blind placebo-controlled trial of 470 patients with IPAH or PAH associated with congenital heart or collagen vascular disease, subcutaneous treprostinil resulted in improvements in hemodynamic parameters and a modest improvement in 6-minute walk distance of 16 m at 12 weeks.[470] In an open-label extension study of participants previously enrolled in the randomized trial, together with de novo patients,

survival up to 4 years was evaluated in 332 IPAH patient for whom baseline hemodynamic measurements were available. Observed survival was 91% and 72% at 1 and 4 years, respectively, compared with survival rates of 69% and 38% at 1 and 4 years predicted by the NIH registry equation.[471]

The major advantage of subcutaneous treprostinil is avoidance of an intravenous catheter and the associated risk of life-threatening bacteremia. While infections can occur at the subcutaneous infusion site, these are usually mild and manageable with oral antibiotics. Other side effects are similar to those seen with intravenous prostenoid therapy (nausea, diarrhea, flushing, and jaw discomfort). In addition, however, the major drawback of treproprotinil has been a significant incidence of troublesome infusion site pain. This occurred in 85% of patients in the pivotal clinical trial and led to discontinuation in 8%.[470] Out of 860 total patients in the previously noted open-label study, 196 (23%) discontinued subcutaneous therapy due to infusion site pain or reactions.[471] Management strategies to reduce the occurrence and severity of pain have been reported, including initial "dry" catheter insertions with delayed infusion of medication, less frequent site rotations, and the application of topical analgesics and anti-inflammatory agents.[472] For those with severe pain refractory to these measures, narcotic analgesics may be required. Another relative disadvantage is a slower rate of dosage titration as compared to intravenous therapy, making it less attractive for severely ill patients in need of a rapid response. In select patients, however, subcutaneous treprostinil has proven to be effective therapy with minimal side effects and has allowed for avoidance of the risks and inconveniences of intravenous therapy.

Inhalational Prostenoid Therapy (Iloprost and Treprostinil) Inhaled prostenoid therapies have been developed in the hopes of avoiding the need for an invasive delivery system. Iloprost is an inhaled prostacyclin analog. Conflicting results of efficacy were seen in uncontrolled studies,[473–475] but a 12-week randomized, placebo-controlled trial of 203 patients demonstrated a placebo-corrected improvement of 36 m in 6-minute walk distance.[476] Most of the patients studied had IPAH; the remainder had PAH associated with anorectic agent or collagen vascular disease, or had CTEPH. Functional class and quality-of-life measures also improved in association with treatment. Hemodynamic variables were improved at 12 weeks when measured following a dose of iloprost, although preinhalation values were unchanged. As in other trials of PAH therapies, hemodynamic variables were worse compared to baseline following 12 weeks of placebo. Following another 3-month placebo-controlled study, 52 patients received open-label iloprost therapy. At 2 years, 36 (69%) remained on iloprost while treatment was discontinued in 16 patients due to death, lack of efficacy, and adverse events in 2, 6, and 6 patients, respectively. The study included patients with PAH and non-PAH forms of disease. The 2-year event-free survival was 74% in the IPAH patients, as compared to a predicted survival of 63% according to the NIH formula.[477]

Treprostinil is also available for inhalational therapy. A 12-week double-blind, placebo-controlled randomized trial of 235 patients with PAH already receiving either endothelin receptor or phosphodiesterase type 5 inhibition therapies demonstrated an overall 20-m improvement in postinhalation 6-minute walk distance as compared to baseline (14 m in preinhalational distance), as well as improved measures of quality of life. There was no difference in the time until clinical worsening.[478] An open-label extension of 206 patients from this trial found a median 18-m improvement over baseline 6-minute walk distance after 24 months.[479]

In addition to the lack of need for invasive administration equipment, inhaled prostenoid therapy is easier to initiate. Frequent dosing, however, is required (four times daily for treprostinil and between 6 and 9 while awake for iloprost) and compliance may be a challenge. In addition, as the hemodynamic effects wane prior to each administration, whether patients receive the same benefit as with continuously infused prostenoid therapy is unclear.[480]

Iloprost inhalational therapy is initiated at a dosage of 2.5 and increased to 5 μg with the subsequent dose if tolerated. Treprostinil is started at 18 μg (3 breaths) four times a day, with dose escalation suggested every 1 to 2 weeks to a maximum and target dose of 54 μg (nine breaths) four times daily. Inhaled prostenoids are each administered with drug-specific portable delivery devices. Prostenoid side effects are seen with inhalational therapy, including headache, nausea, diarrhea, flushing, and jaw discomfort. Systemic hypotension and syncope may also occur although have not been associated with further clinical deterioration in clinical trials.[476]

Oral Prostenoid Therapy An orally active prostacyclin analog, beroprost, has been studied in two randomized placebo-controlled trials of patients with various forms of PAH and appears to result in a nonsustained improvement in exercise capacity. An initial trial of 130 patients demonstrated an improvement in 6-minute walk distance after 12 weeks of therapy but in a subsequent study of 116 patients the effect was not sustained beyond 6 months.[481,482] Neither trial demonstrated significant hemodynamic improvement as compared with placebo, and beroprost is currently only approved for use in Japan. An oral formulation of treprostinil was ineffective at improving exercise capacity in patients already receiving oral endothelin receptor antagonists or phosphodiesterase type 5 inhibitors.[483]

Combination Pharmacotherapy

Despite the improvements in exercise capacity and functional status that many patients achieve with individual agents, PAH a life-threatening disease and many patients fail to improve with or maintain a positive response to initial treatment, or suffer progressive decline. With further clinical deterioration it is tempting to replace one agent for another. Alternatively, additional agents are added and used in combination. Indeed, 41% of 2438 patients enrolled in the multicenter US-based REVEAL cohort were receiving two PAH-specific therapies (excluding calcium channel antagonists) and 7.5% were receiving three.[191] Unfortunately, despite such widespread adoption of combination therapy, data regarding the most efficacious and safest approach to using multiple drugs in patients with PAH are limited.

In the only randomized controlled study of upfront combination therapy for PAH, 33 patients with IPAH were randomized to receive either bosentan or placebo 2 days after the initiation of epoprostenol. Both groups demonstrated improved exercise capacity and hemodynamics, but no statistically significant difference was seen as a result of the combination therapy. The small sample size may have precluded identification of differences in efficacy or safety.[484] Other randomized trials of combination therapy have involved sequential ("add-on") therapy in which a second PAH-specific agent has been added to the regimen of a patient already on at least one other drug. In a 12-week trial of 67 patients with PAH, the addition of inhaled iloprost to background bosentan therapy resulted in a 26-m increase in 6-minute walk distance as compared with placebo over 12 weeks. Iloprost also delayed the time to clinical worsening in this study.[485] In a 16-week study of 267 PAH patients, the addition of sildenafil (up to 80 mg three times daily) to continuous intravenous epoprostenol infusion increased 6-minute walk distance by 29 m and improved hemodynamic variables and measures of health-related quality of life.[486] Patients on background bosentan therapy experienced a 23-m placebo-corrected increase

in 6-minute walk distance when tadalafil was added in a 16-week trial.[149] In contrast, the addition of oral treprostinil to background endothelin and/or phosphodiesterase type 5 inhibitors for 16 weeks did not improve 6-minute walk distance.[483]

SURGICAL INTERVENTIONS FOR PULMONARY ARTERIAL HYPERTENSION

Lung transplantation is addressed in detail in Chapter 107. Here, it will suffice to note that lung transplantation remains an important consideration for some patients with PAH whose disease fails to respond adequately to medical therapy. Although changes in the method of allocating donor lungs within the United States have improved wait times, mortality on the wait list for patients with PAH remains excessive compared to patients with other indications for lung transplantation.[487] To address this issue, PAH patients who are deteriorating despite optimal medical therapy and who have a cardiac index <1.8 L/min/m^2 or a right atrial pressure >15 mm are now granted special priority.

Atrial septostomy has been performed as a palliative measure, as well a "bridge" to lung transplantation in some patients with severe PAH and symptoms refractory to other therapies. The creation of a right-to-left shunt is aimed at decreasing the pressure overload of the right ventricle, and simultaneously increasing preload of the left ventricle thereby improving systemic perfusion. Controlled studies have not been performed, and evidence-based selection criteria have not been established. Significant palliation of patients has been reported, but deaths have been reported as well.[488] The procedure should only be performed at experienced institutions.[489]

ACUTE COR PULMONALE OR RESPIRATORY FAILURE IN PULMONARY ARTERIAL HYPERTENSION

Patients with PAH may become acutely unstable due to a number of factors, including infection, volume overload with dietary indiscretion, or complications of medicines (Table 72-10). Often a clear acute precipitating source of decompensation is not identified. Regardless of the inciting event,[490] in many patients an acute stress will convert stable cor pulmonale into rapidly progressive hemodynamic failure. Acutely worsened hypoxemia, if not the precipitating cause of the hemodynamic instability will usually develop quickly as well.[491] Although the precipitating events may differ, each tends to lead to a vicious cycle that will result in worsening right ventricular function and hypotension (Fig. 72-16). Increased work of the right heart, be it from acute hypoxia and pulmonary vasoconstriction, or due to fever and infection, will increase ventricular wall stress further impeding ventricular performance. A decreased CO will impede myocardial perfusion, as will the increase in intraventricular pressure. Increases in right ventricular volume and pressure will, through displacement of the interventricular septum and increases in pericardial pressure, impede left ventricular filling and function. The resultant hypoxemia and ventricular ischemia, as well as acidemia from either respiratory insufficiency or poor systemic perfusion, can worsen the situation.

The goals of management are the same as for any patient who is hemodynamically unstable or in respiratory distress: to decrease the demand for oxygen while improving its delivery. Supportive care therefore aims to reverse the hypotension and hypoxemia through judicious fluid management, the reduction of RV afterload, support of cardiac function, and provision of supplemental oxygen and, if necessary, ventilator support (Fig. 72-17). Few data are available to guide the management of acute hemodynamic instability in patients with PAH. Available studies of various agents have frequently been performed in patients with acute right heart dysfunction following cardiac surgery, who generally do not suffer from severe underlying pulmonary vasculature disease. It is similarly important to recognize the limitations in extrapolating data from acute vasodilator trials performed on an elective basis in patients with PAH to the care of a hemodynamically unstable PAH patient.

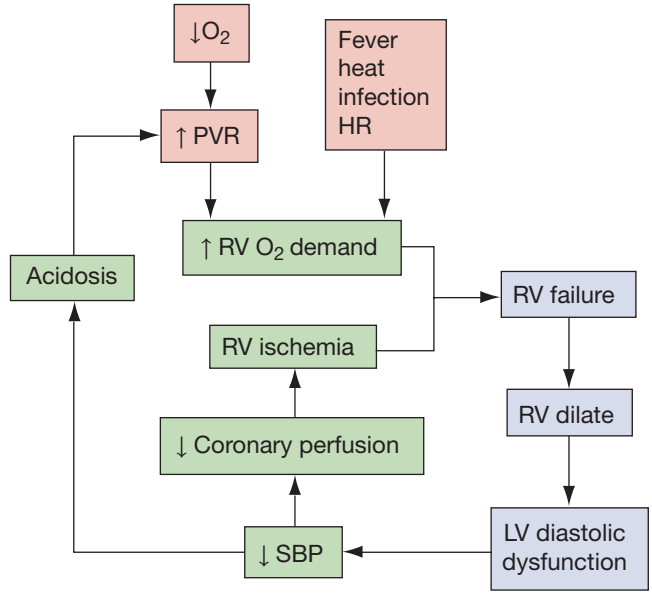

Figure 72-16 Interacting mechanisms in the acute development of worsened right heart function in patients with pulmonary arterial hypertension. A vicious cycle frequently results in both respiratory failure and hemodynamic instability. *(Reproduced with permission from Jeffery ME, Taichman DB. Management of the acutely ill patient with pulmonary arterial hypertension. In: Pulmonary Vascular Disease, Mandel J, Taichman DB. Philadelphia: Elsevier Science; 2006.)*

TABLE 72-10 Clinical Presentations of Patients with Pulmonary Arterial Hypertension with Acute Hemodynamic Instability

Acute recognition/late presentation • Syncope, shock, renal failure, ascities, hypoxemia
Acute medication failure • Medical noncompliance, interrupted infusions • Intolerance (calcium channel antagonist)
Dietary indiscretion/fluid retention
Infection (sepsis with infused therapy)
Fever (environmental causes, infection)
Venous thromboembolism
Medical/surgical procedures/anesthesia
Pregnancy
Tachydysrhythmia (atrial fibrillation, atrial flutter)
Increased activity of underlying disease (flare of systemic lupus erythematosis with worsened PAH that may be responsive to increase immunosuppression)

Source: Adapted with permission from Jeffery ME, Taichman DB. Management of the acutely ill patient with pulmonary arterial hypertension. In: Mandel J, Taichman DB, eds. Pulmonary Vascular Disease. Philadelphia, PA: Saunders/Elsevier; 2006.

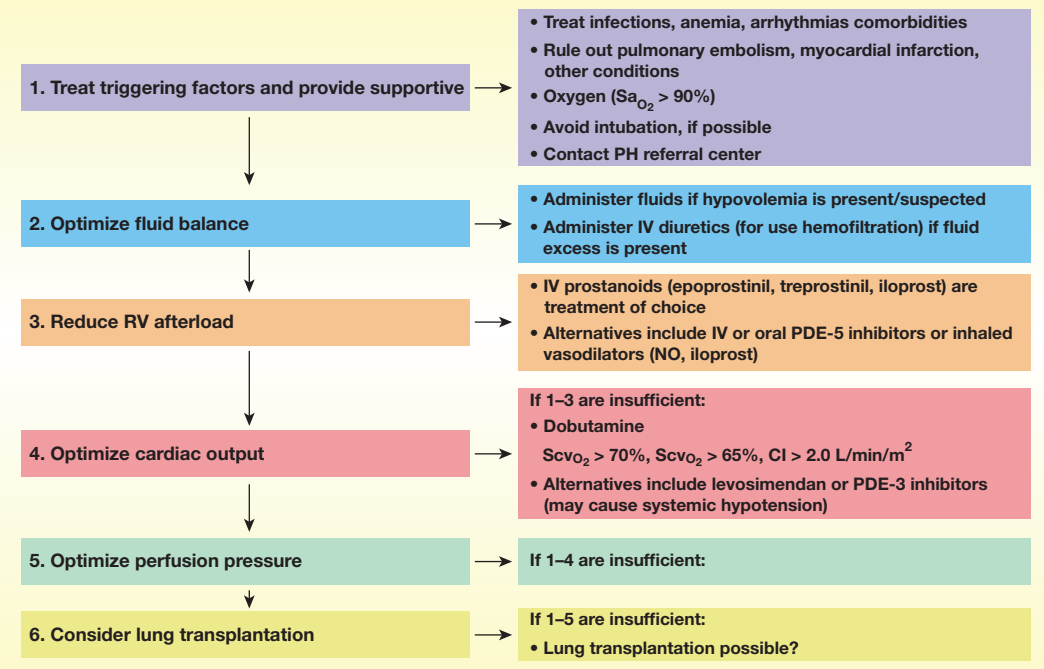

Figure 72-17 Hemodynamic management of critically ill patients with right ventricular failure due to pulmonary arterial hypertension. Which measures are necessary will depend on the individual patient. On many occasions, these treatment strategies need to be administered simultaneously rather than sequentially. CI, cardiac index; IV, intravenous; PDE-5, phosphodiesterase-5; PH, pulmonary hypertension; RV, right ventricular; Scv_{O_2}, central venous oxygen saturation; Sv_{O_2}, mixed venous oxygen saturation. *(Reproduced with permission from Hoeper MM, Granton J. Intensive care unit management of patients with severe pulmonary hypertension and right heart failure. Am J Respir Crit Care Med. 2011;184(10):1114–1124.)*

Although administration of intravenous fluids is the usual first, and frequently most important, intervention for hypotension causing critical illness, fluid challenges for hypotension in the patient with PAH and right ventricular failure must be pursued cautiously with the clinician paying close attention to the potential for making the situation worse. A fluid challenge is often an appropriate initial measure for hypotension, especially when infection or other factors that might predispose to hypovolemia exist. In many patients with PAH and chronic cor pulmonale, however, acute hypotension is caused or complicated by worsened right heart dilation further impairing both right and left ventricular functions. In such cases, fluid removal is required to recover right ventricular function. Vasopressors may be needed for hemodynamic support while fluid removal is accomplished with diuretics.

There are few data to firmly guide the choice of vasopressors.[492] Norepinephrine or dobutamine are often employed for their inotropic properties, while agents that may constrict pulmonary vessels such as phenylephrine are usually avoided if possible.[493–495] Tachycardia and a resultant further impairment of ventricular filling and output may limit the use of any of these agents. If tolerated, the use of intravenous pulmonary vasodilators (e.g., epoprostenol) may result in significant improvement both acutely and longer term. Attempts to promote pulmonary vasodilatation with intravenous or oral agents are, however, frequently complicated by hypotension from the systemic effects of the drugs. In the setting of acute hemodynamic instability, the use of inhaled agents (iloprost, nitric oxide, aerosolized epoprostenol, or milrinone) is often preferable.[496–498] The phosphodiesterase type 5 inhibitor sildenafil has been administered intravenously in a small series of hemodynamically stable patients with PAH; whether it might prove useful for therapy of critically ill patients has not been studied.[499]

Oxygen is a potent pulmonary vasodilator and should be administered at concentrations adequate to prevent hypoxemia. Mechanical ventilation is avoided if possible due to the hemodynamic effects of positive pressure ventilation as well as required sedatives. Unfortunately, invasive ventilator support may be unavoidable. When mechanical ventilation is required, the same principles apply as in other patients with respiratory failure, although certain points are worth noting in the management specifically of patients with PAH. While intra-alveolar vessels are stretched and their resistance increased with overdistention of alveoli, compression of extra-alveolar vessels with atelectasis at low lung volumes might increase their vascular resistance. Thus, at either extreme PVR might increase. The application of positive end-expiratory pressure must also be done with attention to possible overdistention of alveolar vessels and a resultant increase in their resistance. As hypercarbia tends to promote pulmonary vasoconstriction, lung-protective strategies that permit hypoventilation (and hypercapnea) must be carefully monitored to be certain of overall benefit.[500] Hyperventilation to induce mild alkalemia and pulmonary vasodilation has been used empirically, but with attention to avoid dynamic hyperinflation. Finally, care must be taken to avoid agitation with noxious procedures (such as endotracheal suctioning) that might promote further surges in vascular resistance; sedation and analgesia should be employed judiciously with such procedures.[501]

Some acutely ill patients may be candidates for lung transplantation. Although experience is limited, extracorporeal membrane oxygenation (ECMO) has been used in the successful support of individual acutely ill patients with PAH and right ventricular failure awaiting transplantation.[502,503] Newer dual channel cannulas inserted into the internal jugular vein permit patients to remain ambulatory while on ECMO. A pumpless oxygenation system implanted between the pulmonary artery and left atrium has been used to provide support to acutely ill patients while awaiting lung transplantation.[504]

CHAPTER 73

Pulmonary Thromboembolic Disease

Peter F. Fedullo
Gordon L. Yung

INTRODUCTION

Pulmonary thromboembolic disease refers to the condition in which blood clot(s) (thrombus or multiple thrombi) migrate from the systemic circulation to the pulmonary vasculature. Most of these thrombi arise from the deep veins of the lower and upper extremities (deep venous thrombosis [DVT]). From the clinical standpoint, DVT and pulmonary embolism (PE) can be considered a continuum of the same disease, and the two terms are often collectively referred to as venous thromboembolism.

The annual incidence of PE in the United States remains uncertain. In a retrospective analysis of data involving 2218 Olmsted County residents over a 10-year period, community residents who were not hospitalized within a 90 days period had an incidence of PE of 3.6 per 10,000 person-years.[1] A slightly lower incidence of 2.3 per 10,000 person-years was reported in an earlier study in Massachusetts.[2] This translates to an annual incidence of approximately 100,000 cases in the United States. However, the true incidence of PE is likely to be much higher since many cases remain undiagnosed. A recent systematic review revealed that silent PE was present in 32% of patients with DVT.[3] An earlier report estimated that as many as 630,000 patients develop PE every year in the United States with 200,000 related deaths, the majority in patients in whom the diagnosis was never made (Fig. 73-1).[4] Although considerable effort is directed toward the development of new diagnostic techniques and therapeutic agents, a considerable impact on mortality related to the disease would arise from the routine use of prophylactic strategies, an understanding of the often subtle clinical presentation of the disease, and the appropriate application of existing diagnostic techniques.

SOURCES OF EMBOLI

Most cases (80%–95%) of PE occur as a result of thrombus originating in the lower extremity. Thrombus often begins at a site where blood flow is turbulent, such as at a venous bifurcation, or behind a venous valve (Fig. 73-2). When thrombus propagation exceeds the rate of thrombus organization and adherence to the endothelium, part or all of thrombus may break away and migrate via the venous system to the lungs. Most thrombi originate in the deep veins of the

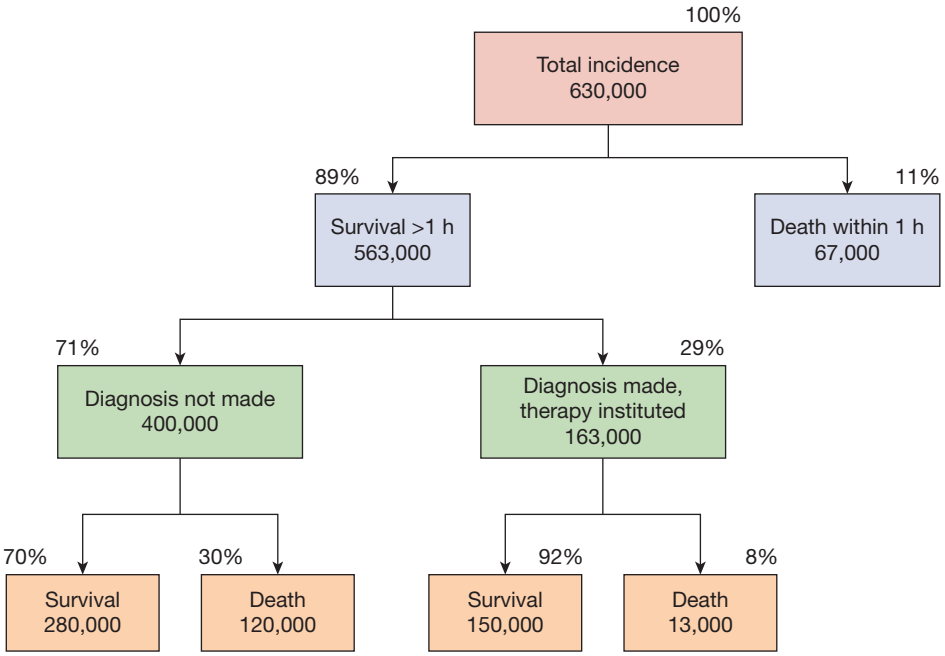

Figure 73-1 Estimated incidence and survival statistics for pulmonary embolism in the United States. *(Reproduced with permission from Dalen JE, Alpert JS. Natural history of pulmonary embolism. Prog Cardiovasc Dis. 1975;17(4):259–270.)*

calf and propagate proximally to the popliteal and femoral veins. Calf-limited thrombi pose a minimal embolic risk while those that extend into and above the popliteal vein represent the most common source of acute symptomatic PE. This is not meant to imply that calf-limited thrombosis represents a benign condition. Proximal propagation may occur in as many as 15% of untreated patients along with a higher risk of thrombotic recurrence and postphlebitic syndrome.[5]

Emboli may originate from other sources, most often from the pelvic veins, in which case a predisposing factor such as pregnancy, pelvic thrombophlebitis or pelvic infection, prostate disease, or recent pelvic surgery can often be identified. Emboli may also originate from upper extremity thrombosis associated with central venous catheters or intravascular cardiac devices, or may be associated with thoracic outlet obstruction or effort thrombosis (Paget–von Schroetter syndrome).[6] A small number of patients with PE may have evidence of right ventricular thrombus at presentation and this has been associated with more hemodynamic instability and an increase in mortality.[7]

Although the majority of cases of PE are the result of thrombus migration (hence, *thromboembolism*), other materials may occasionally obstruct the pulmonary vascular bed. These include blood-borne parasites (such as schistosomiasis), sickle cell disease, and various "contaminants" of illicit injected drugs (talc, cloth fibers, etc.). Air embolism is usually iatrogenic and typically enters the blood stream accidentally through a central venous catheter. Less commonly, a patient's own tissues or cells may enter the blood stream and lodge in the pulmonary vasculature. Examples include amniotic fluid embolism, which can occur during or immediately after labor or late-term abortion; fat embolism, which is usually associated with long bone fractures; and tumor embolism. PE due to sickle cell disease is caused by "clumping" of abnormal red blood cells in the setting of hypoxia and stress, and can cause both acute respiratory distress as well as a more progressive disease with secondary pulmonary hypertension.

PREDISPOSING FACTORS

Rudolf Virchow first described the phenomena of "embolism" and "thrombosis" in the mid-nineteenth century, and identified three main factors contributing to the formation of venous thrombosis (Virchow's triad): venous stasis, hypercoagulability, and injury to the venous wall (endothelium). One hundred and fifty years later, this basic classification remains useful in helping clinicians stratify individual patient's risk of developing venous thromboembolism (Table 73-1). It is important to recognize that there is an interplay between acquired and genetic risk factors, that multiple mechanisms lead to the development of DVT and/or PE, and that multiple factors can often be found in individual patients.

■ ACQUIRED RISK FACTORS

The risk imposed by a major surgical procedure is well recognized. Without prophylaxis, venous thrombosis occurs after approximately 20% of all major surgical procedures with associated embolism after 1% to 2%.[8] The incidence of thromboembolism without prophylaxis is even higher in orthopedic patients with over 50% of major orthopedic procedures complicated by venous thrombosis.[9] In the absence of prophylaxis, the frequency of fatal postoperative PE ranges from 0.1% to 0.4% in patients undergoing elective general surgery and from 1% to 5% in patients undergoing elective hip or knee surgery, emergency hip surgery, major trauma, or spinal cord injury.

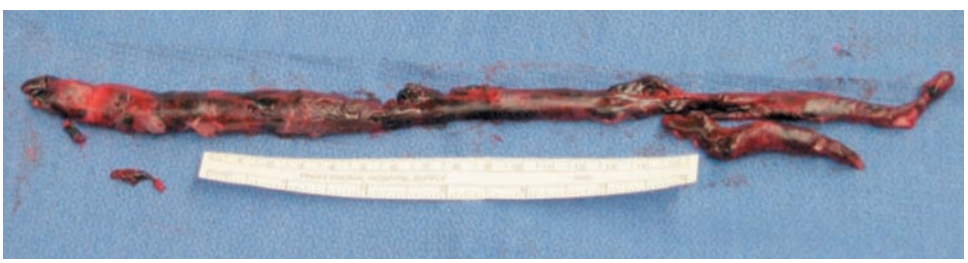

Figure 73-2 Large, well-organized embolus representing "cast" of a lower extremity vein removed from pulmonary artery at pulmonary embolectomy.

TABLE 73-1 Virchow's Triad: Clinical States Predisposing to Venous Thrombosis

Stasis	Immobility
	Bed rest
	Anesthesia
	Congestive heart failure/cor pulmonale
	Prior venous thrombosis
Hypercoagulability	Malignancy
	Anticardiolipin antibody
	Nephrotic syndrome
	Essential thrombocytosis
	Estrogen therapy
	Heparin-induced thrombocytopenia
	Inflammatory bowel disease
	Paroxysmal nocturnal hemoglobinuria
	Disseminated intravascular coagulation
	Protein C and S deficiencies
	Antithrombin III deficiency
Vessel wall injury	Trauma
	Surgery

Major traumatic injuries, most notably those of the head, spine, and pelvis, are also associated with high risk. The basis for this risk is multifactorial, involving all three components of Virchow's triad.

Although initially recognized and studied in surgical patients, it is now appreciated that hospitalized medical patients may be equally prone to develop DVT.[10] In about 80% of the cases, one or more risk factors may be present when extensive investigative testing is performed. Major risk factors include New York Heart Association class III and IV congestive heart failure, chronic obstructive pulmonary disease, sepsis and other inflammatory disorders, advanced age, stroke, critical illness, and prolonged bed rest.

Any prolonged period of immobilization may increase thromboembolic risk and explains the occurrence of thrombosis under such circumstances as paralysis, bed rest, and prolonged air travel. Long distance traveling (economy class syndrome) is associated with a 1.5- to 3-fold increase in thromboembolic risk, depending on the travel duration.[11] Despite the relative increase in risk, the actual incidence of PE associated with air travel is quite low.[12]

Pregnancy is the most common cause of venous thromboembolism in women younger than 40 years old, and if untreated may account for 20% to 50% of all pregnancy-related deaths. Compared with nonpregnant women, the risk of venous thrombotic events is increased fivefold during pregnancy and 60-fold in the first 3 months after delivery.[13,14] The increase may be a result of decreased mobility, pregnancy-related hypercoagulable state (increases in factors II, VII, VIII, X, acquired activated protein C resistance, and decreased free protein S level), and venous obstruction from uterine compression. The incidence is estimated at 0.76 to 1.72 cases per 1000 pregnancies and occurs in roughly equal distribution over all trimesters. Most cases of postpartum DVT occur within the first 6 weeks after delivery. Cesarean section, premature birth, multiple births, preeclampsia, advance maternal age, and maternal history of cardiac disease have all been identified as contributing factors. Interestingly, 90% of all DVT cases are noted in the left leg, presumably because of the anatomic relationship between the uterus and inferior vena cava (IVC).

The use of oral contraceptive agents and hormonal replacement therapy has also been associated with an increased risk of venous thromboembolism.[14,15] Although the risk of venous thromboembolism is higher among users of oral estrogen-containing contraceptives, the absolute risk is low. In terms of oral contraceptive agents, the relative risk of developing venous thrombosis is a four- to sixfold increased risk. There appears to be a synergistic effect of oral contraceptives with obesity.[16]

Hormone replacement therapy appears to be associated with a two- to fourfold increased risk of venous thromboembolism.[17] Studies have suggested that venous thromboembolic risk is lower with transdermal hormone preparations. However, none of these studies are randomized trials. Given that the baseline risk of thrombosis increases with age, the use of hormonal replacement therapy in a postmenopausal population has a considerably higher impact on absolute rates of thrombosis.

Obesity has been associated with venous thromboembolism, particularly in women. The Nurses' Health Study found that a body mass index greater than or equal to 29 kg/m^2 was an independent risk factor.[18] The metabolic syndrome, defined by abdominal obesity, elevation of blood pressure, elevated fasting blood sugar and triglycerides, and low levels of high-density lipoprotein cholesterol, appears to be associated not only with an increased risk of atherosclerotic disease but also of venous thromboembolism.[19]

The risk of venous thromboembolism increases with age. A recent study, using hospital discharge surveys over a 21-year period, found that patients 70 years or older have an approximately 25-fold increased risk, compared with those 20 to 29 years of age.[20] Presumably the difference may be due to decrease in mobility and increase in comorbidities in this population. Elderly patients also appear to have a higher mortality due to PE, and PE is suspected less commonly prior to death in the elderly patient.

Cancer patients, particularly those with primary malignancies from lung, pancreas, breast (mucin-secreting adenocarcinoma), prostate, stomach/colorectal, and genitourinary tracts are at a high risk for venous thromboembolism. Cancer is estimated to increase the risk of venous thromboembolism by four- to sixfold. Patients with cancer also have a higher risk of thromboembolic recurrence and those with venous thromboembolism have a higher overall mortality rate than cancer patients without thrombosis. Multiple factors are probably involved and include the development of abnormalities in the hemostatic system related to the malignancy itself, hemostatic alterations induced by chemotherapeutic agents, immobility, infectious complications, and the presence of chronic indwelling central venous catheters. Although most instances of cancer-associated venous thromboembolism occur after the diagnosis of the malignancy, approximately 5% to 10% of patients with "idiopathic" venous thrombosis have a malignancy diagnosed within the next 2 to 3 years. There is no evidence at this time to recommend an aggressive search for cancer in patients with idiopathic or unprovoked thrombosis. Recent data suggest that a limited approach (routine laboratory testing, chest radiograph, tumor markers, abdominal ultrasound) may have the capacity to identify approximately one-half of malignancies in patients who were negative on routine examination.[21] More extensive screening utilizing chest and abdominal computed tomography (CT) appears to result in excessive false-positive results without an effect on outcome.[22]

Various hematologic conditions such as polycythemia vera, essential thrombocytosis, and acute leukemia may result in significant overproduction of different cell lines, which in turn may increase the risk of venous thromboembolism by increasing blood viscosity (hyperviscosity syndromes) and through the release of

procoagulants.[23] This type of thrombosis seems to occur more frequently in the hepatic or portal veins and may be the presenting symptoms of the underlying disorder.

Paroxysmal nocturnal hemoglobinuria is a rare condition associated with an incidence of venous thromboembolism of approximately 40%.[24] Many cases involve nonlower extremity sites, particularly in the intra-abdominal vessels. The reason for thrombosis is not clear but may be related to a decrease in blood complement levels in these patients.

The presence of antiphospholipid antibodies, most notably the lupus anticoagulant, appears to be an independent risk factor for venous thromboembolism.[25] Among patients with venous thrombosis, a lupus anticoagulant has been reported in 5% to 15% and this abnormality has been estimated to lead to a ninefold increased risk of thrombosis.

The frequency of venous thromboembolism in patients with nephrotic syndrome may be as high as 40%.[26] There is a higher tendency for the thrombosis to present in unusual locations such as the cerebral sinus or as arterial thrombosis. Rarely, thrombosis may also be the presenting symptom of the nephrotic syndrome. The mechanism for venous thromboembolism in these patients is not clear but various factors such as functional or quantitative changes in coagulation factors, diminished fibrinolytic activity, platelet hyperreactivity, and increased blood viscosity have been proposed.

Patients with inflammatory bowel disease are at substantially increased risk of both venous and arterial thromboses.[27,28] The exact pathogenetic mechanism remains unclear. The majority of thrombotic complications occur during an active phase of the disease and inflammatory mechanisms have been proposed.

INHERITED RISK FACTORS

Many patients who develop venous thromboembolism are found to have an inherited risk factor due to either abnormal levels of or functional abnormalities in coagulation factors (inherited thrombophilia). The relative risk of thrombosis varies widely depending on the hemostatic defect. In general, this group of patients tends to be younger (less than 50 years) and has a tendency to develop recurrent venous thromboembolism.

The first known inherited thrombophilic trait was antithrombin III deficiency, originally described in 1965. Subsequently, a number of other genetic mutations associated with venous thromboembolism have been reported. The most common of these inherited predispositions was first described in 1993 by Dahlback and designated as a factor V Leiden mutation.[29] It is the consequence of a single point mutation on the factor V gene (adenine for guanine) resulting in factor Va with diminished sensitivity to the natural anticoagulant effect of activated protein C. Approximately 5% of Caucasians in Europe and North America are heterozygous for this genetic defect; lower rates of carrier frequency have been reported among Native American, African, and Asian populations. The heterozygous state carries a 5- to 10-fold increase in lifetime risk for venous thromboembolism, whereas the risk among patients homozygous for this mutation may be increased 80-fold. Factor V Leiden mutation appears to be an important risk factor for venous thromboembolism during pregnancy, in the postpartum period, and during oral contraceptive use.[30] Compared with women who do not use oral contraceptives and are not carriers of the factor V mutation, the risk of thrombosis among those with both risk factors is increased approximately 30-fold.[31]

Another common mutation has been identified in the 3' untranslated region of the prothrombin gene (substitution of A for G at position 20210) and is present in 2% to 4% of the general population.[32] This mutation results in an overproduction of prothrombin, which is otherwise normal. It is associated with a three- to fourfold increased risk of lower extremity venous thrombosis and appears to act in a synergistic manner with other forms of thrombophilia in increasing both the initial and recurrent thrombosis risk.

In clinical practice, factor V Leiden mutation and prothrombin gene mutation are the most common inherited conditions and account for more than half of the cases of inherited thrombophilia-related venous thromboembolism; three other conditions (deficiencies in antithrombin III, protein C, or protein S) account for most of the remainder. Occasionally one may also encounter venous thromboembolism patients who may have other conditions, particularly related to dysfibrinogenemias. It is important to recognize that, when multiple inherited risk factors coexist (such as factor V Leiden and prothrombin gene mutation), the risk of recurrent venous thromboembolism may increase substantially, and lifelong anticoagulation may be necessary in these patients.

PATHOPHYSIOLOGY

Once detached from their point of origin, emboli travel via the systemic venous system, through the right chambers of the heart, and eventually reach the pulmonary arterial system. The physiologic effects and clinical consequences of pulmonary thromboembolism vary widely, ranging from asymptomatic disease to hemodynamic collapse and death. Major factors that determine the outcome include (1) size and location of emboli; (2) coexisting cardiopulmonary diseases; (3) secondary humoral mediator release and vascular hypoxic responses; and (4) the rate of resolution of emboli.

HEMODYNAMIC CONSEQUENCES

Obstruction of the pulmonary vascular bed by embolism acutely increases right ventricular afterload. The normal pulmonary arterial system is a low-pressure system capable of accommodating substantial increases in blood flow with only modest increases in pressure. The thin-walled right ventricle is poorly equipped to generate the pressure necessary to overcome any significant increase in pulmonary vascular resistance. Compensatory mechanisms exist that allow up to 70% obstruction of the pulmonary vascular bed before right ventricular failure develops.[33–36]

In the absence of pre-existing cardiopulmonary disease, obstruction of less than 20% of the pulmonary vascular bed results in minimal hemodynamic consequences as a result of recruitment and distention of pulmonary vessels. When the degree of pulmonary vascular obstruction exceeds 30% to 40%, modest increases in right ventricular pressure occur, but cardiac output is maintained through an increase in heart rate and myocardial contractility. Compensatory mechanisms begin to fail when the degree of pulmonary artery obstruction exceeds 50% to 60%. Cardiac output begins to fall and right atrial pressure increases dramatically. Mixed venous oxygen saturation falls and a lactic acidosis may develop. With further acute obstruction, the right heart dilates, right ventricular wall tension increases, right ventricular ischemia may develop, the cardiac output falls, and systemic hypotension develops. In patients without prior cardiopulmonary disease, the maximal mean pulmonary artery pressure capable of being generated by the right ventricle appears to be 40 mm Hg (pulmonary artery systolic pressure of approximately 70 mm Hg).[34]

Other factors may affect the hemodynamic consequences of PE. Patients with pre-existing cardiopulmonary disease often have diminished pulmonary vascular reserve and even a relatively minor embolus may result in significant hemodynamic instability (Fig. 73-3). Alternatively, if the right ventricle has had time (months to years) to hypertrophy in response to a gradual increase in demand (left ventricular disease, idiopathic pulmonary arterial hypertension, chromic thromboembolism, etc.) a significantly higher pulmonary artery pressure may be seen.

Several observations suggest that other mechanisms are involved in hemodynamic consequences of acute PE. For example, patients

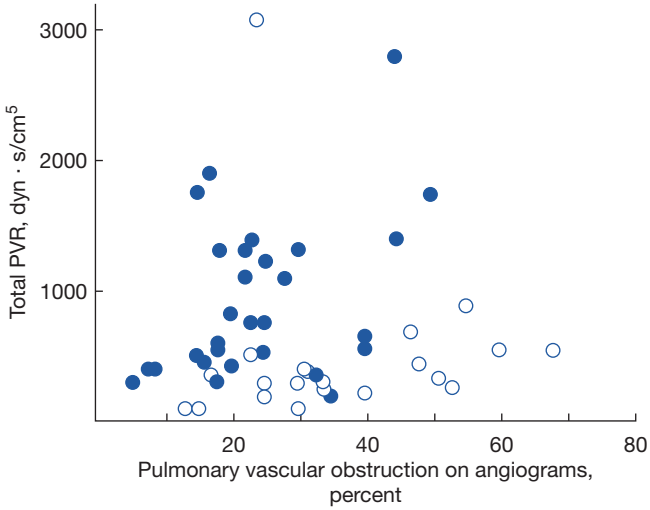

Figure 73-3 Hemodynamic consequences of pulmonary embolism and the underlying state of the pulmonary vasculature. Patients in whom the pulmonary vasculature was previously normal (*open circles*) develop little increase in pulmonary vascular resistance (PVR) until the clot burden exceeds 50%. In those with antecedent cardiopulmonary disease (*solid circles*), the PVR increases appreciably with only modest clot burden. *(Reproduced with permission from Sharma GV, McIntyre KM, Sharma S, Sasahara AA. Clinical and hemodynamic correlates in pulmonary embolism. Clin Chest Med. 1984;5(3):421–437.)*

develop only minimal hemodynamic instability during elective lobectomy, pneumonectomy, or even single lung transplantation despite complete and acute interruption of blood supply during cross-clamping. In the experimental setting, cyproheptadine (a nonselective serotonin antagonist) and ketanserin (a selective serotonin antagonist) have been shown to diminish some of the hemodynamic and airway responses that occur after pulmonary embolization. Certain patients develop disproportionately large and fluctuating pulmonary hemodynamic changes in response to relatively small emboli, suggesting that other mechanisms such as reflex vasoconstriction and release of vasoactive compounds may also be involved.[37,38]

As expected, large or multiple emboli tend to cause more severe symptoms and changes in oxygenation and hemodynamics. Given the large surface area of the peripheral pulmonary vascular bed compared to the central, symptomatic improvement may occur when a large central embolus is fragmented by forces generated by cardiac contractions or even with chest compressions during cardiopulmonary resuscitation. Eventually, the emboli may either resolve by fibrinolysis, or organize and become scar-like tissue that adheres to the vascular endothelium (Fig. 73-4). Recent data suggest that complete resolution is uncommon and that as many as 50% of patients have some residual obstruction 6 months after the embolic event.[39,40]

■ GAS-EXCHANGE ABNORMALITIES

Hypoxemia is the most common immediate physiologic consequence of PE. Obstruction of the pulmonary vasculature prevents systemic venous blood from reaching the pulmonary capillaries of the involved vessels and redirects the blood flow to other parts of the pulmonary vascular bed. This results in an increase in ventilation–perfusion (V/Q) inequality, intrapulmonary shunting, and decreases in the mixed venous O_2 level, thereby magnifying the effect of the normal venous admixture.[41,42] Further shunting and increase in alveolar dead space can also occur as a result of alveolar hemorrhage or to atelectasis related to loss of surfactant. Despite an increase in alveolar dead space, patients with PE often develop hypocapnia. This is thought to be due to hypoxia-induced intrapulmonary reflex

Figure 73-4 Chronic thromboembolic material dissected from pulmonary arteries at pulmonary thromboendarterectomy. Resolution of emboli is occasionally complete but certain patients may be left with significant emboli residua.

vagal stimulation, with resulting hyperventilation. Finally, embolic events large enough to increase right atrial pressure may result in intracardiac right-to-left shunting through a patent foramen ovale.

One uncommon consequence of PE is pulmonary infarction. Infarction is uncommon because the pulmonary parenchyma has three potential sources of oxygen: the pulmonary arteries, bronchial arteries, and airways. Two of these three sources apparently must be compromised before infarction develops (Fig. 73-5). Therefore, in a patient with no coexisting cardiopulmonary disease, infarction is rare.[43] Infarction occurs in approximately 20% of patients with significant cardiac or pulmonary disease that compromise either bronchial arterial flow or airway patency. In patients with left ventricular failure, increased pulmonary venous pressure may decrease bronchial flow and infarction may occur.

DIAGNOSIS OF PULMONARY EMBOLISM

The diagnostic approach to PE has undergone a fundamental transition over the past decade. V/Q scanning, the mainstay of diagnosis for almost three decades, has been relegated to a secondary role. The prospective investigation of pulmonary embolism diagnosis (PIOPED) trial demonstrated the shortcomings of this technique while providing valuable insight into the diagnostic utility of clinical assessment.[44] CT, highly sensitive D-dimer assays, stratification according to clinical assessment, and the application of Bayesian analysis to the diagnostic pathway have become the cornerstones of the current diagnostic approach. What has not changed is the understanding that clinical evidence per se, although capable of raising suspicion of the disease, is incapable of reliably confirming or excluding the diagnosis in the absence of objective testing. Recognition of the clinical signs and symptoms associated with embolism is valuable because clinical findings and clinical suspicion represent an essential first step in the diagnostic pathway.

■ CLINICAL PRESENTATION

The mainstay for the diagnosis of PE is a high index of suspicion tempered by the reality that most patients with embolism have one or more factors predisposing them to the condition. These predisposing factors need not be major or readily apparent. Advancing age, a period of bed rest, a prolonged air flight, or a minor traumatic injury can result in the development of venous thromboembolism. The absence of a known clinical or thrombophilic predisposition, however, should not dissuade an objective evaluation if the clinical presentation is consistent with embolism.

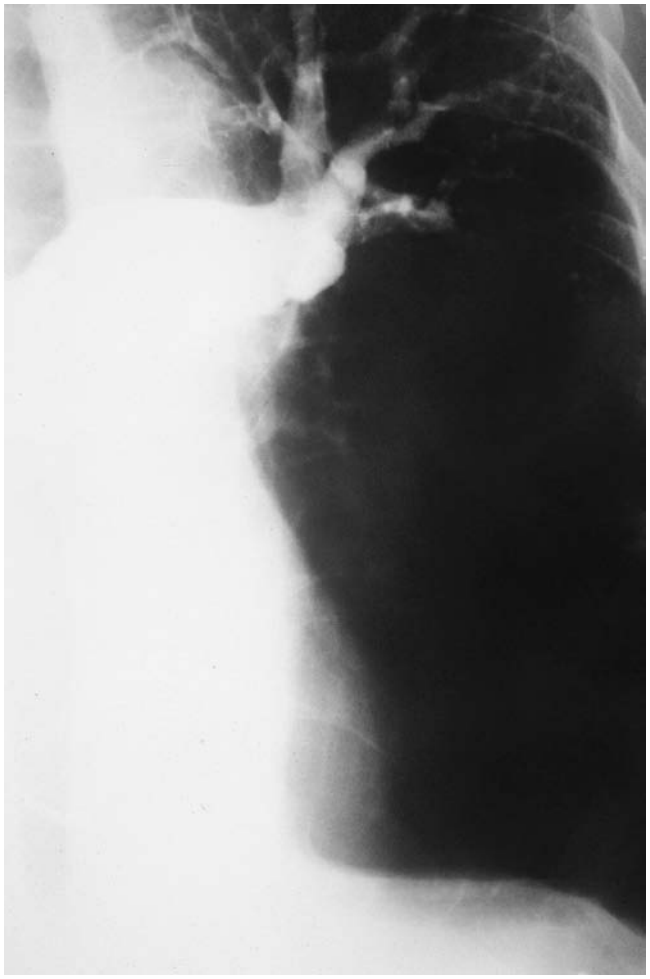

Figure 73-5 Pulmonary angiogram demonstrating thromboembolic obstruction of left pulmonary artery with absent blood flow to lingula and lower lobe. Despite extension obstruction, infarction did not occur as a result of lung's dual blood supply.

Although a somewhat arbitrary classification (as presenting symptoms and signs of embolism frequently overlap), the presentation of acute PE can be categorized into one of the three clinical syndromes: (1) isolated dyspnea; (2) pleuritic pain or hemoptysis; and (3) circulatory collapse.[45,46] Among patients without prior cardiopulmonary disease in the PIOPED study, the syndrome of pleuritic pain or hemoptysis was found to be the most common mode of presentation, occurring in approximately 60% of patients. Isolated dyspnea occurred in approximately 25%, whereas circulatory collapse occurred in 10%.

Two additional modes of presentation are also possible: subclinical clot and chronic, nonresolving or propagating clot. With the increasing use of computed tomographic studies, incidental emboli are occasionally found.[47] Typically, these emboli are found in the peripheral segments of the pulmonary arterial vasculature and do not correlate with any clinical symptoms. At this time, the short- and long-term significance of these incidental findings is not clear. In patients who are known to be at high risk of recurrent disease, such as those with inherited thrombophilia and hormonal use or those with poor cardiopulmonary reserve, it is reasonable to consider treatment with anticoagulation or at least the use of more aggressive prophylactic therapies during at-risk situations, such as prolonged hospitalization or air travel.

Complete anatomic resolution of PE appears to be uncommon. When there is sufficient residual pulmonary vascular obstruction, some patients may develop chronic thromboembolic pulmonary hypertension (CTEPH).[48] Although exact values for frequencies vary, it is estimated that approximately 0.5% to 1% of patients may develop this condition following an initial, symptomatic episode of PE.[49] The diagnosis should be considered even in the absence of a history of acute embolism. Approximately 30% of patients who present with CTEPH do not have a history of precedent acute embolism and are diagnosed during the evaluative process for unexplained dyspnea or pulmonary hypertension.

The most common presenting symptom of acute PE is the sudden onset of dyspnea.[45,46] Dyspnea usually occurs over minutes to hours but in approximately 15% occurs over days. Although usually present at rest, dyspnea may only be noted with exertion. It is important to recognize that dyspnea does not occur in approximately 25% of patients ultimately proven to have embolism. Other symptoms include pleuritic chest pain, cough, leg swelling or pain, and hemoptysis. The most common physical finding is unexplained tachypnea (respiratory rate greater than 20/min) present in approximately 70% of patients with embolism. Less frequent physical findings include rales, tachycardia, and an increased pulmonic component of the second heart sound. Fever may develop some hours after the event and often reaches, but rarely exceeds, 38.3°C.[50]

Obviously, these symptoms and signs are nonspecific (Table 73-2). In the PIOPED study, none of the presenting symptoms or

signs with the exception of the presence of rales, a fourth heart sound, and an increased pulmonic component of the second heart sound could differentiate between those with positive and negative angiograms.[45]

CLINICAL ASSESSMENT

A major advance in the diagnostic approach to PE has been a transition from a purely technique-oriented approach to one that uses Bayesian analysis. In doing so, the pretest probability of the disease, calculated independently of a particular test result using either empiric means or a standardized prediction rule, is calculated. This pretest probability aids in the selection and interpretation of further diagnostic tests to create a posttest probability of the disease. This posttest probability can then be used as a basis for clinical decision making. For PE, a number of such scores have been developed and validated (Tables 73-3–73-5). Wells et al.[51] have prospectively tested a rapid seven-item bedside assessment to estimate the clinical pretest probability for PE. An alternative scoring system, the Geneva score, involved seven variables and required gas exchange and radiographic information.[52] A revised Geneva score requiring eight clinical variables without gas exchange or radiographic information was validated and published.[53] Other clinical decision rules include the PISA rule, the PERC (pulmonary embolism rule-out criteria) rule, and the Charlotte rule.[54–56] Although such scoring systems have not proved to be more accurate than clinical assessment, they do provide a method of standardization that compensates for variability in physician experience and judgment.

LABORATORY FINDINGS

Routine laboratory testing is not useful in confirming or excluding the diagnosis of PE but may be helpful in suggesting other diagnoses. A modest leukocytosis may accompany embolism but rarely exceeds 20,000/mm^3.[57]

As noted, hypoxemia is common in acute PE although the diagnosis cannot be excluded based upon a normal P_{O_2}.[58,59] The more massive the obstruction, the more severe the hypoxemia is likely to be. However, many other conditions also cause hypoxemia and,

conversely, acute PE does not necessarily cause hypoxemia or even a widening of the $(A\text{-}a)_{O_2}$ gradient.[58] In the PIOPED trial, no combinations of blood–gas abnormalities were identified that reliably excluded PE. Although most patients with embolism have a low Pa_{O_2}, low Pa_{CO_2}, or high $P(A\text{-}a)_{O_2}$ gradient, the absence of such abnormal values, alone or in combination, did not exclude PE. Hypercapnia resulting from increased dead space ventilation is rare and appears with PE only in patients with marked antecedent ventilatory limitation or when such limitation has been imposed because the patient is on controlled mechanical ventilation when the embolism occurs.

■ ELECTROCARDIOGRAM

The electrocardiogram is nonspecific in the diagnosis of PE, and its major value may be in identifying other clinical disorders (e.g., acute myocardial infarction and pericarditis) that may be confused with PE. Findings in acute PE are generally nonspecific and include T-wave changes, ST-segment abnormalities, and left- or right-axis deviation (Fig. 73-6).[46] Atrial arrhythmias may occur but appear to be more common in patients with underlying cardiopulmonary disease. The S1Q3T3 pattern, commonly considered to be specific for PE, is seen in only a minority of patients. Electrocardiographic findings can offer insight into the extent and hemodynamic consequence of the embolism. The electrocardiogram is rarely normal in the setting of PE associated with right ventricular dysfunction. The presence of an S1Q3T3 pattern, right bundle branch block, or T-wave inversion in leads V1 toV3 in a patient with PE should suggest the presence of right ventricular dysfunction.[60,61]

■ CHEST RADIOGRAPHY

Most patients with PE have abnormal but nonspecific chest radiographic findings.[46,62] Common radiographic findings include atelectasis, pleural effusion, pulmonary infiltrates, and mild elevation of a hemidiaphragm. Classic findings of pulmonary infarction – such as Hampton's hump or decreased vascularity (Westermark sign) – are suggestive but infrequent. There is some confusion about the diagnostic configuration of infiltrates due to embolism. These infiltrates, although usually abutting a pleural surface, can be of any shape, not necessarily wedge shaped. Although pleural effusions occur in almost half of the patients, the majority of effusions are small and involve only blunting of the costophrenic angle. The main use of the chest radiograph in suspected PE is to exclude alternative diagnostic possibilities such as pneumothorax, which may simulate the disease. A normal chest radiograph in a patient with otherwise unexplained acute tachypnea, dyspnea, or hypoxemia should raise the possibility of PE.

■ D-DIMER

The development of a rapid and accurate blood test capable of diagnosing venous thromboembolism has been the subject of considerable investigative interest. A number of different hemostasiologic markers have been investigated. Of these, D-dimer, alone and in combination with other noninvasive studies has been subjected to the most rigorous clinical evaluation.[63,64] D-dimer testing has proven to be highly sensitive but not specific. Increased levels are present in nearly all patients with venous thromboembolism, but also occur in a wide range of other circumstances, including advancing age, pregnancy, trauma, infections, the postoperative period, inflammatory states, and malignancy. Therefore, the role of D-dimer testing is limited to one of venous thromboembolism exclusion. The study is of limited utility in inpatients given the high frequency of positive results in this population.[65]

Multiple assays for D-dimer have been developed with a range of sensitivities and specificities.[66] Highly sensitive assays such as the enzyme-linked immunosorbent assay (ELISA) are capable of excluding venous thromboembolism but are associated with such a high frequency of false-positive results, especially when applied to an inpatient population, as to limit their clinical utility. Less sensitive assays (e.g., latex agglutination, red cell agglutination) lack the ability to exclude venous thromboembolism in isolation but have been used successfully in combination with either a clinical probability estimate or noninvasive diagnostic study. D-dimer testing has been used successfully as part of a number of different diagnostic strategies. Negative results of standardized, highly sensitive assays (ELISA) have proved capable of safely excluding PE in outpatients presenting with a low or intermediate clinical likelihood of the disease. Certain non-ELISA assays are capable of excluding embolism as a stand-alone study in outpatients with a low probability of disease but are more appropriately used in a multibranch diagnostic pathway.

■ VENTILATION–PERFUSION SCANNING

V/Q scanning had been the pivotal diagnostic test for suspected PE for many years but has been replaced by CT imaging. Despite limitations, V/Q lung scanning can provide valuable information if used and interpreted appropriately. The PIOPED trial provided valuable insight into the strengths and limitations of V/Q scanning.[44] A negative study is capable of ruling out the diagnosis of PE with the same degree of certainty as a negative pulmonary angiogram and with a higher degree of certainty than can be achieved by a negative CT scan (Fig. 73-7). The positive predictive value of a "high probability" study (one characterized by multiple, segmental-sized, mismatched

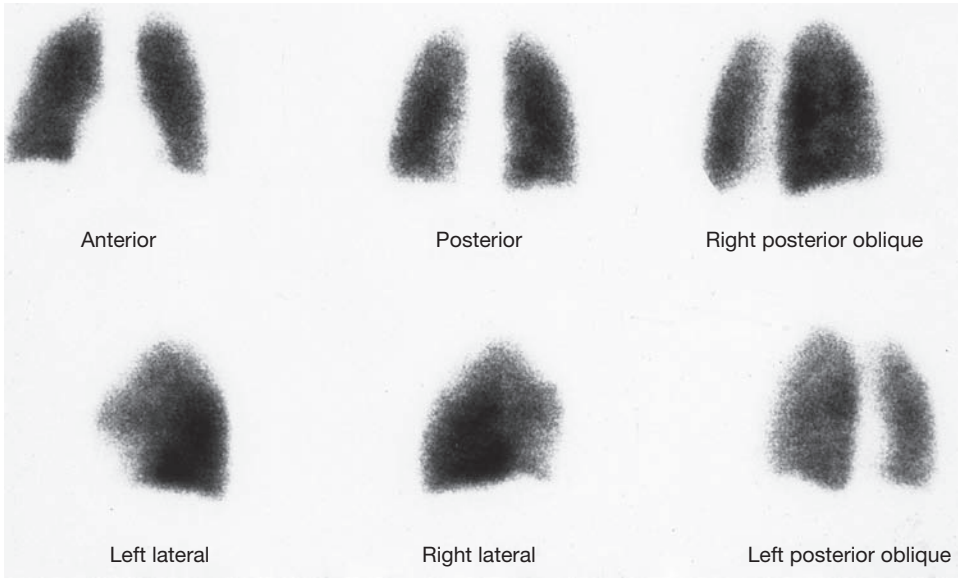

Figure 73-7 Normal six-view perfusion scan. Such a scan finding has a negative predictive value equivalent to a negative pulmonary angiogram and higher than that of a negative computed tomographic study.

defects) approximates 88%; when coupled with a high clinical probability of embolism, the positive predictive value increased to 96% (Fig. 73-8). However, only 28% of patients in PIOPED had scans characterized as high probability or normal, the only categories that can be considered definitive. The majority of patients with PE do not have a high probability scan, whereas the majority of those without embolism do not have a normal scan.

The PIOPED study also undertook to correlate the clinical impression of the likelihood of PE with the interpretation of the lung scan (Table 73-6). When interpretation of the lung scan and clinical assessment were concordant (both high and low probability), diagnostic accuracy was greater than that of the lung scan alone. In contrast, when interpretation of the lung scan and clinical assessment were discordant, the predictive value of the lung scan was decreased. In as many as two-thirds of patients suspected of PE, the combination of the lung scan and clinical assessment were either discordant or indeterminate and failed to diagnose or exclude PE.

There are certain situations in which V/Q scanning may be preferred over CT-pulmonary angiography (CT-PA). IV contrast is not required for V/Q scanning making it a more desirable option in patients with renal dysfunction or a severe iodinated contrast allergy. In addition, with a portable gamma scintillation camera the perfusion portion of the study can be performed at the bedside, which may be a major advantage in a critically ill patient for whom transportation to the CT scanner may be deemed too high risk. The role of V/Q scanning versus CT-PA in pregnancy remains unsettled but V/Q scanning appears to offer similar diagnostic performance in this setting with significantly lower levels of maternal radiation.[67]

■ ECHOCARDIOGRAM

The overall sensitivity of transthoracic echocardiography in PE approximates 50%.[68] Under appropriate clinical circumstances, the detection of unexplained right ventricular volume or pressure overload should suggest the possibility of PE and lead to confirmatory testing. Transthoracic echocardiography has emerged as a potentially important tool for risk assessment and treatment guidance in patients with acute PE. The presence of right ventricular dysfunction on a baseline echocardiogram in normotensive patients appears to represent an independent predictor of an adverse outcome or early death.[69,70] Properly performed transesophageal echocardiography has demonstrated sensitivity and specificity exceeding 90% in the detection of proximal emboli involving the pulmonary trunk and the right and left main pulmonary arteries.[71] Echocardiography also may prove valuable in the evaluation of competing diagnostic possibilities such as right ventricular infarction, endocarditis, pericardial tamponade, and aortic dissection in patients with unexplained shock and evidence of elevated central venous pressure.

■ LOWER EXTREMITY EVALUATION

Duplex ultrasonography, which refers to the combination of Doppler venous flow detection and real-time B-mode imaging, has assumed a central role in the noninvasive diagnosis of symptomatic lower extremity DVT.[72] A number of criteria are used to diagnose DVT, the most reliable of which is noncompressibility of a venous segment. Secondary, less reliable criteria include the presence of echogenic material within the venous lumen, loss of phasicity with respiration, attenuated increase in venous diameter in response to Valsalva, and lack of augmentation of flow in response to calf compression. The absence of an echogenic luminal mass cannot be considered useful in excluding the diagnosis of venous thrombosis because acute thrombus may not demonstrate echogenicity. Multiple studies over the past decade have demonstrated sensitivities and specificities exceeding 95% in *symptomatic* patients with proximal DVT.

While duplex ultrasonography is highly sensitive and specific in the diagnosis of DVT in symptomatic patients, its accuracy in the diagnosis of asymptomatic DVT is less clear. A meta-analysis of studies comparing ultrasound to contrast venography in asymptomatic patients found that ultrasound was accurate for the detection of asymptomatic proximal DVT, but the data was limited almost entirely limited to postoperative orthopedics patients.[73] Approximately 30% to 40% of patients with PE will also have signs and/or symptoms of DVT and 60% to 80% will have evidence of proximal DVT when subject to duplex ultrasonography. However, given that the overwhelming majority of patients with suspected PE will not prove to have that diagnosis, duplex ultrasonography as the initial diagnostic study should be reserved for those patients with clinical evidence of DVT and for special populations in which avoidance of radiation or contrast material is preferred.[74–77]

The role of CT venography as a stand-alone test for DVT is limited. CT venography appears to be comparable to ultrasonography with respect to sensitivity and specificity, but it requires contrast injection with its associated risks and radiation exposure. A potential advantage of CT venography is the ability to visualize the pelvic veins and vena cava. The concept of combined CT-PA and venography is attractive. Such an approach would provide visualization of the embolus and its source in a single study as well as potentially increase diagnostic yield in comparison with the use of CT-PA alone.[78] However, the absolute increase in diagnostic yield appears to be modest and comes at the cost of increased expense, substantial pelvic radiation exposure, and the risk of hemorrhagic complications from providing anticoagulation to patients with false-positive studies.

■ MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) techniques for detecting DVT and PE have been investigated. The PIOPED III trial was the largest, multicenter study designed to assess magnetic resonance angiography (MRA) for the diagnosis of PE.[79] Three hundred and seventy-one patients were enrolled in whom PE was confirmed or excluded by CT-PA or V/Q. Approximately 25% of studies were technically inadequate and could not be interpreted. However, this seemed to vary by site (11%–52%) suggesting that some sites may have had more experience and were able to limit their number of inadequate scans. The sensitivity and specificity of MRA among patients with technically adequate scans was 78% and 99%, respectively. These figures fell considerably when the technically inadequate scans were included in the calculations. Sensitivity for PE involving the main or lobar pulmonary arteries was only 79%.

There are patients in whom CT-PA may not be possible due to IV contrast allergy or in whom avoidance of radiation is preferred (e.g., pregnancy). In these patients it seems that MRA may be a reasonable alternative. The risk of gadolinium-related nephrogenic systemic fibrosis has dampened the initial enthusiasm for MRI scanning in patients with renal insufficiency.[80]

■ COMPUTED TOMOGRAPHY

CT-PA has become the first-line imaging test for PE (Fig. 73-9). CT technology has evolved from single detector scanners to 64-multidetector-row CT (MDCT) scanners. Using the latest generation scanners, visualization of the entire chest with submillimeter resolution extending to the sixth generation arteries can now be performed within a single breath hold. The PIOPED II trial, which used predominantly 4-MDCT technology and a composite reference standard, demonstrated sensitivity for the diagnosis of PE of 83%, specificity of 96%, positive predictive value of 86%, and negative predictive value of 97% (Table 73-7).[46] The predictive value of CT-PA varied substantially when clinical assessment was taken into account, with the major variance occurring when there was discordance between the clinical assessment and CT-PA finding. Both the positive predictive value in patients with a low clinical probability and the negative predictive value in those with a high clinical probability were in the range of 60%.

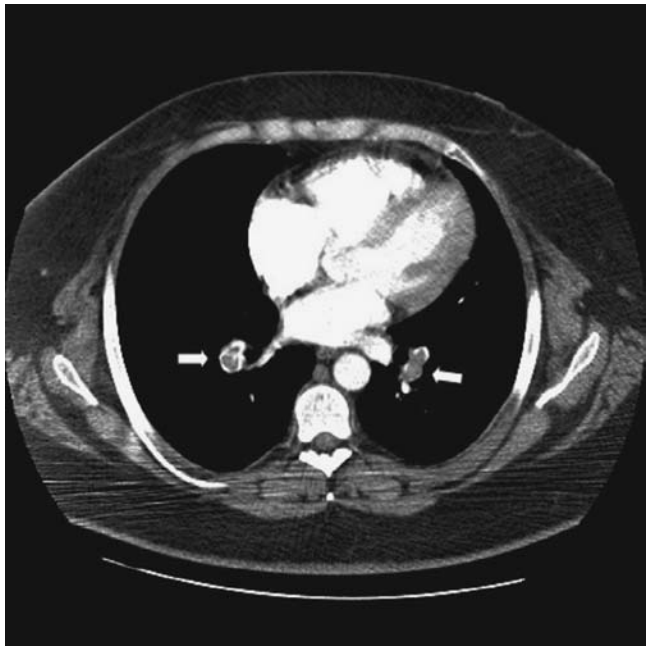

Figure 73-9 Computed tomographic angiogram demonstrating nearly occlusive thrombus in both lower lobe pulmonary arteries (*arrows*).

At the present time, CT can be considered confirmatory in excluding embolism in patients with a low or intermediate likelihood of disease and confirming embolism in patients with intermediate or high probability of disease. When discordance exists between the clinical assessment and CT findings, additional studies should be considered.

Concerns have been raised that the widespread utilization of CT-PA is resulting in the overdiagnosis of PE, defined as diagnosing clinically insignificant disease. The highest level of evidence thus far is a randomized controlled trial by Anderson et al.[81] of pulmonary CT-PA versus V/Q scan for suspected PE that showed comparable mortality and false-negative rates for the two imaging modalities with a 51% higher rate of PE diagnosis for CT. It has been suggested, based on the known natural history of subsegmental embolism, that patients with isolated subsegmental PE do not necessarily need to be treated with anticoagulants provided they meet the following criteria: (1) good cardiopulmonary reserve; (2) no evidence of DVT with serial lower extremity studies; (3) a transient (reversible) major risk factor for PE that is no longer present; (4) no history of central venous catheterization and no history of atrial fibrillation; and (5) a compliant and trustworthy patient who would return for serial noninvasive lower extremity studies.[82] Concerns have also been raised that CT-PA, as a result of its easy availability, is being overutilized in outpatients without adequate patient screening through validated methods such as the Wells criteria/D-dimer model or the PERC.[55,83]

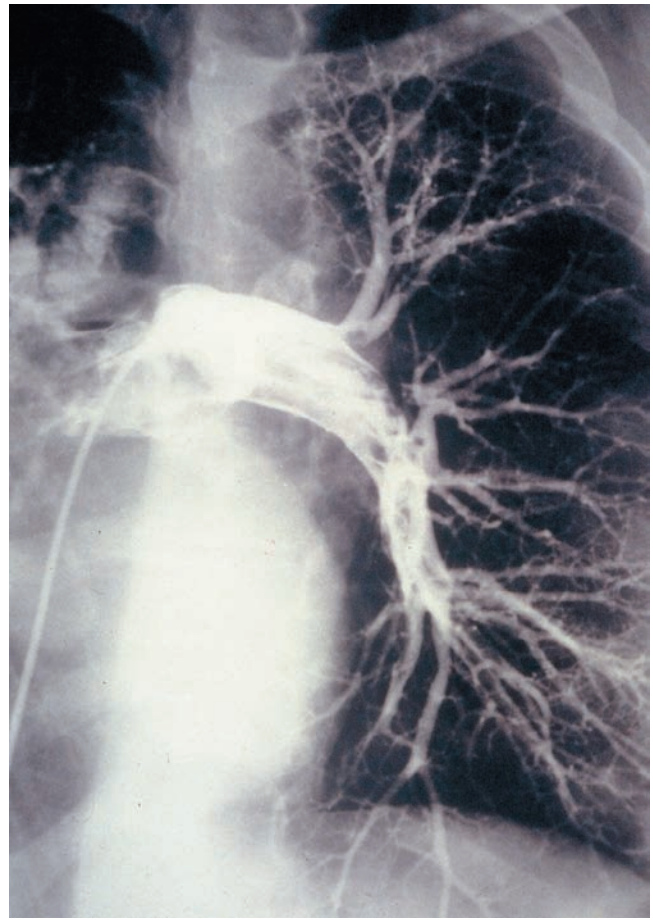

Figure 73-10 Conventional contrast pulmonary angiogram demonstrating extensive embolus within the left main pulmonary artery and extending into lobar branches.

■ CONVENTIONAL PULMONARY ANGIOGRAPHY

Prior to widespread acceptance of CT-PA, pulmonary angiography was considered the accepted "gold standard" for PE diagnosis although it had a number of limitations (Fig. 73-10). It requires expertise in study performance and interpretation. It is invasive and

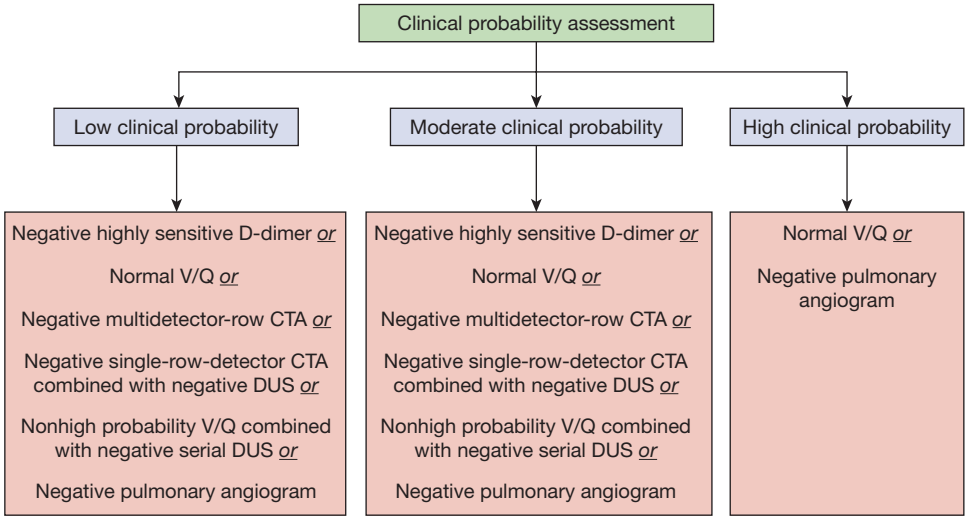

Figure 73-11 Current diagnostic strategies capable of excluding diagnosis of pulmonary embolism.

has associated risks, although published studies suggest that the use of modern techniques and contrast materials has reduced the risk well below its lingering perception. Pulmonary angiography can be performed quite safely if certain safeguards are observed and experienced personnel are involved. In the 1111 angiograms performed in the original PIOPED trial, pulmonary angiography was nondiagnostic in 3% of patients and associated with a major complication rate of 1% and death rate of 0.5%.[84] Major complications occurred more frequently among patients sent for angiography from the medical intensive care unit than in patients from elsewhere (4% vs. 1%). The procedure has other limitations. One is accessibility and the need for transportation. The other limitation is interpretation. Interpretation of pulmonary angiograms is heavily influenced by three factors: the location of the thromboembolic obstruction, the quality of the images, and the experience of the interpreters. Only two angiographic findings are diagnostic of acute embolism: a filling defect and abrupt cutoff of a vessel. Technical adequacy of the angiogram is critical to accurate identification of both. Flow artifacts can falsely suggest a filling defect. It is essential that good vessel opacification be obtained and that the filling defects be identified as real on a sequence of films.

Angiography is reserved for the small subset of patients in whom the diagnosis of PE cannot be established or excluded by less invasive means and for the evaluation of suspected chronic thromboembolic disease.

DIAGNOSTIC APPROACH

The diagnostic approach to PE should be targeted toward the patient population being studied (Figs. 73-11 and 73-12). For outpatients, the use of a clinical prediction rule coupled with D-dimer testing or the use of the PERC criteria can substantially reduce the number of imaging studies performed. In the outpatient setting, D-dimer results would not alter the need for an objective imaging study in patients with a high probability of PE. In patients with a low or intermediate clinical likelihood of PE, a negative D-dimer study is sufficient to exclude the diagnosis, assuming a highly sensitive assay is used. An imaging study should be performed in all patients with a high probability of disease as well as those with a low or intermediate probability whose D-dimer tests are positive.

Patients with signs or symptoms of lower extremity DVT should initially undergo lower extremity duplex ultrasonography. A positive lower extremity study, although not proving PE has occurred, has the same therapeutic implications. Although such an approach will yield a confirmatory study in only about 20% of patients suspected of having PE, it avoids the cost and radiation exposure associated with CT-PA. A negative study is insufficient to exclude the possibility of PE.[77]

In patients without lower extremity symptoms or signs who have a high or intermediate clinical probability of PE, a positive CT-PA confirms the diagnosis. In patients with a low or intermediate clinical probability, a negative CT-PA excludes the diagnosis. The only patients who may require additional testing (duplex ultrasonography and/or conventional angiography) are those in whom the clinical assessment and CT findings are discordant (low clinical probability and positive CT scan or high clinical probability and negative CT scan) unless the CT scan is of adequate quality and demonstrates evidence of PE in the main or lobar arteries in a patient with a low clinical probability assessment.

An approach utilizing V/Q scanning as the primary imaging tool can be used in settings such as pregnancy, contrast allergy,

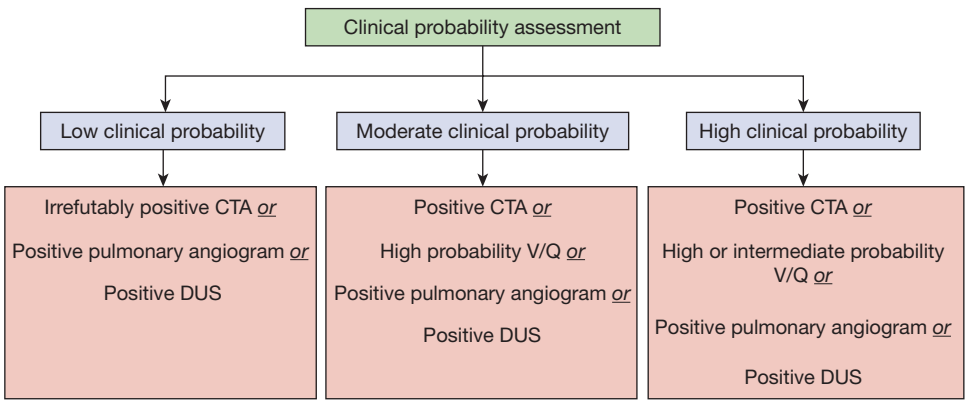

Figure 73-12 Current diagnostic strategies capable of confirming diagnosis of pulmonary embolism.

or renal insufficiency. This approach should be reserved for those with normal chest radiographs and no history of chronic pulmonary disease. Lower extremity evaluation should be considered before chest imaging given the likelihood that the V/Q scan will not be diagnostic. A negative V/Q scan is capable of excluding the diagnosis regardless of the clinical assessment as does a low probability scan in conjunction with a low clinical suspicion. A high probability scan is capable of confirming the diagnosis in patients with a high clinical suspicion. All other circumstances (high clinical probability with low or intermediate V/Q result, intermediate clinical probability regardless of V/Q result, and low clinical probability with a high or intermediate V/Q scan result) require additional testing.[44]

Whatever approach is undertaken, the treating physician should be aware of the type of D-dimer assay, discriminant value of that particular assay, and generation of CT scanner used. "Negative" findings on a low-sensitivity D-dimer assay or a single-row CT scanner have very different implications than similar findings using a highly sensitive D-dimer assay or 64-MDCT scanner.

The role of D-dimer testing and clinical assessment in hospitalized patients is limited. A substantial proportion of hospitalized patients have a positive highly sensitive D-dimer result related to an active inflammatory process, malignancy, recent surgery, liver disease, and even advancing age.[85] In a recent study that evaluated the use of the Wells prediction rule in conjunction with a latex agglutination or rapid ELISA D-dimer assay in hospitalized patients, only 10% of over 600 patients tested fell into the low probability category.[85] Furthermore, comorbid conditions affect the clinical likelihood assessment. Therefore, a far higher proportion of hospitalized patients require an imaging study to confirm or exclude the diagnosis of venous thromboembolism. In patients with limited cardiopulmonary reserve, high clinical probability assessment, and negative CT scan, pulmonary angiography should be considered given the potentially fatal consequences of a recurrent embolic event. In patients with adequate cardiopulmonary reserve under the same circumstances, a strategy incorporating sequential lower extremity evaluation can be undertaken.

TREATMENT

Management of acute PE consists of a systematic approach that involves early intervention, patient risk stratification, selection of therapy, and determination of treatment duration. The goals of therapy in PE are severalfold—to assure adequate oxygenation, provide hemodynamic support, and prevent thrombus propagation and embolic recurrence.

When a diagnosis of venous thromboembolism is suspected, empiric treatment should be considered until the diagnosis is either objectively excluded or confirmed. Given the ready availability of rapid D-dimer assays and CT, diagnostic confirmation or exclusion should require a relatively short period of time. Early empiric treatment should be initiated if diagnostic tests are not readily available. An exception can be made in those patients with a low clinical likelihood of disease, adequate cardiopulmonary reserve, and a high risk of bleeding complications.

The availability of low–molecular-weight heparin (LMWH) potentially allows carefully selected patients to be managed in the outpatient setting as demonstrated in the recently published study.[86] Although there are good data to support treating uncomplicated cases of DVT entirely in the outpatient setting, most physicians still advocate a short period of hospitalization in patients with newly diagnosed acute PE. Hospitalization should be mandatory for older patients who may have less cardiopulmonary reserve, or significant coexisting illnesses, or those who may not be able to follow instructions or have adequate follow-up. Other indications for hospitalization include hypoxemia, hypotension, hemodynamic instability, or sufficient renal disease to contraindicate the use of LMWH or a factor Xa inhibitor.

HEPARIN

Anticoagulation with heparin remains the standard initial therapy. The major anticoagulant effect of heparin is to reduce thrombus propagation and prevent embolic recurrence. Choices include either intravenous unfractionated heparin (UFH) or subcutaneous LMWH preparations. Given that failure to achieve rapid therapeutic levels of anticoagulation appears to be associated with an increased recurrence rate, it is reasonable to attempt to ensure adequate anticoagulation as soon as possible.[87]

Physician practices in the administration of intravenous unfractionated heparin have often resulted in substantial delays before adequate prolongation of the activated partial thromboplastin time (aPTT) is achieved. To overcome these problems, standardized protocols for unfractionated heparin administration and monitoring have been recommended. One commonly employed dosing regimen using an initial intravenous bolus of 80 units of heparin per kilogram followed by a continuous infusion initiated at 18 U/kg/h has been demonstrated to reach therapeutic thresholds more quickly than regimens using fixed dosing.[88] The heparin drip is adjusted based on monitoring of the aPTT, drawn 6 hours after the initial bolus dose, then 6 hours after each dose adjustment, with a target aPTT ratio of 1.5 to 2.5. Because attempts to straddle the lower therapeutic range may result in periods of inadequate anticoagulation, it is prudent to maintain the ratio in the upper range of the recommended target.

More recently, an approach using a fixed dose of subcutaneous unfractionated heparin without aPTT monitoring, administered as an initial dose of 333 U/kg followed by a dose of 250 U/kg every 12 hours, has been demonstrated to be as safe and effective as LMWH in patients presenting with DVT and PE.[89]

With the exception of special circumstances, LMWH preparations have displaced unfractionated heparin as the anticoagulant of choice in uncomplicated venous thromboembolism including PE.[90] Situations in which the use of UFH is appropriate include renal insufficiency, extremes of body weight, and circumstances in which a rapid adjustment or reversal of anticoagulation is needed, such as women in the late stage of pregnancy who may need Cesarean sections, patients with recent surgery or recent history of bleeding, and hemodynamically unstable patients with venous thromboembolism who may need surgical procedures such as emergency embolectomy.

Available evidence suggests that LMWH is at least as effective as unfractionated heparin in treating acute PE.[91] Advantages of LMWH compared with UFH include (1) longer half-life and ease of use; (2) ability to consistently achieve early therapeutic anticoagulation; (3) no need to monitor anticoagulant effects; and (4) reduced incidence of major bleeding complications. There are few data comparing different LMWH preparations. Even though there are differences in their Food and Drug Administration (FDA)-approved indications in the United States, it is not clear if their actions differ significantly.

In general, therapeutic monitoring is not needed with LMWH, but there are situations where the therapeutic effects may be less predictable and monitoring with anti-Xa levels is indicated. Typical examples include (1) patients with antiphospholipid antibodies or other circulating anticoagulants who have elevated baseline aPTT; (2) extremes of body weight (less than 40 kg and greater than 150 kg); (3) significant renal disease (creatinine clearance less than 30 mL/min); (4) pregnancy; and (5) unexplained bleeding or recurrent thrombosis during therapy. A therapeutic target range for peak anti-Xa levels ranges from 0.6 to 1.0 IU/mL, 4 hours after administration. The target range for peak anti-Xa levels with once daily enoxaparin is likely to be greater than1.0 IU/mL whereas it is greater than 0.85 IU/mL with tinzaparin and 1.3 IU/mL and 1.05 IU/mL with nadroparin and dalteparin, respectively.[92]

FACTOR XA INHIBITORS

Fondaparinux, a synthetic pentasaccharide, represented the first in a new class of antithrombotic agents. Unlike unfractionated heparin and LMWH, the antithrombotic properties of fondaparinux are selective for factor Xa. By binding rapidly and strongly to antithrombin, fondaparinux catalyzes specifically the inhibition of factor Xa, which results in inhibition of thrombin generation. It does not bind to other plasma components or platelets, has a half-life of approximately 17 hours, and is excreted almost completely by the kidneys. Fondaparinux was shown to be as effective and safe as intravenous unfractionated heparin in a large, open-label study.[93] It has been approved for prophylaxis in patients undergoing hip, knee, and abdominal surgery as well as for treatment of DVT and PE in conjunction with warfarin.

Rivaroxaban represents the first in a new generation of oral factor Xa inhibitors. In a large, open-label randomized study, rivaroxaban proved noninferior to conventional therapy (LMWH followed by a vitamin K antagonist) in patients with symptomatic DVT.[94] Patients with acute PE were excluded from the acute phase of the study. Although not specifically designed to determine efficacy in acute PE, the incidence of subsequent PE was equivalent between the two study groups. In a subsequent study involving 4832 patients, a fixed-dose regimen of rivaroxaban alone was noninferior to standard therapy for the initial and long-term treatment of PE with or without DVT.[95] Ongoing trials are underway evaluating the efficacy and safety of other oral factor Xa inhibitors, including apixaban and edoxaban in venous thromboembolism.[96]

Intravenously administered direct thrombin inhibitors (lepirudin, argatroban) represent another class of anticoagulant agents that have been approved for the management of patients with venous thromboembolism in the setting of heparin-induced thrombocytopenia (HIT).[97] Their mechanism of action differs from that of heparin and the synthetic pentasaccharides in that they directly inhibit the active site of thrombin and do not require interaction with antithrombin to produce an anticoagulant effect. Argatroban is a synthetic agent derived from arginine. It has a half-life of approximately 45 minutes and is cleared by the liver. Lepirudin is a recombinant polypeptide similar to hirudin. It has a half-life of 40 to 60 minutes and is cleared by the kidneys. Both agents are administered by continuous intravenous infusion and dose adjustments made with monitoring of the aPTT. Both agents affect the international normalized ratio (INR), thereby complicating the transition to oral warfarin therapy. Although demonstrating promise, data supporting the use of fondaparinux in the management of HIT is far less robust than that of the intravenous direct thrombin inhibitors.[98] Based on its size, the drug is less immunogenic than unfractionated heparin or LMWH. Fondaparinux has not been approved by the FDA for this indication.

THROMBOLYTIC THERAPY

Unlike anticoagulants, thrombolytic drugs cause direct lysis of thrombi by increasing plasmin production through plasminogen activation. The potential benefits, however, are often offset by the relatively high incidence of hemorrhagic complications.

Multiple thrombolytic agents are available. Those most studied for the management of acute PE include streptokinase, alteplase (rt-PA), and urokinase, all of which are FDA approved for use in the United States. The PEITHO (pulmonary embolism thrombolysis) trial, a large multicenter study designed to enroll 1000 patients, is currently underway and will evaluate the efficacy and safety of tenecteplase in normotensive patients with evidence of right ventricular (RV) dysfunction.[99]

The exact role of thrombolytic agents in acute PE remains controversial. While thrombolytic therapy does appear to accelerate the rate of thrombolysis, there is no convincing evidence to suggest that it decreases mortality, increases the ultimate extent of embolic resolution when measured at 7 days, reduces thromboembolic recurrence rates, improves symptomatic outcome, or decreases the incidence of thromboembolic pulmonary hypertension.[100] The one issue about which there can be little controversy is that the use of thrombolytic agents is associated with a substantially increased risk of bleeding, including intracranial hemorrhage. Intracranial hemorrhage has occurred in 0.5% to 3.0% of patients treated with thrombolytic agents in trials evaluating the use of these agents in both PE and myocardial infarction.[101]

Based on these data, and assuming there is no contraindication to its use, the use of thrombolytic therapy in PE appears to be appropriate when an accelerated rate of thrombolysis may be considered lifesaving. Specifically, this applies to patients with PE who present with hemodynamic compromise (in whom the mortality rate approaches 30%), patients who develop hemodynamic compromise during conventional therapy with heparin, and patients with PE associated with intracavitary right heart thrombi.[36]

The role of thrombolytic therapy in patients with anatomically massive embolism or echocardiographic evidence of right ventricular dysfunction in the absence of systemic hypotension is less well defined. Risk stratification strategies using echocardiography, troponin levels, or brain natriuretic peptide (BNP) levels are currently under investigation and may help resolve this area of controversy.[102] At the present time, the finding of right ventricular dysfunction on echocardiography in the absence of hemodynamic instability would not appear to serve as a justification for the routine use of thrombolytic therapy. Approximately 40% to 50% of patients with symptomatic PE have echocardiographic evidence of right ventricular dysfunction.[103] Clinical scoring systems have also been constructed capable of estimating 30-day mortality rates in patients with acute PE (Table 73-8).[104,105] However, these scoring systems appear best suited in identifying patients with a low mortality risk who may be suitable for home management rather than those with a sufficiently high mortality risk to justify the use of thrombolytic therapy.

Normotensive patients with evidence of right ventricular dysfunction, as determined by echocardiography or an elevated BNP or troponin level, appear to be at risk for an adverse outcome when

compared with patients without right ventricular dysfunction. However, until criteria have been established that more clearly define that subset of patients who will benefit from thrombolytic therapy, there is little basis for exposing all such patients to the considerable risk of hemorrhagic complications associated with this intervention. It is hoped that the ongoing PEITHO trial will help resolve this uncertainty.[99]

Because of the side effects and the prolonged period of infusion required, many physicians are reluctant to use thrombolytics in cases of DVT, whether delivered systemically or by local catheter-directed infusion. In selected patients with symptomatic iliofemoral thrombosis, catheter-directed thrombolysis either alone or combined with angioplasty or stent placement may result in increased venous patency and may improve quality of life.[106]

INTERVENTIONAL RADIOLOGIC TECHNIQUES

Interventional thrombus fragmentation represents a potential alternative to systemic thrombolysis or surgical embolectomy for treatment of PE.[107] If the bleeding risk is not exceedingly high, catheter fragmentation may be combined with local or systemic thrombolysis. A wide variety of devices designed to either fragment and/or remove fresh embolic material have been tested in patients with PE.[108] In general, the devices use either pressured saline or a rotating impeller to fragment central thrombi. The fragments are either aspirated through a separate port on the catheter or allowed to migrate distally. Most of the devices appear to be effective, safe, and potentially lifesaving in the presence of central, acute clots. However, none of the devices has been investigated in a large controlled trial, and all commercially available devices have important limitation. These limitations include a risk of paradoxical embolism from the clot fragments. Therefore, the intervention is contraindicated in patients who have an intracardiac communication, such as a patent foramen ovale.

PULMONARY EMBOLECTOMY

Embolectomy has been used for the emergency removal of PE. Small observational studies comparing surgical embolectomy and thrombolytics did not show significant advantage using embolectomy, although there was a trend toward better survival and lower bleeding rates in the surgical group. In a recent review of 3770 patients undergoing surgical embolectomy for acute PE between 1999 and 2008, all-cause inhospital case fatality rate was 28%; mortality was 24% in patients considered stable and 40% in those unstable.[109] Based on current data, it is reasonable to consider surgical embolectomy in patients with persistent hypotension, shock, or cardiac arrest who either failed thrombolysis or have a contraindication to thrombolytic management.

LONG-TERM MANAGEMENT

Long-term management includes use of traditional anticoagulants, including warfarin and heparin, as well as a variety of new pharmacologic agents. In addition, insertion of devices in the inferior vena cava to prevent additional embolic events has been employed.

WARFARIN

Recurrence is common following an acute thromboembolic event. Therefore, treatment should be continued until the benefits of ongoing therapy no longer outweigh the potential risks.

Oral anticoagulation using warfarin, a vitamin K antagonist, is generally used for long-term treatment of venous thromboembolism because of its proven efficacy. Warfarin inhibits gamma carboxylation activation of coagulation factors II, VII, IX, and X as well as proteins C and S. With proper monitoring, less than 3% of patients using warfarin develop significant bleeding. The drug is usually started soon after the initiation of heparin therapy. Use of warfarin without heparin is strongly discouraged as it generally takes 3 to 5 days of warfarin to achieve full therapeutic efficacy. In patients with protein C deficiency, skin necrosis or paradoxical thrombosis may occur in the absence of concurrent heparin therapy.

Warfarin has a narrow therapeutic index and patients are generally monitored closely by measuring the prothrombin time corrected to the reagent being used (the INR). To maximize efficacy while minimizing side effects, an INR range between 2 and 3 is recommended for most patients. Even in the setting of an antiphospholipid antibody, high-intensity warfarin therapy does not appear superior to standard treatment but is associated with an increased incidence of minor bleeding complications.[110,111] Besides bleeding complications, warfarin has been associated with fetal abnormalities particularly when given during the 6th to 12th weeks of gestation. Another rare complication of warfarin use is cholesterol microembolism ("purple toes" syndrome), which is thought to be due to cholesterol crystal release from ulcerated intravascular plaques.[112]

Individuals metabolize warfarin differently and age, genetic variations in CYP2C9 alleles, nutritional factors, and concomitant medications can affect anticoagulant levels significantly. Multiple mechanisms of drug interaction are possible including alterations of absorption (cholestyramine), induction of hepatic CYP450 (barbiturates, carbamazepine), inhibition of CYP3A4 (amiodarone), inhibition of CYP2C9 (metronidazole, clotrimazole), and displacement of protein-bound warfarin (phenytoin).[113]

Suggested dosing regimens involve an initial daily dose of 5 or 10 mg with use of a standardized nomogram to dose adjust based on INR values obtained on days 3 and 5.[114] Beginning with a 10-mg dose appears to hasten the achievement of a therapeutic INR without an increase in bleeding complications.[115,116] Elderly, malnourished, and debilitated patients tend to require less warfarin and the initial dose should be lowered accordingly. Some medical conditions, such as concomitant liver or kidney failure, alcoholism, malignancy, and recent history of gastrointestinal bleeding or trauma, are additional factors that may predict dose titration difficulties and higher risk of bleeding.

To minimize potential subtherapeutic anticoagulation, it is generally recommended that patients should receive at least 5 days of combined heparin and warfarin therapy, including at least 2 days in which the INR is in a therapeutic range before stopping heparin. The safety and effectiveness of both short- and long-term anticoagulation can be optimized by a systematic, evidence-based approach to therapy, often in the context of dedicated anticoagulation management services.[117] In carefully selected patients, self-management of warfarin therapy using INR measurement with "point of care" devices may also be done.[118]

HEPARIN

There are occasional instances in which heparin should be considered for long-term anticoagulation despite the cost and inconvenience associated with subcutaneous administration. Because of the teratogenic potential of warfarin, unfractionated heparin or LMWH should be used in pregnant women who developed venous thromboembolism in the first and possibly early second trimesters. Since the risk of venous thromboembolism may be highest in the postpartum period, anticoagulation should be continued for at least 3 to 6 months, including a minimum of 4 to 6 weeks after delivery. Patients with cancer complicated by thromboembolism appear to have fewer recurrent thromboembolic events and bleeding complications when treated with LMWH compared with warfarin.[119] Whether this is a specific effect of LMWH or simply a reflection of fluctuating INR levels in patients with cancer treated with warfarin is uncertain. LMWH therapy is now recommended over warfarin as

a first-line treatment to reduce the risk of recurrent venous thromboembolism in patients with active cancer.[120]

NOVEL AGENTS

Novel agents have been used successfully for long-term management of patients with venous thromboembolism. As noted previously, rivaroxaban alone was noninferior to standard therapy for the initial and long-term treatment of PE with or without DVT.[95] Dabigatran, an oral direct inhibitor of thrombin, has also proven effective for long-term management. In the RE-COVER trial involving 2539 patients with acute venous thromboembolism, 786 of whom had PE, dabigatran administered at a dose of 150 mg twice daily after initial treatment with heparin was as effective as warfarin therapy in preventing thromboembolic recurrence while significantly reducing nonmajor bleeding.[121] In the AMPLIFY-EXT (apixaban after the initial management of PE and deep vein thrombosis with first-line therapy-extended treatment) trial, apixaban reduced the risk of recurrent venous thromboembolism without increasing the rate of major bleeding in patients with venous thromboembolism who had completed 6 to 12 months of anticoagulation therapy and for whom there was clinical equipoise regarding the continuation or cessation of anticoagulation therapy.[122]

The role of aspirin in the long-term management of patients with venous thromboembolism remains incompletely defined. In the WARFASA (the warfarin and aspirin study) trial, the use of aspirin reduced the risk of thromboembolic recurrence by 40% when given to patients with unprovoked venous thromboembolism following discontinuation of anticoagulant therapy.[123] In the ASPIRE (aspirin to prevent recurrent venous thromboembolism) trial, however, aspirin, as compared with placebo, did not significantly reduce the rate of recurrence of venous thromboembolism but resulted in a significant reduction in the rate of major vascular events, with improved net clinical benefit.[124]

DURATION OF THERAPY

Over the past decade, data have emerged that have significantly changed our recommendation regarding duration of anticoagulation after venous thromboembolism. Central to this change has been awareness that venous thromboembolism often represents a recurrent disease and that the risk for recurrence is based on the initiating factors, persistence or resolution of those factors, and anatomic consequences of the initial event.

Patients with venous thromboembolism associated with a transient risk factor appear to be at a low risk of recurrence. Patients who experience postoperative venous thromboembolism appear to be at lowest risk. However, the annualized risk of recurrent disease is still in the region of 3%.[125] A 3-month course of anticoagulation appears to be adequate in this group (assuming the risk factor has resolved). Patients with idiopathic (unprovoked) thromboembolism have a substantially higher rate of recurrence, corresponding to an annualized event rate of 7.9% per patient-year.[125] In these patients, anticoagulation may simply delay subsequent recurrent thromboembolic events and ongoing risk factors may be present that have yet to be identified. Therefore, it is recommended that strong consideration be given to extended therapy in those with a low risk of bleeding complications.[126] Determining which patients remain at increased risk of thromboembolic recurrence is the target of ongoing investigative efforts. A number of clinical and serologic factors have been identified that predict a higher likelihood of recurrent venous thromboembolism following an initial course of therapy. These include PE as the initial presenting manifestation, age greater than 65, male gender, evidence of residual lower extremity DVT by ultrasonography, and elevated D-dimer levels measured at the end of warfarin therapy and then 1 month after its discontinuation.[127] How these factors should influence decisions about duration of anticoagulation in an individual patient remains to be determined.

In patients with venous thromboembolism associated with an irreversible risk factor, the absolute recurrence risk depends on the underlying disease or condition.[128,129] Patients heterozygous for the factor V Leiden mutation or the prothrombin G20210A mutation, although at higher recurrence risk than those without the mutation, do not appear to warrant prolonged anticoagulation while those homozygous for either of these mutations, or with a combined thrombophilia (i.e., heterozygous factor V Leiden combined with heterozygous prothrombin mutation), do. Patients with antiphospholipid antibody syndrome, those with active cancer, and those with deficiencies of protein S, protein C and antithrombin III are at considerable risk for thromboembolic recurrence and consideration should be given to lifelong therapy. In patients with two or more episodes of recurrent venous thromboembolism, the current recommendation is to consider lifelong anticoagulation with interval reassessment of the risk–benefit ratio. In summary, long-term anticoagulation should be individualized based on the risk for recurrent thromboembolism and bleeding. This is especially true in patients with cancer in whom the recurrent thrombosis risk and bleeding risk are substantially increased.[130] The appropriateness of ongoing therapy should be continuously re-evaluated, and the prophylaxis stopped if the benefit no longer appears to exceed the risk.

VENA CAVA INTERRUPTION AND VENA CAVA FILTER

The concept of vena cava interruption came from the historical practice of surgical ligation (by complete vascular ligation or partial interruption using surgical suture) of the IVC in an attempt to prevent thrombus migration. A variety of vena cava filters are now available, both permanent and temporary, and surgical ligation is rarely performed in the modern era.

The central indication for IVC filter placement is to prevent PE in patients who have a contraindication to anticoagulation. Recent data suggests that the utilization of IVC filters has dramatically expanded over the past decade and that IVC filters are being placed for alternative reasons, including prophylaxis.[131] Much of this expansion in utilization can be attributed to the development of retrievable IVC filters, which in many instances are not removed.[132] Guidelines for filter placement, albeit based on limited data, have been established by the American College of Chest Physicians and the Society of Interventional Radiologists.[133,134] These recommendations are somewhat disparate with the recommendations of the latter society being considerably more liberal than those of the former.

Despite the obvious theoretical benefit, carefully controlled trials that demonstrate the ability of IVC filters to decrease recurrence rates or mortality from PE have not been performed.[135] In one of the largest trials to date examining the effectiveness of IVC filters, 400 patients with proximal DVT were randomly assigned to either standard anticoagulation alone or anticoagulation plus insertion of a Vena Tech, Greenfield, Bird's Nest, or Cardial IVC filter.[136] During the first 12 days after randomization, significantly fewer patients in the IVC filter group suffered PE (1% vs. 5%). However, after a 2-year follow-up period, there were no significant differences in survival or symptomatic PE between the two groups, and a significantly higher rate of recurrent DVT was observed among patients who had received an IVC filter (21% vs. 12%).[137]

Given that IVC filters may decrease the incidence of early, recurrent PE, an argument can be made for their use in patients with residual lower extremity DVT who have suffered hemodynamically massive PE or who have poor cardiopulmonary reserve. Data on the effectiveness of IVC filters purely for prophylactic reasons are limited and randomized controlled trials are warranted to provide better practice-based evidence for or against this indication. Placement of an IVC filter is not a benign procedure and carries several possible

risks including potential DVT formation, filter migration, filter tilt, filter thrombosis, and the possibility of a higher incidence of lower extremity thrombotic events and postthrombotic syndrome.[138,139]

CHRONIC THROMBOEMBOLISM

Anatomic resolution of PE is rarely complete.[39,140] However, resolution in most patients is adequate to permit normalization of pulmonary hemodynamics and exercise tolerance. In some cases, however, the residual thromboembolic burden is sufficiently extensive to cause CTEPH. Estimates of the incidence of CTEPH range from 0.5% to 3.8% following an initial episode of PE to 13.4% following recurrent episodes of venous thromboembolism.[141–143] Approximately 30% of patients who develop CTEPH have no documented history of acute DVT or PE, and this feature greatly impedes the diagnosis. Anticardiolipin antibodies or lupus anticoagulants have been detected in approximately 10% to 20% of patients and elevated factor VIII levels detected in 40%.[144,145] No other defined thrombophilic or fibrinolytic abnormality has been encountered in this population. Age greater than 70, systolic pulmonary artery pressure greater than 50 mm Hg at the time of diagnosis of acute PE or at the time of hospital discharge following acute PE, previous PE, prior splenectomy, ventriculoatrial shunts, the presence of antiphospholipid antibodies, and a larger degree of pulmonary vascular obstruction at the time of acute PE have been identified as risk factors for CTEPH.[146]

The mortality of untreated CTEPH is high, with a 5-year survival of only about 10% in those who have a mean pulmonary artery pressure exceeding 50 mm Hg.[147,148] The treatment of choice for CTEPH is pulmonary thromboendarterectomy, which involves the dissection of endothelialized thrombi under cardiopulmonary bypass and deep hypothermia.[149] For the majority of patients, successful pulmonary thromboendarterectomy is considered curative. However, the hemodynamic outcome is incomplete in approximately 20% of patients. These patients have been successfully treated with medical therapies that are used in patients with idiopathic pulmonary arterial hypertension.[150] Indications for medical therapy in CTEPH include: (1) surgically accessible CTEPH in patients who elect not to undergo surgery for personal choice or where comorbidities are so substantial as to exclude the patient from consideration of thromboendarterectomy; (2) distal chronic thromboembolic disease or limited central disease that is so disproportionate to the severity of the pulmonary hypertension that the surgical mortality risk is prohibitive; (3) use as a preoperative therapeutic "bridge" to surgery in patients with severe right ventricular dysfunction; and (4) management of persistent pulmonary hypertension following pulmonary thromboendarterectomy. Patients with inoperable CTEPH or persistent pulmonary hypertension despite thromboendarterectomy may be considered for lung transplantation.

PROPHYLAXIS

The use of prophylactic strategies in hospitalized patients represents a major opportunity to prevent the morbidity and mortality associated with venous thromboembolism. Current data suggests, however that thrombosis prophylaxis is underutilized in patients at risk, especially medical patients whose risk approximates that of their moderate-risk surgical counterparts.[10,151,152]

Patients should be stratified according to DVT risk, and certain prophylactic measures are more appropriate for some patients than for others. The intensity of a prophylactic regimen should take into account the relative risk for thrombosis. Initial assessment should focus on the following questions: (1) What is the risk of venous thromboembolism in this patient? (2) What type(s) and intensity of prophylaxis should be used? (3) When is the best time to use prophylaxis? A patient's thrombotic risk may change over time and periodic assessment of the best prophylactic strategy should also be done. Most hospitalized patients are at risk of venous thromboembolism and should receive some form of prophylaxis unless its use is contraindicated. Prophylaxis may not be necessary in rare instances, as in the case of a young (less than 40 years) ambulatory patient who is admitted for a short (less than 48–72 hours) hospital stay without a history of prior venous thromboembolism history or recent surgery.

Four categories of drugs have been used successfully: unfractionated heparin, LMWH (enoxaparin, dalteparin), factor Xa inhibitors (fondaparinux, rivaroxaban), and the vitamin K antagonist warfarin. With the exception of warfarin, prophylactic dosing is subtherapeutic but sufficient to decrease the likelihood of thrombus formation. Recommended, evidence-based prophylactic strategies for a wide range of clinical circumstances in medical, surgical, and orthopedic patients have been published by the American College of Chest Physicians.[153–155]

When administered correctly in appropriate patients, prophylactic anticoagulation is safe and effective with an absolute reduction in the incidence of venous thromboembolism in the range of 40% to 60%. Major bleeding complications occur in less than 1% of patients.

Prevention of venous thromboembolism may also be achieved by the use of mechanical devices. These devices fall into two categories, graduated compression stockings and intermittent pneumatic compression stockings. Although studied less rigorously than pharmacologic methods of prophylaxis, the use of pneumatic compression has been shown in selected patients to be as effective as subcutaneous unfractionated heparin in preventing thrombosis. Mechanical methods of prophylaxis are especially useful in patients at bleeding risk and as an adjunct to pharmacologic methods in patients at high risk of thrombosis.[156]

Whatever form of prophylaxis is used, its intensity should be based on a patient's thrombotic risk determined by both individual and clinical circumstances. Prophylaxis adequate for a 41-year-old patient undergoing an elective appendectomy would be inadequate for a 70-year-old patient with cancer undergoing hip replacement surgery. Risk scores have been developed in an attempt to objectively and quantitatively describe the relative risk of venous thromboembolism in hospitalized patients and to help define the intensity of the prophylactic regimen.[157] The introduction of electronic medical records provides the opportunity to identify patients at risk, to alert the physician, and to develop decision-support, evidence-based recommendations for prophylaxis.

Thromboembolic risk does not necessarily end at the time of hospital discharge. The trend toward early hospital discharge has only served to transfer risk to the outpatient setting. Whether on an inpatient or outpatient basis, prophylaxis should continue until the thrombotic risk has resolved.[158]

The potential for bleeding complications associated with prophylaxis is a common dilemma in surgical or trauma patients, for whom bleeding may occur from the surgical site, especially in the immediate postoperative period. On the other hand, effective prophylaxis depends on timely administration of therapy before a thrombus develops. Recommendations can be drawn from multiple studies with regard to the appropriate timing for anticoagulation in different surgical settings. In cases in which anticoagulation may be delayed, it is customary to use either graduated compression stockings or pneumatic compression devices before surgery begins or as soon as surgery has been completed. Although evidence-based data are lacking, it may be reasonable to consider placement of a retrievable IVC filter in high-risk patients in whom pharmacologic prophylaxis is absolutely contraindicated.

OTHER VARIETIES OF EMBOLIC DISEASE

Because the lung receives all of the blood flow returned from the venous system, the pulmonary vascular bed serves as a "sieve" for all particulate substances entering the venous blood and is the first

vascular bed to be exposed to any toxic substance injected intravenously. As a result of its strategic position, the pulmonary vascular bed is, therefore, exposed to a wide variety of potentially obstructing and injurious agents.

VENOUS AIR EMBOLISM

An increasingly common form of nonthrombotic embolism in the United States is venous air embolism. The increasing frequency of the problem reflects the wide variety of invasive surgical and medical procedures now available, the broad use of indwelling central venous catheters, the use of positive pressure ventilation with high levels of positive end-expiratory pressure, and the frequency of thoracic and other forms of trauma. The simple inadvertent transection or loss of closure of a large-bore intravenous catheter, particularly in the jugular or subclavian vein, can result in ingress of substantial quantities of air. Air bubbles enter the pulmonary vascular bed and, from there, can enter the arterial system and are diffusely distributed throughout the body by way of either an intracardiac shunt (atrial septal defect, patent foramen ovale) or, more likely, through microvascular pulmonary shunts.

Physiologic consequences are related to the volume of air entrainment and rate of accumulation. An abrupt rise in pulmonary artery pressure and noncardiogenic pulmonary edema may develop, lung compliance falls, and hypoxemia ensues. The symptoms of venous air embolism are variable and nonspecific, and may include alterations in sensorium, chest pain, dyspnea, or a sense of impending doom.[159] These and other consequences appear to be due to two phenomena: actual lodgment of the bubbles in capillary beds that interfere with nutrient supply to the affected organs, and the formation of platelet–fibrin aggregates, creating diffuse microthrombi. Thrombocytopenia may be seen as a consequence of this latter event. The most serious consequences result from cerebral or coronary artery air embolism, the severity of the consequences depending upon the rate and volume of air gaining access to the circulation.

The best approaches to air embolism are prevention and early detection. Treatment consists of measures designed to restore flow and promote reabsorption of the intravascular air.[160] Measures designed to restore flow include patient positioning (Trendelenburg position with the left side down), removal of air through central venous catheters or direct needle aspiration, and closed chest cardiac massage. Measures designed to increase absorption include the use of 100% oxygen and hyperbaric oxygen therapy. Using such aggressive measures, mortality from venous air embolism has been dramatically reduced.

FAT EMBOLISM

Fat embolism represents another form of nonthrombotic embolism.[161,162] In its full-blown form, a rather characteristic syndrome follows entry of neutral fat into the vascular system, consisting of dyspnea, hypoxemia, petechiae, and mental confusion. Seizures and focal neurologic deficits have been described. There is a variable lag time of 24 to 72 hours in the onset of the syndrome following the inciting event; rarely, cases occur within 12 hours or as late as 2 weeks after the event.

By far, the most common inciting event is traumatic fracture of long bones, with incidence rising with the number of fractures. However, orthopedic procedures and trauma to other fat-laden tissues (e.g., fatty liver) occasionally can lead to the same syndrome. Although considerably less common, fat embolism syndrome has been reported following both liposuction and lipoinjection procedures.

The basis for the variability in the incidence and severity of the syndrome after apparently comparable injuries has not been well defined, nor has the delay in clinical presentation. The pathophysiologic consequences appear to derive from two events: (1) actual vascular obstruction by neutral particles of fat; and (2) the injurious effects of free fatty acids released by the action of lipases on the neutral fat. The latter effect is probably the more important, causing diffuse vasculitis with leakage from cerebral, pulmonary, and other vascular beds. The time necessary to produce toxic intermediaries may explain the delay from the inciting event to clinical presentation.

The diagnosis of fat embolism syndrome is a clinical one suggested by the constellation of dyspnea, neurologic abnormalities, petechiae, and fever in the proper clinical context. Petechiae, typically distributed over the head, neck, anterior chest, and axillae, are present in only 20% to 50% of cases. Therefore, their absence should not preclude consideration of the disease. No laboratory test is diagnostic of the syndrome. Fat can be demonstrated in the serum of a majority of fracture patients with evidence of fat embolism syndrome. The finding of lipid-laden cells in bronchoalveolar lavage fluid appears to occur commonly in patients with traumatic injuries irrespective of the presence of fat embolism syndrome.

Although a variety of treatments have been suggested (e.g., intravenous ethanol, albumin, dextran, heparin), none has proved effective. The role of corticosteroid therapy to prevent the onset of fat embolism syndrome after an inciting event remains controversial.[163] Supportive treatment, including mechanical ventilatory support when necessary, is the primary approach, and survival is now the rule with meticulous support.

AMNIOTIC FLUID EMBOLISM

Another special form of embolism is amniotic fluid embolism, a rare, unpredictable and potentially catastrophic complication of pregnancy. Amniotic fluid embolism is reported to occur in approximately 2.0 per 100,000 deliveries and represents a leading cause of maternal mortality.[164] This disorder occurs during or after delivery when amniotic fluid gains access to uterine venous channels and, therefore, to the pulmonary and general circulations. The delivery may be either spontaneous or by Cesarean section and usually has been uneventful. Most cases occur during labor, but delayed onset of symptoms up to 48 hours after delivery can occur. Advanced maternal age, multiparity, premature placental separation, fetal death, and meconium staining of amniotic fluid have been associated with increased risk of amniotic fluid embolism.

Amniotic fluid embolism syndrome should be suspected with the sudden onset of severe respiratory distress, cyanosis, hypotension, cardiovascular collapse and, often, disseminated intravascular coagulation.[165] Occasionally, seizure activity occurs. It has been postulated that there is a biphasic pattern of hemodynamic disturbance: an initial period of pulmonary hypertension, commonly seen in animal models, followed by left ventricular dysfunction and cardiogenic shock. Patients who survive the first several hours develop noncardiogenic pulmonary edema coincident with improvement in left ventricular dysfunction.[166]

Amniotic fluid contains particulate materials that can cause pulmonary vascular obstruction, but the major pathogenetic mechanism of the syndrome remains uncertain. Amniotic fluid has thromboplastic activity that leads to extensive fibrin deposition in the pulmonary vasculature and, occasionally, other organs. As a consequence of fibrin deposition, severe consumptive coagulopathy develops, including marked hypofibrinogenemia and thrombocytopenia. Following the acute event, an enhanced fibrinolytic state often occurs.

The diagnosis of amniotic fluid embolism is based on a compatible clinical picture, often enhanced by finding amniotic fluid components in the pulmonary circulation. The presence of squamous cells in pulmonary arterial blood, once considered pathognomonic, has proved to be a nonspecific finding. Serologic assays and immunohistochemical staining techniques have been described as having high sensitivity for amniotic fluid embolism.

Although various forms of therapy have been suggested (e.g., antifibrinolytic agents such as aminocaproic acid, cryoprecipitate), the best approach is supportive. Pulmonary artery catheterization is useful to monitor left ventricular function and volume status and to guide the appropriate use of inotropic and vasoactive agents. Even in the setting of aggressive supportive measures, however, maternal mortality has approached 80%.

SEPTIC EMBOLISM

Septic embolism is another special disorder that, unfortunately, is increasing in frequency owing to widespread intravenous drug abuse and the expanding use of indwelling intravenous devices. Previously, septic embolism was almost exclusively a complication of septic pelvic thrombophlebitis due to either septic abortion or postpuerperal uterine infection.[167] However, almost any venous structure can be involved, either as a focus of primary infection or from intravascular or contiguous spread: septic cavernous sinus thrombosis resulting from meningitis, sinusitis, or facial cellulitis; septic portal venous thrombosis resulting from diverticulitis or liver abscess; septic tonsillar or internal jugular venous thrombosis (Lemmiere syndrome) resulting from oropharyngeal infection. Increasingly common causes are those related to intravenous drug use and those that are iatrogenic; namely, infections secondary to indwelling catheters inserted for a variety of diagnostic or therapeutic purposes.[168–170]

Microscopically, septic phlebitis consists of purulent material admixed with fibrin thrombus. Embolization from such material does occur and can result in obstruction of small pulmonary vessels, but the major consequence is pulmonary infection. Characteristically, the chest roentgenogram displays scattered pulmonary infiltrates that undergo cavitation. An increasing number of such infiltrates develop over periods of hours to a few days. Symptoms and signs include fever, dyspnea, cough, pleuritic chest pain, and hemoptysis. Initial treatment consists of appropriate antibiotics. If an indwelling catheter is the source of the infection, it should be removed. If there is not a prompt response to this regimen, surgical isolation of the septic vein, if present, should be considered. The role of systemic anticoagulation remains uncertain. Endocarditis may complicate septic phlebitis, or mimic it, particularly in drug addicts.

TUMOR EMBOLISM

Involvement of the pulmonary vascular bed by tumor cells is not unusual given the frequency with which circulating tumor cells can be identified in patients with a wide range of malignancies and the frequency with which tumor emboli are discovered as an incidental finding at autopsy.[171] Tumor embolism becomes clinically apparent, however, in only a minority of patients with malignancy.

Microvascular tumor embolism is associated with a wide range of malignancies, the most common of which are breast, lung, prostate, stomach, and liver cancer. Tumor embolism of large fragments occurs rarely and may mimic acute thromboembolic disease. In this setting, survival following tumor embolectomy has been reported.

The clinical presentation of microvascular tumor embolism is typically subacute and involves progressive dyspnea, tachycardia, and tachypnea. Jugular venous distention, a prominent P2, tricuspid regurgitation or a right-sided S3 may be present on physical examination if the extent of pulmonary vascular obstruction is sufficient to cause pulmonary hypertension.

The development of pulmonary hypertension is a common accompaniment of symptomatic, microvascular tumor embolism and remains a major cause of mortality. Pulmonary hypertension appears to result from an obliteration of the pulmonary vascular bed by an admixture of tumor cells and thrombus as well as the development of medial hypertrophy, intimal fibrosis, and fibrinoid necrosis encountered in other etiologies of pulmonary hypertension.

Hypoxemia and a compensated respiratory alkalosis are commonly present. The chest radiograph is most often normal but focal or diffuse infiltrates, which may be fleeting, have been described. V/Q scanning most commonly demonstrates a mottled appearance or peripheral, subsegmental defects; segmental or larger defects, indistinguishable from those associated with thromboembolic embolism, may occur in those rare instances of large-vessel involvement. CT may demonstrate peripheral, wedge-shaped defects consistent with infarcts; a pattern of multifocal dilatation and beading of the peripheral pulmonary arteries has been described.[172]

Pulmonary angiographic findings may include delayed vascular filling, pruning, and tortuosity, similar to that seen in other forms of small-vessel pulmonary hypertension. The angiographic findings in large fragment tumor embolism may be indistinguishable from those seen in acute thromboembolic disease.

Pulmonary microvascular cytology on specimens aspirated through a wedged pulmonary artery catheter may demonstrate malignant cells. Positive cytologies, however, can also be obtained in the setting of lymphangitic carcinomatosis. The misidentification of megakaryocytes as tumor cells obtained in this manner has been reported to lead to false-positive results.

Although diagnosis by transbronchial biopsy has been reported, diagnostic confirmation may require surgical lung biopsy. Before proceeding to that step, however, it must be stressed that the impact of early diagnosis on outcome is uncertain. This intervention should only be considered in the setting of a primary malignancy for which effective chemotherapeutic options are available.

The differential diagnosis of tumor embolism includes thrombotic embolism, parenchymal metastasis, lymphangitic carcinomatosis, malignant pericardial effusion, and chemotherapy-related lung toxicity. The premortem diagnosis is often one of exclusion. Parenchymal metastasis, lymphangitic carcinomatosis and chemotherapy-related lung toxicity can be differentiated from tumor embolism by findings on high-resolution CT. Differentiation of tumor embolism from thrombotic embolism may be somewhat more problematic, especially if there is large-vessel involvement.

SICKLE CELL DISEASE

Sickle cell disease affects the lungs by causing local thrombosis and occasionally by embolization of bone marrow elements. Small pulmonary arteries, arterioles, and capillaries are generally affected.[173,174] Thrombosis in the pulmonary circulation is part of the general proclivity of red blood cells containing S hemoglobin to sickle under appropriate circumstances, particularly hypoxia; stagnation and clotting follow sickling. In some instances, the thrombus organizes, the vascular lumen is obliterated, and perivascular fibrosis ensues in the adjacent lung; in others, the thrombus recanalizes. Occasionally, infarction occurs.

Of the factors that predispose to thrombosis in the lungs in sickle cell disease, the most important is the low oxygen saturation of mixed venous blood. Not only is the mixed venous oxygen inordinately low but also the O_2 dissociation curve is shifted to the right, thereby handicapping O_2 uptake in the lungs. Patients with sickle cell disease are prone to develop pneumonia, which, in turn, can lead to local areas of hypoxia favoring sickling and thrombosis in the lung. Patients with severe sickle cell anemia and large fractions of hemoglobin S in their red blood cells are particularly susceptible to intense sickling and thrombosis anywhere, including the lungs. However, vulnerability is not restricted to states of hemoglobin S. In some heterozygous sickle states – for example, hemoglobin SC, S-thalassemia, and hemoglobin SA – enough hemoglobin S is present to cause extensive thrombosis and infarction during an episode of severe hypoxemia, acidosis, or septicemia associated with fever and leukocytosis.

The clinical picture of pulmonary infarction in patients with sickle cell disease can mimic or coexist with bronchopneumonia. An

episode often begins with chest pain, fever, and sputum that is blood streaked but fails to disclose any specific bacterial cause. A fleeting episode of breathlessness is usually overlooked. The subsequent course is characterized by an unconvincing response to antibiotics and slow clearing; often a linear scar in the lungs remains as a residue of the infarction.

Distinguishing between in situ thrombosis and thromboembolism can be difficult clinically and even with invasive procedures such as angiography, although in situ thrombosis tends to be in small, distal vessels. Moreover, because radiographic contrast materials may promote sickling, they have to be used cautiously. To complicate matters, some patients with sickle cell disease are also at increased risk of thromboembolism because of predisposing factors, such as bed rest, congestive heart failure, and dehydration.

Sometimes, occlusive disease is sufficiently extensive to cause pulmonary hypertension and cor pulmonale. For this sequence to evolve, many severe episodes of sickling are required. The cor pulmonale that results is unusual because of its association with a high cardiac output (due to anemia) and with the intrinsic myocardial damage that generally complicates sickle cell disease.[175]

Management of the patient with pulmonary thrombosis and infarction in sickle cell disease is largely supportive and includes supplemental oxygen, intravenous hydration, and pain control.

Simple or exchange transfusions are recommended for patients with significant hypoxemia and pulmonary infiltrates (i.e., acute chest syndrome). Anticoagulants are generally not used in sickle cell crisis. Their utility in larger-vessel pulmonary artery thrombosis is uncertain since there are no data to substantiate their effectiveness. Because it implicates large vessels' occlusion, pulmonary artery thrombosis during acute chest syndrome should be amenable to the same therapeutic approach as currently used for venous thromboembolic disease.[174]

■ OTHER EMBOLI

Because of its sieve function, the lung may also be the target of embolization by a wide variety of other materials.[176–179] Trophoblastic tissue can escape the uterus and lodge in the pulmonary circulation during pregnancy. After head trauma, brain tissue has been found in the lungs; the same is true of liver cells following abdominal trauma and bone marrow after cardiopulmonary resuscitation.

Finally, noninfectious vasculitic–thrombotic complications are seen in association with the intravenous use of drugs intended for oral use. Medications associated with pulmonary complications include methylphenidate hydrochloride, oral opiates (pentazocine, meperidine), and antihistamines. Particulate and irritant drug carriers (e.g., talc, cellulose) and occasionally the drugs themselves may cause vascular inflammation and secondary thrombosis. The clinical presentation may be diverse and includes lower lobe emphysema, diffuse interstitial fibrosis, and progressive massive fibrosis. Repetitive insults may lead to severe and irreversible pulmonary hypertension. In many intravenous drug users, perfusion scans demonstrate segmental or smaller defects. Distinguishing these defects from those due to venous thromboembolism may be difficult.

The diagnosis is often suggested by the clinical history. Radiographic findings include small, diffuse, well-defined nodular densities. These nodules can progress and massive fibrosis may ensue. Lower lobe emphysematous changes may also be present. Diagnostic confirmation often requires transbronchial or surgical lung biopsy. Occasionally, fine crystalline deposits may be seen in the retinal microvasculature on funduscopic examination, confirming the diagnosis noninvasively. The prognosis is generally poor with most patients experiencing progressive pulmonary disease.

CHAPTER 74 Pulmonary Vasculitis

Ulrich Specks

NOMENCLATURE AND DEFINITIONS

Pulmonary vasculitis is usually a manifestation of a systemic disorder leading to inflammation of vessels of different sizes by a variety of immunological mechanisms. Vasculitis can be categorized into primary vasculitis and secondary vasculitis. The primary systemic vasculitides are a heterogeneous group of syndromes of unknown etiology, which share a clinical response to immunosuppressive therapy (Table 74-1). Their wide spectrum of frequently overlapping clinical manifestations is defined by the size and location of the affected vessels as well as the nature of the inflammatory infiltrate. Secondary vasculitis may represent significant management problems in the context of a well-defined underlying disorder, such as diffuse alveolar hemorrhage caused by systemic lupus erythematosus (SLE). Alternatively, secondary vasculitis may be an incidental histopathological finding, for instance, in the context of an infection or necrotizing sarcoid granulomatosis.

Classification schemes and definitions of the various forms of vasculitis have evolved over the past decades. Historically, the classification of the vasculitis has been based on the size of the most prominently affected vessels. The primary purpose of classification and nomenclature is to standardize communication between clinicians and investigators and to facilitate more uniform treatment approaches. Ideally, they reflect the current understanding of pathogenesis. The first international consensus conference on the nomenclature of systemic vasculitides held in 1992 in Chapel Hill aimed to reconcile definitions and classification schemes used by European and American investigators. The resulting nomenclature and definitions were based mainly on histopathological criteria, particularly the size of the vessels involved, but allowed for radiographic and clinical surrogates to fulfill the definitions. These definitions, nomenclature, and classification found wide acceptance. The terminology was recently revised and updated at the second 2012 Chapel Hill International Consensus Conference so that it reflects novel insights into the pathogenesis of various vasculitides while avoiding the use of eponyms as much as possible.[1] In this chapter, the specific definition of each form of vasculitis is discussed in detail as part of the description of the clinical manifestations and differential diagnosis of each entity.

TABLE 74-1 Chapel Hill Consensus Nomenclature of the Primary Systemic Vasculitides

Name	Respiratory Manifestations	Presence of ANCA
Large vessel vasculitis		
Giant cell arteritis	Rare	No
Takayasu arteritis	Frequent	No
Medium-sized vessel vasculitis		
Polyarteritis nodosa	Rare	No
Kawasaki disease	No	No
Small vessel vasculitis *ANCA-associated vasculitis*		
Granulomatosis with polyangiitis (formerly Wegener's)	Frequent	>80%
Microscopic polyangiitis	Frequent	>80%
Eosinophilic granulomatosis with polyangiitis (formerly Churg–Strauss syndrome)	Frequent	>50%
Immune complex small vessel vasculitis		
Anti-GBM disease	Frequent	No
IgA vasculitis	Rare	IgA-ANCA reported
Cryoglobulinemic vasculitis	No	No
Hypocomplementemic urticarial vasculitis	Frequent	No
Variable vessel vasculitis		
Behçet disease	Rare	No

The 2012 Chapel Hill nomenclature is clinically very useful to pulmonologists as it reflects the clinical and histopathological pulmonary features and facilitates the therapeutic approach to individual patients. The three small vessel vasculitides that present most often with respiratory symptoms are granulomatosis with polyangiitis (GPA [formerly Wegener granulomatosis]), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA [formerly Churg–Strauss syndrome]). Most patients with these syndromes have antineutrophil cytoplasmic autoantibodies (ANCA) detectable in the serum at the time of initial presentation.[2] Consequently, this group of small vessel vasculitides is referred to *in cumulo* as "ANCA-associated vasculitis." In patients with vasculitis, two types of ANCA are of clinical significance. In more than 80% of patients with GPA (Fig. 74-1), ANCA occur and are associated with a cytoplasmic immunofluorescence pattern (C-ANCA) on ethanol-fixed neutrophils that react with the neutrophil granule enzyme, proteinase 3 (PR3-ANCA). In contrast, ANCA that cause a perinuclear immunofluorescence pattern (P-ANCA) on ethanol-fixed neutrophils and react with myeloperoxidase (MPO-ANCA) occur in fewer than 10% of patients with GPA but in the majority of patients with MPA (Fig. 74-2). MPO-ANCA are also the predominant type of ANCA encountered in patients with EGPA, in which PR3-ANCA are the exception. Despite these circulating autoantibodies, hardly any immunoglobulin deposits can be detected in the tissue lesions of ANCA-associated vasculitis, and they are consequently called "pauci-immune" lesions.

EPIDEMIOLOGY

The primary systemic vasculitides are rare and few epidemiological studies have been conducted, mostly in ethnically homogeneous populations.[3] Giant cell arteritis is the most frequent form of systemic vasculitis with an annual incidence of 13 per million adults (40 per million over the age of 60). It appears to be increasing in frequency and becoming cyclical over time. The latter observation has been interpreted as possibly suggesting a relationship with

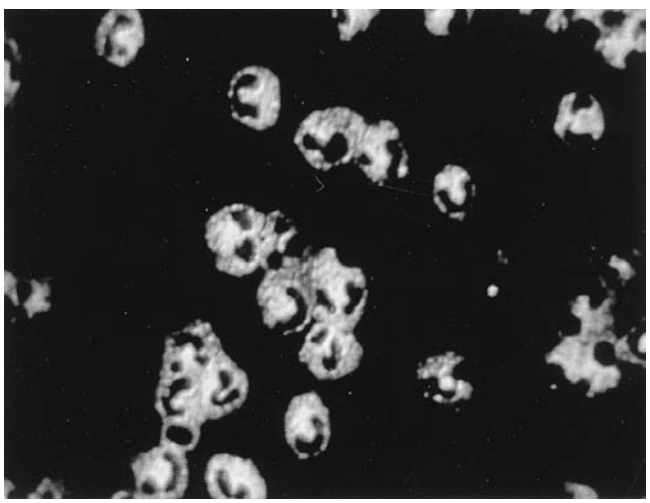

Figure 74-1 Cytoplasmic indirect immunofluorescence (C-ANCA) pattern in ethanol-fixed neutrophils caused by ANCA reacting with PR3.

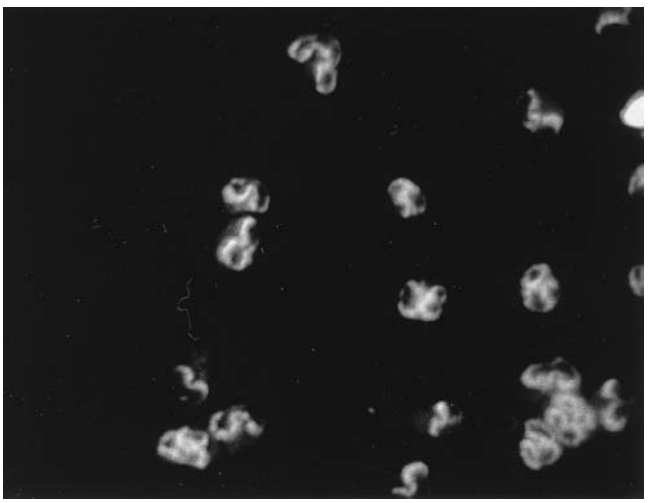

Figure 74-2 Perinuclear indirect immunofluorescence (P-ANCA) pattern in ethanol-fixed neutrophils caused by ANCA reacting with MPO.

TABLE 74-2 Organ Systems Affected by ANCA-Associated Vasculitis

Feature	Granulomatosis with Polyangiitis (formerly Wegener's)	Microscopic Polyangiitis	Eosinophilic Granulomatosis with Polyangiitis (formerly Churg–Strauss)
Upper airway disease	90–95%	No	50–60%
Pulmonary parenchymal disease	54–85%	20%	30%
Alveolar hemorrhage	5–15%	10–50%	<3%
Glomerulonephritis	51–80%	60–90%	10%–25%
Gastrointestinal tract	<5%	30%	30–50%
Eyes	35–52%	<5%	<5%
Nervous system	20–50%	60–70%	70%–80%
Heart	8–16%	10–15%	10–15%
Skin	33–46%	62%	50–60%
Eosinophilia	Rare	Rare	Yes
Asthma	No[a]	No[a]	Yes
Granulomatous inflammation	Yes	No	Yes

[a]*Not more than general population.*

infections. Respiratory manifestations rarely represent significant management problems in these patients. Various studies from different regions of the world report a fairly uniform annual incidence of one to two cases per million for Takayasu arteritis. Pulmonary vascular complications occur in about half of the afflicted patients. The estimated annual incidence of GPA has been rising over the decades from 0.5 to 0.7 per million during the 1970s and early 1980s to current estimates of about 10 to 12 per million. Similar increases in annual incidence have been observed for MPA and EGPA. The average frequency of MPA is similar to that of GPA; for EGPA it is estimated to be of the order of one to three per million. The ANCA-associated vasculitides have different ethnic predilections: GPA affects predominantly whites, and northern Europeans appear more prone to develop GPA. In contrast, individuals of southern European and Mediterranean descent appear to be relatively more apt to develop MPA. GPA and MPA can affect individuals of any age. However, the incidence of GPA plateaus after age 50, whereas the likelihood of developing MPA continues to increase with age.

The annual incidence of the secondary vasculitides varies widely. The reported frequencies for rheumatoid vasculitis and vasculitis in SLE are 12.5 per million and 3.6 per million, respectively. Behçet disease has a peculiar geographic distribution along the old Silk Road, with the highest prevalence being reported from Turkey, Central and far eastern Asia, where the frequencies range from 100 to 380 per 100,000, compared with only 1 per 100,000 in western Europe.

The available population-based studies need to be interpreted with some caution because they do not distinguish between whether the observed increased incidence of systemic vasculitis is true, or the result of more frequent recognition of the disease. Moreover, whether individual diagnoses are accurate and consistent is challenged by the changing definitions of the syndromes over time.

ANCA-ASSOCIATED VASCULITIS

The ANCA-associated vasculitides include granulomatosis with polyangiitis, microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis. The clinical presentation, diagnosis, pathophysiology, and treatment of these entities are discussed below.

GRANULOMATOSIS WITH POLYANGIITIS: CLINICAL PRESENTATION AND DIAGNOSIS

GPA is the most common form of vasculitis to involve the lung. The Chapel Hill Consensus Conference defined GPA as "necrotizing granulomatous inflammation usually involving the respiratory tract, and necrotizing vasculitis affecting predominantly small- to medium-sized vessels."[1] However, it is important to recognize that GPA is a systemic disease that can affect almost any organ (Table 74-2). The most frequently involved sites are the upper airways, lungs, and kidneys.[4] Symptoms and clinical disease manifestations are the result of necrotizing granulomatous inflammation and small vessel vasculitis that occur in variable degrees of combination.

In the 1960s the term "limited Wegener granulomatosis" was introduced to indicate patients with GPA who lacked renal disease. The use of this term and its implications have evolved over the last two decades. Even in the absence of renal involvement, patients may have life-threatening pulmonary or neurological disease requiring aggressive immunosuppressive treatment. For instance, a patient who "only" has alveolar hemorrhage in the absence of glomerulonephritis should never be classified as having "limited" GPA. Consequently, today, the use of the term "limited GPA" implies that (a) the pathology is predominantly a necrotizing granulomatous inflammation, and the vasculitis seen on biopsy is of lesser clinical significance; and (b) there is no immediate threat either to the patient's life or that the affected organ is at risk for irreversible damage. In this sense, the terms "limited" or "nonsevere" GPA are now used interchangeably as distinction from "severe" GPA, which by definition either threatens the patient's life (alveolar hemorrhage) or a vital organ with the risk of irreversible damage (rapidly progressive glomerulonephritis, scleritis, or mononeuritis multiplex). These definitions and distinctions form the basis for stratification of current standard therapy.

Over 90% of patients with GPA first seek medical attention for symptoms arising from either the upper and/or lower airway. Nasal and sinus disease is characterized by congestion and epistaxis due to mucosal friability, ulceration, and thickening. Patients may also have features of chronic sinusitis and recurrent or chronic serous otitis. Perforation of the nasal septum and/or saddle nose deformity may result from ischemia of the nasal cartilage (Fig. 74-3). Oral manifestations include gingival hyperplasia (Fig. 74-4) and oropharyngeal ulcerations. Subglottic stenosis occurs in approximately 20% of patients and can cause life-threatening compromise of the airway. Subglottic stenosis may occur in the absence of other features of active GPA, and its symptoms may be nonspecific, for example, dyspnea, hoarseness, cough or stridor; the latter is occasionally mistaken for wheezing.

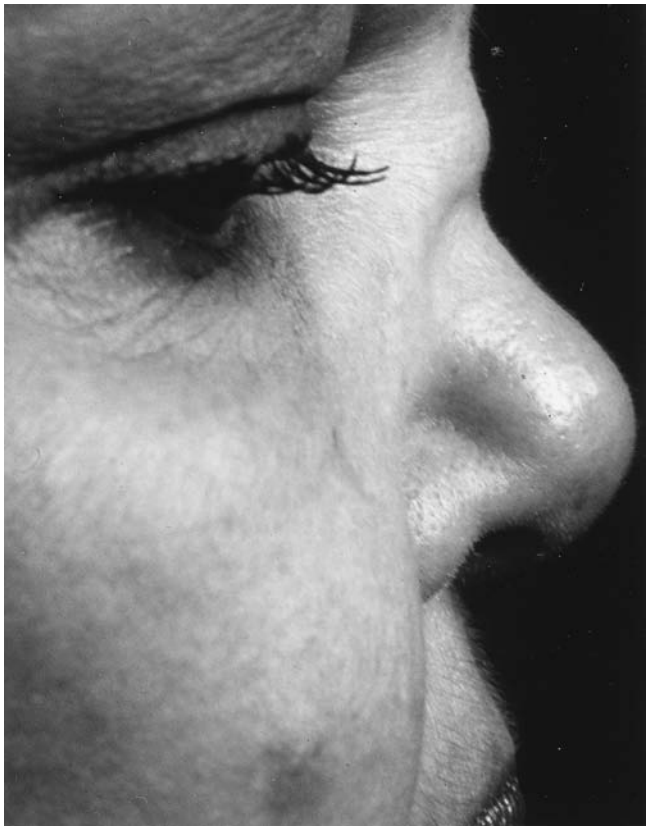

Figure 74-3 Saddle nose deformity of granulomatosis with polyangiitis.

GPA involving the lower airways can affect the pulmonary parenchyma, the bronchi, and rarely the pleura. Presenting features of parenchymal involvement may include cough, dyspnea, chest pain, or hemoptysis. However, some patients may be completely asymptomatic. Patients with diffuse alveolar hemorrhage usually present with progressive dyspnea and anemia (Fig. 74-5). Hemoptysis is absent in about one-third of patients. Patients with diffuse alveolar hemorrhage may deteriorate rapidly and experience respiratory failure, which has a mortality rate up to 50%.

The clinical presentation of alveolar hemorrhage is caused by pulmonary capillaritis (Fig. 74-6). The predominant inflammatory cells are neutrophils. However, eosinophils or monocytes may also be present. Capillaritis usually causes fibrinoid necrosis of alveolar and vessel walls and may culminate in the destruction of the underlying architecture of the lung. An important hallmark of capillaritis is the presence of pyknotic cells and nuclear fragments from

Figure 74-4 Strawberry or mulberry gums in a patient with granulomatosis with polyangiitis.

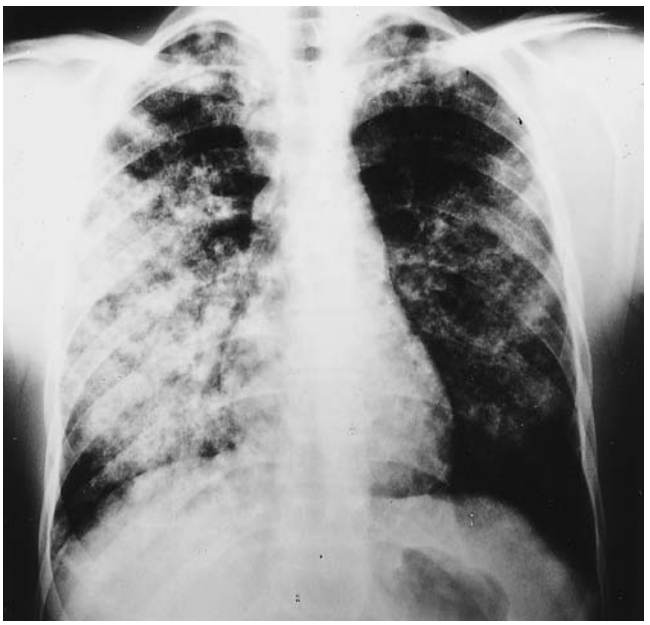

Figure 74-5 Chest radiograph of a patient with granulomatosis with polyangiitis displaying an alveolar filling pattern indicative of diffuse alveolar hemorrhage.

neutrophils undergoing apoptosis, a feature called leukocytoclasis. This hallmark enables distinction between true capillaritis and margination of neutrophils related to surgical trauma. Depending on the acuteness and duration of alveolar hemorrhage, hemosiderin-laden macrophages and interstitial hemosiderin deposits may be present.

The most common form of pulmonary involvement in GPA is caused by necrotizing granulomatous inflammation and presents radiographically as nodules or mass lesions, which may cavitate (Figs. 74-7–74-9). These lesions may be incidental findings on thoracic imaging studies as they cause little symptoms and do not result in significant abnormalities of pulmonary function. Prominent air–fluid levels can be seen when the necrotic center of the inflammatory lesion gets superinfected (Fig. 74-8). These necrotizing granulomatous lesions are a disease-defining feature of GPA. Their presence easily separates GPA from MPA. In the absence of other features of small vessel vasculitis in other organs, the differential diagnosis of these lesions consists primarily of infections, particularly caused by fungal or mycobacterial organisms, and less likely of malignancies or necrotizing sarcoid granulomatosis.

The lung nodules of GPA have very characteristic histopathological features. Small necrotizing microabscesses appear to be the earliest lesion. They enlarge and coalesce until the typical geographic and basophilic appearance of the necrosis has developed (Fig. 74-10). The necrotic center is surrounded by palisading histiocytes and scattered giant cells. Occasionally the necrosis may be bronchocentric. When this type of necrotizing granulomatous inflammation extends into the walls of small vessels it is referred to as granulomatous vasculitis (Fig. 74-11). In contrast to capillaritis, this type of vasculitis seems to be a secondary phenomenon of the necrotizing granulomatous inflammation affecting the lung parenchyma. The inflammatory background of the granulomatous necrosis and vasculitis consists of a mixed cellular infiltrate containing lymphocytes, plasma cells, scattered giant cells, and eosinophils. It may cause extensive parenchymal consolidation mimicking organizing pneumonia. Well-defined sarcoid-like nonnecrotizing granulomas are not found in GPA.

Inflammation and stenosis of the tracheobronchial tree occur in at least 15% of patients with lung involvement.[5,6] Endobronchial disease may be an incidental finding on bronchoscopy or present

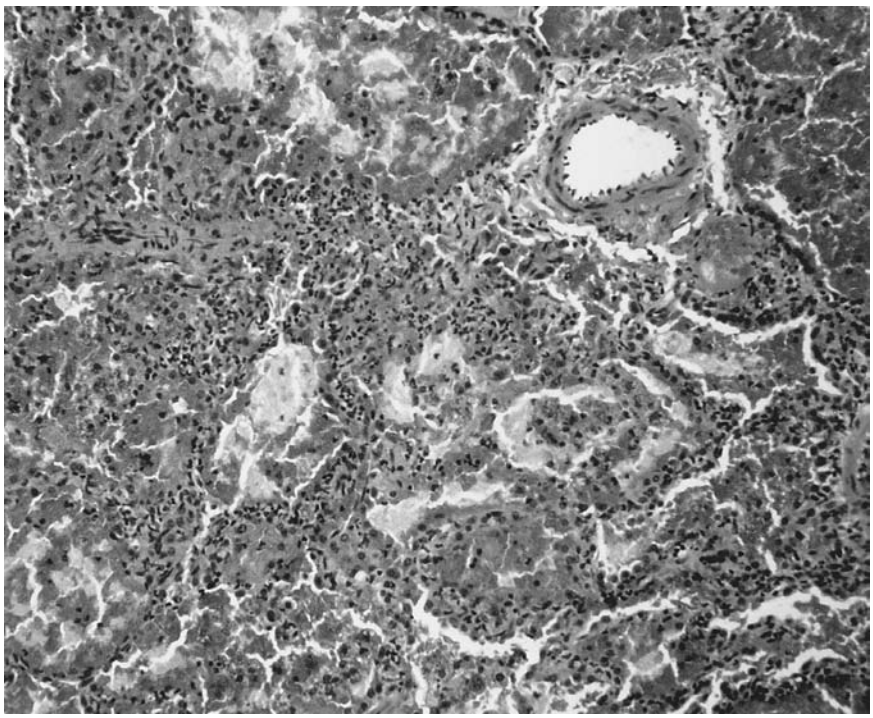

Figure 74-6 Alveolar capillaritis causing pulmonary hemorrhage in granulomatosis with polyangiitis.

with cough, hemoptysis, wheezing, dyspnea, or symptoms related to parenchymal collapse or postobstructive infection. Spirometry including inspiratory and expiratory flow–volume loops may show characteristic abnormalities indicative of degree and location of airway narrowing. Subglottic stenosis represents a fixed airway obstruction resulting in flattening of both the inspiratory and expiratory loops. If the intrathoracic trachea, or more commonly, one or both mainstem bronchi are affected, flattening of the expiratory curve can be found. Pleural effusions may occur, but are usually small, asymptomatic, and incidental findings (Fig. 74-9). Other thoracic manifestations of GPA include inflammatory pleural pseudotumors or hilar adenopathy. The latter should raise the suspicion of infection, sarcoidosis, or lymphoma.

Glomerulonephritis is among the most concerning disease manifestations of GPA as it can progress to complete renal failure in the absence of symptoms. It is usually detected by the presence of abnormal laboratory results such as active urine sediment with microscopic hematuria and red cell casts, proteinuria, and declining renal function. Continued vigilance for glomerulonephritis is essential as it is present at diagnosis in less than half of all patients. However, over the course of their disease, the kidneys are affected in 80% of patients.

A renal biopsy is useful to establish a diagnosis of ANCA-associated vasculitis and to determine the renal prognosis. The glomeruli are not affected uniformly (focal) by segmental, necrotizing inflammation (Fig. 74-12), and cellular crescents (Fig. 74-13) are frequently found. The number of glomeruli affected, degree of crescent formation, and destruction of individual glomeruli as well as the amount of sclerosis found determine the chance of recovery of renal function. In addition, tubular fibrosis and atrophy affect renal outcomes. Direct immunofluorescence reveals no or only scant immune deposits (pauci-immune glomerulonephritis). Granulomatous inflammation affecting the renal parenchyma and tubulointerstitial nephritis can also be found rarely.

A wide spectrum of ocular manifestations has been observed in GPA, which may threaten vision by affecting the eye directly or involving its contiguous structures. Manifestations may include conjunctivitis, episcleritis, scleritis, keratitis, corneal ulceration, uveitis, and retinal vasculitis. Involvement of the lacrimal system

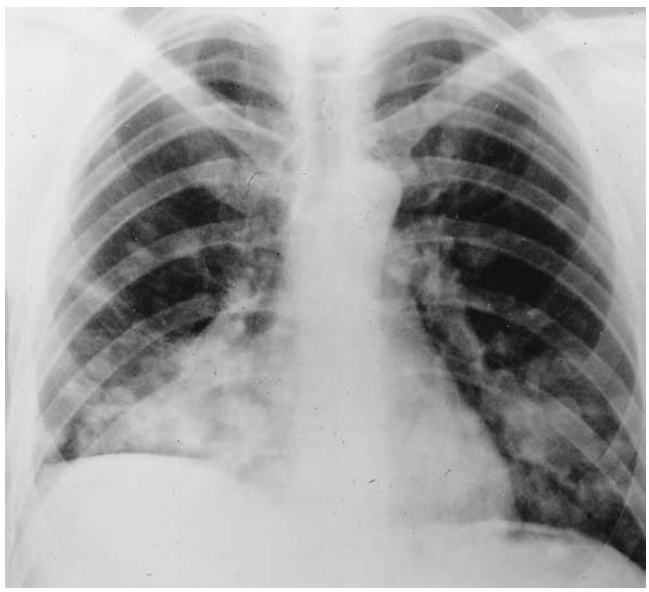

Figure 74-7 Chest radiograph of a patient with granulomatosis with polyangiitis displaying multiple nodules with and without cavitation.

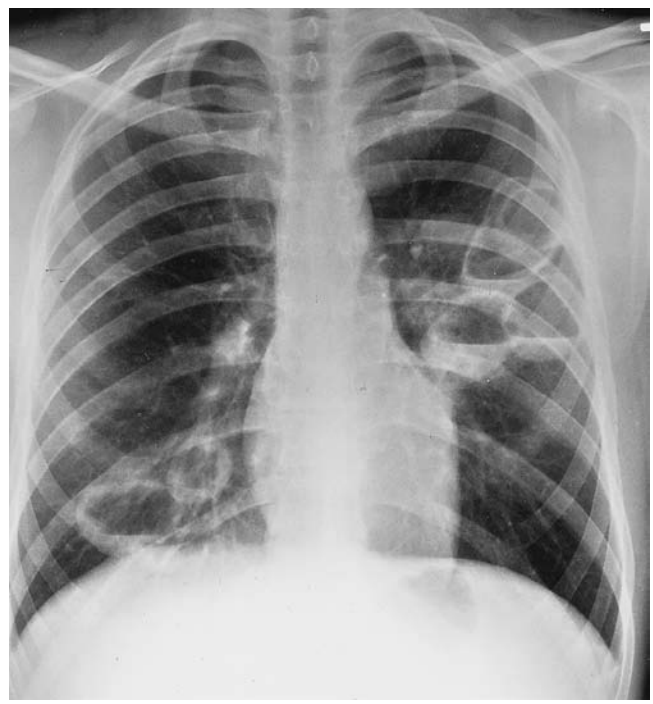

Figure 74-8 Chest radiograph of a patient with granulomatosis with polyangiitis showing multiple large cavities, some with air–fluid levels.

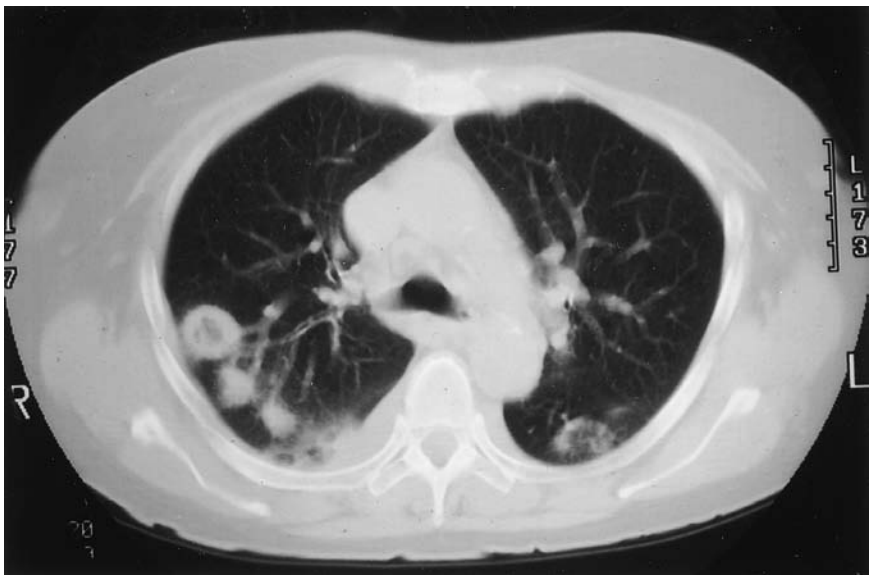

Figure 74-9 Computed tomography scan of a patient with granulomatosis with polyangiitis showing multiple nodules, some with cavitation. There are also small bilateral pleural effusions.

may result in epiphora, dacryocystitis, and fistula. Retro-orbital inflammatory pseudotumors may affect one or both the eyes, threaten the vision, and represent the most difficult challenge in the management of GPA (Figs. 74-14 and 74-15). Any patient with GPA who presents with eye pain or redness, proptosis, change in visual acuity, diplopia, or loss of visual field should be referred for emergent ophthalmological consultation.

Nervous system involvement may occur in up to one-third of patients. Mononeuritis multiplex of the peripheral nervous system caused by inflammation of the vasa nervorum as well as central nervous system vasculitis and pachymeningitis represent severe disease manifestations with substantial risk of irreversible damage, persisting even after the acute inflammation is adequately controlled.

Cardiac involvement may be occult. Regional wall motion abnormalities with a noncoronary distribution pattern are frequent echocardiographic findings.[7] It is unclear whether this type of cardiomyopathy is the result of small vessel disease or inflammatory infiltration of the cardiac muscle. Pericarditis, valvulitis, and inflammatory pseudotumor have also been described.

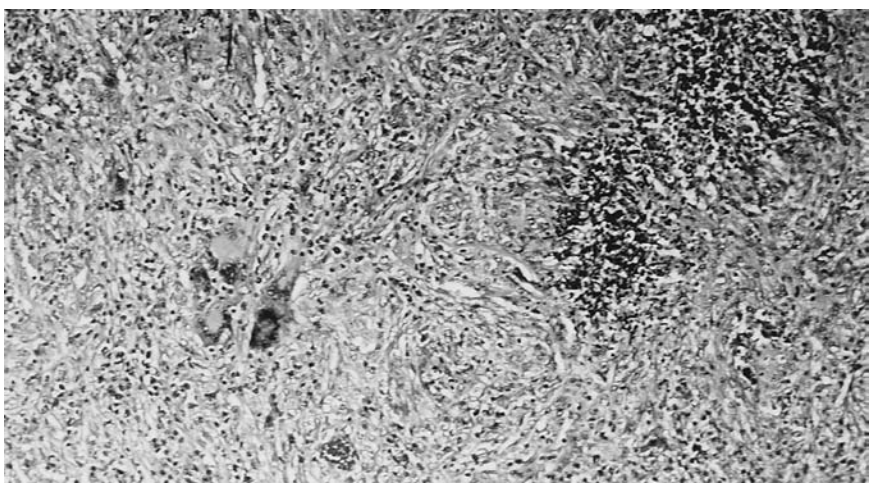

Figure 74-10 Geographic basophilic necrosis with palisading histiocytes and giant cells from a lung nodule in a patient with granulomatosis with polyangiitis.

A wide spectrum of cutaneous manifestations may be observed in GPA. Leukocytoclastic vasculitis presenting as palpable purpura is most common, followed by pyoderma gangrenosum–like lesions (Fig. 74-16) and so-called Churg–Strauss granulomas.

■ MICROSCOPIC POLYANGIITIS: CLINICAL PRESENTATION AND DIAGNOSIS

Histopathologically, the necrotizing small vessel vasculitis of MPA causing necrotizing crescentic glomerulonephritis and pulmonary capillaritis is indistinguishable from that encountered in GPA.[8] Consequently, there is substantial overlap in organ manifestations and symptoms between the two syndromes (Table 74-2). A timely diagnosis of MPA may be delayed by a gradual onset or the nonspecific nature of symptoms such as fever, malaise, and weight loss. All organ systems may be involved. The kidneys are most commonly affected in up to 80% of patients. Other commonly encountered disease manifestations include diffuse alveolar hemorrhage due to pulmonary capillaritis affecting 10% to 30% of patients. MPA is the most frequent cause of pulmonary renal syndrome. Several cases of MPA in association with severe obstructive airway disease or bronchiectasis have also been described. More recently, several case series have highlighted an association between usual interstitial pneumonia and MPO-ANCA–positive MPA. In these cases, the fibrotic changes either precede the development of MPA or are already present at the time of diagnosis of MPA.

Palpable purpura caused by leukocytoclastic vasculitis of the skin, and musculoskeletal complaints, such as arthralgias and myalgias, are also common. Gastrointestinal involvement occurs in about one-third of patients. This is in contrast to GPA, in which gastrointestinal involvement is very rare. Visceral angiography is generally not helpful for the evaluation of abdominal symptoms as the vessels involved are too small to be visualized. CT with or without contrast injection may be more helpful if gastrointestinal involvement is suspected. However, the use of contrast is relatively contraindicated in patients with active renal involvement. Sinusitis and asthma are rarely found in MPA, and should lead to the consideration of an alternative diagnosis.

Most patients with MPA have ANCA, and in 40% to 80% they are of the P-ANCA variety, reacting with MPO. C-ANCA reacting with PR3 is seen less frequently. Occasionally patients with MPA later develop granulomatous inflammation and are reclassified as having GPA; this is more likely to occur in patients with C-ANCA.

As in GPA, a histopathological diagnosis may be necessary to confirm the diagnosis before the patient is committed to prolonged immunosuppressive therapy. The biopsy specimen should be sought from the most accessible site. Renal biopsy shows pauci-immune focal segmental–necrotizing glomerulonephritis, with extracapillary proliferation forming crescents. In contrast to GPA, granulomatous inflammation is not a feature of MPA. All other histopathological features are indistinguishable from those of

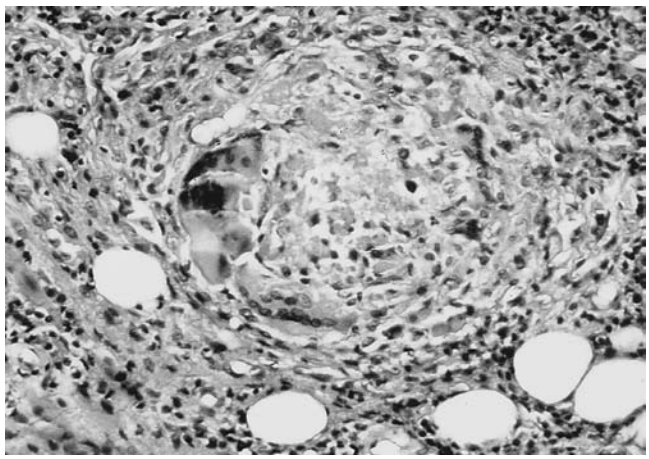

Figure 74-11 Granulomatous vasculitis with giant cells in a lung biopsy of a patient with granulomatosis with polyangiitis.

GPA. Treatment of MPA should follow the principles applied to the management of GPA. Consequently, most cases of MPA require immunosuppressive therapy used for patients with severe GPA.

■ EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS: CLINICAL PRESENTATION AND DIAGNOSIS

EGPA is the third type of vasculitis that commonly affects the lung. The 2012 Chapel Hill Consensus definition for the disease is "eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory, and necrotizing vasculitis predominantly affecting small- to medium-sized vessels, and associated with asthma and eosinophilia."[1] EGPA is included among the ANCA-associated vasculitides even though only 40% to 70% of patients with active EGPA are ANCA positive.[9–11] EGPA is primarily distinguished from GPA and MPA by a high prevalence of asthma and peripheral blood and tissue eosinophilia. Three distinct phases of the disease have been described. The first is a prodromal allergic phase with asthma. This phase may last for a number of years. The second is an eosinophilic phase with prominent peripheral and tissue eosinophilia. This phase may also last a number of years and the manifestations may remit and recur over this time period. The differential diagnosis for patients in this phase of the disease includes parasitic infection and chronic eosinophilic pneumonia. The third vasculitic phase consists of systemic vasculitis and may be life threatening. The three phases are not seen in all patients and do not necessarily occur in this order; they may even concur. However, asthma usually predates vasculitic symptoms by a mean of 7 years (range 0–61). Formes frustes of EGPA have also been described with eosinophilic vasculitis and/or eosinophilic granulomas in isolated organs without evidence of systemic disease.

Pulmonary parenchymal involvement occurs in 38% of patients. Transient alveolar-type infiltrates are most common (Fig. 74-17). These have a predominantly peripheral distribution and are indistinguishable from infiltrates seen in chronic eosinophilic pneumonia. Occasionally, nodular lesions may be seen in EGPA. In contrast

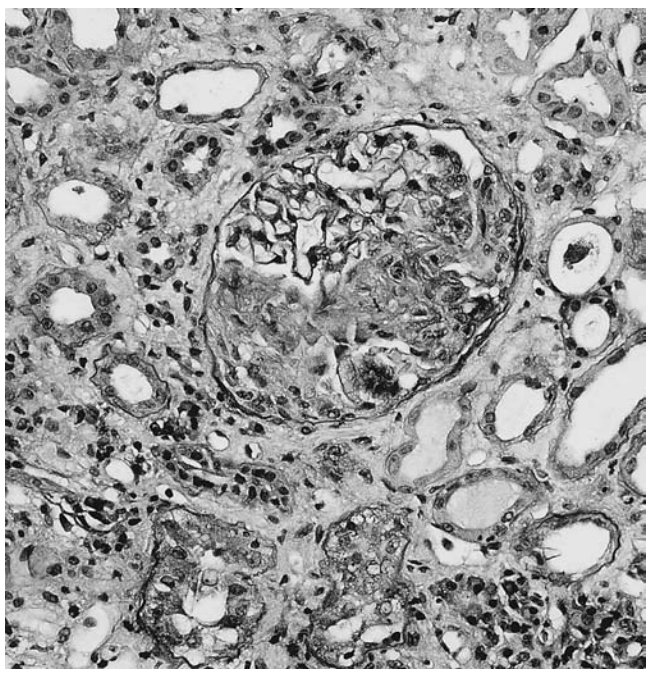

Figure 74-12 Focal necrotizing glomerulitis of granulomatosis with polyangiitis.

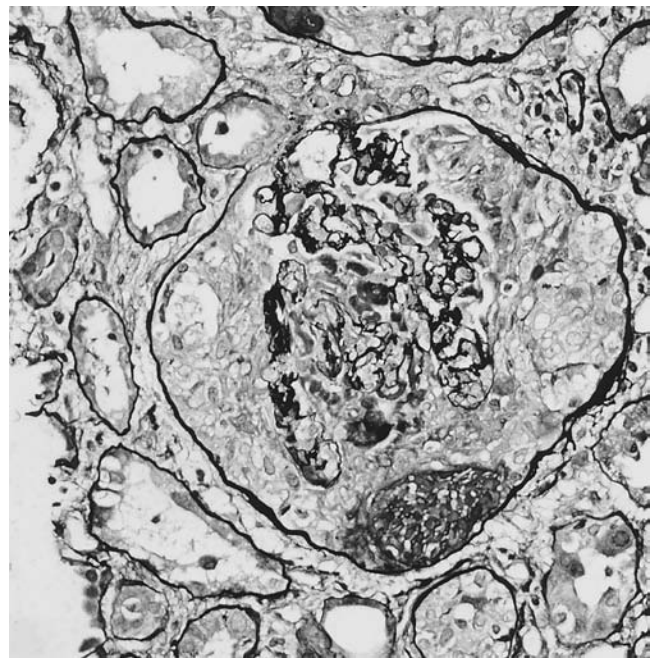

Figure 74-13 Rapidly progressive crescentic glomerulonephritis in granulomatosis with polyangiitis.

Figure 74-14 External ophthalmoplegia of the left eye due to orbital involvement with granulomatosis with polyangiitis.

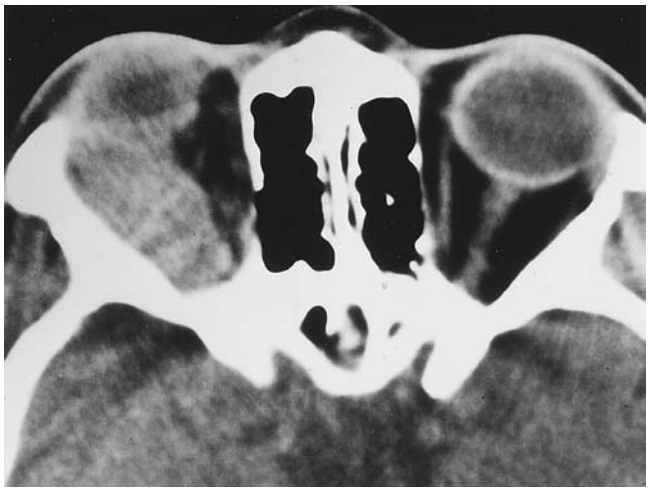

Figure 74-15 Computed tomography scan of the orbits in a patient with granulomatosis with polyangiitis showing a mass in the right orbit causing external ophthalmoplegia.

to GPA and MPA, alveolar hemorrhage is exceedingly rare. Renal involvement in EGPA is less prominent than in GPA and MPA and does not generally lead to renal failure. In contrast, peripheral nerve involvement, typically in the form of mononeuritis multiplex, is more frequent. The peripheral nerve involvement can result from both capillaritis and direct toxicity from eosinophil granule proteins. Skin, heart, central nervous system, and abdominal viscera may also be involved.

The classic histopathological picture consists of necrotizing vasculitis, eosinophilic tissue infiltration, and extravascular granulomas. However, not all features are found in every case, and they are not pathognomonic of the condition. Particularly the finding of a "Churg–Strauss granuloma" on skin biopsy should not be confused with the diagnosis of EGPA. While this type of necrotizing extravascular granuloma may be seen in EGPA, it may occur in other systemic autoimmune diseases, including GPA and rheumatoid arthritis.

If ANCA are present, they are usually P-ANCA reacting with MPO. The ANCA status appears to correlate with disease activity. Recent studies suggest a more vasculitic disease phenotype in the presence of ANCA, with ANCA being particularly frequent among patients with glomerulonephritis. Patients with heart involvement are less likely to be ANCA positive. However, not all studies have found this consistently, and there remains substantial overlap of

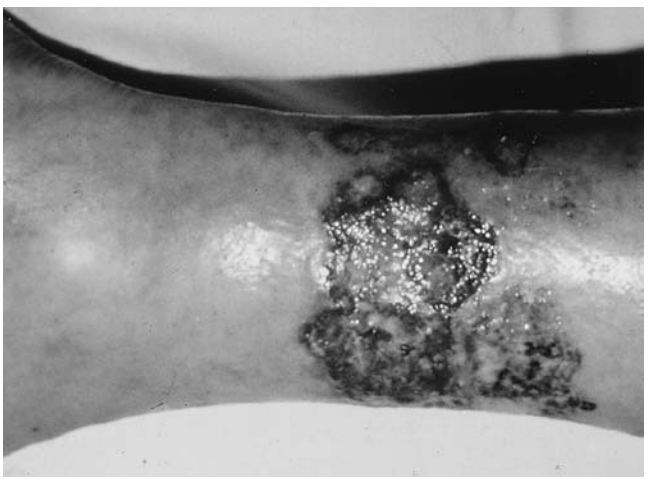

Figure 74-16 Pyoderma gangrenosum of the leg in a patient with granulomatosis with polyangiitis.

organ manifestations between patients with EGPA who are ANCA positive and those who are ANCA negative.

In recent years significant attention has been devoted to EGPA detected in patients using leukotriene receptor antagonists. Available case studies and limited population-based incidence estimates suggest that these agents may lead to unmasking of vasculitic symptoms in asthmatics, by allowing dose reductions or discontinuation of oral glucocorticoid therapy. There is no evidence suggesting that these agents cause EGPA.

The prognosis of EGPA is better than that of GPA and MPA, as the overall mortality is lower and not significantly different from the normal population. Most deaths are secondary to cardiac involvement.

■ PATHOPHYSIOLOGY OF ANCA-ASSOCIATED VASCULITIS

The etiology of ANCA-associated vasculitis remains unknown. Several different pathways and mechanisms have been proposed

for the pathogenesis.[12] A genetic predisposition for autoimmunity, epigenetic factors and environmental triggers seem to play a role in the development of ANCA-associated vasculitis. Currently available clinical and experimental evidence support that infections or other environmental exposures can lead to the loss of tolerance and an inflammatory environment that is conducive for the production of autoantibodies (ANCA) in predisposed patients. In the context of an inflammatory milieu, ANCA can cause specific tissue inflammation and injury by a variety of different mechanisms which involve direct interactions with PR3 or MPO.

Multiple studies have reported skewing in polymorphisms of a variety of immune response genes and genes encoding for ANCA-target antigens and α1-proteinase inhibitor with potential effects on disease outcome. A recent genome-wide association study found major histocompatibility complex (MHC) and non-MHC associations with GPA and MPA and that these syndromes are genetically distinct.[13] Moreover, the associations with the specific ANCA types (PR3-ANCA vs. MPO-ANCA) and the differences between them were stronger than those between patients diagnosed with GPA versus MPA. For PR3-ANCA–positive patients strong associations were found with *HLA-DP*, the serpin A1 gene (*SERPINA1*), which codes for the α1-antitrypsin, the major inhibitor of PR3, and with the *PRTN3* gene which encodes PR3. In patients with MPO-ANCA only an association with *HLA-DQ* was found.

The expression of ANCA-target antigens on the neutrophil surface, particularly PR3, is increased in patients with GPA and genetically determined. Moreover, epigenetic modifications that interfere with the normal silencing of genes coding for the ANCA autoantigens in mature neutrophils may also contribute to the observed inappropriately increased expression of PR3 or MPO by these cells in patients with GPA or MPA.

Many clinical observations suggest that the presence or absence of ANCA as well as the specific type of ANCA (PR3-ANCA vs. MPO-ANCA) defines the disease phenotype. Patients with limited GPA who remain ANCA negative rarely develop systemic vasculitic disease manifestations. Patients with glomerulonephritis and PR3-ANCA lose their renal function much more rapidly than patients with MPO-ANCA. Patients with PR3-ANCA also have a higher relapse rate than patients with MPO-ANCA. Experimental data and animal models support a pathogenic role of ANCA in the development of vasculitis. A couple of recent studies have also suggested a different clinical phenotype of ANCA-positive patients with Churg–Strauss syndrome compared with ANCA-negative patients.

In GPA, the presence of PR3-ANCA appears most closely related to the development of vasculitic complications. Furthermore, systemic vasculitic relapses without recurrence of ANCA are extremely rare. Yet, remission may be maintained for extended periods of time in up to one-half of the patients despite the presence of ANCA. These clinical observations suggest that ANCA alone are not sufficient to cause disease activity, but ANCA seem to be required for the development of vasculitic complications of GPA and systemic relapses.

Many in vitro studies have demonstrated proinflammatory effects of PR3-ANCA and MPO-ANCA on neutrophils, monocytes, and endothelial cells, which enhance and perpetuate endothelial cell and tissue damage. ANCA may increase the adhesion of neutrophils to endothelial cells by enhancing the expression of cell adhesion molecules on endothelial cells. ANCA can activate primed neutrophils, resulting in the release of oxygen radicals and proteolytic enzymes. The latter may in turn induce endothelial cell apoptosis. ANCA-mediated neutrophil activation involves both Fc-γ–receptor engagement and recognition of expressed target antigen on the surface of primed neutrophils. ANCA may also cause endothelial cell damage by direct cytotoxicity or localized immune complex formation with target antigens bound to the endothelial cell surface. The latter may initiate localized complement activation. Finally, ANCA are thought to contribute to the recruitment of more inflammatory cells to the area of tissue injury by stimulating the release of chemotactic chemokines and agents from neutrophils, monocytes, and endothelial cells. For a detailed description of pathways and mechanisms by which ANCA may directly and indirectly contribute to damage of the vascular endothelium, the reader is referred to other recent reviews.

Many patients with ANCA-associated vasculitis relate the onset or recurrence of their disease to preceding infectious episodes. The following link to infection has been hypothesized. Most ANCA-mediated effects on neutrophils and monocytes require priming of the cells. This cytokine-dependent process is not unique to vasculitis. Cytokine stimulation of neutrophils and monocytes, typically by tumor necrosis factor (TNF), with resulting increased surface expression of ANCA-target antigens, occurs normally in the context of infections. Patients with active vasculitis have indeed been shown to have both increased expression of ANCA-target antigens on the surface of their neutrophils and elevated levels of TNF. In combination, these observations allow the hypothesis that neutrophil priming, which occurs in response to cytokine stimulation during infection, enables ANCA to interact with their target antigen on the neutrophil surface. This in turn sets the documented proinflammatory effects of ANCA in motion, which aggravate and perpetuate the inflammatory reaction at the endothelial cell interphase.

Rodent models of MPO-ANCA–associated vasculitis support this hypothesis of a pathogenic role of ANCA. They clearly indicate that ANCA contribute directly to the development of vasculitis and glomerulonephritis, and that the interaction of ANCA with its target antigen is required for the development of lesions. Furthermore, the localization of lesions is determined by the site of this interaction. At the same time, animal models support the significance of genetic determinants for the development of autoimmunity, vasculitis, and a specific phenotype with characteristic organ involvement and histopathological features. Finally, animal model studies indicate that infections may be significant disease modifiers. Even though proinflammatory effects of murine PR3-ANCA could also be documented in vivo, the animals did not develop organ pathology typical for GPA or MPA, and good animal model for PR3-ANCA–associated vasculitis remains elusive. This may be due to substantial differences between human and murine PR3, as the latter behaves more like human elastase than human PR3.

To date, the causes of the production and persistence of ANCA remain poorly understood. Yet infections may be instrumental for the development of this specific type of autoimmunity. ANCA directed against a broad variety of target antigens have been documented in association with viral, fungal, bacterial, and protozoal infections. In the rare instances of C-ANCA/PR3-ANCA observed in infections, the ANCA disappeared with appropriate antimicrobial therapy. These observations may suggest that ANCA can occur transiently in the setting of infection, and that the persistent ANCA response in patients with vasculitis may be the result of molecular mimicry in susceptible hosts. Subsequent diversification of T- and B-cell responses ("epitope spreading") may lead to responses against different epitopes on the same target molecule (intramolecular spreading) or extend to other molecules (intermolecular spreading. Bacterial superantigens have also been implicated in the pathogenesis of ANCA-associated vasculitis. GPA patients colonized with superantigen-producing *Staphylococcus aureus* are at high risk for relapse. GPA patients had expansion of T-cell clones expressing Vβ genes specific for *S. aureus* superantigens more frequently than controls. This supports the theory that *S. aureus* contributes to the pathogenesis of vasculitis. By inducing potent T- and B-cell activity, superantigens produced during an *S. aureus* infection could initiate and maintain both ANCA production and cytokine release, thought to be required for the cascade that results in necrotizing granulomatous inflammation and vasculitis.

■ TREATMENT OF ANCA-ASSOCIATED VASCULITIS

Treatment of granulomatosis with polyangiitis and microscopic polyangiitis, including management of patients who are refractory to standard therapy, is described below. In addition, treatment of eosinophilic granulomatosis with polyangiitis is considered.

Treatment of Granulomatosis with Polyangiitis and Microscopic Polyangiitis

The first goal of therapy for patients with ANCA-associated vasculitis is to induce a remission as quickly as possible, so that irreversible organ damage is minimized. To this end, early diagnosis and prompt application of an appropriate immunosuppressive regimen are crucial. At the same time the treatment plan needs to include the prevention of treatment-related toxicity. Once remission has been induced, the second goal of therapy is to maintain remission with as few side effects as possible. Finally, once the patient has enjoyed a stable remission, surgical interventions aiming to repair damage may proceed as necessary. These overarching principles apply to the therapy of both GPA and MPA.

Remission Induction Therapy

Remission induction therapy is best tailored to the patient's degree of disease severity, extent, and acuity. Patients who present with indolent GPA localized to the upper and/or lower airways and who are ANCA negative can be treated with trimethoprim/sulfamethoxazole (T/S) at a dose of 160/800 mg twice daily. The mechanism of action of T/S is unclear, but possibly related to antimicrobial effects on *S. aureus,* the organism most frequently cultured from the nostrils of patients with GPA. It is also possible that this agent has immune-modulatory effects not shared with other antibiotics. T/S monotherapy should not be used in ANCA-positive patients, in the setting of glomerulonephritis or any other severe disease manifestation, and patients treated with T/S need continued long-term observation, as some will later develop more severe disease manifestations requiring immunosuppressive therapy.

Standard remission induction therapy for most patients categorized as having "limited" or "nonsevere" or "early-systemic" GPA or MPA consists of oral prednisone at doses of 0.5 to 1 mg/kg per day (generally not to exceed 80 mg/d) in combination with methotrexate with a target dose of 20 to 25 mg once a week.[14,15] This dose can be applied orally or subcutaneously. To minimize toxicity and the risk of *Pneumocystis* pneumonia (PCP), this immunosuppressive regimen should be supplemented by folic acid, 1 mg/d and standard PCP prophylaxis.

For the last four decades standard remission induction therapy for patients with severe disease (also called "generalized" or "organ-threatening" disease) has consisted of oral prednisone in combination with oral cyclophosphamide at a dose of 2 mg/kg daily for 3 to 6 months.[16] One randomized controlled trial has shown that intravenous pulse therapy with cyclophosphamide consisting of three pulses of 15 mg/kg given 2 weeks apart followed by 15 mg/kg pulses given every 3 weeks for 6 months, is equally effective to induce remission in severe GPA or MPA.[17] Based on results from a large multicenter randomized double-dummy–controlled trial that compared four once-weekly doses (375 mg/m^2 of body surface) of rituximab to standard oral cyclophosphamide for remission induction in severe ANCA-associated vasculitis, rituximab has now been approved for this indication by most regulatory agencies across the globe.[18] The long-term follow-up of this study has shown that the efficacy of a single course of four once-weekly doses of rituximab (375 mg/m^2 of body surface) remains equivalent to continued standard daily oral immunosuppressive therapy with cyclophosphamide followed by azathioprine for 18 months.[19] These three remission induction regimens have been shown to be equivalent for newly diagnosed patients with severe GPA or MPA. Remission can be achieved in up to 90% of patients with either of these regimens. For patients presenting with a severe disease relapse, rituximab was found to be superior to cyclophosphamide.[18,19] Rituximab is also the preferred agent for young patients in whom fertility needs to be preserved. If oral cyclophosphamide is used, patients need to be monitored carefully to minimize the risk of bone marrow toxicity. The dose of cyclophosphamide should be adjusted in patients with impaired renal function, and the patient's complete blood counts need to be monitored at least biweekly for the duration of therapy. Optimal dosing with oral cyclophosphamide is achieved when the lymphocyte count is reduced, but the total white blood count is maintained above 3500. To avoid bladder toxicity of cyclophosphamide, the entire dose is applied in the morning and patients are instructed to drink at least 3 L of fluid per day.

In patients with rapidly progressive fulminant disease, such as those presenting with alveolar hemorrhage or rapidly deteriorating renal function, intravenous methylprednisolone, 1000 mg per day for 3 to 5 days may be necessary for effective control of inflammation. If this therapy does not generate the desired effects, plasma exchange should be implemented.[20,21]

Remission Maintenance Therapy

Once remission has been induced the prednisone dose is tapered gradually over the course of 5 to 6 months with the goal of complete discontinuation. Patients with limited or "nonsevere" disease should be maintained on methotrexate for remission maintenance.[15] Patients treated with cyclophosphamide for remission induction should be switched to either methotrexate or azathioprine for remission maintenance.[22] Azathioprine is preferred in patients with any degree of renal insufficiency. Mycophenolate mofetil is an alternative for patients who cannot tolerate either methotrexate or azathioprine for remission maintenance. However, mycophenolate mofetil appears less effective than azathioprine for remission maintenance. Remission maintenance therapy is continued for at least 12 months beyond achievement of remission, and longer in patients who have suffered relapses. Early discontinuation of immunosuppressive therapy is associated with an unduly high relapse rate. The need for remission maintenance therapy following remission induction with rituximab in newly diagnosed patients remains unclear. Over 18 months a single remission induction course of rituximab is as effective as oral cyclophosphamide followed by azathioprine, but PR3-ANCA–positive patients with GPA are at risk for relapse once peripheral blood B lymphocytes are reconstituted (after 6–12 months) and may benefit from long-term remission maintenance therapy.[23]

Long-term remission maintenance therapy with T/S beyond immunosuppression may also be beneficial. In one study, patients who received T/S at a dose of 160/800 mg twice daily had a lower rate of disease relapse than those who received placebo.[24]

Treatment of Patients Refractory to Standard Therapy

About 10% of patients do not respond adequately to therapy with cyclophosphamide and fail to achieve remission. These patients are particularly challenging. Anti–TNF-α agents have not been shown to be effective in such patients. One large multicenter, double-blind, placebo-controlled, randomized trial conducted in GPA, has shown no efficacy of etanercept when added to standard therapy.[25] Moreover, a higher frequency of malignancies was observed in the treatment arm compared with the control arm of that trial. All patients with malignancies had also received cyclophosphamide. For this reason, the use of etanercept in patients who have received cyclophosphamide is now strongly discouraged. Smaller, uncontrolled open-label studies with infliximab conducted in Europe have suggested some efficacy of that agent, but many complicated infections were observed in these patients. Over the last decade many cohort studies have found rituximab to be very effective in such patients, and rituximab has now become the *de facto* standard of care for refractory GPA.[26]

Supportive Therapy

PCP still carries a mortality of up to 35%. Therefore, PCP with T/S is recommended for all non–sulfa allergic patients with ANCA-associated vasculitis receiving immunosuppressive therapy including rituximab. Patients who have a sulfa allergy manifesting itself with a skin rash can be desensitized against the drug. Those who fail this approach or have other contraindications for the use of this drug should be given other agents for PCP prophylaxis. Patients receiving methotrexate for remission induction or maintenance should also receive PCP. This can be safely accomplished with T/S at recommended doses for this purpose, provided that folic acid, 1 mg daily, is also given. Patients undergoing intense immunosuppression during the remission induction phase may also benefit from prophylactic antifungal therapy. Finally, every patient treated with glucocorticoids for ANCA-associated vasculitis should receive osteoporosis prophylaxis with calcium and vitamin D supplements and possibly bisphosphonates.

■ TREATMENT OF EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS

Even though mortality of EGPA is lower than that of GPA or MPA, the management of EGPA remains a challenge. Systemic glucocorticoids are the cornerstone of therapy. There are no clinical trials that provide clear guidance. The reports from the French Vasculitis Study Group are difficult to interpret with respect to this disease, because patients with EGPA were not separated from those with polyarteritis nodosa and MPA, two diseases with distinct clinical manifestations, pathophysiology, and prognosis.[27,28] Yet, these studies suggest that it is appropriate to treat EGPA according to the principles applied to the management of GPA and MPA. Accordingly, cyclophosphamide should be added to glucocorticoids for remission induction in all patients with disease manifestations that threaten the patient's life or the function of a vital organ, that is, particularly those with central or peripheral nerve involvement, glomerulonephritis, heart involvement, or alveolar hemorrhage. Methotrexate, azathioprine, and mycophenolate mofetil have been used as glucocorticoid-sparing agents in less severe disease and for remission maintenance. Refractory disease and disease dominated by difficult-to-control eosinophilic inflammation may respond to interferon-α therapy.[29] However, continued long-term interferon-α therapy may be necessary, and this treatment carries the risk of substantial toxicity. More recently, small case series and a formal pilot trial have shown beneficial effects of rituximab, particularly in ANCA-positive patients with renal involvement.[30,31] Two pilot trials have documented substantial glucocorticoid-sparing effects of anti–interleukin-5 therapy with mepolizumab.[32,33]

OTHER DISORDERS PRESENTING WITH PULMONARY VASCULITIS

A broad spectrum of other disorders which may include pulmonary vasculitis is described below.

■ GIANT CELL ARTERITIS

Giant cell arteritis is a generalized inflammatory disorder involving large- and medium-sized arteries.[34] It is the most common form of vasculitis in the white population, and appears to affect predominantly elderly patients. Respiratory symptoms have been reported in up to 25% of patients. However, pulmonologists rarely see patients with giant cell arteritis for the management of its respiratory complications. Cough, hoarseness, and throat pain usually resolve promptly with prednisone therapy.[35] Chest roentgenograms and pulmonary function tests rarely show abnormalities attributable to the disease. Occasionally respiratory symptoms are the initial manifestations of giant cell arteritis. Therefore, this possibility should be considered in any elderly patient with new onset of cough, hoarseness, or throat pain without other identifiable cause, and it is reasonable to measure the erythrocyte sedimentation rate in such patients. Isolated cases with pleural effusion or multinodular pulmonary lesions have also been reported in giant cell arteritis. Such cases are difficult to interpret. Particularly in the latter situation, Wegener granulomatosis should be considered in the differential diagnosis, because it may also present with temporal arteritis.

■ TAKAYASU ARTERITIS

Takayasu arteritis is a large vessel vasculitis affecting predominantly the aorta and its major branches in young patients.[34] Pulmonary complications are the result of a unique arteriopathy predominantly of the large- and medium-sized pulmonary vessels. Progressive defects in the outer media of the arteries and ingrowth of granulation tissue–like capillaries associated with thickened intima and subendothelial smooth muscle proliferation lead to pulmonary artery stenoses and occlusion as well as pulmonary hypertension in up to one-half of all patients. The involvement of pulmonary arteries is common but often asymptomatic. It is detectable by conventional angiography, perfusion scan, or magnetic resonance angiography. CT may show areas of low attenuation as a result of regional hypoperfusion, subpleural reticulolinear changes, and pleural thickening. Fistula formation between pulmonary artery branches and bronchial arteries, as well as nonspecific inflammatory interstitial lung disease, has also been reported.

Therapy for Takayasu arteritis consists primarily of immunosuppression with glucocorticoids. Other immunosuppressive agents, including methotrexate are used as in conjunction with glucocorticoids for remission induction and as glucocorticoid-sparing agents for remission maintenance. Unfortunately, many patients relapse when the glucocorticoid dose is reduced below 15 mg daily. Most recently, the use of anti–TNF-α agents has been reported as beneficial in patients who are refractory to standard therapy. Vascular bypass or stenting procedures may be beneficial in severe disease, but their long-term benefits remain unclear.

■ CLASSIC POLYARTERITIS NODOSA

Since its formal separation from microscopic polyangiitis, this form of vasculitis affecting predominantly medium-sized vessels is diagnosed rarely. Because it does not affect capillaries, it does not cause either glomerulonephritis or alveolar hemorrhage. However, classic polyarteritis nodosa can affect the bronchial or bronchiolar arteries on rare occasions. Most cases of classic polyarteritis nodosa diagnosed today are associated with viral infections, specifically hepatitis B and C. Consequently, antiviral therapy plays a prominent role in the management of such cases in addition to immunosuppression. Classic polyarteritis nodosa is far less likely to relapse than microscopic polyangiitis, and therefore can generally be treated with a shorter course of immunosuppression.

■ BEHÇET DISEASE

Behçet disease is a rare chronically relapsing systemic inflammatory disorder characterized by aphthous oral ulcers and at least two or more of the following: aphthous genital ulcers, uveitis, cutaneous nodules or pustules, or meningoencephalitis. Respiratory manifestations are common in Behçet disease and include cough, hemoptysis, chest pain, and dyspnea.[36] Hemoptysis is often massive and fatal. The vasculitis of Behçet disease is immune complex mediated, and may affect vessels of all sizes. If the veins are affected secondary thrombosis with major venous occlusion can occur. This type of thrombosis may not be preventable by anticoagulation, but the use of aspirin 80 mg/d has been advocated. Massive hemoptysis is the result of destruction of the elastic lamina of pulmonary arteries leading to the characteristic aneurysm formation, secondary erosion of bronchi, and arterial–bronchial fistulae. Pulmonary artery aneurysms are detectable by CT or MR angiography, and pulmonary angiography is no longer

necessary. Recurrent pneumonia as well as bronchial obstruction as a consequence of mucosal inflammation has also been described.

Therapy of the underlying disease consists of immunosuppression. Prednisone alone may not be sufficient to control the vasculitis. The addition of other drugs, such as colchicine, chlorambucil, methotrexate, cyclosporin, or azathioprine is recommended. The addition of azathioprine or cyclophosphamide to glucocorticoids has resulted in resolution of pulmonary aneurysms. Once pulmonary arteritis has been identified in these patients, anticoagulation should be avoided. The prognosis of pulmonary involvement is poor. About one-third of patients die within 2 years of developing pulmonary involvement, most from fatal pulmonary hemorrhage. Embolization therapy may be used as treatment and prevention of hemorrhage from pulmonary artery aneurysms.

IDIOPATHIC PAUCI-IMMUNE PULMONARY CAPILLARITIS

Diffuse alveolar hemorrhage as a result of capillaritis in the absence of symptoms or serological evidence of any detectable underlying systemic disorder may occur rarely.[37] Direct immunofluorescence studies of the lung tissue did not reveal any immune deposits. This isolated pauci-immune pulmonary capillaritis is histopathologically indistinguishable from that of ANCA-associated vasculitis. It is a diagnosis of exclusion, and such patients are best treated with an immunosuppressive regimen according to the guidelines for severe Wegener granulomatosis or microscopic polyangiitis.

SYSTEMIC LUPUS ERYTHEMATOSUS AND OTHER COLLAGEN VASCULAR DISORDERS

The disease manifestations of SLE are highly variable. Pulmonary capillaritis leading to diffuse alveolar hemorrhage is rare in patients with SLE. However, it represents one of the most serious complications of the disease. In contrast to the pauci-immune pathology of ANCA-associated vasculitis, prominent immune complex deposits can be detected by direct immunofluorescence in the affected tissue of patients with SLE (Fig. 74-18). Hence, the development of pulmonary capillaritis in SLE is thought to be immune complex mediated. The onset of diffuse alveolar hemorrhage in patients with SLE is usually abrupt, and it is seldom the first sign of SLE. In the overwhelming majority of patients the rapid development of pulmonary infiltrates is associated with fever. Hemoptysis may be absent in up to one-half of the patients. Consequently, the differentiation of diffuse alveolar hemorrhage from infection may be difficult in patients with SLE, and may require a diagnostic bronchoalveolar lavage. Mechanical ventilation, infection, and cyclophosphamide therapy were identified as negative prognostic factors in one cohort.[38] However, no multivariate analysis was performed, and these factors may simply identify patients with more severe disease. The reported mortality from diffuse alveolar hemorrhage in SLE varies widely, between 0% and 90%. Treatment consists of glucocorticoids and cyclophosphamide.[39] The use of plasma exchange has been suggested, but its benefit remains unproved.

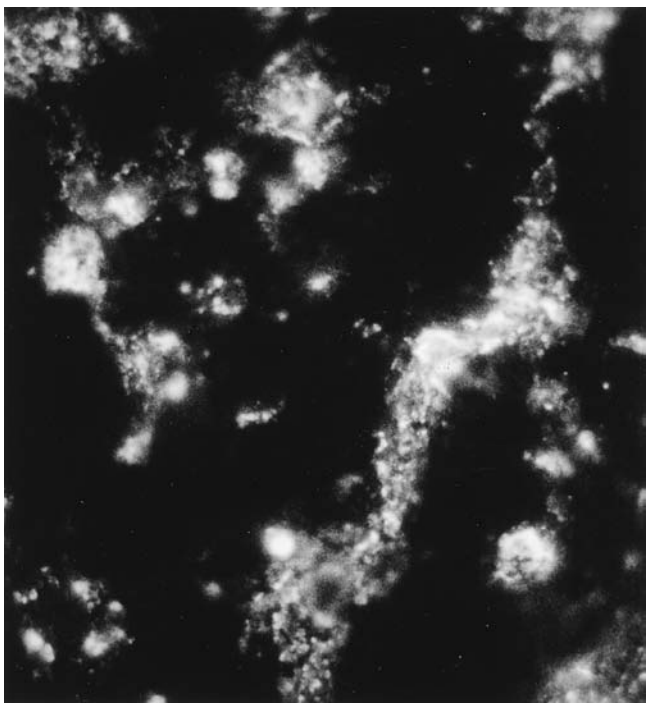

Figure 74-18 Lung biopsy of a patient with lupus erythematosus and alveolar hemorrhage showing so-called lumpy, bumpy deposition of immune complexes as demonstrated by direct immunofluorescence.

Respiratory complications are very common in all other types of collagen vascular or connective tissue disorders. However, pulmonary capillaritis presenting as diffuse alveolar hemorrhage is rare. Isolated cases have been reported with polymyositis, rheumatoid arthritis, and mixed connective tissue disease. Consequently, serological testing performed as part of an evaluation of diffuse alveolar hemorrhage should include studies aimed at the identification of these potential underlying disease entities.

ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid syndrome is defined by arterial and venous thromboses, or recurrent miscarriages occurring in patients with antiphospholipid antibodies (anticardiolipin antibodies, lupus anticoagulant, or both). If antiphospholipid syndrome in the context of another autoimmune disease, malignancy, or drug exposure, it is labeled secondary antiphospholipid syndrome. In the absence of other coexisting disorders, it is considered primary. Hypercoagulability can cause pulmonary embolism and infarction, pulmonary microthrombosis, and pulmonary arterial thrombosis with secondary pulmonary hypertension as consequence. However, primary pulmonary hypertension has also been reported in antiphospholipid syndrome. Acute respiratory distress syndrome (ARDS) is another possible complication of antiphospholipid syndrome. Antiphospholipid syndrome can also be complicated by diffuse alveolar hemorrhage, presenting with cough, dyspnea, fever, and bilateral pulmonary infiltrates. Because of this nonspecific clinical presentation, the possible occurrence of diffuse alveolar hemorrhage in the context of ARDS, and the lack of hemoptysis in over one-half of the reported antiphospholipid syndrome patients with alveolar hemorrhage, and early bronchoalveolar lavage may help in the differential diagnosis. Tissue necrosis from microthrombosis as well as pulmonary capillaritis has been implicated as the cause of alveolar hemorrhage in antiphospholipid syndrome. As in SLE, the capillaritis of antiphospholipid syndrome appears to be immune complex mediated. Most patients respond to glucocorticoids.[40,41] Yet, the coexistence of thrombosis and capillaritis with alveolar hemorrhage represents a therapeutic dilemma, as anticoagulation may need to be interrupted to control the hemorrhage. Early plasma exchange in addition to immunosuppressive therapy should be considered in patients with antiphospholipid syndrome and alveolar hemorrhage.[42]

ANTI–GLOMERULAR BASEMENT MEMBRANE DISEASE

Historically, the syndrome of alveolar hemorrhage and glomerulonephritis has been called Goodpasture syndrome. Today's terminology restricts the use of the term Goodpasture disease to alveolar hemorrhage or necrotizing glomerulonephritis caused by autoantibodies directed against the NC1-domain of the α3 chain of basement membrane collagen type IV. This epitope is only accessible for autoantibodies in the basement membranes of kidneys and lungs. Diffuse alveolar hemorrhage is common in anti–glomerular basement membrane (anti-GBM) disease but is thought

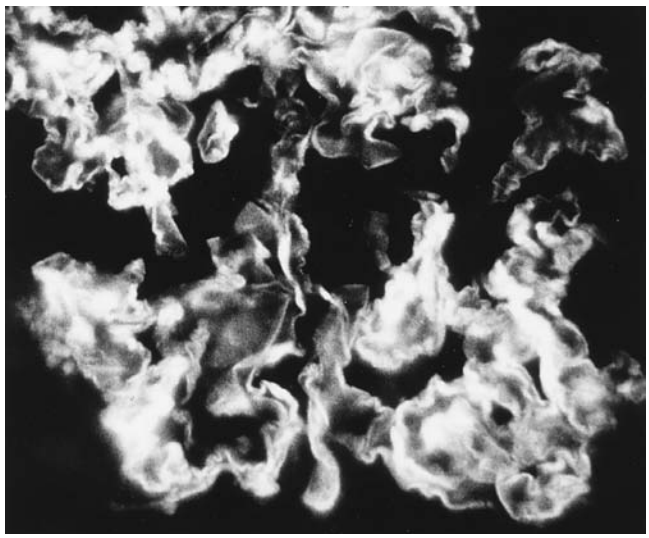

Figure 74-19 Kidney biopsy of a patient with anti–glomerular basement membrane (anti-GBM) disease showing linear immunofluorescence of the GBM due to fixation of IgG anti-GBM antibodies.

to require an additional inhalational injury, particularly smoking for the development of the pulmonary manifestation of this disease. Isolated alveolar hemorrhage in the absence of renal disease is rare in anti-GBM disease. The finding of circulating anti-GBM autoantibodies in the serum may facilitate the early implementation of appropriate therapy. However, methods used for their detection are of highly variable sensitivity and specificity, and a definitive diagnosis depends on the documentation of linear anti-GBM deposits in the kidney or lung (Fig. 74-19). In most patients, tissue from the kidney is more easily accessible for histopathological evaluation than lung tissue. Anti-GBM is arguably not a vasculitis. Bland pulmonary hemorrhage is the most frequently described histopathological pattern in diffuse alveolar hemorrhage associated with anti-GBM disease. However, capillaritis as a secondary histopathological feature has been encountered in some patients. Early implementation of immunosuppressive therapy in conjunction with plasma exchange is the key to a favorable outcome in patients with anti-GBM disease.[43]

IgA VASCULITIS (HENOCH–SCHÖNLEIN)

Henoch–Schönlein purpura has been renamed into IgA vasculitis (Henoch–Schönlein) as at the 2012 Chapel Hill Consensus Conference to reflect the evolving understanding of its pathogenesis. Pulmonary manifestations of IgA vasculitis are rare. Only 26 cases have been reported to date, and capillaritis has been documented histopathologically only in a minority of them.[44] IgA deposits along the pulmonary capillary walls, analogous to those found in vessels of the skin and glomeruli of affected kidneys are pathognomonic features of IgA vasculitis, detectable by direct immunofluorescence.

DRUG-INDUCED VASCULITIS

The list of drugs described in association with vasculitis includes a long list of therapeutic agents as well as drugs of abuse.[45] The clinical spectrum of drug-induced vasculitis ranges from isolated and mild vasculitis of the skin to severe multiorgan system disease. Small- to medium-sized vessels are usually affected. Based on clinical manifestations, drug-induced vasculitis cannot be distinguished from the primary vasculitis syndromes.

The following drug-induced syndromes merit special attention. First, a variety of drugs including propyl-thiouracil, D-penicillamine, hydralazine, sulfasalazine, minocycline, allopurinol, and others can induce an ANCA-associated vasculitis. Pulmonary capillaritis as a manifestation of an ANCA-associated vasculitis induced by these agents is well documented. Drug-induced ANCA-associated vasculitis should be treated with immunosuppression according to the principles for primary ANCA-associated vasculitis. However, once the offending drug has been eliminated, the likelihood of a relapse seems low.

The use of all-*trans*-retinoic acid in acute promyelocytic leukemia can cause a syndrome of fever, leukocytosis, fluid retention, hemorrhage, thrombosis, and organ failure. Pulmonary complications of this syndrome are frequent, and pulmonary capillaritis has been reported in this context.

Some chronic nasal cocaine abusers develop severe midline destructive lesions. In its early stage, such a lesion is clinically and histopathologically difficult to differentiate from limited Wegener granulomatosis, particularly in patients who do not volunteer the history of abuse.[46] The presence of ANCA reacting with human neutrophil elastase (HNE) appears to be an immunological marker separating patients with cocaine-induced midline destructive lesions from those with Wegener granulomatosis.[47]

More recently levamisole has become a common adulterant of cocaine.[48] Levamisole is a polyclonal B-cell–stimulating agent that can induce a variety of autoantibodies including antigranulocyte antibodies, antiphospholipid antibodies, and ANCA. The ANCA reactivity is directed against multiple target antigens including MPO, PR3, and HNE.[49] The clinical picture of patients exposed to levamisole can mimic systemic vasculitis.

PULMONARY CAPILLARITIS AFTER LUNG TRANSPLANTATION

Five cases of acute rejection after lung transplantation with prominent pulmonary capillaritis, histopathologically distinct from typical rejection, have been reported. In these cases, the capillaritis was

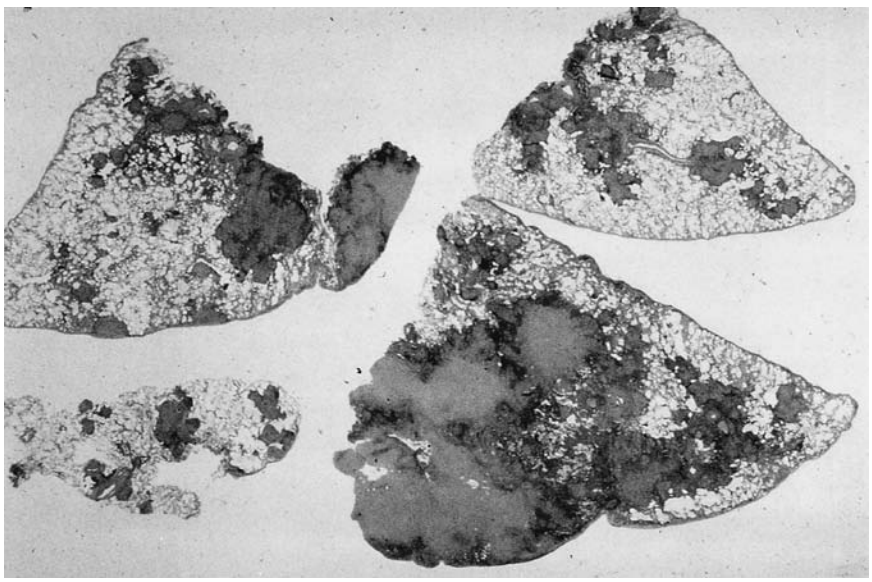

Figure 74-20 Low-power photomicrograph of lung revealing coalescing necrotizing granulomas in a patient with necrotizing sarcoid granulomatosis.

thought to represent a form of severe, acute vascular rejection. Early histological diagnosis and aggressive immunosuppression, possibly in conjunction with plasma exchange, was suggested to control the inflammatory activity and prevent relapses.

NECROTIZING SARCOID GRANULOMATOSIS

Vasculitis is a prominent histopathological feature of necrotizing sarcoid granulomatosis. The disease is usually limited to the lungs. The characteristic pulmonary nodules are bilateral, and may be an incidental finding in asymptomatic patients. Alternatively, patients may complain of cough, dyspnea, or phlegm production. Generalized constitutional symptoms occur rarely. The differential diagnosis of necrotizing sarcoid granulomatosis includes primarily infectious processes. Special sputum and tissue stains and cultures should always be obtained to exclude mycobacterial or fungal disease. Clinically, these patients are difficult to differentiate from limited Wegener granulomatosis. Histopathologically, there are characteristic necrotizing epithelioid granulomas that may form aggregates (Fig. 74-20). In contrast to Wegener granulomatosis, these granulomas are well circumscribed. Vasculitis is a central histopathological feature of necrotizing sarcoid granulomatosis. Liebow originally described three types of vasculitis: an epithelioid-granulomatous form, a form reminiscent of giant cell arteritis with prominent histiocytes and multinucleated giant cells in the inflammatory infiltrate of the vessel wall, and a lymphocytic form lacking granuloma formation and giant cells. The separation from sarcoidosis remains controversial. Yet, the extensive vasculitis and necrosis seen in necrotizing sarcoid granulomatosis are unusual for sarcoidosis. The chest roentgenographic appearance of pulmonary nodules, or masses and pleural involvement are also atypical for sarcoidosis. Finally, extrapulmonary involvement has only rarely been documented in necrotizing sarcoid granulomatosis.

It is debatable whether necrotizing sarcoid granulomatosis should be included with the systemic vasculitides. Most authors would argue against this inclusion because of its limitation to the lungs and good prognosis (spontaneous remission may occur). Therapeutically, necrotizing sarcoid granulomatosis can be approached as cases with chronic pulmonary sarcoidosis. Decisions about the use of oral glucocorticoid therapy should be individualized based on symptoms, pulmonary function data, and their evolution over time.

CHAPTER 75

Pulmonary Arteriovenous Malformations

Daniel M. Goodenberger
Murali Chakinala

HISTORY

Pulmonary arteriovenous malformations (PAVMs) were first described in the late 19th century; Churton[1] reported the autopsy findings in a young boy with cyanosis in 1897. Based on the correlation of physical with postmortem findings, the triad of cyanosis, clubbing, and polycythemia was identified with PAVM in 1932.[2] Hereditary hemorrhagic telangiectasia (HHT) was first connected to PAVM in 1938.[3] As described below (Causes and Disease Associations), HHT is often intimately related to PAVMs—a fact that prompts the following discussion of the history of HHT.

Hereditary epistaxis was first described in 1864,[4] though neither that nor Babbington's description a year later report an association with telangiectasia.[5] These reports were not generally recognized; nor were subsequent descriptions of telangiectasia, hereditary transmission, and epistaxis by Legg[6] in 1876, or a similar kindred reported by Chiari in 1887.[7] The first widely recognized connection of epistaxis to telangiectasia was made by Rendu in 1896.[8] Osler[9] added three cases, and recognized familial occurrence in 1901. Weber[10] elucidated the familial nature and lack of coagulation abnormality, and thus earned his eponymic association. By precedence of description, this eponym should be Rendu–Osler–Weber, even though Osler–Weber–Rendu is the most common usage.

Hanes[11] was responsible for naming the syndrome HHT, the designation now most often preferred, in 1909.

GENETICS

The genetic basis, if any, of isolated PAVMs remains unknown. HHT is an autosomal dominant disease. Its frequency was believed until relatively recently to be less than 3 per 100,000 people.[12] Newer studies suggest a much higher prevalence. The highest frequency reported, 1:1331, occurs in the Afro-Caribbean population of the Netherlands Antilles, presumably due to a founder effect.[13] Other estimates vary geographically; 1:6410 in Denmark,[14] 1:8000 in Japan,[15] and 1:16,500 in Vermont.[16] Phenotypic variation is extreme, ranging from asymptomatic to severely symptomatic, and from cases with no or few mucocutaneous lesions to those with diffuse cutaneous telangiectasias. For many patients, the disease remains undiagnosed by their primary care physicians, suggesting that disease frequency may be greater than reported, and that some patients with "isolated" PAVMs may actually have HHT.

A gene for HHT was first localized to chromosome 9, region q^{33-34} ($9q^{33-34}$).[17–19] Investigation revealed the protein product to be endoglin, which associates with the transforming growth factor-beta (TGF-β) bone morphogenetic protein (BMP) receptor complex and binds TGF-β-1 and -3.[20] The same work showed the disease to be genetically heterogeneous, with multiple mutations in the responsible gene. It rapidly became clear that there were other chromosomal mutations resulting in the same syndrome, and the endoglin mutation disease was designated HHT-I; it was noted to be associated more often with PAVMs than were those with non-$9q^3$ mutations.[21,22] A haploinsufficient mouse model also demonstrated phenotypic heterogeneity which was very dependent on the genetic background.[23]

The activin receptor–like kinase 1 gene (ALK-1 or ACVRL1) on chromosome 12 is the second locus for HHT.[24,25] It produces a TGF-β superfamily type I receptor. Mice heterozygous for a loss-of-function mutation in ALK-1 develop age-dependent vascular lesions in the skin, extremities, oral cavity and in the lung, liver, intestine, spleen, and brain, similar to those seen in HHT patients.[26] Disease resulting from mutations in this gene has been designated HHT-2.

A small number of patients with juvenile polyposis also have HHT. This is due to mutations in MADH4 (encoding SMAD4); SMAD proteins influence the cellular response to TGF-β through interactions with other SMADs as transcription factors.[27,28]

A fourth gene abnormality producing clinical HHT in one family has been described on chromosome 5. The gene product is as yet unidentified.[29]

A fifth genetic abnormality in a family with HHT has been described on the short arm of chromosome 7.[30] The gene product of this mutation is also unknown at present.

Most HHT appears to be caused by mutations in endoglin and ALK-1. Mutations can be identified in up to 88% of affected individuals[31,32]; in one series, 61% were in endoglin, 37% in ALK-1, and 2% in MADH4.[33] ALK-1 mutations appear to be more common in France and Italy, with endoglin mutations more frequent in northern Europe and North America.[31,32,34] PAVMs are more frequent and on the average of larger size in HHT-1.[35]

Genetic testing for mutations in endoglin, ALK-1, and MADH-4 is currently available from six laboratories in North America, and a number of other laboratories in Europe. An up-to-date list with contact information is maintained at http://hht.org. The primary role for testing is to identify a mutation in an index case who meets criteria for a diagnosis of HHT. If this is possible, the index case's children and other first-degree relatives may be screened. Those with negative tests may be reassured, and those with positive tests may be evaluated for complications of HHT. On occasion, a diagnosis may be confirmed in an index case when clinical criteria are insufficient for clinical diagnosis. As with all genetic diseases, testing should be accompanied by genetic counseling.

PATHOPHYSIOLOGY

Important pathophysiologic considerations of PAVM are discussed below.

STRUCTURE

The three essential structural elements of PAVMs are the arterial supply ("feeder vessel"), a draining vein, and the intervening aneurysmal sac. Because of this simple relationship, the label of "AVM" is a bit of a misnomer as these malformations are more characteristic of a fistulous connection between arterial and venous branches without a customary intervening capillary network that is vital for gas exchange. PAVMs appear to develop between precapillary arterioles and venules, with intervening epithelial dysplasia.[36,37]

Approximately 80% of PAVMs have a single feeding and a single draining vessel; the remaining 20% are complex, with two or more of each.[38] By far the most common form of PAVM has a pulmonary arterial supply and pulmonary venous drainage.[39] In one series, 60 of 63 PAVMs had a pulmonary arterial blood supply[40] but arteries from the systemic circulation can also be involved, including arterial branches from the internal mammary artery, intercostal arteries, and subdiaphragmatic arteries. While systemic "feeders" are prone to develop as sequelae of chronic suppuration in the lung (e.g., sequestration), postpulmonary infarction after pulmonary embolism, or postembolization of pulmonary artery-to-vein malformations,[41] this chapter will focus on the classic form PAVMs involving the pulmonary arteries.

PATHOGENESIS

Our evolving understanding of PAVM development was summarized in a recent and thorough review of HHT.[42] Briefly, pathogenesis of PAVMs is presumed to initiate from periods of increased angiogenic activity, possibly triggered at sites of vascular injury,[43] and likely spurred on by an imbalance between proangiogenic signaling and reduced antiangiogenic activity. Angiogenesis is dysregulated due to altered expression of TGF-β–mediated pathways in endothelial cells of the pulmonary circulation, which plays a critical role in endothelial cell homeostasis. Mutations in one of the HHT-causative genes (described earlier) leads to either altered ligand-receptor interaction at the endothelial cell surface (ENG or ACVR1) or intracellular signaling (SMAD4) within endothelial cells. Downregulation of TGF-β expression is postulated to permit excessive endothelial cell proliferation and increase blood vessel formation[44] (under the influence of proangiogenic signals from molecules such as vascular endothelial growth factor [VEGF]), form persistent direct arteriovenous connections,[45] and destabilize vessels due to interactions between endothelial and mural cells (e.g., pericytes, smooth muscle cells).[46] The lack of a capillary network within a PAVM and the direct communication between arterioles and venules exposes thin-walled conduits to arterial blood flow and increased shear forces. Again, genetic defects and dysregulated angiogenesis lead to a muted compensatory response within these "arterialized" veins that must dilate. Furthering this concept, work in an animal model of HHT suggests a two-step dysregulatory sequence culminating in AVM formation, whereby the initial endothelial cell proliferation is mediated by HHT-causing mutations[44] and the subsequent dilation and persistence of downstream arteriovenous communications is independent of the mutations and, indeed, may be a homeostatic response to altered upstream blood flow pattern.[47] Over time, these initial microscopic communications grow into macroscopic communications[48] notable for relatively increased flow and passage of material normally sequestered or cleared in the pulmonary microcirculation (e.g., air bubbles, thrombi, bacteria). Further work in this area should clarify the molecular steps from altered gene expression to dysregulated

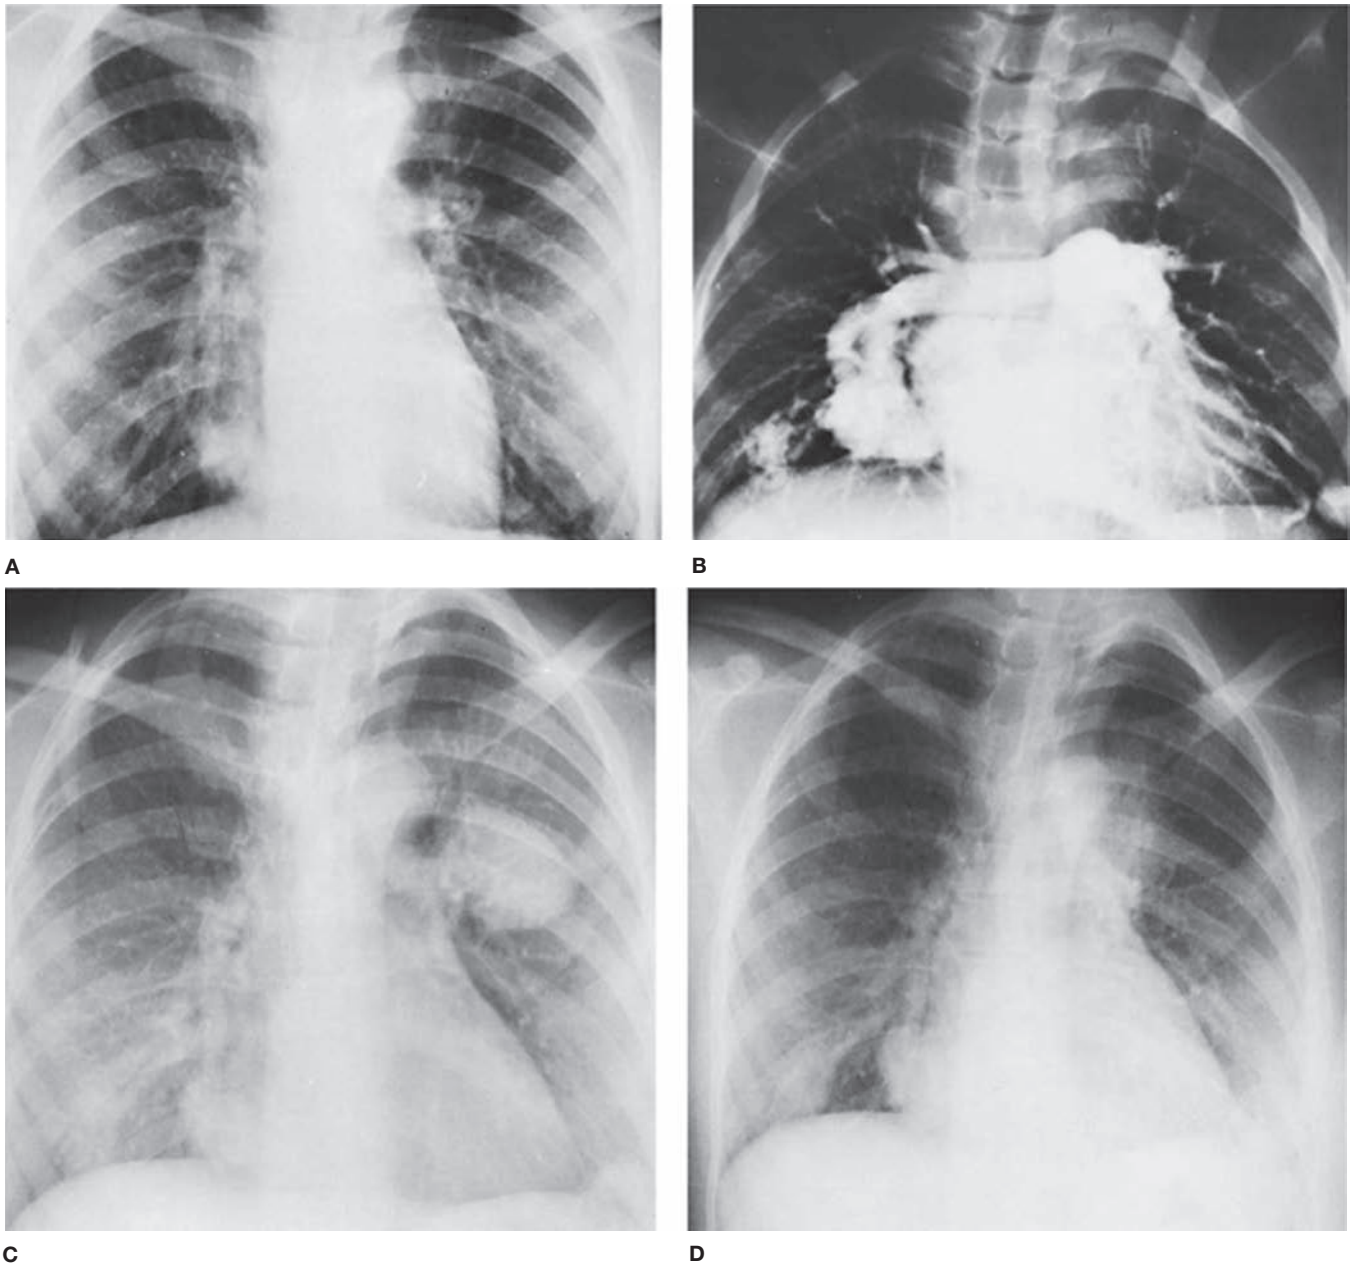

Figure 75-1 Pulmonary arteriovenous fistulas in a pregnant 24-year-old woman with hereditary hemorrhagic telangiectasia. **A.** Before pregnancy. Small nodular densities are seen at both bases and in the left hilus. The shunt was estimated to be 49% of the cardiac output. **B.** Arteriogram before pregnancy demonstrates arteriovenous fistulas of both lower lobes. **C.** Seven months pregnant, the patient was admitted to the hospital with hemoptysis and left hemothorax. The enlargement of the arteriovenous fistulas is striking. The pregnancy was terminated. **D.** Two weeks after termination of pregnancy, the nodular densities have decreased in size. *(Used with permission of Dr. M. Rossman.)*

multistep angiogenesis, discover precipitants of the dysregulated angiogenesis, and identify comediators, associated pathways, and environmental factors that influence angiogenesis.

Growth rates of AVMs remain unknown but is likely subject to intersubject variability and overall blood flow. One observed phenomenon of PAVM growth is accelerated growth during pregnancy leading to potential peripartum hemorrhagic complications,[49] which in part is theorized to occur due to increased blood flow and higher cardiac output of pregnancy but customary hormonal alterations of pregnancy could also be influential (Fig. 75-1).[50]

NUMBER

In one series, more than 60% of individuals present with more than one PAVM.[51] In general, multiple PAVMs correlate with HHT. A small percentage have diffuse, multilobar PAVMs that are typically bilateral and associated with marked hypoxemia.[52,53]

SIZE

PAVMs may vary from malformations too small to be seen by radiography or angiography[54,55] to those greater than 5 cm in diameter.[56]

LOCATION

Up to 65% of PAVMs are located in the lower lobes[55]—a phenomenon that may be due to the increased pulmonary blood flow and pressure, and subsequent "stretch" due to hydrodynamic forces. A recent small series noted less selectivity for the lower lobes in cases of "idiopathic" PAVMs.[57] The lower lobe location is the likely cause of the orthodeoxia (desaturation in an upright position) and platypnea (dyspnea in

an upright position) which are sometimes seen. These symptoms may also occur with cirrhosis, which has pulmonary vascular abnormalities see below "Other Associations". Location may also account for an increase in right-to-left shunt which occurs at total lung capacity.[58]

CAUSES AND DISEASE ASSOCIATIONS

Early observers thought that all PAVMs were due to HHT.[38] The estimates of frequency with which PAVMs are due to HHT have varied substantially, from 36% to 95%.[38,40,50,59,60] Most recent series report HHT in well over 90%.

Estimates of the percentage of patients with HHT who have associated PAVMs have varied widely. Different series have reported frequencies of 15%,[50] 20%,[61] 24%,[36] 33%,[62] 49%,[63] and 57%.[64] Frequency of PAVMs appears to be significantly greater in cases with ENG mutations, as opposed to ACVRL1 mutations.[65] Furthermore, overall PAVM detection rates are being influenced by improving imaging techniques that provide clearer resolution of the vasculature in the peripheral areas of the lung.

OTHER ASSOCIATIONS

Cirrhosis may result in diffuse small arteriovenous connections.[66] Nearly all such patients have cutaneous spider angiomas. The right-to-left shunt is probably due not to true PAVMs but, rather, to vasodilation of pleural vessels, which resemble cutaneous spiders, and increased numbers of peripheral small arteriolar branches with precapillary arteriole-to-venous connections in the peripheral respiratory lobule. As many as 44% to 60% may have positive contrast echocardiography indicative of intrapulmonary shunt;[67,68] many of these patients have shunt eliminated by liver transplantation. A PAVM of significant size, known as a Rasmussen aneurysm, may also develop as a result of tuberculosis.[69] Metastatic thyroid carcinoma, a highly vascular tumor, may mimic pulmonary arteriovenous fistula.[70] Cavopulmonary anastomosis, used in the palliation of functionally univentricular heart disease, results in pulmonary arteriovenous connections similar to those in cirrhosis, in approximately 10% of patients. The reasons are unclear.[71] Rarely, penetrating chest trauma may result in subsequent PAVM.[72]

PRESENTATION AND COMPLICATIONS

PRESENTATION

The occurrence and frequency of symptoms related to PAVMs depend on how the patients are found—that is, whether they present with manifestations of disease or whether they are discovered as a result of screening. When detection occurs as a result of screening in patients with HHT, between 25% and 59% are asymptomatic.[50,73–75]

The age at onset is usually in the third or fourth decade.[38] The mean age at detection in various series is remarkably constant at 38 to 40 years.[50,51,73,74] In one series, the patients ranged in age from 5 to 76 years, with a mean of 36; 26% presented at an age less than 21 years.[55] PAVMs are, however, uncommon in childhood; only 4% of affected persons are under 10.[78,79]

Pulmonary symptoms include dyspnea on exertion, with a frequency ranging from 27% to 71%.[21,40,55,80] Platypnea and orthodeoxia also may occur. Hemoptysis ranges in frequency from 4% to 18%.[21,51,55] Extrapulmonary symptoms include chest pain in 6%[81] and epistaxis (largely seen in HHT), ranging from 32% to 85%.[37,80,82] The mean age at onset of epistaxis in HHT is 12 years, with 54% of patients presenting by age 10. Severity of epistaxis ranges from mild to severe, with up to 45 episodes per month.[76] Headache is also remarkably common in HHT patients, occurring in 43%.[55] Transient ischemic attack (TIA) occurs in up to 57% of patients with PAVM, and symptomatic cerebrovascular accident in 18%.[55,76]

Physical signs due to the PAVM itself are relatively uncommon. As many as 25% of patients may exhibit no findings at all.[40] Hypoxemia, when present, is secondary to the right-to-left shunt, and may result in cyanosis and secondary polycythemia. This tends to occur in advanced disease, and has been reported in 9% to 73% (mean 30%).[40,59,76] The frequency of clubbing has been reported in an average of 32%[76]; it is much less common in our experience.[49,56] Clubbing is nearly always associated with cyanosis. Clubbing may resolve after the PAVM is removed[83] or occluded. A pulmonary bruit, which is often described, is also variable; its frequency, probably influenced by selection bias, ranges from less than 10% to 58%.[40,49,76,80]

Telangiectasia have been reported in up to 66% of patients with PAVM, depending on the frequency of HHT.[84] These small red vascular blemishes occur most frequently on the face, followed in descending order by the lips, nares, tongue, ears, hands, chest, and feet. They often increase in size and number with age, and cutaneous telangiectasias are seldom identifiable until the second or third decade.[37] We have been struck by the frequency with which classic tongue and lip telangiectasias have been passed off as nonspecific blemishes by primary care physicians.

Laboratory results are nonspecific. A complete blood count may show polycythemia, although in patients with HHT, this tendency may be overshadowed by iron deficiency anemia. Anemia was present in 94 of 292 (34%) in our series. This was more often due to GI bleeding when severe. GI blood loss of variable severity was present in 65 of 292 (22%).[56]

The severely affected person may have arterial hypoxemia at rest; those less severely affected may have orthodeoxia documented by supine and upright arterial blood gases.[85] Arterial blood gases, determined on blood samples drawn while the patient is breathing room air, followed by 100% oxygen, may reveal a significant right-to-left shunt.[86]

COMPLICATIONS

Pulmonary and neurologic complications of PAVMs are important considerations.

Pulmonary Complications

Significant hemoptysis occurs in fewer than 10% of patients; in our most recent series, it occurred in 5 of 142 (<4%). Two of five occurred during pregnancy.[56] It may be massive and life-threatening. Bronchial telangiectasias may be the cause,[62] but all cases in untreated patients in our experience have been due to PAVMs. An increasingly frequent problem in recent years is hemoptysis following extensive embolotherapy after a delay of months to years. This has generally been due to postembolization bronchial collateral formation.

Hemothorax has been reported in up to 9% of patients,[87] but is usually less than 2%.[76] Pregnancy has been associated with hemothorax on several occasions, perhaps related to PAVM enlargement.[88–90] Hemothorax may also occur without any other predisposing factors, presumably caused by rupture of large subpleural PAVMs into the pleural space.

Typically, PAVMs are associated with a normal or low pulmonary vascular resistance (PVR) as the direct arteriovenous communications are low-resistance circuits. However, pulmonary hypertension is encountered, albeit uncommonly, in the setting of PAVMs and HHT.[91] Pulmonary hypertension most often develops from increased pulmonary blood flow, which occurs in HHT because of massive hepatic arteriovenous malformations that rapidly return blood to the right side of the heart and lead to a high cardiac output state. The high output can be aggravated by concomitant chronic anemia from blood loss. In this situation, the PVR will be low as the entire pulmonary circuit, not just the PAVM, dilates to accommodate increased pulmonary blood flow; but the capacitance of the circuit has limits and additional blood flow will lead to mild pulmonary hypertension. In distinction, another more devastating

but rarer form of pulmonary hypertension can be seen in the setting of PAVMs, whereby the PVR is quite high due to a proliferative vasculopathy of small pulmonary arterioles.[92] In these rare cases, mutations occur primarily in ACVRL1 gene and represent a form of heritable pulmonary arterial hypertension (HPAH),[93] which is a form of Group I pulmonary hypertension in the Dana Point classification of pulmonary hypertension.[94] When PAH patients are discovered to have ACVRL1 or endoglin mutations during the genetic workup, PAVMs should be excluded as other clues for HHT can be subtle or absent in this rare population and PAH can be detected prior to a diagnosis of HHT being made.[95,96] When PAVMs coexist with significant PAH, caution must be exercised with PAVM embolization (see Treatment section) as sudden obliteration of the low-resistance circuit could significantly increase the PVR and unsettle an already fragile right ventricle or lead to other hemorrhagic complications[97,98]; these rare cases should be managed in a multidisciplinary fashion by individuals familiar with the management of PAVMs and PAH.

Central Nervous System Complications

The pulmonary capillary vascular bed appears to be an important filter for otherwise asymptomatic small emboli, and may also have a significant role in cleansing the bloodstream during transient bacteremia. Most neurologic complications, which occur in 8% to 12% of patients with HHT, are complications of PAVMs. In one series, 60% were due to PAVM, including brain abscess, paradoxical embolus, and hypoxemia.[37,99]

TIAs occur in approximately 37% of patients with PAVMs.[55] PAVMs can cause symptomatic cerebrovascular accidents (Fig. 75-2); the frequency of this complication ranges from 6% to 27%.[40,55,76] In our clinic, 28 of 132 patients screened by magnetic resonance imaging (MRI) had evidence of prior paradoxical embolic stroke.[56] Unfortunately, paradoxical embolization to the brain may be the first manifestation of an occult pulmonary venous malformation. This has been a particularly regrettable repetitive problem in young women who smoke and take oral contraceptives. Care should be taken to avoid air embolism; IV should be free of air and a micropore inline filter used.

Brain abscess occurs in 3% to 10% of patients with PAVMs.[37,76] In a series in our clinic, 5/132 (4%) had prior brain abscess.[56] Up to 1% of HHT patients may have brain abscesses (1000 times the incidence in the general population). In one series, 5 of 31 patients had recurrent abscess[100]; in another, 6 of 128.[101] Up to 8% of brain abscesses in the general population may be due to PAVMs.[102] Unfortunately, brain abscess may also be the first symptom of an occult PAVM (Fig. 75-3), and many years may elapse before diagnosis of PAVM (Fig. 75-4). Most occur following dental work. For that reason, antibiotic prophylaxis following the standard American Heart Association protocol for prevention of endocarditis is recommended.[103]

Migraine is more common in HHT than in the general population, and appears to be more common in those with PAVM. In one series, migraine occurred in 88 patients with HHT, a prevalence of 16.4%. The prevalence of migraine in patients with PAVM was 21.2%, which

was significantly higher than in patients without PAVM (13.3%).[104] In our experience, migraines occurred in 74/292 (25%) with HHT.[56]

Cerebral arteriovenous malformations (CAVMs) occur in 4% to 8% of patients with HHT[55,105] and tend to run in families.[106] Although CAVMs are not complications of PAVMs, they occur more frequently in patients with endoglin mutations, as do PAVMs. In our series of 149 patients screened by MRI, 11 had CAVM (7%). An additional 16 (11%) had telangiectasia or venous angioma (11%).[56] It is recommended that individuals with HHT, including children, be screened for CAVM.[103] The hemorrhage rate in individuals with cerebral AV malformations appears to be 0.5% annually, less than that in the non-HHT population with cerebral AVMs.[107] Cerebral MRI is currently the most sensitive noninvasive test, although it will fail to detect a significant proportion of AVMs.[105] MRI may be performed in patients with pulmonary AVMs embolized with both stainless steel coils and platinum Nester coils in machine with fields up to 3.0 T[108]; we have performed many such cerebral MRI examinations without complications, although the MRI is not done for a minimum of 6 weeks after embolotherapy.

DIAGNOSIS

Diagnostic evaluation of suspected PAVMs includes assessment of chest radiographs and CT scans, supplemented by additional studies, as warranted.

EVALUATION OF A RADIOGRAPHIC ABNORMALITY

Discovery of a nodule on chest x-ray is typically followed by CT scan of the chest. This may show the typical lesion with feeding and draining veins (Fig. 75-5),[3] but vascular tumors may cause false-positive results. Evidence of intrapulmonary right-to-left shunt confirms the diagnosis. A perfusion lung scan may detect a right-to-left shunt. Ordinarily, 95% of the technetium-labeled macroaggregated albumin, with an average diameter of approximately 35 μ, is trapped in the pulmonary capillaries. When there is an intracardiac or intrapulmonary shunt, unusually large amounts may pass through the lung and travel to the brain and kidneys, resulting in excess radioactivity in those areas. However, this method cannot differentiate intracardiac from intrapulmonary shunt.

Echocardiography, using indocyanine green as a contrast material, was found to be effective in the diagnosis of intrapulmonary shunt, with delayed appearance of the contrast material in the left side of the heart.[109] This was simplified and improved by the use of agitated saline as contrast (Fig. 75-6) (Video 75-1).[110] The intrapulmonary nature of the shunt can be determined by the delay, averaging four to five cardiac cycles, of left heart contrast appearance. If contrast echocardiography is negative, a PAVM is very unlikely, and an alternative cause of the pulmonary nodule should be sought. On rare occasions, if the PAVM is fed by a systemic artery, the contrast echocardiogram will be negative, and bronchial and/or internal mammary angiography should be undertaken if suspicion is high.

SCREENING OF PROBANDS OR RELATIVES WITH HHT

Because the majority of PAVMs occur in HHT, it is important to evaluate individuals with PAVMs for HHT, and to screen individuals with HHT for PAVMs. Criteria for diagnosis of HHT include (1) spontaneous and recurrent epistaxis; (2) multiple characteristic telangiectasia (typically found on lips, tongue, malar eminence, pinnae, and digits); (3) visceral lesions (gastrointestinal telangiectasia with or without GI bleeding, PAVMs, hepatic arteriovenous malformations, CAVMs, and spinal AVMs); (4) family history with a first-degree relative with HHT.[111] In addition, relatives of patients with HHT should be evaluated for that diagnosis. Those found to have HHT should be screened for PAVMs. Consensus of an international panel was that screening should occur at the time of diagnosis, including children.[103]

The reported sensitivity of chest radiographs varies widely, depending on whether they are used for screening or in patients with symptomatic disease. Rates of abnormality on the chest radiograph range from 41%[75] to 100%.[40] In our experience, chest

radiography does not reliably detect PAVMs less than 20 mm in size (Fig. 75-7), and it may miss larger PAVMs when they are located in radiographically inopportune places, such as the costophrenic sulci, the retrocardiac region, or the proximal hila (Fig. 75-8).[86]

Arterial blood gases, determined on samples drawn while the patient is supine and upright, have been advocated for screening.[85] However, this technique has not proved useful. Various combinations of shunt measurement utilizing albumin microspheres labeled with technetium-99m, Pa_{O_2} on room air, shunt measurement in subjects breathing 100% oxygen, and erect oxygen saturation measurement have been utilized, but all have insufficient sensitivity, specificity, or both.[14,78,112–114]

Contrast echocardiography is more sensitive than symptoms, plain radiography, measurements of Sa_{O_2}, Pa_{O_2} on room air, and Pa_{O_2} breathing 100% oxygen.[14,63] It is positive in 55% to 73% of those with HHT,[56,112] and may be the only positive screening study in 31% of patients.[113] Eighty percent or more will have persistently positive contrast echo findings after undergoing embolotherapy.[115] In patients with diffuse small PAVMs or telangiectasia, transesophageal contrast echocardiography may provide the definitive evidence.[116] On the basis of the preceding information, a screening algorithm based on contrast echocardiography and anteroposterior chest radiograph, followed by chest CT if either test is positive, is used in many centers.[63] This algorithm is based on studies in which CT without contrast was used as the "gold standard," with confirmatory pulmonary angiogram only if positive, and has been recommended by the international HHT working group.[103]

The sensitivity and specificity of chest CT are unknown, although this modality is significantly more sensitive than are chest radiographs.[85] One early study suggested that CT enabled identification more than 98% of PAVMs and was superior to pulmonary angiography.[117] CT has also been advocated for pretherapy planning.[118]

Our center for many years followed a scheme in which patients with HHT are screened with saline contrast echocardiography. Those with positive findings underwent pulmonary angiography. This approach identified PAVMs in 57% of patients screened. In combination with our observations regarding false-negative chest CT, we believed the frequency of PAVMs identified, greater than in any other series, justified this approach. In ~15% of patients with angiographically detectable PAVMs using this approach, no therapeutic embolization results. These PAVMs represent an opportunity to more fully understand the natural history and complication rates of PAVMs.[64]

Technology has an impact on this approach. Contrast-enhanced 64-row multidetector array chest CT with reconstruction is now used in our center as an alternative to diagnostic angiography (Video 75-2). Results to

date suggest that this technique is at least equivalent to pulmonary angiography (Fig. 75-9).

TREATMENT

The earliest treatment of PAVMs was thoracotomy and resection. Pneumonectomy was the first successful surgical approach, reported in 1942.[119] As thoracic surgery improved, the extent of resections diminished; by 1959, local excision was the procedure of choice.[62] Surgical removal of a PAVM inevitably results in loss of viable lung tissue, a problem for patients with multiple PAVMs; the record is probably held by a patient who underwent staged bilateral thoracotomies with removal of 23 PAVMs, with substantial symptomatic improvement.[120] Thoracoscopic resection has more recently been described.[121] Although surgical mortality can be as low as 0%,[62] the general anesthesia, morbidity of thoracotomy, and loss of viable lung tissue made a new approach desirable.

Embolization of PAVMs has proved to be an excellent alternative. This procedure was first performed using homemade coils. The procedure was refined and perfected at Johns Hopkins by Terry et al.[122] The original procedure utilized silicone balloons unless the feeding vessel was larger than 9 mm in diameter, in which case embolization

coils with thrombogenic Dacron tails were used (Fig. 75-10A–C).[55] Generally, all PAVMs with feeding vessel diameter of 3 mm or larger are embolized. Results have been very good, with success rates greater than 93%,[123] and embolization therapy is now the procedure of choice, with an apparent mortality of 0%, few serious complications, minimal loss of pulmonary parenchyma, and no exposure to anesthesia or thoracotomy. Silicone balloons are no longer available and are of historic interest only. Recently, many interventional radiologists have preferred using vascular plugs for larger feeding vessels, reserving coils for small or more tortuous vessels. Advantages include occlusion with a single device, allowing decreased operative time, and possible reduction in reperfusion (Fig. 75-11A–C).[124]

Pregnant women requiring urgent embolotherapy because of hemoptysis or hemothorax may safely undergo embolization, with radiation exposure to the fetus acceptable after 16 weeks of gestational age, with successful pregnancy outcome.[77] Absent those complications, embolotherapy may be deferred until the patient is postpartum.

Embolotherapy may also be performed safely and effectively in children.[125]

There are some limitations. The feeding vessel must be 2 to 3 mm in diameter or larger. It is technically feasible to embolize most PAVMs, but occasionally this is not possible. All but three patients in our 24-year experience have been able to be treated with embolotherapy (2/132 in the most recent series).[56] A majority will have persistent intrapulmonary shunt and should receive predental antibiotic prophylaxis.[115]

Reperfusion of the embolized vessel may occur in up to 15%.[80,126,127] This may require repeated embolotherapy. The current standard is follow-up by CT at 6 months, and if negative, every 3 years thereafter.[103]

While observations documenting serial growth of small PAVMs are somewhat limited, there is published evidence to support their growth with time.[12,40,60,80,128,129] Progression of PAVMs appears more likely in those with multiple PAVMs.[75] It has been suggested that patients with treated PAVM need follow-up every 5 years to detect growth of small PAVMs that could become large enough to cause paradoxical embolization and stroke.[103]

In general, successful embolization of most or all visible PAVMs results in abatement of hypoxemia and its complications,[128,130] but a

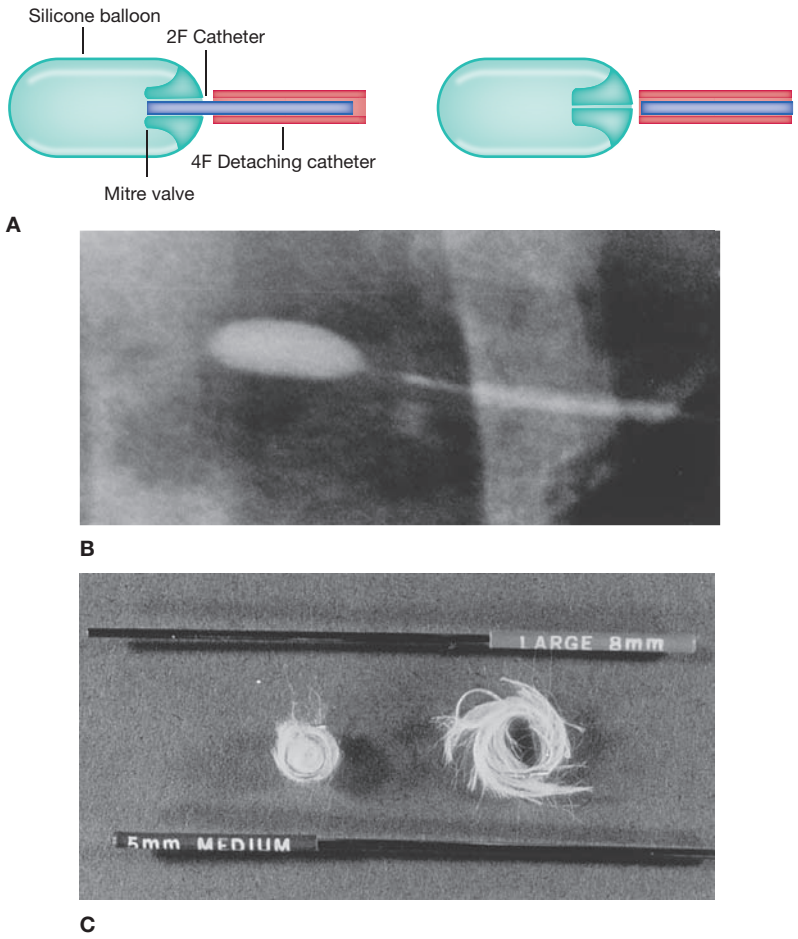

Figure 75-10 Embolotherapy devices. **A.** Detachable balloon mechanism from catheter. **B.** Fluoroscopic image of balloon in vivo. **C.** Embolization coils of two sizes.

small number of patients have diffuse small PAVMs not amenable to embolization.

Occlusion of all PAVMs with feeding vessels 3 mm or larger greatly reduces the risk of embolic stroke. Complex PAVMs must have all feeding vessels embolized for success. Embolotherapy may reduce the risk of brain abscess, but abscess may recur even after successful therapy.[129] Although no data regarding efficacy exist, standard American Heart Association endocarditis guidelines for antibiotic prophylaxis before embolotherapy is recommended.[103] Because of the frequent observation of small persistent left-to-right shunt demonstrated by echocardiography even after successful embolotherapy, antibiotic prophylaxis is recommended for dental and other surgical procedures.[103]

In general, those PAVMs which may feasibly be embolized should be occluded at or around the time of discovery, as immediate embolotherapy on detection results in improved life expectancy and quality-adjusted survival.[131]

Serious complications of embolotherapy are rare. Because of the potential for systemic air and particulate embolism, all intravenous tubing is equipped with micropore filters and embolization precautions are taken. Air embolism during the procedure is rare, occurring in less than 5% in one series. It is generally manifested by perioral paresthesias or angina without permanent effect.[55] The most common postembolization symptom is pleurisy, and has been reported at rates ranging from 10% to 31%.[55,80,132] The onset may be delayed for up to 17 days in our experience, and severity may range from mild pain to a level of discomfort requiring hospitalization. These episodes are sometimes accompanied by large pleural effusions. The effusions and resulting hypoxemia always resolve within several weeks. Other complications have included migration of an embolic device, PAVM perforation, TIA, early cerebral infarction after embolization, and paradoxical embolization of a device during deployment (4%).[128,129,132–134]

Diffuse PAVMs resulting in hypoxemia are difficult to treat with embolization therapy. Multiple embolizations tend to result in modest improvement at best, and posttherapy complications may be severe.[53,135] Those which are not amenable to embolotherapy represent a particularly difficult problem. A few such cases have been successfully treated with lung transplantation.[136,137]

FOLLOW-UP AND PROGNOSIS

Patients with HHT and screening negative for PAVM should have repeat screening (a) after puberty; (b) after pregnancy; (c) within 5 years of planned pregnancy; and (d) every 5 to 10 years routinely.[103]

Early reports suggested a high mortality for patients who did not undergo treatment of PAVMs. Examination of family trees in older reports impresses one with the frequency of death from meningitis, brain abscess, and stroke. Some of this apparently high mortality may have been due to selection bias. More recent studies suggest that the prognosis may be more benign, and complications may be nonexistent when PAVMs are discovered by screening.[75] In one series, mortality was approximately 10%. Two-thirds of deaths were due to cerebrovascular accident, and all of these patients were cyanotic and polycythemic.[40]

In summary, patients with PAVM can be successfully treated, with resolution of essentially all symptoms and substantial reduction in risk of complications. Embolotherapy is the treatment of choice for most patients. The relatives of patients with PAVMs or HHT should be screened with contrast echocardiography to prevent central nervous system complications as the first manifestation of disease. Patients with PAVMs should be fully educated about their diagnosis, potential clinical complications, and the often hereditary nature of the problem. Educational materials for patients with HHT, and the location of specialized centers for managing HHT and PAVM are available from the HHT Foundation International at http://hht.org. Caregivers are also urged to consult the website for updated recommendations.

78 **Pneumothorax** 1197

CHAPTER 76

Nonmalignant Pleural Effusions

John E. Heffner*

INTRODUCTION

Nonmalignant pleural effusions develop as a consequence of diverse extrapleural conditions that secondarily affect the pleural space. These disorders include systemic diseases (e.g., lupus), disorders of individual organ systems (e.g., chronic pancreatitis, congestive heart failure [CHF]), trauma and surgery, and iatrogenic interventions (e.g., drug related). Pleural fluid (PF) collects by one or more mechanisms: (1) pleural injury that causes increased pleural membrane permeability and protein-rich exudates, (2) increased intravascular hydrostatic forces and/or decreased oncotic forces that cause protein-poor transudates, and (3) extravasation of fluid from lymphatic or vascular structures or from an adjacent body compartment into the pleural space.[1]

Determining the etiology of a pleural effusion requires a sequential approach that begins with a detailed history and physical examination. Exposures and past occupations (e.g., tuberculosis, asbestos), underlying known conditions (e.g., rheumatoid arthritis [RA], CHF, pneumonia), and subtle symptoms related to a disorder not yet diagnosed (e.g., muscle weakness from myositis) may suggest the probable cause of an effusion. A thorough physical examination may detect abnormal nails with lymphedema suggesting yellow nail syndrome (YNS) or a malar rash indicating lupus pleuritis. Often the history and physical examination provide more diagnostic information than PF analysis or pleural biopsy, which may be nondiagnostic.

A differential diagnosis formulated from the history and physical examination guides a focused evaluation with imaging studies. Initial studies may examine nonpleural structures rather than the pleural space itself. Echocardiography, for instance, may establish CHF or pericarditis as the cause of a pleural effusion. Abdominal computerized tomography (CT) may detect hydronephrosis that underlies urinothorax. Among pleuropulmonary imaging studies, ultrasonography (US) and chest CT with pleural phase contrast enhancement provide detailed examinations of the pleural space, lung, diaphragm, and mediastinal structures that surpass the diagnostic value of standard chest radiography.

Portable US is highly sensitive and accurate for detecting and measuring the volume of PF.[2] It also gauges pleural thickness and defines pleural masses, loculations, and the viscosity of PF for diagnostic purposes, guiding thoracentesis and pleural biopsy. Chest CT allows imaging of interlobar and paramediastinal pleural surfaces beyond the reach of US in addition to associated lung abnormalities.[3] Like US, CT imaging can guide pleural biopsy and interventions to drain the pleural space. CT angiography allows the diagnosis of pulmonary embolism, which is increasingly recognized as a cause of exudative effusions.[4]

Thoracentesis is indicated for all patients with an undiagnosed pleural effusion in the presence of >1 to 2 cm of layering fluid detected by imaging studies unless CHF is the probable cause. Categorization of the fluid as a transudate or exudate simplifies the differential diagnosis, because conditions associated with PF formation tend to cause effusions of one of these types. Light's three-criteria rule has been the traditional approach for identifying exudative effusions (Table 76-1). Although the Light's criteria rule has a high sensitivity; it requires blood tests, suffers from mathematical coupling with two of its criteria, both using PF lactate dehydrogenase (LDH), and misclassifies with its modest specificity up to 30% of patients, when any one of the three test results return values close to its cutoff point (e.g., 15% of malignant effusions misclassified as transudates).[5] Alternative rules listed in Table 76-1 avoid some of these limitations and perform equally well as Light's criteria.[6–9] A battery of routine and specialized PF tests may be indicated depending on the pre-thoracentesis differential diagnosis (Table 76-2).

Pleural biopsy provides diagnostic value for patients with exudative effusions who remain undiagnosed after thoracentesis. Approaches to pleural biopsy include closed needle biopsy with an Abrams needle, which is indicated when tuberculous pleuritis is likely, image-guided percutaneous pleural biopsy, and biopsy by video-assisted thoracoscopic surgery (VATS), medical thoracoscopy, or pleuroscopy.[10,11]

CAUSES OF PLEURAL EFFUSIONS THAT ARE USUALLY TRANSUDATES

A number of causes of transudative pleural effusions have been recognized. Each is discussed below.

CONGESTIVE HEART FAILURE

CHF represents the most common cause of transudative effusions, present in 50% to 90% of patients hospitalized for CHF.[12,13] PF accumulates when elevated left atrial pressure generates pulmonary edema that provokes leakage of interstitial lung water down a hydrostatic pressure gradient into the pleural space.[14,15] Left ventricular failure has been considered an essential factor for producing CHF-related effusions.[16] However, small pleural transudative effusions may occur in ~20% of patients with pulmonary arterial hypertension and isolated right ventricular failure,[17] which may develop because raised systemic venous pressures increase fluid filtration from chest wall veins into the pleural space and/or impede egress of PF via parietal pleural lymphatics.

Pleural effusions due to CHF are usually bilateral (60%–85%); unilateral effusions are more commonly right sided in a 2-to-1 right-to-left ratio.[18] Although CHF is the most common cause of bilateral pleural effusions,[18] bilateral effusions in the absence of cardiomegaly suggest a malignant etiology. PF may collect in interlobar fissures and produce the imaging finding of a "pseudotumor."

Typical presentations of CHF warrant a trial of diuresis and monitoring for resolution of PF. Thoracentesis is indicated for evaluating atypical clinical presentations and failure of PF to resolve. PF

TABLE 76-1 Rules to Classified Pleural Fluid as Exudate Versus Transudate

Rule	Criteria
Light's criteria	PF/serum protein ratio >0.5, or PF/serum LDH ratio >0.6, or PF LDH > two-thirds upper limits of the laboratory's normal serum LDH
Rule that does not require serum tests	PF protein >2.9 g/dL, or PF cholesterol >45 mg/dL, or PF LDH >0.45 times upper limit of the laboratory's normal serum LDH

LDH, lactate dehydrogenase; PF, pleural fluid; S, serum.

TABLE 76-2 Pleural Fluid Test Results and Commonly Associated Conditions

Test	Result	Most Common Suggested Conditions
Erythrocytes	PF/S HCT >0.5	Hemothorax
Neutrophils	>10,000/μL	Parapneumonic effusion, lupus pleuritis, acute pancreatitis
	>50,000/μL	Empyema
Lymphocytes	>85–95%	TB pleurisy, sarcoid, chronic rheumatoid pleurisy, yellow nail syndrome, chylothorax
Eosinophils	>10%	Hemothorax, pneumothorax, benign asbestos pleurisy, pulmonary infarction, coccidioidomycosis, paragonimiasis and other parasites, drug-induced pleurisy, duropleural fistula, Churg–Strauss syndrome, sarcoidosis, TB pleurisy
Protein	<1 g/dL	Peritoneal dialysis, CVC erosion, duropleural fistula
	>4 g/dL	TB pleurisy
LDH	>1000 IU/L	Bacterial empyema, paragonimiasis, amebic empyema, septic emboli, rheumatoid pleurisy
Glucose	PF/S <0.5	Complicated parapneumonic effusion, chronic rheumatoid pleurisy, paragonimiasis, amebic empyema, esophageal rupture, TB pleurisy, lupus pleuritis, urinothorax
	PF/S >1	Peritoneal dialysis, CVC erosion
pH	<7.30	Esophageal rupture, chronic rheumatoid pleurisy, complicated parapneumonic effusion, paragonimiasis, amebic empyema, TB pleurisy, lupus pleuritis, urinothorax, pancreaticopleural fistula
Amylase	Elevated	Esophageal rupture, acute pancreatitis, pancreaticopleural fistula
Cholesterol	>200 mg/dL	Cholesterol effusion
Creatinine	PF/S >1	Urinothorax
Beta 2 transferrin	Elevated	Duropleural fistula, ventriculoperitoneal shunt migration
Triglycerides	>110 mg/dL	Chylothorax, CVC erosion if lipids infused
Chylomicrons	Present	Chylothorax
Bilirubin	PF/S >1	Biliopleural fistula
Glycine	PF/S >1	Glycinothorax
ADA with lymphocytosis	>40 IU/dL	TB pleurisy

ADA, adenosine deaminase; CVC, central venous catheter; TB, tuberculous.

is characteristically a transudate. Up to 30% of effusions, however, fulfill Light's criteria for an exudate for several possible reasons.[19,20] Most commonly, a coexisting condition that causes exudative effusions, such as pneumonia or pulmonary embolism, is the actual cause of the effusion.[21] Less commonly, diuretic therapy for CHF promotes more rapid reabsorption of intrapleural fluid as compared with protein and LDH, which creates a concentrating effect on PF. Finally, some CHF-related effusions have PF erythrocyte count >10,000/μL, which causes sufficient release of LDH from red cell autolysis to fulfill Light's criteria for an exudate.[22] Several strategies exist to determine that an exudative effusion in the setting of CHF is due to heart failure rather than a comorbid condition (Table 76-3).

Pleural effusions due to CHF gradually resolve as cardiac performance improves with therapy. Patients with large, symptomatic effusions may benefit from therapeutic thoracentesis when a response to cardiac therapy is delayed. Rarely, effusions in patients with refractory heart failure may require pleurodesis to manage PF-related respiratory symptoms, but outcomes data for this approach are limited.[30] Placement of a tunneled catheter for intermittent drainage at home provides additional palliative support.[31–33]

HEPATIC HYDROTHORAX

Hepatic hydrothorax defines a transudative effusion in a patient with cirrhosis and portal hypertension in the absence of another explanation for the effusion.[34] Although only 6% of patients with cirrhosis and portal hypertension have clinically apparent hepatic hydrothorax,[35–37] 15% of cirrhotics have evidence of effusions when examined by CT or US.[38]

Hepatic hydrothorax develops when ascites accumulates, raising intraperitoneal pressure that herniates blebs of peritoneum into the

TABLE 76-3 Rules for Evaluating Heart Failure–Related Effusions Misclassified as Exudates

Test Results	Comments
• PF-to-S albumin gradient >1.2 g/dL • PF/S albumin ratio <0.6 • PF-to-S protein gradient >3.1 g/dL (less accurate than the albumin-based tests above)[20,23]	These three rules more accurately establish CHF as cause of an effusion for patients with a high pretest probability of CHF as compared with Light's criteria[20,24]
• Serum assay of amino terminal fragment of proBNP (NT-proBNP) >1500 pg/mL CHF-related <400 pg/mL CHF-unrelated	More accurate than protein or albumin-based testing rules[18,23,25–27]
• Pleural fluid assay of NT-proBNP >1500 pg/mL CHF-related <400 pg/mL CHF-unrelated[18]	High accuracy but no advantage over serum NT-proBNP[23,25–28]
• Pleural fluid BNP >400 pg/mL CHF-related <100 pg/mL CHF-unrelated	Lower discriminative properties as compared with NT-proBNP[29]

BNP, brain natriuretic peptide; PF, pleural fluid; S, serum.

chest through small diaphragmatic stomata. When these blebs burst, ascites flows from the relatively high-pressure peritoneal space into the lower-pressure pleural space.[39] Because stomata occur more commonly in the tendinous portion of the right hemidiaphragm as compared with the thicker and more muscular left hemidiaphragm, 80% of hydrothoraces are right sided, 18% left sided, and 2% bilateral.[40] Although 20% of patients will not have clinically apparent ascites because most of the ascites fluid has decompressed into the pleural space,[41] US or CT will demonstrate residual ascites in nearly all patients.[42]

The clinical presentation of hepatic hydrothorax ranges from an incidental radiographic finding to varying degrees of dyspnea, which depends on the volume of PF, the volume of ascites that stiffens the diaphragm, and presence of underlying cardiopulmonary disease. Rapid-onset respiratory failure may rarely occur when ascites suddenly ruptures into the pleural space.[43]

Diagnosis requires thoracentesis to profile PF as transudative and exclude other causes of pleural effusion. Thoracentesis presents a low risk of complications despite the presence of cirrhosis and coagulopathy.[44] PF is transudative by Light's criteria in 90% of patients,[19] although PF protein levels are usually higher than the concomitant protein concentration in the ascites fluid because of a concentrating effect.[45] Diuretic therapy may convert a transudative pleural effusion to an exudate akin to the diuretic effect in CHF.[19] Correct classification as a transudate may require calculation of protein and/or albumin gradients as commonly done for CHF patients (Table 76-3).[20] Any suspicion of a true exudate, however, warrants evaluation for an empyema or tuberculosis. Although injection of a radionuclide tracer into ascites fluid may detect tracer flow from the abdomen to the chest, scintigraphy confirmation of the diagnosis is usually unnecessary.

Treatment centers on limiting sodium retention and lowering portal vein pressures. Therapeutic thoracentesis provides only transient relief of dyspnea because effusions rapidly recur making paracentesis preferred initial management for symptomatic patients. Chest tube drainage is avoided because of risks of massive fluid loss and poor healing of the chest wall tract after chest tube removal.[46–48] Transjugular intrahepatic portosystemic shunts may decrease PF in 88% of patients, but the 1-year survival is only 50%.[49–55] Hepatic hydrothorax does not represent a contraindication for liver transplantation.[53] Failing other interventions, VATS for closure of diaphragmatic fenestrations and performing talc pleurodesis may benefit some patients, but the risks of this procedure are high.[56–58] Chemical pleurodesis by chest catheter or VATS is challenging because of the rapid reaccumulation of PF that prevents apposition of pleural membranes.[59–61] Tunneled pleural catheters may provide palliation.[62] Spontaneous infection of a hydrothorax represents an important complication being found in 15% of patients admitted with cirrhosis and pleural effusions.[38,42] PF features of this condition include a PF neutrophil count >250 cells/μL with a positive PF culture or a PF neutrophil count ≥500 cells/μL with a negative culture in the absence of pneumonia.[49]

■ CONSTRICTIVE PERICARDITIS

More than 50% of patients with constrictive pericarditis develop a pleural effusion that can be the presenting manifestation of pericardial disease.[63–65] The pathogenesis of the effusions is unknown but may relate to migration of coexisting ascites into the pleural space or compromised left ventricular function that causes a CHF-related effusion. Both of these mechanisms would cause a transudative effusion.[63] Exudative effusions[65] and chylothoraces,[66,67] however, can also occur. PF may be bilateral or unilateral, with equal side distribution when unilateral.[64]

■ RENAL

Nephrosis

A transudative pleural effusion may develop in patients with nephrotic syndrome because of severe hypoalbuminemia. The effusions are typically small and bilateral in distribution.[68] Larger effusions require the exclusion of pulmonary thromboembolism (PTE) because of the high risk of this condition in nephrosis.

Urinothorax

Urinothorax occurs when urine dissects from the retroperitoneal space into the pleural space most often as a consequence of obstructive uropathy at the level of the bladder or urethra. Obstruction at the renal or ureteral level may produce urinothorax in the presence of a nonfunctioning contralateral kidney.[69] Other causes include kidney biopsy, renal transplantation, lithotripsy, failed tube nephrostomy, urinary tract malignancies, retroperitoneal trauma, and surgical complications.[69,70] Patients present with mild to moderate respiratory symptoms due to the space occupying effects of the effusion, which are usually unilateral.[69,71]

PF looks and smells like urine and meets definitions of a transudate by a low protein concentration. The PF LDH, however, is often elevated into the exudative range.[70,72] The PF pH[73] and glucose[74] values may be low, making urinothorax the only cause of a low pH and low glucose transudate in the absence of systemic acidemia and hypoglycemia. The PF/serum creatinine ratio is greater than 1 (mean value >10 in reported cases) in all instances, although the specificity of this finding is less than 100%.[70] Elevated ratios in other conditions, however, are closer to 1. Renal scintigraphy can demonstrate tracer flow from the urinary tract to the pleural space to establish the diagnosis. Urinothoraces typically resolve with relief of urinary obstruction.

Peritoneal Dialysis

Pleural effusions develop as a consequence of peritoneal dialysis (PD) in 2% to 10% of patients[75,76] with 88% being right sided and a minority bilateral.[76] Effusions range in size from small to moderate with 75% of patients having dyspnea,[76] but effusions may be massive.[77] PF forms due to the migration of dialysate from the relatively high-pressure peritoneal cavity into the low-pressure pleural space.[78] Clinicians may note decreased effectiveness of ultrafiltration as the first sign of migration of dialysate into the pleural space.

PF is transudative with a PF protein <0.5 g/dL and glucose >200 to 2000 mg/dL.[79,80] PF-to-serum glucose gradients range from 1 mg/dL to 1885 mg/dL with 20% of patients having gradients <50 mg/dL.[81] The PF/serum glucose ratio is always >1.[81] Peritoneal scintigraphy using technetium-99 m tagged macroaggregated albumin (28–30) or Tc-99 m sulfur colloid detects the flow of dialysate into the pleural space.[75,77,82] Management begins with reduction of dialysate volume or temporary discontinuation of PD.[75,83,84] Discontinuation of PD for 4 to 6 weeks may allow diaphragmatic conduits to heal.[85] Up to 58% of patients may resume PD without recurrence of their effusions.[86,87]

■ CENTRAL NERVOUS SYSTEM

Cerebrospinal Fluid Leakage into the Pleural Space

Cerebrospinal fluid (CSF) can leak into the pleural space when a duropleural fistula forms from a malignancy or after spinal surgery (particularly cervical laminectomy),[88] thoracic surgery,[89] or blunt or penetrating trauma.[90] Symptoms include dyspnea, meningitis,[91] CSF pressure headaches,[91] and various neurologic symptoms.[89,91] PF appears as clear as CSF with essentially no cells and a PF protein <1 g/dL, low LDH, and glucose and pH values similar to serum. Beta-2 transferrin is a protein found in CSF and inner ear perilymph that has a sensitivity and specificity of 100% and 95%, respectively for establishing CSF-related effusions.[92] Duropleural fistulae rarely heal spontaneously and present risks for CNS infection and pneumocephalus. CT myelography can visualize the fistula tract in preparation for surgical repair.[89,93]

Ventriculoperitoneal Shunts

Pleural effusion is a rare complication of ventriculoperitoneal (VP) shunting that occurs most commonly in children but has been reported in adults.[94] PF accumulates either from migration of the shunt catheter into the thorax[94–100] or from flow of CSF ascites into the pleural space.[95,100–102] PF analysis demonstrates no cells, a low protein and LDH content, and presence of beta-2 transferrin.[102,103] A radionuclide shuntogram can confirm the diagnosis.[104] Reports also exist of fibrothorax,[105] tension hydrothorax,[106] bronchopleural fistulae,[107] and empyema[108] subsequent to migration of a VP shunt.

■ PLEURAL

Trapped Lung

Remote pleural inflammation that causes fibrotic membranes to form on the visceral pleura can prevent lung expansion and create negative intrathoracic pressures that cause a hydrostatic gradient for PF formation.[109,110] A trapped lung should be suspected when PF drains incompletely by thoracentesis or recurs quickly and when a hydropneumothorax forms after thoracentesis with a similar configuration of the lung margin as compared with the pre-thoracentesis chest radiograph. Because of the chronic nature of the effusion, most patients are asymptomatic. The PF is usually a transudate. If sampled during the early formation of a trapped lung when inflammation may be present, the effusion may be exudative.[111] Pleural manometry performed during thoracentesis demonstrates rapid drops in measured pleural pressure as fluid is removed with calculated lung elasticity values >14.5 cm H_2O/L. A CT scan shows thickened visceral pleural membranes.[110] For patients with dyspnea, surgical decortication can be considered to allow lung reexpansion. Patients must be evaluated thoroughly for other causes of dyspnea, considering the difficulty and risks of decortication for established trapped lungs.[109]

■ PROCEDURAL IATROGENOSIS

Central Venous Catheter Migration

Initial misplacement of central venous catheters into the mediastinum or subsequent erosion of catheters through vascular walls allows infusates to flow into the mediastinum and subsequently the pleural space.[112–117] The resulting unilateral or bilateral pleural effusions vary in size depending on the rate of fluid infusion. Unilateral effusions may be ipsilateral or contralateral to the catheter insertion site.[112] Various catheter configurations apparent on chest radiographs and CT studies may identify patients at risk for catheter erosion.[112,118,119] The PF profile reflects the nature of the infusate with glucose containing solutions having a PF/serum glucose ratio >1.[112] Infusion of lipid-containing formulations causes increased pleural triglyceride levels. Most infusates are low in protein so PF protein is <1.0 g/dL. Infusion of chemotherapeutic agents into the pleural space may cause an inflammatory exudate and acute chest pain.[120]

Glycinothorax

Right-sided pleural effusions may rarely occur in patients undergoing bladder instrumentation with bladder irrigation using glycine solutions.[121,122] Perforation of the bladder allows glycine solutions to pass through the peritoneal cavity into the pleural space. The PF is a sanguineous transudate with a high concentration of glycine.

■ VASCULAR

Pleural effusions may develop in 13% of patients with isolated right heart failure due to pulmonary arterial hypertension.[17] Most of the effusions are trace to small (63%) and right sided in 58% and bilateral in 26%. Of the four patients reported with thoracentesis, all of the effusions were transudates.

Pulmonary veno-occlusive disease is a rare condition associated with specific pathologic changes of the postcapillary (venous) pulmonary circulation that produce pulmonary arterial hypertension.[123] Chest CT commonly detects unilateral or bilateral pleural effusions in this condition.[123–127] The nature of the effusions is uncertain but presumed to be transudative because of the raised pulmonary venous hydrostatic forces. Pulmonary capillary hemangiomatosis has also been reported to cause pleural effusions and presumed to be transudative in nature.[124,128]

CAUSES OF PLEURAL EFFUSIONS THAT ARE USUALLY EXUDATES

A number of causes of exudative pleural effusions have been recognized. Each is discussed below.

■ PATHOGEN RELATED

Parapneumonic Effusions

Twenty to 57% of patients hospitalized for community-acquired pneumonia develop a parapneumonic effusion,[129,130] as defined by a pleural effusion caused by pneumonia. PF forms when inflammatory cells migrate to the pleural space from an adjacent zone of lung infection and release proinflammatory mediators that alter pleural membrane permeability and recruit additional inflammatory cells.[131–133] An influx of protein-rich fluid creates an initially sterile, free-flowing effusion. Subsequent invasion of bacteria promotes a procoagulant effect in PF, which generates fibrin[132–134] that deposits on pleural surfaces and begins the formation of intrapleural loculations and a pleural rind. Infected PF eventually evolves into pus and a frank empyema. Although the development of an empyema represents a continuous sequence of pathophysiologic events, it has been arbitrarily described as a three-stage process to assist management (Table 76-4).[135] Parapneumonic effusions have also been classified as "uncomplicated" (treatable by antibiotics alone) or "complicated" (pleural space drainage is required).[136,137]

The incidence of pleural infections has increased during the last several decades across all age groups[138–140] with 30-day mortality that ranges from 5% to 27% depending on the extent of intrapleural suppuration, patient age, and presence of comorbid conditions.[138,140–142]

TABLE 76-4 Stages of an Empyema

Exudative	Increased permeability of pleural membranes with influx of inflammatory cells and protein-rich exudate. Most patients will respond to antibiotics without pleural drainage.
Fibrinopurulent	
Early Fibrinopurulent	Increased procoagulant activity in the pleural space promotes deposition of fibrin with early septation of the effusion. Pleural fluid becomes more viscous with increasing LDH and decreasing glucose and pH. Some patients may respond to antibiotics alone but drainage becoming increasingly likely.
Late Fibrinopurulent	Extensive fibrin deposition on pleural membranes causing loculations and pleural rind. Viable bacteria present with markedly increase PF LDH and low glucose and pH. Pleural fluid appears macroscopically purulent. Pleural fluid drainage and, possibly decortication, required.
Organizing	Fibroblast proliferation generates a fibrous pleural peel that requires decortication. A trapped lung may occur if the empyema space is not obliterated.

Risk factors for parapneumonic effusions include diabetes, immunosuppression, alcoholism, cancer, poor dental hygiene, and increased severity of the index pneumonia.[130]

Signs and symptoms of a parapneumonic effusion merge with those of the underlying pneumonia with fever, productive cough, and dyspnea predominating. Pleuritic chest pain increases the probability of a parapneumonic effusion and, along with tachycardia and leukocytosis above 15,000/mm^3, increases risk that the effusion is complicated.[99] Subacute or chronic constitutional symptoms of malaise, anorexia, and weight loss with fetid breath represent characteristic findings of an anaerobic empyema. Failure of a patient with pneumonia to respond to antibiotics as expected suggests the possibility of a partially treated empyema.

Chest imaging identifies approximately 90% of clinically significant parapneumonic effusions.[143,144] Most effusions are apparent as a dependent fluid collection with a meniscus on standard two-view chest radiographs. The only radiographic sign of an effusion, however, may be obscuration of a diaphragm that may be incorrectly attributed to lower lobe consolidation.[144] Consequently, a parapneumonic effusion should be suspected and evaluated by US in the presence of a diaphragmatic silhouette sign. Presence of intrapleural air-fluid levels indicates a bronchopleural fistula with empyema. A loculated effusion in a nondependent location suggests a complicated parapneumonic effusion.

US has a higher sensitivity and specificity for detecting PF as compared with standard radiographs.[145–148] Echogenic PF and septations suggest the presence of a complicated parapneumonic effusion in the fibrinopurulent or organizing stage and thereby increasing the likelihood that drainage will be required.[149–152] Ultrasound also allows image-guidance for thoracentesis, which improves the success and safety of the procedure in the presence of pleural loculations.[153,154] Contrast-enhanced chest CT can establish the presence, location, and extent of parapneumonic effusions for patients with complex PF collections and uncertain radiographic and US findings.[3,143] Loculated empyemas with interlobar and paramediastinal fluid collections can only be imaged by chest CT. Characteristic CT findings include the "split pleura sign" (enhanced pleurae that surround a loculated effusion), pleural thickening, and increased attenuation of extrapleural subcostal fat.[143] Chest CT can also differentiate between an empyema and a peripheral lung abscess adjacent to the chest wall.[155] Ultrasound, however, is more sensitive as compared with chest CT for detecting septations.

Thoracentesis and PF analysis to provide diagnostic and therapeutic information are indicated when PF is greater than 1 to 2 cm in depth by US or decubitus radiographs.[156,157] PF may appear grossly turbid, serosanguineous, or frankly purulent. A fetid odor suggests an anaerobic empyema. Appropriate PF tests with their clinical implications are listed in Table 76-5. PF procalcitonin levels do not provide value in guiding drainage decisions.[158,159] Clinical practice guidelines recommend basing the decision to drain a parapneumonic effusion on a combination of clinical, imaging, and PF findings (see Chapter 127).[160,161]

Uncomplicated parapneumonic effusions resolve after effective antibiotic therapy for the underlying pneumonia. Although it is widely accepted that complicated parapneumonic effusions by definition require drainage of infected PF, consensus does not exist regarding the initial approach to drainage.[168] Insertion of an image-guided, small-bore (<15 Fr) intercostal catheter connected to suction and flushed with saline every 6 hours provides effective therapy for many patients.[169–171] Limited data indicate that viscous effusions that fail to drain after catheter insertion may subsequently drain with intrapleural instillation of tissue plasminogen activator (tPA) to lyse fibrin adhesions and deoxyribonuclease (DNase) to thin PF.[172–176] Up to 30% of complicated parapneumonic effusions, however, require surgical drainage either by VATS or thoracotomy, depending on the degree of loculation, extent of pleural peels and need for debridement or decortication, and operability of the patient.[177] Studies have not validated any clinical or imaging findings that reliably identify patients who are unlikely to respond to catheter drainage and should be triaged directly to surgical drainage.[163] Moreover, studies have not demonstrated advantages with surgery as a routine, first-line therapy for empyema.[178,179] Regardless of the drainage approach adopted, unnecessary delays in draining infected PF increase hospital stay, morbidity, and mortality.[180–183] Organized empyemas may require more extensive surgery to promote long-term open drainage and eventual closure of the empyema cavity.[184]

TABLE 76-5 Commonly Ordered Pleural Fluid Tests

Test	Clinical Significance
Cell count and differential	Leukocyte counts vary depending on the stage of empyema formation; frank empyemas may have low leukocyte counts because cells have undergone lysis. The effusions are neutrophil predominant although a mononuclear cell predominance may exist with partially treated parapneumonic effusions.
Protein	Defines an exudate when >3.0 g/dL. Tuberculous effusions almost invariably >4.0 g/dL. Values >7.0 g/dL suggest Waldenström macroglobulinemia, multiple myeloma, or a cholesterol effusion.
LDH	Defines an exudate in Light's criteria rule; usually >1000 IU/L in empyemas.
Microbiologic staining and culture	Microbiologic staining and culture with sensitivity blood culture bottles.[162] Cultures positive in ~60% of patients who have signs of pleural infection.[141,163]
pH and glucose	Pleural fluid pH and glucose decrease because of intrapleural bacterial metabolism and inflammatory cell activity that utilize glucose and release lactic acid.[164–166] A PF pH <7.20 and glucose <60 mg/dL suggest that a parapneumonic effusion is complicated and requires drainage.[167] The studies upon which these recommendations are based, however, have extensive limitations in design.[167]
Amylase (ordered in selected settings)	Elevated in patients with empyema secondary to esophageal rupture (elevated salivary isoenzyme of amylase); elevated in pancreaticopleural fistula (elevated pancreatic isoenzyme of amylase).

LDH, lactate dehydrogenase; PF, pleural fluid.

Tuberculous Pleurisy

Tuberculous pleurisy can occur with primary infection or as reactivation disease.[185] It accounts for 30% to 80% of all pleural effusions in developing countries and occurs in up to 30% of patients who present with pulmonary tuberculosis.[186,187] Its prevalence is lower in developed nations accounting for 1% of all pleural effusions and occurring with pulmonary tuberculosis in only 3% to 5% of patients.[186] HIV-positive patients, however, have a higher incidence of tuberculous pleurisy presenting with underlying pulmonary tuberculosis.[188] Patients with tuberculous pleurisy commonly resolve their effusions spontaneously but present within 2 years with pulmonary tuberculosis.[189,190]

PF develops from an intrapleural hypersensitivity response to mycobacterial antigens released by rupture into the pleural space of a subpleural caseous focus.[191,192] The number of viable acid-fast organisms in PF is insufficient to allow reliable diagnosis by standard PF staining and culture techniques. Patients present with

subacute symptoms characterized by cough, pleuritic chest pain, dyspnea, and fever; although some patients present more acutely simulating bacterial pneumonia and others more indolently with weight loss and fatigue. Purified protein derivative skin tests are positive in only 50% of patients but usually convert to positive within 2 months.[193,194] The effusion is usually unilateral encompassing less than two-thirds of the hemothorax.[194] Standard chest radiographs and chest CT scans detect active parenchymal tuberculosis in 20% and 80% of patients, respectively.[194,195]

Any undiagnosed exudative pleural effusion should prompt consideration of tuberculous pleurisy with highest suspicion for lymphocyte predominant effusions (>60% lymphocytes) with protein concentrations >5 g/dL.[196] Up to 17% of patients, however, have lymphocyte percentages <50%.[196] The PF cell differential may be neutrophil predominant within the first 2 weeks of symptom onset.[197] PF mesothelial cell percentages are nearly always <5%.[198] PF glucose and pH mirror serum levels although some patients have PD levels lower than serum.

PF staining for acid-fast organisms has a low yield except in the presence of HIV-infection wherein 20% may be smear positive.[199] Although PF culture has traditionally been reported to have a sensitivity <50%,[194,200,201] studies using liquid culture techniques report a sensitivity of 63% to 75%.[196,202] Sputum mycobacterial cultures may be positive in >50% of patients[196,203] with positivity of either sputum and/or PF cultures in 79%.[196]

Adenosine deaminase (ADA) is found in increased concentrations in tuberculous effusions and some other inflammatory and neoplastic pleural conditions. In regions with a high prevalence of tuberculosis, a PF ADA >40 IU/L in a lymphocyte predominant effusion confirms tuberculous pleurisy,[200,201,204–206] allowing a diagnosis for 90% of patients after a single thoracentesis.[10] An ADA value <40 IU/L adequately excludes the diagnosis in high prevalence settings.[207] In regions with low or intermediate prevalence of tuberculosis, PF ADA assay has insufficient sensitivity and specificity, and most patients with negative PF microbiologic evaluations require pleural biopsy.[10,208–210] Although elevated ADA concentrations in the pleural space represent the ADA2 isoform, ADA2-specific PF assays provide only negligible benefits over ADA.[211] Although several other biomarkers (interferon-gamma, interferon-gamma–induced protein of 10 kDa, and dipeptidyl peptidase [DPP] 4 levels in unstimulated PF) provide similar diagnostic value as compared with PF ADA,[212–216] none has comparable availability for routine use.[215,217,218] Commercially available T-cell interferon-gamma release assays performed on both blood and PF have inadequate diagnostic accuracy[219,220] as do PF nucleic acid amplification tests.[216,221,222]

Pleural biopsy may be required in complicated settings. Tuberculous granulomata are diffusely distributed over pleural surfaces, which allows up to 70% to 87% of patients to be diagnosed by closed (blind) needle biopsy using an image-guided Abrams needle technique.[194,200,200,223–226] This approach is appropriate when the pretest probability of tuberculosis is high for an undiagnosed exudative pleural effusion.[201] Six pleural biopsies are recommended.[201,224] For other patients, thoracoscopy provides a 100% diagnostic yield.[200,201,208] Biopsied pleural tissue must be cultured for acid-fast organisms and examined for organisms and granulomata. Microscopic-observation drug-susceptibility culture as compared with Lowenstein–Jensen culture has a higher diagnostic yield.[227]

Drug therapy for tuberculous pleurisy is the same as for pulmonary tuberculosis with a four-drug regimen for susceptible organisms.[228] Evidence does not support a role for adjunctive corticosteroids.[229] When examined with chest CT after chemotherapy, nearly 70% of patients will have some degree of residual pleural thickening that may contribute to measureable pulmonary restriction.[230] Some experts recommend therapeutic thoracentesis to prevent pleural fibrosis for moderate to large tuberculous effusions,[228] although evidence of benefit is uncertain.[231,232] Ultrasonographic detection of complex septated pleural space, CT evidence of extrapleural fat proliferation or loculated effusion, and long duration of symptoms at initiation of therapy may identify patients at greatest risk of pleural thickening 1 year later.[230,233]

Pleural Effusions Caused by Viral Infections

Acute viral respiratory infections may be associated with transient pleural effusions. The incidence of viral-related pleural effusions is unknown because most patients have a mild clinical course and do not undergo testing for viruses or imaging studies. Recent case series that review the chest studies of patients with documented viral pneumonias, however, demonstrate a low incidence of pleural effusions.[234–236] The presence of a pleural effusion in a patient suspected with viral pneumonia and sufficiently ill to require hospitalization, therefore, should prompt consideration of a bacterial coinfection and a parapneumonic effusion. Notably, pneumonia due to swine-origin influenza A (H1N1) is commonly associated with pleural effusions.[237,238]

Fungal and Parasitic-Related Pleural Effusions

A wide spectrum of fungal infections causes pleural effusions in diverse clinical settings. Immunocompromised hosts may develop fungal empyema secondary to pleural seeding from a fungal pneumonia or more distant sites of infection. Common pathogens include *Aspergillus*[239,240] and *Cryptococcus* species.[240,241] Cryptococcal pleuritis suggests the presence of disseminated disease.[241] In immunocompetent patients, chylothoraces may occur secondary to mediastinal granulomatous disease caused by *Histoplasma capsulatum*.[242] Patients with allergic bronchopulmonary aspergillosis may develop eosinophilic pleural effusions[242] or erosion of fungus balls into the pleural space.[243,244] Finally, pulmonary fungal infections may lead to pleural effusions, which may be sterile or infected with fungal elements. Coccidioidomycosis represents the most common and distinctive endemic fungus presenting in this manner.[245,246] Fifteen percent of patients hospitalized with acute pulmonary coccidioidomycosis have pleural effusions[247,248] with nearly a quarter of patients progressing to empyema.[248] PF is exudative with eosinophilia being commonly present.[248]

Anecdotal reports exist of a broad range of parasitic infestations associated with pleural effusions.[249–257] Among these, pleural effusions related to rupture of an amebic liver abscess across the diaphragm into the pleural space producing an empyema[258] and pulmonary infestation with *Paragonimus* (a genus of flatworms)[254,256,259,260] are the most common. Amebic empyema is most commonly right sided, with PF having an anchovy paste or chocolate-milk appearance. A reactive pleural effusion can also occur secondary to transdiaphragmatic inflammation.[257] Paragonimiasis produces pleural effusions and pulmonary parenchymal changes that may simulate malignancies or tuberculosis.[256] Chest CT series indicate that pleural effusions are the most common intrathoracic imaging findings of the North American form of paragonimiasis (*Paragonimus kellicotti*).[259] PF has a markedly increased LDH and may also assume characteristics of a chylothorax.[251] Blood or PF eosinophilia are variable findings. Pulmonary echinococcosis can produce pleural effusions, hydropneumothorax, and secondary pleural hydatidosis when pulmonary or hepatic echinococcal cysts rupture into the pleural space.[257,261] A reactive pleural effusion may also occur because lung echinococcal cysts are usually subpleural in location. PF may be an eosinophilic exudate[262] or empyema.[263] Other parasites rarely involve the pleural space.[257]

■ VASCULAR

Pulmonary Thromboembolism

Up to 40% of patients with PTE have associated pleural effusions when examined by standard radiographs with 47% having effusions on chest CT images.[264–268] Lung ischemia results in increased

pleural membrane permeability with an influx of protein-rich fluid into the pleural space; effusions related to PTE are almost always exudates.[265,269] Effusions are unilateral in 85% of patients with approximately equal distribution of right- versus left-sided locations occurring ipsilateral or contralateral to the site of the PTE.[265,269] Less than 20% of effusions occupy more than one-third of the hemithorax[264,265,269] with most only blunting the costophrenic angle. Delayed diagnosis may cause the effusions to loculate.[265,270]

PF findings are nonspecific with erythrocyte counts greater than 10,000/μL in 67% of patients, neutrophil predominance in 60%, and eosinophil counts >10% in 18%.[269] Only 57% have bloody PF.[269] Thoracentesis, therefore, has a limited role in evaluating PF for suspected PTE but has value for excluding other conditions, such as pleural infection or hemothorax. PF usually reabsorbs during anticoagulant therapy. The presence of a bloody effusion does not obviate systemic anticoagulation because hemothorax rarely occurs. When pleural bleeding does occur, it presents with sudden cardiopulmonary compromise usually during the first week of anticoagulation.[271–273]

Nonthrombotic Pulmonary Emboli

Septic Emboli Septic emboli typically lodge in lung periphery, which can cause sterile or infected pleural effusions. Common causes of septic emboli include infected venous catheters,[274] septic thrombophlebitis (e.g., Lemmiere syndrome),[275] and right-sided endocarditis. Patients with intravenous drug addiction may present with pyopneumothorax.[276,277] Common CT imaging findings include peripheral nodules with clearly identifiable feeding vessels and/or air bronchograms, metastatic lung abscesses, and subpleural, wedge-shaped densities with or without necrosis.[278–280] PF reflects acute sterile inflammation or evidence of an empyema.[281]

Hemothorax

Hemothorax is defined by the presence of bloody PF with a PF hematocrit (hct) >50% of the simultaneous blood hct value.[282] Because erythrocytes undergo spontaneous lysis in the pleural space, a PF hct between 25% and 50% measured a few days after the onset of pleural effusion supports the diagnosis. Hemothoraces result from blunt and penetrating chest trauma, procedures that damage vasculature in or near the pleural space, and underlying conditions that promote spontaneous intrapleural hemorrhage (Table 76-6). Hemothorax carries a potential for unabated hemorrhage, respiratory compromise, and shock. Principles of management include drainage of the pleural space by thoracentesis in the absence of ongoing bleeding, or by chest tube to monitor ongoing bleeding rates, removal of intrapleural blood, and prevention of a subsequent trapped lung or empyema. Pleural drainage also apposes pleural membranes to tamponade pleural-based bleeding sites. Patients may require emergency thoracotomy or VATS to control bleeding and evacuate intrapleural clots.[283]

Catamenial hemothorax represents a unique form of hemothorax occurring in young, multiparous, and menstruating women with pelvic endometriosis.[292,293] Two-thirds of patients have intrapleural endometriosis noted during VATS.[293] Unilateral and right sided in 80% of instances, bilateral pleural effusions occasionally occur.[293] Catamenial pneumothorax[294] and hemoptysis[293,295] may occur simultaneously with hemothorax. Intrapleural bleeding is usually mild and self-limited, which may delay diagnosis until the temporal relationship with menses is noted. Once diagnosed, most patients are sufficiently stable to allow medical management with hormonal therapies that provide only partial effectiveness.[282,296] Patients with recurrent hemothorax may require surgical resection of intrathoracic endometriomas, although relapse commonly occurs.[292]

Vasculitis

Pleural effusions can occur in granulomatous polyangiitis (GP, also termed Wegener granulomatosus) as a result of primary pleural involvement with necrotizing vasculitis or secondary to renal disease, pneumonia, or CHF as complications of vasculitis.[297–299] Small patient series indicate that 10% to 20% of patients with GP have pleural effusions usually as incidental findings.[298,300] Patients may rarely present, however, with a pleural effusion[301,302] and massive effusions with bronchopleural fistulae have been reported.[303] From the limited reports of PF analyses, the effusions are exudates with neutrophil predominance.[304,305] Pleural biopsy may detect evidence of granulomatous vasculitis or only nonspecific fibrosis.[306,307]

Up to 30% of patients in the vasculitic phase of Churg–Strauss syndrome have pleural effusions, although most are small and asymptomatic.[308,309] Massive effusions, however, have been reported.[310] Only rare reports exist of PF analysis, which characterize the fluid as having increased eosinophils.[310–312] One report noted a low pH and glucose.[312] Effusions may respond to corticosteroid therapy.[312]

Pleural effusions rarely occur in patients with giant cell arteritis[313–320] and may represent the presenting feature of the disease.[313,315,316,320] PF is exudative with neutrophil predominance and a normal glucose, although lymphocyte predominance[314] and transudative effusions have been reported.[315] Pleural biopsy is nonspecific.[317] The effusions respond to prednisone therapy.[313,319]

Behçet disease is a chronic, relapsing inflammatory disorder of unknown etiology. Vascular involvement represents the major risk for mortality with any sized vessel in the venous, arterial, or capillary circulation being potentially affected. Among a myriad of intrathoracic complications,[321] Behçet disease can cause abnormalities of

TABLE 76-6 Cases of Hemothorax

Condition	Comments
Coagulopathy and bleeding diatheses	Hemothorax due to primary coagulopathies, thrombocytopenia, anticoagulant therapy, or systemic and intrapleural fibrinolytic therapy rarely occur[284–286]
Pneumothorax and ruptured lung bullae	Hemothorax uncommon with spontaneous pneumothorax but can occur especially with ruptured lung bullae[282]
Neurofibromatosis	Rupture of friable vasculature in patients with neurofibromatosis may occur by vascular invasion or arterial dysplasia[287]
Arteriovenous malformations	Arteriovenous malformations rarely bleed into the pleural space with one-half of instances related to Osler–Weber–Rendu disease[282]
Aneurysms	Dissection or rupture of a major intrathoracic artery is a common and usually clinically apparent cause of hemothorax[288] Most commonly aortic but also pulmonary vasculature
Ehlers–Danlos disease	Associated with internal mammary artery rupture[289,290]
Connective tissue diseases	Rare reports
Extramedullary hematopoiesis	Rare reports
Endometriosis	Varying degrees of hemorrhagic effusions or hemothorax
Exostoses	Formation of new bone on the surface of existing bone creates sharp boney edges that can erode adjacent vascular structures and cause hemothorax[291]
Postpartum	Related to thoracic pressure changes during labor straining

pleural membranes and various types of pleural effusions. High-resolution CT scans commonly detect pleural thickening and nodularity that may represent resolved pulmonary infarctions, spread of subpleural pulmonary inflammation, and/or pleural vasculitis.[322–326] Pleural effusions commonly occur in patients with vascular obstruction and can be transudates in patients with superior vena cava (SVC) obstruction[327] or chylothoraces in patients with thrombosis of the SVC or other major intrathoracic vessels.[328–332] Effusions respond variably to corticosteroid therapy[330,331] and may require anticoagulation, immunosuppressive drug therapy,[333] and/or pleurodesis.[330]

Superior Vena Cava Syndrome

More than 60% of patients with SVC syndrome develop pleural effusions that are nearly always exudative in nature, with 18% being chylothoraces.[334] The etiology of the effusions is unknown, but increased resistance to lymphatic duct drainage into the brachiocephalic vein may contribute to chylothorax.[335] Effusions are equally right sided or left sided and most effusions occupy less than 50% of a hemithorax.[335] The effusions usually resolve with resolution of the SVC syndrome.

■ GASTROINTESTINAL AND INTRA-ABDOMINAL DISORDERS

Pancreatitis and Pancreatic Fistulae

Pleural effusions are apparent in 50% of patients hospitalized with acute pancreatitis.[336,337] Several potential mechanisms exist for PF formation, which include release of proinflammatory mediators from the pancreas into the circulation, transdiaphragmatic transit of parapancreatic inflammatory exudates, lipolysis of mediastinal fat, and early formation of pancreaticopleural fistulae.[338,339] Early onset of pleural effusions represents a negative prognosticator for acute pancreatitis.[337,340,341] The PF profile includes a neutrophil predominant exudate with an elevated amylase usually greater than twice the serum value.[342]

Predominantly left-sided effusions may develop in patients with chronic pancreatitis who develop a pseudocyst with a sinus tract through the retroperitoneum into the pleural space. Most patients are male (70%) with a history of chronic alcoholic pancreatitis (50%), but other causes of pancreatitis, such as choledocolithiasis, also occur.[343] Patients present with dyspnea (65%), abdominal pain (29%), cough (27%), and chest pain (23%).[344] PF pancreatic amylase is markedly elevated (>1000 IU/L). Visualization of the pancreaticopleural fistula with its drainage into the pleural space can be achieved by helical CT scanning, endoscopic retrograde cholangiopancreatography, or magnetic resonance cholangiopancreatography (MRCP) with MRCP being the most sensitive initial examination.[343–348]

No validated algorithm for treatment of pancreaticopleural fistula exists, but most centers initiate a sequential approach that begins with alimentary nutrition and observation supplemented with octreotide to suppress exocrine secretion.[345,347–349] Thirty-five percent of patients will fail conservative therapy and require endoscopic placement of a pancreatic stent followed by surgery, if the stent is unsuccessful.[343,344,346–348,350] Prolonged medical therapy only delays recovery, so patients should be evaluated for definitive operative intervention early in the course of treatment.[343]

Esophageal Perforation

Rupture or perforation of the esophagus with decompression of gastroesophageal contents into the pleural space represents a life-threatening condition. Esophageal disruption results from forceful vomiting (Boerhaave syndrome), esophageal lesions (retained foreign bodies or neoplasms), or esophageal instrumentation (endoscopy, gastric banding for weight loss).[351] Boerhaave syndrome presents with chest pain and signs of sepsis with a rapidly progressing, usually left-sided effusion. Meckler's triad of vomiting, chest pain, and subcutaneous emphysema suggests the diagnosis. Imaging studies demonstrate a rapidly progressing pleural effusion or hydropneumothorax often associated with mediastinal, paraesophageal, and/or subcutaneous emphysema.[352,353] PF findings include high salivary amylase, low pH, low glucose, high LDH, and evidence of pleural infection. Cytologic examination may identify food particles and/or squamous epithelial cells.[354] Gastrografin-contrasted chest CT or endoscopy may localize the esophageal injury and fistula tract, but negative studies do not exclude the diagnosis. Adequate surgical debridement with drainage of the mediastinum and pleural space within 24 hours of presentation improves outcome in Boerhaave syndrome.[355,356] Iatrogenic esophageal perforation may be managed more conservatively.[357]

Endometriosis

Endometriosis involving the peritoneum complicated by ascites may rarely cause a pleural effusion that is characteristically right sided with bloody or chocolate-brown appearing PF.[358,359] The effusions are linked temporally with menses and contain hemosiderin-laden macrophages. In contrast to catamenial hemothorax due to intrathoracic endometriosis, this condition is characterized by endometrial tissue that is confined to the abdominopelvic region with secondary flow of fluid into the pleural space.

Intra-Abdominal Diseases

Infradiaphragmatic abscesses and various ischemic and inflammatory lesions of abdominal organs (e.g., perihepititis[360] and splenic ischemia[361]) can cause exudative effusions that may become infected if intra-abdominal pathogens migrate into the pleural space. Depending on the location of the intra-abdominal locus of infection or inflammation, the effusions may be predominately right sided (e.g., hepatic abscess) or left sided (e.g., splenic abscess or infarction). CT scanning establishes the diagnosis in most instances and directs both pleural and abdominal drainage.

Biliothorax

Bile can flow into the pleural space causing a right-sided pleural effusion as a complication of percutaneous biliary drainage,[362–365] radiofrequency ablation or catheter embolization of liver lesions,[366–368] or spontaneous pancreaticopleural or cholecystopleural fistulae.[369,370] PF has a green tint with neutrophil predominance and a PF/serum bilirubin ratio >1.

■ SYSTEMIC DISEASES

Connective Tissue Diseases

As many as 30% of patients with systemic lupus erythematosus (SLE) experience pleuritis at some time during the course of their disease.[371,372] Pleuritis is an independent predictor of mortality in lupus.[371] Associated pleural effusions are usually small to moderate, but large effusions can occur. Usually bilateral, they have an equal side distribution when unilateral.[373] Concomitant anti-Sm and anti-RNP antibody seropositivity, greater severity and longer duration of lupus, and young age at SLE onset are associated with a higher rate of pleural disease.[371] Typical PF profiles are shown in Table 76-7.[374,375] Detection of a positive PF antinuclear antibody (ANA) does not provide incremental diagnostic value to a positive serum ANA.[376] Rarely, lupus pleuritis may progress to fibrothorax and trapped lung.[377] Effusions respond to nonsteroidal anti-inflammatory drugs as initial therapy, or corticosteroids if necessary, in most patients, but pleuritis tends to recur, often on the contralateral side. Refractory massive pleural effusions rarely occur and may require high-dose steroids and cyclophosphamide, intravenous immunoglobulins, and occasionally pleurodesis.[378]

Pleural involvement is the most frequent manifestation of RA in the chest and causes pleural effusions in up to 20% of patients.[373,379] As many as 11% of patients within the first year of RA diagnosis have evidence of pleural thickening or pleural effusions on high-resolution CT imaging.[380] Pleural effusions occur most often in

TABLE 76-7 Pleural Fluid Test Results in Common Autoimmune Causes of Pleuritis

Finding	Lupus Pleuritis	Rheumatoid Arthritis
Appearance	Clear	Variably serous, purulent, milky, hemorrhagic
Protein	Low in exudative range	High in exudative range
Glucose	Similar to serum	Often low <30 mg/dL
Leukocytes	3–5000/μL	Usually <10,000/μL
Complement	Low	Low
Immune complexes	High	High
PF ANA	Positive	Variable
LDH	Twice upper limits of normal for serum	High
Rheumatoid factor	Low	Elevated

PF, pleural fluid; LDH, lactate dehydrogenase; ANA, antinuclear antibody.

men who have active arthritis, subcutaneous rheumatoid nodules, elevated rheumatoid factors, and radiographic evidence of underlying rheumatoid lung lesions.[379] Patients with RA may rarely present with pleurisy.[381] Pleural effusions are small to moderate in size, more often left sided, and asymptomatic.[382] Symptomatic effusions warrant thoracentesis to exclude empyema that can occur spontaneously with RA pleural effusions.[379] Sterile RA effusions have the pleural profile listed in Table 76-7. Effusions have a neutrophil predominance at onset but may convert to lymphocytic predominance in 7 to 11 days.[383] PF cytology may demonstrate, elongated macrophages and multinucleated giant cells (tadpole cells), and granular debris.[383] Sterile RA effusions often have a low glucose (<30 mg/dL) and pH (<7.20) that complicates differentiation from pleural infection. Pleural biopsy may demonstrate replacement of parietal pleural mesothelial cells with a palisade of macrophage-derived cells,[383] but biopsy is usually not needed for diagnosis. Most effusions resolve spontaneously but some persist or progress to fibrothorax.[379] No therapy has demonstrated value for RA pleural effusions. RA may also cause cholesterol effusions[384] and bronchopleural fistulae.[385]

Although recurrent pleuritic chest pain commonly occurs in patients with Sjögren syndrome,[386] pleural effusions rarely develop. Among 343 patients reported with Sjögren syndrome, only 9% had pulmonary manifestations, of which 4 patients had pleural effusions.[386] Limited data indicate that the effusions associated with Sjögren syndrome are lymphocyte predominant exudates with high PF levels of anti–SS-A/SS-B antibodies.[387] An effusion should suggest lymphoma, which occurs with increased frequency in Sjögren syndrome.

Up to 7% of patients with systemic sclerosis may have a pleural effusion that can result from pleural involvement with sclerodermal tissue changes or secondary causes of pleural effusions associated with scleroderma, such as CHF.[388] PF is a lymphocyte predominant exudate unless it is a transudate due to associated CHF or renal failure.[388,389]

Mixed connective tissue disease (MCTD) has clinical features of SLE, scleroderma, and polymyositis–dermatomyositis and is defined by the presence of high serum titers of antibodies against uridine-rich RNA-small nuclear ribonucleoprotein (snRNP).[390] Pleuropulmonary complications commonly occur in up to 50% of patients having pleural effusions and 20% having symptoms of pleurisy.[391–393] Pleural effusions are usually incidental imaging findings, but may rarely be the presenting feature of the disease.[394] The PF profile is poorly defined, but a report exists of a granulocyte predominant exudate.[395]

Exudative effusions with normal PF glucose levels have been rarely reported in patients with ankylosing spondylitis.[396–399] Associated nonspecific pleuritis has been demonstrated on pleural biopsy specimens.[399] Effusions may be transient[399] or recurrent.[396]

Polymyositis and dermatomyositis cause interstitial lung disease in approximately 10% to 20% of patients and have the potential for provoking respiratory failure, especially in patients with the antisynthetase syndrome.[400] Although pleural irregularities are noted in a high proportion of patients,[401] pleural effusions rarely occur and, when present, invariably exist in association with interstitial lung disease and should prompt consideration of an alternative underlying diagnosis.[402–404] The PF profile has been reported to be lymphocyte predominant with rare reports of increased eosinophils.[402]

Sarcoidosis

Pleural effusions rarely occur in patients with sarcoidosis with a reported prevalence of 0.7% to 10%.[405–411] A large case series reported 1.1% prevalence of sarcoid-related effusions in asymptomatic ambulatory patients examined by US.[407] Thirty-three percent of patients examined by CT scanning have evidence of pleural thickening and subpleural nodules, which are assumed related to sarcoidosis.[412,413] Sarcoid effusions are usually small to moderate sized, unilateral, and asymptomatic although large, symptomatic effusions can occur. Only 20% of effusions are bilateral.[407] Most effusions are lymphocyte predominant exudates[407,414] with one report of the lymphocyte populations having a high CD4/CD8 ratio.[415] Chylothorax,[409] eosinophilic effusions,[416,417] trapped lung,[418] and hemorrhagic effusions[419] may occur. Pleural biopsy may demonstrate sarcoid granulomas.[405,408,410] Most sarcoid effusions resolve spontaneously.

Myedema

Both transudative and exudative effusions have been reported in patients with myxedema.[420–425] Most of these effusions respond to thyroid replacement therapy.

Amyloid

Exudative or transudative pleural effusions can develop from infiltration of amyloid into parietal pleural surfaces, increasing capillary permeability and blocking reabsorption of PF through lymphatic stomata.[426,427] Most effusions are associated with light chain amyloidosis. Pleural effusions can also occur through indirect mechanisms of amyloid-induced hypothyroidism, nephrosis, and CHF, the latter two of which may cause transudative effusions in this setting.[428] Amyloid-related exudative effusions rarely resolve spontaneously and may require repeated thoracentesis or pleurodesis.

Extramedullary Hematopoiesis

Extramedullary hematopoiesis involving the mediastinum and pleural membranes has been associated with exudative pleural effusions,[429–432] hemothorax,[433] and chylothorax.[434] Detection of normoblasts[435] and myeloblasts[432] in PF suggests the diagnosis. Symptomatic effusions have been successfully managed by low-dose thoracic radiotherapy, pleurodesis, and hydroxyurea.[429,430,434]

■ DRUG RELATED

A wide spectrum of drugs can cause pleural effusions through a variety of mechanisms. A listing of these drugs is available at http://pneumotox.com/indexf.php?fich=clin0&lg=en.

One unique form of drug-induced pleural effusions is represented by ovarian hyperstimulation syndrome (OHSS) that develops during induced ovulation with human chorionic gonadotropin hormone. This condition is characterized by massive increases in ovarian size, extravascular fluid shifts, and hemoconcentration that can result in shock and organ failure. Signaling by vasogenic molecules released from corpus lutae is thought to provoke increased epithelial

membrane permeability.[436,437] Unilateral and bilateral pleural effusions commonly occur during the full expression of the syndrome but also as isolated findings.[438–441] Limited data exist regarding the PF profile, which is considered exudative.[442] PF may contain high levels of cytokines.[443] In most instances, OHSS is self-limited and spontaneous regression occurs although chest catheters may be required initially for draining large volumes of PF.[444]

■ ENVIRONMENTAL—ASBESTOS

Up to 3% of patients with an occupational exposure to asbestos will develop transient exudative pleural effusions, [445–447] termed benign asbestos pleurisy.[446,448] Asbestos exposure may underlie many undiagnosed exudative pleural effusions.[447,449] The pathophysiology of benign asbestos pleurisy is uncertain, but asbestos fibers can provoke pleural inflammation both by direct toxicity to mesothelial cells and also by indirect effects through stimulating the release of growth factors and inflammatory cytokines from the lung.[450] Mean latency time from first asbestos exposure to pleural effusions is 30 years but ranges from 1 to 58 years.[451] Symptoms of dyspnea, chest pain, and/or fever develop in only 35% to 50% of patients.[447,451] Pleural effusions range from small to large and present most often as unilateral effusions with equal side distribution or as bilateral effusions in 15%.[446,451] PF appears hemorrhagic in 50% of patients, and 25% have increased numbers of eosinophils.[449,451] The effusions almost always follow a benign course with spontaneous resolution within 1 to 10 months (median 3 months),[451] but some effusions recur.[447] Patients with heavy asbestos exposure may have residual pleural thickening,[445–447,449,452] which may require decortication if lung restriction occurs.

■ LYMPHATICS AND LIPID-RELATED EFFUSIONS

Chylothorax

Chylothorax is defined by the presence of chyle in the pleural space,[453] which denotes a leakage of lymphatic fluid from the thoracic duct or its tributaries. Chyle contains lipids in transit from the digestive tract to the venous circulation via the cisterna chyli near the junction of the left jugular and subclavian veins. Disruption of these lymphatic channels anywhere along their course can result in a pleural effusion. Lymphatic fluid also contains a high content of lymphocytes and immunoglobulins. A classification of chylothorax and listing of common causes are shown in Table 76-8.

TABLE 76-8 Causes of Chylothorax

Classification	Comments
Traumatic	Account for 50% of chylothoraces with thoracic surgery most common cause.[454] Also occur after neck surgery, central venous catheter and pacemaker insertion, blunt chest injury, traction injuries to the chest and neck, and sudden pressure changes with sneezing, vomiting, or labor and delivery.
Nontraumatic	Lymphoma has decreased in incidence to 11% because of earlier lymphoma diagnosis.[453] Less common causes include congenital or acquired lymphatic disorders, constrictive pericarditis, SVC syndrome, lymphangiomatosis, lymphangiectasias, lymphangioleiomyomatosis, Noonan syndrome, yellow nail syndrome, Down syndrome, granulomatous infections, and thyroid goiter[453]
Idiopathic	Small number idiopathic despite a complete diagnostic evaluation

Chylothoraces usually present as unilateral effusions, but 20% may be bilateral. The thoracic duct ascends on the right side of the mediastinum crossing to the left side near the fifth thoracic vertebral body (T5). Consequently, a right- versus left-sided chylothorax suggests the presence of disruption to the thoracic duct below or above a T5 level, respectively. Because of the noninflammatory nature of chyle, patients do not experience pleuritic pain but present with dyspnea. The PF appears free flowing and nonloculated without pleural thickening on imaging studies. PF is grossly white, milky, and opalescent in 50% of patients but may be serous or serosanguineous when patients are fasting. PF analysis demonstrates a lymphocyte predominant exudate with an elevated protein but not LDH. A transudate may occur in 14% to 32% of patients,[455] which suggests a coexisting condition such as CHF or hepatic hydrothorax.[456] PF triglyceride concentration is usually above 110 mg/dL but 15% of patients have lower values that may be <50 mg/dL.[455] PF triglyceride testing, therefore, has a high positive but low negative predictive value for chylothorax.[455] In the absence of elevated triglyceride levels, analysis of PF for chylomicrons is indicated.

With an established diagnosis, some centers perform conventional lymphangiography or lymphoscintigraphy imaging studies to visualize thoracic lymphatics and identify the anatomical site of chyle leakage. The value of these studies for directing therapy, however, has not been established. No evidence-based algorithm exists for managing patients with chylothorax, and extensive practice variation exists. Generally accepted principles of care, however, encourage identification of the underlying etiology; guidance of therapy in a stepwise manner based on the severity of symptoms, size of the effusion, rate of fluid reaccumulation after thoracentesis, and the patient's overall clinical condition, comorbidities, and ability to tolerate invasive procedures; and avoidance of prolonged PF drainage by chest tube, which results in nutritional depletion and immunosuppression.[457]

Observation may suffice for stable and small to moderate effusions with mild symptoms. Nonsurgical, conservative measures resolve 50% of traumatic chylothoraces but prove less successful for nontraumatic forms of the disease, which usually require surgery.[458] Only two-thirds of patients with nontraumatic chylothoraces, however, respond to surgical interventions. Most patients with traumatic chylothorax respond to surgical interventions, if required.[458] Dietary measures include restriction of fat except for medium chain triglycerides that are absorbed directly into the portal circulation. Available surgical interventions include pleurodesis, pleurectomy, thoracic duct repair or ligation, lymphovenous anastomosis, and pleuroperitoneal shunting. VATS for localizing and managing thoracic duct disruptions has improved outcomes as compared with open thoracotomy.[459–461] Recent interest in percutaneous transabdominal embolization of the thoracic duct has developed.[462,463] Patients nonresponsive to therapy or patients with terminal conditions may benefit from placement of a pleuroperitoneal shunt.[464,465]

Cholesterol Effusions

Cholesterol pleural effusions, also termed *pseudochylous* or *chyliform* effusions, usually present as unilateral effusions with 30% of patients being asymptomatic.[459] PF appears grossly turbid or milky due to high lipid content, largely composed of cholesterol and lecithin–globulin complexes. The pathogenesis of cholesterol effusions is unknown. Because they most often develop in patients with chronic (>5 years) exudative effusions and thickened pleural membranes, they have been considered a form of "trapped lung" wherein erythrocytes and neutrophils lyse and release their intracellular lipids that cannot be reabsorbed across thickened pleural membranes.[459] Reports exist, however, of cholesterol effusions after shorter intervals of exudative effusions without pleural membrane thickening.[384] The most common underlying conditions associated with cholesterol effusions include tuberculous pleurisy, chronic pneumothorax,

chronic hemothorax, and chronic rheumatoid pleuritis.[466] Less commonly associated conditions include pleural echinococcosis, paragonimiasis, and malignancies.

PF analysis demonstrates a cholesterol concentration >200 mg/dL and usually a neutrophil predominant exudate. The triglyceride concentration is usually but not always <110 mg/dL. If the triglyceride level is elevated, the PF cholesterol/triglyceride ratio is >1.0.[459] Some PF samples demonstrate cholesterol crystals but chylomicrons are not present. Pleural biopsy may assist in diagnosing an underlying etiologic condition although biopsy samples are diagnostic in only 17%.[467] Most patients with cholesterol effusions do not require therapy directed at the pleural space. Symptomatic effusions, however, may benefit from periodic therapeutic thoracentesis, pleurodesis, or rarely decortication. Some effusions may stabilize or resolve with drug therapy for underlying RA if present.[384]

Lymphatic Abnormalities

Lymphangioleiomyomatosis Ten to 40% of patients with lymphangioleiomyomatosis develop pleural effusions that are almost always chylous.[468] Chylothorax occurs as a consequent of obstruction or disruption of the thoracic duct or its tributaries, generalized oozing from pleural lymphatics, and/or transdiaphragmatic flow of chylous ascites.[469] Effusions may be unilateral or bilateral,[469] and chyloptysis may also occur.

Chylous effusions follow a variable clinical course. They most often progress in size and recur after thoracentesis,[470] but may remain stable over years[471] or resolve spontaneously.[472] Symptomatic patients do not respond well to low-fat diets. Chemical or mechanical pleurodesis with or without thoracic duct ligation performed close to the diaphragm is successful in most patients, but pleurectomy with or without thoracic duct ligation may be required.[469]

Yellow Nail Syndrome The YNS is a rare, acquired disorder characterized by the triad of abnormal nails (yellowing, slow growth, ridging, onycholysis, excessive long-axis curvature, and/or diminished lunulae), lymphedema, and pleural effusions.[453] Some patients have associated bronchiectasis, recurrent lower respiratory tract infections, and chronic sinusitis. The diagnosis is suspected by the presence of two of the triad findings in the absence of another more likely explanation. The etiology is unknown, but both anatomic and functional abnormalities of lymphatic ducts have been proposed.[473–475] Histologic analyses of pleural membranes do not consistently detect lymphatic vessel abnormalities.[476,477]

Most (80%) patients have symmetric, lower extremity, nonpitting lymphedema, which is a finding in 30% of patients who present with pleural effusions. Lymphedema can also involve the face, arms, larynx, and peritoneal cavity producing ascites. Up to 40% of patients having pleural effusions are most often bilateral. The fluid is lymphocytic predominant with an elevated protein meeting exudative criteria, but often an LDH and cholesterol in the transudative range.[476,478] Up to 30% of effusions are chylothoraces.[476] Management is supportive with therapeutic thoracentesis for symptomatic effusions, pleurodesis or pleuroperitoneal shunting for recurrent effusions, and VATS with thoracic duct ligation for chylothoraces.[479]

KIDNEY RELATED

Pleural effusions occur for a variety of reasons in patients with end-stage renal disease undergoing long-term hemodialysis. Approximately 50% of hemodialysis patients with acute respiratory complaints have pleural effusions when evaluated by CT.[480] Although the most common etiologies of symptomatic effusions are cardiac failure, pneumonia, tuberculosis, malignancies, and volume overload;[480–482] pleural effusions can develop as a direct consequence of uremia (uremic pleuritis).[480]

The onset or size of effusions related to uremic pleuritis does not correlate with the severity of underlying uremia or timing of hemodialysis.[483] Most patients have chest pain, cough, dyspnea, and/or fever. PF is exudative with a predominance of lymphocytes. The diagnosis is one of the exclusion that requires careful consideration of alternative explanations, such as infection, heart failure, and malignancy. Most patients respond to continuation of hemodialysis, but some patients may develop pleural fibrosis with a trapped lung.[110]

EFFUSIONS AFTER CARDIAC SURGERY

Most patients develop exudative pleural effusions after cardiac surgery in the immediate postoperative period as a direct consequence of the surgery itself in the absence of complications of the procedure, such as hemothorax or chylothorax. Effusions after coronary artery bypass graft surgery (CABG-related effusions) have received the greatest attention,[484–487] but nonspecific exudative effusions also occur after cardiac valve replacement.[488] CABG-related effusions have been separated into early (within 30 days of surgery) and late onset (30 days after surgery).[489] The pathogenesis of these effusions is unknown but may relate to topical cardiac cooling, surgical interruption of lymphatic channels, direct surgical injury of the pleura, and/or pericarditis.[487,490–492]

Ninety percent of CABG-related effusions encompass <25% of a hemithorax and most are left sided and asymptomatic. Large effusions, however, may cause dyspnea, but chest pain and fever are uncommon.[484] Because these effusions resolve spontaneously, thoracentesis is indicated only in certain instances based on the timing of onset, progression, and persistence of the effusion and any associated cardiopulmonary symptoms. Small- to moderate-sized effusions, effusions that develop within days of surgery, asymptomatic effusions, and nonprogressive effusions may be observed for resolution. Symptomatic, large, or progressive pleural effusions require thoracentesis either to manage dyspnea or to evaluate patients for the alternative diagnoses. PTE should be considered with appropriate studies.

When thoracentesis is performed, effusions that occur within the first 30 days of surgery are typically bloody in appearance and may contain >10% eosinophils.[493,494] Late-onset effusions are nonbloody with lymphocyte predominance.[493,494]

Postcardiac injury syndrome (Dressler syndrome) develops 1 week or more after myocardial injury and is characterized by pericarditis, pulmonary infiltrates, and pleural effusions.[495] Patients commonly have pericardial chest pain, fever, leukocytosis, and pleuropericardial friction rubs. Pleural effusions occur in 60% to 80% of patients and are typically small and unilateral, most often left sided.[496,497] PF is hemorrhagic in 70% with a neutrophil predominant exudate during the acute presentation that evolves to lymphocyte predominance.[496] The effusion usually resolves with anti-inflammatory drug therapy.

IATROGENIC PROCEDURES AND TREATMENTS

Thoracic Irradiation

Small exudative pleural effusions may occur in 10% of patients with radiation pneumonitis after external beam radiotherapy, with higher incidences in patients with esophageal cancer treated with extensive mediastinal radiation.[498] In addition to direct effects on pleural membranes, lymphatic structures, and pulmonary parenchyma, radiotherapy can promote PF formation by causing constrictive pericarditis.[63] The differential diagnosis includes pneumonia with parapneumonic effusions, venous thromboembolism, malignant pleural effusion, drug-induced effusions, and pericarditis. In contrast to malignant effusions, postirradiation effusions do not progress and tend to resolve over time.

Feeding Tubes

Pleural effusions can occur after inadvertent transbronchial placement of a feeding tube into the pleural space.[499,500] Cardiopulmonary

collapse due to massive hydrothorax can occur if misplacement is not promptly recognized and infusates discontinued.[501]

■ OBSTETRICAL AND GYNECOLOGICAL

Postpartum Pleural Effusions

One case series demonstrated small, asymptomatic pleural effusions by chest radiographs in 46% of postpartum patients; the effusions had no relationship with method of delivery or antepartum complications.[502] A subsequent study using US did not confirm these observations finding pleural effusions in only one patient, who had severe preeclampsia.[503] Another study using US detected pleural effusions in 6 of 34 patients with moderate or severe preeclampsia.[504] Considering these observations in aggregate, detection of small, asymptomatic effusions in a healthy woman during antepartum or postpartum periods should not trigger a diagnostic evaluation unless respiratory symptoms exist or other clinical features suggest a pathologic etiology for the effusion.

Meigs Syndrome

Meigs syndrome is defined by the presence of pleural effusions and ascites in a patient with a benign ovarian fibroma or fibrothecoma. The effusions and ascites resolve with resection of the ovarian tumor. The tumors generate large volumes of fluid that flow transdiaphragmatically into the pleural space causing usually right sided, exudative effusions.[505] Meigs syndrome may be associated with marked elevations of serum CA125, which denotes ovarian cancer in other clinical settings.[506–508]

CHAPTER 77
Malignant Pleural Effusions

Steven A. Sahn
John T. Huggins

A malignant pleural effusion is diagnosed by detecting exfoliated malignant cells in pleural fluid or demonstrating these cells in pleural tissue obtained by percutaneous pleural biopsy, thoracoscopy, thoracotomy, or at autopsy. In a number of patients, even though the pleural effusion is caused by the malignancy, neoplastic cells cannot be detected in pleural fluid or pleural tissue and, in fact, probably are not present in these tissues. It is logical to categorize these pleural effusions associated with malignancy, in which there is no direct pleural involvement with tumor and no other cause for the effusion is found, as paramalignant effusions (Table 77-1). Lymphatic obstruction appears to be the most common mechanism for the development of a paramalignant effusion. Other local effects of the tumor causing a paramalignant effusion are bronchial obstruction resulting in pneumonia or atelectasis. Furthermore, it is important for the clinician to recognize that effusions can result from systemic effects of the tumor and adverse effects of therapy.

The presence of a malignant pleural effusion secondary to lung cancer portends a poor outcome.[1] Similarly, a malignant effusion secondary to a nonlung primary is a manifestation of far advanced disease and is associated with limited survival.

TABLE 77-1 Causes of Paramalignant Pleural Effusions

Cause	Comment
Local effects of tumor	
Lymphatic obstruction	Predominant mechanism for pleural fluid accumulation
Bronchial obstruction with pneumonia	Parapneumonic effusion; does not exclude operability in lung cancer
Bronchial obstruction with atelectasis	Transudate; does not exclude operability in lung cancer
Chylothorax	Disruption of thoracic duct or its major tributaries; lymphoma a common cause
Systemic effects of tumor	
Pulmonary embolism	Hypercoagulable state; adenocarcinomas
Hypoalbuminemia	Serum albumin <1.5 g/dL; anasarca typically present
Complications of therapy	
Radiation therapy	
Early	Pleuritis 6 wk to 6 mo following completion of radiation
Late	Mediastinal fibrosis
	Constrictive pericarditis
	Vena caval obstruction
Chemotherapy	
Methotrexate	Pleuritis or effusion ± blood eosinophilia
Procarbazine	Blood eosinophilia; fever and chills
Cyclophosphamide	Pleuropericarditis
Mitomycin	In association with interstitial disease
Bleomycin	In association with interstitial disease

MALIGNANCIES ASSOCIATED WITH PLEURAL EFFUSIONS

Carcinoma of any organ can metastasize to the pleura. However, carcinoma of the lung is the most common malignancy to invade the pleura and produce malignant and paramalignant effusions (Table 77-2). Carcinoma of the breast is second in incidence and, in some populations, exceeds lung cancer as a cause of malignant effusions. Together, both malignancies account for 65% of all malignant pleural effusions.[2] After lung and breast cancer, the frequency declines markedly, with ovarian and gastric cancer representing up to 5% of malignant pleural effusions. Lymphoma accounts for approximately 10% of all malignant pleural effusions and is a common cause of chylothorax. Carcinomas of the lung, breast, ovary, and stomach and lymphomas account for about 80% of all malignant pleural effusions. In approximately 7% of patients with malignant pleural effusions, the primary site is unknown when the diagnosis of a malignant pleural effusion is first established.[3]

A less common cause of a malignant pleural effusion, other than metastatic carcinoma and lymphoma, is a primary tumor of the pleura, malignant mesothelioma. The association of asbestos exposure and malignant mesothelioma was documented in the 1960s following an initial report from the North Western Cape Province of South Africa and a subsequent study of insulation workers in this country. Owing to the long latency period of 20 to 40 years between exposure and onset of disease, death due to a malignant mesothelioma is expected to reach 9000 annually in Europe and 2200 annually in the United States in 2020.

PATHOGENESIS

Lymphatics are situated beneath the parietal pleura over the intercostal spaces. An important feature of the parietal pleura is lymphatic stomata, 2- to 12-μm openings between parietal pleural mesothelial cells. The stomata and their associated lymphatic channels form lymphatic lacunae immediately beneath the mesothelial layer. These lacunae coalesce into collecting lymphatics, which join the intercostal trunk vessels with flow directed mainly toward the mediastinal lymph nodes. The lymphatic system of the parietal pleura plays a major role in the resorption of pleural liquid and protein. Interference with the integrity of the lymphatic system between the

TABLE 77-2 Causes of Malignant Pleural Effusion[a]

Tumor	*n*	Percent
Lung	641	36
Breast	449	25
Lymphoma	187	10
Ovary	88	5
Stomach	42	2
Unknown primary	129	7
All other malignancies	257	14

[a] *n = 1793. Combined data from nine series.*

parietal pleura and mediastinal lymph nodes can result in a pleural effusion.[4–7] Autopsy series have indicated that impaired lymphatic drainage from the pleural space is the predominant mechanism for the accumulation of fluid associated with malignancy: A strong relationship was found between carcinomatous infiltration of the mediastinal lymph nodes and the occurrence of pleural effusion. In contrast, no relationship was found between the extent of direct pleural involvement by metastasis and the occurrence of a pleural effusion. Further support for this mechanism is provided by the observation that pleural effusions generally do not develop when the pleura is involved by sarcoma because of the characteristic absence of lymphatic metastases.

When pleural metastases develop, tumor cells either "seed" the mesothelial surface or invade the subserous layer: When the mesothelial surface is involved, abundant tumor cells can be found in pleural fluid; with subserous involvement, a paucity of malignant cells are exfoliated into the pleural space. Tumor involvement of the pleura causes reactive changes in the mesothelium that may lead to mesothelial shedding, mesothelial thickening, and, on occasion, marked pleural fibrosis. Pleural fibrosis, usually observed in the more advanced stage of tumor involvement of the pleura, is at least partially responsible for the low concentrations of glucose and the low pH seen in some malignant pleural effusions and for the failure to achieve pleurodesis after instillation of chemical agents.

A bloody, malignant pleural effusion usually results from direct invasion of blood vessels, occlusion of venules, tumor-induced angiogenesis, or possibly increased capillary permeability due to vasoactive cytokines and chemokines. Malignant pleural effusions usually contain a large number of morphologically normal lymphocytes, usually in the 50% to 70% range, but typically less than that occurs with tuberculous pleurisy (usually ≥80%). Although the explanation for the lymphocytosis is unclear, these lymphocytes are predominantly T lymphocytes that appear to play a role in the local defense against tumor invasion of the pleural cavity. The percentage of mesothelial cells in malignant effusions is variable, ranging from few to a large percentage of the total cells. An abundance of mesothelial cells occur early in the course of pleural infiltration, before pleural fibrosis and marked infiltration with tumor; in more advanced stages of pleural metastasis, fewer mesothelial cells are generally seen because of pleural fibrosis.

Autopsy findings in patients with malignant effusions have provided valuable information about the pathogenesis of pleural metastases. When carcinoma of the lung metastasizes to the pleura, both the visceral and parietal pleural surfaces tend to be involved. The visceral pleural surface is rarely, and the parietal pleural surface is almost never, the sole site of involvement. Parietal pleural involvement in lung cancer most likely results from neoplastic spread across the pleural cavity from visceral pleural sites along pleural adhesions that are either preformed or secondary to the malignant process.[4–7] The pathogenesis of visceral pleural metastasis in lung cancer appears to be through pulmonary artery invasion and embolization.[5] The histological type of lung cancer does not appear to determine the propensity for pulmonary arterial invasion. Adenocarcinoma of the lung is the most common cell type to involve the pleura because of its peripheral location and spread by contiguity. Bilateral pleural metastases in lung cancer are almost always associated with hepatic involvement and parenchymal invasion of the contralateral lung.

Pleural metastases from primary sites below the diaphragm generally are a manifestation of tertiary spread from established liver metastases. The data with breast cancer are conflicting; some studies show a high incidence of ipsilateral pleural effusion, while others show no such predilection. Probably two mechanisms are operative, chest wall lymphatic invasion resulting in an ipsilateral effusion and hepatic spread with bilateral or contralateral disease.

At diagnosis, pleural effusions are rare in Hodgkin disease but not infrequent in non-Hodgkin lymphoma. Pleural effusions can be found in previously untreated patients with non-Hodgkin lymphoma, even in the absence of detectable intrathoracic lymphadenopathy; however, the pleural effusion is usually not an isolated manifestation of the disease. At autopsy in Hodgkin disease, lymphomatous infiltration of the lung rather than direct pleural invasion or mediastinal adenopathy has been found in association with the pleural effusion. Lymphomatous invasion of the pleura appears to be an uncommon and late finding in Hodgkin disease but is seen with increased frequency in non-Hodgkin lymphoma. As Hodgkin disease progresses, the incidence of pleural effusion increases and approaches 30%. At autopsy, a 30% to 60% incidence of pleural effusions and a 7% to 30% incidence of pleural nodular infiltrative lesions have been noted.[8]

While pleural effusion in lymphoma can be due to impaired lymphatic drainage secondary to mediastinal adenopathy, pleural or pulmonary infiltration, or thoracic duct obstruction, impaired lymphatic drainage appears to be the primary mechanism in Hodgkin disease and direct pleural infiltration the predominant cause in non-Hodgkin lymphoma.[9]

Malignant mesothelioma (see Chapter 79) is usually a unilateral disease (Fig. 77-1); bilateral tumors are present in less than 10% of patients. An early manifestation of the tumor is a pleural effusion that is reabsorbed or organized and then largely replaced by tumor and fibrosis. At autopsy, the lung is often encased in tumor that involves both visceral and parietal pleural surfaces. The pleural space is often obliterated, and the amount of pleural fluid is variable. The tumor seldom penetrates deeply into the lung parenchyma; instead, it extends into interlobar fissures. Hilar lymph nodes are involved by tumor in less than 50% of patients. Distant hematogenous metastases are unusual but have been described in liver, bone, adrenals, thyroid, and kidneys.[10–13]

The two distinct histological types of malignant mesothelioma (epithelial and sarcomatous) generally behave differently. Some patients have mixed tumors with both epithelioid and sarcomatous features. The clinical features of epithelial mesothelioma are similar to those of metastatic carcinoma of the pleura associated with tumor spread by direct extension, that is, a large pleural effusion and metastases to regional lymph nodes. In contrast, patients with sarcomatous mesotheliomas tend to have features characteristic of sarcomas, that is, distant metastases are common, whereas there is little or no pleural effusion. These data are consistent with the pathogenesis of pleural effusions in carcinoma of the pleura, that is, the pleural effusion is primarily due to invasion of the lymphatic system. Moreover, the large bulk of tumor on the pleural surface would be expected to interfere with the removal of pleural fluid by the parietal pleural lymphatics, even if the lymphatics were not directly involved with tumor.

Benign asbestos pleural effusion probably develops as a result of the pleural inflammation that occurs during the passage of asbestos fibers across the pleural space to the parietal pleural lymphatics.

CLINICAL PRESENTATION

Patients with carcinoma involving the pleura most often present with symptoms attributable to a large pleural effusion—dyspnea on exertion and cough. The presence and degree of dyspnea depends on the size of the effusion and the patient's underlying pulmonary function. A therapeutic thoracentesis results in relief of dyspnea in most patients.[14] However, the volume of pleural fluid removed at thoracentesis does not correlate with the change in lung volume. The increase in total lung capacity (TLC) approximates one-third of the volume of fluid removed, while the forced vital capacity (FVC) increases to about one-half of the TLC. Indeed, the mechanism of dyspnea caused by a large pleural effusion appears to be multifactorial in origin, probably entailing a decrease in the compliance of the chest wall, a contralateral shift of the mediastinum, inversion of the ipsilateral

diaphragm, and a decrease in ipsilateral lung volume modulated by neurogenic reflexes from the lungs and chest wall. Other factors that may contribute to dyspnea and cough are postobstructive pneumonia or atelectasis due to a central bronchial lesion, or the presence of infiltrative malignant disease of the pulmonary parenchyma.[15]

Since malignant involvement of the pleura signifies far advanced disease, these patients commonly have substantial weight loss and appear chronically ill. Chest pain may be present because of involvement of the parietal pleura, ribs, or chest wall. However, in a large series of patients with metastatic carcinoma of the pleura, almost 25% were "asymptomatic" at the time of presentation. In these patients, the malignant pleural effusion was first suspected on physical examination or diagnosed on routine chest radiograph. In almost 50% of patients, the pleural effusion was the first indication of cancer.

The respiratory symptoms of patients with pleural effusion due to lymphoma are indistinguishable in nature and frequency from those due to carcinoma. About 20% of patients with lymphoma have no respiratory symptoms when the malignant pleural effusion is diagnosed.

Most patients with carcinoma of the pleura have evidence of a pleural effusion on physical examination when first seen by the physician. Physical signs of pleural effusion are to be expected, since the volume of pleural fluid in most malignant effusions is greater than 500 mL. Cachexia and lymphadenopathy are present in about one-third of patients on initial presentation. Ipsilateral chest wall tenderness and a pleural friction rub are rare.

In contrast to patients with carcinomatous involvement of the pleura, virtually all patients with malignant mesotheliomas are symptomatic when first seen by the physician. In six series of patients encompassing 160 cases of malignant mesothelioma, only one patient was asymptomatic at presentation.[10–12] Chest pain is the most common presenting symptom and occurs in 60% to 70% of patients. Dyspnea and cough are next in frequency and are present in about 25% and 20% of patients, respectively.

Benign pleural effusion due to asbestos exposure is a diagnosis of exclusion. Its frequency of occurrence in exposed workers is estimated to be up to 7%. Benign asbestos pleural effusion is the most common manifestation of asbestos-related pleuropulmonary

disease in the first 20 years after initial asbestos exposure. Two-thirds of patients with benign asbestos pleural effusions are asymptomatic at presentation, with the effusion diagnosed on a routine chest radiograph. Approximately 20% of patients present with pleuritic pain and 10% with dyspnea.[16] The effusion generally persists for several months and resolves within 1 year. Recurrent effusions, either on the ipsilateral or contralateral side, occur in approximately 25% of patients. The differential diagnosis centers around distinguishing benign asbestos pleural effusion from mesothelioma. Since benign asbestos pleural effusion occurs sooner after initial exposure than does mesothelioma (20 years being the rough dividing line), a pleural effusion in a young asbestos-exposed individual is more likely to represent a benign effusion than is an effusion that occurs 20 to 40 years after initial exposure.[16] Also, an asymptomatic pleural effusion is more apt to be benign. The absence of other radiographic manifestations of asbestos exposure is not helpful in distinguishing between a benign effusion and mesothelioma. Preoccupation with asbestos-related disease occasionally leads to overlooking treatable causes of pleural effusion, such as tuberculosis.

CHEST RADIOGRAPHY

A pleural effusion ipsilateral to the primary lesion is the rule in carcinoma of the lung. When the primary site of the cancer is elsewhere than the lung and with the possible exception of breast cancer, there seems to be no ipsilateral predilection and bilateral effusions are common.

In three of four patients who present with carcinomatous involvement of the pleura, the pleural effusion is moderate to large, with volumes ranging from 500 to 2000 mL of fluid. Approximately 10% present with effusions of less than 500 mL; another 10% present with massive pleural effusions (complete opacification of the hemithorax) (Fig. 77-2). Some 70% of patients with a massive pleural effusion have a malignancy.

The finding of bilateral effusions with a normal heart size also suggests a malignant etiology (Fig. 77-3). Approximately 50% of patients who present with this radiographic finding have a malignant effusion. However, lupus pleuritis, hypoalbuminemia, constrictive pericarditis, rheumatoid pleurisy, benign asbestos pleural effusions, and cirrhosis must also be considered in the differential diagnosis.

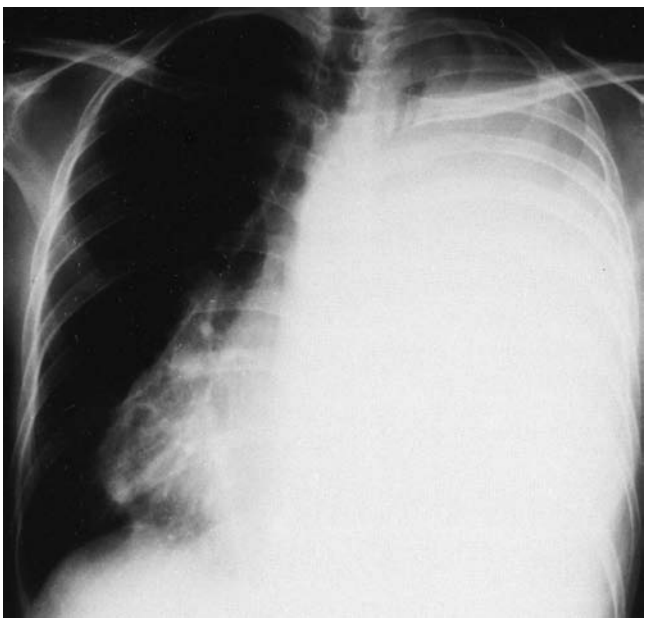

Figure 77-2 Carcinoma of the cervix metastatic to the left pleura and mediastinum. The massive pleural effusion is associated with a contralateral shift of the mediastinum.

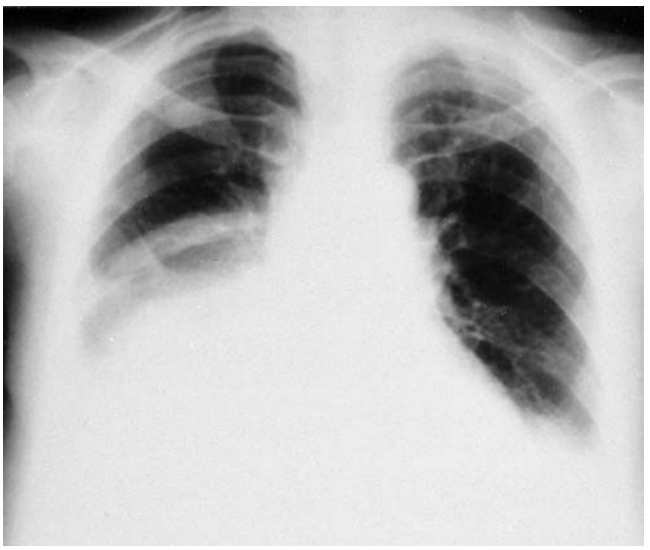

Figure 77-3 Carcinoma of the lung involving right lower lobe, with metastasis to right pleura and mediastinal lymph nodes. The pleural effusions are bilateral and the heart size is normal.

If the mediastinum does not shift contralaterally in the face of a large pleural effusion (>1500 mL), malignancy is highly likely. The following diagnoses are then considered: (1) Carcinoma of the ipsilateral mainstem bronchus resulting in atelectasis (Fig. 77-4); (2) a fixed mediastinum due to malignant lymph nodes; (3) malignant mesothelioma (the radiodensity represents predominantly tumor with only a small effusion); and (4) extensive tumor infiltration of the ipsilateral lung, radiographically mimicking a large effusion. Interstitial infiltrates with effusions (lymphangitic carcinomatosis) and multiple nodules with effusions also suggest malignant disease.

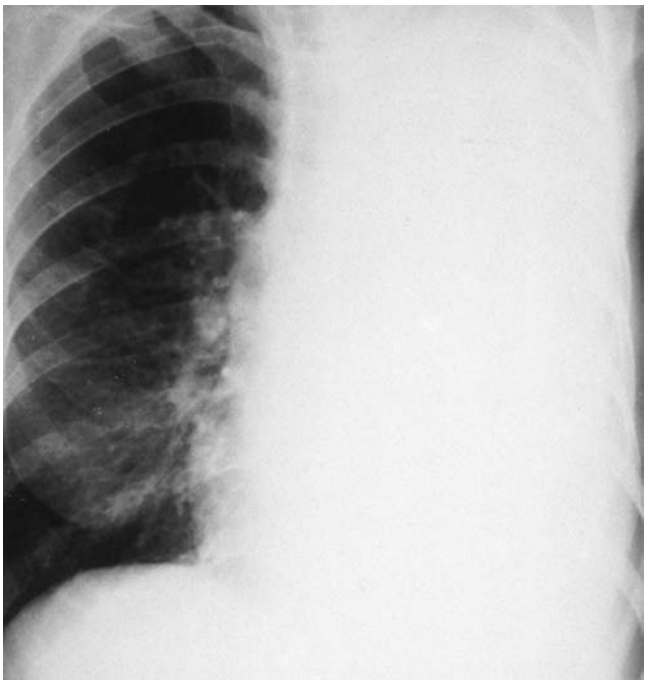

Figure 77-4 Carcinoma of the left mainstem bronchus resulting in complete atelectasis of the left lung. The left hemithorax is completely opacified, and the mediastinum has shifted to the side of the bronchial occlusion. The radiographic opacity represents a combination of collapsed lung and pleural fluid.

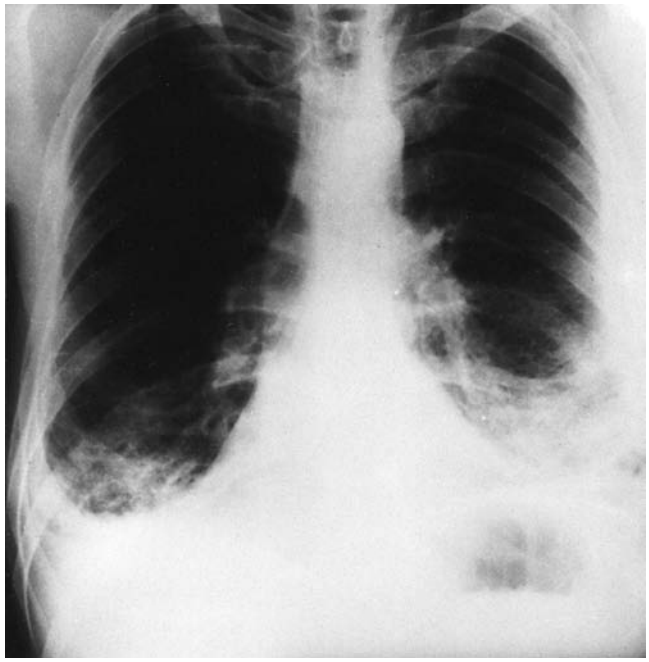

Figure 77-5 Bilateral pleural thickening in a 44-year-old man exposed to asbestos for 18 months 20 years ago. Bilateral pleural effusions were succeeded by progressive pleural thickening.

Depending on the stage of the mesothelioma at the time of presentation, the chest radiograph may show a moderate to large pleural effusion (early) or a nodular, thickened pleura with extension to the apex of the hemithorax (late). Contralateral mediastinal shift often occurs early, that is, when the pleural effusion is large; but, as fluid resorbs and is replaced by tumor, the ipsilateral hemithorax shrinks in size and the mediastinal structures either remain in the midline or shift ipsilaterally (Fig. 77-1).[10–12] Contralateral manifestations of asbestos-induced pleuropulmonary disease, such as pleural plaques with or without calcification and interstitial lung disease, often reinforce the diagnosis. In the more advanced stages of malignant mesothelioma, other radiographic findings are mediastinal widening due to lymph node involvement, an enlarged cardiac silhouette due to pericardial involvement with effusion, and extrapleural lesions, such as soft tissue masses or rib destruction.

Benign asbestos pleural effusions are small to moderate (<1000 mL) unilateral effusions with evidence of pleural plaques or asbestosis identifiable in less than 20% of patients.[16] Calcified pleural plaques are rare, since calcifications require 25 to 40 years from the time of initial asbestos exposure, whereas benign asbestos pleural effusion tends to be the earliest manifestation of asbestos pleuropulmonary disease. Some patients are left with normal chest radiographs, but most have residual abnormalities. These include a blunted costophrenic angle (most common), crow's feet (converging fibrous strands creating a likeness of a bird's foot), rounded atelectasis (in which a portion of the lung periphery has become atelectatic due to pleural adhesions that collapse small bronchi), and diffuse pleural thickening that is sometimes progressive (Fig. 77-5).

PLEURAL FLUID CHARACTERISTICS

Malignant pleural fluid may be serous, serosanguineous, or grossly bloody. The number of nucleated cells in the pleural fluid is modest (1500–4000/μL) and consists of lymphocytes, macrophages, and mesothelial cells. In about one-half of malignant pleural effusions, lymphocytes predominate (50% –70% of nucleated cells). Malignant cells in pleural fluid are rare in some patients; in others, they constitute virtually the complete population. Polymorphonuclear leukocytes usually represent less than 25% of the cell population; but, rarely, when pleural inflammation is active, they predominate. The reported prevalence of pleural eosinophilia in malignant effusions ranges from 8% to 12%.[17] However, malignancy was as frequent in eosinophilic as noneosinophilic pleural effusions. Therefore, the finding of pleural fluid eosinophilia should not be considered a predictor of benign disease.

The pleural fluid in patients with carcinoma of the pleura is typically an exudate with a protein concentration of about 4 g/dL. However, protein concentrations have been reported in the range of 1.5 to 8.0 g/dL. Often unappreciated is the fact that less than 5% of malignant pleural effusions can be transudates. These transudates are due either to concomitant congestive heart failure, atelectasis from tumor obstructing a major bronchus, or the early stages of lymphatic obstruction. Since protein can exit from the pleural space only by parietal pleural lymphatics, a few weeks are necessary for protein to accumulate (from the 1.5 g/dL of normal pleural liquid) to a level of greater than 50% of the serum concentration. Chronic pleural effusions and those with a low pleural fluid pH and glucose tend to have a higher total protein concentration and are virtually never transudates. Sometimes, the total protein pleural fluid to serum ratio may be low (<0.50), but the fluid would qualify as an exudate by lactate dehydrogenase (LDH) criterion alone.

In about one-third of patients with malignant pleural effusions at the time of diagnosis, the pleural fluid pH is low (<7.30), ranging from 6.95 to 7.29. In these low-pH effusions, the glucose concentration is also low (<60 mg/dL, or the ratio of pleural fluid to serum glucose is below 0.5), the lactate concentration is high, the P_{CO_2} is high, and the Po_2 is low.[1,18] As a rule, the glucose concentrations are in the range of 30 to 55 mg/dL though on rare occasions, the glucose is as low as 5 mg/dL. These low-pH, low-glucose effusions have usually been present for several months and are associated with a large tumor burden and fibrosis of the pleura. The markedly abnormal pleura interferes with glucose transport from blood to pleural fluid; the glucose that does enter is metabolized by normal and malignant pleural cells to form CO_2 and lactate. The abnormal pleura impairs the efflux of these end products of glucose metabolism from the pleural space, resulting in pleural fluid acidosis. About 10% of malignant pleural effusions have high amylase concentrations. The finding of a high level of salivary-like isoamylase in a patient without esophageal rupture essentially establishes the diagnosis of malignancy, most likely adenocarcinoma of the lung.

Early in the course of malignant mesothelioma, the pleural fluid may be serous; later, it tends to be hemorrhagic. The effusion associated with malignant mesothelioma is an exudate with a protein concentration in the range of 4 to 5 g/dL and a modest number of nucleated cells (<5000/μL), predominantly mononuclear. The LDH concentration tends to be higher than in the patient with carcinoma of the pleura; frequently the concentration exceeds 600 IU/L. In 60% of patients with malignant mesothelioma, at the time that the diagnosis is established, the pleural fluid pH is low (below 7.30) and the glucose concentration is also low (pleural fluid/serum ratio below 0.5); in contrast, the incidence of low pH and low glucose concentration in carcinoma of the pleura is about 30%. The natural progression of malignant mesothelioma, resulting in large tumor masses and concomitant fibrosis that obliterate the pleural membrane, provides a reasonable explanation for these biochemical findings. In some instances of malignant mesothelioma, the viscosity of pleural fluid is greatly increased because of a high concentration of hyaluronic acid. Although a high concentration of hyaluronic acid in pleural fluid does raise the question of malignant mesothelioma as the cause, this test is not specific and only moderately sensitive; thus, it is of no diagnostic value.

The pleural fluid in benign asbestos pleural effusions is a sanguineous, lymphocyte-predominant exudate, with pleural fluid eosinophilia

in 30% of cases. During the acute stage, there may be a moderate number of polymorphonuclear leukocytes. The pH and glucose are in the normal range (above 7.30 and 60 mg/dL, respectively).

DIAGNOSIS

A malignant pleural effusion can be diagnosed only by demonstrating malignant cells in pleural fluid or pleural tissue. Cytology is a more sensitive test for the diagnosis than percutaneous pleural biopsy, because pleural metastases tend to be focal and the latter is a blind sampling procedure. The yield of either procedure increases as the disease becomes more advanced. It appears, based on thoracoscopy, that initial pleural metastases originate near the mediastinum and diaphragm; as the disease progresses, tumor spreads cephalad and costally. The yield from pleural biopsy with a proven malignant effusion averages 50% to 60%. With improved techniques, the yield from exfoliative cytology now approaches 90% to 95%. If the clinician suspects a malignant effusion, several hundred milliliters of fluid should be removed at the initial diagnostic thoracentesis and at least 60 mL sent for cytological examination.[19] This maneuver will not improve the yield on the initial study but, if it is negative, a repeat procedure several days later may provide fluid with fewer degenerative mesothelial cells and freshly exfoliated malignant cells. Percutaneous pleural biopsy should be reserved for the second thoracentesis if the initial pleural fluid cytological examination is negative. If the second cytological examination and initial pleural biopsy are negative, a third cytological examination and second pleural biopsy soon after, usually is not diagnostic.

There are several options for the patient with suspected malignancy and a negative pleural fluid and pleural tissue examination. These include observation for a few weeks with repeat studies, thoracoscopy, or open pleural biopsy. Before proceeding to more invasive procedures, other causes of an exudative pleural effusion must be excluded. Tuberculous pleurisy should always be considered in the patient with a lymphocyte-predominant exudate with or without a positive tuberculin skin test. The yield from pleural biopsy culture and histology, in conjunction with pleural fluid culture, should provide a bacteriological diagnosis of tuberculous pleurisy in 90% to 95% of cases. Even if diagnostic studies are negative, patients with a positive purified protein derivative skin test or interferon-γ release assay and a lymphocyte-predominant exudate should be treated presumptively for tuberculous pleurisy because of the high risk (43%–65%) of developing active pulmonary or extrapulmonary tuberculosis within 5 years if untreated. Bronchoscopy has a low diagnostic yield for an idiopathic pleural effusion without parenchymal lesions on chest radiograph, ipsilateral mediastinal shift, or hemoptysis. The value of computed tomographic examination of the chest in an undiagnosed exudative effusion is unknown and probably not cost-effective. If observation is the course undertaken, the clinician would expect a malignant pleural effusion to be stable or progress and an effusion not due to malignancy to be stable or regress over time. Failure to identify a malignant pleural effusion for several weeks is rarely a disservice to the patient, who has incurable disease. Exceptions are those malignancies that tend to be responsive to therapy, such as breast cancer, prostate cancer, thyroid cancer, small-cell lung carcinoma, germ-cell neoplasms, and lymphomas.

The diagnostic utility of immunohistochemistry in the diagnosis of malignant pleural effusions secondary to adenocarcinoma, mesothelioma, and lymphoma has been established. Carcinoembryonic antigen (CEA), Leu-M1, B 72.3, Ber-EP4, and BG-8 are the best markers for the diagnosis of adenocarcinoma.[20] Calretinin and cytokeratin 5/6 are the best markers for mesothelioma.[11,20] Flow cytometry is useful in the evaluation of lymphocytic pleural effusions in which lymphoma is a possible diagnosis.[21] The ability of tumor markers to discriminate between benign and malignant pleural effusions is poor. Markers such as CEA, vascular endothelial growth factor (VEGF), carbohydrate antigens (e.g., CA 15-3, 19-9, and 72.4), cytokeratin 19, and enolase have significant overlap between benign and malignant pleural effusions. Hyaluronan does not appear to discriminate between pleural effusions from adenocarcinoma and mesothelioma.[22]

Inflammatory processes involving the pleura may mimic mesothelioma, and patients are often subjected to a battery of tests and consultations before the diagnosis is established. An accurate diagnosis is imperative for proper epidemiological records, appropriate therapeutic intervention, and litigation. Early in the course of a mesothelioma, establishing a definitive diagnosis may be problematic. Pleural fluid cytology and pleural biopsy may allow the diagnosis of malignancy but often cannot distinguish between mesothelioma and adenocarcinoma. Sarcomatous type mesothelioma can be confused with rare tumors, such as fibrosarcomas or hemangiopericytomas. Thoracoscopic biopsy or open thoracotomy is usually necessary to obtain adequate tissue to confirm the diagnosis. Thoracoscopic biopsy has a high diagnostic yield for mesothelioma, approaching 100% in some series, while the yield for pleural fluid cytology alone is 25% and that for combined pleural fluid cytology and closed pleural biopsy is 40%. Histochemical and immunochemical studies, in conjunction with electron microscopy, have improved the accuracy of the diagnosis of malignant mesothelioma.

PROGNOSIS

The diagnosis of a malignant pleural effusion signals a poor prognosis. Patients with carcinoma of the lung, stomach, and ovary tend to have a survival time of only a few months from the time that the malignant effusion is diagnosed; patients with breast cancer tend to survive longer, several months to years, depending on the response to chemotherapy. Patients with lymphomatous pleural effusions tend to have survival times intermediate between those of breast cancer and other carcinomas.

Several studies have suggested that when pH and glucose concentrations in the malignant pleural effusion are low (below 7.30 and 60 mg/dL, respectively), the survival time is less (average 2 months) than in those with a normal pH and glucose (average 10 months). However, in a systematic review of 433 patients with malignant effusions, pleural fluid pH was of marginal clinical utility in predicting survival less than 3 months.[1] Performance status at the time of diagnosis may be the only true predictive marker for mortality. A Karnofsky score less than 30 is associated with a median survival of 1.1 months compared to a median survival of 13.2 months in association with a Karnofsky score more than 70.

A pleural effusion in the setting of lung cancer usually excludes operability; however, approximately 5% of these patients have a paramalignant effusion or an effusion from another cause and may be operable and curable. Thus, it is essential to establish the cause of the pleural effusion before deciding that the patient is not a candidate for curative surgery.

Survival following the diagnosis of malignant mesothelioma is related to the stage of the disease at the time of presentation. Those patients with only ipsilateral involvement of the pleura and lung survive the longest, whereas those with distant hematogenous metastases have the shortest survival. Chest pain portends a worse prognosis than dyspnea, reflecting a more advanced stage of disease. Overall, the median survival in malignant mesothelioma is about 9 months. The epithelial type has a median survival approximately twice that of the sarcomatous type; long-term survivors of more than 3 years are seen almost exclusively with the epithelial type. As in metastatic carcinoma of the pleura, a low-pH effusion in malignant mesothelioma is also predictive of a short survival with one study reporting an association with increasing pH and survival.

Benign asbestos pleural effusions tend to resolve within 3 to 4 months, leaving some residual on the chest radiograph. Although

malignant mesothelioma occasionally develops in patients with benign asbestos effusions, it does not appear to be a harbinger of mesothelioma. Obviously, the risk of developing mesothelioma is greater in these asbestos-exposed individuals than in the general population.

TREATMENT

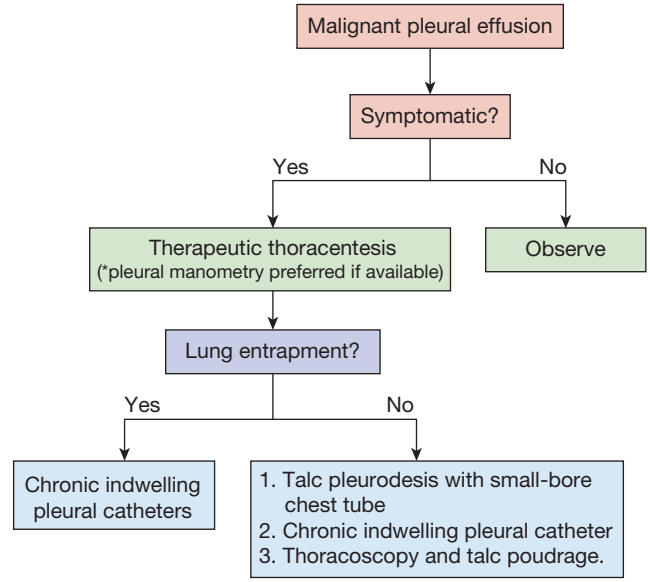
When the pleural effusion has been proved to be malignant or paramalignant and the patient is not a surgical candidate, the type of palliative therapy is weighed, taking into account the patient's general condition, symptoms, performance status, primary tumor type and expected response to therapy, expected survival, and degree of lung reexpansion following pleural fluid evacuation. Several management options are available (Table 77-3 and Fig. 77-6). Asymptomatic patients need not be treated; however, most will develop progressive pleural effusions that will evoke symptoms and require therapy, but some will reach a steady state of pleural fluid formation and removal and not progress to a symptomatic stage. In the debilitated patient in whom a short survival is expected based upon the general health, extent of disease, and biochemical characteristics of the pleural fluid, periodic therapeutic thoracentesis as an outpatient is often preferable to hospitalization for tube thoracostomy and intrapleural instillation of a chemical agent. However, outpatient pleurodesis using small-bore catheters can be accomplished successfully with decreased cost and morbidity.

The most important mechanical factor governing pleurodesis success is the degree of visceral and parietal pleural apposition. Lack of apposition following pleural fluid drainage will not allow for a successful pleurodesis. Current guidelines and treatment strategies rely on the postthoracentesis chest radiographs following thoracentesis to determine if lung reexpansion has occurred. The identification of a pneumothorax "ex vacuo" will typically preclude attempts at pleurodesis if less than 50% of pleural apposition is seen on the chest radiograph.

An unexpandable lung is characterized as the inability of the lung to expand to the chest wall allowing for normal visceral and parietal pleural apposition. Unexpandable lung is the direct result of either pleural disease, endobronchial obstruction resulting in lobar collapse,

TABLE 77-3 Management of Malignant and Paramalignant Pleural Effusions

Option	Comment
Observation	Small asymptomatic effusion; most will progress and require therapy
Therapeutic thoracentesis	Prompt relief of dyspnea; recurrence rate variable
Chemotherapy	May be effective in lymphoma, small-cell lung cancer, breast cancer
Radiotherapy	Mediastinal radiation may be effective in lymphoma and lymphomatous chylothorax
Indwelling catheter	Patient-controlled symptom relief; spontaneous pleurodesis in 50% by 2 mo. Effective for symptomatic relief with lung entrapment.
Chest tube drainage with talc slurry	Control of effusion in >90% of cases if lung entrapment not present
Thoracoscopy with talc poudrage	Control of effusion in >90% of cases if lung entrapment not present
Pleuroperitoneal shunt	When other options have failed or not indicated; may be useful for chylothorax
Pleural abrasion and partial pleurectomy	Virtually 100% effective; requires VATS or thoracotomy



*Pleural space elastance (PEL) > 19 cm H_2O/L with the first 500 mL of fluid removed was shown to have a complete pleurodesis failure at 1 month. PEL > 14.5 cm H_2O/L during the terminal stages of drainage probably have a high predictive pleurodesis failure and we would advocate the use of chronic indwelling pleural catheter in this group.

Figure 77-6 Management algorithm for malignant pleural effusions.

or chronic atelectasis.[23–25] Unexpandable lung occurring as a consequence of active or remote pleural disease may present as a postthoracentesis hydropneumothorax or inability to completely drain the effusion due to the development of anterior chest pain. We believe that pleural manometry is the gold standard for identifying an unexpandable lung during initial pleural drainage. Unexpandable lung occurring as a consequence of active or remote pleural disease has been separated into two distinct clinical entities termed trapped lung and lung entrapment. We define an unexpandable lung with a visceral pleural peel in the absence of malignancy or active pleural inflammation as a trapped lung. In contrast, an unexpandable lung resulting from a visceral pleural peel secondary to active pleural inflammation, infection, or malignancy is defined as lung entrapment.[23–26]

Abnormal lung expansion, detected with pleural manometry, is associated with pleurodesis failure. A pleural space elastance more than 19.0 cm H_2O/L during the first 500 mL of pleural fluid removed was predictive of a 100% pleurodesis failure at 1 month.[27] Abnormalities of lung expansion detected during later stages of pleural drainage are more common in malignant pleural effusions and may affect immediate or delayed pleurodesis outcomes. The frequency with which abnormalities of lung expansion occur in this setting is quite common and approaches 50% of our malignant pleural effusion cases at our institution.

The use of indwelling catheters (PleurX, Denver Biomaterials, Golden, Colorado) has gained popularity because it is an outpatient procedure, and the patient and family can manage the pleural effusion in a timely fashion at home. These catheters have become the mainstay of treatment for a symptomatic refractory or recurrent malignant pleural effusion in most centers in the United States, because they can successfully palliate the symptoms of dyspnea regardless of whether lung entrapment is present or not. Approximately 50% of patients develop spontaneous pleurodesis by 2 months.[28–30] The infection rate appears to be low. However, the expense of the drainage bottles can be prohibitive for some patients. An option with the indwelling catheter is to perform chemical pleurodesis through the catheter 1 or 2 weeks following insertion depending upon the clinical situation. In situations where the patient

with a malignant pleural effusion has lung entrapment, there are two mechanisms responsible for the accumulation of fluid. The patient is instructed to remove fluid when dyspnea occurs and stop drainage immediately when chest pain develops. The onset of substernal chest pain signals the point when the "malignant fluid" has been evacuated, leaving the unexpandable lung from tumor involvement of the visceral pleural surface. The remaining fluid simply represents hydrostatic equilibrium.

Pleural abrasion and/or pleurectomy are highly effective in obliterating the pleural space and controlling a malignant pleural effusion. Although mechanical abrasion can be performed thoracoscopically, pleurectomy is a major surgical procedure associated with considerable morbidity and some mortality.[31] Accordingly, this procedure is reserved for patients who are in good general condition and have a reasonably long expected survival or who have failed a sclerosing agent procedure.

In general, systemic chemotherapy is disappointing for the control of malignant pleural effusions. However, some patients with lymphoma, breast cancer, or small-cell carcinoma of the lung manifest a good response to chemotherapy. In patients with carcinoma of the breast, assessment of steroid receptor status from the malignant pleural fluid can provide valuable information relating to the potential response to hormonal manipulation.

As a rule, radiation of the hemithorax is contraindicated in malignant pleural effusions from lung cancer, since the adverse effects from radiation pneumonitis outweigh possible benefits of therapy. However, radiation may be helpful in patients with lymphoma and lymphomatous chylothorax when involvement of mediastinal nodes predominates.

Until recently, the most common method of controlling a malignant pleural effusion was chest tube drainage and intrapleural instillation of a chemical agent. A number of antineoplastic and nonantineoplastic chemical agents have been used for pleurodesis with variable success. Currently, the most widely used agents are talc, doxycycline, and bleomycin.[32–35] Talc pleurodesis, by either poudrage or slurry, has been shown by numerous investigators to have a success rate of about 90%. In head-to-head comparisons with tetracycline and bleomycin, talc has been shown to be more effective. Talc is available to administer as slurry or an aerosol. When used as slurry through a chest tube, talc is less expensive than doxycycline and substantially less expensive than bleomycin. The use of VATS to administer talc significantly increases the cost and usually requires a few days of hospitalization. The degree of pain associated with talc has been variously reported from nonexistent to severe. Fever following talc poudrage and slurry is common, occurring 16% to 69% of the time. Fever, occasionally as high as 102°F, characteristically occurs 4 to 12 hours after talc instillation and may last for 72 hours. Other complications that have been reported with talc include empyema, arrhythmia, and respiratory failure, including adult respiratory distress syndrome (ARDS) and pneumonitis. The method of administration (poudrage or slurry) does not appear to be associated with the development of respiratory failure, and both high (10 g) and low (2 g) doses have been implicated. The size of the talc particles may be the major risk factor for respiratory failure, with fewer episodes reported with large particle size. Patients with severe pulmonary impairment appear to be at greatest risk of developing acute respiratory failure.[31]

Before instituting chest tube drainage for intrapleural instillation of a chemical agent, it is necessary to demonstrate that fluid removal improves dyspnea. Determination of the FVC and P_{O_2} during the first 12 hours after therapeutic thoracentesis can be misleading. Some patients experience a transient decrease in P_{O_2} and minimal improvement in pulmonary function, despite relief of dyspnea, as dyspnea is largely related to decreased chest wall compliance and stimulation of the neurogenic receptors of the chest wall and lung.

Following the initial therapeutic thoracentesis, the recurrence rate and the interval for return of symptoms should be noted. If recurrence is rapid, with return of dyspnea, pleurodesis should be considered. If the expected survival is at least several weeks, the patient is not debilitated, and the pleural fluid pH is above 7.30, the patient is a suitable candidate for pleurodesis. However, it is fruitless to attempt pleurodesis if the lung cannot be expanded fully, as with bronchial occlusion or lung entrapment. Furthermore, demonstrating a low pleural fluid pH not only suggests a shorter survival but also predicts a lower likelihood of response to chemical pleurodesis. A large tumor bulk involving the pleural surfaces, seen with low-pH, low-glucose pleural effusions, is associated with diminished effectiveness of the chemical agent.

Ideally, when contemplating chemical pleurodesis the patient should undergo pleural manometry with therapeutic thoracentesis.[26] A simple water manometer connected to a digital analog system can determine whether the patient has lung entrapment. If lung entrapment is present, the pleurodesis procedure will not be completely successful. Pleural manometry measures elastance of the pleural space by evaluating the pressure change in relationship to the volume of fluid removed. Individuals with lung entrapment have a significant decrease in pleural pressure with removal of fluid. When the patient's pleural elastance is normal (<14.5 cm H_2O/L of fluid removed) there is a high likelihood of successful pleurodesis with proper technique.[26] The pleural space should be drained as completely as possible so that the pleural surfaces remain in close contact during the time of the initial inflammatory insult. This is best accomplished by tube thoracostomy. A small-bore chest tube, 14 to 16Fr, is as effective as a standard large-bore chest tube and causes less morbidity for the patient. When the follow-up chest radiograph demonstrates that the effusion has been drained and the lung is fully expanded, 5 g of talc slurry should be instilled into the pleural space. Following instillation, the tube should be clamped for 1 to 2 hours. It has been demonstrated that the instillation of radiolabeled tetracycline through a chest tube disperses rapidly and completely in the pleural space without patient repositioning. However, with talc slurry, it is currently recommended that the patient be rotated frequently during the period when the chest tube is clamped, including Trendelenburg and sitting upright. The chest tube should be removed when drainage is less than 150 mL in 24 hours. If a large volume of drainage persists, a repeat dose of talc should be instilled. With the properly selected candidate and rigorously applied technique, the malignant effusion is controlled with talc slurry in about 90% of cases.

A further option available for the patient with an intractable, symptomatic, malignant effusion, who cannot undergo pleurodesis, is a pleuroperitoneal shunt.[36] These shunts have been found to be safe and effective. The shunt may be particularly beneficial in refractory chylothorax, as it allows recirculation of chyle.[37,38] Few complications have been associated with shunt placement, and it can be inserted in patients who are poor surgical candidates. With experienced operators, palliation is obtained in 80% to 90% of properly selected patients. The major problem has been shunt failure, which is most commonly due to clotting of the catheter. It is unknown whether patients who have experienced shunt occlusion are at greater risk for occlusion after a new shunt is placed.

In general, there is a nihilistic attitude regarding the management of patients with malignant mesothelioma because of the tumor's poor response to chemotherapy and radiation therapy. Early in the course of some patients with a mesothelioma, a large unilateral pleural effusion can cause substantial dyspnea. Pleurodesis may be successful in some patients; however, in others, the procedure is unhelpful because of lung entrapment from the tumor burden in the pleural space.

CHAPTER 78

Pneumothorax

S. Rodrigo Burguete
Daniel T. DeArmond
Nilam J. Soni
Jay Peters

DEFINITION

The abnormal presence of air in the pleural cavity, separating the visceral from the parietal pleura, with subsequent collapse of the adjacent lung, is known as pneumothorax. Traditionally, pneumothorax has been classified as having occurred spontaneously or as a result of trauma. Spontaneous pneumothorax is then further subclassified as having occurred without an apparent cause, in a background of clinically normal lungs (primary spontaneous pneumothorax [PSP]) or having occurred in the setting, and as a consequence of, underlying lung disease (secondary spontaneous pneumothorax [SSP]). Although it is now believed that the majority of PSPs occur in the setting of occult lung disease with underlying anatomical abnormalities such as subpleural blebs, this method of classification is still in common practice.

Traumatic pneumothorax occurs as a result of either blunt or penetrating trauma to the chest with a subsequent disruption of the structural integrity of the lung, chest wall, esophagus, trachea, or bronchi. Iatrogenic pneumothorax is a subtype of traumatic pneumothorax resulting as a consequence of diagnostic or therapeutic procedures such as central-line insertions, thoracentesis, or mechanical ventilation.

PATHOPHYSIOLOGY

As alluded to above, air does not normally exist within the pleural space. The pressure within the pleural space is negative with respect to the alveolar pressure during the entire respiratory cycle. Despite this, air does not enter the pleural space from the alveoli. The reason for this lies in the fact that the partial pressure of all gases in the venous blood averages only 706 mm Hg, thereby driving the net movement of alveolar air (760 mm Hg at sea level during end-inspiration) into the capillaries and not into the pleural space, which would require a pleural pressure lower than 706 mm Hg to pull the air in. Under normal circumstances, most individuals do not generate a net negative inspiratory force of −54 mm Hg.[1]

The negative pressure in the pleural space results from the inherent tendency for the lung to collapse (elastic recoil) and of the chest wall to expand. The negative intrapleural pressure is not uniform throughout the pleural space; a gradient of 0.25 cm of water per centimeter of vertical distance can be measured between the apex and the base of the lung. At the apex, the pressure is more negative than at the base, and this pressure difference tends to favor a greater distention of the alveoli located in this region.

The presence of air in the pleural cavity is thought to occur by one of three events: a communication between the pleura and the alveolus, a communication between the atmosphere and the pleural space, or the presence of a gas-producing organism within the pleura.[1] When a communication develops between an alveolus and the pleural space, air will move from the alveolus into the pleural space until there is equalization of pressure or until the communication is sealed. The same happens with a communication between the chest wall and the pleural cavity. The greater the amount of air that enters the pleural cavity, the more the lung collapses. If unabated, enough air may enter the pleural space to cause a shift of the mediastinum and eventually lead to hemodynamic compromise, a condition referred to as tension pneumothorax.

Although the mechanism responsible for PSP is not completely understood, experimental overdistention of normal lungs results in rupture of subpleural alveoli.[2] Air can dissect along the bronchovascular sheath medially to produce pneumomediastinum, which may be accompanied by subcutaneous emphysema or pneumothorax (Fig. 78-1), or it can dissect to the peripheral portion of the lung.[3] Peripheral dissection of air may result in an air-containing space within or immediately beneath the visceral pleura. Pathologic studies of resected lungs from patients with PSP usually show one or both of these types of airspaces, a bleb or a bulla. A pneumothorax may occur when these peripheral bullae or blebs become distended and rupture into the pleural space.

Clinically, the results of a pneumothorax are dependent on the degree of lung collapse but the main physiologic consequences of a pneumothorax are a decrease in the vital capacity of the lung and a decrease in the Pa_{O_2}. The reduction in arterial Pa_{O_2} appears to be caused by low ventilation–perfusion (V/Q) ratios, anatomic shunts, and, occasionally, alveolar hypoventilation. Total lung capacity, functional residual capacity, and diffusing capacity are also reduced, though less than vital capacity. Air in the pleural space eliminates the gravitational gradients of pleural pressure and regional lung volume so that regional ventilation is more uniform and reduced. Anthonisen reported that lungs demonstrate airway closure at low lung volumes and suggested that airway closure is the main cause of V/Q imbalance in patients with pneumothorax.[4] If perfusion to the collapsed lung is preserved, there is an increase in pulmonary

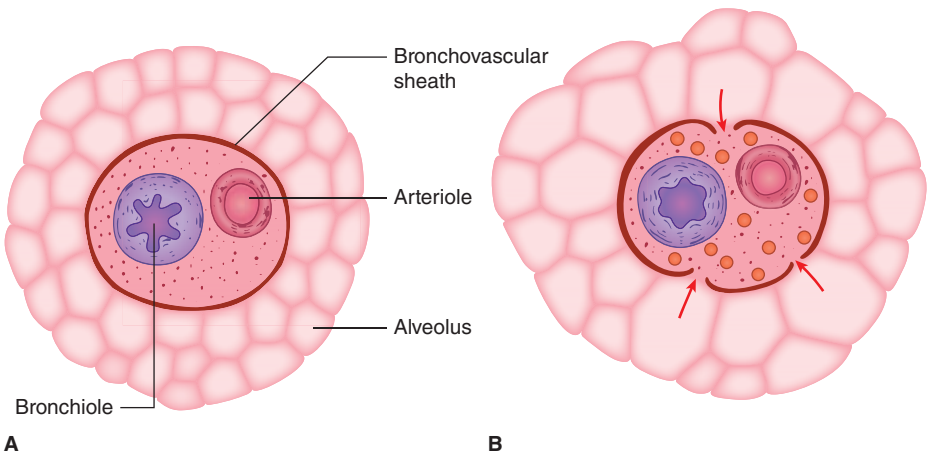

Figure 78-1 Proposed mechanism of alveolar rupture in spontaneous pneumothorax. **A.** Normal structures. **B.** Overdistention of marginal alveoli. Pressure in the adjacent bronchovascular sheath remains lower than in the overdistended alveoli. This pressure gradient may lead to rupture of the alveoli with dissection of air toward the pleura or mediastinum. *(Reproduced with permission from Maunder RJ, Pierson DJ, Hudson LD. Subcutaneous and mediastinal emphysema: pathophysiology, diagnosis, and management. Arch Intern Med. 1984;144(7):1447–1453.)*

shunt and substantial hypoxemia. If perfusion to the collapsed lung is reduced by hypoxic vasoconstriction, hypoxemia may be minimal. In general, pneumothoraces occupying less than 25% of the hemithorax are not usually associated with significant shunts.[5] Under normal circumstances, despite the degree of pneumothorax; hypoxemia tends to abate within 24 hours, presumably from redistribution of pulmonary blood flow.

In the healthy person, the decrease in vital capacity and Pa_{O_2} is typically well tolerated. In patients with compromised pulmonary function prior to pneumothorax, the decrease in vital capacity may result in significant hypoxemia, alveolar hypoventilation, and respiratory acidosis. Upon evacuation of air from the pleural space, the Pa_{O_2} usually improves. In animal studies, the Pa_{O_2} returns to baseline immediately after reexpansion of the lung.[6] In humans, normalization of the Pa_{O_2} takes longer and may occur over hours to several days. The delay in improvement may be related to the duration of the pneumothorax.

REABSORPTION OF PLEURAL GASES

The time required to absorb all gases in a pneumothorax is quite variable. It has been estimated that between 1% and 6% of a pneumothorax is absorbed in 24 hours.[7] Gas reabsorption from the pleural space is achieved by simple diffusion from the pleural space into the venous blood. The rate of gas reabsorption depends on four variables: (1) the pressure gradient for the gases between the pleural space in relation to the venous blood, (2) the diffusion properties for the gases present in the pleural space, (3) the area of contact between the pleural gas and the pleura, and (4) the permeability of the pleural surface. (i.e., a thickened, fibrotic pleura will absorb less than normal pleura.)

The solubility and diffusion properties of different gases vary considerably, and the speed of reabsorption will depend on the type of gas. Oxygen will be absorbed 62 times faster than nitrogen, the slowest gas to be reabsorbed. Carbon dioxide will be absorbed 23 times faster than oxygen, and carbon dioxide and water vapor will equilibrate almost instantaneously. Under normal circumstances, the total gas pressure in the pneumothorax is within a few millimeters of mercury of that of the atmosphere, or 760 mm Hg. Tissue gas tensions are close to those of systemic venous blood: typically pCO_2 = 46 mm Hg, pO_2 = 40 mm Hg, pH_2O = 47 mm Hg, and pN_2 = 569 mm Hg, giving a total pressure of 702 mm Hg as mentioned above. This positive-pressure gradient between the pneumothorax and the venous blood constitutes the driving force responsible for gas reabsorption from a pneumothorax.

When breathing room air, this driving force is only 58 mm Hg (760–702 mm Hg) and this limits the rate of resorption (Fig. 78-2). During inhalation of 100% oxygen, the total gas pressure is about 146 mm Hg. This difference is due to the reduction in partial pressure of nitrogen from 569 to zero mm Hg. Though this is associated with an increase in oxygen in arterial blood from 100 to 640 mm Hg, oxygen consumption in the tissues ensures that the partial pressure in the end-capillary blood rises only slightly (from 40 mm Hg to about 54 mm Hg). The results of one, small prospective human trial and one experimental, animal model trial suggest that administration of high-flow oxygen can expedite resolution of a pneumothorax.[8,9]

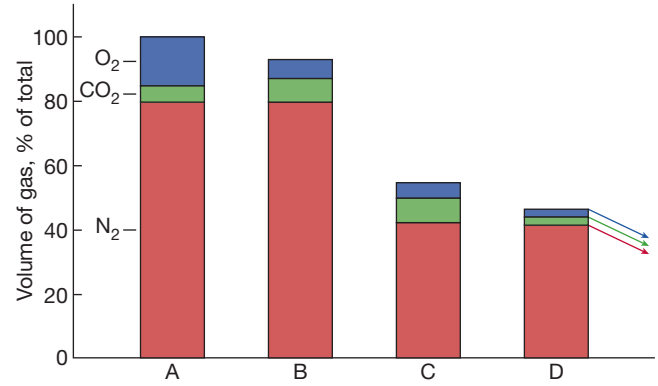

Figure 78-2 Hypothetical representation of the resorption of a spontaneous pneumothorax. **A.** Closed pleural space after leak has stopped. The alveolar gas in the space contains 15% O_2, 5% CO_2, and 80% N_2. **B.** CO_2 and O_2 have quickly equilibrated with the surrounding tissues; the amount of N_2 in the pneumothorax is unchanged. The pneumothorax is already decreased by about 10%. **C.** The number of N_2 molecules is unchanged, but the total volume of the pneumothorax has decreased (see **B**). Therefore, the outward diffusion of N_2 increases because pN_2 in the pleural space is greater than pN_2 in the tissues. As N_2 diffuses out, the total volume of gas in the pleural space decreases and concentrations of O_2 and CO_2 increase. As a result, O_2 and CO_2 diffuse out of the pleural space. **D.** The high N_2 concentration promotes the exit of N_2 from the pleural space and continues the cycle by which the pneumothorax grows smaller. *(Reproduced with permission from Farhi LE. Atmospheric nitrogen and it's role in modern medicine. JAMA. 1964;188:984–993.)*

SYNDROMES

■ PRIMARY SPONTANEOUS PNEUMOTHORAX

Epidemiology

The age-adjusted annual incidence of PSP ranges from 7.4 to 18 cases per 100,000 population in males and 1.2 to 6 cases per 100,000 in females. The male-to-female ratio ranges from 3:1 to as high as 6:1 and the characteristic patient is a tall, thin male in the third to fifth decade of life.[1,10]

Patients with PSP tend to be taller and thinner than control populations. A study of military recruits who developed spontaneous pneumothorax found subjects to be, on average, 2 in taller and 25 lb lighter than the typical military recruit.[11] In another study, the frequency of PSP rose with increasing stature and reached an incidence of 200 per 100,000 person-years for subjects at least 76 in tall.[10]

In addition to stature and male sex, tobacco smoking significantly increases the risk of spontaneous pneumothorax and has been associated with a ninefold or greater risk of developing a first PSP.[12] The relative risk of PSP has been shown to exhibit a dose–response relationship with the quantity of cigarettes per day and the length of exposure, increasing more than 20 times in men who smoke one-half pack per day and 100 times in men who smoke one pack per day compared to nonsmokers. The lifetime risk in healthy smoking men may be as high as 12%, as opposed to 0.1% in nonsmokers.[12] One review of 402 patients with spontaneous primary pneumothorax reported that 92% of the patients were smokers or ex-smokers.[5] Another study showed that patients who had stopped smoking more than 1 year before their first spontaneous pneumothorax had no recurrence during a follow-up of 5.2 years.[13]

Etiology

Although the diagnosis of PSP is restricted to patients without primary lung disease, it is likely that many of these patients do in fact have underlying lung pathology. Thus, a more accurate description of PSP is pneumothorax occurring in patients with no *obvious* lung disease.[14] While the exact mechanism by which a spontaneous communication between the alveolar space and the pleura has not been elucidated, most authors believe that rupture of a previously unidentified bleb or bulla adjacent to the pleura is to blame for the development of PSP.[15] These subpleural blebs and bullae are typically referred to as emphysema-like changes (ELCs) when seen on CT scan and, although it has been shown that the majority of patients with PSP have ELC, no causal relationship has clearly been established. These blebs are demonstrated by chest radiograph in only 20% of cases of PSP, but can be seen in approximately 80% of affected patients by both CT imaging and by surgical evaluation.[16,17]

In two studies, ELCs were found in 89% on the ipsilateral side and up to 80% bilaterally, while only 20% of those without PSP had these changes.[18,19] Another study showed that 81% of nonsmokers with healed PSP had ELCs while those nonsmokers without PSP had none.[20] Despite this clear association, a causative relationship is still debated. In part, this is due to the observation that only a minority of blebs are observed to be ruptured at the time of surgery, and other lesions, termed pleural porosity, are observed.[1] Pleural porosity is believed to predispose the pleura to air leakage by disruption or replacement of the mesothelial cells of the visceral pleura with inflammatory cells that increase pleural permeability.[17]

The pathogenesis of these bullae, blebs, and pleural porosity is not definitively known but has been associated with a variety of elements, most commonly with airway inflammation.[21,22]

Airway inflammation secondary to cigarette smoking may be associated with or contribute to the development of these blebs. Respiratory bronchiolitis in smokers may be an important element in the development of PSP.[23] Pathologic evidence of respiratory bronchiolitis was found in more than 88% of smokers undergoing surgery for PSP.[24]

In addition to airway inflammation, other factors have been linked to ELC and pleural porosity, including connective tissue abnormalities, hereditary influences, increased negative pressure at the apices associated with ectomorphic body habitus, anatomical bronchial abnormalities, and overdistention of alveoli with poor collateral ventilation. Pleural pressure is most negative at the apices, and the degree of negativity relates to the height of the lungs. The alveoli of taller persons are subjected to greater mean distending pressures. Over a long period, this phenomenon could lead to the formation of subpleural blebs in a taller population genetically predisposed to bleb formation.

There are multiple reports of genetic associations or patterns of PSP. Some reports suggest that PSP is inherited through an autosomal dominant gene with variable penetrance[25] while others report an associated autosomal recessive[26] or an X-linked recessive inheritance pattern.[25] Genetic risk factors that have been associated to PSP include the HLA haplotype $A_2B_{40,}$[27] the α_1-antitrypsin phenotypes M_1M_2, and the FBN1 gene mutations.[28]

The rate of recurrence after a PSP is approximately 25% (range: 23%–52%) and recurrence usually occurs within 1 to 2 years after the first episode.[29] The rate of recurrence may increase with each successive pneumothorax. In one study, the risk of recurrence increased to more than 60% after the second pneumothorax and to 83% after the third.[30] Although there is no predilection for the right or left hemithorax with the initial episode, more than 75% of recurrences occur on the same side as the first pneumothorax. Despite the documentation that pleural blebs occur bilaterally in many patients with PSP, the risk of contralateral pneumothorax is only 5% to 10%. Risk factors for recurrence that have been identified include greater height, lower weight, and smoking status.[31]

Death rarely occurs after PSP.[32] In a study of spontaneous pneumothorax in which patient ages ranged from 15 to 34 years (most likely representing patients with PSP) the mortality rate was reported to be 0.09% for men and 0.06% for women.[33]

■ SECONDARY SPONTANEOUS PNEUMOTHORAX

Epidemiology

SSP is a more serious event than PSP because, by definition, the patient has underlying lung disease. A pneumothorax in a patient with already diminished pulmonary reserve can be life-threatening and requires more immediate medical attention and intervention.

The incidence of SSP is similar to that of PSP. An epidemiologic study in Olmsted County, Minnesota, documented an incidence of SSP of 6.3/100,000 year for males and 2/100,000 year for females.[10] On average, patients with SSP are 15 to 20 years older than patients with PSP due largely to the older age of patients with emphysematous lung disease. The risk of recurrence for SSP is somewhat higher than for PSP and ranges from 40% to 80%, again, likely due to the underlying lung pathology.

Etiology

A variety of pulmonary diseases have been associated with spontaneous pneumothorax, but chronic obstructive pulmonary disease (COPD) is the most common. The Veterans Administration Cooperative Study on Pneumothorax noted that pneumothorax tended to occur in patients with moderately severe COPD, with a quarter of the participants having an FEV_1 below 1 L and a mean FEV_1/FVC ratio of 57%.[34] Persistent bronchopleural fistula was also noted to be common in patients with obstructive lung disease, and 35% of patients had an air leak for more than 5 days.

Although airway diseases (COPD, cystic fibrosis [CF], and severe asthma) are the most common underlying lung disorders, a wide spectrum of pulmonary diseases has been associated with SSP (Table 78-1).[35]

In contrast to the low mortality rate associated with PSP, patients with SSP have a much higher risk of death. The VA Cooperative study reports an analysis of three papers that combined, reveal a

TABLE 78-1 Etiology of Secondary Spontaneous Pneumothorax

Obstructive Lung Disease
Chronic obstructive pulmonary disease (COPD)
Asthma
Interstitial Lung Disease
Idiopathic pulmonary fibrosis (usual interstitial pneumonitis [UIP])
Nonspecific interstitial pneumonitis
Langerhans cell histiocytosis
Lymphangioleiomyomatosis

Other
Catamenial pneumothorax
Pulmonary infarction
Pulmonary alveolar proteinosis
von Recklinghausen disease
Granulomatosis with polyangiitis (Wegener)

mortality of 16% for SSP.[34] Videm et al.[36] showed that SSP increased the mortality of age-matched COPD patients by 3.5 times.

Cystic Fibrosis

Pneumothorax is a common and potentially serious complication of CF lung disease. It occurs more frequently in CF than in the general population and results in significant morbidity and mortality, typically occurring with more advanced disease. Approximately 3.5% of patients with CF will suffer this complication at some point in their lives. The majority occur in adulthood, with a median age of 21 years.[37] Pneumothorax may also be a marker of poor prognosis with one study showing the median survival after the first spontaneous pneumothorax to be only 29.9 months.[38]

The pathophysiology of spontaneous pneumothorax in CF is likely related to chronic airway inflammation that eventually leads to structural changes with severe airflow obstruction; inflammation with poor clearance of thick, inspissated secretions; air trapping in the distal airways; and eventual rupture of the pleural surface with rising alveolar pressures.[37]

The risk of developing pneumothorax increases with age and with declining pulmonary function (FEV_1). A recent study of pneumothorax in CF demonstrated that the risk of pneumothorax increased by 50% when FEV_1 was <30% predicted.[39] Other important risk factors for the development of pneumothorax include the presence of *Pseudomonas aeruginosa, Burkholderia cepacia,* or *Aspergillus* in the airways, and the use of Dornase alfa. The presence of these airway pathogens may increase inflammation and secretions leading to obstruction and the use of inhaled Dornase alfa may cause bronchospasm leading to acute decline in FEV_1 with inhalation.[40]

CF-specific recommendations exist regarding the management of pneumothorax.[41] A full discussion of these is beyond the scope of this chapter but several points regarding airway clearance in the setting of pneumothorax are of particular importance. With small pneumothoraces it is recommended that most airway clearance modalities could be continued, with the exception of those providing positive-pressure or percussive ventilation, which could further increase the size of pneumothorax. With large pneumothorax, it is recommended that airway clearance modalities should be held. Though the use of inhaled medications could provoke coughing, it is not recommended that these be held.

Recurrence of pneumothorax is more frequent in this population. An estimated failure rate of 37% with tube thoracostomy alone has been reported, but up to 70% of all patients have either an initial treatment failure, or an ipsilateral recurrence, ultimately needing more definitive treatment.[42] Despite the recurrence rate being so high, the guidelines recommend reserving pleurodesis for large recurrent pneumothoraces.[41] However, because the recurrence rate in CF is high, many CF centers still consider pleurodesis after the first episode. In the past, there was concern that pleurodesis would preclude patients from lung transplantation. However, recent studies have shown that pleurodesis does not add appreciably to complications during lung transplantation.[43–45] Although center-dependent, pleurodesis is no longer considered a contraindication to transplantation.[43]

Catamenial Pneumothorax

Catamenial pneumothorax is a rare condition that occurs in women and is defined as recurrent pneumothoraces occurring within 72 hours of onset of menses. One study reported a mean of 3.17 episodes (range: 2–10) in a population of women prior to surgical treatment.[46] This syndrome, by designation, occurs during the reproductive years, usually in the third or fourth decade of life; however, cases associated with hormone replacement have been reported.[47] Though initially felt to be extremely rare, the condition is becoming increasingly recognized. A series from the Mayo Clinic found the condition in 5.6% of women with spontaneous pneumothorax over a 21-year period; however, more recent studies suggest the incidence of this disorder may actually be much higher.[48,49]

There is no single, definitive etiology for the development of catamenial pneumothorax. One theory suggests pleural and/or diaphragmatic endometriosis as the basis for this disorder; yet, only a fraction of women is found to have endometrial deposits at the time of surgical exploration. Alternative mechanisms that have been proposed include peritoneal air entering the thoracic cavity through diaphragmatic defects during menstruation or intercourse, endometrial implants in the terminal bronchioles causing obstruction, and increased circulating levels of prostaglandin $F_{2\alpha}$ during menstruation resulting in bronchospasm and vasospasm.[47] It is possible that various pathogenic mechanisms are at work.

The diagnosis, as mentioned above, is based on *recurrent* pneumothorax occurring within 72 hours of the onset of menses. Onset is typically heralded by chest pain and dyspnea. Over 90% of catamenial pneumothoraces affect the right hemithorax, but isolated left-side or bilateral pneumothoraces have been reported.

Given the unacceptably high recurrence rate of 50% to 100% with medical treatment alone, management with surgery followed by medical/hormonal therapy is typically indicated.[47,49,50] Surgical treatment, which can be accomplished with video-assisted thoracoscopy, involves excision of endometrial implants, closure of any diaphragmatic defects, stapling of any blebs, and pleurodesis. Medical treatment is aimed at suppressing the ectopic endometrium and ovulation and at preventing further seeding. This is typically accomplished by using oral contraceptives, danazol, or gonadotropin-releasing hormone agonists. No controlled trials have examined the efficacy of one medication over another. If menses is not suppressed, there is a risk of recurrence, even after surgical treatment. Hysterectomy with bilateral oophorectomy will induce surgical menopause and has been employed to prevent pneumothorax.[47]

Pneumothorax in Acquired Immunodeficiency Syndrome

Patients with acquired immunodeficiency syndrome (AIDS) have a significantly increased risk of developing pneumothorax. Roughly 2% to 5% of AIDS patients experience spontaneous pneumothorax. In one study, pneumothorax complicated 1.2% of 599 HIV patient admissions over 3 years.[51] Mortality was significantly higher (30.8%) in patients with pneumothorax than in those without (5.8%).

Pneumothorax in AIDS patients is associated with multiple infectious etiologies. *Pneumocystis jiroveci,* bacterial infections, Kaposi sarcoma, cytomegalovirus, pulmonary Cryptococcus, coccidiomycosis, and mycobacterial disease have all been associated with spontaneous pneumothoraces. Other risk factors for the development of pneumothorax in HIV include tobacco use, treatment with inhaled pentamidine, and the presence of a pneumatocele on chest radiograph.

Most studies have shown *Pneumocystis jiroveci* pneumonia (PCP) to be the primary etiology. However, a recent observational study of 105 HIV patients with spontaneous pneumothoraces found bacterial pneumonia to be the major underlying etiology (34.3%) followed by PCP (29.5%) and pulmonary tuberculosis (15.2%).[52] In addition, the authors noted that bacterial pneumonia was a more common cause among drug users and those with CD4+ count over 200 cells/mL whereas PCP was a more common cause among patients with sexually transmitted HIV and CD4+ counts less than 200 cells/mL. Bilateral pneumothoraces were more commonly associated with PCP. Given the strong association with PCP, evaluation and treatment for PCP is recommended in any patient with

AIDS who presents with an otherwise unexplained spontaneous pneumothorax.

The high frequency of pneumothoraces seen in patients with PCP is thought to be secondary to the presence of subpleural cysts and subpleural necrosis associated with this entity. Extensive tissue invasion within the alveolar interstitium is common in severe PCP and may result in subpleural necrosis. These cystic changes are thought to be due to repeated episodes of inflammation and cytotoxic effects of HIV on pulmonary macrophages with elastase production and necrosis of lung tissue.[44,53] These lesions occur most frequently at the apices of the lungs and consist of necrotic alveoli filled with *P. jiroveci* organisms, macrophages, eosinophilic exudate, and fibrinous material.[54] Histologic examination of patients who have recovered from PCP demonstrates subpleural blebs and bullae as well as pneumatoceles. Because of the necrotizing nature of the pneumonia, spontaneous pneumothorax from PCP is notoriously difficult to treat. Persistent air leaks often require tube thoracostomy for several weeks, and up to one-quarter of patients require surgical intervention. Some authors recommend early thoracoscopic therapy in good surgical candidates to avoid prolonged hospitalization.

The incidence of bilateral cystic disease in these patients is extremely high, and the incidence of contralateral pneumothorax was about 50% in one study.[55] Therefore, if surgical intervention is planned, some authors recommend preoperative CT scan of the chest and median sternotomy in patients with significant bilateral disease to facilitate bilateral pleurodesis.

With the rise of AIDS, the frequency of pulmonary tuberculosis has increased. Pneumothorax has been reported in approximately 7% of HIV patients with pulmonary tuberculosis.[56] All pneumothoraces associated with tuberculosis should be treated and often require prolonged periods of chest tube drainage. In cases of tuberculosis, it has been suggested that thoracotomy should not be considered until the patient has received antituberculous therapy for at least 6 weeks; however, objective evidence that this affects outcome is lacking.

TRAUMATIC PNEUMOTHORAX

Trauma is the most common cause of pneumothorax. Patients who have either polytrauma or trauma to the thorax are at risk for pneumothorax. In one study of over 300 pneumothoraces, trauma was responsible for 56% of cases, the majority of which were iatrogenic.[10] Noniatrogenic, traumatic pneumothorax can result from either penetrating or nonpenetrating chest injury. The diagnosis needs to be considered in any patient who is evaluated for significant trauma.

Penetrating chest trauma produces a pneumothorax by allowing air to enter the pleural cavity directly through the chest wall. In addition, if the visceral pleural is penetrated, air may leak from the tracheobronchial tree. If the continuity of the chest wall is disrupted, an open pneumothorax is produced. If the opening in the chest wall is larger than the diameter of the trachea (1.2–1.5 cm in an adult), air movement occurs through the pathway of least resistance, and air is preferentially inspired into the thoracic cavity through the open chest wound. Any open chest wound must be occluded to assure adequate ventilation of the patient.

Pneumothorax is also a frequent finding in patients with blunt trauma to the chest. The visceral pleura may be lacerated secondary to a rib fracture or dislocation; however, in almost one-half of patients with pneumothorax secondary to blunt trauma, there are no associated rib fractures. This is especially common with blunt trauma to the chest secondary to blast injuries and high-altitude falls into water. In such incidents, the abrupt increase in the pressure gradient between the alveolus and the adjacent bronchovascular sheath causes disruption of the alveolar membrane. Dissection of air through the interstitial space results in either pneumothorax or pneumomediastinum.

Occasionally, patients with traumatic pneumothorax have coexisting injuries of the tracheobronchial tree or of the esophagus. In a patient with a traumatic pneumothorax, fiberoptic bronchoscopy should be performed in the presence of hemoptysis or a persistent air leak. Eighty percent of injuries to the tracheobronchial tree are within 2.5 cm of the carina, most commonly on the right side at the membranous–cartilaginous interface. The main lobar bronchi and the cervical trachea are the next most common sites of injury.

Traumatic rupture of the esophagus usually produces a hydropneumothorax. Therefore, if a patient with a traumatic pneumothorax also has a pleural effusion, the possibility of esophageal rupture should be entertained. Almost all patients with perforation of the thoracic esophagus also have dysphagia and pneumomediastinum. An elevated pleural fluid amylase concentration is a reliable screening procedure for esophageal rupture. Once the diagnosis is suspected, contrast radiographic studies of the esophagus should be performed as soon as possible. Untreated, esophageal rupture results in mediastinitis and septic shock; therefore, a high index of suspicion is essential in making an early diagnosis.

Increasing utilization of invasive diagnostic and therapeutic interventions has significantly increased the rate of iatrogenic pneumothorax. These cases may result in considerable morbidity, prolonged hospitalization, and even death, for the affected patient.[57] Iatrogenic pneumothorax can occur as a complication of multiple procedures, but the leading cause of iatrogenic pneumothorax is transthoracic needle aspiration followed by subclavian vein catheter insertion, thoracentesis, transbronchial biopsy, pleural biopsy, and positive-pressure ventilation.[58] The incidence ranges between 20% to 40% with transthoracic needle aspiration; risk factors include COPD, depth of lesion within the lung, and lesions smaller than 2 cm.[59–61] Pneumothorax may also occur with transbronchial needle aspiration, liver biopsy, intercostal nerve block, mediastinoscopy, and tracheostomy among others.

Central venous catheterization carries the second highest risk of iatrogenic pneumothorax. The reported risk ranges from 2% to 12% when using anatomic landmarks for guidance. Subclavian catheterization carries a higher risk than internal jugular catheterization. The increasing use of real-time sonographic guidance for central venous catheterization has significantly decreased this risk for both internal jugular and subclavian approaches.[62,63] Similarly, the routine use of real-time ultrasound guidance for localization of needle puncture site during thoracentesis may decrease the risk of pneumothorax, which develops in approximately 5% of cases.[64]

Another cause of pneumothorax that is frequently overlooked is chest tube malfunction. Common causes of chest tube malfunction include inadequately securing the chest tube to the drainage system, failing to fill the U-tube manometer in the water seal chamber, failing to refill the water in the suction control chamber, and permitting intermittent disconnection of the system during diagnostic or therapeutic studies.

Mechanical ventilation is a frequent, potentially lethal cause of iatrogenic pneumothorax. The overall incidence of pneumothorax during mechanical ventilation ranges from 4% to 15%, but may be significantly higher in patients with underlying inflammatory diseases such as aspiration pneumonia.[65] The incidence of pneumothorax is also increased during mechanical ventilation if patients have chronic pulmonary disease, are on increased amounts of positive end-expiratory pressure, or have right mainstem intubation.[65] The incidence of pneumothorax has been reported to be 6.9% to 14% of patients with acute respiratory distress syndrome (ARDS).[66,67]

Another study reported a 48.8% incidence of pneumothorax in patients with severe ARDS requiring extracorporeal support.[68]

A pneumothorax should be suspected in any patient whose clinical status acutely decompensates on the ventilator. Bedside clues include a sudden increase in respiratory rate or appearance of patient-ventilator dyssynchrony. An increase in the peak and plateau pressures on the ventilator can be a sensitive indicator if the patient is on volume-cycled ventilation. The peak inspiratory pressure often rises suddenly as the lung compliance falls. If the patient is on pressure control ventilation, decreased tidal volumes will be a sign of pneumothorax.

Radiographs of critically ill, mechanically ventilated patients are frequently obtained only in the supine or semisupine position. In one study, supine and semierect radiographs were obtained in 88 critically ill patients with 112 cases of pneumothorax.[69] The radiologist initially failed to detect the pneumothorax in 30% of the cases. Patients with extensive infiltrates, such as in the setting of ARDS, may have no suggestion of lung collapse on chest radiograph. In these patients, the only radiologic sign that may be evident is that of a deep sulcus on the side of the pneumothorax. This finding, as well as any increased lucency on a supine film, should raise suspicion of a pneumothorax and be evaluated by either erect or decubitus views, or ultrasound. If erect or decubitus films cannot be obtained or ultrasound is unavailable, CT scans of the chest may be necessary.

It should be noted that recipients of bilateral lung transplants and patients who have had a "clamshell" thoracotomy do not have an intact mediastinum. Because of this, the normally separate pleural spaces may be in direct communication with each other. Physicians performing procedures on these patients need to be aware that the patient can develop bilateral pneumothoraces because of this anomaly.[70]

CLINICAL FEATURES

The main symptoms with the development of a pneumothorax are chest pain and dyspnea, which occur in 95% of patients. The pain is usually acute, localized to the side of the pneumothorax, and typically pleuritic. Cough, hemoptysis, orthopnea, and Horner syndrome are uncommon manifestations of a pneumothorax.[5,71] A small percentage of patients are asymptomatic or complain only of generalized malaise.

Spontaneous pneumothorax usually occurs at rest, and fewer than 10% occur during strenuous exercise. In PSP, both the dyspnea and chest pain may subsequently abate over the first 24 hours. This may explain why nearly half of patients have symptoms for 2 days before seeking medical attention and why 18% wait for more than a week.[5] Most patients with SSP have more severe symptoms than patients with PSP, and dyspnea frequently seems out of proportion to the size of the pneumothorax.[72]

Small pneumothoraces (<20%) are usually not detectable on physical examination. In patients with obstructive lung disease, even larger pneumothoraces may be difficult to detect since decreased breath sounds and hyperresonance may already be present.[73] On physical examination, vital signs are usually normal, with the exception of moderate tachycardia. Examination of the chest may reveal the affected side to be larger and move less during respiration. Tactile fremitus is absent, the percussion note is hyperresonant, and breath sounds are absent or reduced on the side with the pneumothorax. Hamman sign may be detected. This sign, also heard with pneumomediastinum, has been described as crunching or clicking noises synchronous with the heartbeat but influenced by respiration and body position. Severe tachycardia, with a heart rate above 140 beats a minute, hypotension, cyanosis, or tracheal deviation, suggests the possibility of a tension pneumothorax.

Arterial blood gases often show hypoxemia and perhaps hypocarbia from hyperventilation. Hypoxemia is usually mild in PSP when less than 25% of the lung is affected. When more than 25% of the lung is involved, pulmonary shunts occur more frequently and hypoxemia may be severe. In patients with SSP, pulmonary reserve is already diminished and life-threatening hypoxemia and hypercapnea may be present. In one study, the mean Pa_{O_2} was 48 mm Hg and the mean pCO_2 was 58 mm Hg when patients with emphysema presented with a spontaneous pneumothorax.[73]

Patients with a left pneumothorax may show changes on EKG suggesting an anterolateral myocardial infarction. A rightward shift of the frontal QRS axis and clockwise rotation of the heart result in a diminution of precordial R-wave voltage, a decrease in the QRS amplitude, and precordial T-wave inversion.[74] These electrocardiographic features differ from a transmural myocardial infarction because of the absence of ST-segment elevation or significant Q waves. An anterior subendocardial infarction may present with T-wave inversion but without the rightward shift in the frontal axis. The electrocardiographic changes with a left pneumothorax may normalize when the patient is in the upright or right lateral decubitus position.

RADIOGRAPHIC APPEARANCE

Below are considered the radiographic (plain radiography and CT) and ultrasound findings in pneumothorax.

PLAIN RADIOGRAPHY

Classically, the diagnosis of pneumothorax is established by demonstrating the outer margin of the visceral pleura (and lung) separated from the parietal pleura (and chest wall) by a lucent space devoid of pulmonary vessels (Fig. 78-3) on chest radiograph,

Figure 78-3 A patient with nodular silicosis and a spontaneous secondary pneumothorax. The visceral pleural line is clearly seen with the absence of vascular workings beyond the pleural line. There are cicatricial bullae in both bases.

ultrasound, or CT scan. The pleural line may be difficult to detect with a small pneumothorax unless high-quality upright films are obtained. In erect patients, pleural gas collects over the apex, and the space between the lung and chest wall is most notable there. In the supine position, gas migrates along the broad ventral surface of the lung, making detection on a frontal radiograph difficult. In the supine position, the juxtacardiac area, the lateral chest wall, and the subpulmonic region are the best areas to search for evidence of pneumothorax. Lateral decubitus studies of the appropriate side may be helpful; however, several studies have shown that expiratory films have little or no advantage over upright inspiratory films in the diagnosis of pneumothorax.[75–77] The most recent British Thoracic Society guidelines do not recommend the routine use of expiratory chest films in the evaluation of suspected pneumothorax.[78]

It is very important to differentiate the pleural line of a pneumothorax on chest radiographs from that of a skinfold, clothing, tubing, or chest wall artifact. Careful inspection of the film may show that the artifact extends beyond the thorax, or that lung markings are visible beyond the apparent pleural line. In the absence of underlying lung disease, the pleural line of a pneumothorax usually parallels the shape of the chest wall. Artifactual densities generally do not parallel the course of the chest wall over their entire length. Avascular bullae or thin-walled cysts can be mistaken for a pneumothorax. The pleural line caused by a pneumothorax is usually bowed at its center toward the lateral chest wall. As opposed to a pneumothorax, the inner margins of bullae or cysts are, in general, concave rather than convex and do not exactly conform to the contour of the costophrenic sulcus. A pneumothorax with a pleural adhesion may also simulate bullae or lung cysts. An adhesion tends to form a straight line connecting the lung to the parietal pleura; bullae or cysts have rounded edges. Such features are not 100% specific, and if there is any doubt as to whether the patient has a bulla or cyst or a pneumothorax, a CT scan should be obtained as CT can usually differentiate the two.[79] Pleural effusions may occur coincident with pneumothorax in up to 20% to 25% of cases. Hemopneumothorax occurs in 2% to 3% of cases of spontaneous pneumothorax. Bleeding is believed to represent rupture or tearing of vascular adhesions between the visceral and parietal pleura as the lung collapses.

Quantification of the size of a pneumothorax on chest radiographs is helpful but the methods for quantifying lack uniformity and are by no means precise. Light suggested measuring the average diameters of the collapsed lung and of the affected hemithorax, then cubing these diameters to estimate the percentage of collapsed lung by the following equation: $100 \times (1 - \text{diameter of collapsed lung}^3/\text{diameter of hemithorax}^3)$.[71] For example, if the diameter of the collapsed lung is 6 cm and the diameter of the hemithorax is 10 cm, the collapsed lung is estimated by the formula $100 \times (1 - 6^3/10^3)$. Thus, the estimated size of the pneumothorax is 78%.[71] Rhea et al.[80] proposed the use of a nomogram to calculate the size of the pneumothorax. With this method, the average intrapleural distance is calculated by measuring the interpleural distance at the apex and at the midpoints of both the upper and lower lungs. These three values are then averaged, and the number is reported on a nomogram, which gives an estimated size of the pneumothorax. An example of these calculations is shown in Figure 78-4.

The most common radiographic manifestations of tension pneumothorax are mediastinal shift, diaphragmatic depression, and rib cage expansion (Fig. 78-5). Any significant degree of displacement of the mediastinum from the midline position on maximum inspiration, or any depression of the diaphragm, should be taken as evidence of tension. The degree of lung collapse is an unreliable sign for or against the presence of a tension pneumothorax, since underlying lung disease may prevent collapse even in the presence of tension.

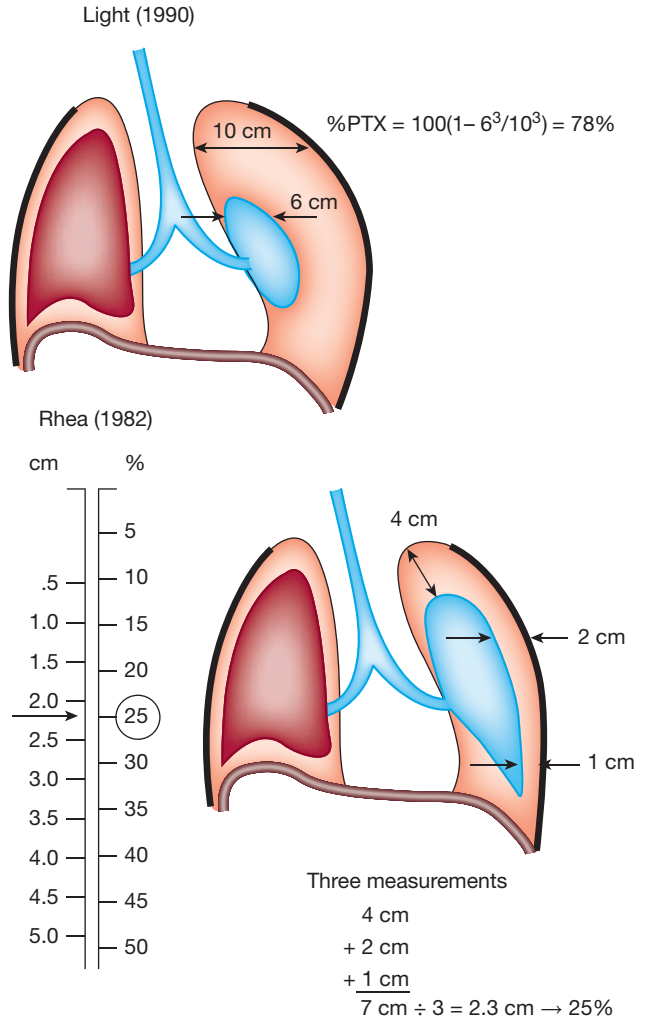

Figure 78-4 Estimation of the size of the pneumothorax according to the method described by Light[32] and Rhea et al.[49] *(Reproduced with permission from Beauchchamp. In: Pearson, ed. Textbook of Thoracic Surgery; 1995.)*

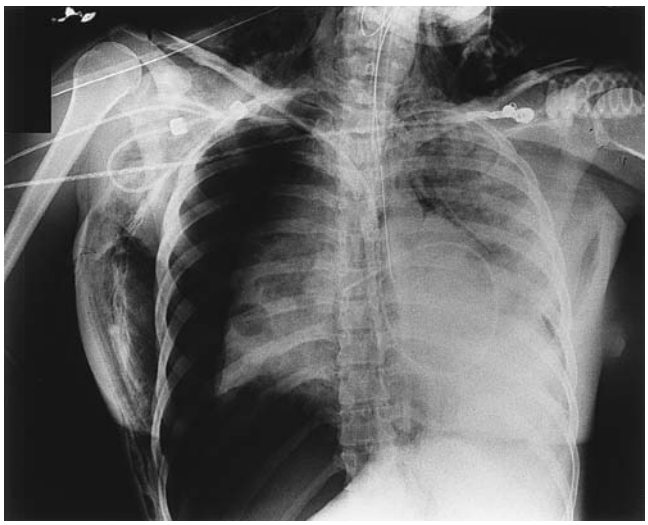

Figure 78-5 Right tension pneumothorax in a young patient with staphylococcal endocarditis and septic emboli. There is marked depression of the right hemidiaphragm, shift of the mediastinum, and subcutaneous emphysema. *Note:* The pulmonary artery catheter, endotracheal tube, and nasogastric tube (midchest) are all displaced to the left.

Video 78-1 Normal lung sliding. This sagittal view using two-dimensional ultrasound shows normal lung sliding through an anterior chest interspace. Two ribs that cast shadows are seen on the left and right edges of the image. The pleural surface is seen below the ribs. The visceral and parietal pleura are apposed giving a shimmering, glistening appearance as the visceral pleura slides back and forth against the parietal pleura with respirations (See also Video 31-9). *Access at www.fishmansonline.com*

LUNG ULTRASOUND

Ultrasound has evolved to become an indispensable bedside tool for rapid diagnosis of pneumothorax. Since the early 1990s, our understanding of lung and pleural ultrasonography has continued to mature as new research has emerged and more clinicians have integrated point-of-care ultrasound into clinical practice. In an observational study of 260 consecutive patients admitted to an intensive care unit (ICU) with acute respiratory failure, experienced physicians performing lung ultrasound alone without additional clinical information were able to correctly diagnose the cause of acute respiratory failure in 90.5% of patients.[81] An observational study of critically ill patients demonstrated that lung ultrasound facilitated diagnosis in 66% and guided management in 47% of patients.[82] A similar more recent observational study in mechanically ventilated patients demonstrated that lung ultrasound changed management in 41% and revealed diagnoses not suspected by the treating physician in 21% of patients.[83]

Lung ultrasound is more sensitive than chest x-ray for detection of pneumothorax when using chest CT as the gold standard. Early studies by Lichtenstein et al. established superiority of lung ultrasound compared to chest x-ray to detect pneumothorax, with sensitivities and specificities ranging from 66% to 100% and 91% to 100%, respectively.[84–87] Meta-analyses (13–21 studies) report a pooled sensitivity of 79% to 95% and specificity of 98% to 99% for lung ultrasound in detecting pneumothorax. Pooled sensitivity and specificity for chest radiography have been reported at 40% to 52% and 99% to 100%, respectively.[88–90]

Normal lung and pleura are characterized by two ultrasound findings: lung sliding and A-lines. By conventional two-dimensional ultrasonography, normal visceral and parietal pleura appear as a bright white (hyperechoic) line that glistens with respirations as the visceral pleura slides back and forth against the parietal pleura (Video 78-1). A principal finding to diagnose pneumothorax is absence of lung sliding (Video 78-2). The presence of air in between the visceral and parietal pleura in pneumothorax prevents propagation of ultrasound waves beyond the parietal pleura, and the sliding, shimmering appearance created by apposed pleura is not seen.[91,92] Presence of lung sliding definitively rules out pneumothorax with a negative predictive value of 100%[84]; however, absence of lung sliding is not specific to pneumothorax and can be seen with any cause of pleural symphysis (chemical pleurodesis, infectious/inflammatory adhesions, fibrosis) or lung volume loss (mainstem intubation, massive atelectasis, mucus plug, pneumonectomy, apnea).[91] If lung sliding is absent, identification of the lung point, a specific sign of pneumothorax, can confirm the diagnosis. The lung point is the edge of a pneumothorax, or boundary between collapsed and aerated lung, and a lung point is 100% specific to rule in pneumothorax.[87] The defining feature of lung point sign is visualization of aerated lung sliding into the field of view next to collapsed lung (Videos 78-3 and 78-4). The lung point can be found anteriorly when the pneumothorax is small, and laterally when it is large.[92]

Evaluation of lung sliding should be confirmed using M-mode, or motion mode. M-mode displays movement of tissues over time. The normal M-mode pattern of lungs includes: horizontal, linear lines at the top, corresponding to the chest wall; a hyperechoic line corresponding to the pleura; and a granular pattern at the bottom corresponding to aerated lung parenchyma. The normal M-mode pattern is called "seashore" sign with the lung parenchyma representing the beach and the chest wall representing the ocean (Fig. 78-6). In pneumothorax, the granular pattern of lung parenchyma is lost, and horizontal, linear lines are seen throughout the display. The M-mode pattern of pneumothorax is often called "stratosphere" or "barcode" sign (Fig. 78-7).[91] The lung point will display a distinct M-mode pattern with alternating segments of "seashore" and "barcode" patterns (Fig. 78-8).

A-lines are ultrasound image artifacts due to repeated reflections, or reverberations, between the highly reflective pleura and transducer. A-lines are seen as a series of equidistant horizontal white lines deep to the pleura (Fig. 78-9). A-lines are seen in normal lungs but also in pneumothorax, pulmonary embolism, COPD, or asthma. Therefore, presence of A-lines supports a diagnosis of pneumothorax but is not specific for pneumothorax. In contrast, the presence of B-lines, an artifact arising from the pleura, rules out pneumothorax with a negative predictive value of 100% (Video 78-5).[86]

A focused lung ultrasound examination to evaluate for pneumothorax can be performed rapidly—in less than 1 minute in one study by experienced clinicians.[87] A phased array, linear array, or microconvex transducer is required. Specifically for evaluation of pneumothorax, a high-frequency (5–10 MHz), linear array transducer is preferred because of its higher resolution and sensitivity (82% vs. 76%) compared to convex array transducers.[90] Air in the pleural space accumulates in the least dependent parts of the chest, which are anterior and inferior in supine patients. In a longitudinal plane with the transducer marker oriented cephalad, place the transducer in the midclavicular line, and scan each interspace sequentially evaluating for lung sliding. If absence of lung sliding is detected, move the transducer laterally in search of the lung point and to qualitatively assess the size of the pneumothorax. Use M-mode to confirm the presence or absence of lung sliding.[92]

Video 78-2 Absence of lung sliding due to pneumothorax. Using two-dimensional ultrasound in a sagittal plane, the absence of lung sliding can be appreciated as the shimmering, glistening appearance of the pleura is not seen below the ribs (See also Video 31-10). *Access at www.fishmansonline.com*

Video 78-3 Lung point sign (lateral chest wall). The edge of a pneumothorax, or lung point, can be seen on the curvature of the lateral chest of a mechanically ventilated patient with a large, postprocedural pneumothorax. Aerated lung superiorly *(left)* slides into the field of view next to the collapsed, nonsliding portion of lung *(right)*. *Access at www.fishmansonline.com*

Video 78-4 Lung point sign (anterior chest wall). The edge of a pneumothorax, or lung point, can be seen on the anterior, inferior chest wall of a patient with a small, spontaneous pneumothorax. Aerated lung slides in and out of the field of view next to the collapsed, nonsliding portion of lung (See also Video 31-11). *Access at www.fishmansonline.com*

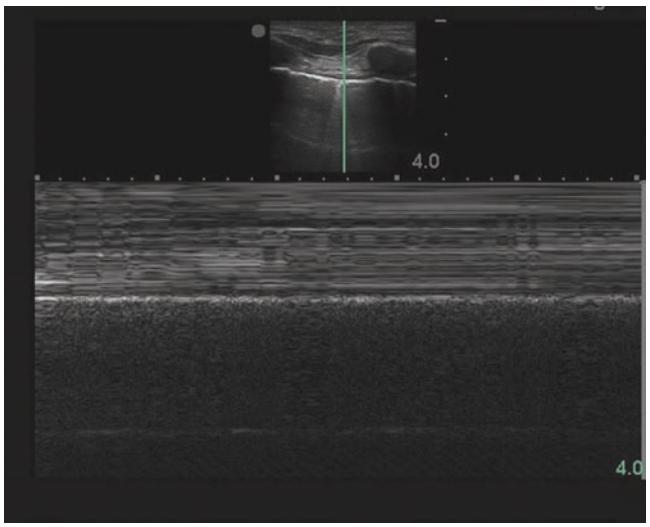

Figure 78-6 Normal lung in M-mode. A two-dimensional ultrasound image at the top shows the sample line along which the movement of all tissues is recorded and displayed below. The chest wall creates a series of horizontal lines. Also noted are the hyperechoic line of the pleura and a granular pattern created by aerated lung.

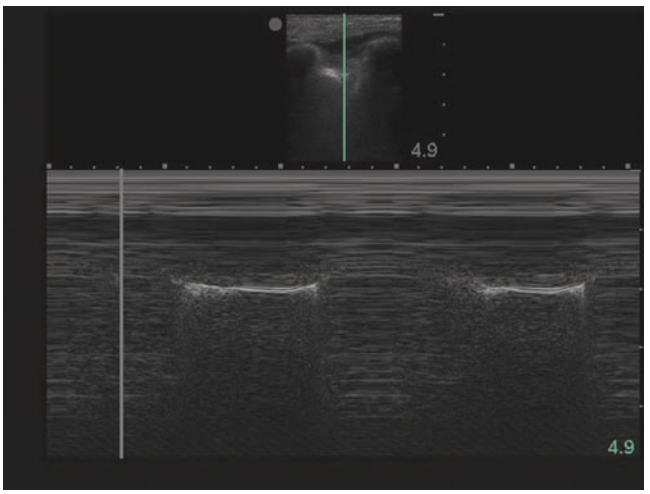

Figure 78-8 Lung point in M-mode. This M-mode image displays alternating patterns of normal lung and pneumothorax as normal, aerated lung slides over the area of collapsed lung.

■ COMPUTED TOMOGRAPHY

CT scans of the chest are being used with increasing frequency in patients with pneumothorax. CT scans may be necessary to diagnose pneumothorax in critically ill patients when upright or decubitus films are not possible. CT scans may also prove helpful in predicting the rate of recurrence in patients with spontaneous pneumothorax. One study demonstrated that patients who have larger or more numerous blebs on thoracic CT scans are more likely to have recurrence.[93]

Traumatic pneumothoraces, if large, can be detected both clinically and with chest radiography. However, a small, posttraumatic pneumothorax may be easily missed by both physical examination and chest radiograph. One prospective series revealed that 51% of trauma patients presented with an occult pneumothorax that was not seen on initial chest radiograph, but identified on CT imaging.[94] In another large series looking at multiple trauma patients, 4.4% had a pneumothorax and 38.8% of these were detected only by CT scan.[95] Early incorporation of a routine CT scan in all patients with chest trauma or multiple traumatic injuries may be required to successfully diagnose traumatic pneumothoraces.

Given the difficulties associated with diagnosing small pneumothoraces by plain chest radiograph, as well as the cost and delay of CT scans, thoracic ultrasound is quickly emerging as a valuable tool for the diagnosis of occult pneumothorax. The small size and portability of newer machines, as well as the advantage of immediate bedside interpretation, make ultrasound especially helpful in the management of critically ill and hemodynamically unstable patients. Most data has come from trauma literature

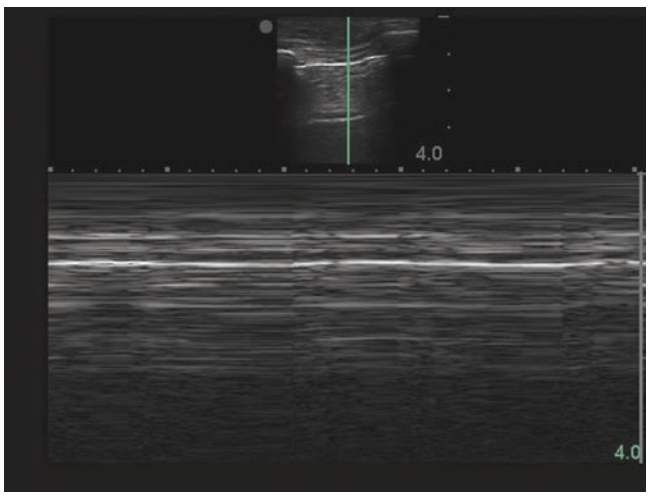

Figure 78-7 Pneumothorax in M-mode. The separation of visceral and parietal pleura by air from a pneumothorax prevents ultrasound waves from reaching the visceral pleura resulting in loss of the granular pattern of normal lung at the bottom of the M-mode image. A series of horizontal lines is seen throughout the M-mode image and is often called "stratosphere sign" or "bar code sign."

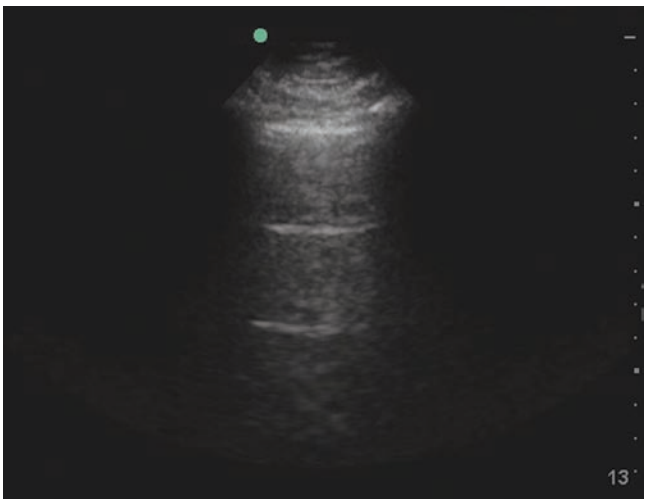

Figure 78-9 A-lines. A-lines are a type of reverberation artifact seen as equidistant horizontal lines that are generated from reflections of the pleura. A-lines are seen in normal, aerated lungs, but are also seen in pneumothorax, pulmonary embolism, chronic obstructive pulmonary disease, and asthma.

Video 78-5 B-lines. B-lines are a type of reverberation artifact, also known as comet-tail artifacts, that arise from the pleural surface and extend vertically to the bottom of the screen as discrete, hyperechoic rays that slide with pleural movement. Presence of B-lines rules out pneumothorax (See also Video 31-12). *Access at www.fishmansonline.com*

where ultrasound has a more well-established role. Hand-held ultrasonography was shown to have better sensitivity (48.8 vs. 20.9%) and similar specificity compared with chest radiograph for detection of traumatic pneumothorax using CT as the gold standard.[96] A review of ultrasound specifically in ICU patients concluded that ultrasound had a sensitivity of 95% and specificity of 94% compared to CT for the detection of pneumothorax.[97] Ultrasound has the additional advantage of serving as a guide to direct the site of drainage.[98]

THERAPEUTIC OPTIONS

Therapy for pneumothorax is dependent on the size of the pneumothorax, symptomatology, and etiology. The basic tenets of therapy are to evacuate the space, achieve closure of the leak, and either prevent or reduce the risk of recurrence. A variety of treatment methods and adjuncts exist. The choice of therapy depends on many factors, including the clinical status of the patient, the cause of the pneumothorax, evidence for concomitant lung disease, prior history of pneumothorax, risk of recurrence, and, finally, the experience and preferred techniques of the physicians caring for the patient as well as the availability of specific therapeutic options.[99] Major categories of treatment methods are listed below, followed by suggested guidelines for their application.

OBSERVATION

Simple observation of the patient with a pneumothorax requires evidence that the air leak is sealed (i.e., that there is no further progression of the pneumothorax). This form of management is generally reserved for asymptomatic patients with a small (<20%) unilateral pneumothorax.

A suggested protocol is the performance of serial chest radiographs over the initial 24 hours to assess for further progression of the pneumothorax. Some have suggested that this approach could be performed safely on an outpatient basis with close observation and limited patient activity. This form of management is risky because complications may occur rapidly, with potential morbidity. In one study of observation, 5% mortality was reported owing to the development of tension pneumothorax from an unrecognized pleural leak.[29] Inpatient monitoring during the initial phase of therapy also allows the use of adjunct measures such as supplemental oxygen, which increases the rate of absorption of pleural gas. Depending on the circumstances and level of patient compliance, continued follow-up may be done on an outpatient basis.

ASPIRATION

Aspiration of pneumothorax has been advocated by some but has shown varied levels of success and there is poor consensus between guidelines as to which patients warrant this approach.[100] The British Thoracic Society guidelines recommend simple aspiration as first-line therapy for all clinically stable patients with "large" first-time spontaneous pneumothorax.[78] This is in contrast to the American College of Chest Physicians Delphi Consensus Statement on this issue, which advocates placement of a pleural catheter and drainage.[101] The differences between selected guidelines are highlighted in Table 78-2.[78,101–103]

TABLE 78-2 Comparison of Management Techniques by Society Guidelines

Society	Management Technique	Indication
ACCP	Catheter drainage	>3 cm interpleural distance at apex
BSP	Aspiration or catheter drainage	Pleural gap along entire lateral chest wall
BTS	Simple aspiration	>2 cm interpleural distance anywhere
SEPAR	Aspiration or catheter drainage	Pleural gap along entire lateral chest wall

ACCP, American College of Chest Physicians; BSP, Belgian Society of Pulmonology; BTS, British Thoracic Society; SEPAR, Spanish Society of Pulmonology and Thoracic Surgery.

A meta-analysis of randomized controlled trials of simple aspiration versus chest tube insertion concluded that simple aspiration was advantageous because of shorter hospitalization times and no significant difference in recurrence rates at 1 year.[104] In these studies, approximately 66% of patients had resolution of their pneumothorax. Patients with secondary or a recurrence of spontaneous pneumothorax generally do not have good results with simple aspiration.[100,105–107]

The procedure consists of insertion of a 16- or 18-gauge plastic catheter under local anesthesia using sterile technique. The recommended point of insertion is the second anterior intercostal space in the midclavicular line. The catheter is connected to a three-way stopcock and a large-volume syringe. Aspiration is performed until no further gas can be withdrawn. Follow-up chest radiographs are performed. Again controversy exists regarding a second attempt at aspiration if the first attempt is unsuccessful. If large volumes are aspirated without resolution or the second attempt is unsuccessful, a tube thoracostomy should be performed.

TUBE THORACOSTOMY

This entails the placement of an indwelling catheter into the pleural space for continual removal of the intrapleural gas. The classic method is the use of standard tube thoracostomy. For uncomplicated pneumothorax without evidence of significant amounts of fluid or blood, one may use standard thoracostomy tubes ranging from 20 to 24 French to minimize the discomfort of a larger tube in the intercostal space. Generally, a safe site for a chest tube or pleural catheter placement is the lateral chest wall above the fourth to sixth ribs in the mid- to anterior axillary line. If possible, tube placement in the back to posterior axillary line should be avoided because patients will tend to lie on them, increasing the risk of tube kinking and patient discomfort.

The tube is then connected to a pleural drainage system. Commercial systems commonly employ variations on the three-chamber system (Fig. 78-10). The three-chamber system consists of a fluid collection chamber attached to a water seal chamber to allow egress of gas from the pleural space, but in a one-way fashion. The final connection is to a manometer bottle, which regulates the degree of suction being applied to the system. After placement of tube thoracostomy, care should be taken with regard to immediate placement to suction because of the potential for reexpansion pulmonary edema (REPE) (see below). In many cases it may be prudent to leave the tube to water seal and allow the lung to expand gradually. Once the majority of the pneumothorax is evacuated, suction is applied for the next 24 hours. If an air leak exists, as evidenced by

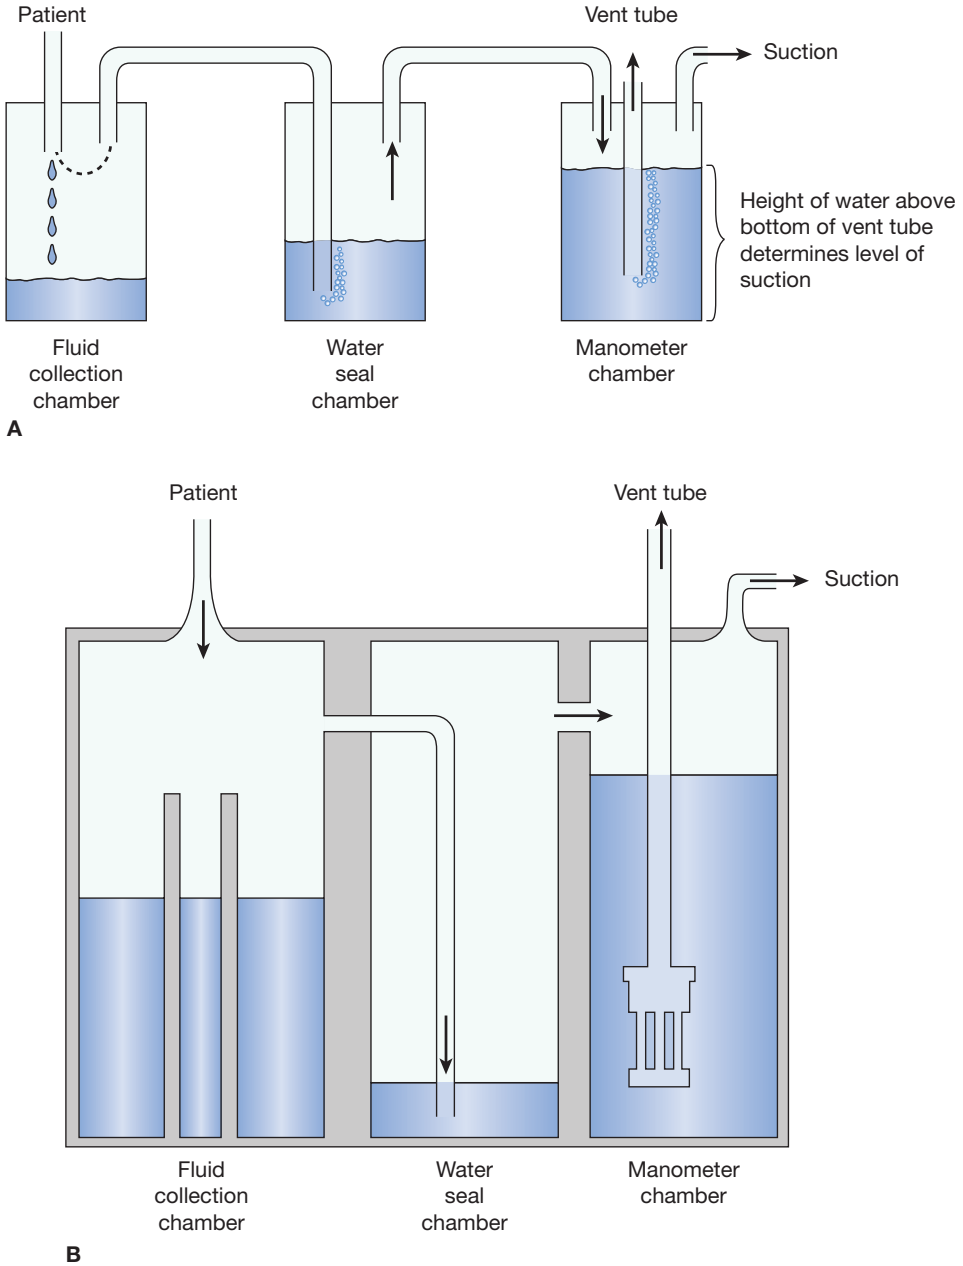

Figure 78-10 **A.** Three-bottle chest tube drainage system. The system consists of a collection bottle, a water-seal bottle, and a suction-control bottle. The collection bottle allows sterile drainage from the pleural spaces. The water-seal bottle acts as a one-way valve in the absence of suction, and the suction bottle allows for the regulation of negative pressure applied to the pleural space. **B.** Commercially available, compartmentalized plastic drainage system.

continual or intermittent egress of gas through the water seal chamber, suction is maintained. Once there is no evidence of an active air leak, the tube may be placed to water seal. After an additional period of observation of 12 to 24 hours, the chest tube may be removed if the pneumothorax does not recur.[108] Tube thoracostomy alone will result in closure of an air leak in most cases by complete evacuation of the pleural space and apposition of the visceral and parietal pleura. Persistence of an air leak for more than 72 to 96 hours generally presages a leak that will not close by this regimen and should prompt consideration of more aggressive therapy, usually surgical with or without some form of pleurodesis.[109]

To have a less traumatic method of placement of an indwelling tube, as well as to minimize the discomfort from a large-bore tube in the intercostal space, a variety of smaller catheters have been suggested for use as an interpleural drain.[110] The method of placement is similar to needle aspiration in terms of preparation and location of entry. Once the pleural space is entered with the needle, the Seldinger technique is used to pass a soft tip wire. The 8-French pigtail catheter is then placed over the wire into the pleural space and the wire withdrawn. The catheter is left in place and attached to pleural drainage system as described above. Potential problems with smaller catheters relate to a greater propensity for blockage of the tube. Also, the smaller size makes them more prone to kinking, clotting from blood or fluid, and sealing around the tube by the lung, resulting in a loculated pneumothorax. In cases in which the pneumothorax is associated with significant amounts of blood or fluid, tube thoracostomy using a larger-bore chest tube (26–32 French) is recommended.[111]

Use of these types of catheters has created the possibility of a form of hybrid therapy in which these catheters are placed and simple aspiration performed as noted. If the lung fails to reexpand or the volume of air obtained excessively large suggesting a continued air leak, the catheter may be left in and connected to longer-term drainage.

A variation on the use of pleural drainage systems is the substitution of a one-way valve to permit greater mobility by the patient.[112] The most common is the Heimlich flutter valve, which is useful in cases in which long-term indwelling catheterization is required but surgical therapy is declined or not possible. This valve is not widely recommended; however, owing to a potential for problems

with blockage, which may not be immediately recognized on an outpatient basis.

PLEURODESIS

Pleurodesis is an adjunct to the other forms of therapy. The goal is to achieve pleural symphysis, or adhesion of the visceral and parietal pleura to obliterate the pleural space. Sealing the visceral and parietal pleura together will prevent future air leaks and prohibit the lung from "falling away" from the chest wall. The basic mechanism entails chemical or physical irritation of the pleural surface to promote an inflammatory response and subsequent adhesion formation.

The goal of pleurodesis is to prevent recurrence in both PSP and SSP. There is good consensus for the use of pleurodesis in both; however, when and how to achieve pleurodesis depends on both the kind of pneumothorax as well as if there has been a recurrence.

Chemical pleurodesis may be used in combination with tube thoracostomy or surgical therapy. In patients who are unable to undergo a surgical procedure (e.g., severe comorbidity), pleurodesis can be achieved by administering the sclerosing agent through a chest tube. The success of the antibiotics (tetracycline, doxycycline, minocycline) and talc by slurry have been shown to be superior to chest tube drainage alone, but not as good as thoracoscopic treatment.[13]

As an adjunct to tube thoracostomy, the chemical of choice is suspended in fluid and instilled through the tube. The tube is clamped for 6 to 8 hours, then placed back to either suction or water seal. Periodically changing patient position during this period has not been shown to improve outcome.[113,114] Success is largely dependent on apposition of the visceral and parietal pleura during the period of inflammation while the tube is clamped. Excessive pleural fluid will dilute the sclerosing agent, and an air leak will allow the lung to separate from the chest wall. Doxycycline pleurodesis in the face of an air leak has been tried,[115–117] but in our experience it has a significantly reduced success rate.

The ideal agent should be effective, safe, easy to administer, and widely available and affordable. A number of pleural irritants have been suggested, including quinacrine, silver nitrate, bleomycin, autologous blood, antibiotics (doxycycline), and talc. Minor side effects of pleurodesis with a sclerosing agent include chest pain and low-grade fevers.

Tetracycline was shown to be very effective in creating sufficient pleural fibrosis formation when compared to hydrochloric acid, quinacrine, nitrogen mustard, bleomycin, or sodium hydroxide.[2] A randomized study comparing the recurrence rates in PSP after drainage alone with that of drainage plus tetracycline or talc found recurrence rates of 36, 13, and 8%, respectively.[116] Tetracycline, however, is no longer commercially available. Minocycline and doxycycline have been suggested as a replacement for tetracycline with experimental data that suggests equal efficacy.[101,118,119] Typical doses of these antibiotics are 0.5 to 1 g of doxycycline in 50 to 100 mL normal saline and 600 mg of minocycline in 50 to 100 mL of normal saline.

Talc has also been shown to be a very effective sclerosing agent when applied as slurry via a chest tube or by talc poudrage during thoracoscopy. In an experimental study, talc was noted to be as efficacious as mechanical abrasion.[120] In a meta-analysis, talc achieved a success rate of 91%.[121] Doses between 2 to 10 g of talc in 100 to 200 mL of normal saline have been reported. There is no standardized practice when using talc administered by chest tube. The drawbacks of talc slurry are prolonged pleural drainage and inhomogeneity of deposition. The distribution of talc may lead to loculation and incomplete symphysis. The advantages are it can be performed easily at the bedside. There are data, however, that suggest an increased incidence of adult respiratory distress syndrome associated with the use of talc as a sclerosant. The size of the talc particles (<15 μm) and the dose (>5 g) may be associated with a higher incidence of ARDS. In a comprehensive literature review, Sahn et al.[122] found acute respiratory failure in 0.15% of patients treated with talc poudrage.

As an adjunct to surgical therapy, the most commonly described material is talc. Sterile, asbestos-free talc is insufflated during thoracoscopy or thoracotomy to coat the visceral pleural surface. Typically, 2 to 10 g are used.[121,123]

Mechanical pleurodesis is performed as part of a surgical procedure. It may consist of simple abrasion of the parietal pleural surface or may entail stripping of the parietal pleura (pleurectomy). The second method has a greater potential for complications, including injury to an intercostal neurovascular bundle or excessive bleeding from the large raw surface area. Also considered in this category is the use of an Nd:YAG laser or an argon beam coagulator, which essentially cauterizes the pleural surface.[124] Experimental studies have not borne out their effectiveness.[120]

The performance of pleurodesis in someone who may need future thoracic surgery is somewhat debatable and relates to the degree of pleural symphysis that can be obtained and the method utilized. Currently, guidelines suggest evaluation for pleurodesis in patients with prolonged air leaks for greater than 4 days, recurrent pneumothorax, and as part of the treatment of catamenial pneumothorax and pneumothorax associated with HIV.[78,101] Either chemical or mechanical pleurodesis, may result in rather significant adhesion formation. Clearly there is a significant reduction in the incidence of recurrence. However, in some cases, there are concerns that future surgical procedures, such as pulmonary resection, open lung biopsy, and lung transplantation, may be hampered by this degree of pleural symphysis. The application of pleurodesis thus depends on an assessment of the risk of recurrent pneumothorax and the potential morbidity to the patient should a recurrence occur versus the potential for later operative procedures in the thorax. One suggested compromise is limitation of the pleurodesis to the apical area, as this is the most common location for air leaks to occur. Later thoracic procedures may be done, albeit with more difficulty, by entrance inferior to the area of pleurodesis and subsequent adhesion lysis apically. Localized pleurodesis is not possible when it is performed as an adjunct to tube thoracostomy. A second potential compromise is the use of tetracycline analogs such as doxycycline or minocycline. Experimental studies and anecdotal reports indicate that with the use of tetracycline, the degree of pleural symphysis and density of adhesions are not as great as with talc or mechanical pleurodesis.[116–120]

OPERATIVE THERAPY

Operative treatment (mechanical pleurodesis with or without stapling of blebs or pleurectomy) is generally thought to be the most effective in assuring expansion of the lung, with complete evacuation of the pleural space, and providing for the best means of reducing the risk of recurrence. In addition, it provides a means of potentially identifying an air leak and closing it. However, increased patient discomfort, risks of general anesthesia, and greater costs of the procedures, combined with moderate success of the less invasive methods, result in restricted application of surgery for pneumothorax.

Operative therapy is indicated in cases in which the above-mentioned, less invasive techniques have failed, with persistence or recurrence of the pneumothorax, or in cases of initial presentation of patients with limited pulmonary reserve. This risk of recurrence should include an assessment of the potential morbidity or mortality to the patient should another pneumothorax occur.

Longitudinal studies have indicated that the recurrence rate is approximately 30% after tube thoracostomy alone for treatment of a spontaneous pneumothorax. Among patients in whom the disease recurs once, the subsequent recurrence rate continues to increase.[125]

Evidence suggests that a more definitive procedure – namely surgery – is indicated with the first recurrence. In patients with localized lung disease, such as congenital lobar emphysema or a single large bulla, surgery may be indicated for the initial episode of pneumothorax. Patients who have high-risk lifestyles, such as pilots or scuba divers, or patients who may not have ready access to medical care may possess a relative indication for surgical treatment of a first occurrence of spontaneous pneumothorax because of the risk to the patient should a pneumothorax occur. Patients who present with bilateral or tension pneumothorax may also fall in this category of morbidity assessment.

Patients with a pneumothorax from any cause who have a persistent air leak despite prolonged chest tube drainage should also be considered for operative therapy. An air leak that fails to close after 72 to 96 hours of suction has a very low chance of closing spontaneously. This is the recommended time for surgical referral.[109] Finally, patients in whom the previous forms of therapy result in incomplete reexpansion of the lung should be considered for surgery. This situation may reflect loculation of the pneumothorax or trapping of the lung by a fibrotic "peel," which will require surgery to be released.

■ VIDEO-ASSISTED THORACOSCOPIC SURGERY

In recent years, video-assisted thoracoscopic surgery (VATS) has emerged as the preferred surgical approach when surgical intervention for pneumothorax is required. It is associated with less postoperative discomfort and decreased length of hospital stay compared to standard thoracotomy. The decreased morbidity is the result of the ability to examine the pleural space and manipulate the lung without significant muscle division or rib spreading.[123]

In most cases, the technique requires general anesthesia with double-lumen endotracheal ventilation (single lung ventilation). Those patients who are at high risk (elderly or significant underlying lung disease) can undergo this procedure under local and epidural anesthesia.[126] Up to three separate ports are placed in the intercostal spaces to effect installation of the camera as well as manipulating devices. The entire lung can be inspected and a search for the air leak carried out. Generally speaking, the apical area is the location, and this area can then be closed with the use of a stapler. In patients with concomitant lung disease, particularly COPD, the staple line can be reinforced with the aid of bovine pericardium to minimize persistence of air leaks.[127] The pleural surface can then be abraded or talc insufflated, as mentioned above, to achieve some degree of pleural adhesion following reexpansion of the lung. Long-term follow-up of recurrence rates has shown results similar to those for open thoracotomy. Stapled resection of bullae and talc poudrage can be performed safely.

The less invasive nature of VATS compared to open thoracotomy has prompted earlier and more frequent surgical referral. While the risks associated with general anesthesia remain, overall costs are generally less than thoracotomy owing to shorter hospital stay. The cost of VATS as an initial procedure for spontaneous pneumothoraces may be less in the course of the treatment of the disease as compared to more conservative therapies for both PSP and SSP.[128] These conclusions, however, are not based on prospective randomized trials and should be verified in larger prospective studies.

■ OPEN THORACOTOMY

Classically, thoracotomy was believed to be the ultimate and most effective form of therapy for pneumothorax. Recurrence rates are generally less than 2%.[129] Thoracotomy allows examination of the lung for the site of an air leak, enables lysis of previous adhesions that may lead to a loculated pneumothorax, and enables the release of a fibrotic peel that occasionally forms, leading to incomplete reexpansion of the lung. Drawbacks include the potential risks associated with general anesthesia, increased costs, and the significant amount of patient discomfort. Discomfort is generally most severe with a standard lateral or posterolateral thoracotomy with muscle division and rib spreading.

In an effort to minimize the level of discomfort, variations have been developed, including the use of smaller incisions, the so-called muscle-sparing thoracotomies, and the axillary thoracotomy. Lung examination and air leak closure and possible pleurodesis or pleurectomy can then still be performed.[129]

While VATS has supplanted thoracotomy as the surgical treatment of pneumothorax in many institutions, open thoracotomy remains a valuable option in the treatment of complicated cases.

SUGGESTED GUIDELINES FOR MANAGEMENT

Based on the relative efficacy of the various forms of therapy combined with relative risks for the major categories of pneumothorax, the following guidelines are suggested.

■ PRIMARY PNEUMOTHORAX

Patients with a first-time PSP who are asymptomatic and whose pneumothorax is thought to be less than 20% may be treated with observation and sometimes adjunct measures, including the use of supplemental oxygen. Patients with PSP who are symptomatic or whose pneumothorax is greater than 20% should undergo an attempt at catheter aspiration or insertion of a small 8- to 10-French pneumothorax catheter. Subsequent small- or large-tube thoracostomy is indicated for failure of simple aspiration.

Patients who undergo successful tube thoracostomy with complete lung reexpansion and absence of an air leak may opt for a chemical pleurodesis while the chest tube is in place. Since the risk of recurrence is low (approximately one in five), most physicians recommend patients in good general health defer this procedure until a second pneumothorax occurs. Patients with persistent air leaks for more than 72 to 96 hours after insertion of a chest tube should be referred for surgical therapy. Because of the progressive increase in risk of recurrence, patients with their first recurrence of a primary pneumothorax should undergo chemical pleurodesis or be referred for surgical therapy, preferably VATS, with stapling of any air leak and pleural abrasion or chemical pleurodesis.

■ SECONDARY PNEUMOTHORAX

In general, therapy for secondary pneumothorax should be more aggressive because of the higher rate of recurrence due to the underlying lung pathology. Specific conditions with pneumothorax as a common occurrence are as listed below.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Most cases of pneumothorax in patients with COPD should be treated with some form of long-term aspiration, typically tube thoracostomy. In patients who are not good surgical candidates, chemical pleurodesis with doxycycline or talc should be performed once there is complete reexpansion and absence of an air leak. In COPD patients who are good surgical candidates or in patients with a persistent air leak longer than 72 hours, more aggressive therapy should be considered.[36] Recommended therapy includes VATS or thoracotomy with talc insufflation, mechanical pleurodesis, stapling resection, and/or pleurectomy. This approach provides a more effective way of achieving a lower risk of recurrent pneumothorax.

CYSTIC FIBROSIS

Although there are no clinical trials to guide therapy in patients with CF and pneumothorax, retrospective reports offer suggestions for management. Clinically stable patients with small pneumothoraces may be followed with observation. Clinical instability or large pneumothorax requires chest tube placement. Pleurodesis should be considered after recurrence of a large pneumothorax. Surgical

pleurodesis is associated with fewer recurrences in the CF population and is the preferred modality. Noninvasive positive-pressure ventilation, positive expiratory pressure devices, and intrapulmonary percussive ventilation should be stopped until the pneumothorax has resolved but aerosols need not be held. Because of the growing application of lung transplantation to patients with CF, localized pleurodesis is recommended as an adjunct to surgical closure of the air leak.[39,41]

AIDS

For most AIDS patients presenting with a pneumothorax, tube thoracostomy is the primary mode of initial treatment. Because of the high primary and secondary treatment failure rates, patients who have no air leak with complete lung reexpansion should undergo talc slurry pleurodesis. For patients with a persistent air leak who are felt to be poor surgical risks because of severe debilitation, a Heimlich valve may be utilized. For patients who are deemed good risks for surgery, thoracoscopy with talc insufflation is recommended.[44]

OTHER CONDITIONS

While there are insufficient data to make firm recommendations for all situations, some suggestions are offered. Patients with pneumothorax secondary to iatrogenic causes may be treated with observation or aspiration according to the guidelines previously listed. In patients who have a pneumothorax secondary to trauma, we suggest large-bore tube thoracostomy, because there is a high association with hemothorax and the patient's physiologic reserve and ability to tolerate the pneumothorax may be decreased owing to other injury. However, recent publications question the need for large-bore chest tubes.[130]

Patients who experience a pneumothorax while on positive-pressure ventilation should have tube thoracostomy placement to avoid progression to a tension pneumothorax.[130] Patients who present with bilateral pneumothoraces or a tension pneumothorax, but who are not on positive-pressure ventilation, should have placement of tube thoracostomy. Further therapy with regard to chemical pleurodesis versus surgery is dependent on underlying lung pathology.

COMPLICATIONS

TENSION PNEUMOTHORAX

A tension pneumothorax is present when the intrapleural pressure is greater than atmospheric throughout expiration and often during inspiration as well. The term *expiratory tension pneumothorax* has been proposed to highlight the fact that in a spontaneously breathing person, pleural pressure must be negative in relation to atmospheric pressure during part of the respiratory cycle for air to enter the pleural space. The mechanism responsible for tension pneumothorax relates to the disruption of the visceral or parietal pleura in such a manner that a one-way valve develops. During inspiration, the respiratory muscles contract and create negative intrapleural pressure, allowing for air movement into the pleural space. Then, during expiration, when the expiratory muscles relax, the pleural pressure becomes positive and the one-way valve prevents the egress of air from the pleural space. As tension pneumothorax progresses, the pleural pressure remains positive during a greater portion of the inspiratory cycle. If the patient is on mechanical ventilation, the alveolar pressure remains positive throughout inspiration and expiration.

A tension pneumothorax can occur after any type of pneumothorax; it is independent of the etiology. It can sometimes occur after a spontaneous pneumothorax but is more common after a traumatic pneumothorax, with mechanical ventilation, or during cardiopulmonary resuscitation.

The clinical picture associated with the development of a tension pneumothorax is striking. The patient will appear acutely ill, develop severe dyspnea, marked tachycardia, profuse diaphoresis, and cyanosis. On physical examination, the patient may demonstrate profound hypotension and hypoxemia, distended neck veins, tracheal deviation to the side opposite the pneumothorax, subcutaneous emphysema, and unilateral chest hyperinflation. The involved hemithorax can enlarge, with widened interspaces. Arterial blood gases reveal severe hypoxemia and can show a severe respiratory acidosis. Chest radiographs may show mediastinal shift to the contralateral side of the pneumothorax. Patients receiving mechanical ventilation often develop a sudden increase in their peak and plateau pressures, with an associated decrease in the oxygen saturation. If the patient is on pressure control ventilation and is paralyzed, arterial blood gases will show a respiratory acidosis, as the patient is unable to increase his respiratory rate.

The development of a tension pneumothorax is a medical emergency requiring immediate chest drainage to relieve the intrapleural pressure. It should be suspected in any patient with a pneumothorax whose condition deteriorates acutely or in any patient with cardiopulmonary collapse after a procedure known to cause a pneumothorax, or with mechanical ventilation. One should also suspect a tension pneumothorax in any patient undergoing cardiopulmonary resuscitation who is difficult to ventilate or develops electromechanical dissociation. A tension pneumothorax may also develop because of improper connection of a one-way flutter valve to the chest tube. It can occur even if there is a chest tube in place, due to either malpositioning of the tube or disconnection at the site of tube or the site of the pleurevac container.

When the diagnosis of a tension pneumothorax is considered, the patient should be given a high concentration of oxygen to alleviate the extreme hypoxemia seen with this syndrome. Radiographic documentation may not be possible in an emergency situation. Tension pneumothorax is a clinical diagnosis and therapy should not be held up by confirmation of the chest radiograph. A large-bore needle should be inserted into the second anterior intercostal space. Optimally, the needle should be connected to a syringe partly filled with sterile saline. Air bubbling outward through the fluid confirms the diagnosis. The needle or its plastic outer sheath should be left in place, and the patient should be prepared for immediate tube thoracostomy.

Cardiopulmonary decompensation in patients with tension pneumothorax is usually attributed to diminished venous return and marked decrease in the cardiac output. Animal studies demonstrate that cardiac output is maintained by tachycardia and the increase in negative intrathoracic pressure during inspiration.[131] The importance of negative intrathoracic pressure swings in maintaining cardiac output was demonstrated by the precipitous fall in cardiac output when mechanical ventilation was initiated.[132] Deterioration has been shown to be related to severe hypoxemia, probably because of increased shunting and V/Q mismatch in the compressed lung. Preterminally, CO_2 retention and respiratory acidosis are noted.

BRONCHOPLEURAL FISTULA

A bronchopleural fistula is a communication between the pleural space and the bronchial tree. It is a rare, but serious complication associated with several pulmonary conditions. In the setting of a pneumothorax, it is manifested by a prolonged air leak.

Most air leaks seal within 24 to 48 hours after tube thoracoscopy. Only 3% to 5% of patients with pneumothorax have a persisting air leak.[133] Few air leaks that persist for more than 48 hours will seal over the next 7 to 10 days with continuous suction alone.[134] Current guidelines recommend that patients with air leaks persisting over 3 to 4 days should be evaluated for surgery to close the air leak and perform a pleurodesis procedure to prevent recurrence.[78] VATS is the preferred procedure for managing bronchopleural fistulas. Use of an additional chest tube may occasionally help, but surgery should be considered after 3 to 4 days of tube drainage.[109]

Patients with CF or COPD are at increased risk for the development of persistent bronchopleural fistula. For those who are not candidates for surgical intervention, the fistula may be localized by bronchoscopic balloon catheter occlusion and subsequently injected with a variety of substances to promote sealing of the air leak. Fibrin glue, liquid bioadhesive (isobutyl 2-cyanocrylate), sterile gelatin sponge, and even lead shot have been used for this purpose.[127] In addition, after localization by balloon catheter occlusion, one-way endobronchial valves have been placed bronchoscopically as a nonoperative therapy for persistent air leaks.[135] Autologous "blood patch" pleurodesis has also been accomplished, using 50 to 120 mL of the patient's blood and injecting it into the chest tube. While high success rates have been reported in postoperative patients, we have observed limited success in patients with spontaneous pneumothorax.[136,137]

REEXPANSION PULMONARY EDEMA

REPE is a rare but potentially lethal condition that can occur with the rapid reexpansion of a collapsed lung after tube thoracostomy is used to drain air (pneumothorax) or fluid (pleural effusion) from the pleural space.[138] The incidence of this complication is uncertain. There were no cases reported in the Veterans Administrative Cooperative study of more than 200 patients with spontaneous pneumothoraces. The single largest retrospective study ($n = 21$) reported an incidence of 14%.[139]

The pulmonary edema is most commonly unilateral (involving the reexpanded lung), but on occasion, can become bilateral. Occasionally, associated hypoxemia and respiratory distress is sufficiently severe to require intubation and mechanical ventilation. Although the mortality rate is not well defined, one older study reported that 11/53 cases (21%) resulted in death.

The pathogenesis of REPE is not completely understood. A number of mechanisms have been suggested. It appears that, at least to some degree, REPE is due to increased permeability of pulmonary capillaries that are damaged by mechanical stress during reexpansion of the lung. Reperfusion injury due to free radicals may also be responsible for increased capillary permeability. Other theories include decreased surfactant, airway obstruction, and decreased lymphatic flow.[140]

The duration of pneumothorax prior to drainage has been shown to be significant risk factor for development of REPE. Animal models demonstrate that REPE occurs when a pneumothorax has been present for 3 days or more and the lung has been expanded with more than −20 cm H_2O pleural pressure. The severity of the pneumothorax may also be predictive of developing REPE. In one series, no patient with a pneumothorax less than 30% of the lung field developed this complication compared to 17% of patients with total collapse and 44% of patients with tension pneumothorax. Finally, use of suction and rapid rate of expansion have been implicated as potential risk factors.

The clinical presentation of REPE can be relatively benign or present as a life-threatening event. When serious, its onset is sudden and dramatic. The majority of patients presenting with symptoms do so within 1 hour of reexpansion and all are symptomatic within 24 hours. Symptoms include severe persistent cough and chest pain. In more severe cases, patients develop hypoxemia, tachypnea, tachycardia, and hypotension. Symptoms may worsen for 24 to 48 hours. Chest radiographs demonstrate patchy or diffuse alveolar infiltrates in the reexpanded lung. If the patient survives the first 48 hours, recovery is usually complete.

Treatment is supportive and, in severe cases, includes mechanical ventilation. The best strategy is prevention, though there are no randomized trials to guide practice. It is recommended that when tube thoracostomy is performed for a spontaneous pneumothorax of unknown duration, the tube should initially be connected to water seal rather than to negative pressure. If the lung fails to fully expand after 12 to 24 hours, negative pressure can be applied to the pleural space.

CHAPTER 79

Malignant Mesothelioma and Other Primary Pleural Tumors

Edmund K. Moon
Leslie A. Litzky
Daniel H. Sterman

The pleura is a membranous structure covering the entire surface of the lung and lining the inside of the chest cavity. It is composed of a thin mesothelial layer with underlying fibroblasts and varying amounts of collagenous fibrous tissue with interdigitating capillaries and venules. The most common tumors of the pleura are metastatic neoplasms, predominantly of lung, breast, or colonic origin. Tumors arising primarily from the pleura are rare, but still constitute a variety of benign and malignant lesions from several different cells of origin, some of which have yet to be identified.

MALIGNANT MESOTHELIOMA

The most common primary malignant tumor of the pleura is malignant mesothelioma, an insidious neoplasm with a generally dismal prognosis arising from the mesothelial surfaces of the pleural and peritoneal cavities, as well as from the tunica vaginalis and pericardium. Eighty percent of all cases of mesothelioma are pleural in origin.

EPIDEMIOLOGY

The incidence of mesothelioma in the United States is estimated to be 3300 cases per year.[1] The incidence within the United States peaked in the year 2000 and is now declining, secondary to control of asbestos exposure.[2] However, incidence is increasing in other parts of the world, such as Europe, Japan, and Australia. In Great Britain, mesothelioma death rates rose from 153 per year in 1968 to 1848 per year in 2001. Similar numbers of deaths are expected annually until the year 2015 when a peak of up to 2450 deaths per year is expected.[3] After that time, mesothelioma rates are expected to drop in England and other developed countries because of legislation aimed at reducing asbestos exposure in the workplace and the general environment. In contrast, mesothelioma incidence rates are predicted to escalate for much longer times in the Third World because of poor regulation of asbestos mining and widespread industrial and household utilization of asbestos.[3–5]

ETIOLOGY

Inhalational exposure to asbestos has been clearly established as the predominant cause of malignant mesothelioma in humans. Approximately 70% of cases of pleural mesothelioma are associated with documented asbestos exposure. In ancient Greece, the philosopher Pliny first established the association between asbestos exposure and lung disease by making the observation that slaves working in asbestos mines were less healthy than other slaves. It was not until 1960, with the publication by Wagner et al.[6] of a series of 33 mesothelioma cases occurring in a crocidolite mining community in South Africa, that the etiologic connection between asbestos and mesothelioma was established. Wagner's study was soon followed by several other accounts of mesothelioma afflicting asbestos workers at locations around the world. In addition to asbestos miners and workers, other occupations at especially high risk include plumbers/pipefitters, mechanical engineers, ship and boat building and repairing.[4]

The lifetime risk of developing mesothelioma among asbestos workers is thought to be as high as 8% to 13%.[7] There is a latency period of approximately 30 to 40 years from the time of asbestos exposure to the development of mesothelioma. It remains unclear whether there is a dose–response relationship between asbestos exposure and development of mesothelioma. The possibility of a dose–response relationship was demonstrated in a cohort study of over 4500 people who resided in an Australian city that produced crocidolite asbestos but who did not directly participate in its mining or milling. In this study, the incidence of mesothelioma increased significantly with greater environmental exposure, based upon the neighborhood and duration of residence. In a cohort of textile workers with heavy exposure to asbestos, the risk of pleural mesothelioma was increased and was proportional to the latency period. In contrast, many well-documented cases of mesothelioma occur after brief, but intense, or longer-term low-level exposures to asbestos (i.e., spouses of asbestos workers exposed by washing clothes).[8]

Asbestos is not a specific compound, but the commercial name for a group of hydrated magnesium silicate fibrous minerals divided into two major types: the serpentines and the amphiboles. Serpentine chrysotile fibers, which account for more than 95% of the asbestos previously used for industrial purposes in the United States, are spiral-shaped, pliable, easily breakable, and soluble in tissues, whereas the amphiboles (crocidolite, amosite, tremolite, anthophyllite, actinolite) are rigid, long and needle-like, with a longer biologic persistence than the serpentine fibers. The carcinogenicity of asbestos is thought to depend on dose, biodurability, surface reactivity, and the physical properties of the fibers. Fibers with a high length-to-width ratio, such as crocidolite, which are able to more readily penetrate through the lung to the pleural surface, are considered more carcinogenic. Among the remaining asbestos fibers, amosite has an intermediate carcinogenic risk, chrysotile the lowest. It is unclear whether the cases of mesothelioma attributed to chrysotile exposure are caused primarily by the chrysotile itself or by contamination with tremolite fibers. All asbestos fiber types, however, have carcinogenic potential.[3,4]

The development of malignant pleural mesothelioma has also been associated in rare cases with other etiologic factors, including therapeutic ionizing irradiation to supradiaphragmatic fields,[9–13] intrapleural thorium dioxide (Thorotrast), and inhalation of other fibrous silicates such as erionite. Epidemiologic studies of a region in central Anatolia (Turkey) with an abnormally high incidence of pleural mesothelioma (22 per 10,000 individuals over 25 years old) implicated routine household use of a locally ubiquitous silicate, erionite, as a potential etiologic agent. However, it appears that only specific families (who appear to have as yet to be defined genetic abnormality) are susceptible to erionite-induced mesothelioma.[14]

MOLECULAR PATHOGENESIS

The latency period from asbestos exposure to the development of mesothelioma ranges from approximately 20 to 50 years, suggesting the necessity of multiple genetic alterations for eventual malignant transformation of the mesothelium. Despite extensive

investigation, the exact mechanisms of asbestos carcinogenesis have not yet been fully elucidated. In rodent model systems, asbestos fibers act like tumor promoters in combination with a carcinogen, eliciting proliferation of mesothelial cells. Asbestos fibers can also interact with the mitotic spindle to cause missegregation of chromosomes and aneuploidy. In rat pleural mesothelial cells, asbestos fibers and erionite have been shown to induce the protooncogenes c-fos and c-jun in a prolonged and dose–responsive manner. Several growth factors, secreted by mesothelial/mesothelioma cells in an autocrine fashion, have been implicated in various stages of mesothelioma tumorigenesis. Platelet-derived growth factors A and B (PDGF A and B), insulin-like growth factors 1 and 2 (IGF-1 and IGF-2), basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), hepatocyte growth factor, transforming growth factor-β1, 2, and 3 (TGF-β1, 2, and 3) constitute a complex mixture of autocrine and paracrine stimuli for mesothelioma cell proliferation as well as initiation of tumor angiogenesis. More recently, asbestos has been shown to induce necrotic cell death with resultant release of high mobility group protein B1 (HMGB-1) in the extracellular space, which leads to a chronic inflammatory response involving macrophage accumulation and secretion of tumor necrosis factor α (TNFα). This in turn activates NF-κB leading to survival of human primary mesothelial cells that have accumulated genetic damage from asbestos exposure. There is also evidence implicating aberrant activation of the Wnt signaling pathway in mesothelioma.[15,16]

It has been well established that chronic inflammation predisposes to cancer development. Asbestos fibers appear to stimulate the production of chronic oxidative stress in lung macrophages and other cells for many years. In animal models, crocidolite fibers clearly induce specific DNA adducts (8-hydroxydeoxyguanosine, 8-OHdG) associated with oxidative damage in the DNA from peritoneal cells and macrophages of asbestos-exposed animals. These same type of 8-OHd DNA adducts have been observed in the blood lymphocytes of asbestos-exposed individuals decades after exposure suggesting chronic exposure to oxidant stress.[17]

The pathogenesis of malignant mesothelioma involves molecular changes such as chromosomal alterations in tumor suppressor genes, allele loss, gene silencing by DNA methylation in specific chromosomal regions, epigenetic dysregulation of tumor suppressor genes by histone acetyltransferase and histone deacetylase (HDAC) chromatin condensation/decondensation balance, and gene mutations. Analysis of explanted human mesotheliomas and cultured human mesothelioma cell lines has revealed a number of cytogenetic aberrations that may predispose to the development of the malignant phenotype. Partial or total loss of chromosomes 1, 3, and 4, deletions of 9p, and monosomy of chromosome 22 are the most common abnormalities seen. For mesotheliomas, 9p deletions have been associated with the loss of function of the $p16^{INK4}$ cdk inhibitor, a putative tumor suppressor gene, engendering unchecked cdk4-mediated phosphorylation of the retinoblastoma 1 (Rb1) gene product and leading to loss of regulation of cell division. Monosomy 22, the most frequent numerical cytogenetic abnormality in mesothelioma, has recently been correlated with mutations in the neurofibromatosis 2 (NF2) tumor suppresser gene mutations more commonly associated with acoustic neuromas, schwannomas, and meningiomas. The product of NF2, Merlin, appears to inhibit cell proliferation and cell cycle progression by repressing cyclin D1 expression as well as inhibiting invasiveness. The presence of the Wilms tumor suppresser gene (WT1) in human mesotheliomas raises the possibility that alterations in this gene or binding of the WT1 gene product to the p53 tumor suppressor may predispose to mesothelial cell carcinogenesis.[15,16,18]

VIRAL ONCOGENES

Simian virus-40 (SV-40) is a polyoma virus with oncogenic potential in humans. Its actions are thought to result from inactivation of tumor suppressor genes such as the retinoblastoma gene (Rb) and wild-type p53 (wt p53) by a peptide known as the SV-40 large T-antigen (Tag). SV-40 is a potent oncogenic virus in human and rodent cells; SV-40 DNA sequences have been identified in brain tumors, osteosarcomas, and lymphomas.[19] SV-40 is the only agent known to cause malignant transformation of human primary mesothelial cell in vitro.[20] When cell lines are exposed to both SV-40 and asbestos fibers, the rate of transformation increases significantly. Animal studies have also shown that crocidolite asbestos and SV-40 can act as cocarcinogens.[21] Several studies have documented the presence of SV-40 in patients with mesothelioma (some of whom did not have obvious asbestos exposure), as well as in cases of atypical mesothelial proliferation.[22–26] As an example, one report examined 35 archival mesothelioma specimens and found that SV-40–like sequences were present in 86% of cases.[23] However, the possibility that technical factors can produce false-positive results suggestive of SV-40 infection also has been raised.[27,28] Despite the fact that there was worldwide dissemination of SV-40 contaminated polio vaccines in the 1950s and 1960s, there is no convincing epidemiologic evidence linking SV-40 exposure to the development of malignant mesothelioma.

Nonetheless, it is possible that Tag interference with Rb and wt p53 may play an accessory role in the carcinogenesis of malignant mesothelioma.[29] If this hypothesis is validated, novel strategies of vaccination to prevent mesothelioma or molecular techniques to improve early diagnosis may become possible.

GENETIC PREDISPOSITION

Gene polymorphism studies are in their early stages in asbestos-exposed populations. Some suggestive associations in DNA repair genes with mesothelioma development have been reported, but need validation. One study reported an increased incidence of mesothelioma among asbestos-exposed individuals in Finland found to be lacking the glutathione-S-transferase M1 (GSTM1) gene and carrying the "slow-acetylator" type of the *N*-acetyltransferase 2 (NAT-2) gene.[30] The GSTM1 gene is important in the detoxification of several carcinogens, including polycyclic aromatic hydrocarbons; NAT-2 is associated with the biotransformation of aromatic amines. Some genetically predisposed families have been identified, but without identification of a specific "mesothelioma" gene. An increased frequency of polymorphisms in the nod-like receptor pyrin domain (NLRP) inflammasome complex among a cohort of Italians with mesothelioma has also been described.[31] Inactivation of the nuclear deubiquitinase BAP1, which appears to regulate key histones and transcription factors related to the development of tumors, is associated with malignant pleural mesothelioma.[32] A so-called BAP1 "syndrome" has been described in some families bearing this gene mutation, in which there is higher frequency of mesothelioma, ocular melanoma, and melanocytic lesions of the skin, sometimes even occurring simultaneously in the same individual.[33]

PATHOLOGY

Gross and microscopic pathologic findings in malignant mesothelioma are discussed below.

Gross Pathology

The vast majority of malignant mesotheliomas involving the pleura are those tumors that diffusely involve the pleura and are properly termed "diffuse malignant mesothelioma." A rare localized gross

Figure 79-1 **A.** Transverse section of an extrapleural pneumonectomy surgical specimen with the entire right lung, parietal and visceral pleurae, portions of pericardium, and the majority of the right hemidiaphragm. Note the thick rind of tumor along the pleural surface encasing the lung and invading the diaphragm. **B.** Postmortem mesothelioma specimen with overnight formalin inflation and fixation. The right lung pictured is covered by a thick, whitish rind of tumor involving the entire pleural surface, which has also infiltrated and demarcated the interlobar fissures.

variant of malignant mesothelioma that forms a single mass arising in the pleura but is otherwise microscopically identical to diffuse malignant mesothelioma has been described and termed "localized malignant mesothelioma." Diffuse malignant mesothelioma begins as multiple discrete nodules that, in earlier stages, tend to preferentially involve the parietal pleura over the visceral pleura. In time, these nodules tend to coalesce on the visceral and parietal pleural surfaces with subsequent fusion of the pleurae. Progressive tumor growth typically leads to partial or complete encasement of the lung with rinds of pleural tumor that can be several centimeters in thickness, but may show only minimal penetration of the underlying lung parenchyma (Fig. 79-1). Advanced cases show more extensive spread along interlobar fissures, deeper invasion into the underlying lung parenchyma and through the diaphragm, as well as contiguous involvement of the chest wall, pericardium, and mediastinum. Although it is rare for patients with mesothelioma to present clinically with metastatic disease, peribronchial lymphovascular spread, regional lymph node metastases, and extrathoracic hematogenous metastases become increasingly common over the course of the disease. Seventy percent of patients have mediastinal lymph node involvement at autopsy. Hematogenous metastases follow the exact same pattern of spread as non–small cell lung carcinomas with involvement of the contralateral lung and pleura, liver, adrenals, bone, brain, and kidney.

Histology

The 2004 revision of the WHO classification of pleural tumors recognizes four major histologic subtypes—epithelioid, sarcomatoid, desmoplastic, and biphasic. In the 2004 WHO classification, the use of the term "well-differentiated papillary mesothelioma" is restricted to an exceptionally rare and distinctive mesothelial tumor that has bland cytologic features, stout papillary architecture, and a tendency toward superficial spread without invasion. Part of the diagnostic utility of the WHO classification is that each subtype is associated with a particular differential diagnosis that guides the pathology workup. This workup requires additional time and expense. Multiple sections may be taken and ancillary studies are usually required for definitive diagnosis. From a prognostic perspective, most studies have shown that the purely epithelioid subtype has the longest survival but these differences in survival, on the basis of histologic subtype, are within the range of only a few months. It should be recognized that the larger the tissue sample, the more frequent the histologic variation and the higher the incidence of biphasic tumors.

The epithelioid variant is the most common with a wide range and mix of histologic patterns. Typical histologic appearances of this subtype include tubulopapillary, glandular/microglandular, and solid sheet-like patterns (Fig. 79-2A). A myxoid matrix may be prominent and may be mistaken for mucin, but this matrix is

actually hyaluronate and shows hyaluronidase-sensitive staining with Alcian blue.

Sarcomatoid mesotheliomas can also have a wide variety of histologic patterns. The most frequently encountered pattern is that of fibroblastic-like spindle cells arranged in storiform, fascicular, or haphazard patterns that mimic a fibrosarcoma (Fig. 79-2B). Other variants include a malignant fibrous histiocytoma-like tumor and malignant mesotheliomas with malignant smooth muscle, chrondroid, osseous, or rhabdomyoblastic differentiation.

Desmoplastic mesotheliomas, by definition, have areas of densely collagenized tissue with atypical cells arranged in a storiform or "patternless" pattern. This pattern should comprise at least 50% of the tumor. The deceptively bland appearance of the tumor makes its separation from fibrous pleuritis exceedingly difficult, particularly with limited sampling. Studies that have examined the criteria used for diagnosis have highlighted the importance of "interface biopsies" in which unequivocal evidence of invasion into the underlying adipose tissue, skeletal muscle, or lung may be demonstrated. Other criteria, which may require multiple tissue sections to detect,

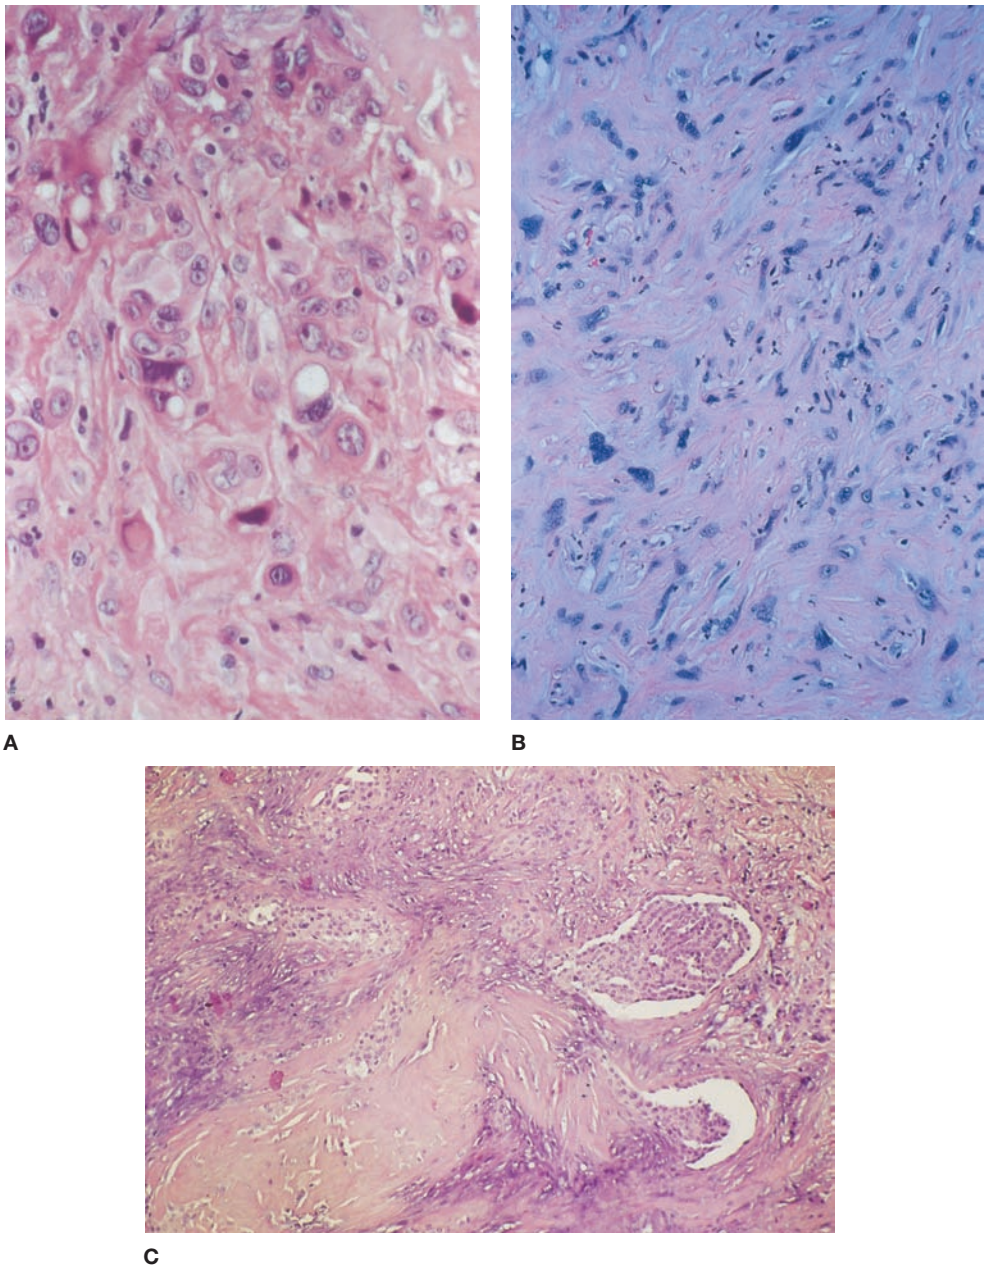

Figure 79-2 **A.** Photomicrograph of an epithelial malignant mesothelioma. These sheets of pleomorphic cells are epithelial in appearance, with eosinophilic cytoplasm and fairly well-defined cell borders. Note the cytoplasmic vacuoles, which can lead to confusion with a signet ring type of adenocarcinoma. By electron microscopy, these vacuoles can be shown to contain crystallized hyaluronic acid (H&E, ×400). **B.** Photomicrograph of a sarcomatoid malignant mesothelioma. This tumor has a malignant mesenchymal appearance with bizarre spindled cells and a growth pattern resembling that of a sarcoma. These cells demonstrated strong cytokeratin positivity on immunohistochemical staining, distinguishing this tumor from a sarcoma (H&E, ×400). **C.** Photomicrograph of a biphasic malignant mesothelioma. This tumor demonstrates several areas of epithelioid histology with a papillary growth pattern seen against a background of spindled and more poorly differentiated epithelioid cells (H&E, ×200).

include obvious sarcomatoid areas, foci of necrosis, and distant metastases. Bone metastases similarly may be deceptively bland and confused with a primary benign fibrous tumor of bone.[34,35]

Biphasic mesotheliomas have both epithelioid and sarcomatoid components (Fig. 79-2C). Each component should represent at least 10% of the tumor for the designation of biphasic. Biphasic mesotheliomas represent about 30% of cases. As previously noted, the percentage of biphasic tumors, which have a prognosis that is intermediate between the epithelioid and sarcomatoid subtypes, increase with larger tumor samples. In recent years, the percentage of sarcomatoid component within biphasic mesotheliomas has been shown to be prognostic factor, with greater than 50% sarcomatoid elements corresponding to decreased overall patient survival.[34]

Immunohistochemistry

Immunohistochemistry (IHC) has largely replaced electron microscopy as the gold standard for diagnosis. This is because of the comparative low cost, ease, and greater availability of IHC, as well as the expanded array of commercially available antibodies that are reliable markers of mesothelial differentiation. Because there is no single marker with sufficiently high sensitivity and specificity for malignant mesothelioma, it is standard practice for pathologists to employ a panel of markers (both positive and negative) to confirm the diagnosis of malignant mesothelioma. Institutions will vary somewhat in their selection of which markers to include and these panels are typically refined as publications appear with comparative utility studies. As in any instance in which IHC is used as an adjunct in tumor diagnosis, careful consideration must be given to the tumor's histologic appearance as well as the clinical-radiographic context and the differential diagnosis that is generated from this information.[36]

Broad-spectrum cytokeratin (CK) antibody cocktails are essential in the diagnosis of malignant mesothelioma. In epithelioid tumors, strong and diffuse CK positivity can be used to exclude the rare case of large cell lymphoma, epithelioid vascular tumors, or melanoma involving the pleura. CK reactivity usually differentiates malignant mesotheliomas from many sarcomas, although there are occasional CK-negative sarcomatoid mesotheliomas as well as focally CK-positive sarcomas. Although CK positivity does not distinguish malignant mesothelioma from reactive lesions, positive CK staining may help to highlight invasion into adjacent structures.

Common affirmative immunohistochemical markers, which, if positive, can be used to support a diagnosis of malignant mesothelioma include calretinin, CK5/6, the Wilms tumor I (WT1) antigen, and D2-40 (Fig. 79-3).[36] These markers are most useful in the narrow differential diagnosis of malignant epithelioid mesothelioma versus primary pulmonary adenocarcinoma. It should be noted that these markers do not invariably exclude other tumors, including metastases from nonpulmonary primary sites. A wide variety of markers can be used to support a diagnosis of adenocarcinoma, as opposed to malignant mesothelioma. Markers such as CEA, Leu-M1 (CD15), thyroid transcription factor-1 (TTF-1),

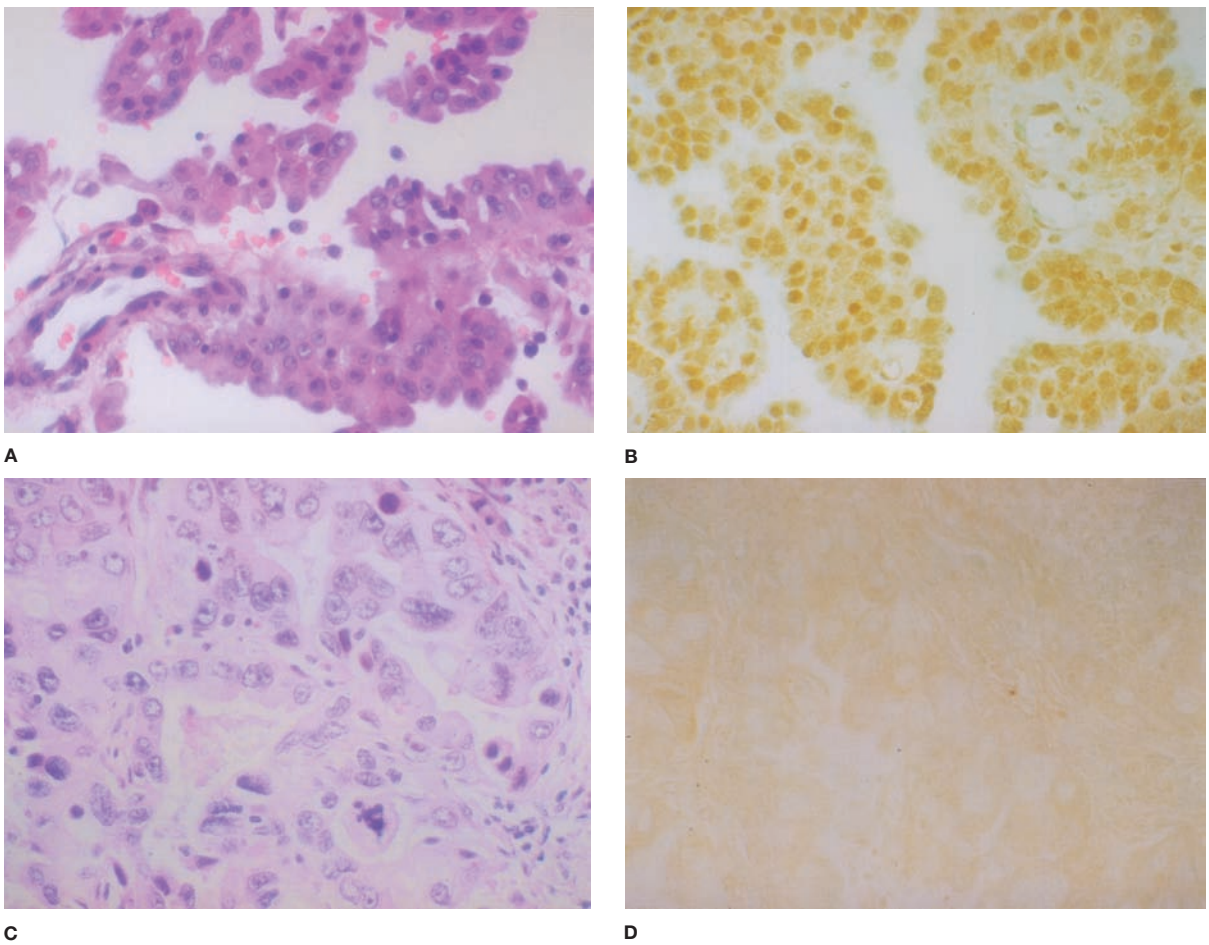

Figure 79-3 **A.** Photomicrograph of an epithelial mesothelioma (H&E, ×400). **B.** Photomicrograph of epithelial mesothelioma demonstrating positive nuclear staining with an antibody to the Wilms tumor 1 (WT1) gene product (×400). **C.** Photomicrograph of an adenocarcinoma metastatic to the pleura (H&E, ×400). **D.** Photomicrograph of pleural adenocarcinoma stained with an anti-WT1 antibody (×400). Only minimal background staining is present.

Ber-EP4, B72.3, Bg8, and MOC 31 are commonly included in such panels.[36] The sensitivity and specificity of both the affirmative mesothelioma markers as well as the adenocarcinoma markers vary greatly when the differential diagnosis is broadened to include other subtypes of primary pulmonary carcinoma such as squamous cell carcinoma or metastases from extrapulmonary sites such as the kidney and ovary. Both categories of markers are generally less reliable in the differential diagnosis of sarcomatoid lesions. The immunohistochemical panel that is recommended for the initial evaluation of a sarcomatoid tumor involving the pleura includes CKs (including AE1/3, CAM5.2, CK18, and CK7), calretinin, and D2-40.[37–39] If other types of sarcomas are being considered, then the marker panel should be expanded accordingly to include antibodies such as CD31, CD34, desmin, myoglobin, and S-100.

OTHER ANCILLARY STUDIES

Histochemical stains for the presence of intracytoplasmic mucin are still commonly used as a means of differentiating adenocarcinomas from epithelioid malignant mesotheliomas. Mucicarmine and periodic acid-Schiff (PAS) with diastase are the two most frequently used. These stains are technically easy to perform, inexpensive, and rapid. Care must be taken to exclude the possibility of false-positive staining that can be seen with hyaluronate. The use of histochemical staining (Alcian blue with hyaluronidase) to detect the high levels of hyaluronic acid in mesothelioma cells was used far more frequently before the widespread use of IHC.

Electron microscopy had traditionally been considered the gold standard for the diagnosis of malignant mesothelioma and ultrastructural analysis can still be useful in occasional problematic cases. The predominant epithelioid form is composed of polygonal cells with numerous long surface microvilli, prominent desmosomes, and abundant tonofilaments (Fig. 79-4). Electron microscopy of the sarcomatoid variant reveals the presence of elongated nuclei, CK and vimentin filaments, as well as copious rough endoplasmic reticulum, some intracellular attachments, and rare microvilli. Electron microscopic studies may be inconclusive in poorly differentiated tumors of either subtype and have no utility in the diagnosis of desmoplastic malignant mesothelioma. Molecular analysis can be performed on formalin-fixed, paraffin-embedded tissue to demonstrate the X:18 translocation characteristic of synovial sarcoma—a biphasic or monophasic sarcomatoid tumor that can involve the pleura. As discussed at the end of the chapter, synovial sarcoma should be considered in the differential diagnosis of a pleural tumor with a biphasic or monophasic spindle cell appearance.[40,41]

MOLECULAR PROFILING

As compared with routine histologic evaluation and classification, the examination of multiple expressed genes and/or proteins within individual tumors may be more informative for making diagnoses, estimating prognosis, and response to therapy. The development of microarray methodology, which permits the expression of thousands of genes to be assayed simultaneously, represents a powerful technique to read the "molecular signature" of an individual patient's tumor, a process termed gene expression profiling. Gene expression profiling studies have been used to identify genes with potential pathogenic significance, such as aurora kinases or key inhibitors of apoptosis proteins. Profiles have also been identified that help to reliably differentiate different subtypes of mesothelioma. By using gene expression ratios, it is possible to reliably distinguish between epithelioid mesothelioma and lung adenocarcinoma or ovarian carcinomas from peritoneal mesotheliomas.[42,43] An area of active investigation is the use of expression profiles as a means of predicting outcome and clustering groups of patients with pleural mesothelioma into those with good risk (i.e., more likely to be cured using aggressive therapy) and poor risk disease (i.e., with a low cure rate despite aggressive therapy). Some groups have found this approach to be highly predictive, whereas others suggest the accuracy has been overestimated.[44]

Pietra, Department of Pathology and Laboratory Medicine, University of Pennsylvania Medical Center, Philadelphia.)*

CLINICAL PRESENTATION

Malignant pleural mesothelioma most commonly presents in the fifth to seventh decades of life. Most patients diagnosed with mesothelioma earlier in life have a history of childhood asbestos exposure. The most frequent presenting symptoms of pleural mesothelioma, which are caused by the presence of extensive intrathoracic disease, are nonpleuritic chest pain (60%–70% of patients), dyspnea (25%), and cough (20%). Some patients are asymptomatic at diagnosis, with unilateral pleural effusions found incidentally on routine chest radiographs. Mesothelioma is typically a unilateral disease—only 10% of patients with mesothelioma have bilateral involvement at presentation. In more advanced stages of disease, physical findings may include unilateral dullness to percussion and decreased air movement throughout the hemithorax, asymmetric chest wall expansion during respiration, palpable chest wall masses, and scoliosis toward the side of the malignancy.

RADIOGRAPHIC PRESENTATION

The most common initial radiographic manifestation of pleural mesothelioma is a large unilateral pleural effusion, often with contralateral mediastinal shift (Fig. 79-5A). Sixty percent of patients have right-sided lesions, putatively related to the gravitational predilection for inhaled asbestos fibers and dusts to travel directly to the right lower lobe airways. Occasionally, mesothelioma can present as unilateral, concentric, plaque-like, or nodular pleural thickening, but effusions may obscure the presence of the underlying pleural thickening. The tumor frequently extends into the fissures, which become thickened and irregular in contour. Only 20% of patients with pleural mesothelioma have radiographic signs of asbestosis (i.e., bibasilar interstitial fibrosis), although many have evidence of pleural plaques and/or calcifications. In later stages of disease, ipsilateral mediastinal shift is seen secondary to encasement of the lung by a thick rind of tumor and resultant significant unilateral loss of lung volume. Patients with advanced mesothelioma may also have other radiographic signs of volume loss: diaphragm elevation and intercostal space narrowing. They may also have mediastinal widening owing to direct tumor invasion or lymph node involvement, enlargement of the cardiac margins secondary to pericardial invasion with effusion, and evidence of rib destruction or soft tissue masses extending from the chest wall.[45] Chest computed tomography (CT) is important in detecting invasion of chest wall, ribs, and mediastinal structures, as well as extension along the pleural surfaces and diaphragm (Fig. 79-5B). Furthermore, CT scans can distinguish between pleural thickening and effusion.[46] Coronal magnetic resonance imaging (MRI) is helpful in discerning the extent of disease, particularly invasion of the chest wall, endothoracic fascial involvement, and extension of pleural mesothelioma through the diaphragm into the peritoneal cavity.[47] In one study of 95 patients with pleural mesothelioma, MRI was directly compared with CT scan. The overall diagnostic accuracy for mediastinal nodal disease was approximately 50% for both modalities, but MRI outperformed CT for detection of diaphragmatic invasion (82% vs. 55% accuracy, respectively), and for detecting invasion of endothoracic fascia or chest wall (69% vs. 46%).[48]

No definite calcified pleural plaques are seen. **B.** Computed axial tomographic image from a patient with pleural mesothelioma, illustrating complete encasement of the ipsilateral lung with a thick rind of tumor, neoplastic invasion of the interlobar fissures, small residual pleural effusion, and marked unilateral volume loss.

POSITRON EMISSION TOMOGRAPHY

The role of positron emission tomography (PET) imaging, particularly PET/CT, in the care of patients with mesothelioma is multifold. It can be used in diagnosis and staging by evaluating the extent of pleural disease, establishing mediastinal lymph node involvement, evaluating tumor invasion into the lung and thoracic wall, and detecting extrathoracic metastases. It is becoming particularly useful to assess the treatment response to chemotherapy and radiotherapy and also plays an important role in the planning of radiation therapy.

The role of PET scans with 18-fluorodeoxyglucose (FDG) in staging and preoperative evaluation is evolving. In a small study of 28 patients with suspected pleural mesothelioma who underwent 18-FDG PET scanning followed by thoracoscopic or open surgical biopsy, PET was shown to be better than CT for differentiating malignant from benign pleural processes. Uptake of FDG was significantly higher in malignant lesions, and an overall sensitivity and specificity of 91% and 100% could be achieved with PET scanning for the detection of malignant as compared with benign disease. However, hypermetabolic lymph nodes were detected in 12 patients (of whom nine had a normal CT scan), and only five had histologically proven malignant nodal disease.[49]

In another small study, PET assessment demonstrated pleural lesions in 12 of 13 patients with malignant pleural disease (malignant pleural mesothelioma in ten patients, adenocarcinoma in two and liposarcoma in one), also revealing distant metastases in two patients. A patient with an epithelial mesothelioma had a false-negative result. In a study of 16 patients with pleural changes, PET correctly identified all 12 malignant cases; conversely, the four

patients (4/4) who had no FDG uptake all had benign pleural disease (fibroma, tuberculous pleurisy, empyema, and pleural fibrosis).[50]

PET scan appears more sensitive than CT for finding extrathoracic disease, but has limited sensitivity for locoregional staging (i.e., determining potential resectability). In one retrospective study, 60 patients with malignant pleural mesothelioma were identified who had undergone PET scans preoperatively and the results of clinical staging were compared with surgical and pathologic results. FDG uptake was detected in 59, and the one false-negative case had disease limited to the parietal pleura (stage IA). The sensitivity of PET scans for determining the presence of T4 (unresectable) disease was only 19% (7 of 21 patients). Among the 31 patients whose nodal status was assessed pathologically, only one of nine patients with N2 disease was correctly identified by PET scan, and the overall sensitivity for nodal disease was only 11%.[51]

PET scanning may help differentiate between benign and malignant pathology when patients present with a chest radiograph demonstrating pleural abnormalities. One study demonstrated that dual timepoint FDG PET scanning, which measures uptake of (18)F-FDG over time, could distinguish between benign and malignant pleural diseases among 55 suspected cases.[52]

One of the potential future uses of PET that needs to be further evaluated is its utilization in the screening of patients with a history of significant asbestos exposure. These patients may potentially harbor microscopic disease, not apparent on CT or MRI, which may be amenable to early aggressive therapy. Because of the limits of detection of current 18-FDG PET technology, the use of PET for screening for pleural mesothelioma must await the development of novel radiopharmaceuticals.

PET scans can also be used to predict survival and response to therapy. One study involving 177 patients with mesothelioma found that patients with tumors demonstrating intense FDG avidity (standardized uptake value >5) had a far worse prognosis. Another study showed that decreased radiopharmaceutical uptake on follow-up PET scans performed early after treatment may be an excellent predictor of overall clinical response.[53] Furthermore, there is evidence supporting the use of PET scans after neoadjuvant chemotherapy to determine those who will benefit most from moving onto surgical resection.[54]

LABORATORY STUDIES

Although there are no specific pleural fluid biomarkers for malignant mesothelioma, evaluation of pleural fluid chemistries may still be beneficial. Effusions associated with mesothelioma are strongly exudative, with elevated protein concentrations in the range of 4 to 5 g/dL and a lymphocytic predominance. Pleural fluid lactate dehydrogenase (LDH) concentrations often exceed those of patients with carcinomatous pleural effusions, with levels greater than 600 IU/L. In patients with advanced disease and extensive involvement of visceral and parietal pleura, pleural fluid pH and glucose are commonly low. In patients with mesothelioma, the presence of a low pleural fluid pH denotes both a poor overall prognosis and refractoriness to achieving successful palliative pleurodesis. In addition, the pleural effusion associated with mesothelioma is characteristically highly viscus, presumably because of elevated concentrations of hyaluronic acid.[55] An increased pleural fluid hyaluronidase level is suggestive but not diagnostic of mesothelioma.[56] The cytokine profile of pleural effusions related to mesothelioma is somewhat unique in that the tumor constitutively produces high concentrations of interleukin-6 (IL-6) and transforming growth factor-β (TGF-β), but relatively low levels of IL-1β and TNFα. These elevated intrapleural levels of IL-6 in patients with malignant mesothelioma are postulated to induce systemic manifestations such as fever, cachexia, and thrombocytosis.[57,58]

Pulmonary function testing typically demonstrates a restrictive pattern resulting from pleural effusions, tumor encasement of the lung, or chest wall involvement.

MESOTHELIN AND OTHER NOVEL SERUM MARKERS

There is increasing evidence supporting the clinical utility of a monoclonal antibody–based serum assay for a soluble form of the protein mesothelin (soluble mesothelin–related peptide [SMRP]). Mesothelin is a 40-kDa glycoprotein that is found in low levels on the cell surface of normal mesothelial cells (lining the pleura, peritoneum, pericardium, and tunica vaginalis), but is highly expressed on mesothelioma, pancreatic cancer, and ovarian cancer cells.[59,60] Multiple studies have observed that SMRP can be elevated in serum and pleural fluid of patients with mesothelioma.[61] Increased levels of SMRP were found in serum samples from 37 of 44 patients with mesothelioma (87%), compared with 3 of 160 patients with other cancers or inflammatory lung or pleural diseases (2%), and none of 28 controls without a past asbestos exposure.[62] At the present time, SMRP levels play an adjunctive role in the diagnosis of patients with mesothelioma. A meta-analysis of 16 diagnostic studies found that the sensitivity ranged widely from 19% to 68%, depending on the specific criterion for positivity.[61] SMRP has also been measured in pleural fluid. In a retrospective study of 52 patients with malignant mesothelioma, the assay had a sensitivity of 67% with a specificity of 98% in 84 patients with benign pleural effusions.[63] It is intriguing to posit that SMRP may also play a role in screening of high-risk patients for incipient mesothelioma. In one report, 7 of 40 asbestos-exposed individuals had elevated levels and 4 of these 7 subsequently developed mesothelioma or lung cancer within 1 to 5 years.[62] However, measurement of SMRP is indicated currently only for monitoring patients in whom the diagnosis has already been established.

Osteopontin, a glycoprotein that mediates cell–matrix interactions and is overexpressed in several types of cancer, was higher in patients with malignant mesothelioma than in patients with asbestos-related nonmalignant pleural disease or no prior asbestos exposure in a study of 190 patients.[64]

Fibulin-3 is an extracellular glycoprotein that is encoded by the epidermal growth factor–containing fibulin-like extracellular matrix protein 1 (EFEMP1) gene. Initial studies found that elevated levels of fibulin-3 in the plasma had high sensitivity and specificity (97% and 96%, respectively) in distinguishing patients with pleural mesothelioma from those with a history of asbestos exposure but without mesothelioma and from those with other malignancies or benign causes of pleural effusion. Levels of fibulin-3 decreased in patient with mesothelioma who underwent surgical resection. Additional studies will be required to determine its role as a biomarker for early diagnosis and monitoring of patients who have undergone therapy.[65]

DIAGNOSIS

The differential diagnosis of malignant pleural mesothelioma includes both benign and malignant processes. Inflammatory reactions such as chronic, organized empyema can mimic the dense pleural thickening and large, viscous pleural effusions characteristic of mesothelioma. As discussed, epithelial mesotheliomas can be extremely difficult to distinguish grossly and histologically from metastatic adenocarcinoma to the pleura from any number of primary sources, including lung, breast, stomach, kidney, ovary, and prostate. Sarcomas such as fibrosarcoma can present in similar fashion and infiltrate-like sarcomatoid mesotheliomas. The mixed-cellular (biphasic) subtype of mesothelioma can bear a significant histologic resemblance to sarcomatoid carcinomas and synovial sarcoma.

Thoracentesis or closed pleural biopsy can often establish the diagnosis of pleural malignancy, but may not provide enough diagnostic material to determine the specific diagnosis of mesothelioma. Immunohistochemical markers and monoclonal antibodies may aid in differentiating mesothelioma from other carcinomas on cytology specimens. In addition, certain cytopathologic features of cells obtained from pleural fluid have been found to correlate well with the presence of mesothelioma, including papillary aggregates, multinucleation with atypia, cell-to-cell apposition, nuclear pleomorphism,

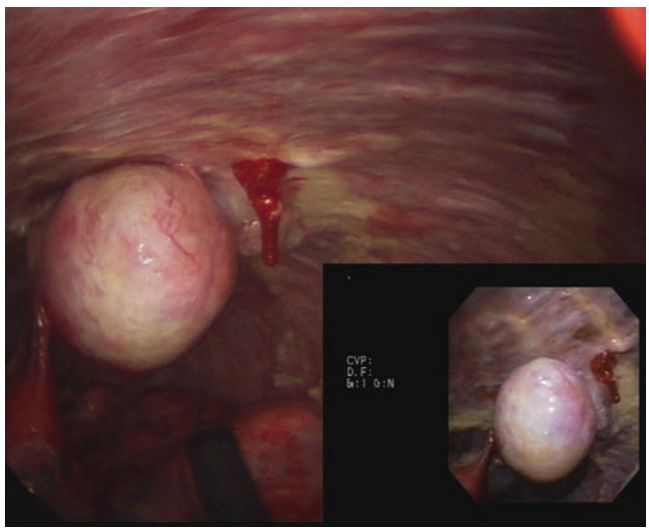
and macronucleoli. Gene expression ratios may also be increasingly helpful in this regard. Negative results from thoracentesis and/or pleural biopsy do not exclude the diagnosis of mesothelioma and therefore surgical biopsy, which has a higher diagnostic yield, should be pursued in patients with high clinical suspicion.

Surgical intervention, via video-assisted thoracoscopic surgery (VATS) or open thoracotomy, is often necessary to firmly establish the diagnosis. Boutin et al. from Marseille prospectively evaluated VATS for the diagnosis of malignant pleural mesothelioma in 188 consecutive patients from 1973 to 1990 and found that thoracoscopic biopsy was diagnostic in 98% of cases, compared with only 26% for thoracentesis alone, and 39% for fluid cytology and closed pleural biopsy. These thoracoscopic procedures were performed under local anesthesia in an endoscopy suite with minimal morbidity or complications.[66] It is important to note that approximately 10% of patients who undergo a transthoracic diagnostic procedure for mesothelioma may seed the biopsy site with tumor cells, later developing chest wall recurrences. This complication can potentially be prevented by prophylactic radiation therapy to the surgical incision or thoracentesis sites (Fig. 79-6).

Concurrent bronchoscopy may be important in distinguishing between mesothelioma and metastatic adenocarcinoma of the lung, as endobronchial lesions are rarely seen in mesothelioma. In addition, both endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) and mediastinoscopy play important roles in the diagnosis and staging of mesothelioma, as several studies have documented the significant negative prognostic implications of mediastinal nodal invasion in this disease. In comparative trials, EBUS-TBNA may actually have a higher sensitivity and specificity for determining mediastinal nodal involvement than mediastinoscopy.[67,68]

STAGING

The staging of malignant mesothelioma has proved to be more controversial than that of many other tumors. The most commonly used schema was devised by Butchart in 1976 (Table 79-1). Although useful, its ability to predict survival is weakened by lack of inclusion of lymph node involvement and chest wall invasion. For this reason, the Union Internationale Contre le Cancer (UICC) in 1990 first proposed a staging system based on the TNM (tumor/node/metastasis) standard used for many other tumors. In the TNM staging system, stages I and II disease have pleural involvement, potentially including diaphragmatic muscle or pulmonary parenchyma, but no evidence of lymph node involvement, distant metastases, or locally advanced, unresectable disease. Stage III mesothelioma includes those cases with regional lymph node involvement. Stage IV includes those with locally advanced and unresectable disease, contralateral lymph node involvement, supraclavicular lymph node involvement, and/or distant metastases.[69] More recently, Rusch et al. from the International Mesothelioma Interest Group (IMIG) proposed an updated staging system based upon tumor descriptors, providing precise anatomic definitions of the local extent of the primary tumor. This staging system (Table 79-2) was designed to provide the framework for proper analysis of prospective clinical trials of new treatment modalities.[70]



A B

Figure 79-6 **A.** View of a mesothelioma tumor in the pleural cavity attached to the visceral pleura through surgical thoracoscope. **B.** View of the same tumor through a flexible medical pleuroscope.

TABLE 79-1 Butchart Staging System

Stage I	Tumor confined within the "capsule" of the parietal pleura
Stage II	Tumor invading chest wall or involving mediastinal structures
Stage III	Tumor penetrating diaphragm to involve peritoneum; involvement of opposite pleura; lymph node involvement outside the chest
Stage IV	Distant blood-borne metastases

CLINICAL COURSE AND COMPLICATIONS

The morbidity and mortality associated with mesothelioma is chiefly related to inexorable local invasion. Patients typically develop dyspnea and chest pain as tumor and fibrosis gradually obliterate the pleural space and replace any pleural fluid. As the tumor spreads, it covers both visceral and parietal pleural surfaces, encasing the

TABLE 79-2 International Mesothelioma Interest Group (IMIG) Staging System

T1	T1a: Tumor limited to ipsilateral parietal pleura T1b: Tumor involving ipsilateral parietal pleura, with scattered foci of tumor on visceral pleural surface
T2	Tumor involving all ipsilateral pleural surfaces with diaphragmatic invasion or extension into underlying pulmonary parenchyma
T3	Involvement of the endothoracic fascia; mediastinal fat; solitary, resectable chest wall focus; or nontransmural pericardial invasion
T4	Diffuse extension into chest wall, peritoneum, spine, mediastinal organs, contralateral pleura, internal surface of pericardium or myocardium
NO	No regional lymph nodes metastases
N1	Metastases in the ipsilateral bronchopulmonary or hilar lymph nodes
N2	Metastases in the subcarinal or ipsilateral mediastinal lymph nodes
N3	Metastases in the contralateral mediastinal or internal mammary lymph nodes or any supraclavicular node metastasis
Staging	
Stage I	Ia: T1aN0M0 Ib: T1bN0M0
Stage II	T2N0M0
Stage III	Any T3M0, any N1M0, any N2M0
Stage IV	Any T4, any N3, any M1

ipsilateral lung with a thick, fibrous peel that extends into interlobar fissures and occasionally into lung parenchyma. Deoxygenated blood is shunted through the trapped lung, leading to significant dyspnea and to hypoxemia that is often refractory to supplemental oxygen. Dyspnea also results from abnormal chest wall mechanics secondary to tumor invasion into ribs as well as intercostal nerves and muscles. Local invasion of crucial thoracic structures can result in dysphagia, hoarseness, cord compression, brachial plexopathy, paralysis, Horner syndrome, and superior vena cava syndrome. Hilar and mediastinal lymph node involvement occurs at diagnosis in less than 50% of patients, but is a harbinger of poor prognosis. Transdiaphragmatic spread into the abdominal cavity rapidly leads to intraperitoneal dissemination, with encasement of the mesentery and small and large bowel. Local invasion into the pericardial space can lead to pericardial effusion and tamponade. Distant metastatic disease by hematogenous spread, is unusual early in the course of mesothelioma but may present in liver, bone, brain, adrenals, thyroid, and kidney. Widespread metastatic disease is more often a manifestation of end-stage malignant mesothelioma.[5,71–74]

MORTALITY

Median survival of patients with mesothelioma is between 8 and 14 months and varies depending on stage, histologic subtype, and concomitant medical problems. Patients with pleural mesothelioma most commonly die from local extension and respiratory failure, primarily related to spread to the contralateral hemithorax. As mentioned, tumor extension below the diaphragm may result in death from small bowel obstruction. Patients may also die from arrhythmias, heart failure, or stroke caused by tumor invasion of the heart or pericardium.[5,71–74]

PARANEOPLASTIC SYNDROMES

Disseminated intravascular coagulation, migratory thrombophlebitis, thrombocytosis, Coombs-positive hemolytic anemia, hypoglycemia, and hypercalcemia associated with secretion of a parathyroid hormone–like peptide have all been described in the setting of mesothelioma.[74]

PROGNOSTIC FACTORS

Poor prognosis at the time of presentation is indicated by the presence of thrombocytosis, leukocytosis, low hemoglobin, fever of unknown origin, sarcomatoid or mixed histology, age greater than 65 to 75 years, poor performance status, and male gender. Good prognosis at presentation is associated with epithelial histology; stage I disease; age under 65 years; Eastern Cooperative Oncology Group (ECOG) performance status of 0 to 1; absence of chest pain; and the presence of symptoms for more than 6 months prior to diagnosis.[75–79]

The prognostic scoring systems derived by the Cancer and Leukemia Group B (CALGB) and the European Organization for Research and Treatment of Cancer (EORTC) are the most useful clinical prognostic scoring schemes available. They incorporate both the extent of disease, as well as systemic factors. The CALGB evaluated the impact of clinical characteristics on the survival of 337 patients treated with chemotherapy for advanced mesothelioma in sequential phase II treatment studies over a 10-year period. In multivariate analysis, serum LDH greater than 500 IU/L, poor performance status, chest pain, platelet count over 400,000/μL, nonepithelial histology, and age older than 75 years jointly predicted poor survival. Six distinct prognostic subgroups were generated with median survival times ranging from 1.4 to 13.9 months. The median survival overall was 7 months. This prognostic schema was subsequently validated in an American phase II trial evaluating the investigational agent ranpirnase, and in an independent European data set.[78]

The EORTC Prognostic scoring system was derived from an analysis of data from 204 adults who were entered into five consecutive phase II trials over 9 years. When five factors were taken into consideration (poor performance status, high WBC count, male gender, sarcomatoid cell type, and the certainty of the diagnosis), favorable and poor prognostic groups could be delineated, with 1-year survival rates of 40% and 12%, respectively. Median survival from the date of study entry was 8.4 months.[80,81] The relevance of these earlier prognostic indicators is somewhat limited given that the study was performed in the pre-pemetrexed era. However, the prognostic significance of the EORTC index has subsequently been confirmed in a multivariate analysis of a phase III trial assessing cisplatin plus raltitrexed.

CURRENT APPROACHES TO THE TREATMENT OF PLEURAL MESOTHELIOMA

Over the past decade, advances have been made that have improved our ability to treat malignant pleural mesothelioma and, possibly, the quality and quantity of life for patients with mesothelioma. Multimodality treatment programs that combine surgical cytoreduction with novel forms of radiation therapy and more effective chemotherapy combinations may offer significant increases in survival for certain subgroups of mesothelioma patients. Innovative palliative approaches have proved successful in alleviation of the symptoms experienced by many mesothelioma patients. Experimental treatments such as immunotherapy and gene therapy present a window of hope for all mesothelioma patients, and in the future, may be combined with "standard therapy" in multimodality protocols.

Chemotherapy

Over the past 20 years, several phase II single-agent and combination chemotherapy studies have been performed in mesothelioma. These studies have demonstrated evidence of antitumor activity with anthracyclines, platinum derivatives, and antimetabolites. Combination chemotherapy has been associated with higher overall response rates but not, until recently, longer median survivals.[82]

The current standard of care for first-line chemotherapy in good performance status patients with unresectable mesothelioma is combination treatment with cisplatin and pemetrexed. Pemetrexed (Alimta®, Eli Lilly and Company, Indianapolis, IN) is an antifolate compound that targets multiple enzymes in the folate metabolism pathway. Pemetrexed is a potent inhibitor of thymidilate synthase, the rate-limiting step in the synthesis of thymidilate, which is required for DNA synthesis. Thymidilate synthase is also the enzyme inhibited by the cytotoxic agents, 5-fluorouracil and raltitrexed.

In 2003, Vogelzang et al. reported the results of a phase III randomized clinical trial in chemotherapy-naive mesothelioma patients comparing treatment with pemetrexed and cisplatin with cisplatin monotherapy. A total of 456 patients were randomized: 226 received pemetrexed and cisplatin, 222 received cisplatin alone, and eight never received therapy. Median survival time in the combination pemetrexed/cisplatin arm was 12.1 months versus 9.3 months in the cisplatin-only arm ($p = 0.02$). The hazard ratio for death of patients in the combination arm versus those in the control arm was 0.77. Median time to progression was significantly longer in the pemetrexed/cisplatin arm: 5.7 months versus 3.9 months ($p = 0.001$). Response rates were 41.3% in the pemetrexed/cisplatin arm versus 16.7% in the control arm ($p < 0.0001$). The addition of folic acid and vitamin B12 to chemotherapy resulted in reduction in the severity and frequency of hematologic and nonhematologic toxicities in the pemetrexed/cisplatin arm.[83] Another randomized phase III study of cisplatin with a newer-generation antifolate, raltitrexed showed similar increases in survival.[84] Pemetrexed plus carboplatin may be an alternative regimen if cisplatin toxicity is a particular concern, particularly in elderly patients or those with compromised renal function.[85]

The combination of gemcitabine and cisplatin or carboplatin is also a valid first-line option in the treatment of mesothelioma owing to its acceptable toxicity profile, good response rate, and palliative effects.

A Northern Italian phase II study of gemcitabine and carboplatin in patients with pleural mesothelioma reported a 26% partial response rate and a median response duration of 55 weeks. There were also significant palliative benefits, decreased dyspnea in 46% of patients, weight gain in 40%, and pain reduction in 26%. Median survival for patients in this study was 66 weeks.[86] The potential value of the gemcitabine plus cisplatin regimen was also demonstrated in a second multicenter phase II trial, in which 106 previously untreated patients were treated with gemcitabine plus cisplatin and randomly assigned to receive either bevacizumab or placebo. The median survival was approximately 15 months in both treatment arms, consistent with the results seen with cisplatin plus pemetrexed. The trial showed no benefit from the addition of bevacizumab to the regimen.[87] An ongoing randomized clinical trial in Europe is evaluating the benefit of bevacizumab in combination with standard front-line pemetrexed-based chemotherapy.

There is no current standard of care for second-line chemotherapy in mesothelioma following treatment with cisplatin and pemetrexed. The most commonly used second-line regimens include gemcitabine, or other drugs with single-agent activity such as vinorelbine. A large, double-blinded, randomized clinical trial of the HDAC inhibitor vorinostat in second-line therapy for mesothelioma showed no survival benefit for study drug over placebo.[88] There exists insufficient evidence to recommend second-line chemotherapy as a standard treatment. Patients with adequate performance status should be enrolled onto clinical trials of second-line experimental therapies.

Radiation Therapy

Contrary to the prevailing wisdom that malignant pleural mesothelioma is a radioresistant neoplasm, it has been demonstrated that mesothelioma cell lines are actually more responsive to ionizing radiation in vitro than non–small cell lung cancer cell lines. External beam radiation therapy for mesothelioma is, however, somewhat limited by the large treatment volumes required and the radiation sensitivity of the surrounding organs (heart, lung, esophagus, spinal cord). Although palliative radiotherapy with an attempt to treat the entire involved pleural surface is technically challenging, and associated with a high risk of radiation pneumonitis, myelitis, hepatitis, and myocarditis, it can provide effective local palliation in up to 50% of patients.[89]

There are anecdotal reports of long-term survivors following high-dose external beam irradiation, and even after intrapleural administration of radioactive isotopes. However, most studies have shown no significant effect upon overall survival in patients with mesothelioma.[90]

Radiation therapy may play a role by preventing chest wall recurrences after invasive procedures, and in improving local control after pleurectomy or extrapleural pneumonectomy (EPP).[4,90–92] Mesothelioma frequently implants along the tracts of biopsies, chest tubes, thoracoscopy trocars, and surgical incisions, producing uncomfortable subcutaneous nodules. This can be prevented with prophylactic radiotherapy. In a small randomized trial, Boutin et al. demonstrated that 21 Gy administered in three daily fractions, 10 to 15 days after thoracoscopy, decreased local recurrence from 40% to 0%.[93] These findings have been confirmed by other investigators as well.

Multimodality approaches commonly include adjuvant radiation following surgery, although there are no randomized trials that demonstrate its efficacy. Because the lung remains in place after pleurectomy, radiotherapy doses must be lower than when EPP is performed. The Radiation Oncology group at The University of Texas MD Anderson Cancer Center reported encouraging results using intensity-modulated radiotherapy (IMRT) following extrapleural pneumonectomy.[94,95] Employing careful treatment planning and IMRT, radiation doses of up to 50 to 60 Gy were possible without severe toxicity. With the combination of EPP and IMRT, local recurrences after surgery were virtually eliminated; however, novel distant disease patterns have begun to emerge. These data suggest that the combination of EPP and IMRT requires an additional treatment modality (i.e., chemotherapy or immunotherapy) to limit distant tumor growth. Although IMRT following EPP appeared to be more effective for local disease control in this initial series, a second series from the Dana-Farber Cancer Center suggested there was a significant increase in severe toxicity. In that report, 6 of 13 patients developed fatal pneumonitis in the contralateral lung.[96] More recent studies have demonstrated safety and efficacy of IMRT, either after EPP or in the adjuvant setting post–radical pleurectomy (RP) in the presence of an intact lung.[97–99] Novel forms of radiation therapy, including proton beam therapy, are currently under investigation for treatment of mesothelioma.[100,101]

Surgical Approaches

Although associated with substantial morbidity, surgical management of mesothelioma has made significant strides in palliating the major symptoms of the disease, as well as potentially offering some improvement in survival for highly selected patients. The increased use of VATS, in conjunction with novel biomarkers, has facilitated early diagnosis of mesothelioma in more patients, at which point they may be candidates for more aggressive attempts at "definitive" surgical treatment (along with neoadjuvant/adjuvant therapies). However, definitive surgical intervention is only possible in a small percentage of patients. Furthermore, fewer than 25% of those who undergo aggressive surgical intervention will be alive at 5 years, and even fewer will be disease free at that timepoint.[102] The vast majority of pleural mesothelioma patients have locally advanced disease at the time of presentation, which, along with advanced age and/or other comorbid medical illnesses, often precludes aggressive surgical intervention.

EPP is a radical surgical procedure involving complete removal of the ipsilateral lung along with the parietal and visceral pleura, pericardium with portions of the phrenic nerve, and the majority of the hemidiaphragm (Fig. 79-7 and Video 79-1). EPP achieves the greatest degree of cytoreduction, and, because the lung has been removed, allows higher radiation doses to be delivered to the ipsilateral hemithorax. It is the only debulking procedure possible when a thick tumor rind obliterates the pleural space. There is a small group of long-term survivors following EPP when it is a component of a multimodality treatment program, suggesting that this procedure may alter the natural history of the disease in appropriately selected patients with early-stage disease.[103] Unfortunately, the benefits of EPP with adjuvant chemotherapy +/– local radiotherapy are limited to otherwise healthy patients with early-stage disease, epithelial histology, and no mediastinal lymph node involvement. Patients with

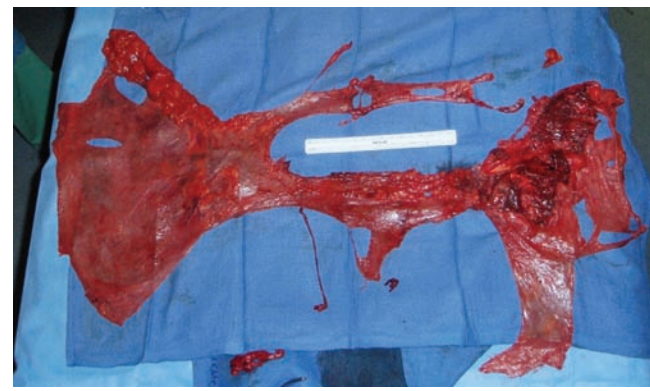


Figure 79-7 Gross photograph of a surgically resected pleurectomy/decortication specimen from a patient with malignant pleural mesothelioma. This involves the removal of the diseased pleura as an attempt to free the underlying lung to allow it to expand more freely. The steps involved are usually (1) incision and exposure of the parietal pleura, (2) dissection of parietal pleura from endothoracic fascia, diaphragm, and mediastinum, (3) incision of the parietal pleura and exposure of the visceral pleura, (4) decortication of the visceral pleura, and (5) reconstruction.

Video 79-1 Video recording from intraoperative thoracoscopic view of radical pleurectomy for malignant pleural mesothelioma performed through a thoracotomy incision. This surgical therapy for MPM is an alternative to extrapleural pneumonectomy. The procedure often takes up to several hours and involves extrapleural dissection, dissection of the diaphragm and pericardium, visceral pleurectomy, and lymph node dissection. *Access at www.fishmansonline.com*

biphasic or sarcomatoid histology and/or mediastinal or hilar node positivity have an ominous prognosis.[92,104]

EPP alone is an excellent means of palliating the profound dyspnea and orthopnea associated with the severe ventilation/perfusion mismatch resulting from lung encasement by mesothelioma. However, EPP alone has no influence on survival in the absence of adjuvant therapy.[105,106] In most EPP series, median survival from surgical debulking alone is less than 2 years, and 10% to 20% of patients are 5-year survivors. Biphasic/sarcomatoid histology and/or involvement of mediastinal lymph nodes confer a poorer prognosis and lack of demonstrable survival benefit from surgical intervention.

Several approaches for adjuvant therapy in conjunction with EPP have been studied. Investigators at Brigham and Women's Hospital have combined EPP with sequential postoperative chemotherapy and up to 55 Gy of adjuvant radiation therapy to the postoperative hemithorax.[107] More recently, the Brigham Thoracic Program has been investigating the role of hyperthermic intracavitary chemotherapy as an adjuvant to maximal cytoreductive surgery, in combination with hemithoracic irradiation and systemic chemotherapy.[108,109] In addition, several investigators have evaluated the utility of postresectional photodynamic therapy (PDT) with or without adjuvant chemotherapy or immunotherapy.[110] One randomized trial conducted by Pass et al.[111,112] at the National Cancer Institute failed to confirm any benefit for adjuvant PDT compared with surgery alone. Novel photosensitizers are currently under study that may provide better local control, decreased photosensitivity, and perhaps improved induction of systemic antitumor immune responses. Other novel multicenter clinical trials combine maximal surgical debulking with adjuvant IMRT or alternatively assess the role of neoadjuvant chemotherapy prior to cytoreductive surgery to improve long-term outcomes. EPP in these contexts is designed as a cytoreductive, not a curative procedure.[113–115]

Parietal pleurectomy, that is, open surgical stripping of the pleura from the apex of the lung to the diaphragm, is more successful than talc pleurodesis in reducing the recurrence of pleural effusion in mesothelioma. (Fig. 79-8) Thoracoscopic pleurectomy has been employed to achieve similar results as the open procedure, but with less morbidity.[91,116]

Complete parietal and visceral pleurectomy (pleurectomy/decortication or RP), has not been shown by itself to prolong survival in patients with mesothelioma.[117]

Investigators have evaluated the combination of pleurectomy/decortication with postoperative intrapleural radiation therapy, external beam irradiation, and/or systemic chemotherapy.[90,118–121] One single institution study reported a median survival of 22.5 months and a 2-year survival rate of 41% in a group of 27 patients, predominantly with the epithelial subtype.[118,120] There is some evidence in retrospective studies for better survival for mesothelioma patients who underwent pleurectomy/decortication compared with those treated with EPP despite a higher rate of local recurrence.[122,123]

RP is a recent modification of pleurectomy or pleurectomy decortication in which a maximal cytoreduction is achieved while leaving the ipsilateral lung intact. There have been several recent reports describing cytoreductive RP as the mainstay of multimodality treatment for both early-stage and locally advanced malignant pleural

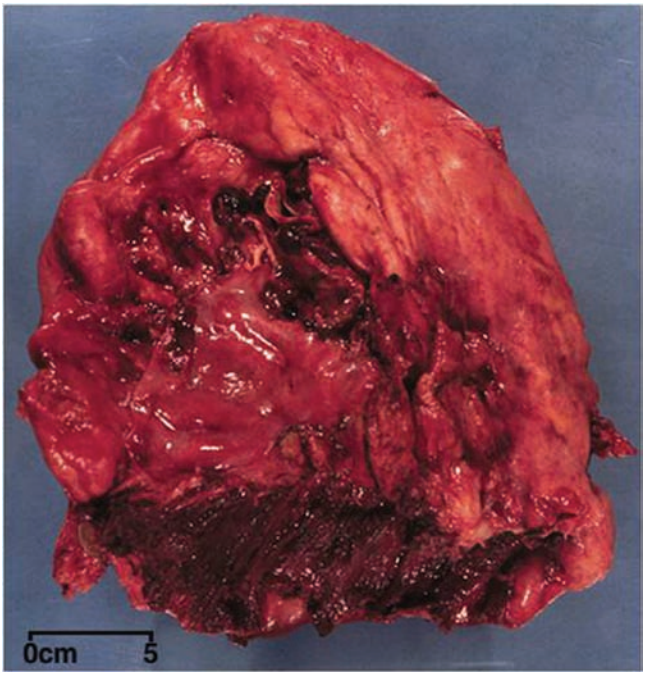

Figure 79-8 Gross photograph of a surgically resected extrapleural pneumonectomy specimen from a patient with malignant pleural mesothelioma. The specimen includes the completely removed lung along with the parietal and visceral pleura, pericardium with portions of the phrenic nerve, and the majority of the hemidiaphragm.

mesothelioma with various adjuvant intraoperative therapies such as intrapleural PDT,[124] intrapleural hyperthermic chemotherapy (cisplatin, gemcitabine),[125] and hyperthermic perfusion with povidone-iodine.[126] These have also been administered in association with IMRT in the presence of intact lung with demonstration of preserved/improved pulmonary function. In all cases, adjuvant chemotherapy was administered, unless patients had received preoperative chemotherapy (neoadjuvant).

Management of Pleural Effusions

The most common and discomforting symptom in mesothelioma is debilitating dyspnea from large, unilateral pleural effusions. A reasonable palliative approach is complete drainage of the pleural effusion (by tube thoracostomy or VATS) and instillation or insufflation of a sclerosing agent into the pleural space to induce pleurodesis. At present, the most widely used compound for pleurodesis is sterile, asbestos-free talc, administered either as a powder or slurry.[127,128] Thoracoscopic application (poudrage) may be more successful than other methods of pleurodesis (e.g., by tube thoracostomy). The effect of talc may be enhanced by an ability to induce apoptosis in some mesothelioma cell lines in vitro.[129] Interestingly, there have been reports of prolonged survival in mesothelioma patients after talc pleurodesis with no other active therapy for the disease.[130]

Entrapment of the lung by a thick visceral pleural peel of tumor compromises the efficacy of pleurodesis in patients with pleural mesothelioma. In the setting of trapped lung, the use of a semipermanent tunneled intrapleural catheter for intermittent drainage of recurrent effusions provides excellent palliation of dyspnea.[131,132] Pleuroperitoneal shunting, an alternative approach for dealing with lung entrapment in pleura mesothelioma, carries the overt risk of malignant seeding of the peritoneal cavity. The primary concerns regarding the use of tunneled pleural catheters in mesothelioma are the development of tumor implants at the insertion site or along the subcutaneous tunnel, as well as the risk of chest wall and/or intrapleural infections with long-term use of the catheter. Recent reports of tunneled catheters for mesothelioma

show equivalent results for the control of effusions compared with talc slurry pleurodesis.[133,134] Therefore, these catheters should be considered for management of symptomatic effusions in patients with mesothelioma, even in those whose lungs are able to expand.

Treatment of Nonpleural Forms of Mesothelioma

In patients with peritoneal mesothelioma, the second most common form of mesothelioma after the pleural form, most often present with abdominal pain, distention, and ascites. In addition, peritoneal mesothelioma can be associated with hypoalbuminemia, night sweats, inguinal and umbilical hernias, and hypercoagulability. Laboratory investigation shows an increased platelet count in about 50% of patients and many patients also have elevation of the tumor marker CA-125. As with pleural mesothelioma, single-agent chemotherapy for the peritoneal variant has a response rate of 10% to 15%, whereas combination chemotherapies, such as cisplatin plus pemetrexed, improve the response rate to about 25%. Immunotherapeutic agents such as interferons and various cytokines may have a role in treating this disease, especially when the extent of disease is minimal.[135–137]

Patients diagnosed with peritoneal mesothelioma appear to have a better overall prognosis relative to the pleural form. This may reflect the technical ease of delivery of intraperitoneal chemotherapy as well as the capacity for multiple resections/debulking of peritoneal masses. One-third of patients with peritoneal mesothelioma in a Dana-Farber phase II series of 25 patients remained disease free at 2 to 3 years after treatment.[136] Multimodality treatment protocol includes surgical debulking followed by intraperitoneal administration of cisplatin, doxorubicin, and interferon-gamma, second laparotomy with attempted resection of any residual disease and intraoperative hyperthermic perfusion with cisplatin and mitomycin followed subsequently by whole abdominal radiotherapy. In one study, the median overall survival of the 27 patients treated in this study was 68 months.[138]

Pericardial mesothelioma is quite rare, but characteristically presents with pericardial effusion and, often, tamponade physiology. Mesotheliomas of the tunica vaginalis are even less common than the pericardial variant, but typically present with a bloody hydrocele. There is no effective therapy for mesothelioma of the pericardium or tunica vaginalis other than palliation; these neoplasms share the dismal prognosis of the pleural form of the disease.

Novel and Evolving Therapeutic Approaches

Despite the small but significant improvement in survival achieved with intensive multimodality therapy for mesothelioma, it is obvious that less morbid, more effective interventions are needed. Many investigators, focusing on the hemithorax as the primary site of disease, have attempted to treat this disease primarily by direct instillation of chemotherapeutic and other compounds into the pleural space, but with minimal success. Based on anecdotal reports that mesothelioma patients with greater amounts of intratumoral lymphocytic infiltration had improved median survival rates, several groups have looked at immunotherapy as an alternative means of achieving better tumor response rates.

Immunotherapy The use of compounds to stimulate an antitumor immune response against pleural malignancy stemmed from the observation that patients who developed empyemas postthoracotomy for primary lung carcinoma had improved survival rates.[139,140] Subsequently, intrapleural bacille Calmette-Guérin (BCG) was studied as a surgical adjuvant, but no significant benefit was seen.[141] Several systemic immunotherapies have been administered to patients with mesothelioma, including interleukin-2 (IL-2) and interferon-gamma (IFN-γ), both of which demonstrated limited efficacy and significant side effects. Subcutaneous IFN-α-2a was found to have some efficacy; one complete response and three partial responses were documented in one study of 25 patients and the therapy was well tolerated.[142] One European phase I/II study of intrapleural IL-2 administered by continuous infusion via an intrapleural catheter revealed a 19% partial response rate with marked dose-related toxicity, primarily the development of ipsilateral empyemas. Of note were the high ratios of intrapleural/systemic IL-2 levels approaching 1000:1, particularly in the highest doses.[143]

Boutin et al. in Marseilles, France pioneered the intrapleural administration of immunostimulants to treat mesothelioma, and demonstrated significant local tumor responses with both intrapleural IL-2 and IFN-γ. Most impressive were the results of intrapleural IFN-γ in patients with early-stage mesothelioma (Butchart stages I and II). A total of 89 patients were treated over 46 months with an overall response rate of 20%. Eight patients had histologically confirmed complete responses and nine had partial responses with greater than 50% reduction in tumor volume. Overall, patients with stage I disease had a response rate of 45%. The effectiveness of IFN-γ against mesothelioma was thought to be mediated in part by direct inhibitory effects on mesothelioma cell growth as well as by decreased intrapleural IL-6 production, with resultant activation of tumor-directed macrophages and cytotoxic T-lymphocytes.[144,145] Other groups have demonstrated only limited activity with the combination of intrapleurally administered autologous-activated macrophages and IFN-γ. The overall response rate was 11% in a trial of 19 patients, with one patient having a partial response that lasted for 30 months.[146]

Immunotherapy trials in Australia demonstrated tumor regression with repeated intralesional injection of granulocyte macrophage colony–stimulating factor (GM-CSF), but with substantial complications related to the catheters used for cytokine instillation.[147–149]

"Targeted" Therapy The presence of platelet-derived growth factor (PDGF) and epidermal growth factor (EGF) pathways in some mesothelioma cell lines in vitro suggested that novel inhibitors of these pathways might prove useful clinically, either as monotherapy, or in combination with chemotherapy. Unfortunately, early-phase clinical trials in mesothelioma of imatinib mesylate and gefitinib (and erlotinib), inhibitors of the tyrosine kinases essential to PDGF and EGF signaling, respectively, failed to demonstrate any significant clinical benefits.[150–152] Clinical trials have been conducted with other novel targeted agents, such as the antiangiogenic agents, bevacizumab and thalidomide, and the copper-chelating agent, tetrathiomolybdate, which depletes copper, a key cofactor in tumor angiogenesis. Only the latter compound has demonstrated any demonstrable benefit to date in human trials.[153–155] Currently, there are several clinical trials of combinations of targeted agents to see if they may have synergistic effects upon growth of mesothelioma in patients with advanced disease.

Gene Therapy In the absence of other effective, nontoxic therapies for malignant mesothelioma, several groups of investigators have looked to the newly evolving technologies of gene therapy for new treatment modalities.[156] Gene therapy is attractive because mesothelioma remains localized initially and pleural access to the tumor is easy and safe. A large number of approaches have been used in cell culture and in animal models. Gene therapy vectors have included liposomal/DNA complexes and modified herpes, vaccinia, and adenoviruses. Transgenes have included suicide genes, cytokines, tumor suppressor genes (i.e., p53), and proapoptotic genes. Studies have also been done using replication-restricted, tumor selective adenoviruses and herpes viruses as well as carrier cells, such as modified ovarian carcinoma cells.[156,157]

Some phase I clinical trials have been performed. These include a "suicide" gene therapy strategy employing the instillation of recombinant adenovirus (rAd) genetically engineered to contain the herpes simplex virus thymidine kinase "suicide gene" (HSVtk).[158,159] The rationale for the suicide gene approach for mesothelioma was that

administration of rAd.HSVtk into the pleural cavity would sensitize the cells to the normally nontoxic antiviral agent ganciclovir. The vector was well tolerated, gene transfer was seen at higher doses, and a number of patients had clinical responses, including patients with minimal radiographic evidence of disease 7 years after treatment, with no other intervening antineoplastic therapy. The HSVtk gene was also introduced into patients using an irradiated allogeneic ovarian cancer cell line. No information on clinical responses has been reported. A few early phase trials have recently completed using adenoviral-mediated immunogene therapy delivering the cytokines interferon-alpha and beta (IFN-α, IFN-β), which have a number of antitumor immune effects. The vector was well tolerated (most common adverse events were lymphopenia, hypoalbuminemia, hypotension, anemia, hypocalcemia, and mild cytokine release syndrome), resulted in detectable intrapleural levels of the interferon proteins in most patients, and was accompanied by antitumor immune responses in multiple patients. A number of patients with low tumor burdens had disease stability or clinical responses.[160–162] Currently a phase I/II clinical trial testing first-line standard chemotherapy with intrapleural Ad-IFN-α is nearing completion.

Other gene therapy approaches have been studied by various groups attempting to achieve high-level expression of other immunostimulatory cytokines like IL-2, IL-12, tumor necrosis factor (TNF), and GM-CSF. In addition, there are ongoing phase I trials of intrapleural delivery of oncolytic viruses, including measles, herpes simplex, and vaccinia viruses, all of which have shown significant antitumor activity against mesothelioma in vitro and in preclinical models.[156]

Adoptive Cellular Therapy Adoptive transfer of T cells and other immune cells into patients after ex vivo expansion has demonstrated very promising results in diseases like malignant melanoma and leukemias. Groups have attempted to acquire tumor-reactive tumor-infiltrating lymphocytes (TILs) from mesothelioma samples, expanding them ex vivo, then reinfusing them back into the host with minimal success. Researchers at the University of Pennsylvania have successfully genetically modified T cells to express a chimeric antigen receptor (CAR) that recognizes the tumor antigen mesothelin through the variable chain of an antimesothelin antibody that activates the T cell through the internal signaling domains of the T cell receptor.[163,164] The mesothelin CAR T cells were able to eradicate large mesothelioma tumors in mice, and a phase I clinical trial has begun testing the feasibility and safety of multiple doses of CAR T cells reactive to mesothelin.

Other cellular therapies that are being investigated are injection of mesothelioma tumor lysate-pulsed dendritic cells and lymphokine-activated killer cells.[165,166]

SOLITARY FIBROUS TUMOR OF THE PLEURA

Solitary fibrous tumors of the pleura had been previously referred to in the literature as "benign mesothelioma." This is an inappropriate expression, both in terms of histogenesis and the potential for confusion with malignant mesothelioma. Solitary fibrous tumors have also been called localized fibrous tumor because of the occasional incidence of multiple masses. Solitary fibrous tumor is a mesenchymal tumor of probable fibroblastic origin and similar tumors have been described in other extrathoracic sites.[167] It is important to note that there is no significant association of solitary fibrous tumors with asbestos exposure or other environmental agents.[168,169] Although the peak age range of affected patients is similar to that of mesothelioma (40–70 years), solitary fibrous tumors can affect patients of all ages, including children as young as 5 years old.

CLINICAL PRESENTATION

Patients with solitary fibrous tumors of the pleura are usually asymptomatic and are diagnosed incidentally by routine chest radiography, but they can present with nonpleuritic chest pain, dyspnea, cough, or pleural effusion. A significant proportion (up to 40%) of patients present with symptomatic hypoglycemia, thought to be secondary to elaboration of insulin-like growth factors. Clubbing of fingers and toes is common, as are diffuse arthralgias, but the incidence of pulmonary hypertrophic osteoarthropathy is controversial.[168–171]

RADIOGRAPHY

Solitary fibrous tumors typically present radiographically as large, rounded, well-circumscribed pleura-based masses, but occasionally they can appear to be intraparenchymal. Some of these masses can be very large (over 30 cm in diameter) and can cause clinically significant compression of the lung. About 17% present with an ipsilateral pleural effusion.[169,172]

GROSS PATHOLOGY

The typical solitary fibrous tumor of the pleura arises from a pedicle off of the visceral pleura surface and rarely invades beyond the visceral pleura itself (Fig. 79-9A). The tumors are usually well-circumscribed, firm, often pedunculated masses that vary in size from 1 cm to more than 30 cm in diameter. When sectioned, the cut surface has a whorled appearance. Attention should be paid to areas of hemorrhage or necrosis. Malignant solitary fibrous tumors have been described, although they are less frequent.[167,173,174]

MICROSCOPIC PATHOLOGY

Histologically, solitary fibrous tumors have what has been described as a "patternless pattern" (Fig. 79-9B). Sections typically show alternating areas of hypocellularity and hypercellularity with short fascicles of interlacing spindle cells, creating a storiform pattern. These fascicles are interspersed between areas of variably collagenized tissue. A hemangiopericytoma-like branching vascular pattern is also quite typical. Histologic criteria that may predict a malignant course include high cellularity, infiltrative growth, moderate to marked cytologic atypia, and high mitotic rate (>4 mitoses per 10 high-power fields). Immunohistochemical stains confirm the diagnosis. These tumors are CD34 (Fig. 79-9C) and bcl-2 positive but CK negative. Malignant solitary fibrous tumors are not always positive for CD34 and bcl-2; therefore, the diagnosis requires the exclusion of other malignant tumors such as malignant mesothelioma, monophasic synovial sarcoma, and peripheral nerve sheath tumors.[173,174]

TREATMENT

Surgical resection of solitary fibrous tumors of the pleura is curative with little risk of recurrence. There is typically a discrete separation between the tumor and underlying compressed lung, so extensive pulmonary resection is usually unnecessary. Some tumors may require a limited chest wall resection. A small percentage of patients develop recurrences several decades after surgical resection and may die from extensive local disease. Some of these recurrent fibrous tumors of the pleura demonstrate more aggressive histologic features but are often successfully cured by surgical excision, in particular the pedunculated lesions.[169–171]

Even with malignant solitary fibrous tumors of the pleura, complete resection portends a favorable prognosis in most patients. In one series, complete resection was achieved in over 90% of patients with disease-free survival rates of 72% and 61% at 5 and 10 years, respectively.[171]

OTHER PRIMARY PLEURAL TUMORS

As discussed in the differential diagnosis of sarcomatoid mesotheliomas, there are other relatively rare malignant mesenchymal tumors that can be primary within the pleura. These tumors include vascular tumors (pleural epithelioid hemangioendothelioma/angiosarcoma) and synovial sarcoma.

Pleural epithelioid hemangioendothelioma is a low- to intermediate-grade vascular tumor. High-grade epithelioid vascular tumors

C

Figure 79-9 **A.** Gross photograph of a surgically resected, solitary, benign pleural fibrous tumor. Note the well-circumscribed nature of this firm, slightly lobulated mass with its smooth-cut surface and punctate areas of hemorrhage and necrosis. **B.** Photomicrograph of a typical solitary fibrous tumor demonstrating the "patternless-pattern" (H&E, ×400). **C.** Photomicrograph of a section of solitary fibrous tumor stained with an antibody directed against CD34, a cell surface marker found commonly on endothelial cells and some smooth muscle and vascular tumors (×400). Positive staining for CD34 helps distinguish these lesions from mesotheliomas and other pleural neoplasms. *(Used with permission of Dr. Matt van de Rijn, Department of Pathology and Laboratory Medicine, University of Pennsylvania Medical Center, Philadelphia.)*

are termed epithelioid angiosarcoma. The clinical presentation of patients with these tumors, as well as the radiographic features and gross appearance, are essentially identical to malignant mesothelioma. Patients present with diffuse pleural thickening, pleural effusion, and/or chest pain. Microscopic examination with the ancillary use of IHC is required for diagnosis. These tumors usually have a biphasic pattern with nests of epithelioid cells embedded within a spindle cell stroma. The epithelioid cells characteristically have intracytoplasmic vacuoles and the associated stroma typically has a distinctive myxohyaline or chondroid appearance. As with malignant mesotheliomas, a tubopapillary pattern may also be present. Vascular differentiation is demonstrated by strong positive staining with one or more endothelial markers (CD31, CD34, Fli1, or factor VIII). CK positivity may also be present and can be misleading if the diagnosis of a vascular tumor is not considered. These tumors behave aggressively and there is, at the current time, no effective therapy.[175–178]

The diagnosis of pleural synovial sarcoma has improved with increased awareness and the greater availability of molecular testing for its distinctive X:18 translocation that now can be demonstrated in formalin-fixed paraffin-embedded tissue. Synovial sarcomas present as either a biphasic epithelioid and spindled cell tumor or as a monophasic spindle cell tumor. In either instance, synovial sarcoma can be mistaken for malignant mesothelioma or a pulmonary sarcomatoid carcinoma. On average, patients tend to be younger than those with malignant mesothelioma but there is a wide reported age range that encompasses older patients into their eighth decade. There is a similar overlap in clinical presentation with malignant mesothelioma that includes chest pain, pleural effusions, dyspnea, and pneumothorax. Although pleural synovial sarcoma is more commonly a localized, solid tumor, diffuse pleural thickening does occur. The tumors can be quite large (mean size of 13 cm) and can have areas of necrosis and cystic degeneration. There are some histologic features that are suggestive of synovial sarcoma, in particular its long interweaving fascicles, but the immunohistochemical profile of these tumors is not distinctive. The epithelioid component may show focal positive staining for CK, EMA, CEA, or BER-EP4. The spindled cell component may express calretinin. Confirmation of the diagnosis requires molecular testing for the X:18 translocation. Pleural synovial sarcoma is an aggressive disease with a generally poor prognosis.[179–184]

CHAPTER 80

Nonneoplastic Disorders of the Mediastinum

Cameron D. Wright

ANATOMY

The boundaries defining the mediastinum, as well as its subdivisions or compartments, and important anatomical considerations regarding mediastinal lymphatics are discussed below.

BOUNDARIES

The mediastinum is defined as the potential space between the two pleural cavities bounded by the sternum anteriorly, the vertebral column posteriorly, the thoracic inlet superiorly, and the diaphragm inferiorly (Fig. 80-1).[1] The major mediastinal structures are the heart and great vessels, the trachea and main bronchi, and the esophagus, all closely related to one another and connected by loose connective tissue. Also present are the thymus, lymph nodes, and fat. Hence, air or infection can disseminate widely throughout the mediastinal space, contained laterally only by the mediastinal pleural reflections. The mediastinum communicates with both the neck and the retroperitoneum, and these portals can also serve as routes of egress from the mediastinum. Fascial planes connect the neck, mediastinum, and retroperitoneum and thus facilitate movement of air or infection from one location to another.

COMPARTMENTS

Several subdivisions of the mediastinum have been emphasized in the surgical and radiologic literature but there is no consensus. Most often, three compartments are proposed: anterior, middle (visceral), and posterior (paravertebral sulcus) (Fig. 80-2).[2] The boundaries of these divisions are not agreed upon, further emphasizing their nonanatomic origins. Shields proposed a simple three-compartment subdivision in 1972 that makes both anatomic and surgical sense. The anterior compartment is bounded by the sternum and the anterior surface of the pericardium and great vessels. The middle (visceral) compartment extends from the posterior limit of the anterior compartment to the anterior surface of the vertebral columns and then to the thoracic inlet. The posterior compartment (paravertebral sulcus) extends from the anterior surface of the vertebral column to the anterior surface of the paravertebral ribs. The structures in these compartments are listed in (Table 80-1). The pericardial sac is the only true compartment of the mediastinum and it provides a strong barrier to infection. Subdividing the mediastinum into compartments proves most helpful when one is interpreting a plain radiograph that shows a mediastinal mass. Knowledge of the contents of the involved compartment facilitates arriving at a proper diagnosis.

LYMPHATICS

The mediastinal lymphatic system is quite complex and variable. Mediastinal lymph nodes are interconnected; thus, involvement of one group of lymph nodes in a pathologic process frequently leads to involvement of other groups. Similar to subdividing the mediastinum into compartments, naming individual nodal stations is somewhat arbitrary and leads to the mistaken notion that these nodal stations are discrete. To the contrary, the mediastinum is covered in a dense network of lymphatic vessels and

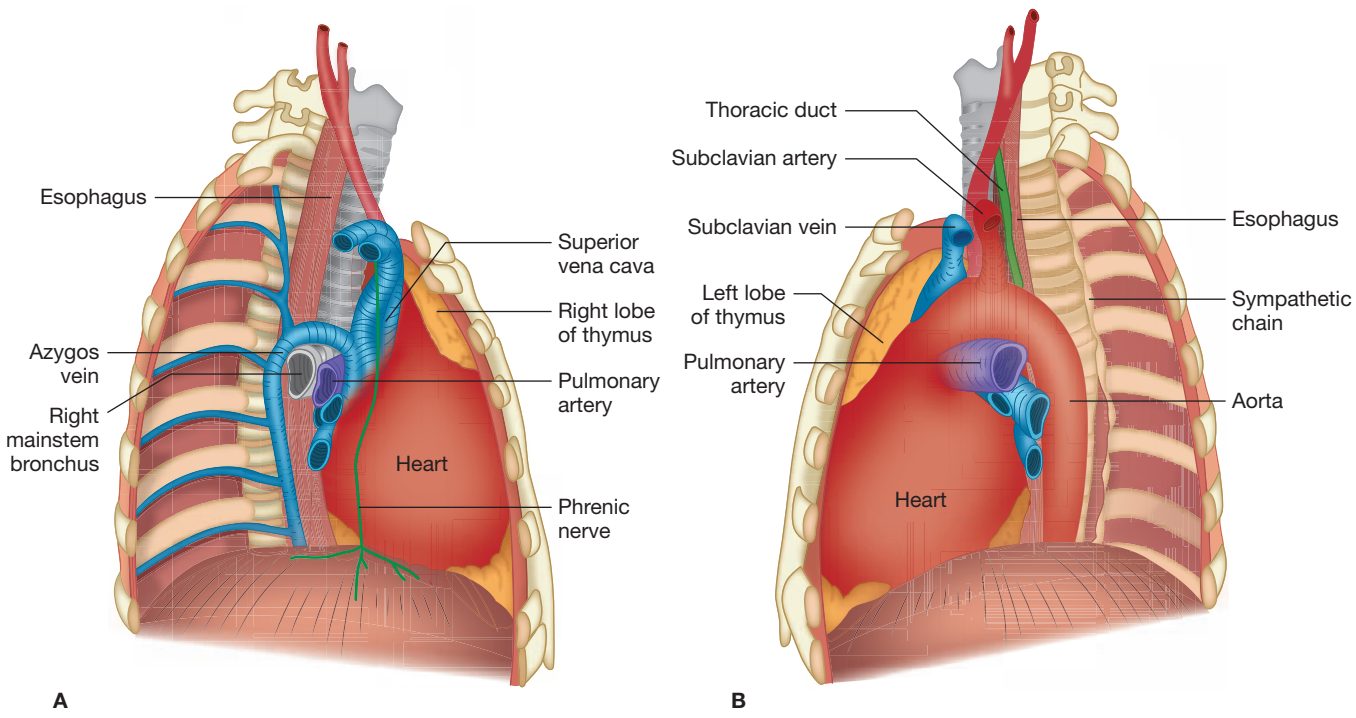

Figure 80-1 **A.** Lateral view of the mediastinum as seen through a right thoracotomy. **B.** Lateral view of the mediastinum as seen through a left thoracotomy. *(Reproduced with permission from LoCicero J. Median sternotomy and thoracotomy. In: Shields TW, ed. Mediastinal Surgery. Philadelphia, PA. Lea & Febiger; 1991.)*

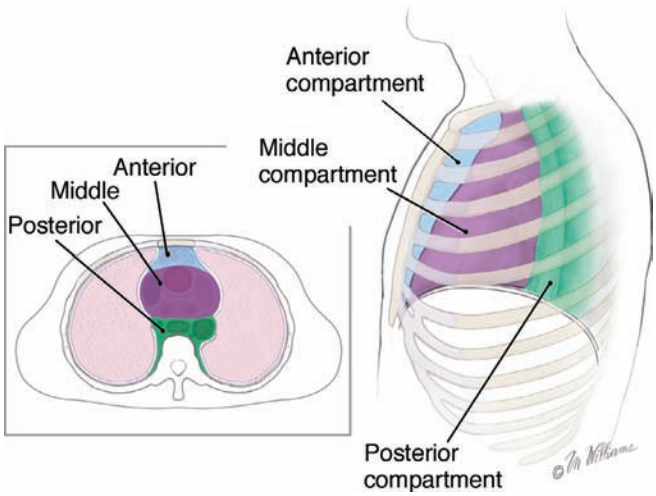

Figure 80-2 Mediastinal tumors are divided for the convenience of diagnosis and surgical approach into three compartments: anterior, middle, and posterior. *(Used with permission of Marcia Williams.)*

lymph nodes with no predictable boundaries. Nonetheless, there are commonly accepted nodal stations that have clinical importance, especially in the staging of lung cancer. The lymph node map proposed by Naruke in 1978 has been widely accepted and serves as a standard for communication of lymph node involvement (Fig. 80-3).[3]

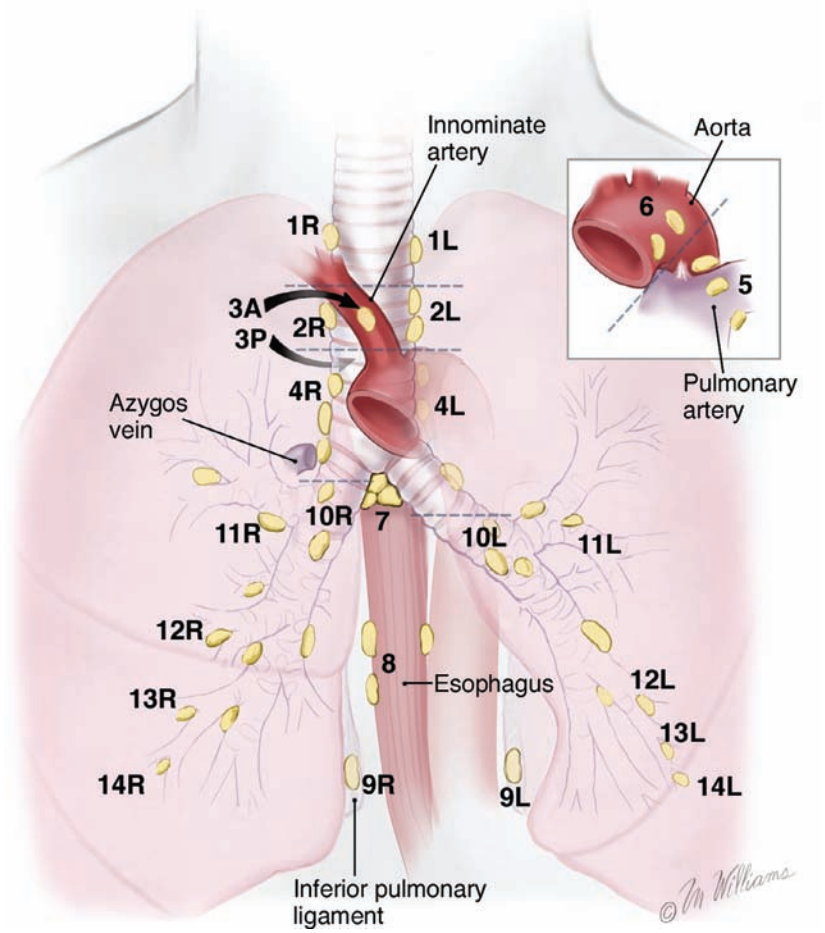

Figure 80-3 Lung cancer lymph node stations map. Note that any double-digit numeral is considered N_1 disease. L = left; R = right; A = anterior; P = posterior. *(Used with permission of Marcia Williams.)*

TABLE 80-1 Contents of Mediastinal Compartments

Anterior	Middle	Posterior
Thymus gland	Pericardium	Azygos and hemiazygos veins
Pericardial fat	Heart	
Lymph nodes	Trachea and main bronchus	Thoracic duct
	Esophagus	Sympathetic trunk
	Aorta	
	Phrenic and vagus nerves	Intercostal nerves
	Lymph nodes	

PNEUMOMEDIASTINUM

Pneumomediastinum (mediastinal emphysema) is an uncommon condition characterized by the accumulation of air or gas in the mediastinum. Depending on the cause, management may be expectant or may involve specific treatment directed at the underlying abnormality.

ANATOMIC CONSIDERATIONS

Pneumomediastinum is frequently associated with other forms of extra-alveolar air, including pulmonary interstitial emphysema, pneumopericardium, pneumothorax, subcutaneous emphysema, pneumoretroperitoneum, and pneumoperitoneum. The key to understanding the distribution of extra-alveolar air lies in the recognition of the common fascial planes that unite these areas. In the neck, the deep layer of the deep cervical fascia ensheaths the trachea and esophagus as they descend into the mediastinum. The trachea and esophagus are thus enclosed in this visceral space; therefore, air or infection can readily travel from the mediastinum to the neck or retroperitoneum (Fig. 80-4).[4] This fascial plane extends into the hilum of the lung and merges with the bronchovascular sheaths that surround the terminal bronchioles, arteries, and veins. The bronchovascular sheath also merges with and is continuous with the pericardium. After alveolar rupture, air enters the perivascular interstitium and dissects proximally within the bronchovascular sheath toward the mediastinum (Fig. 80-5). Air can then enter the pericardial space, resulting in pneumopericardium, or it may dissect along the adventitia of the great vessels (Fig. 80-6). More commonly, mediastinal air can decompress by extension into the cervical, subcutaneous, and retroperitoneal spaces. A pneumomediastinum that ruptures into the free pleural space results in a pneumothorax. Pneumothorax may also result from air dissecting out toward the visceral pleural surface of the lung and rupturing. Macklin, in 1944, in an elegant experimental cat model, confirmed this theory of progression of extra-alveolar air following alveolar rupture.[5] Pneumomediastinum usually results from a ruptured alveolus due to a Valsalva maneuver or mechanical ventilation. There are many other

possible sources, however, that must be considered when the physician has to manage a patient with pneumomediastinum (Table 80-2). Dental procedures, especially those on the mandible with the addition of compressed air to maintain a clear field, are an occasional cause of mediastinal emphysema.

■ SPONTANEOUS PNEUMOMEDIASTINUM

Idiopathic spontaneous pneumomediastinum is a rare self-limited condition that most commonly affects young adult men. Hamman[6] is credited with the original description of this entity in 1939, including the characteristic crepitation synchronous with the heartbeat heard in these patients (Hamman sign). The majority of patients with spontaneous pneumomediastinum have predisposing factors that cause increase in airway pressure, which leads to alveolar rupture.[7,8] Most commonly, this results from straining against a closed glottis (i.e., the Valsalva maneuver) as during vomiting, coughing, or exercising. Other mechanisms include

TABLE 80-2 Etiology of Pneumomediastinum

Upper respiratory tract
Head and neck infection
Fracture of facial bones
Trauma to hypopharynx and larynx (especially intubation)
Dental procedures (especially mandibular)
Lower respiratory tract
Trauma
Bronchoscopy, especially therapeutic bronchoscopy (i.e., YAG laser, rigid core-out, dilation, and transbronchial biopsy)
Lung
Trauma
Surgery
Spontaneous alveolar rupture
Straining and Valsalva maneuver
Local airway obstruction
Scuba diving
Mechanical ventilation
Gastrointestinal tract
Esophageal perforation
Perforated viscus
Infection
Acute mediastinitis
Descending necrotizing mediastinitis
Air from outside the body
Trauma
Surgery (especially mediastinoscopy, tracheostomy, and sternotomy)
Pneumoperitoneum (especially with laparoscopic hiatus hernia repair)

sudden and/or severe increases in lung volume, as occur during marijuana smoking, inhaling of cocaine, or during a seizure. Localized airway obstruction from tumor, foreign bodies, asthma, or parenchymal lung disease can also cause alveolar rupture. An accurate history is most important to define the mechanism in a particular patient.

Spontaneous pneumomediastinum almost always presents with substernal pain, often pleuritic, which may radiate to the neck or back. Additional symptoms that may occur, either separately or in combination, include dyspnea, dysphagia, odynophagia, and dysphonia. Air in the subcutaneous tissues of the neck produces a characteristic change in voice quality, a higher-pitched nasal tone that the experienced clinician easily recognizes. Examination often reveals palpable subcutaneous emphysema in the neck. Auscultation of the chest may reveal a crunching or clicking sound heard over the pericardium, synchronous with the heartbeat (Hamman sign). Low-grade fever is present in about one-third of cases and mild leukocytosis in about one-half. Nonspecific electrocardiographic changes, such as ST-T wave changes and ST elevation, may also be present. A chest radiograph usually demonstrates a thin radiolucent strip along a mediastinal fascial plane, most commonly along the left heart border. The aortic knob may be highlighted as well (see Fig. 80-6). Computed tomography (CT) is more sensitive in detecting air than are plain radiographs (Fig. 80-7). Air may be evident deep in the neck as well as in the subcutaneous tissue.

The differential diagnosis is broad and includes musculoskeletal, pleural, pulmonary, cardiac, and esophageal causes. Although most

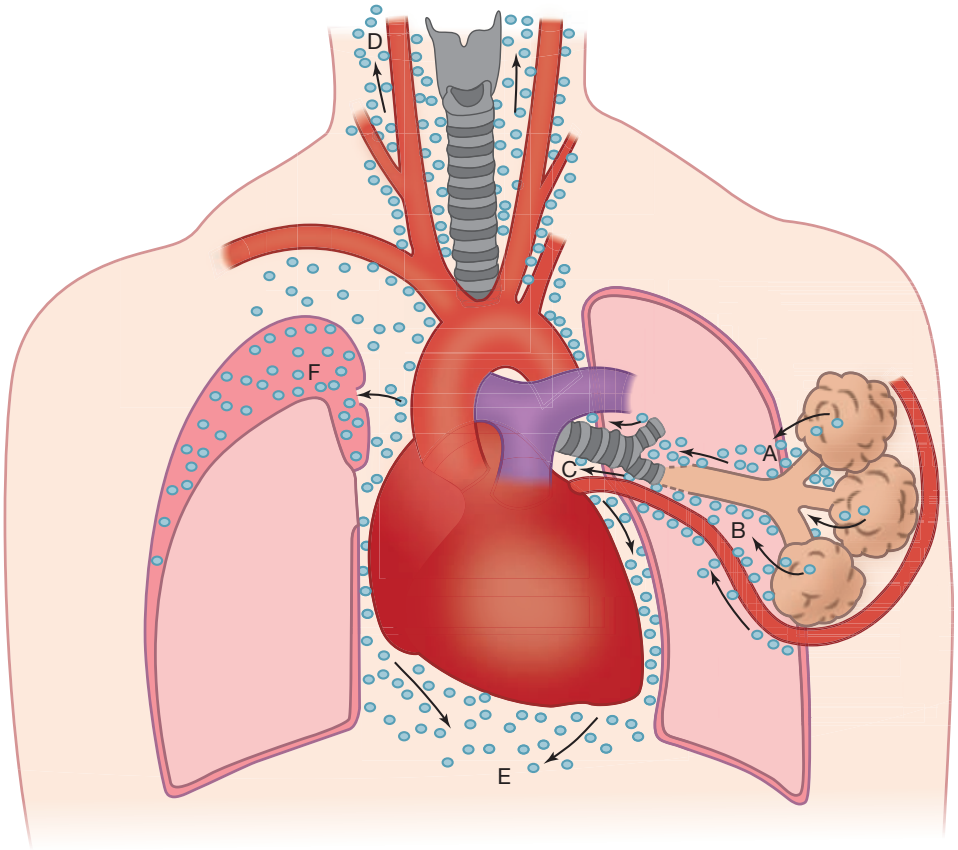

Figure 80-5 Possible routes of air following alveolar disruption. Air from the alveolus (**A**), enters perivascular interstitium (**B**), dissecting proximally within bronchovascular sheath toward mediastinum (**C**), as mediastinal pressure rises, decompression occurs in cervical (**D**), subcutaneous, and retroperitoneal (**E**), soft tissue spaces. A pneumothorax is possible if the pleura (**F**) is ruptured. *(Reproduced with permission from Cooley JC, Gillespie JB. Mediastinal emphysema: pathogenesis and management. Report of a case. Dis Chest. 1966;49(1):104–108.)*

patients who present are not acutely ill, an occasional patient may suffer an acute, catastrophic onset with hypotension and hemodynamic compromise. Esophageal perforation is the condition most likely to be confused with spontaneous mediastinal emphysema. Worrisome features suggestive of esophageal perforation include recent esophageal instrumentation, a history of esophageal problems, severe retching, the presence of a pleural effusion, or shock. A contrast esophagogram should be obtained immediately if there is any question of an esophageal perforation, since a delay in making this diagnosis often proves fatal. A high index of suspicion regarding esophageal perforation should always be present whenever a patient presents with mediastinal emphysema.

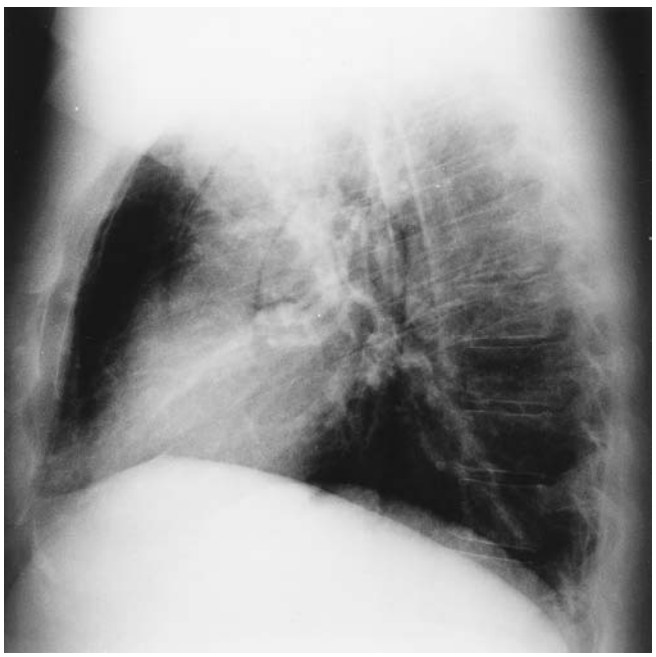

Figure 80-6 Lateral radiograph of a middle-aged patient with an acute asthma attack causing pneumomediastinum requiring hospital admission. Mediastinal air is seen outlining the aorta and esophagus. This resolved spontaneously.

Treatment of spontaneous mediastinal emphysema is supportive and is primarily directed at pain relief and reassurance. Appropriate management of contributing causes such as foreign bodies, asthma, and parenchymal lung disorders should be instituted. The patient should be followed both clinically and radiographically to exclude another cause for mediastinal emphysema and detect a possible pneumothorax. Prompt resolution is the rule. Supplemental oxygen to hasten reabsorption (similar to that proposed for pneumothorax) has been reported but is probably not necessary. Needle aspiration or skin incision to relieve subcutaneous emphysema is almost never necessary. Prophylactic tube thoracostomy is unnecessary. For patients who present with minimal findings and a clear inciting factor (such as coughing), only a short period of observation in the emergency department is required. Most patients require admission for a short period of pain control and observation. Recurrence is rare.

A recent large case series reinforces these principles. Macia et al.[8] reported on 41 patients over a 16-year period. The incidence of spontaneous pneumomediastinum was 22 cases per 1,000,000 emergency department visits. The mean age was 21 and 83% were men. Asthma and illicit drug use were the most common predisposing factors and exercise, vomiting, and coughing were the most common precipitating factors. Common symptoms included chest pain (85%), dyspnea (49%), neck pain (44%), odynophagia (37%), cough (24%), and dysphonia (12%). Common signs included subcutaneous emphysema of the neck (66%) and chest (29%) and Hamman sign (12%). All chest radiographs demonstrated pneumomediastinum and 66% revealed subcutaneous air in the neck. An elevated WBC was seen in 42% of patients. The mean length of stay was 5 days and all were treated with just supportive care.

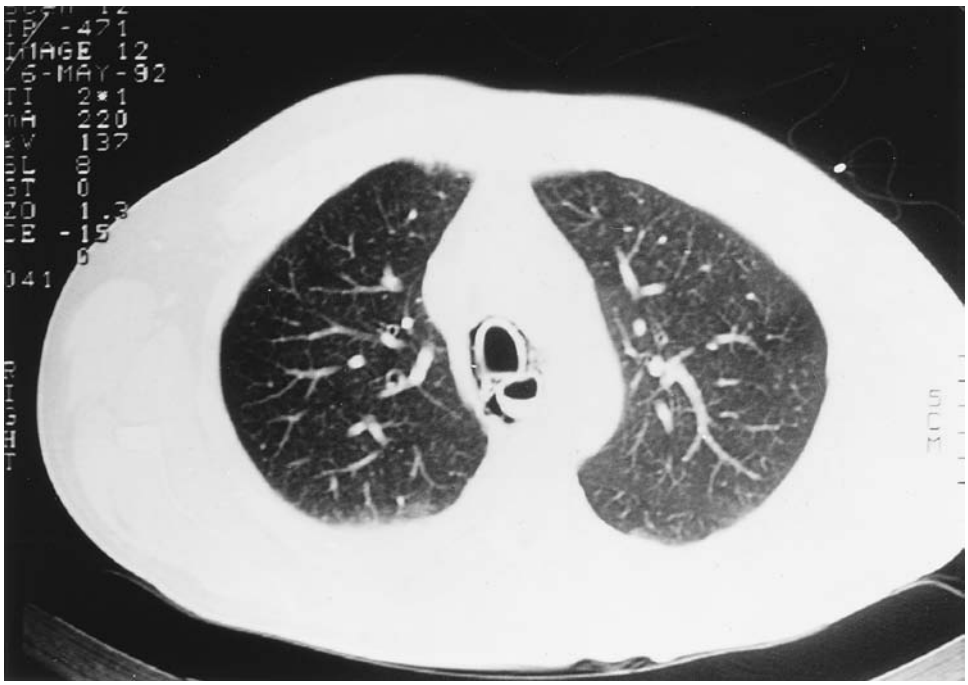

Figure 80-7 Computed tomography of a man with an 8-hour-old postemetic esophageal rupture. Posteroanterior radiograph was normal. Mediastinal air is seen outlining trachea and esophagus.

■ PNEUMOMEDIASTINUM ASSOCIATED WITH MECHANICAL VENTILATION

Mechanical ventilation is commonly associated with pneumomediastinum and may often lead to life-threatening tension pneumothorax. Alveolar rupture results from high peak inspiratory pressures, which increases alveolar pressures in patients with abnormal airways or parenchyma (decreased compliance). Classic predisposing factors include high tidal volumes, high levels of positive end-expiratory pressure (PEEP), and "fighting" the ventilator. Air trapping with occult positive end-expiratory pressure (auto-PEEP) is an underrecognized cause of barotrauma. It is not clear if one mode of ventilation (pressure-controlled vs. volume-limited) is associated with a decreased incidence of barotrauma.

Unlike spontaneous mediastinal emphysema, pneumomediastinum occurring in a patient on mechanical ventilation is potentially catastrophic because of its frequent association with tension pneumothorax. The chest radiograph should be closely examined to detect even a small pneumothorax and, if such is present, tube thoracostomy should be promptly performed. Obviously, a sudden deterioration marked by hypotension and increased pulmonary pressures should prompt immediate attention with insertion of unilateral or bilateral chest tubes, depending on the clinical examination. The issue of inserting a tube prophylactically is controversial if pneumomediastinum without pneumothorax is identified. At a minimum, a thoracostomy tray should be kept at the patient's bedside and the nursing staff reminded of the signs of a pneumothorax in a mechanically ventilated patient. If a physician is not readily available around the clock, it may be advisable to perform bilateral prophylactic tube thoracostomy in certain patients. Removing the patient from mechanical ventilation as soon as possible is appropriate. Since this is seldom possible, efforts should be directed at minimizing alveolar distention. These efforts include relief of bronchospasm, minimizing "fighting" the ventilator, reducing tidal volume and PEEP, and manipulation of inspiratory flow and timing to reduce auto-PEEP.

■ PNEUMOPERICARDIUM

Pneumopericardium as a form of barotrauma is much more frequent in neonates, presumably due to immature fascial planes. Hemodynamically significant tamponade is also much more likely to occur in infants rather than adults and has resulted in collapse and death. Pericardial drainage with a subxyphoid tube should be performed promptly in the neonate. In the adult, drainage should be performed only if there is hemodynamic embarrassment.

ACUTE MEDIASTINITIS

Acute mediastinitis is a life-threatening disorder that causes severe morbidity in the afflicted patient. All three mediastinal compartments can be affected; the anterior compartment most commonly after sternotomy for cardiac surgery, the middle compartment usually from esophageal perforation, and the posterior compartment from direct extension from the neck, lung, or spine. Instrumental perforation of the esophagus is the most common cause of acute mediastinitis in the United States.

■ MEDIASTINITIS FROM ESOPHAGEAL PERFORATION

Instrumental perforation of the esophagus now accounts for almost one-half of all esophageal perforations.[9] Perforation is more common after rigid esophagoscopy, dilation of a stricture, and pneumatic dilation for achalasia, but it also occurs after variceal sclerosis, esophageal tube placement (nasogastric, Sengstaken–Blakemore, and salivary bypass tubes), and simple flexible esophagoscopy. Boerhaave syndrome (postemetic rupture) was described in 1724 but still represents a diagnostic challenge and remains a major consideration in patients with otherwise unexplained mediastinitis (Fig. 80-8). Patients usually present with the abrupt onset of severe substernal chest pain, which is pleuritic after forceful vomiting or retching. Dyspnea is common even in the absence of pneumothorax. Shock develops quickly and the patient usually appears gravely ill. Examination reveals tachypnea, tachycardia, fever, hypotension, splinting of the chest and abdomen, and cervical emphysema. Radiographic findings include cervical or mediastinal emphysema, pneumothorax, and pleural effusion. A contrast esophagogram (usually with water-soluble contrast) should be performed immediately when the diagnosis is suspected, but one should be aware that this study has a false-negative rate of 10%. A chest CT scan is the next best study in a patient in whom esophageal perforation is suspected but who has a negative esophagogram. Prompt diagnosis and, therefore, a high index of suspicion are essential, as the frequency of

Figure 80-8 Water-contrast esophagogram of a patient with Boerhaave syndrome. Note extensive extravasation of contrast and mediastinal emphysema.

complications and the mortality rate are directly dependent on the time elapsed between perforation and treatment. The differential diagnosis is broad and includes perforated ulcer, acute pancreatitis, myocardial infarction, pneumonia, aortic dissection, and pulmonary embolism.

Treatment should be instituted urgently and involves surgical debridement of necrotic tissue, secure closure of the perforation, correction of any distal obstruction, and wide drainage, usually performed through a left thoracotomy.[10] Recent reports suggest favorable results in appropriately selected patients' management with covered esophageal stents and image-directed drainage.[11] Appropriate broad-spectrum antibiotics with anaerobic coverage and the maintenance of proper nutrition are also integral components of the management plan. Esophagectomy is occasionally required in the presence of a perforated, nondilatable stricture, a destroyed esophagus in which direct repair is not possible, or cancer. Nonoperative treatment is rarely appropriate but may be instituted in highly selected cases (i.e., contained, asymptomatic instrumental perforations) in which a significant interval has passed and the patient is clinically stable. Mortality is less than 10% if the perforation is recognized and repaired within 24 hours, whereas mortality increases to 30% to 40% if more than 24 hours have elapsed between perforation and repair. The mortality rises even higher with advanced age of the patient.

TRACHEOBRONCHIAL PERFORATION

Tracheobronchial perforation is rare and is most commonly seen following trauma or instrumentation. Less common causes include anastomotic dehiscence after lung transplantation or airway surgery and necrotizing infections involving the airway. Severe mediastinitis is rare after tracheobronchial disruption, presumably due to the less noxious nature of its contents and better containment. Intubation is now the most frequent cause of tracheobronchial injury, but injury can be avoidable with gentle and proper technique. Blood in the airway, airway obstruction (infrequent), subcutaneous and mediastinal emphysema, and pneumothorax are the common presenting signs. Prompt recognition and operative repair are necessary and yield excellent results, although small tears in the cervical trachea may often be managed with antibiotics alone, without operation.

DESCENDING NECROTIZING MEDIASTINITIS

Mediastinitis occasionally develops after severe deep head and neck infections that originate from the oropharynx or hypopharynx.[12–18] Most patients present with a mixed aerobic and anaerobic infection. Previously these infections had a fulminant, often lethal course with mortality as high as 40%. Extension of the cervical infection down the layers of the deep cervical fascia into the mediastinum leads to this syndrome of descending necrotizing mediastinitis. Downward spread is aided by gravity, negative intrapleural pressure, and lytic dissolution of fascia and fat. The deep cervical fascia consists of three layers: the superficial (buccopharyngeal) layer, the middle (visceral) layer, and the deep layer that is further subdivided into the alar and prevertebral layers. All layers originate from the base of the skull. The superficial layer terminates at the superior chest. The visceral layer terminates as a continuation of the pericardium. The potential space between the superficial and middle layers, called the retropharyngeal space, allows infection to descend to the middle of the chest. The alar layer terminates at the diaphragm. The potential space between the middle and the alar layer confines infection above the diaphragm. Rare infections between the alar and prevertebral layers may allow the spread of infection below the diaphragm. Endo et al.[15] classified descending necrotizing mediastinitis according to the extent of the infection to guide the surgical management according to this classification: Type 1, infection above the carina, Type IIA, infection to the level of the lower anterior mediastinum, and Type IIB, infection involving the lower anterior and posterior mediastinum.

The criteria for diagnosing descending necrotizing mediastinitis were established by Wheatley et al.[14] in 1990 and include (1) severe head and/or neck infection, (2) radiographic evidence of mediastinitis, (3) evidence of necrotizing infection, and (4) establishment of a relationship between the cervical infection and necrotizing mediastinitis. Ridder et al.[13] recently reported a large series and performed an updated meta-analysis of collected series that illustrate the cardinal features of this important clinical problem. Patients present with odyophagia (66%), neck swelling (41%), neck pain (21%), dyspnea (21%), and chest pain (5%). Signs include fever (100%) and swelling and redness of the oropharynx (69%). About 2/3 of patients have comorbidities that are associated with immunosuppression or chronic illnesses. Common causes include tooth abscesses, pharyngitis, peritonsillar abscess, epiglottis, and perforation of the pharynx. A period of delay of either presentation or diagnosis is common.

CT with intravenous contrast should be performed on all severe neck infections and suspected cases of descending necrotizing mediastinitis to identify radiologic signs of mediastinitis that may not be clinically apparent (Fig. 80-9). *Streptococcus* species are the most common aerobic organisms and *Bacteroides* species are the most common anaerobic organisms isolated. Antibiotics should be started upon clinical suspicion of this diagnosis. All patients require cervical incision, exploration, drainage, and treatment of the underlying condition. Many patients also require transthoracic drainage by a variety

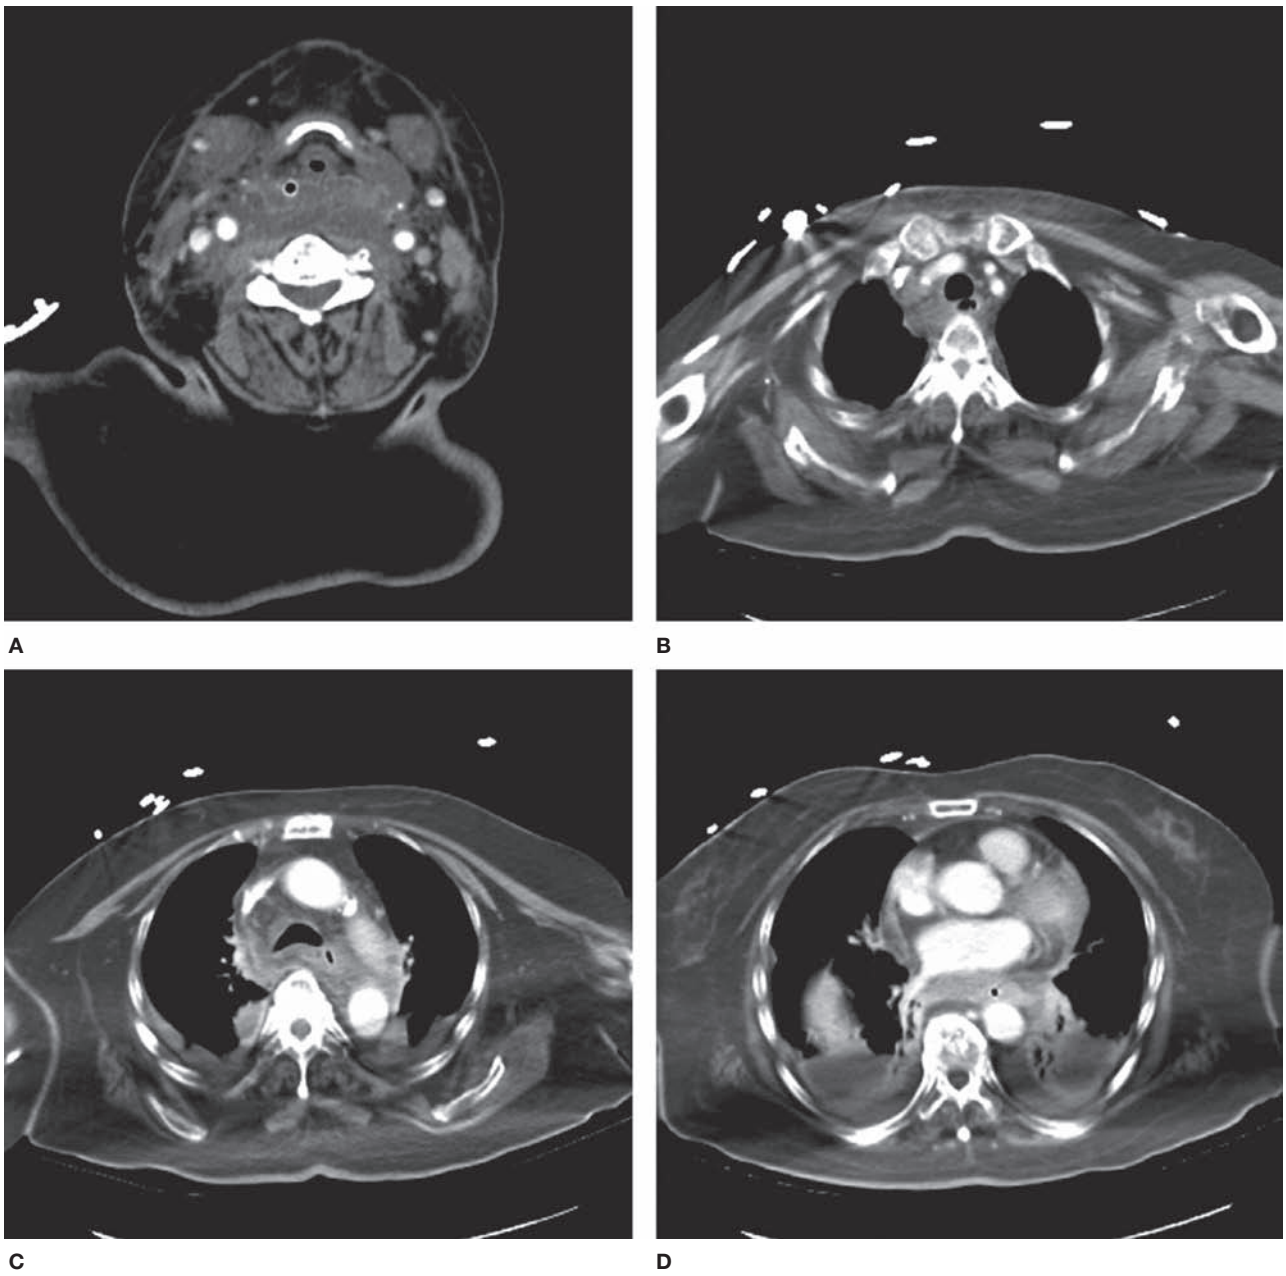

Figure 80-9 Representative CT images from a patient with descending necrotizing mediastinitis from a retropharyngeal abscess. **A.** Low-density collection surrounding the trachea and retropharyngeal space. **B.** Right paratracheal collection. **C.** Collection surrounding the airway and esophagus with small loculated empyemas. **D.** Bilateral empyemas. This patient required transcervical and transthoracic drainage. *(Reproduced with permission from Chen KC, Chen JS, Kuo SW. of routes, including thoracotomy, videothoracoscopy, transmediastinal, and subxyphoid. Many patients require several trips to the operating room for repeat debridements and drainage procedures. Tracheostomy is often required due to the severity of upper airway swelling. The mean length of stay is 36 days reflecting the severity of this illness. Recent series report an average mortality of 11%.

■ MEDIASTINITIS FROM DIRECT EXTENSION

Necrotizing pneumonias may cause mediastinitis by direct extension, most often in immunocompromised patients. Aspergillosis of the posterior mediastinum has been reported with increasing frequency and is highly lethal. Treatment involves reversal of immunosuppression (if possible), appropriate antibiotic therapy, and surgical drainage and debridement.

Pancreatitis can extend from the retroperitoneum into the mediastinum and may present as a mediastinal process with evidence of mediastinitis. Pancreatic pseudocysts can also erode into the mediastinum and cause pleural effusions with increased levels of amylase. Treatment is directed at providing adequate drainage of the pseudocyst, usually by internal drainage into the stomach. The pleural effusion(s) may require tube thoracostomy drainage.

■ POSTSTERNOTOMY MEDIASTINITIS

Sternal wound infection with resulting mediastinitis is a relatively new entity, which emerged in the era of modern cardiac surgery. The incidence remains low at 0.5% to 1% of all sternotomies, but such infection is a source of major morbidity, prolonged hospital stay, and significant mortality (0%–30%; average, 15%). Multivariate analysis

has demonstrated that prolonged preoperative stay, advanced age, BMI >30 kg/m^2, chronic obstructive pulmonary disease, diabetes, reoperation, blood transfusions, and reexploration for bleeding are significant risk factors.[19,20] *Staphylococcus aureus* is the most common causative organism. Other organisms commonly isolated include *Staphylococcus epidermidis*, various gram-negative organisms, as well as Candida species and atypical mycobacteria. The etiology appears to be a combination of intraoperative contamination and hematogenous seeding of mediastinal clot in the early postoperative period. Most patients with poststernotomy mediastinitis have an insidious presentation with low-grade fever and leukocytosis, wound problems (erythema, drainage, sternal instability), and eventually bacteremia. Infections caused by gram-negative organisms tend to become manifest earlier than those caused by gram-positive organisms. Most infections occur within the first or second week following the operative procedure. A high index of suspicion must be maintained so that an early diagnosis can be made and appropriate treatment instituted. Wound aspiration, local wound exploration, and CT imaging aid in making the diagnosis. Exploration in the operating room remains the definitive diagnostic maneuver and material should be obtained for culture at that time if it has not been obtained before or has been unrevealing.

If the infection is relatively early and the bony sternum appears viable, debridement, drainage, and saline (or antibiotic) irrigation with reclosure are indicated.[20] Although it may seemingly violate time-honored surgical principles (leaving contaminated wounds open, to close by secondary intention), primary closure of the early, infected sternum yields excellent results in many patients if adequate debridement is carried out. Of course, proper and prolonged antibiotic therapy is necessary. Reported mortality rates approach zero for these early infections if managed appropriately. Late sternal wound infections with mediastinitis present a more formidable challenge, in part due to the extensive sternal osteomyelitis and necrotic soft tissue which, when debrided, result in significant dead space, thereby creating a favorable environment for continued bacterial proliferation and persistent infection. The presence of prosthetic material, such as sutures, Teflon pledgets, or prosthetic grafts further complicates the problem and may lead to catastrophic hemorrhage with a fatal outcome. Mediastinitis in the presence of a prosthetic aortic graft is a particularly disastrous complication. Most surgeons favor extensive sternal debridement, usually with total sternal excision and rotation of pectoralis muscle flaps (bilateral) or transposition of gastrocolic omentum to fill the dead space with viable tissue. More recently successful outcomes have been reported with the use of negative pressure wound therapy (vacuum-assisted closure [VAC]).[21] Caution is required to protect the right ventricle when using negative pressure wound therapy to prevent erosion of the ventricle against the sternum.[22]

■ ANTHRAX MEDIASTINITIS

Anthrax, caused by *Bacillus anthracis*, was previously found primarily in the Middle East, with farm animals as the primary reservoir.[23,24] Following the advent of substantial immigration and bioterrorism, anthrax has been diagnosed in the United States and has been prominent in the mainstream media. An index case of fatal inhalational anthrax complicated by hemorrhagic mediastinitis due to bioterrorism in the United States has been reported in detail.[25] The inhalation of anthrax spores allows entry into the lungs with subsequent transport to the mediastinal lymph nodes by alveolar macrophages. A hemorrhagic mediastinitis typically quickly ensues and death is common. Gram-positive bacilli are present in tissue specimens. The initial treatment involves the initial use of either ciprofloxacin or doxycycline plus one or two additional antimicrobial agents with activity against *B. anthracis*.

CHRONIC MEDIASTINITIS

Several important clinical entities within the spectrum of chronic mediastinits, including mediastinal granuloma, fibrosing mediastinitis, and compression syndromes arising from fibrosing mediastinitis, are presented below.

■ MEDIASTINAL GRANULOMA

Granulomatous mediastinitis is a disease of the mediastinal lymph nodes usually resulting from infection by *Histoplasma capsulatum* and occasionally from tuberculosis, other fungi, and sarcoidosis. In certain areas of the country (e.g., Mississippi river valley) where *Histoplasma* is endemic, this disease is fairly common. Coalescence of caseous mediastinal lymph nodes can result in a single large mass that incites a considerable fibrotic response, which can result in encapsulation and produce a mediastinal granuloma.[26] The right paratracheal area is the most common site for development of an encapsulated mass. When calcification is absent and the patient presents with what appears to be mediastinal adenopathy, a tissue diagnosis is required to exclude malignancy. With progressive increase in the size of this "benign" mass, compression of the trachea, superior vena cava, or esophagus can occur. In a report from the Mayo Clinic, 34% of patients with mediastinal granuloma went on to develop mediastinal fibrosis over a 2-year period.[27] Based on such reports, most authors suggest that there exists a spectrum of diseases ranging from mediastinal granuloma to fibrosing mediastinitis. Caseating lymph nodes can also erode into and rupture in the esophagus, be associated with esophageal diverticula (Fig. 80-10), and erode into the airway, causing obstruction or bleeding.

Mediastinal granulomas should be excised if symptomatic. Although complete excision is sometimes possible, the intense

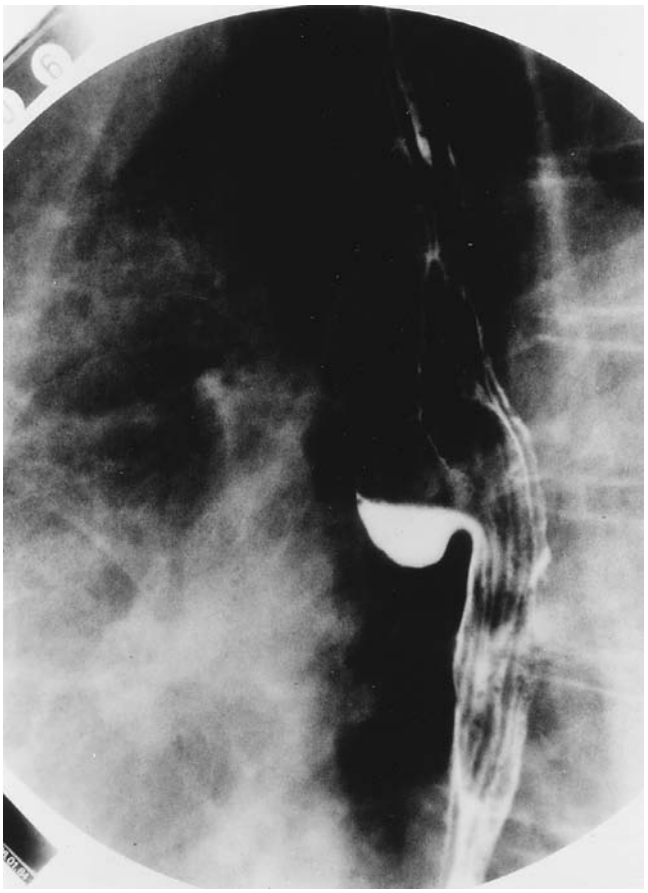

Figure 80-10 Barium swallow of an elderly woman with a history of treated tuberculosis with symptomatic diverticulum of midesophagus adjacent to the subcarinal lymph nodes.

surrounding fibrosis places important structures at risk for operative injury. Evacuation of the granulomatous mass is usually a safer option. Specimens for culture and special stains should be obtained at the time of operation, but organisms can rarely be identified or grown in culture.

Mediastinal lymph nodes involved by the granulomatous process may become calcified as individual masses and – because of the proximity of lymph nodes to the tracheobronchial tree – ultimately erode into the airway. The presence of calcified lymph node masses within the bronchi is referred to as *broncholithiasis.* Erosion into the airway, if it occurs, does so over a prolonged period of time and may remain clinically silent, only to be noted if a bronchoscopy is performed for some other indication. Broncholithiasis may also present with symptoms of cough, obstruction, or bleeding. Symptomatic broncholithiasis should prompt bronchoscopy for documentation of findings. Rarely, if ever, should broncholiths be removed bronchoscopically, the exception being the occasional "stone" that is completely free within the bronchus. An effort to remove a broncholith that is not completely detached from the wall of the bronchus may be accompanied by catastrophic hemorrhage due to the close proximity of pulmonary artery branches to the bronchus. Most symptomatic broncholiths should be removed at thoracotomy, where the pulmonary artery may be managed. These can be extremely difficult and hazardous operations and should be carried out by thoracic surgeons experienced in the management of granulomatous disease. Usually lobectomy or segmentectomy is required, since removal of the calcified mass will almost certainly take a portion of the bronchial wall.

Fistulas occurring between the trachea and esophagus or esophagus and mediastinum as a result of granulomatous lymphadenitis should be closed and reinforced with viable tissue.[28] There is no consensus regarding management of large asymptomatic mediastinal granulomas but some have recommended excision to forestall the development of compression syndromes or fibrosing mediastinitis.

FIBROSING MEDIASTINITIS

Fibrosing mediastinitis may cause a variety of clinical syndromes due to the compression and/or obstruction of vital mediastinal structures by the dense fibrous tissue reaction that is present.[29] In North America fibrosing mediastinits is most commonly associated with *Histoplasma capsulatum* infection. Other rare causes include other fungi, tuberculosis, silicosis, sarcoidosis, the drug methysergide, autoimmune disorders, and familial multifocal fibrosclerosis.[30–32] Fibrosing mediastinitis is labeled as idiopathic if there is no identifiable cause. Goodwin proposed the most widely accepted hypothesis that fibrosing mediastinitis results from a delayed hypersensitivity reaction to fungal, mycobacterial, or other antigens. Pathologic features include the presence of dense fibrotic tissue surrounding the trachea and hila of the lungs, often extending into contiguous structures. Compression of the airway, esophagus, pulmonary arteries, or pulmonary veins may occur because of this process. Histologic features include dense hyalinized collagenous tissue, aggregates of plasma cells and lymphocytes, and occasionally granulomas. Cultures are almost always negative, as are special stains for organisms. Some cases present with radiographic features that suggest malignancy, particularly if calcification is minimal, leading to surgical biopsies for diagnosis.

Symptoms are primarily caused by compression of vital mediastinal structures. Fibrosis around the right peritracheal area commonly causes superior vena cava syndrome. Subcarinal fibrosis can extend posteriorly to encase the esophagus or extend laterally to involve the pulmonary veins. Hilar fibrosis can obstruct either the tracheobronchial tree or pulmonary arteries (Fig. 80-12). Rarely, constrictive pericarditis or obstruction of the trachea or proximal main bronchi can also occur. The signs and symptoms may progress over a period of time.

The optimal treatment of fibrosing mediastinitis remains unknown. Case reports have suggested that antifungal, anti-inflammatory, or antifibrotic treatment may have some benefit, but large case series mostly refute these observations. Interventions to relieve compression of mediastinal structures have been reported with moderate success, but sometimes with relatively high periprocedure morbidity.

Peikert et al.[29] from the Mayo Clinic recently reviewed a large series of patients with fibrosing mediastinitis that nicely summarizes our current limited understanding of this disease. Their clinical definition of fibrosing mediastinitis was radiographic evidence of an infiltrative mediastinal process with associated vascular, airway, or esophageal compression. The pathologic definition was that of a predominance of extensive pauci-cellular fibrotic tissue infiltrating and obliterating adipose tissue with or without patchy infiltration of mononuclear cells. The median age of their patients was 42 years with an equal gender distribution. There was evidence of histoplasmosis (by culture, fungal stains, or positive serologic titer) in 83% of patients. The involved mediastinal organs that were compressed were vascular (48%), bronchial (27%), superior vena cava only (20%), and esophagus (3%). Only 5% of patients were asymptomatic at presentation. Presenting symptoms included dyspnea (47%), cough (21%), symptoms compatible with the superior vena cava syndrome (21%), chest pain (20%), and hemoptysis (20%). Focal mediastinal imaging findings were seen in 95% of patients while only 5% had diffuse infiltration. Calcifications were seen in 73% of patients. PET scans, when obtained for the suspicion of malignancy, were uniformly positive. Medical therapy with antifungal treatment in 28 patients was minimally effective with only an 18% rate of a partial response. Endovascular interventions were successful in 4 of 15 patients but the majority required repeat interventions. Bronchoscopic interventions were not successful. Surgical interventions were successful in 95% of patients. There were no periprocedural deaths. Long-term survival of these patients was identical to age-matched controls.

McNeeley et al. recently reported a review of imaging of fibrosing mediastinitis.[33] The chest radiograph is usually abnormal in fibrosing mediastinitis but findings are usually nonspecific. The most common findings include mediastinal widening, lymphadenopathy, and calcified nodes. Contrast-enhanced CT is the imaging modality of choice and shows fibrotic tissue with variable enhancement. Multiplanar reformatted views are especially helpful in demonstrating compression of vessels and airways and for planning an intervention. A practical differential diagnosis for granulomatous fibrosing mediastinitis includes lung cancer, mediastinal nodal metastases (especially sclerosing adenocarcinomas), sclerosing non-Hodgkin lymphoma, nodular sclerosing Hodgkin lymphoma, and tuberculosis.

COMPRESSION SYNDROMES ASSOCIATED WITH FIBROSING MEDIASTINITIS

The most common mediastinal compression syndrome seen in fibrosing mediastinitis is the superior vena cava syndrome, which occurs in 20% to 50% of patients.[29] In the vast majority of patients, the superior vena cava syndrome is due to malignant disease; fibrosing mediastinitis is the most common benign cause. Patients present with distention of the veins in the neck; edema and plethora of the face, neck, and arms; and central nervous system complaints such as headache and visual disturbances. Men often note as a first sign an increase in collar size; and symptoms become worse upon bending over. Because this syndrome is usually of gradual onset, venous collaterals develop over the anterior chest wall and, in many patients, provide adequate decompression (Fig. 80-11). Confirmation of the diagnosis of superior vena cava syndrome is easily made with contrast CT or venography, which demonstrate blockage of contrast at the thoracic inlet and the presence of collateral vessels. Bilateral upper extremity venograms demonstrate the precise anatomy of the involved veins and are helpful if surgical decompression is

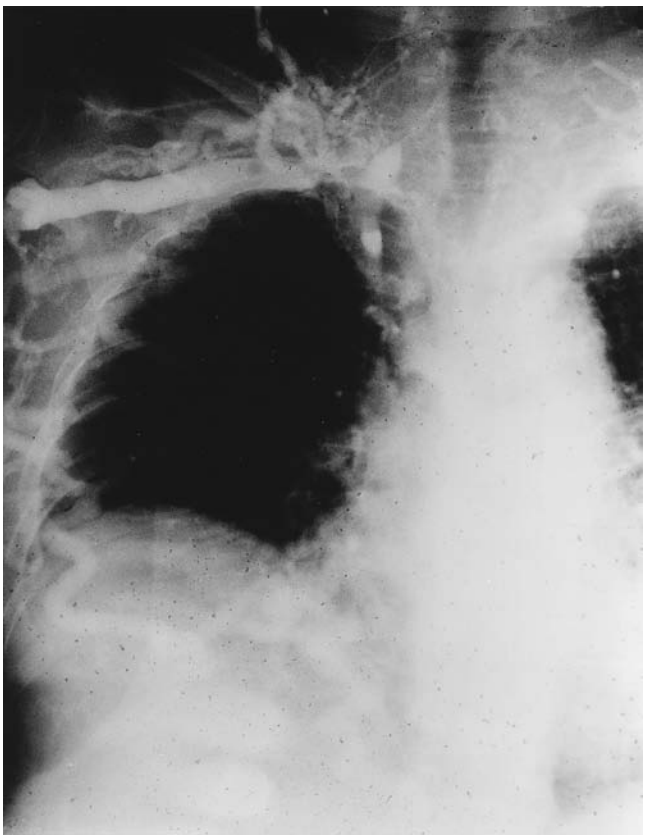

Figure 80-11 Patient with SVC syndrome secondary to mediastinal fibrosis due to histoplasmosis. Numerous dilated and tortuous collateral veins present on the chest wall are characteristic of chronic SVC obstruction.

contemplated. Surgical bypass is reserved for patients with intractable symptoms and is performed by connecting an unobstructed large brachiocephalic vein to the right atrial appendage with a graft of either a saphenous vein or an externally supported polytetrafluoroethylene graft. Favorable long-term results have been reported. Percutaneous angioplasty and stenting of a stenotic superior vena cava has been reported, but long-term follow-up is limited.

Tracheobronchial compression is also common and leads to dyspnea, obstructive pneumonias, wheezing, hemoptysis, cough, and the middle lobe syndrome (see Fig. 80–12). A localized stenotic area sometimes can be dilated, but often pulmonary resection is required. Resection is the procedure of choice if chronic infection has been present. Bronchoscopic interventions are appropriate if lung parenchyma remains normal. The bronchoscopic placement of stents into the trachea and/or mainstem bronchi may allow for adequate management of a compressed airway. A Y-bifurcation stent and individual self-expanding stents placed in the trachea or bronchi are available. Airway management must be individualized based on findings at bronchoscopy. Often the airway strictures are so fibrotic that they are not amenable to stenting.[28]

Complete or partial unilateral or bilateral pulmonary artery obstruction can result from fibrosing mediastinitis (see Fig. 80-12).[28,31,32] Dyspnea and signs of right heart failure can be present. The differential diagnosis should include chronic pulmonary thromboembolism. The fibrosis may also extend to involve the pulmonary veins, producing a syndrome mimicking pulmonary venoocclusive disease. Some patients present with complaints similar to those of patients presenting with mitral stenosis: dyspnea, cough, and hemoptysis. Surgical correction of these disorders is rarely possible due to the extreme fibrosis present around the vessels. Angioplasty and/or stenting of the pulmonary veins has been reported. If the situation is unilateral with associated airway obstruction a pneumonectomy may be an alternative.

Esophageal obstruction resulting from fibrosing mediastinitis most frequently involves the middle third of the esophagus because of its relationship to the subcarinal space. Dilation, enucleation of scar, and resection are therapeutic options. Fistulas may also occur between the subcarinal lymph nodes and the esophagus or into the tracheobronchial tree. Operative treatment for fistula formation is directed at closing the fistula and separating the airway and esophagus using viable tissue such as muscle. An esophageal diverticulum may form from inflammatory adherence to the subcarinal lymph nodes but is usually asymptomatic (see Fig. 80-10).

MISCELLANEOUS MEDIASTINAL PATHOLOGY: SPONTANEOUS MEDIASTINAL HEMORRHAGE

Spontaneous mediastinal hemorrhage is quite rare. Mediastinal hemorrhage due to aortic dissection, contained rupture of a thoracic aortic aneurysm, or iatrogenic injury is much more common. Symptoms are usually of sudden onset and consist of substernal pain, dyspnea, and, rarely, hemodynamic compromise. The hemorrhage is usually brief and self-limited. Treatment is supportive, and secondary causes of mediastinal hemorrhage must be excluded. Mediastinal fibrosis has rarely been reported following mediastinal hemorrhage.

CHAPTER 81

Congenital Cysts of the Mediastinum: Bronchopulmonary Foregut Anomalies

Alberto de Hoyos
Malcolm M. DeCamp Jr.

Mediastinal masses represent a diverse collection of tumors, vascular abnormalities, and cysts arising from and associated with each of the organs and structures found within the thorax.[1–4] Cystic lesions account for up to 25% of reported mediastinal masses.[1,3–5] These cysts may be congenital or acquired or may represent cystic degeneration of a previously solid tumor. In this chapter, we focus on congenital cystic lesions within the mediastinum, specifically addressing the spectrum of foregut cysts including bronchogenic cysts, esophageal duplication cysts, and neurenteric cysts. Together they constitute up to 9% of all primary mediastinal masses. In addition, we briefly consider simple cysts arising from the thymus, pericardium, and thoracic duct. Many other solid mediastinal neoplasms (dermoids, teratomas, thymomas, parathyroid adenomas, and thyroid goiters) may present with cystic components. These lesions are discussed in Chapter 82.

ANATOMY

Cysts arise in each of the three distinct anatomic regions of the mediastinum:

- The *anterosuperior compartment* extends from the manubrium of the sternum and the first rib to the diaphragm. The anterior border of this region is the posterior sternal table, while the posterior margin includes the pericardium and the innominate vessels. Thymic cysts and endocrine lesions, such as thyroid goiters and cystic adenomas of the parathyroid gland, are found in this compartment.[6]
- The *middle mediastinum* is the site of origin of most bronchopulmonary foregut cysts. The boundaries of the middle mediastinum include the pericardial reflections superiorly and anteriorly and the diaphragm inferiorly. The posterior margin of the middle mediastinum is the anterior border of the spine. Pericardial cysts, as well as bronchogenic cysts, are found in this compartment.[7]
- The *posterior mediastinum* extends from the superior aspect of the first thoracic vertebral body to the diaphragm. Its anterior border is the ventral aspect of the vertebral bodies and it extends posteriorly to the articulation of the vertebral transverse process with each rib. The posterior mediastinum includes both costovertebral sulci and segmental nerve roots as well as the sympathetic chain. Other structures found within the posterior compartment include the esophagus, vagus nerves, the thoracic duct, the azygos vein, as well as the descending aorta. Neurenteric cysts, thoracic duct cysts, as well as some esophageal duplication cysts, and occasional bronchogenic cysts are found in this compartment.[7,8]

Lesions that arise primarily within the mediastinum may extend above the chest into the neck or below the diaphragm into the retroperitoneum, where they present as extrathoracic mass lesions. In addition, cysts within one mediastinal compartment may also extend into the adjacent compartment since there are no strict anatomic barriers.

EPIDEMIOLOGY

In reported series of mediastinal masses, the prevalence of primary cysts ranges from 10% to 25% and has remained steady for the past six decades (Table 81-1) with relatively similar incidences in males and females. Some minor heterogeneity over this time span is accounted for by variations in the ages of patients reported in each series.[1,3–5,9,10]

Bronchogenic cysts account for approximately 40% of mediastinal cysts, while pericardial cysts account for 35%, enteric for 10%, and nonspecific cysts for 15%. The etiology and distribution of cystic mediastinal masses are different in children and adults. Cysts of foregut origin account for only half of the lesions found in adults, whereas they constitute nearly 90% of cystic lesions reported in pediatric series (Table 81-2). Conversely, pericardial cysts account for up to one-third of all cystic lesions in adults, whereas true pericardial cysts are exceedingly rare in children. Among congenital lesions of the foregut and tracheobronchial tree seen in children – including pulmonary sequestrations, congenital lobar emphysema, cystic adenomatoid malformations, arteriovenous malformations, and bronchial atresias – simple foregut cysts (bronchogenic, enterogenous, and neurenteric) comprise between 13% and 29% of reported cases.[4,5,9–11]

Although the relative frequencies of cystic and solid mediastinal masses have remained fairly constant, the advent of cross-sectional imaging techniques, such as computed tomography (CT) and magnetic resonance imaging (MRI), has increased the detection of all mediastinal lesions.[12–16]

Multidetector computed tomography (MDCT) with volumetric acquisition provides fast acquisition of high-resolution images and multiplanar reconstruction. Both 2D and 3D imaging may help with improving diagnostic accuracy, surgical planning, and in assessing resectability. In most cases, CT imaging provides enough information to make accurate diagnostic and therapeutic decisions without further testing. In selected cases, MRI may offer advantages over other modalities for detecting and identifying cystic, or fluid-filled mediastinal masses because of the intrinsic high soft tissue contrast and direct multiplanar imaging capabilities. In addition, sagittal or coronal CT and MRI reformations can provide additional anatomic information that the transaxial images cannot.

BRONCHOGENIC CYSTS

The embryology, clinical presentation, diagnosis, and management of bronchogenic cysts are discussed below.

EMBRYOLOGY AND TERMINOLOGY

The primitive respiratory and upper gastrointestinal systems have a common embryologic endodermal origin. The primitive foregut gives rise to a variety of aerodigestive organs and tissues, beginning with the pharynx and subsequently giving rise to the larynx, upper and lower respiratory tracts, esophagus, stomach, proximal duodenum, liver, pancreas, and associated ducts.[17] Cystic malformations of foregut origin may have a variety of epithelial linings that reflect the embryologic tissues from which they are derived. The lung bud develops caudally from the laryngotracheal tube, beginning in the fourth week of gestation. By the fifth week, the single bud has divided into right and left main bronchi, which grow into the surrounding splanchnic mesenchyme that is destined to become bronchial cartilage and smooth muscle as well as visceral pleura. Dichotomous branching of the primitive bronchi continues until about the 24th week, when the terminal bronchioles begin to give rise to primitive alveoli.

Throughout this period of embryogenesis, abnormal bronchi and bronchioles may form larger saccular structures, which are clinically recognized as bronchogenic cysts. Such saccular malformations may be invested by their own splanchnic mesenchyme (neopleura). Abnormal bud separation may lead to cyst formation lined with respiratory epithelium. Some investigators believe that mediastinal bronchogenic cysts arise early in the cycle of bronchial branching, whereas intrapulmonary bronchogenic cysts represent derangements later in fetal development. If the separation occurs early, the cyst is associated with the large airways within the mediastinum. Delayed bud separation may lead to cyst formation more distally within the lung parenchyma. Approximately three-quarters of bronchogenic cysts are within the mediastinum and associated with the large airways and one-quarter are intraparenchymal.[16] Cysts abutting the trachea, carina, or hilum, are termed *mediastinal bronchogenic cysts* and they rarely maintain communication with the respiratory tract (Figs. 81-1 and 81-2). Less frequently, these lesions are contained within the pulmonary parenchyma, most commonly in the lower lobes and are termed *intrapulmonary bronchogenic cysts* (Fig. 81-3). Other locations include the neck, esophageal wall, pleura and diaphragm, and, rarely, in the skin. Bronchogenic cysts are lined by respiratory epithelium and may contain cartilage within their walls. Because they uniformly arise before alveoli form (at 28 weeks), bronchogenic cysts have no gas

exchange potential even if their bronchial communications persist, an extremely rare event.

PRESENTATION AND DIAGNOSIS

Bronchogenic cysts represent the most frequent cystic lesions found in the mediastinum and represent up to 15% to 20% of all mediastinal masses. The majority of the mediastinal bronchogenic cysts are located below the carina (77%), while the remainder occur above the carina (23%). Most young patients with bronchogenic cysts have symptoms at the time of diagnosis (Table 81-3), although in a significant minority of patients (20%–30%), the cysts may be identified incidentally on CT scans performed for other reasons. The pediatric population is particularly predisposed to symptomatic cysts due to the smaller size of their thorax and more malleable airways.[1,5,9,11] Eraklis et al.[18] noted life-threatening respiratory compromise in 70% of infants with foregut cysts. Mass effects from the cysts, which caused compression, "ball valving," or differential ventilation, were the predominant causes of respiratory distress. These neonates were often cyanotic, with wheezing or stridor, and their radiographs demonstrated inhomogeneous aeration, lobar collapse, and/or mediastinal shift. In series of nonneonatal children, up to 95% had symptoms. Signs and symptoms of infection may be present, especially in the older children population.

In adults, symptomatic bronchogenic cysts are less common.[1,4,10,19,20] In a large series, symptoms were present in about one-third of patients and included chest pain, cough, wheezing, stridor, dyspnea, dysphagia, cyanotic spells, and pneumonia. Other manifestations include compression of the superior vena cava or left atrium, or evidence of infection such as pneumonia or empyema (Fig. 81-3C). In more recent series, 75% to 95% of patients were asymptomatic when the lesions were detected.[20–24] With long-term follow-up, however, two-thirds of patients who were initially asymptomatic eventually developed symptoms.

The presence of a bronchogenic cyst is suggested by plain chest radiographs in up to two-thirds of cases in any age group. The usual appearance is that of a 2- to 10-cm ovoid, smooth, homogeneous mass that abuts the mediastinum or hilum or splays the carina.[25] An air–fluid level connotes either persistent bronchial communication or secondary infection of the cyst (Fig. 81-3). As mentioned earlier, some cysts (especially in infants) may exert a mass effect, causing airway compression, parenchymal atelectasis, or cardiovascular compression (Fig. 81-2B). In 60% to 65% of patients, posteroanterior and lateral plain chest radiographs make it possible to diagnose these lesions and to document their precise location.

Ultrasonography is helpful in confirming the cystic nature of mediastinal lesions in infants and children. Prenatal diagnosis is also feasible. Such forewarning allows for the expeditious management of these infants antenatally or at the time of delivery, when most affected infants quickly develop symptoms coincident with inflation of the lungs. In the adult, surface ultrasonography has little to offer in the acoustic visualization of suspected bronchogenic cysts because air within the lungs is a poor conductor of sound. Esophageal ultrasound can be useful in the diagnosis of mediastinal bronchogenic cysts due to the proximity of the endoscopic probe to the cyst. However, needle aspiration through the esophagus should not be performed due to the possibility of infection and sepsis.[26,27]

Cross-sectional imaging techniques, using either CT or MRI, have become the diagnostic procedures of choice for investigating mediastinal masses. These methods provide helpful details of cyst structure, including the density and type of cyst fluid, amount of calcium in the cyst wall, vascularity of the cyst, and the relationships of the cyst to adjacent mediastinal structures. MRI and CT are probably equally useful in the diagnosis of mediastinal-based cysts, although in most situations, a CT scan will provide all the necessary information. CT is superior for the examination of intrapulmonary cysts because of its ability to delineate more sharply the cystic lesion from the surrounding air-filled parenchyma (Figs. 81-1–81-3). On CT, bronchogenic cysts appear as a single, smooth, round, or elliptic mass with a well-defined, thin, smooth wall and nonenhancing homogeneous cyst mass. Half of these lesions have the same density as water with attenuation values in a range consistent with serous fluid (0–20 Hounsfield units [HUs]) and others have a CT density that varies depending on the cyst's protein content.[15,16,25] Higher attenuation in the range of 30 to 130 HU is the result of the presence of calcium, proteinaceous fluid, mucus, and/or blood within the cyst. The presence of especially high attenuation fluid within the cyst on CT scan suggests a high calcium content (milk of calcium).[16] On MRI, bronchogenic cysts frequently show signal intensity higher than that of muscle on T1-weighted images. Variable signal intensity may be due to variable cystic

components and presence of protein, blood, or mucoid material. On T2-weighted images, cysts show high signal intensity.

Bronchoscopy is normal in the majority of cases, but abnormalities include extrinsic compression of the airways, secretions from infected cysts, and rarely, direct communication with the cyst cavity. Rupture into the airway, esophagus, or pericardium has been documented.

THERAPY

The treatment options for bronchogenic cysts include observation, resection, and aspiration. In the absence of definitive diagnosis, surgical exploration is recommended for nearly all patients with an abnormal mediastinal mass. Bronchogenic cysts are the most commonly treated mediastinal foregut anomaly and account for 60% of all mediastinal masses. Once a bronchogenic cyst is diagnosed, surgical excision is indicated to relieve clinical symptoms, to address enlarging cysts, or to prevent possible complications such as infection, malignant transformation, tracheal or vascular compression, or hemoptysis.[28–30] Complete excision of the cyst should be performed, thus minimizing the chance of recurrence and the potential for complications. Traditionally, a thoracotomy was necessary. Since most cysts are located in the subcarinal area, a right fifth interspace thoracotomy is usually recommended. With the right lung mobilized anteriorly, access is gained to the area below the azygos vein. The mediastinal pleura is incised and the cyst is meticulously dissected from the surrounding structures, paying particular attention to the areas of attachment to the airway, esophagus, and pericardium. Video-assisted thoracoscopic surgery (VATS) is being utilized with increasing frequency to resect mediastinal cysts with excellent results, low conversion rates to open procedure (7%–30%), and no significant increases in recurrence rates.[31–34] A standard three-port technique is typically utilized. Large bronchogenic cysts located in the subcarinal area may extend to the mid or distal left main bronchus and may be densely adherent to the airway or esophagus, making thoracoscopic dissection difficult or even risky with potential for injury to the adjacent structures. Decompression of the cyst by aspiration of its content may make handling and dissection somewhat easier.[33]

Urschel and Horan[35] described piecemeal resection of a mediastinal bronchogenic cyst using a Carlens mediastinoscope introduced through a small suprasternal incision. This may be particularly helpful in the treatment of recurrent subcarinal cysts previously approached through a thoracotomy. Partial resection of a bronchogenic cyst may occasionally be necessary, if the cyst is found to be densely adherent to and inseparable from the membranous airway, main pulmonary vessels, esophagus, phrenic nerve, or aorta. In these cases, the majority of the wall of the cyst should be excised and the mucosa lining the remaining cyst wall should be ablated with electrocautery in an effort to prevent recurrences. When subtotal excision is necessary, symptomatic recurrences requiring re-excision have been reported.

Aspiration of a cyst to confirm a benign diagnosis and to instill a sclerosing agent (ethanol or bleomycin) has been used to manage some cysts. The advent of endobronchial ultrasonography with transbronchial intervention has resulted in an even less invasive management option. However, the fluid is almost always thick and viscous and unlikely to be drained through a long, small needle. Reports of long-term follow-up for this approach to both the diagnosis and therapy of bronchogenic cysts are scant. However, it may represent a useful form of therapy for inoperable patients.

Whatever the operative approach, the goal of surgery should be complete excision of all elements of the cyst. Occasional case reports of malignancy arising from the cyst mucosa support the general concept of complete resection for any bronchogenic cyst.[36] A variety of tumors have been associated with bronchogenic cysts including adenocarcinoma, squamous cell carcinoma, carcinoid tumors, anaplastic carcinoma, and leiomyosarcoma in both children and adults.

Treatment of asymptomatic cysts remains controversial.[37] A conservative approach can be considered for small, asymptomatic cysts that do not compress adjacent structures, do not enlarge over time, do not display atypical characteristics, or arouse suspicion of malignancy.

ENTEROGENOUS CYSTS

The embryology, clinical presentation, diagnosis, and management of enterogenous cysts are discussed below.

EMBRYOLOGY AND TERMINOLOGY

Enterogenous cysts are also termed *esophageal duplications*. They arise from the elongating esophagus, which separates from the respiratory tract at about the fifth week of gestation (see Chapter 4). As with most intestinal duplications, enterogenous cysts represent failure of normal recanalization during embryogenesis.[38] Most esophageal duplications are of the closed and cystic type. Rarely are they tubular or demonstrate preserved communication with the alimentary tract.

PRESENTATION AND DIAGNOSIS

After leiomyomas and benign polyps, esophageal cysts are the third most common esophageal mass, although they remain much less common than bronchogenic cysts. Of all mediastinal cysts, only 5% to 15% are esophageal in origin. The majority of esophageal duplication cysts occur in infants or children and nearly 75% of esophageal duplication cysts are recognized before 16 years of age.[39–41] In up to 60% of patients they are located adjacent to or within the lower one-third of the esophageal wall in the lower posterior mediastinum with a two-to-one predilection for cysts to be on the right side. Most adults are asymptomatic, with cysts incidentally identified on chest CT.[42] The natural history of esophageal cysts is variable, but if left untreated most will become symptomatic. Symptoms are usually due to compression of the airways resulting in cough, dyspnea, and occasionally stridor.[43–45] Dysphagia is surprisingly infrequent. In asymptomatic patients, the most common clue leading to this diagnosis is the coexistence of other gastrointestinal duplication(s). Associated conditions include other intestinal cysts, esophageal atresia, tracheoesophageal fistula, and spinal abnormalities. Unlike bronchogenic cysts, which are always lined with respiratory mucosa, enterogenous cysts may have a variety of epithelial linings, including the squamous epithelium native to the esophagus. From 50% to 60% of esophageal cysts contain ectopic gastric mucosa, with some containing pancreatic tissue. The presence of gastric mucosa containing parietal cells capable of acid secretion may explain events such as spontaneous hemorrhage and perforation.[44]

Esophageal duplications usually present radiographically as smooth-walled, posterior mediastinal lesions at the base of the right hemithorax (Fig. 81-4A). A barium swallow demonstrates deviation of the lumen around the cyst, but rarely shows communication with it (Fig. 81-4B). Proximal esophageal dilatation is not common because the cysts usually are not obstructive. In patients with suspected duplication, a technetium pertechnetate nuclear scan may suggest the presence of ectopic gastric mucosa within the chest. Cross-sectional imaging (CT or MRI) is almost routinely employed to characterize the contents of a cyst and to define the relationship of the cyst to contiguous structures (Fig. 81-4C). The characteristic CT and MRI findings are identical to those of bronchogenic cysts, except that the wall may be thicker and in closer contact with the esophagus. Endoesophageal ultrasound has provided a useful, minimally invasive tool to investigate these lesions and to allow sampling of cyst

Figure 81-4 **A.** Frontal radiograph demonstrating smooth-walled posterior mediastinal mass consistent with an enterogenous cyst. The lesion is easily separable from the right heart border *(arrows)*. **B.** Barium esophagogram of the same patient demonstrating deviation of the true esophageal lumen around the smooth extramucosal lesion *(arrows)*, found at resection to be an enterogenous cyst (esophageal duplication). **C.** Oral and intravenous contrast-enhanced CT image of the enterogenous cyst. The lesion is radiographically inseparable from the esophagus but free of all cardiac structures.

contents to confirm that the lesion, in an otherwise asymptomatic patient, is benign.[26,46] There is however, potential risk of infection and aspiration should be avoided if the echo characteristics suggest a simple cyst. Esophagoscopy, when performed, will demonstrate a smooth, soft, compressible mass without mucosal abnormality or communication with the extraluminal mass.

THERAPY

As in the case of bronchogenic cysts, esophageal duplications are likely to become larger or infected over time. Thus, resection is recommended for all enterogenous cysts, whether for current symptoms or for the high likelihood of future complications. Esophageal duplication cysts can be approached through a standard thoracotomy, VATS, or robotic techniques.[47–53] Regardless of the approach, the following steps should be emphasized: (1) Preservation of the muscular layer for repair, (2) identification and preservation of the vagus nerves, and (3) assessment of mucosal integrity via air insufflation under water. In most cases a plane of dissection in the submucosa can be achieved to complete the resection. Despite the lack of communication with the esophageal lumen, cyst resection may leave defects in the esophageal wall that must be meticulously repaired. If the mucosa is breached, the esophagus should be closed primarily in layers, and the repair should be reinforced with a locally procured flap of vascularized tissue. Options for buttressing include the pericardial fat pad, pleura, intercostal muscle, pericardium, or omentum. Case reports documenting the occurrence of an adenocarcinoma in esophageal duplication cysts underscore the need for resection at the time of diagnosis.

NEURENTERIC CYSTS

The embryology, clinical presentation, diagnosis, and management of neurenteric cysts are discussed below.

■ EMBRYOLOGY AND TERMINOLOGY

During the third week of normal embryogenesis, the notochord should separate from the primitive foregut (see Chapter 4). If this separation is incomplete, the mesodermal masses, which normally encircle the neural tube, cannot enclose it and vertebral anomalies arise. The attached foregut often spawns an associated mediastinal enteric cyst. This form of congenital cyst accounts for only 5% to 10% of all foregut lesions and is consistently associated with bony anomalies of the spine.[54] The spectrum of vertebral anomalies includes butterfly vertebrae, hemivertebrae, and anterior spina bifida. They occur primarily in the lower cervical and upper thoracic regions and are usually cephalad to the cystic lesion, since the esophagus descends (or the pharynx ascends) during fetal development. The fluid within the cyst may be nearly identical to CSF or may be milky, cream-colored, yellowish, or xanthochromic. Neurenteric cysts may be intradural, extramedullary, and situated ventral or ventrolateral to the spinal cord.[55]

■ PRESENTATION AND DIAGNOSIS

Neurenteric cysts are exceedingly rare; virtually all present within the first year of life.[56] More than half of afflicted children have neurologic complaints or findings. These include back pain, motor deficits of a lower extremity, and gait disturbance, especially if there is communication with the spinal canal. Often times the triad of a mediastinal mass, airway symptoms, and a vertebral anomaly will be present. The diagnosis is often made after detection of vertebral anomalies on the chest radiograph. CT scans show vertebral abnormalities in 50% of affected patients and can define bony abnormalities and demonstrate extension of the cystic lesion into the spinal canal. MRI has supplanted CT myelography and provides a complete, noninvasive assessment of the bony abnormality, the intraspinal extent of the cyst, and the degree of spinal cord or nerve root compression associated with a neurenteric cyst.[57]

■ THERAPY

Careful imaging of suspected neurenteric cysts is paramount for successful extirpation. MRI is useful to exclude extension of the cystic component into a neural foramen or the spinal canal proper and to exclude an associated meningocele. Such findings would require a staged resection employing a posterior neurosurgical approach first, to decompress the cord or its nerve roots, followed by resection of the mediastinal component by standard thoracotomy or VATS.[57–60] Complete cyst excision is the treatment of choice. When preoperative diagnostic imaging shows no intraspinal extension of the cyst, thoracoscopic excision may be possible. When there is only minimal involvement of the vertebral body, resection can be accomplished with VATS or more commonly a posterolateral thoracotomy. If the spinal abnormality is severe a combined neurosurgical and thoracic approach is recommended.

THYMIC CYSTS

The thymus is derived from the third pharyngeal pouch. Its development is incomplete at birth, and the gland continues to grow throughout childhood into adolescence. Cysts within the gland are thought to occur during adulthood, when gland architecture involutes and central cells degenerate and are replaced by fat.

Thymic cysts are rare congenital or acquired lesions embryologically derived from the pharyngeal pouches. They account for only 3% to 5% of all anterior mediastinal masses.[4–6,9,11,16] Most thymic cysts are asymptomatic and discovered incidentally on imaging studies performed for other reasons. Although thymic cysts are benign, they must be distinguished from thymomas, germ cell tumors, and lymphomas—all of which may have areas of cystic degeneration. These cysts arise in the anterior mediastinum (Fig. 81-5) and may extend to the middle mediastinal compartment, especially in the

Figure 81-6 Equivalent axial-enhanced CT (**A**) and axial MRI (**B**) images of an aortopulmonary window mass that appears to compress if not invade the left pulmonary artery (LPA). Coronal MR image (**C**) of the same lesion demonstrating an intact tissue plane separating the benign thymic cyst (TC) from the pulmonary artery (PA).

aortopulmonary window (Fig. 81-6).[61] Congenital cysts are typically unilocular and contain clear fluid and an imperceptibly thin wall. Multilocular thymic cysts are usually acquired lesions. Plain radiographs do not differentiate thymic cysts from other nonlobulated thymic masses, therefore CT and MRI are employed for diagnosis. Both CT and MRI demonstrate clear tissue planes separating the cyst from other vital structures (Figs. 81-5 and 81-6). If hemorrhage or infection occurs, the cyst may show high signal intensity. In older patients, benign cysts may degenerate and present as a complex, thickened cystic mass with calcified walls that contain heterogeneous fluid (Fig. 81-5). Such lesions are easily confused with a mediastinal teratoma. Multiloculated thymic cysts can occur in association with thymic neoplasms, including thymoma and thymic carcinoma. Complete thymic excision can be accomplished through sternotomy, thoracotomy, VATS, or robotically.[33,34,51–53]

PERICARDIAL CYSTS

Pericardial diverticula and pericardial cysts represent slightly different stages of a lesion that has a common embryogenesis. When a communication exists between the pericardial sac and the extrapericardial fluid collection, the lesion is a diverticulum. Absence of communication defines a pericardial cyst.[62] Both diverticula and cysts derive from the ventral recess of the pericardial celom, rather than from the pericardial lacunae. The discovery that a diverticulum-like structure in the ventral recess of the pericardial celom occurred during development of the pericardium at the site where so many of these lesions were found led to speculation as to their possible relationship. Persistence of the recess results in formation of a diverticulum, while constriction of the proximal part of the persistent recess accounts for either a diverticulum with a narrow neck or a cyst in communication with the pericardial cavity. If the proximal portion of the recess is completely pinched off, an isolated pericardial cyst occurs in the cardiophrenic angle.

Pericardial cysts are simple, smooth-walled cystic lesions (Fig. 81-7) that are commonly located at the lateral basal edge of the pericardium, where it fuses with the diaphragm at the right cardiophrenic angle.[63] They can be mistaken for foramen of Morgagni hernias or prominent pericardial fat pads. They can be differentiated from more solid mediastinal tumors by CT or MRI. Pericardial cysts characteristically contain clear, low-density serous fluid. The appearance of these thin-walled, translucent cysts containing crystal-clear fluid gave rise to the term "spring water cysts."[62] They have no malignant potential and rarely get infected. Potential complications include hemorrhage or spontaneous rupture. Needle aspiration is

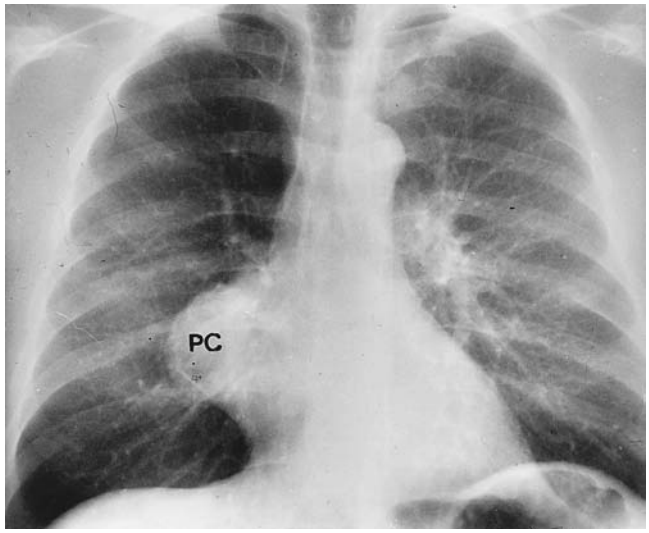

Figure 81-7 Frontal radiograph of a mediastinal mass, isodense with and inseparable from the right heart border. Thoracoscopy showed this to be a broadly based pericardial cyst (PC).

often followed by reaccumulation of fluid, and is not generally recommended. Surgery for pericardial cysts or diverticula is not indicated in the majority of cases because these lesions are always benign and most are asymptomatic. Resection should be reserved for cysts that cause symptoms (hemodynamic compromise, arrhythmia, chest discomfort, substernal pain, atelectasis) or for those demonstrating significant enlargement over time.[63] The operative approach, whether endoscopic or open is dependent upon the location, size, and proximity of the cyst to vital structures. Most often, a right VATS approach is successful in excising the cyst. In most cases, standard two or three incision technique is utilized. Because pericardial cysts often overlie the right phrenic nerve, an unroofing procedure or subtotal resection is acceptable therapy if total excision would jeopardize diaphragmatic function.

THORACIC DUCT CYSTS

Lymphatic channels develop from the lateral plate mesoderm, either as outgrowths of the venous system or by the fusion of mesenchymal clefts into vessels. The lymphatic sacs, which develop by the second month of gestation, are connected by these primitive lymphatic channels. It is these channels that unite the jugular lymph sacs to the cisterna chyli to form the thoracic duct. A congenital weakening of the thoracic duct wall is postulated to be responsible for some thoracic duct cysts.[64] These cysts are exceedingly rare; less than 40 cases have been reported in the literature. Histologically, they are similar to the thoracic duct, with the presence of occasional endothelial cells lining the cyst. They occur anywhere along the course of the duct from the cisterna chyli to the supraclavicular area.[65–67] Age at detection varies widely, and up to half of all patients are asymptomatic. Symptoms arise from compression of adjacent structures resulting in dyspnea, cough, chest pain, dysphonia, or dysphagia.[67–69] Plain films may demonstrate a middle or posterior mediastinal mass, with CT demonstrating a smooth, homogeneous cystic mass (Fig. 81-8).[12] MRI is superior to CT for evaluation, permitting superior delineation of the cyst boundaries (Fig. 81-9). As thoracic duct cysts can contain varying degrees of lipids and proteins, their MRI characteristics may vary accordingly. Contiguity with the thoracic duct and dilation of the thoracic duct aid the radiologist in making the correct diagnosis.[70] Confirmatory diagnosis may be made using lymphangiography or the presence of high triglyceride content in aspirated fluid, but these techniques are not commonly employed.

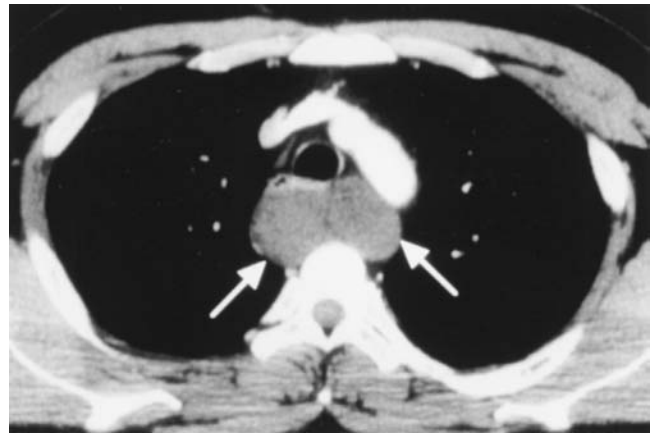

Figure 81-8 Axial contrast-enhanced CT scan of the chest revealed a large cystic mass measuring 3 × 5 × 15 cm *(arrows)* in the posterior mediastinum, displacing the esophagus and trachea anteriorly. *(Reproduced with permission from Chen F, Bando T, et al. Mediastinal Thoracic Duct Cyst. Chest. 1999;115(2):584–584.)*

Endobronchial ultrasound with transbronchial needle aspiration can also lead to the correct diagnosis.[71] Small cysts are generally observed whereas symptomatic and larger cysts should be resected. Successful surgical management is contingent upon appropriate control of both

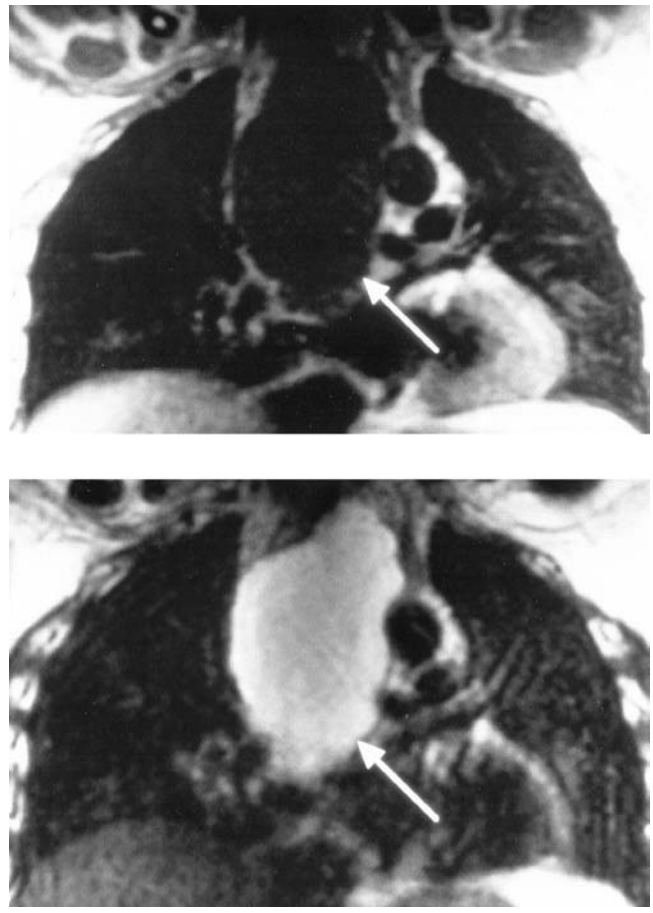

Figure 81-9 MRI scan. Top: Coronal T1-weighted imaging showing a low-intensity mass with a well-circumscribed margin *(arrow)*. Bottom: Coronal T2-weighted imaging showed a high-intensity mass *(arrow)*. *(Reproduced with permission from Chen F, Bando T, et al. Mediastinal Thoracic Duct Cyst. Chest. 1999;115(2):584–584.)*

afferent and efferent thoracic duct pedicles to avoid postoperative chylothorax. Excision can be accomplished through thoracotomy or VATS with application of clips or energy devices that fuse the vessel walls to control the afferent and efferent lymphatic channels.[65,71,72]

CHAPTER 82

Benign and Malignant Neoplasms of the Mediastinum

Bryan M. Burt
Joseph B. Shrager

INTRODUCTION

Primary lesions of the mediastinum are less common than lesions that secondarily involve the mediastinum. Overall, the majority of masses discovered in the mediastinum will be found to be metastases from a primary lung cancer. Neoplasms that arise primarily in the mediastinum, however, are often encountered in the clinic and are represented by a variety of lesions. This chapter first reviews the anatomy of the mediastinum and then focuses on the benign and malignant neoplasms that arise within each of the anatomic regions of the mediastinum. Covered elsewhere in this textbook (see Chapter 80) are nonneoplastic disorders of the mediastinum that include pneumomediastinum, acute mediastinitis, chronic mediastinitis, and other miscellaneous disorders. Likewise, congenital lesions of the mediastinum, such as bronchogenic, enterogenous, neurogenic, thymic, pericardial, and thoracic duct cysts, are also covered elsewhere (see Chapter 81).

ANATOMY OF THE MEDIASTINUM

The mediastinum comprises an anatomic space located between the thoracic inlet and the diaphragm, and bordered on the left and right sides by the pleural cavities. This central anatomic location houses or borders vital structures of almost every major organ system including the heart and great vessels of the circulatory system, the esophagus, and major airways of the aerodigestive tract, the thymus of the immune system, and important nerves such as the phrenic and vagus nerves. Further, various endocrine organs may project into it, distant malignancies may metastasize to it, and infectious processes can manifest themselves within it.

The mediastinum is compartmentalized based upon the borders of anatomic structures as seen on a lateral chest radiograph (Fig. 82-1). We believe that the most anatomically appropriate and clinically useful model of the mediastinum is the three-compartment model.[1] The three-compartment scheme divides the mediastinum into anterior, middle, and posterior compartments. Here, the anterior mediastinum extends from the thoracic inlet superiorly to the diaphragm inferiorly and is bounded anteriorly by the posterior table of the sternum, and posteriorly by the anterior pericardium and the aorta, innominate vein, and brachiocephalic vessels. The content of the anterior compartment includes the thymus, variable amounts of fat and lymphatic tissues, and the internal mammary arteries and veins. The middle compartment of the mediastinum is bounded anteriorly by the pericardium and posteriorly by the pericardium and posterior wall of the trachea, extending only as high as the pericardial reflection. The middle mediastinum contains the heart, pericardium, superior and inferior vena cava, ascending and transverse aorta, trachea and mainstem bronchi, and lymphatic tissues. The posterior mediastinum extends from the thoracic inlet to the diaphragm, and in this "three-compartment scheme," lies posterior to the posterior pericardium and airway. It includes the descending aorta, thoracic duct, esophagus, vagus nerves, and lymph nodes, as well as structures emerging from the spinal canal such as intercostal nerves.

One of the main advantages of categorizing the anatomy of the mediastinum is the ability it confers to generate a differential diagnosis for a mediastinal mass based on the structures naturally contained within the compartment in which it arises (Table 82-1). Such a classification scheme allows a clinician to proceed systematically to determine the appropriate diagnostic or therapeutic approach depending on the differential diagnosis.

EPIDEMIOLOGY AND INCIDENCE

The incidence and type of primary mediastinal neoplasms varies with patient age. In combined series totaling 3017 mostly adult patients, the incidence of mediastinal masses in decreasing frequency were thymomas and thymic cysts (26.5%), neurogenic tumors (20.2%), germ cell tumors (GCTs) (13.8%), lymphomas (12.7%), foregut cysts (10.3%), and pleuropericardial cysts (6.6%). In children, combined series totaling 718 patients demonstrated that neurogenic tumors were most common (41.6%), followed by GCTs (13.5%), foregut cysts (13.4%), lymphomas (13.4%), angiomas and lymphangiomas (6.1%), and thymic tumors or cysts (4.9%).[2] In general, the incidence of anterior lesions is higher in adults, and posterior lesions predominate in children. Further, the incidence of malignancy differs among primary mediastinal masses arising in each of the different compartments. In one of the largest series, Davis and colleagues demonstrated that among patients with mediastinal masses, malignancy was found in 59% of those in the anterior mediastinum, 29% of those in the middle mediastinum, and 16% of those in the posterior mediastinum.[3]

As discussed below, mediastinal masses are often incidentally detected on imaging studies obtained for other reasons. An estimate of the frequency of "incidental" mediastinal masses has been provided by a large lung cancer screening study. In 9263 individuals at high risk for lung cancer who underwent a computed tomography (CT) screening examination, a mediastinal mass was found in 71 patients (0.77%). The majority of these incidental masses were thymic and most were treated successfully with a conservative approach.[4]

SIGNS AND SYMPTOMS

Signs and symptoms of mediastinal tumors can vary widely at presentation and usually offer only nonspecific clues to the nature of the underlying disease process. While over 60% of patients do present with symptoms, it is also quite common for an asymptomatic mass to be detected on a routine screening examination. Most asymptomatic patients with a mediastinal mass will have a benign lesion, while the majority of patients that present with symptoms have an underlying malignant process. In Davis' series of 400 patients with mediastinal masses, 83% of the lesions found on routine chest radiographs were benign, whereas 57% of lesions in symptomatic patients were malignant.[3]

The presenting symptoms of a mediastinal mass vary widely and are influenced by anatomic location and the presence of malignant invasion or mass effect. Dyspnea or cough may result from airway invasion or abutment, tamponade, or the presence of a pleural effusion. Dysphagia is seen with esophageal compression, and chest pain may represent chest wall or neural invasion or abutment. Invasion of the airway may result in hemoptysis, invasion of the recurrent laryngeal nerve may present as hoarseness, and invasion of the superior vena cava can present with facial swelling and superior vena cava syndrome. Constitutional symptoms such as fever

and night sweats are often associated with mediastinal lymphoma, and myasthenic symptoms may be suggestive of thymoma.

ANTERIOR MEDIASTINAL NEOPLASMS

Neoplasms of the anterior mediastinum are discussed below.

■ EVALUATION OF THE ANTERIOR MEDIASTINAL MASS

In a patient with an anterior mediastinal mass, it is often possible to make a strong provisional diagnosis based upon clinical evaluation and imaging data.[5] Whereas specific workup for common anterior mediastinal mass lesions is described in the following sections, some general principles are reviewed here.

History and Examination

In an individual younger than 40 years, lymphoma is the most likely diagnosis and the presence of International Working Formulation (IWF) group B symptoms or palpable lymphadenopathy further increases the level of suspicion. In contrast to lymphoma, thymic neoplasms are very uncommon before the fourth decade of life. The presence of a paraneoplastic syndrome associated with an anterior mediastinal mass essentially clinches the diagnosis of thymoma. The majority of GCTs (benign or malignant) are diagnosed in the second or third decade of life. Whereas patients with a thymoma often have an indolent presentation, patients with a lymphoma or a malignant GCT often have a rapid onset of symptoms. Workup must include examination of the testes to rule out a testicular primary GCT.

Serum Studies

Autoantibodies to the acetylcholine receptor (anti-AChR) should be measured as their presence is virtually diagnostic of myasthenia gravis, even if the patient is without obvious symptoms. Characteristic serum tumor markers such as beta-human chorionic gonadotropin (β-HCG) and alpha-fetoprotein (AFP) are elaborated by most malignant GCTs but not by benign GCTs.[6] Elevated

TABLE 82-1 Structures and Primary Neoplasms in the Three-Compartment Model of the Mediastinum

Structures	Common Lesions	Rare Lesions
Anterior compartment		
Thymus	Thymomas	Thymic carcinoma; benign thymic tumors
Fat and lymphatics	Lymphomas	Vascular lesions
Internal mammary vessels	Germ cell tumors	Mesenchymal tumors
Thyroid (occasional)		Endocrine tumors (e.g., ectopic parathyroid, goiter)
		Castleman's disease
Middle compartment		
Heart	Foregut cysts	Pleural and pericardial cysts
Pericardium	Lymphoma	Castleman disease
Aorta		
Superior and inferior vena cava		
Trachea and main bronchi		
Lymph nodes		
Posterior compartment		
Descending aorta	Nerve sheath tumors	Vascular tumors
Esophagus	Neurogenic tumors	Mesenchymal tumors
Vagus nerves		Lymphatic lesions
Thoracic duct		Neurenteric cysts
Sympathetic chain		
Lymph nodes		

serum LDH is suggestive of lymphoma. Evidence of hypo- or hyperthyroidism, as measured by thyroid-stimulating hormone (TSH) and thyroid hormones (T3 and T4), suggests mediastinal goiter, though goiter is not invariably associated with abnormal hormone production.

Imaging Studies

CT provides valuable data about the anatomic location of the tumor, its physical characteristics (fatty, solid, or cystic) and degree of invasiveness. Occasionally, magnetic resonance imaging (MRI) provides useful additional information concerning obliteration of normal tissue planes and vascular invasion. Although imaging is most often not diagnostic of the specific type of tumor, some imaging features can be pathognomonic. For example, the finding of a well-encapsulated lesion in the anterior mediastinum containing several tissue elements – calcium, fat, fluid – is essentially diagnostic of a mature teratoma.

Need for Biopsy

The decision whether to perform a biopsy of an anterior mediastinal mass is not simple. Routine biopsy should not be endorsed, not only because of the unnecessary morbidity and costs associated with the procedure, but also because of the potential risk of tumor spread. Well-encapsulated lesions believed not to be lymphoma are often resected for both diagnosis and treatment, without a preceding biopsy. Conversely, for locally invasive or frankly unresectable anterior mediastinal masses, a biopsy should often be performed as such lesions may represent lymphoma, aggressive thymomas that could benefit from neoadjuvant treatment, malignant GCTs, or other rare diseases.

Once a clinical diagnosis of thymoma is made, the goal is to proceed directly to resection without preliminary biopsy, as these tumors have a predilection for local recurrence once the thymic capsule has been violated. When palpable peripheral nodes are present, the diagnosis of lymphoma is often most easily obtained by excision of one of them. Patients with suspected lymphoma and an isolated anterior mediastinal mass should undergo either a CT-guided core needle biopsy or a Chamberlain procedure (anterior mediastinotomy) for diagnosis, depending upon the pathologist's level of comfort in classifying lymphoma on the basis of specimen size at one's institution. Resection of lymphoma is not indicated and can almost always be avoided by performing a diagnostic biopsy when lymphoma is suspected. Surgical extirpation is the mainstay of treatment for mature GCTs, and biopsy is not indicated for these lesions if they have the characteristic imaging characteristics. Malignant GCTs, on the other hand, are treated primarily with chemotherapy, radiotherapy, or both. In situations where these lesions are suspected but tumor markers (AFP and β-HCG) are not markedly elevated, biopsy should be performed.

■ THYMOMA

Clinical assessment and management of thymoma are discussed below.

Presentation

The age distribution of patients with a thymoma is represented by a broad peak between approximately 35 and 70 years with a median age of about 54 years.[7] The ratio of men to women with this disease is about equal. Approximately one-third of patients with a thymoma will not report significant symptoms and an additional one-third will report symptoms of cough, dyspnea, or chest pain reflective of compression or invasion of adjacent structures. Patients may also present with symptoms of an associated paraneoplastic syndrome. Forty to 45% of patients with a thymoma will present with myasthenia gravis and, conversely, 5% to 15% of patients with myasthenia gravis will be found to have a thymoma.[8,9] Notably, myasthenia gravis can develop some time after diagnosis of thymoma, and occasionally following resection, highlighting the necessity of complete resection of both the thymoma and the entire thymus gland. Thymomas may also be associated with pure red cell aplasia, agammaglobulinemia, systemic lupus erythematosus, and other autoimmune disorders.

Diagnosis

A clinical diagnosis of thymoma is often sufficient to proceed to resection without biopsy. The presence of a paraneoplastic syndrome associated with an anterior mediastinal mass essentially clinches the diagnosis of thymoma. Autoantibodies to the acetylcholine (Ach) receptor should be measured, and their presence is virtually diagnostic of myasthenia gravis and also clinches the diagnosis of thymoma. Interestingly, Ach receptor antibodies are demonstrated in approximately 60% of patients who have thymoma without neurologic symptoms.[10] It is not necessary to obtain a preoperative tissue biopsy for a small, resectable anterior mediastinal tumor whose radiographic features are typical of thymoma in an asymptomatic patient. Although there are no pathognomonic imaging features that differentiate thymoma from several other mediastinal tumors, in a patient without B-symptoms to suggest lymphoma, the diagnosis of thymoma is strongly suggested by a CT scan demonstrating a well-circumscribed, solid anterior mediastinal mass without

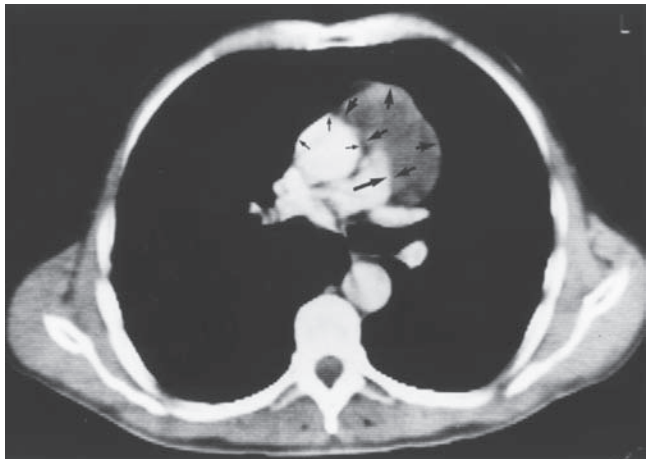

Figure 82-2 Thymoma. Axial section from a CT scan demonstrates a 4-cm mass abutting the thoracic aorta without any evidence of invasion *(arrows)*.

the low-density areas that would suggest the cystic and fatty components of a teratoma (Fig. 82-2). Most thymomas are solid tumors, but up to a third may have components that are necrotic, hemorrhagic, or cystic. Several small studies have investigated the utility of PET in evaluation of thymoma and have suggested that FDG uptake is greater in thymoma than in thymic hyperplasia, and that thymic carcinomas demonstrate the highest FDG avidity.[11] However, PET is not required to stage a thymoma preoperatively when it appears noninvasive/nonmalignant on CT.

Once a diagnosis of thymoma is suggested, the goal is to proceed directly to resection without preliminary biopsy, as these tumors have a predilection for local recurrence once the capsule has been violated. A definitive tissue diagnosis is needed primarily when a presumed thymoma is so advanced that it would be best treated either nonoperatively or with neoadjuvant chemotherapy or chemoradiotherapy, or in instances where there is a strong possibility of lymphoma. If required, the pathologic diagnosis of thymoma can usually be achieved by image-guided core needle biopsy, or if that fails, through open surgical biopsy. The success rate of needle biopsy in establishing the diagnosis of thymoma is approximately 60% and the success rate of surgical biopsy is approximately 90%.[12] In our opinion, video-assisted thoracoscopic surgical (VATS) biopsy of an anterior mediastinal mass in which thymoma is in the differential should be assiduously avoided, due to the great potential of spread into the pleural space. If core needle biopsy fails and a diagnosis is required, a Chamberlain procedure (anterior mediastinotomy) should be performed.

All patients with suspected thymoma should be evaluated for myasthenia gravis. This evaluation usually begins with a careful assessment for the presence of ocular, bulbar, and limb muscle weakness. The diagnosis of myasthenia gravis in a patient with a characteristic history and physical examination requires two positive confirmatory tests among pharmacologic (Tensilon test), serologic (anti-AChR antibodies), and electrodiagnostic (EMG) studies. If there is any suggestion of myasthenia gravis on initial presentation, the patient should undergo preoperative evaluation by a neurologist. Medical optimization prior to surgery using some combination of cholinesterase inhibitors, intravenous immunoglobulin, plasmapheresis, and occasionally steroids, can help avoid respiratory failure in the perioperative period. Other paraneoplastic syndromes are also associated with thymoma, including hypogammaglobulinemia in 10% of patients, and pure red cell aplasia in 5% of patients.

TABLE 82-2 Staging of Thymic Malignancies

Stage	Description	10-y Survival (%)
I	Encapsulated tumors without gross or microscopic invasion	90 (75–100)
II	Transcapsular invasion	75 (42–100)
IIA	Microscopic invasion	
IIB	Macroscopic invasion	
III	Macroscopic invasion of surrounding tissues (lung, pericardium, vena cava, or aorta)	56 (26–84)
IVA	Disseminated disease within the chest	38 (22–47)
IVB	Distant metastases	Unknown

Source: Data from Detterbeck FC. Evaluation and treatment of stage I and II thymoma. J Thorac Oncol. 2010;5(10 Suppl 4):S318–S322.

Staging

The most widely utilized classification scheme for thymoma was proposed by Masaoka in 1981 and is based on the local invasiveness of the tumor (Table 82-2).[13] The Masaoka classification system has prognostic value[14] and permits stratification for adjuvant therapy. One difficulty with this system is that it is based upon the findings at the time of surgical resection, thus precluding its use for triaging some patients to neoadjuvant therapy.

Thymomas are also classified histologically. A thymoma is composed of a mixture of thymic epithelial cells with bland features as well as lymphocytes in various stages of development. The neoplastic cell of origin is believed to be the thymic epithelial cell and not the lymphocyte,[15] and thymomas appear histologically benign even when they are invasive. In 1985, Müller-Hermelink proposed a novel histologic classification system to separate all thymomas into categories of cortical, medullary, or mixed, based on the histologic appearance of the thymic epithelial cells.[16] Cortical thymomas are composed of large, round, or polygonal epithelial cells and medullary thymomas contain smaller, spindle cell–shaped epithelial cells with irregular nuclei. This histologic classification system was found to reliably predict tumor behavior and prognosis, with medullary thymomas behaving in an essentially benign fashion and cortical thymomas more frequently demonstrating evidence of invasive and malignant disease.[17] Later studies have demonstrated that both the Masaoka staging and Müller-Hermelink grading systems are strong and independent prognostic indicators of both overall as well as disease-free survival.[14,18,19]

More recently, the World Health Organization (WHO) proposed a histologic classification system (resembling the Müller-Hermelink system) that has become the histologic grading system of choice in the current era and is useful to distinguish between thymoma, thymic carcinoma, and thymic carcinoids (Table 82-3).[20] It is now accepted that the Masaoka staging criteria used in combination with the WHO grading criteria provide the most accurate prognostic information for survival and recurrence in thymoma.[21,22]

Treatment

Surgical resection is the mainstay of treatment of Masaoka stage I–III thymoma while the treatment of stage IVa thymoma is controversial. Resection of even a small, stage I thymoma without myasthenia gravis should include removal of the entire thymus en bloc along with the tumor because (1) myasthenia gravis can potentially develop postoperatively (and total thymectomy is an appropriate treatment for myasthenia gravis), and (2) a second focus of tumor within the thymus is occasionally found. The gold standard surgical approach to thymoma remains median sternotomy but minimally

TABLE 82-3 World Health Organization (WHO) Histologic Classification System

Type	Description
A	Tumor in which foci having features of type A thymoma are admixed with foci rich in lymphocytes
B1	Tumor resembles normal functional thymus; combines large expanses having an appearance practically indistinguishable from that of normal thymic cortex with areas resembling thymic medulla
B2	Tumor in which neoplastic epithelial component appears as scattered plump cells with vesicular nuclei and distinct nucleoli among a heavy population of lymphocytes; perivascular spaces are common and sometimes very prominent; a perivascular arrangement of tumor cells resulting in a palisading effect may be seen
B3	Thymoma predominantly composed of epithelial cells having a round or polygonal shape and exhibiting no or mild atypia; they are admixed with a mild component of lymphocytes, resulting in a sheet-like growth of the neoplastic epithelial cells
C	Thymic tumor exhibiting clear-cut cytologic atypia and a set of cytoarchitectural features no longer specific to the thymus, but rather analogous to those seen in carcinomas of the other organs; type C thymomas lack immature lymphocytes; whatever lymphocytes may be present are mature and usually admixed with plasma cells

invasive approaches including VATS and robotic techniques are likely equally effective for smaller tumors in experienced hands. Certainly if there is suspicion of invasion into adjacent structures, sternotomy is the preferred approach as it is critical that the involved portions of these structures are resected en bloc with the thymus gland and tumor. This can require resection of lung, pericardium, innominate vein, superior vena cava, phrenic nerve, and even aorta.

Stage I thymomas are treated adequately with complete resection alone. Although in the past adjuvant radiotherapy was frequently administered to patients with stage II thymoma, accumulated data suggest that adjuvant radiotherapy is of little additional benefit following complete resection.[23–25] Thymoma is a radiosensitive tumor however, and for patients who have incomplete resection, postoperative radiotherapy is recommended. For patients with advanced disease (stage III or IV thymoma), chemotherapy is recommended and is often followed by radiation for patients with incompletely resected disease. For thymoma that is initially considered unresectable, induction chemotherapy followed by surgical resection can result in favorable rates of overall and disease-free survival.[26,27] Further, surgical resection plays an important role in the management of recurrences and complete resection of a recurrence can result in improved overall survival.[28]

Outcome

Although thymomas are generally indolent tumors, they should be considered a malignant neoplasm as they have the ability to metastasize to the pleura, pericardium, and (less commonly) distant sites. One study reported that 4% of 207 patients evaluated for surgical resection of a thymoma had lymph node or distant metastases at presentation, and another 16% developed nodal or distant metastases at some point in their course.[29] Others have shown that distant metastases can occur with any stage or histology.[30,31] Detterbeck reviewed overall survival in compiled surgical series of at least 100 patients (2437 patients total) and demonstrated favorable 10-year survival rates of approximately 90% and 70% for stage I and II, and 55% and 35% for stage III and IVa thymoma, respectively.[12] Completeness of resection is the most important predictor of recurrence and survival; significantly better survival is demonstrated when resection is complete in all large studies examining this issue.

Locoregional recurrence is far more common than distant recurrence, and about half of all local recurrences involve the pleural space or the lung. The average recurrence rate for stage I tumors is 3% but increases to 11% and 30% for stage II and III tumors, respectively.[7] The relatively indolent nature of a thymoma is reflected by an average time to recurrence of 5 years, with rare recurrences seen as far out as 20 years. The presence of myasthenia gravis is no longer considered a negative prognostic factor, as it was in older studies, and over 30% of patients with myasthenia and thymoma ultimately achieve a complete remission of the myasthenia following thymectomy.[32] Similarly, approximately one-third of patients with associated red cell aplasia experience improvement following thymectomy. In contrast, hypogammaglobulinemia associated with thymoma generally does not respond to thymectomy.

■ THYMIC CARCINOMA

Clinical assessment and management of thymic carcinoma are discussed below.

Presentation

Thymic carcinomas (WHO type C) are highly aggressive neoplasms of thymic epithelial origin and are very different from thymomas (WHO types A, AB, and B). Thymic carcinomas are rare, constituting approximately 10% of all thymic neoplasms.[28] They can occur at any age but are most frequently observed in persons between 30 and 60 years of age. The majority of patients with thymic carcinoma present with symptoms of local invasion or compression such as cough, chest pain, or superior vena cava syndrome. Pericardial and/or pleural effusions are often seen. Thymic carcinoma is typically not associated with myasthenia gravis. Unlike thymomas, thymic carcinomas frequently metastasize to lymph nodes and distant sites. Eighty percent of patients have local invasion of contiguous mediastinal structures at the time of presentation, and 40% of cases have metastatic spread to bones, lung, pleura, liver, or lymph nodes.[33] Over half of the patients will present with locally advanced, although potentially resectable, disease.[34,35]

Diagnosis

Thymic carcinomas can be distinguished from thymomas based on their malignant histologic features and different immunohistochemical and genetic characteristics. Imaging studies often reveal an invasive presentation, and for this reason, percutaneous needle biopsy should generally be undertaken.

Staging

The Masaoka staging system and WHO histologic classification system are used to stage thymic carcinoma. In the WHO system, thymic carcinomas are type C lesions. These tumors are distinct from thymoma and should not be considered in the same light as a thymoma with local invasion. Histologically, thymic carcinoma contains a number of different cell types, but they are unified by their unequivocal malignant appearance on light microscopy. Division of patients into those with low-grade histology and those with high-grade histology has prognostic significance. The median survival for patients with low-grade histology (squamous, mucoepidermoid, and basiloid thymic carcinomas) is 29 months, as compared to 11 months for patients with high-grade histology (sarcomatoid and clear cell thymic carcinoma).[36]

Treatment

While there is no standard-of-care approach to patients with thymic carcinoma, a multidisciplinary strategy is recommended. The prevailing practice is that patients with stage I–III and some IVa patients should be treated with some combination of surgical resection plus chemotherapy and/or radiotherapy.[37] Although thymic carcinomas generally respond poorly to chemotherapy, carboplatin and paclitaxel are recommended because this combination has shown the highest response rates in clinical trials. For the rare thymic carcinoma patients with clearly resectable disease, surgery is considered the primary therapeutic modality. For those with disease thought to be initially unresectable or disease that appears clearly to be invading one or more surrounding organs or major vascular structures, neoadjuvant chemotherapy and/or radiation may improve operability and permit subsequent resection.[36,38,39]

Outcome

The prognosis for patients with thymic carcinoma is much worse than for patients with thymoma, with 5-year overall survival rates for thymic carcinomas in the range of 30% to 50%.[35,40,41] A more recent clinicopathologic study of 65 cases of primary thymic carcinoma, however, reported a more favorable 5-year survival rate of 66%. In this study, 63% of the patients received additional therapy in the form of chemotherapy or radiation.[34] Similar to thymoma, patients with completely resected thymic carcinomas have longer overall and progression-free survival rates than those who undergo incomplete resection or are unresectable. In a recent series of 60 patients with thymic carcinoma (40 treated surgically), completely resected lesions and early Masaoka stages are the most important factors associated with successful disease control and long-term survival. Five-year survival of 85% was obtained after complete resection, compared with 29% in those with incomplete resection.[42] In another series of 16 patients, a multimodality approach that included surgery resulted in complete resection in 88% of the patients and a mean survival of 4.2 years for the entire group.[43]

■ OTHER THYMIC NEOPLASMS

Clinical assessment and management of a variety of other thymic neoplasms are considered below.

Thymic Hyperplasia

Thymic hyperplasia is a term used to describe either a histologically normal thymus that is enlarged for the patient's age, or a thymus that histologically shows cellular hyperplasia, which is also generally associated with gross enlargement of the gland. This condition can present as a spectrum of disease ranging from respiratory compromise due to impingement on the airway (almost always in the pediatric population) to the more common situation of an incidental finding on an unrelated imaging study. Many of the thymus glands removed from patients with myasthenia gravis demonstrate "true thymic hyperplasia" (cellular hyperplasia), and this is thought to contribute to the pathogenesis of myasthenia gravis. In addition to myasthenia gravis, thymic hyperplasia can be seen following severe or chronic illness, the so-called "thymic rebound." Steroid use will also generally lead to substantial thymic hyperplasia. Practically speaking, when a diffusely enlarged thymus without a discrete mass is discovered in an otherwise asymptomatic patient, this can be followed expectantly, as these glands have a negligible incidence of harboring significant thymic disease.[44]

Thymolipoma

Thymolipomas are distinguished from simple mediastinal lipomas by their location within the thymic capsule. Histologically, these neoplasms composed of mature adipocytes as well as normal thymic components.[45] Thymolipomas, like thymomas, can be associated with thymic paraneoplastic syndromes such as red cell aplasia, hypogammaglobulinemia, and aplastic anemia. These lesions can grow to significant size and result in compressive and obstructive symptoms. The treatment of thyolipomas is surgical excision.

Thymic Carcinoid

Thymic carcinoids are very rare neoplasms of the thymus that are classified as neuroendocrine carcinomas. They have a strong association with endocrinopathies such as multiple endocrine neoplasia type I. Unlike other carcinoids, they rarely present with carcinoid syndrome, but many do secrete ACTH resulting in Cushing syndrome. Thymic carcinoids tend to be very aggressive tumors. Upon presentation, the majority of thymic carcinoids are locally invasive and approximately half of all patients will have metastatic disease.[46] Surgery is the therapy of choice for resectable neuroendocrine carcinomas of the thymus and should include aggressive local resection. The prognosis is poor despite aggressive therapy, and most patients present with local recurrence or metastases within 5 years of surgery and will die within 10 years.[47]

■ GERM CELL TUMORS

GCTs comprise a group of neoplasms that arise from gonadal tissue. The anterior mediastinum is the most common location for occurrence of extragonadal GCTs. GCTs account for 15% of all anterior mediastinal masses in adults (85% of which are benign mature GCTs) and 25% of anterior mediastinal masses in children (essentially all of which are benign).[48] GCTs typically occur in young adults in the second to fourth decades of life with no gender predilection.

While previously thought to be metastatic from a gonadal primary, it is now accepted that these neoplasms are primary mediastinal tumors. The precise origin of the germ cells that form these tumors in sites heterotopic to the gonads is still not completely clear, but this may result from aberrant migration of germ cells during embryonic development or as a part of normal embryogenesis. Because primordial germ cells are undifferentiated cells from which a variety of different tumors can arise, there have been numerous overlapping and sometimes confusing classification and grading systems proposed for these tumors. Even more confusing for classifying GCTs is that it is common to see two or more GCT histologies arising from within a single mass. Based on the need for standard classification, investigators from the Armed Forces Institute of Pathology developed a reproducible histologic classification system (Table 82-4) and clinical staging system (Table 82-5) based on review of more than 300 cases.[49]

TABLE 82-4 Classification of Mediastinal Germ Cell Tumors (GCTs)

Mature teratoma
Immature teratoma
Teratomas with malignant component: Type I: with an associated GCT (seminoma, etc.) Type II: with another epithelial malignancy (squamous, adenocarcinoma, etc.) Type III: with sarcomatous component (rhabdomyosarcoma, osteosarcoma, etc.) Type IV: a combination of any of the above
Seminoma
Yolk sac tumor (endodermal sinus tumor)
Embryonal carcinoma
Choriocarcinoma
Combined GCT without teratomatous component

TABLE 82-5 Clinical Staging of Mediastinal Germ Tumors

Stage	Characteristics
I	Well-circumscribed tumor with or without focal adhesions to the pleura or pericardium but without microscopic evidence of invasion into adjacent structures
II	Tumor confined to the mediastinum with macroscopic and/or microscopic evidence of infiltration into adjacent structures (pleura, pericardium, great vessels)
III	Tumor with metastases
IIIA	With metastases to intrathoracic organs (lymph nodes, lung, etc.)
IIIB	With extrathoracic metastases

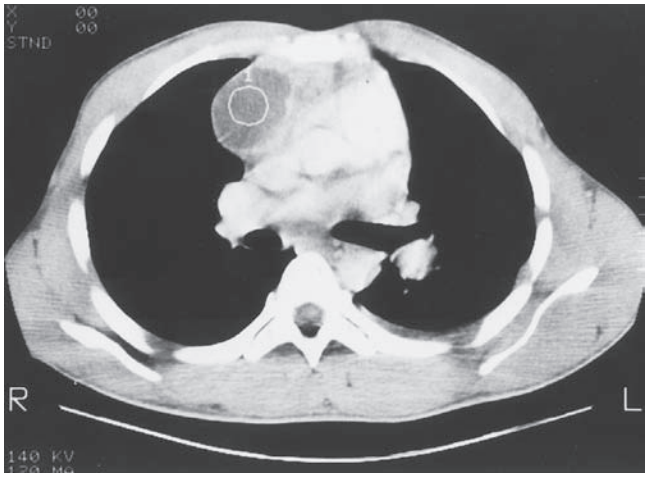

Figure 82-3 Mediastinal seminoma. Axial section from a CT reveals a homogeneous mass within the anterior mediastinum.

Mediastinal GCTs are composed of benign and malignant neoplasms that for descriptive purposes can be simplified into three categories. Benign mediastinal GCTs are composed primarily of benign mediastinal teratomas, which account for 60% of all mediastinal GCTs. Malignant tumors are divided into seminomatous GCTs, which account for 40% of malignant mediastinal GCTs, and nonseminomatous GCTs (NSGCTs) which account for 60% of malignant mediastinal germ tumors. NSGCTs include embryonal cell carcinomas, choriocarcinomas, yolk sac tumors, and malignant teratomas.

Mediastinal Teratomas

Teratomas are defined by the presence of tissue from more than one of the three primitive germ cell layers. Mature (benign) teratomas are composed of well-differentiated elements such as fat, muscle, and cartilage (mesoderm); hair, skin, and teeth (ectoderm); and intestinal tissue (endoderm). Mature teratomas can be symptomatic or asymptomatic upon presentation. Symptoms include chest pain, dyspnea, cough, or fever (if they become infected). Occasionally the tumor may erode into an airway and a patient may cough up hair (trichophytosis) or oily sebum that is pathognomonic of a benign mediastinal teratoma.

CT with contrast is the diagnostic procedure of choice and usually demonstrates a thick-walled cystic mass. Calcification is often present and when intermixed with areas of fat and/or fluid density, the diagnosis is made with a high degree of certainty.[50] Benign teratomas can also be primarily solid, and in these cases the diagnosis is more challenging. Tumor markers such as β-HCG and AFP should be measured and will not be elevated in benign teratoma. Needle biopsy of a mass that is highly suspected to be a benign teratoma based on imaging is not necessary. Such a patient should go directly to surgical resection.

The treatment for benign GCTs is total resection before the development of complications. Even benign teratomas are frequently adherent to adjacent structures such as lung, blood vessels, and pericardium; en bloc resection of involved structures is sometimes required. Radiation and chemotherapy play no therapeutic role, unless concurrent malignant disease is present. Outcome after resection of a benign teratoma is excellent, on the order of 93% 10-year survival.[51] Occasionally, teratomas will contain less well-differentiated tissues and behave more aggressively, resembling malignant teratomas (see below).

Malignant Seminomatous Germ Cell Tumors

Malignant GCTs, both seminomatous and nonseminomatous, are almost exclusively diseases of men. Seminoma usually presents in men during the third or fourth decade of life as a large anterior mediastinal mass, although it rarely occurs in the middle and posterior mediastinum. Most patients are symptomatic upon presentation; symptoms are variable and most commonly include chest pain and dyspnea.[52]

Careful bimanual examination and ultrasound of the testicles should be performed to rule out a testicular primary tumor, and a thorough staging workup should be performed including CT scan of the abdomen along with the chest. Measurement of serum tumor markers is critical to the diagnosis and follow-up of patients with mediastinal seminomas. Patients with mediastinal seminomas will demonstrate mild elevation of β-HCG (<100 mIU/mL), whereas higher levels than this should raise the suspicion of a mixed tumor or a NSGCT.[53] An elevated AFP level excludes the diagnosis of seminomatous tumor and defines the tumor as a NSGCT or mixed GCT. Chest CT is the most useful imaging modality for a seminoma, which typically appears as a large, bulky homogeneous mass that may obscure tissue planes or invade adjacent structures, and is often surrounded by bulky lymphadenopathy (Fig. 82-3). These tumors are frequently FDG-avid and PET may be useful in monitoring response to therapy. A biopsy is usually necessary to secure the diagnosis and percutaneous core needle biopsy is the preferred initial approach, saving open surgical biopsies for cases where percutaneous sampling is inconclusive.

Sixty to 70% of patients with mediastinal seminoma will present with metastatic disease, primarily to intrathoracic organs, although distant metastases can also be found. The treatment of primary mediastinal seminomatous tumors has evolved over the past 20 years from a primarily surgical approach to a chiefly nonsurgical approach. It has become clear that the first line of treatment in all cases of mediastinal seminoma should be chemotherapy, and 5-year survival rates upward 90% are achieved with cisplatin-based chemotherapy regimens.[54,55] As is the case with testicular seminomas, pure mediastinal germ cell seminomas are radiosensitive. Whereas radiotherapy alone may achieve complete remission in only about 65% of patients,[56] the addition of radiotherapy to chemotherapy appears to enhance the benefit of chemotherapy alone. The role of surgical resection in this disease remains controversial. Surgery is generally reserved for patients with residual mediastinal masses following chemotherapy and radiation when residual active disease is a concern (e.g., with persistently elevated or rising markers, or increasing FDG avidity on PET). The benefits of surgical resection in this setting would be to document if there is residual malignant seminomatous tumor (as opposed to necrotic debris) and to completely resect it; in addition, occasional patients are identified who

have a previously unrecognized nonseminomatous malignant component of the tumor.

Nonseminomatous Germ Cell Tumors

NSGCTs are malignant tumors that are seen almost exclusively in men and there is a particular propensity for men with Klinefelter syndrome to develop these tumors. A variety of nonseminomatous histologies have been categorized and their incidence is best gathered from the largest series of 229 cases.[49] NSGCTs are composed of teratocarcinoma (41%), endodermal sinus (yolk sac) tumor (35%), choriocarcinoma (7%), embryonal carcinoma (6%), and mixed histologies (11%). Further, non–germ cell components including sarcoma or epithelial carcinoma were found in 58% of teratocarcinomas.

Mediastinal NSGCTs are characterized by rapid local growth and early distant metastases, and patients often present with advanced disease. Most patients will have symptoms caused by compression or invasion of adjacent structures, and constitutional symptoms including weight loss, fever, and weakness are more common in patients with NSGCT compared with pure seminoma. Like seminoma, sites of metastases in NSGCT include the lung, pleura, lymph nodes, and liver; 85% to 95% of patients with an NSGCT will have at least one site of metastases.[57,58]

Workup should include CT of the chest and abdomen and measurement of serum tumor markers. Chest CT will typically reveal a large, irregular anterior mediastinal mass with poorly defined margins and multiple areas of necrosis and hemorrhage (Fig. 82-4). Unlike seminoma, over 90% of patients with NSGCT will have an elevation of either β-HCG (30%–35% of patients) or AFP (80% of patients), and an AFP level greater than 500 ng/mL is essentially diagnostic of NSGCT.[53,59] NSGCTs, especially those with yolk sac histology, are associated with a variety of hematologic malignancies including leukemia, and these occur independently of the chemotherapy used to treat the tumor.[60]

As most patients present with bulky or metastatic disease, surgical resection is not the first line of treatment. Historically, patients with NSGCT had an exceedingly poor prognosis, but this has dramatically improved with the implementation of intensive cisplatin-based chemotherapy protocols. A summary of studies of patients treated with first-line cisplatin-based combination chemotherapy

C

Figure 82-4 Nonseminomatous germ cell tumor. A 19-year-old male presented with a 1-month history of fever, heaviness in the chest, and cough. Examination revealed a tall, thin male with dystrophic testes (habitus consistent with Klinefelter syndrome). Serum AFP was 32,000 and β-HCG was 25,000. **A.** PA radiograph of the chest reveals a large mediastinal mass projecting into the right hemithorax. **B.** Axial section from a CT at the level of the diaphragm demonstrates an inhomogeneous mass; diaphragmatic invasion could not be assessed. **C.** Sagittal view of an MRI demonstrates that the mass is contained above the diaphragm. Biopsy revealed embryonal cell carcinoma.

regimens showed an overall long-term survival rate of 42%.[61] After completion of chemotherapy, patients should be restaged with a CT of the chest and abdomen and serum tumor markers should be remeasured. The majority of patients will be found to have residual masses or radiographic abnormalities after completing chemotherapy. Regardless of whether tumor markers are elevated or not, these patients should undergo surgical resection of residual masses if technically feasible because salvage chemotherapy is usually ineffective,[62] and surgical resection is curative in a substantial portion of patients.[63] In addition, occasional patients will be found to have a previously unrecognized mature (benign) teratoma component, which can only be cured by resection.

LYMPHOMA

Both Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL) can present as anterior mediastinal masses. HL accounts for approximately 50% to 70% of mediastinal lymphomas. The three most common types of lymphoma found in the mediastinum are nodular sclerosing HL, large cell lymphoma, and lymphoblastic lymphoma.[64] In general, these are systemic diseases that also involve the mediastinum, although some patients do present with disease limited to the mediastinum alone. Due to the generally widespread nature of these diseases, treatment is centered on systemic chemotherapy and radiation is the primary modality used for local control. Surgery is not typically utilized as a therapeutic option but may be required to make a histologic diagnosis.

Hodgkin Lymphoma

HL has a bimodal age distribution with its incidence peaking in young adulthood and again after 50 years of age. HL is divided into four subtypes: nodular sclerosing (most common), lymphocyte-rich, mixed cellularity, and lymphocyte-depleted. Most patients present with asymptomatic lymphadenopathy, but up to 25% of patients will experience B symptoms consisting of fever, night sweats, and weight loss.[65] Over half of all patients with HL will have involvement of the mediastinum, almost always in the anterior mediastinum or involving paratracheal lymph nodes (Fig. 82-5). Suspicion for HL warrants a tissue biopsy and the presence of Reed–Sternberg cells is pathognomonic. Because the tumors tend to be quite fibrotic, with only scattered malignant cells, surgical biopsy is often required to establish a diagnosis—either by cervical mediastinoscopy (for paratracheal nodes) or by anterior mediastinotomy (for anterior mediastinal masses). PET generally demonstrates high FDG avidity in lymphomas, and therefore PET/CT may be useful in guiding sites for biopsy. The Ann Arbor staging system (Table 82-6) is still widely used for staging HL and invasive staging (laparotomy and splenectomy) has fallen out of favor.

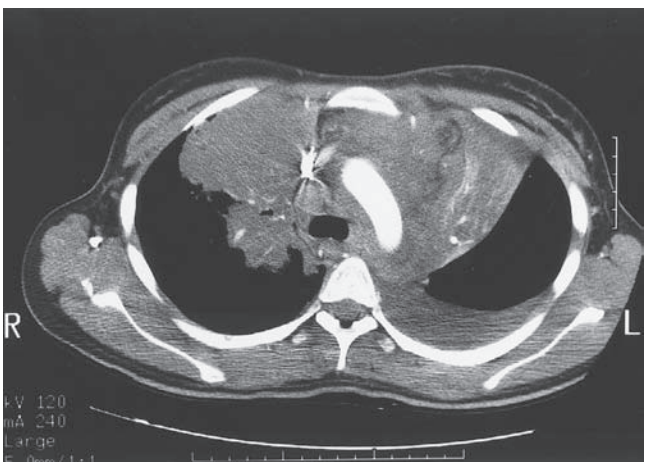

Figure 82-5 Hodgkin Disease. Axial section from a CT shows a bulky mediastinal mass and pleural effusion.

TABLE 82-6 Ann Arbor Staging System with Cotswolds Modification For Hodgkin Disease

Stage	Characteristics
I	Involvement of one lymph node region or lymphoid structure
II	Two or more lymph node regions on the same side of the diaphragm
III	Lymph nodes on both sides of the diaphragm
IV	Involvement of extranodal sites
Modifications	
A	No symptoms
B	Fever, night sweats, weight loss >10% in 6 mo
X	Bulky disease (greater than 1/3 widening of the mediastinum or >10 cm diameter of nodal mass
E	Involvement of single, contiguous, or extranodal site

Treatment approaches to HL are separated into those for early-stage disease (stage I and II) and advanced stage disease (stage III and IV). Modern treatment protocols most often involve chemotherapy regimens combined with limited (involved field) radiation. Patients with advanced stage disease as well as patients with B symptoms are treated with chemotherapy regimens such as ABVD (adriamycin, bleomycin, vinblastine, dacarbazine). Radiation is sometimes additionally employed in cases of bulky disease and patients who relapse may benefit from a hematopoietic stem cell transplant. Cure rates are greater than 90% for stage I and II HL, 30% to 90% for stage IIIA, 60% to 70% for stage IIIB, and 50% to 60% for stage IV.[64,65]

Non-Hodgkin Lymphomas

NHL is a heterogeneous group of systemic diseases that are categorized into many classes and grades. Mediastinal tumor burden in NHL is more likely to be part of the generalized disease process than the main focus of disease, and only 20% of patients with NHL will have involvement of the mediastinum at the time of presentation. This disease is not limited to the anterior mediastinum and can occur in the middle and posterior mediastinal compartments. Of patients with primarily mediastinal disease, the majority will have either lymphoblastic lymphoma or large B-cell lymphoma. The mean age of presentation for these patients is between 28 and 35 years.

Lymphoblastic lymphomas are highly aggressive tumors, and invasive symptoms including cough, wheezing, dyspnea, and manifestations of superior vena cava syndrome, cardiac tamponade, or tracheal obstruction are common. The central nervous system, skin, and gonads may be involved and bone marrow involvement with blasts is relatively common.[64] Primary mediastinal B-cell lymphoma is composed histologically of large cells with expression of the B-cell–associated antigen CD20; immunohistochemistry and/or flow cytometry are critical to the diagnosis. Presentation with symptoms related to invasion or obstruction of adjacent structures is common, but there is less involvement of extrathoracic sites and bone marrow than in lymphoblastic lymphoma. Staging of NHL is also performed according to the Ann Arbor staging system, and CT scan of the chest, abdomen, and pelvis is the initial and often only necessary imaging (Fig. 82-6).

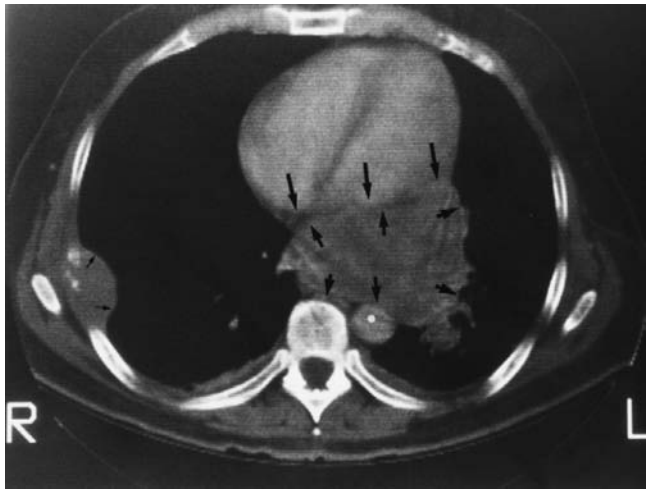

Figure 82-6 Non-Hodgkin lymphoma. Axial section from a CT demonstrates a large middle and posterior mediastinal mass with distant metastasis to a rib in the contralateral chest. This skip involvement is typical of non-Hodgkin lymphoma.

Treatment regimens for mediastinal NHL are dependent upon stage and histologic subtype. Due to its propensity to involve the bone marrow, lymphoblastic lymphoma commonly employs a treatment regimen similar to that for acute lymphoblastic leukemia, often including intrathecal chemotherapy and bone marrow transplantation. Patients with primary mediastinal B-cell lymphoma can be treated with conventional chemotherapy regimens, but high-dose chemotherapy and "involved field" radiotherapy are sometimes employed. In general, relapses in NHL are common and the long-term prognosis is worse than for HL.

■ OTHER ANTERIOR MEDIASTINAL NEOPLASMS

Other anterior mediastinal neoplasms include substernal thyroid and parathyroid adenoma.

Substernal Thyroid

Substernal and ectopic thyroid tissue can present as an anterior mediastinal mass and may involve the middle mediastinum, if the thyroid tissue descends more caudally into the paratracheal space. In the majority of cases, the substernal thyroid is a euthyroid goiter and an enlarged thyroid gland will be palpable in the neck. We have found that a noncontrast CT is the single most useful test in differentiating substernal thyroid from other mediastinal masses. Because of its iodine content, substernal thyroid tissue shows enhancement on a noncontrast CT scan and this usually confirms the diagnosis. Surgical resection is recommended, as needle biopsy cannot rule out malignancy in such a large lesion and substernal goiters will often cause symptoms of airway compression as they continue to grow. Nearly all substernal goiters can be removed by cervical incision.

Parathyroid Adenoma

The anterior mediastinum is the most common location for an ectopic parathyroid tumor. Often, ectopic parathyroid glands will present as persistent primary hyperparathyroidism after an unsuccessful neck exploration. Before proceeding with mediastinal exploration, localizing studies such as Technetium-99m-sestamibi scintigraphy and CT are recommended. MRI may be useful to reveal a well-defined mass, however they are usually small (<3 cm). The adenoma is typically embedded in the thymus gland. Surgical resection of the adenoma, typically requiring resection of the thymus itself, is curative. We find the surgical technique of transcervical thymectomy, performed via the neck with a retractor lifting the sternum anteriorly, is ideal for this disease process and can be performed on an outpatient basis.

MIDDLE MEDIASTINAL NEOPLASMS

Metastatic bronchogenic carcinoma is the most common etiology of middle mediastinal masses, as the mediastinal lymph nodes in the middle mediastinal compartment are a frequent site of lung cancer metastases. The most common primary masses of the middle mediastinum are lymphoma (described above) and benign cysts. Cysts comprise 12% to 20% of all primary mediastinal masses and are found chiefly in the middle compartment of the mediastinum. These cysts comprise congenital foregut cysts, bronchogenic cysts, neurenteric cysts, and pericardial cysts and are reviewed in Chapter 81.

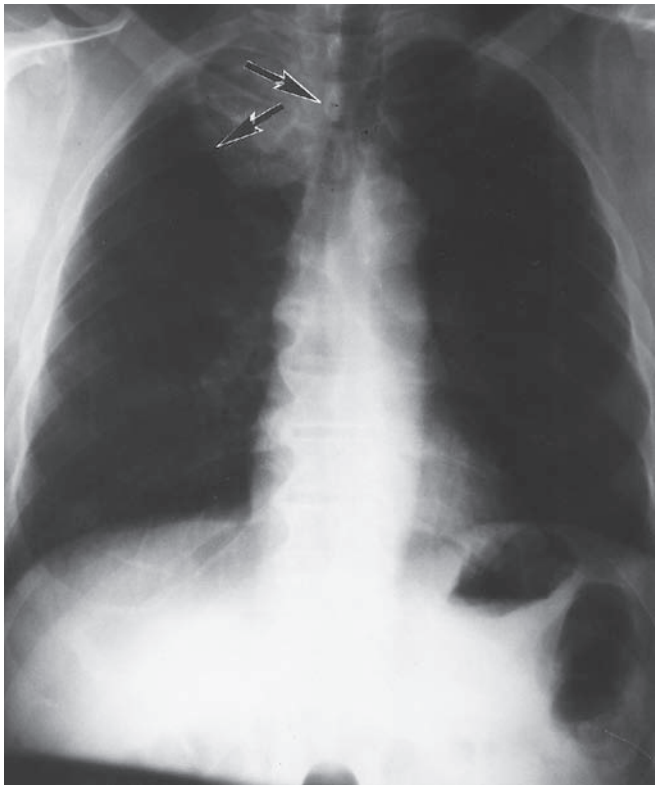
POSTERIOR MEDIASTINAL NEOPLASMS

Neurogenic tumors are the most common neoplasms of the posterior mediastinum, collectively representing 12% to 21% of all mediastinal masses and occurring almost exclusively (95%) in the posterior compartment.[66] Neurogenic tumors are categorized into three groups based on the neurogenic tissue of origin. Neoplasms arising from the nerve sheath include schwannoma, neurofibroma, and malignant nerve sheath tumors. Nerve sheath tumors are the most common neurogenic tumors found in the adult. Neoplasms arising from the sympathetic ganglion include ganglioneuroma, ganglioneuroblastoma, and neuroblastoma and these tumors are more commonly found in children. Neoplasms arising in parasympathetic ganglia include paraganglioma and chemodectoma, both of which occur in the posterior mediastinum and are exceedingly rare. Approximately 98% of neurogenic mediastinal tumors in adults are benign, whereas it is estimated that more than 50% of neurogenic tumors in children are malignant.

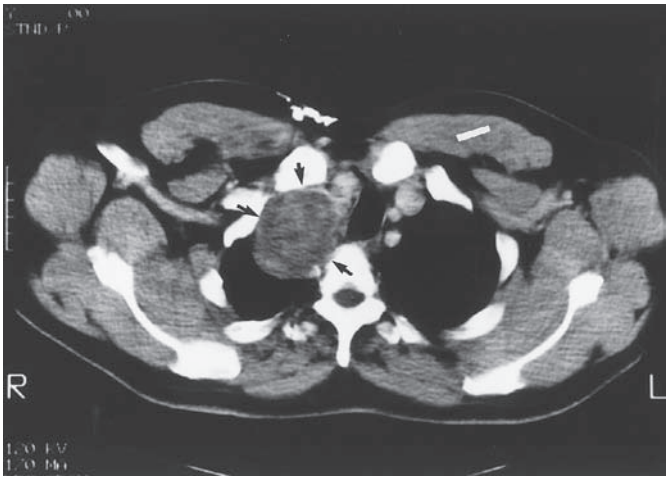
■ NERVE SHEATH TUMORS

Schwannoma (neurilemmoma) and *neurofibroma* are the most common mediastinal neurogenic tumors.[67] Both of these lesions are benign, slow-growing tumors. Most commonly, they appear as encapsulated and well-marginated masses found in the costovertebral sulci where they arise from intercostal nerve rami. Less frequently they can be found in the middle mediastinal compartment when they occur as tumors of the vagus or phrenic nerves. CT typically reveals a solitary, smoothly rounded mass in the upper half of either paravertebral sulcus abutting the vertebra (Fig. 82-7). An MRI should be employed to rule out intraspinal extension, if there is any possibility of this on CT. Upon presentation, most patients are asymptomatic, although neurologic symptoms from intercostal nerve involvement or intraforaminal extension can be present.[68] Thus, many of these are identified as incidental findings on scans performed for other reasons. Over one-third of patients with neurofibromas will have neurofibromatosis (von Recklinghausen disease), and these patients tend to present at an earlier age and may have café au lait spots suggesting the diagnosis.[68,69]

Surgical resection is the definitive treatment for these benign nerve sheath tumors, commonly performed via VATS with favorable results.[70,71] There may be a role for chemotherapy and radiation when complete resection is not possible. Excellent long-term survival is obtained with complete surgical excision of the tumors and recurrence is uncommon.[66,70] However, additional neurofibromas or schwannomas may develop in patients with neurofibromatosis. Ten percent of these tumors extend through the intervertebral foramen and create a "dumbbell" appearance on imaging studies. For these lesions, combined thoracic and neurosurgical *en bloc* resection can be achieved with low morbidity.[72] Typically this is accomplished with a posterior laminectomy followed by an anterior thoracoscopic approach.



A



B

Figure 82-7 Schwannoma. A 67-year-old man who had undergone a total thyroidectomy 20 years earlier presented with chronic cough. **A.** PA chest radiograph demonstrates a superior mediastinal mass projecting into the right hemithorax. **B.** Axial section from a CT demonstrates this neurogenic tumor high in thoracic inlet.

Malignant nerve sheath tumors are essentially spindle cell sarcomas of the mediastinum and include malignant schwannoma, neurofibrosarcoma, and malignant neurofibroma. These tumors are rare, affect men and women equally in the third to fifth decades of life, and are closely associated with neurofibromatosis. Malignant schwannomas remain one of the most poorly characterized of all soft tissue sarcomas. In general, patients with malignant schwannomas present with large invasive tumors and have a poor prognosis. Complete surgical resection is rarely possible, and even when accomplished, local recurrence is common. Neurofibrosarcoma likely evolves from the malignant degeneration of a neurofibroma. Unlike benign nerve sheath tumors, patients with neurofibrosarcoma generally have symptoms of pain and nerve impingement.[73] On CT imaging, these tumors often appear as round masses with central areas of necrosis and hemorrhage. Radical surgical excision provides the only hope of cure; however, the 5-year overall survival rates are low (16% in patients with neurofibromatosis) and no survival benefit is gained by adjuvant chemotherapy.[73,74] Chemotherapy and radiotherapy are options for unresectable tumors.

■ SYMPATHETIC GANGLION TUMORS

Tumors of the sympathetic ganglia likely represent malignant degeneration of the nerve cell rather than the nerve sheath. These tumors are represented by the spectrum of ganglioneuroma, ganglioneuroblastoma, and neuroblastoma. Mature tumors such as ganglioneuroma occur in older children (median age of ~7 years) and tend to behave in a benign fashion, whereas immature tumors such as neuroblastoma tend to occur in younger patients (median age under 2 years) and behave aggressively.[75]

Ganglioneuromas are the most benign type of sympathetic ganglion tumor. They are typically diagnosed in the second or third decade of life and are the most common neurogenic tumors occurring in childhood. Most patients with ganglioneuroma are asymptomatic upon presentation, although larger tumors may result in symptoms such as cough, dyspnea, dysphagia, chest pain, and Horner syndrome, and symptoms related to the secretion of catecholamines have been reported. Ganglioneuromas are generally large, well-circumscribed, and encapsulated tumors located in the paravertebral sulci. Surgical resection is a highly successful treatment for ganglioneuromas.[76]

Ganglioneuroblastoma is a tumor that demonstrates histologic elements similar to the well-differentiated ganglion cells seen in a ganglioneuroma as well as less-differentiated neuroblastoma-like features, and the degree of malignant behavior is related to the extent of the latter. Presentation is in the first decade of life and both sexes are equally affected. Approximately half of patients will present with symptoms. Most children present with a solitary mass that is amenable to complete surgical resection. The treatment of ganglioneuroblastoma is primarily surgical although chemotherapy is indicated in intermediate and high-risk groups. Overall these tumors are associated with relatively high 5-year survival rates, reported to be 88% in one large series.[77]

Neuroblastomas are the most malignant of the sympathetic ganglion tumors. These highly aggressive and readily metastasizing tumors are found almost exclusively in children, with 95% occurring in patients less than 5 years old.[78] Most patients present with symptoms that include chest pain, dyspnea, myelopathy from spinal canal involvement, and symptoms of excess catecholamine production. Distant metastases are common.[79] On CT, mediastinal neuroblastomas appear as elongated paraspinous masses often impinging on adjacent structures and causing bony destruction. Eighty percent of tumors demonstrate calcification.[80] MRI is useful for determining nodal, chest wall, and intraspinal involvement. The International Neuroblastoma Staging System (INSS) is the most commonly used staging system for this disease. It includes factors such as tumor size, lymph node metastases, and extent of unresectable disease and can be used to predict survival.[81] Amplification of the oncogene N-myc has additionally been shown to correlate with worse prognosis.[82] The treatment of neuroblastoma depends primarily on stage. For patients with stage I disease, resection alone is usually curative.[83,84]

For patients with partially resectable stage II and III diseases, surgical resection is followed by postoperative multiagent chemotherapy. Patients with stage IV disease are generally treated with chemotherapy and radiation, and the role of surgery is more controversial.

NEOPLASMS ARISING IN PARASYMPATHETIC GANGLION

Paragangliomas are rare tumors that arise from specialized neural crest cells associated with autonomic ganglia, called paraganglia. Paragangliomas can be categorized into two groups based upon association with either the parasympathetic system or the sympathetic system. Parasympathetic paragangliomas do not secrete catecholamines and are termed *chemodectomas*. Chemodectomas may arise from mediastinal chemoreceptors including the aortopulmonary glomulus or anywhere along the vagus nerve and are chromaffin-negative tumors. Tumors connected with the sympathetic nervous system are divided into functional paragangliomas and nonfunctional paragangliomas based on their ability to secrete catecholamines. These tumors have been previously referred to as extra-adrenal pheochromocytomas.

Both genders are equally affected by mediastinal paragangliomas, usually in the third or fourth decade of life. The clinical presentation includes symptoms of local mass effect as well as varying degrees of hypertension and hypermetabolism secondary to the production of epinephrine and norepinephrine. Excess plasma and urinary levels of catecholamines can often be detected. Preoperative localization is essential. CT, MRI, and echocardiography can be useful for anatomic imaging and functional imaging studies such as ^{131}I-metaiodobenzylguanidine (MIBG) scintigraphy can be used to localize lesions not seen on other scans. Treatment requires surgical excision, and presurgical conditioning with alpha and then beta blockade is usually necessary for functional lesions to prevent severe hypertension intraoperatively.

OTHER MEDIASTINAL TUMORS

Additional neoplasms of the mediastinum include those seen in Castleman's Disease and a variety of mesenchymal tumors.

CASTLEMAN'S DISEASE

Castleman's disease is a rare lymphoproliferative disorder that can involve enlargement of one (unicentric Castleman's disease) or multiple (multicentric Castleman's disease) lymph nodes. Most adults with unicentric disease are asymptomatic. The mediastinum is the most common location of unicentric disease and lesions most frequently occur in the anterior and middle compartments.[85,86] Multicentric Castleman's disease is characterized by peripheral lymphadenopathy and hepatosplenomegaly; a subset of patients also demonstrate mediastinal and intra-abdominal adenopathy. Human herpesvirus 8 infection has been implicated in the pathogenesis of multicentric but not unicentric disease.

Castleman's disease is categorized into two histologic types (hyaline vascular and plasma cell), but it appears that centricity rather than histology is more important in predicting long-term outcome in this disease. Complete surgical resection should be performed in unicentric disease and is associated with greater than 95% overall survival and greater than 80% disease-free survival at 5 years.[86] Multicentric Castleman's disease can be rapidly progressive and often fatal and the role of surgery other than to obtain tissue to establish a diagnosis is uncertain.

MESENCHYMAL TUMORS

Mesenchymal tumors constitute approximately 6% of all tumors that occur in the mediastinum.[3] More than half of these lesions turn out to be malignant. A large variety of categories exist for mesenchymal tumors of the mediastinum and their spectrum runs the entire gamut of soft tissue tumors, including but not limited to adipocytic tumors (lipoma, lipomatosis, liposarcoma), vascular tumors (hemangioma, lymphangioma), fibroblastic tumors (fibrous tumors), smooth muscle tumors (leiomyoma, leiomyosarcoma), skeletal muscle tumors (rhabdomyoma, rhabdomyosarcoma), and chondroosseous tumors (chondrosarcoma, osteosarcoma). Their management is similar to extrathoracic soft tissue tumors, with resection indicated if possible.

Disorders of the Chest Wall, Diaphragm, and Spine

83 Nonmuscular Diseases of the Chest Wall 1274

84 Effects of Neuromuscular Diseases on Ventilation 1289

85 Management of Neuromuscular Respiratory Muscle Dysfunction 1313

CHAPTER 83

Nonmuscular Diseases of the Chest Wall

George E. Tzelepis
F. Dennis McCool

INTRODUCTION

The chest wall is a major component of the respiratory pump and consists of the rib cage and abdomen. It is inflated by the inspiratory muscles of the rib cage and the diaphragm and its integrity is key to sustaining ventilation. Disorders affecting the nonmuscular structures of the chest wall (the thoracic spine, ribs, costovertebral joints, abdominal wall, and sternum) may lead to respiratory dysfunction. When the integrity of these nonmuscular components is severely compromised, respiratory failure may ensue. The pathophysiology of disorders affecting these nonmuscular components is generally related to the imposition of excessive elastic loads placed on the respiratory muscles. In some disorders, such as kyphoscoliosis (KS) and obesity, the load on the respiratory muscles is chronic and progressive. By contrast, with flail chest, the load on the respiratory muscles is acute. If the respiratory muscles had not adapted or had little time to adapt to loads that increase the work of breathing, respiratory failure may quickly ensue. Other disorders, such as ankylosing spondylitis (AS) and pectus excavatum, have a minimal impact on respiratory function. Diseases directly affecting the respiratory muscles are discussed in Chapter 84.

KYPHOSCOLIOSIS

Important physiologic and clinical considerations in kyphoscoliosis are discussed below.

ETIOLOGY AND DIAGNOSIS

KS comprises a group of spinal disorders that are characterized by curvature of the spine in the lateral direction (scoliosis) and sagittal plane (kyphosis) as well as by spinal axis rotation. It is a common spinal abnormality, with estimates of prevalence in the United States ranging from 1 in 10,000 people for severe deformities to 1 in 1000 people for mild deformities.[1] The etiology of KS is unknown for the vast majority of cases (85% classified as idiopathic). With the remainder, KS is due to either neuromuscular disease (paralytic or secondary KS) or is congenital (Table 83-1).[2–4]

Idiopathic KS usually manifests in late childhood or early adolescence and involves primarily females (ratio of 4:1).[5] Individuals with idiopathic KS may complain of back pain or may have psychological problems.[5] When KS is severe, complaints include dyspnea with exertion and constitutional symptoms related to nocturnal hypoventilation. Respiratory failure also may develop.[6] Paralytic or secondary KS may be due to a number of neuromuscular disorders including polio, muscular dystrophy, cerebral palsy, and spinal bifida.[4] With these diseases, KS typically occurs when the individuals become nonambulatory. Congenital KS results from developmental vertebral anomalies that are usually present at birth.[3] Although uncommon, it can lead to serious neurological complications such as paraplegia.

The diagnosis of KS is made by physical examination and radiological assessment. In severe KS, physical examination reveals a dorsal hump involving the rib cage. This is due to angulated ribs and shoulder asymmetry. In addition, there is "hip tilt" that is related to spinal rotation (Fig. 83-1). With mild spinal deformity, kyphosis and scoliosis are less apparent when inspecting the spine and the rib cage. In this context, subtle changes in spinal curvature may be elicited by performing the Adam's forward bend test. With this test, the patient bends forward at the waist with feet together and knees straight, until the spine becomes parallel to the floor. The observer, then, examines for thoracic or lumbar region asymmetry.

Radiographic studies (upright PA and lateral views of the spine) are used to confirm the diagnosis, and to assess severity by measuring the Cobb angle.[7] This angle is formed by the intersection of two lines, each of which is parallel to the top and bottom vertebrae of the scoliotic or kyphotic curves (Fig. 83-2). A spinal deformity with a Cobb angle greater than 10 degrees is considered scoliosis.[5] The greater the Cobb angle, the more severe the deformity. Cobb angles less than 60 degrees are usually not associated with ventilatory impairment, those greater than 100 degrees are invariably associated with respiratory symptoms, and those greater than 120 degrees with respiratory failure.[5,8,9] Sequential radiographic studies are useful in evaluating progression of the spinal deformity.

RESPIRATORY MECHANICS

The pathophysiological hallmark of KS is reduced chest wall distensibility.[10] Namely, chest wall compliance is reduced and the pressure required to inflate the chest wall at any given lung volume is greater than in a healthy individual. Consequently, functional residual capacity (FRC) is invariably decreased, the elastic load placed on the respiratory muscles is increased, and the work of breathing is significantly increased. In idiopathic KS, the compliance of the chest wall and respiratory system both decrease as the Cobb angle increases (Fig. 83-3 A,B) with the most pronounced reductions in chest wall compliance seen in individuals with Cobb angles greater

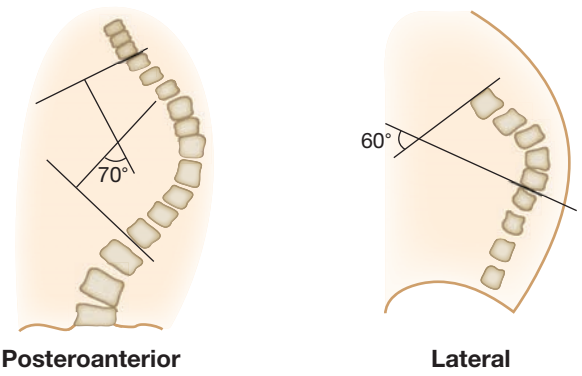

Figure 83-2 Schematic of the posteroanterior radiograph depicting the lines constructed to measure the Cobb angle of scoliosis and the lines drawn on the lateral radiograph to measure the Cobb angle of kyphosis. *(Data of Rochester, Findley, in Murray and Nadel editors, Textbook of Respiratory Medicine. Philadelphia: WB Saunders; 1988.)*

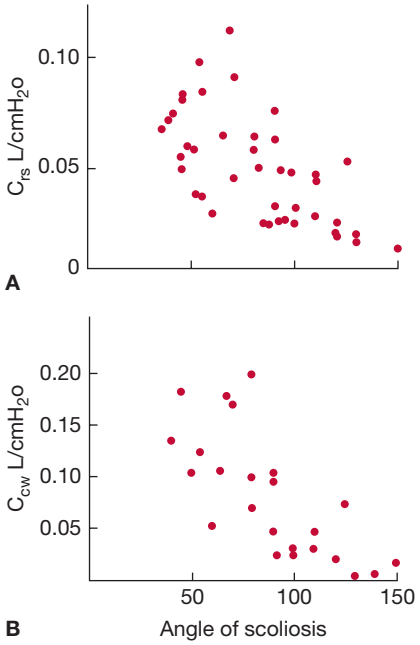

Figure 83-3 Relationship between (**A**) the angle of scoliosis and compliance of the total respiratory system and (**B**) the angle of scoliosis and compliance of the chest wall in patients with idiopathic scoliosis. *(Reproduced with permission from Kafer ER. Mechanical properties of the respiratory system and the ventilatory response to carbon dioxide. J Clin Invest. 1975;55(6):1153–1163.)*

than 100 degrees.[10] Cobb angles up to 50 degrees do not significantly decrease respiratory system compliance.[10]

The reduction in chest wall compliance promotes breathing with shallow tidal breaths and the reduction in FRC leads to breathing at low lung volumes. Both factors predispose to the development of atelectasis. Consequently, lung compliance may be reduced in the absence of any intrinsic lung disease. Although lung compliance may be diminished, it is not as severely affected as the chest wall. Since chest wall compliance decreases with age, respiratory mechanics invariably deteriorate with age even though the spinal deformity may not worsen over time.[11]

Respiratory muscle strength, as reflected in measurements of maximal static inspiratory (PI_{max}) and expiratory pressures (PE_{max}), is usually normal in individuals with idiopathic KS and Cobb angles of less than 50 degrees. With Cobb angles greater than 50 degrees, there may be mild to moderate reductions in PI_{max} and PE_{max} accompanied by only mild reductions in vital capacity (VC).[12,13] The reductions in PI_{max} with idiopathic KS may be due to mechanical disadvantage of the respiratory muscles coupled to a distorted rib cage.[14] However, in patients with secondary KS, reductions in PI_{max} are related to intrinsic muscle weakness.[15] In these individuals, the combination of weakened inspiratory muscles and a stiff, poorly compliant, respiratory system will lead to profound decrements in VC and predispose these individuals to respiratory failure.[16]

The reductions in VC in idiopathic KS are typically seen in patients with severe spinal deformities (Cobb angles greater than 100 degrees). Total lung capacity (TLC) and VC may be reduced to 30% of predicted.[2,8] Forced vital capacity (FVC) decreases in proportion to the reduction in TLC in the absence of obstructive airway disease. Residual volume (RV) may be normal or slightly increased. This is in contrast to the reduction in RV that occurs in restriction due to interstitial lung disease. The disproportionate reduction in TLC relative to RV in KS produces a relatively high RV/TLC ratio.[2] In individuals with mild and moderate degrees of kyphosis and scoliosis (i.e., Cobb angles less than 60 degrees) VC and TLC may be

only mildly reduced. Although uncommon, obstructive dysfunction in nonsmokers has been described.[17] This includes reductions in midexpiratory flow rates or FEV_1 resulting from tracheal displacement or torsion of major bronchi.[18]

Factors other than Cobb angle can contribute to the reduction in TLC and VC. These factors include the location of the spinal curve (thoracic vs. lumbar), number of vertebrae involved, patient's age, degree of spinal rotation, and, most importantly, the presence or absence of inspiratory muscle weakness. Concomitant respiratory muscle weakness will significantly affect the severity of restriction. In patients with paralytic KS (spinal deformity secondary to neuromuscular disease), the degree of lung restriction is primarily determined by the magnitude of respiratory muscle weakness rather than by the degree of spinal curvature.[15,19] Thus, for a similar Cobb angle, patients with paralytic KS are likely to have greater pulmonary function impairment than patients with idiopathic KS.[15,19] In patients with congenital KS, coexisting rib deformities or underlying lung abnormalities similarly lead to a greater loss in VC for a given degree of spinal deformity than seen in patients with idiopathic KS.[20]

The work of breathing is increased in KS because of the elastic load related to the stiff chest wall.[10] Consequently, the oxygen cost of breathing may be three to five times of that seen in healthy subjects. Concomitant inspiratory muscle weakness decreases ventilatory reserve and predisposes the respiratory muscles to fatigue and contributes to respiratory failure in these patients.[16]

EXERCISE CAPACITY

Exercise capacity may be severely limited in KS, especially when the Cobb angle is greater than 60 degrees. Cardiorespiratory dysfunction related to restrictive pulmonary function, reduced respiratory system compliance, increased work of breathing, and respiratory muscle weakness contribute to poor exercise capacity.[21,22] Typically, maximal oxygen consumption is reduced to about 60% to 80% of predicted, heart rate is higher per work load, the ratio of tidal volume to vital capacity (VT/VC) is greater than 0.5, and the ratio of maximum exercise ventilation to maximum voluntary ventilation (VE_{max}/MVV) can reach 0.7. Concomitant pulmonary hypertension in those with Cobb angles greater than 100 degrees may independently contribute to exercise limitation.

Kyphoscoliotic individuals with mild to moderate spinal curves (Cobb angles 20–45 degrees), also may have poor exercise tolerance but any reduction in $\dot{V}O_{2max}$ more likely is due to limb muscle deconditioning rather than ventilatory constraints.[23] In support of this notion, there is recent data reporting weakness of the quadriceps muscle, reduced Type I myosin, and presence of oxidative stress in the quadriceps muscle of these patients.[24]

CONTROL OF BREATHING

Advanced KS is associated with significant alterations in breathing pattern. Typically, individuals with severe KS adopt a rapid shallow breathing pattern consisting of low tidal volumes, shortened inspiratory time (T_I), and an increased respiratory rate (i.e., reduced total breath time, T_{TOT}).[16,25] In young patients with KS and normal blood gases, T_I and duty cycle (T_I/T_{TOT}) correlate negatively with the angle of scoliosis.[25] These changes in breathing pattern likely represent an adaptation to chest wall restriction. The benefit of using this breathing pattern is twofold. First, the work per breath is decreased. Second, the ratio of the pressure needed to inhale (P_{breath}) to PI_{max} is reduced. In theory, reducing P_{breath}/PI_{max} lessens the likelihood of developing inspiratory muscle fatigue and respiratory failure. The disadvantage of a rapid shallow breathing pattern is that it promotes atelectasis, causes hypoxemia, and may lead to a further reduction of lung compliance.

A second means of adapting to the added elastic load of the stiffened chest wall is to increase respiratory drive.[25] Indirect measurements of the neural drive to the respiratory muscles, such as mouth occlusion pressure at 100 ms (P0.1) are usually elevated in these individuals and correlate positively with the degree of scoliosis.[25] The increase in neural drive is not necessarily associated with increased alveolar ventilation as the stiff chest wall and the weak respiratory muscles will limit any augmentation in alveolar ventilation.

SLEEP DISORDERED BREATHING

Nocturnal hypoventilation may occur in severe KS and typically predates the development of chronic hypercapnia.[9,26] While awake, individuals with Cobb angles greater than 100 degrees can maintain adequate alveolar ventilation by increasing respiratory drive to the diaphragm and recruiting accessory inspiratory muscles.[16,25] However, during sleep, neural drive to all the inspiratory muscles is diminished, especially during REM sleep.[27] Since these patients are dependent exclusively on the diaphragm to maintain alveolar ventilation in REM sleep, they are at risk for becoming hypercapnic and hypoxemic. The risk of hypoventilation is amplified if there is any underlying diaphragm dysfunction. Of interest, the magnitude of nocturnal hypoventilation may not correlate with the degree of thoracic deformity.[28] This observation suggests that inspiratory muscle weakness may be a more important factor for developing nocturnal hypoventilation. The presence of sustained nocturnal desaturation and hypercapnia may further weaken the respiratory muscles, compound the hypoxemia, lead to pulmonary hypertension and eventually cor pulmonale. Obstructive sleep apnea, which has a similar prevalence in KS to that of the general population, also may complicate nocturnal hypoventilation.[29] Since nocturnal hypoventilation occurs before development of the typical symptoms and signs of cardiorespiratory failure, the clinician must be alert to sleep-related breathing abnormalities in these patients and promptly diagnose them with overnight polysomnography.[29]

GAS EXCHANGE

Abnormalities in gas exchange are frequently found in patients with KS; normocapnic hypoxemia being the most common abnormality. In nonsmokers with idiopathic KS, Pa_{O_2} correlates directly with VC and inversely with the angle of scoliosis. The age-dependent decrease in Pa_{O_2} is greater than that of normal individuals and oxyhemoglobin desaturation can occur with minimal activity.[11,30] Hypoxemia is primarily due to ventilation–perfusion mismatch and less often to intrapulmonary shunt associated with atelectasis.[30] In severe KS with chronic hypercapnia, hypoventilation also contributes to hypoxemia. Hypercapnia is initially detected only during sleep or with exercise.[26] With aging or as the disease progresses, hypercapnia is seen at rest while awake.

CLINICAL COURSE

Individuals with congenital KS and severe spinal deformities may exhibit a rapidly deteriorating clinical course resulting in pronounced restrictive dysfunction, *cor pulmonale*, and early death.[6,31] Those with secondary KS associated with neuromuscular disease may similarly progress to develop severe restrictive dysfunction and cardiorespiratory failure.[32] In general, when KS manifests early in life (age 0–8 years) there is a greater risk for rapid progression of the spinal deformity during growth, continued progression of the deformity after skeletal maturity, and a greater likelihood of developing respiratory failure.[31]

Individuals with idiopathic KS typically have a more benign course. If the spinal deformity at skeletal maturity is mild, they have an excellent prognosis with little respiratory impairment, and an overall good quality of life.[5] In individuals with idiopathic KS and moderate or severe deformity at presentation (age 12–16 years), the risk of deformity progression and development of respiratory impairment increases significantly.[5] Progressive curvature of the spinal deformity is, in general, greater in skeletally immature individuals, in those with large deformities at presentation, and in those whose curves have a thoracic apex.[5] By rough estimates, individuals

with thoracic deformities greater than 50 degrees at skeletal maturity are at risk for a progressive increase in the spinal curve at a rate of about 1 degree annually.[33]

Most young individuals with idiopathic KS are asymptomatic. As they age, many will develop back pain and dyspnea. Initially dyspnea may only be problematic with activities and eventually may be present at rest if the spinal deformity progresses.[11] Consequently, individuals with severe idiopathic KS, especially those with a Cobb angle greater than 110 degrees and VC of less than 45% of predicted, should be monitored for respiratory compromise as they age.[11] Once cardiorespiratory failure develops, the prognosis is poor; without supplemental oxygen or ventilatory support death may occur within 1 year. The risk of respiratory failure is even greater in patients with inspiratory muscle weakness, sleep disordered breathing, obesity, or concomitant obstructive airway disease. Pregnancy poses no added risk for respiratory failure; however, women with idiopathic KS and a VC reduced to less than 1 L may develop respiratory problems during pregnancy.

TREATMENT

General supportive measures for adults with KS include smoking cessation, maintenance of body weight within a desirable range, engaging in frequent physical activity to improve exercise capacity and minimize deconditioning, immunization against influenza and pneumococci, prompt treatment of respiratory infections, and psychological support for those with diminished self-esteem. Supplemental oxygen may be needed with activity or during sleep if there is evidence of oxyhemoglobin desaturation with exertion or with sleep. Treatment with supplemental oxygen alone may be sufficient if it corrects nocturnal hypoxemia without inducing hypercapnia.[34] However, the development of hypercapnia needs to be closely monitored, especially in individuals with a VC of less than 50% of predicted. If hypercapnia is present, nocturnal noninvasive ventilatory support should be initiated. Dyspnea, morning headaches, poor sleep quality, fatigue, and the presence of *cor pulmonale* are symptoms and signs that should alert the clinician to the presence of nocturnal hypoventilation.[35] Long-term, nocturnal noninvasive ventilation should be offered to all patients with KS and chronic hypercapnic respiratory failure as it reduces mortality (Canadian Thoracic Society, grade 1B).[34,36]

Noninvasive positive pressure ventilation can be delivered via a nasal mask or full-face mask, with or without supplemental oxygen. When prescribing a positive pressure device, either a pressure- or volume-preset ventilator can be used.[9] Apart from the potential for greater leakage with the pressure mode, pressure or volume ventilation has equivalent beneficial effects on physiological and clinical parameters as well as overall health status. Contraindications to noninvasive ventilation include the inability to protect the upper airway due to impaired cough, excessive airway secretions, or inability to cooperate.[35] When noninvasive ventilation has failed or is contraindicated, invasive ventilation should be considered.

Benefits of noninvasive ventilation include improvements in quality of life, gas exchange, sleep efficiency, pulmonary hemodynamics, respiratory drive, and survival (Table 83-2).[9,37] By contrast, measurements of VC, PI_{max}, twitch transdiaphragmatic pressure and respiratory muscle endurance are not improved by noninvasive ventilation.[38] Accordingly, the lower incidence of respiratory failure in patients undergoing positive pressure ventilation may be attributed to improvements in respiratory control rather than improvement of respiratory muscle contractility.[38] Long-term noninvasive ventilation considerably reduces the number of hospitalizations for respiratory failure and the length of hospital stay.[9] Survival benefit of KS patients treated with noninvasive ventilation and supplemental oxygen over those patients treated with just oxygen has been demonstrated by comparative and observational studies (Fig. 83-4).[36]

TABLE 83-2 Therapeutic Benefits of Noninvasive Mechanical Ventilation in Patients with Kyphoscoliosis

Gas Exchange Indices	
Pa_{O_2}	Increase
Pa_{CO_2}	Decrease
Bicarbonate	Decrease

Treatment of chronic respiratory failure in kyphoscoliosis: oxygen or ventilation? Eur Respir J. 2003;22(3):525–528.)*

Traditional surgical approaches to correct spinal deformities in skeletally immature children have included spinal fusion and/or implantation of rods. Spinal fusion has considerable disadvantages as it has been associated with restrictive respiratory defects, decreased ability to carry out daily activities, and poor cosmetic results.[39] In young children (age <10 years), severe restrictive respiratory disease (VC <50% of predicted) may occur in roughly 50% of patients undergoing spinal fusion, especially in those with extensive thoracic fusions or in those with fusions of the proximal thoracic spine.[39] Surgical fusion of the spine may have a role in children with congenital spinal deformities or in children with KS secondary to neurological defects. A nonfusion approach includes implantation of growth-friendly rods such as expandable spinal rods, titanium rib implants, or remotely distractible magnetically controlled rods.[40] These newer techniques permit control of spinal deformity while allowing continued spinal growth and pulmonary development.[40]

THORACOPLASTY

In the pre-antituberculous chemotherapy era, thoracoplasty was the standard surgical approach to control pulmonary tuberculosis. The surgery consisted of different combinations of rib removal, rib fracture, phrenic nerve resection, or lung compression by filling the pleural space with foreign material (i.e., ping pong balls) (Fig. 83-5). Since the procedure was primarily performed in the 1940s and 1950s, very few people who had undergone the procedure are still alive.[41,42] Historically, these individuals commonly developed dyspnea, severe restrictive dysfunction, and chronic hypercapnic respiratory failure as they aged.[41,42] The severity of the restrictive defect was often comparable to that seen in KS (Tables 83-3 and 83-4) and was related to the number of ribs removed, presence of fibrothorax, lung fibrosis secondary to underlying granulomatous disease, prior lung resection, or intentional phrenic nerve damage.[41,42] As in most restrictive chest wall diseases, these patients had impaired gas exchange, limited exercise tolerance, an increased oxygen cost of breathing, and eventually would develop *cor pulmonale*. Progressive scoliosis with aging further impaired respiratory function. Although this procedure is of historical interest, the purpose of reviewing thoracoplasty in this chapter is that the procedure is still occasionally performed. Currently, thoracoplasty is indicated for treatment of bronchopleural fistulae that have failed to close following decortication or for treatment of persistent empyema in which decortication is not feasible or has failed to eradicate the infection.[43] Treatment of individuals who are postthoracoplasty and have developed restrictive disease consists of supplemental oxygen, antibiotics for respiratory infections, and noninvasive ventilatory support.

PECTUS EXCAVATUM

Clinical considerations in pectus excavatum are discussed below.

■ ETIOLOGY AND CLINICAL FEATURES

Pectus excavatum, also known as funnel chest, refers to a congenital chest wall deformity characterized by excessive depression of the sternum and the adjacent ribs producing a caved-in appearance to the rib cage.[44] It is the most common congenital deformity of the chest wall, with a prevalence of about 1 in 1000 live births and a male to female ratio of 3 to 1.[45] A family history may be present in 15% to 40% of cases.[46] It is believed to result from an abnormal growth of cartilage around the sternum due to a defect in collagen formation.[44] In support of this mechanism, is the higher prevalence of pectus excavatum in Marfan syndrome.[47] However, the pathogenesis of pectus excavatum in the majority of cases is unknown.

The sternal depression may be minimal or prominent. In extreme cases, it is usually apparent at birth and progresses as the child grows. The most frequent complaints of individuals with pectus excavatum are cosmetic. The psychological impact of the pectus deformity becomes more troublesome during the teenage years when body image becomes more important. Exertional dyspnea and exercise intolerance may occur in 30% to 70% of patients.[44] However, these symptoms cannot be entirely explained by the mild restrictive pattern, which is sometimes seen (Table 83-3) or by limitations in cardiac output.

The degree of sternal depression is best assessed with a chest CT scan. The ratio of the transverse to anterior–posterior (AP) diameters of the rib cage at the level of the deepest sternal depression (Haller index) can easily be measured using this technique

TABLE 83-4 Respiratory Mechanics in Diseases of the Chest Wall

	KS	Post-THOR	PE	AS

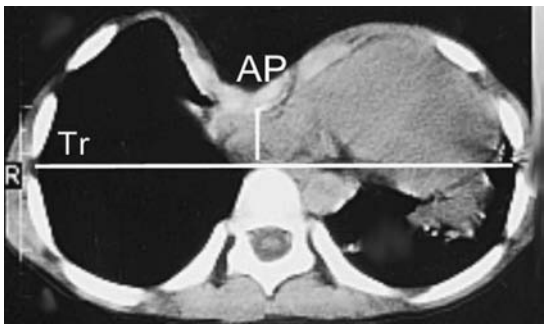

Figure 83-6 Chest computed tomography of a patient with pectus excavatum. The distance between the anterior aspect of the vertebral body and the posterior aspect of the sternum (AP) is decreased. The Haller index is calculated as the ratio of the internal transverse diameter (Tr) to AP distance.

(Fig. 83-6).[44] In normal individuals this ratio is about 2.5. A ratio greater than 3.25 is considered significant sternal depression.[44]

■ PATHOPHYSIOLOGY

Severe pectus deformities may be associated with mild restriction on pulmonary function tests. A Haller index of 5 or higher can be associated with mild reductions in TLC and VC. The restriction may be more pronounced if there is concomitant scoliosis.[48] Although obstructive defects are infrequent (approximately 2% of cases)[48] RV and the RV/TLC ratio are commonly increased. The elevated RV and RV/TLC may be due to stiffness of the rib cage resulting in reduced chest wall compliance in these young individuals rather than air trapping or expiratory muscle weakness. In most cases there is no underlying lung disease, and lung compliance is normal. Unlike AS, the mobility of the rib cage is not impaired at rest or during exercise in pectus excavatum.[49,50]

Cardiopulmonary exercise testing is usually normal in individuals with pectus excavatum. Indices such as maximal work rate, maximum oxygen consumption, and maximal oxygen pulse are not different from those of healthy individuals. In severe deformities, limited exercise capacity with reductions in maximal work rate or oxygen consumption at a given work rate may occur and often are out of proportion to the mild restrictive respiratory impairment found in these patients.[51] The explanation for the limited exercise capacity in this group of patients may be a reduction in venous return to heart associated with right ventricular compression due to sternal depression. Distortion of right ventricular geometry may be detected by echocardiographic or cardiac magnetic resonance imaging studies.[52] However, the role of these findings in limiting exercise capacity is not entirely known.

■ TREATMENT

Although surgery is most often performed for cosmetic reasons, it is clearly indicated when the deformity has significant physiological and psychological repercussions for the individual.[45,53] The optimal timing for repair is around 10 to 14 years of age or at a younger age if there is significant cardiopulmonary compromise. Individuals selected for repair typically have a Haller index greater than 3.25.[45,53]

The most common surgical approaches include modifications of the open-resection method originally described by Ravitch or the minimally invasive approach described by Nuss.[44] The first method involves resection of costal cartilage and a sternal osteotomy, with or without fixation of the sternum by external or internal supports. This procedure may be complicated by sternal necrosis, infection, or recurrence of the deformity. Recurrence may arise in younger children in whom sternal supports are not used. The invasive approach is best suited for individuals with combined pectus excavatum and carinatum, marked asymmetry, or extensive defects involving the upper ribs.[44]

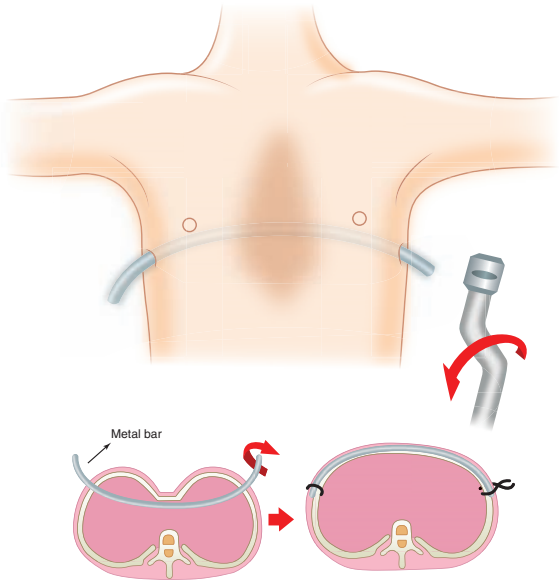

Figure 83-7 Schematic depicting the Nuss procedure in a patient with pectus excavatum. A curved bar is inserted behind the sternum and then rotated to displace the depressed sternum ventrally.

The Nuss procedure, developed in the 1990s, provides a minimally invasive alternative to reconstructing the deformity.[54] It consists of placing a curved metal bar under the sternum at the point of deepest depression through small incisions made on each side of the rib cage. The sternum is then pushed forward and stabilized by the metal bar (Fig. 83-7). With this procedure, the costal cartilage is not resected. The bar is generally left in place for 2 to 4 years, resulting in permanent chest wall remodeling. Complications of this approach include bar displacement or rotation that would require reoperation, as well as pneumothorax, pericarditis, and infection. The use of thoracoscopic techniques has minimized associated complications. Overall, the rate of complications does not differ significantly between the two surgical approaches.[55] Deformity repair with either procedure impacts positively on the psychosocial well-being of the individual.[55]

Improvements in cardiopulmonary function with invasive or minimally invasive procedures remain controversial.[56] If there is improvement, it is mostly modest and clinically insignificant. Improvements in exercise tolerance, cardiac output, and $\dot{V}O_{2max}$ after surgical correction have been described in some but not all studies.[56,57] Discrepancies among studies may be due to differences in patient populations (younger vs. older patients), surgical techniques, the interval at which tests are performed following the operation, or the effects of growth on pulmonary function. One year following surgery, any improvement in pulmonary function is independent of which surgical procedure was performed.

ANKYLOSING SPONDYLITIS

Important physiologic and clinical considerations in ankylosing spondylitis are described below.

■ ETIOLOGY AND CLINICAL FEATURES

AS is a chronic multisystem disease characterized by inflammation of the spine, sacroiliac and peripheral joints as well as involvement of extra-articular organs including the lungs and the heart.[58] Chronic inflammation of the spinal structures, costovertebral, apophyseal, and sacroiliac joints leads to fibrosis and ossification of these structures.[59] Consequently, spinal mobility is reduced and there is considerable limitation of rib cage expansion.[60]

AS affects approximately 0.1% of the general population and is more common in men than in women, with a ratio of 16:1. Its

Figure 83-8 Inflammatory lesions of the anterior chest wall displayed by whole-body MRI in an ankylosing spondylitis patient complaining of anterior chest wall pain. *Arrows* point to bone marrow edema in both parts of the manubriosternal joint. *(Modified with permission from Weber U, Lambert RGW, Rufibach K et al. Anterior chest wall inflammation by whole-body magnetic resonance imaging in patients with spondyloarthritis: lack of association between clinical and imaging findings in a cross-sectional study. Arthritis Research & Therapy. 2012;14(1):R3.)*

etiology is unclear. There is a genetic predisposition for AS, as 95% of whites with AS have the HLA-B27 antigen.[58] Clinically, patients in late adolescence or early adulthood, present with back pain or morning stiffness due to involvement of sacroiliac joints. Onset of symptoms after the age of 45 is rare. Typically, the symptoms are worse in the morning or after prolonged rest. About 30% of individuals with AS have involvement of a peripheral joint or non-granulomatous anterior uveitis. Aortitis and dilatation of the aortic root may occur in up to 25% of patients.

Chest pain due to inflammation of manubriosternal junction and/or the sternoclavicular joints with inability to fully expand the chest on inspiration can occasionally occur (Fig. 83-8).[61] On physical examination, there may be tenderness of the anterior chest wall, the costochondral region, or the manubriosternal junction. Chronic back pain may cause sleep fragmentation resulting in difficulties with daytime somnolence and fatigue.[62] Upper airway obstruction due to cricoarytenoid cartilage involvement is a rare complication.[63]

Individuals with advanced AS have very limited rib cage motion and are more dependent on diaphragmatic breathing. Prominent abdominal excursion during inspiration may be apparent in supine or upright individuals. The degree of rib cage immobility can be assessed by measuring the change in rib cage circumference at the level of the fourth intercostal space between a full inspiration and full expiration. Rib cage expansion less than 2.5 cm should raise the possibility of AS in young patients with chronic low back pain.

■ RESPIRATORY PATHOPHYSIOLOGY

Limited rib cage expansion is the pathophysiological hallmark of AS.[59,64,65] This limitation results from fusion of the costovertebral and sternoclavicular joints and possibly leads to intercostal muscle atrophy.[59] Rib cage motion is similar to that in healthy individuals in terms of direction, but the extent of movement is diminished.[60] Rib

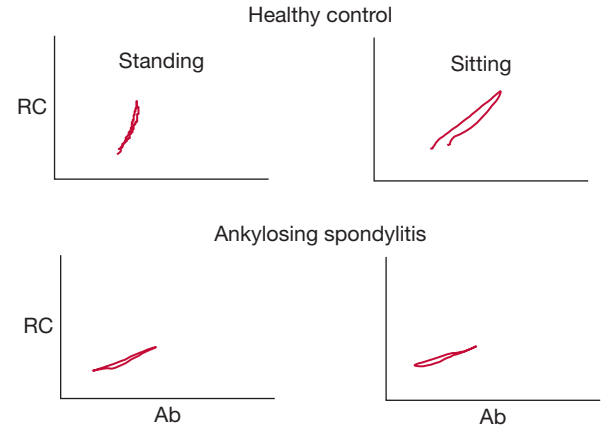

Figure 83-9 Changes in anteroposterior dimensions of the rib cage (RC) and abdomen (Ab) in a healthy individual and one with ankylosing spondylitis (AS). There is limited mobility of the rib cage in all positions resulting in greater motion of the abdomen relative to the rib cage.

cage immobility leads to a reduction in chest wall and total respiratory system compliance but lung compliance is generally normal (Table 83-4).[65]

Only mild reductions in VC or TLC (75%–80% of predicted) may be present despite moderately severe reductions in rib cage mobility (Table 83-3).[66] The restrictive impairment is associated with disease activity, disease duration, and spinal mobility.[66,67] Mild reductions of respiratory muscle strength (PI_{max}, and PE_{max}) may be recorded in individuals with severely limited rib cage expansion. However, diaphragmatic strength is typically intact in these patients.[59] Since rib cage expansion is severely limited in advanced AS, chest wall inflation is primarily accomplished through diaphragmatic displacement of the abdomen (Fig. 83-9). This pathway accounts for most of the change in tidal volume during quiet breathing, speech, or exercise.[68] In this setting, the increased diaphragm shortening and the relatively greater transdiaphragmatic pressure required to inflate a stiff rib cage[59] may potentially provide a training stimulus to the diaphragm.

In the absence of parenchymal lung disease, Pa_{O_2} is either in the normal range or mildly reduced.[66] Exercise capacity may be mildly decreased in patients with AS, especially in those with marked rib cage restriction.[69] The mechanism of limited exercise is most likely related to peripheral deconditioning rather than ventilatory constraints.[69]

■ PLEUROPULMONARY ABNORMALITIES

Upper lobe fibrobullous disease occurs in a small percentage (up to 4%) of individuals with AS.[70,71] It is more common in males with long-standing disease and may manifest as interstitial infiltrates, fibrosis with honeycombing, or cavitation that may mimic tuberculosis.[70,71] The pathogenesis of upper lobe fibrobullous disease is unknown. Possible mechanisms include decreased upper lobe ventilation, mechanical stress due to rib cage rigidity, and recurrent lung infection due to impaired cough. Individuals with fibrobullous disease have an increased propensity for spontaneous pneumothorax and infections with *Aspergillus* or atypical mycobacteria.[71] Fibrobullous disease tends to be progressive and its course is not altered by steroid treatment. Because resection of the lung segment with fibrobullous disease can be complicated by bronchopleural fistula in 50% to 60% of patients, surgery is reserved for treatment of massive hemoptysis.[71] Additional pleuropulmonary abnormalities that can be detected by chest CT include interstitial lung disease, pleural thickening, parenchymal bands, and bronchial wall thickening.[70] These abnormalities are subtle and do not correlate with clinical or functional impairment.

■ SLEEP DISORDERED BREATHING

An increased prevalence of obstructive sleep apnea in AS has been reported, especially in patients with long-standing disease (>5 years).[72,73] Because fatigue is a common complaint in AS, clinicians should have a high index of suspicion for concomitant sleep disordered breathing contributing to excessive daytime sleepiness and screen these patients with polysomnography.[72,73]

■ TREATMENT

Treatment of individuals with AS should incorporate pain relief, physical therapy, and measures to maintain posture. Physical therapy exercises that promote rib cage expansion have beneficial effects on pain and spinal mobility. Smoking should be avoided and baseline chest radiographs and spirometry obtained.

Over the past decade, the use of antagonists of tumor necrosis factor (TNF) has had a dramatic effect on pain control, fatigue, spinal flexibility, and quality of life in these patients.[74] Rib cage expansion is also improved following treatment with biological agents. The effectiveness of TNF-blockade can be maintained for several years with continued treatment. Since anti-TNF agents do not prevent new bone formation in AS patients, their overall effects on the natural history of the disease await further assessment.[75] An adverse effect of the anti-TNF therapy is reactivation of tuberculosis. Therefore, AS patients who are candidates for anti-TNF therapy should be screened for latent tuberculosis and receive prophylactic treatment with isoniazid before starting treatment.[76] Additional rare adverse pulmonary complications of anti-TNF blockade include interstitial lung disease and development of a sarcoid-like disorder.[76]

OBESITY

Obesity is a prevalent problem. Important clinical considerations are discussed below.

■ CLINICAL FEATURES

Obesity has reached an alarming prevalence throughout the world. It is estimated that about two-thirds of adults in the United States are either overweight or obese and 20% of children are obese.[77] The World Health Organization has declared obesity one of the top ten risk conditions worldwide and one of the top five in developed countries.[78] Obesity is associated directly or indirectly with several comorbidities, increased disability and decreased life expectancy.[79] It is a significant contributor to escalating healthcare costs.

Severity of obesity is commonly assessed by calculating the body mass index (BMI), defined as body weight (BW) in kilograms divided by the square of height (Ht) in meters (BW/Ht^2).[80] An individual with a BMI between 18.5 and 24.9 kg/m^2 is normal; a BMI between 25 and 29.9 kg/m^2 is overweight, and a BMI greater than 30 kg/m^2 is considered obese; BMI greater than 40 kg/m^2 is considered morbid obesity. Morbidity and premature mortality usually begin to increase at a BMI of 25 to 29.9 kg/m^2 and further increase with a BMI greater than 30 kg/m^2.

Obesity-associated respiratory morbidity results primarily from derangements in chest wall mechanics and the control of breathing.[81,82] Obesity may decrease lung volumes, decrease respiratory muscle strength, increase the work of breathing and reduce respiratory drive.[81,82] Despite these limitations, most morbidly obese patients remain eucapnic; referred to as simple obesity (SO). However, a subgroup of morbidly obese individuals develops hypercapnia.[81] These individuals have obesity hypoventilation syndrome (OHS) (Table 83-5).

■ PULMONARY FUNCTION AND CHEST WALL MECHANICS

In SO, the most common impairments in pulmonary function include a decrease in expiratory reserve volume (ERV) and FRC.[83] In contrast, TLC is normal or only mildly reduced (Table 83-6).[83] The lower than normal FRC is due to the increased volume of abdominal and thoracic fat that makes pleural pressure less subatmospheric and may decrease chest wall compliance.[82,84,85] Both factors lower resting end-expiratory relaxation volume (FRC). RV may be normal or even slightly increased in SO.[83] As a result, ERV which is the difference between FRC and RV is reduced.[83] Expiratory flow rates and the FEV_1/FVC ratio are usually normal in SO except for modest reductions in FVC when the BMI exceeds 45 kg/m^2.[82]

In OHS, FRC and ERV are more severely reduced than they are in individuals with SO and a comparable BMI (Table 83-6). In OHS, TLC is reduced but to a lesser extent than FRC and ERV.[81,86] These differences in pulmonary function between SO and OHS may be explained by differences in the distribution of adipose tissue. Individuals with OHS, typically have a central pattern of fat distribution. For a given BMI, a central pattern of fat distribution (measured as the waist:hip circumference ratio) is associated with greater impairment in lung function than a peripheral (around the hips) fat distribution.[87,88] This pattern is seen more commonly in men than in women.[89]

Respiratory system compliance is invariably decreased in obese individuals.[84,90,91] In morbidly obese patients, respiratory system compliance decreases exponentially as BMI increases. The reduction in respiratory system compliance can be primarily attributed to a decrease in lung compliance.[85] When FRC is reduced with obesity, lung compliance decreases due to airway closure and the

development of atelectasis. Whether a stiffened chest wall contributes to the reduction in respiratory system compliance remains controversial. Differences among studies reporting either normal or reduced chest wall compliance may be due to difficulties measuring chest wall compliance when the respiratory muscles are not fully relaxed.[90–93] To circumvent this issue, chest wall compliance has been measured in anesthetized, paralyzed obese individuals and found to be normal.[90,94] In this setting, the chest wall pressure–volume curve has the same slope as a nonobese individual but is shifted rightward. This rightward shift is consistent with mass loading of the thorax. Mechanistically, the excess chest wall adipose represents an inspiratory threshold load. Once the threshold load is overcome, the chest wall inflates similar to the normal chest wall.[82,90]

Morbidly obese individuals may have increased airway resistance,[95] exhibit expiratory flow limitation[96] and develop intrinsic positive end-expiratory pressure (PEEP).[96–98] The increase in airway resistance has been attributed to breathing at low lung volumes.[99,100] However, even when correcting for low lung volume, specific airway resistance remains elevated. Thus additional factors must be contributing to increased airway resistance.[95,101] Expiratory flow limitation has been described in obese individuals during tidal breathing, especially in the supine position.[96,97] Flow limitation may be primarily related to shifting FRC to a region on the flow–volume curve where tidal breathing encroaches on the maximal flow–volume envelope.[82] In the supine position, further reductions in FRC[95,100] increase the likelihood that expiration will be flow-limited. Intrinsic PEEP develops as a consequence of expiratory flow limitation especially in circumstances where expiratory time is reduced or tidal volume increased (i.e., exercise). Intrinsic PEEP also may develop in the supine position when FRC is further reduced. Consequently, obese individuals may complain of orthopnea.[96–98]

Respiratory muscle strength, as measured by PI_{max} and PE_{max}, as well as respiratory muscle endurance, as measured by MVV, are generally preserved in SO.[98,100,102] In contrast, individuals with OHS often have a reduction in MVV and exhibit respiratory muscle weakness, with strength diminished to approximately 40% of predicted.[81,102] Mechanisms that potentially explain respiratory muscle weakness in OHS include respiratory acidosis and mechanical disadvantage of the diaphragm related to its rostral displacement by adipose tissue.[81,102] The combination of weakened inspiratory muscles and altered chest wall mechanics contribute to the reduction in TLC in OHS (Fig. 83-10).[95]

CONTROL OF BREATHING

In nonobese individuals, added elastic or threshold inspiratory loads increase neural drive to the respiratory muscles.[103] Likewise, in eucapnic morbidly obese individuals the added elastic and threshold loads increase respiratory drive; usually two to three times that of nonobese subjects.[104] Changing from the sitting to supine position increases further the respiratory drive in obese but not in nonobese individuals.[98] The augmented respiratory drive is strongly associated with BMI and is important for maintaining normocapnia in obesity.[98] Patients with OHS do not exhibit increased respiratory drive in response to loads placed on the respiratory muscles.[105]

Respiratory drive can be assessed by measuring either the ventilatory or mouth occlusion pressure (P0.1) responses to hypercapnia or hypoxia. The ventilatory response to hypercapnia is mildly reduced in SO compared to normal weight individuals.[104,105] The inability of individuals with SO to appropriately increase ventilation in response to CO_2, however, may reflect disordered chest wall mechanics limiting ventilation rather than a true reduction in central respiratory drive. When compared to SO, individuals with OHS have an even lower ventilatory response to hypercapnia and hypoxia, with the response to hypoxia blunted to a greater extent than the response to hypercapnia.[105] As with SO, altered respiratory system mechanics contribute to the inability to appropriately increase ventilation. However, with OHS, other indices of central respiratory drive, such as P0.1 and diaphragmatic EMG, are reduced. Factors that may reduce chemosensitivity in OHS include the presence of sleep apnea, persistent hypoxia, or hormonal mediators such as adipokines.[81] High serum levels of leptin, a hormone produced by adipose tissue, are associated with reduced respiratory drive in severely obese individuals (Fig. 83-11).[81,106]

Basal O_2 consumption and CO_2 production are increased in morbid obesity.[91] Therefore, these individuals require higher levels of alveolar ventilation to maintain eucapnia.[82] In addition, the work of breathing is increased in morbid obesity.[107,108] To attain the requisite levels of ventilation and minimize the work per breath, obese individuals adopt a rapid shallow breathing pattern with breathing frequency about 40% higher than that of nonobese individuals.[103] The increase in breathing frequency is accomplished by shortening both inspiratory and expiratory time while the ratio of inspiration to total breath time (T_I/T_{TOT}) remains normal.[103,107,109] A rapid shallow breathing pattern allows them to minimize the elastic and resistive work per breath. This pattern is amplified in OHS.[104,109] These individuals have a breathing frequency that is higher and a tidal volume that is about 25% lower than individuals with SO.[104,109]

Exercise capacity is near normal in SO.[110] During treadmill exercise, minute ventilation, respiratory rate, heart rate, and oxygen consumption are generally higher in obese individuals than in

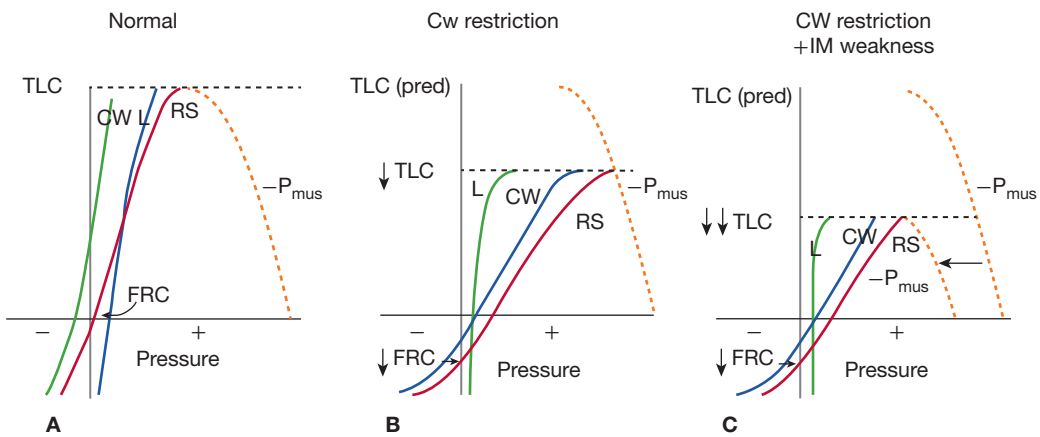

Figure 83-10 Schematic showing the volume–pressure relationships of the chest wall *(dashed line)*, lung *(dot and dashed lines)*, and respiratory system *(solid line)* for (**A**) healthy individuals, (**B**) individuals with chest wall restriction, and (**C**) individuals with chest wall restriction complicated by inspiratory muscle (IM) weakness. In panel B, the reduced chest wall compliance lowers respiratory system compliance, FRC, and TLC. In panel C, maximal inspiratory muscle pressures (P_{mus}) are half of predicted and the restriction is amplified by the presence of IM weakness.

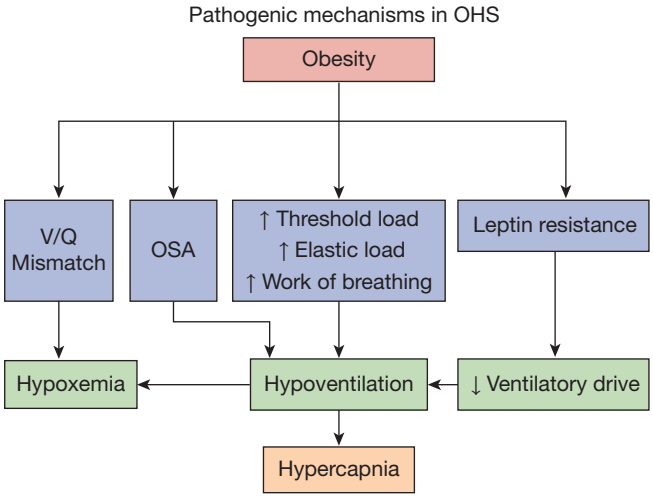

Figure 83-11 Factors involved in the pathophysiology of obesity hypoventilation syndrome.

normal weight individuals.[110,111] However, the anaerobic threshold is lower than in normal weight individuals.[110,111] With weight loss, the metabolic demands are reduced and carbon dioxide production and alveolar ventilation are reduced by approximately 20%.[112]

GAS EXCHANGE

Hypoxemia is either mild or absent in SO whereas it is usually present in OHS.[82] Hypercapnia during wakefulness, the defining characteristic of OHS, rarely occurs in obese individuals with a BMI less than 30 kg/m^2.[82,113] In obese individuals with a BMI greater than 30 kg/m^2, Pa_{O_2} is negatively and Pa_{CO_2} is positively related with BMI (Fig. 83-12).[82,113] In OHS, gas exchange abnormalities are primarily due to hypoventilation, which lowers the partial pressure of O_2 and increases the partial pressure of CO_2 in the alveoli. In addition, venous admixture due to ventilation–perfusion mismatch widens the alveolar–arterial oxygen gradient and worsens hypoxemia.[114] Mismatch of ventilation and perfusion is likely to occur at the lung bases, which are generally well perfused in obesity but poorly ventilated due to airway closure or atelectasis.[94,114] Gas exchange abnormalities are amplified when obese individuals assume the supine position.[115] This can be a major concern during induction of anesthesia as these individuals may become profoundly hypoxemic.[116]

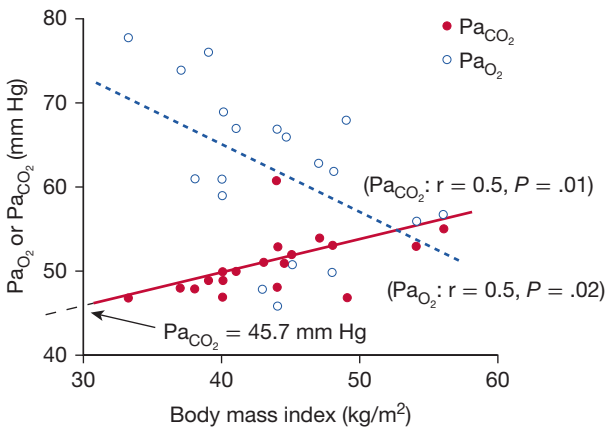

Figure 83-12 Relationship between Pa_{CO_2} and Pa_{O_2} with body mass index in patients with obesity hypoventilation syndrome. *(Reproduced with permission from Mokhlesi B. Obesity Hypoventilation Syndrome: A State-of-the-Art Review, Respir Care. 2010;55(10):1347–1362.)*

TREATMENT

Although difficult, dietary changes combined with exercise and behavioral modifications can lead to weight loss in some obese individuals. However, these modalities are usually not successful in maintaining long-term weight loss.[117] Bariatric surgery has evolved into a relatively common intervention that can produce not only weight loss but also long-term maintenance of weight loss.[118] In patients with OHS and acute or chronic hypercapnic respiratory failure, intermittent noninvasive ventilation may improve gas exchange, daytime somnolence, and quality of life.

Weight loss, induced either by diet or surgical intervention, has beneficial effects on pulmonary function, gas exchange, and ventilatory control in both OS and OHS.[81,119] A weight loss of about 40 kg leads to a significant increase in ERV and, to a lesser extent, increases in FRC, VC, and TLC.[81,119] The Pa_{O_2} increases by about 4 to 8 mm Hg due to improved ventilation of the lung bases. In OHS, the effects of weight loss on ERV and FRC are more pronounced than in SO, with VC increasing as well.[37,114] Similarly, Pa_{O_2} and Pa_{O_2} are significantly improved in OHS.[37,114] Following weight loss, ventilatory drive trends toward normal in both SO and OHS; namely it decreases in SO and increases in OHS.[81,120] The oxygen cost for a given level of exercise is also diminished after weight loss in OHS.[121]

FLAIL CHEST

Flail chest refers to a condition in which multiple rib fractures produce a segment of the rib cage that deforms markedly during breathing. According to a classic definition, double fractures of three or more adjacent ribs or the combination of sternal and rib fractures are required to produce a flail segment of the rib cage and lead to respiratory failure.[122] The flail segment is displaced inward rather that outward during inspiration However, clinical observations suggest that multiple single rib fractures in a single plane can also lead to respiratory failure. In this instance, the term "nonintegrated chest wall" rather than "flail chest" has been used.[123] Flail chest can occur in up to 15% of adults with chest wall trauma[124] The most common cause of flail chest is trauma related to automobile accidents or falls.[124,125] Other causes include rib fractures after aggressive cardiopulmonary resuscitation and rarely pathological rib fractures (i.e., multiple myeloma, other metastases).[126]

The diagnosis of flail chest can readily be made in spontaneously breathing individuals by inspecting the chest wall and observing the paradoxical motion of the flail segment of the rib cage. In fully sedated mechanically ventilated patients the diagnosis may be delayed until patients resume spontaneous breathing.[127] Chest radiographs showing multiple rib fractures confirm the diagnosis but usually miss 50% of rib fractures, especially those at the costochondral junction.[128] Chest CT with reconstruction of the rib cage is the best imaging modality to visualize rib fractures and to demonstrate the extent of injuries to the pleura and pulmonary parenchyma (Fig. 83-13).[129]

The mortality of chest wall trauma with no flail present ranges between 7% and 14%. When chest wall trauma is complicated by flail chest, the mortality rate further increases.[130] This can be attributed to pulmonary complications, such as pulmonary contusion, hemothorax, or pneumothorax, which can occur in up to 60% of patients with flail chest.[130] In addition, trauma sufficient to cause flail chest is often accompanied by extrathoracic injuries such as head trauma, rupture of the aortic arch or other arteries, laceration of the spleen or liver, and fractures of the long bones, all of which increase morbidity and mortality. Patients with multiple trauma and lung contusion complicating flail chest have mortality as great as 56%. Age is another factor strongly associated with mortality in patients with flail chest.[131] In one study, patients with flail chest over the age of 80 had a mortality of 86%.[132] In survivors of flail chest, long-term disability consisting of chest tightness, chest pain, or exertional dyspnea may occur.[133]

The novel use of Nuss bars for reconstruction of a massive flail chest. J Thorac Cardiovasc Surg. 2009;138(5):1239–1240.)*

■ RESPIRATORY FUNCTION AND RESPIRATORY MECHANICS

Disruption of rib cage integrity in flail chest renders motion of the flail segment entirely dependent on pleural pressure changes during breathing. Normally, rib cage expansion is accomplished by (a) the inflationary action of the contracting diaphragm on the lower rib cage; (b) the actions of the intercostal muscles on the upper rib cage; (c) positive intra-abdominal pressure in the zone of apposition of the diaphragm to the rib cage; and (d) the passive outward recoil of the rib cage at low lung volumes. During inspiration, pleural pressure becomes subatmospheric, which is inflationary to the lung and deflationary to the rib cage. When multiple rib fractures uncouple a segment of the rib cage from the remainder of the chest wall, the deflationary effect of subatmospheric pleural pressure is unopposed by the factors that promote rib cage expansion (Fig. 83-14).[64] Consequently, the flail segment moves inward rather than outward during inspiration. During expiration, pleural pressure becomes more positive and the flail segment moves outward. This paradoxical motion of the flail segment is augmented by conditions that load the respiratory system thereby amplifying pleural pressure swings. Specifically, conditions such as a reduction in lung compliance (pulmonary contusion or edema) or increases in airway resistance (bronchial secretions, bronchospasm) will make movement of the flail segment more pronounced.[64]

The most common anatomical location for flail chest is the lateral rib cage. Anterior flail chest occurs when there are separations between the sternum and the ribs.[130] Posterior flail chest is associated with less severe clinical derangements due to splinting provided by the paravertebral muscles. The pattern of paradoxical rib cage and abdominal motion is not unique to the location of the flail segment. Paradoxical chest wall motion may occur within the rib cage itself (i.e., between the upper and lower rib cage), or between the rib cage and abdomen (i.e., lower rib cage and anterior abdominal wall).[64] These different patterns of motion of flail chest may reflect different respiratory muscle recruitment patterns.[64] Supporting evidence for alteration in the pattern of respiratory muscle action is the

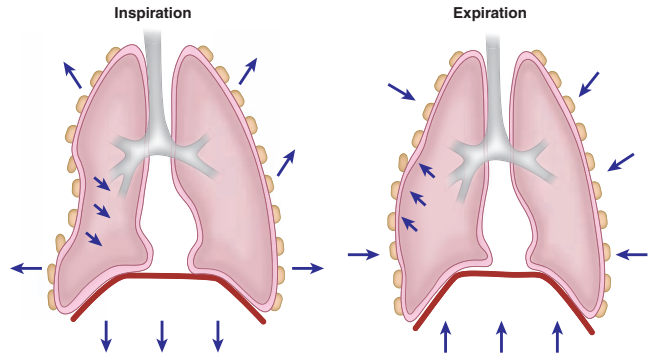

Figure 83-14 During inspiration, pleural pressure becomes more negative causing the flail segment to move paradoxically inward as the remainder of the chest wall is moving outward. During expiration, pleural pressure increases, causing the flail segment to move outward as the remainder of the chest wall becomes smaller.

observation that EMG activity of the external intercostal muscles increases more than threefold in the flail region.[134]

VC and FRC can be reduced to as much as 50% of predicted in patients with flail chest.[127] Paradoxical movement of the flail segment and coexisting pulmonary contusion contribute to reductions in VC. With surgical stabilization of the flail segment, VC usually returns to normal range in about 3 months. In patients with pulmonary contusion complicating flail chest, VC and FRC may remain reduced for up to 4 years due to fibrous changes in the contused area.[127,133,135]

The pathogenesis of respiratory failure in flail chest is complex. The notion that the paradoxical motion of a flail segment contributes to respiratory failure through a pendelluft-like movement of gas from the normal hemithorax to the flail hemithorax is not valid. Rather, factors related to flail-induced changes in lung and respiratory muscle function likely contribute to respiratory failure. Specifically, flail chest is accompanied by considerable pain, which can impair cough effectiveness, cause regional atelectasis, rib cage muscle spasm, and alter the pattern of respiratory muscle activation and recruitment. In addition, flail chest may increase the elastic load imposed on the respiratory muscles through development of regional (near the flail segment) or generalized atelectasis (due to splinting and pain). Associated pulmonary contusion also would increase the elastic load and work of breathing. In addition, the work of breathing is increased because the inspiratory muscles have to shorten more for a given tidal volume. The excessive muscle shortening represents extra work that is not measured using standard calculations of work per breath (the muscles shorten but do not produce measurable flow at the mouth).[64] Another adverse consequence of excessive inspiratory muscle shortening is a reduction in the mean operating length of the inspiratory muscles. When the inspiratory muscles are activated at a shorter than optimal length, inspiratory muscle efficiency is reduced, thereby adding to the oxygen cost of breathing.[64] The combination of added work of breathing, respiratory muscle inefficiency, hypoxemia due to atelectasis, and pulmonary contusion all combine to predispose these patients to respiratory muscle fatigue and respiratory failure (Fig. 83-15).

■ TREATMENT

The basic objective of treatment is to control pain and minimize atelectasis. Improved pain control also would enhance cough efficiency and allow for larger tidal volumes and reduce dead space ventilation. Pain control can be accomplished by use of oral or intravenous narcotics, intercostal nerve blocks, or epidural anesthesia. Adequate pain relief in combination with supplemental oxygen, frequent tracheal bronchial toilet, and cautious fluid replacement

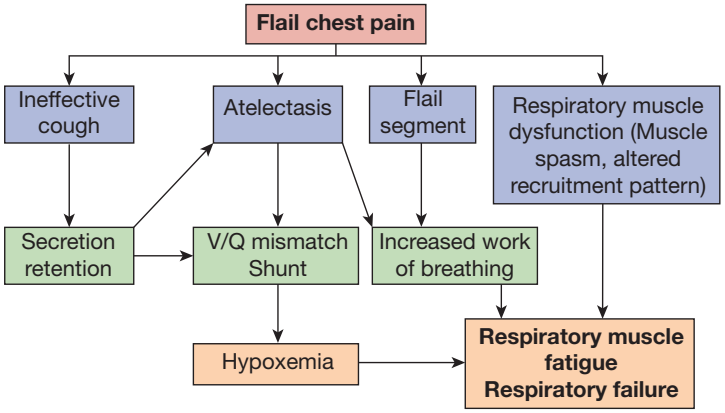

Figure 83-15 Factors involved in the pathophysiology of flail chest.

often prevents development of respiratory failure and leads to successful treatment of flail chest. Stability of the flail chest can be accomplished with the use of positive pressure mechanical ventilation or surgical fixation in selected individuals.

Mechanical ventilation with positive pressure breathing can stabilize the flail segment by eliminating the subatmospheric changes of pleural pressure that occur during spontaneous breathing. Prolonged mechanical ventilation as a means of treating flail chest was proposed in the 1960s and was initially accomplished through tracheostomy. However, complications related to mechanical ventilation, such as pneumonia, increased morbidity and mortality led to abandoning this modality as a primary means of stabilizing the chest wall. Currently, mechanical ventilation is indicated when there is respiratory failure, concomitant central nervous system or intra-abdominal injuries, shock, or the need to operate for other injuries. If mechanical ventilation delivered via an endotracheal tube is instituted, ventilator modes that minimize patient effort and the generation of subatmospheric pleural pressure should be employed. For example, low impedance modes of mechanical ventilation (i.e., high-flow continuous positive airway pressure [CPAP]) are associated with less chest wall distortion during inspiration.[64]

Noninvasive positive pressure ventilation may provide an alternative means of stabilizing the flail segment in selected patients who are breathing spontaneously.[136–138] This modality in conjunction with regional anesthesia can improve gas exchange and enable physiotherapy and early patient mobilization. In selected patients with flail chest, noninvasive ventilation may significantly reduce morbidity and length of hospitalization.[136–138] A randomized control trial comparing patients with mask CPAP versus assist control ventilation found that patients treated with mask CPAP had fewer complications, a shorter hospital and intensive care unit length of stay, and less ventilator time than patients with similar degrees of blunt thoracic trauma treated with assist control ventilation.[136] Larger trials evaluating noninvasive positive pressure ventilation are needed for further validation.

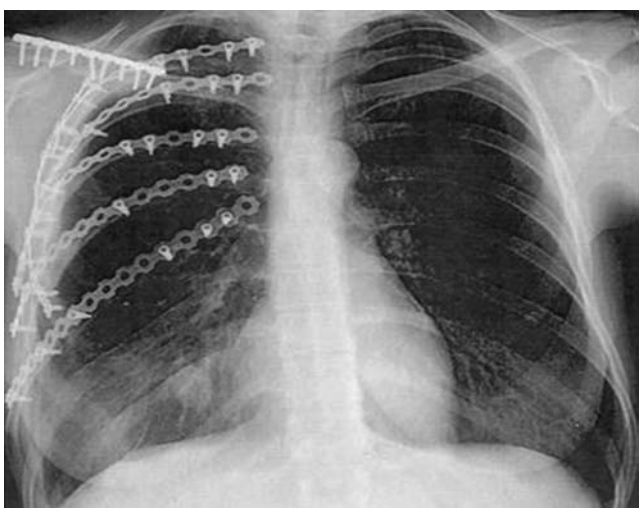

Figure 83-16 Chest radiograph depicting osteosynthesis plates in an individual who has undergone operative chest wall fixation for flail chest. *(Reproduced with permission from Engel C, Krieg JC, Madey SM et al. Operative chest wall fixation with osteosynthesis plates. J Trauma. 2005;58(1):181–186.)*

Surgical fixation of the flail chest can potentially provide substantial benefits to mechanically ventilated patients. In selected patients with flail chest, fixation of the chest wall with wires, steel plates, and splints improves respiratory mechanics and reduces the duration of mechanical ventilation as well as hospital stay (Fig. 83-16).[139–141] Operative fixation will likely benefit patients who are ventilator dependent and able to protect their upper airways. Other potential candidates may be patients undergoing thoracotomy for intrathoracic injuries, young patients with severe chest deformation, or patients with large unstable segments and borderline pulmonary function. The indications for operative fixation remain controversial largely due to the lack of studies comparing operative and nonoperative treatment.[139–141]

CHAPTER 84

Effects of Neuromuscular Diseases on Ventilation

Gerard J. Criner
Nathaniel Marchetti

INTRODUCTION

Neuromuscular diseases comprise a diverse group of disorders that vary markedly in etiology, rate of progression, pattern of respiratory involvement, prognosis, and therapy. Neuromuscular disorders impair the respiratory system as a vital pump; however, depending on the particular disease, the respiratory pump may be impaired at the level of the central nervous system (e.g., cerebral cortex or brainstem), spinal cord, peripheral nerve, neuromuscular junction, or respiratory muscle (Table 84-1).

The pattern of ventilatory impairment among these disorders is highly dependent on the specific neuromuscular disease. For example, some disorders may impair ventilation at only one level (e.g., isolated diaphragm paralysis) or simultaneously affect it at different levels (e.g., multiple sclerosis [MS]). In addition, the severity of impairment may be minimal and totally resolve with time and proper treatment (e.g., Guillain–Barré syndrome [GBS]) or is characterized by relentless progression to eventual respiratory death (e.g., amyotrophic lateral sclerosis [ALS]). Moreover, some neuromuscular diseases concomitantly affect several structures (e.g., swallowing dysfunction in poliomyelitis, interstitial lung disease in polymyositis), increasing ventilatory workload in patients who already have diminished ventilatory reserve.

This chapter describes the etiology, pathophysiology, and treatment of ventilatory dysfunction in neuromuscular diseases.

TABLE 84-1 Levels of Respiratory System Dysfunction Induced by Neuromuscular Diseases and Conditions

Level	Disease or Condition
Upper motor neuron	Parkinson disease
Cerebral	Vascular accidents Cerebellar atrophy Trauma
Spinal cord	Trauma Tumor Syringomyelia Multiple sclerosis
Lower motor neuron	
Anterior horn cells	Poliomyelitis Spinal muscle atrophy Amyotrophic lateral sclerosis
Motor nerves	Cardiac surgery Charcot–Marie–Tooth disease Diabetes Polyneuropathy Toxins Guillain–Barré syndrome
Neuromuscular junction	Neuralgia amyotrophy Critical illness polyneuropathy Myasthenia gravis Eaton–Lambert syndrome
Muscle	Botulism Organophosphate poisoning Drugs Dystrophy Acid maltase deficiency Malnutrition Corticosteroids Polymyositis

RESPIRATORY PATHOPHYSIOLOGY

Substantial information exists concerning the ventilatory function of patients with neuromuscular disease at rest and during sleep, as well as the effects on maximum static inspiratory and expiratory efforts and responses associated with these disorders to hypoxic and hypercapnic challenges. In general, the response of the respiratory system to moderate or severe neuromuscular disease is relatively stereotyped. The typical features are a reduced forced vital capacity (VC), reduced respiratory muscle strength, and, in some cases, malfunction of the neurons that control breathing.

CONTROL OF BREATHING

The breathing pattern is often abnormal in patients with neuromuscular disease. In comparison with healthy subjects, patients with respiratory muscle weakness have a low tidal volume and a high respiratory rate that persists in response even to hypoxic or hypercapnic challenge. Moreover, this rapid, shallow breathing pattern is not due to abnormalities in gas exchange (i.e., hypoxemia or hypercapnia) but is more likely to be due to severe muscle weakness and/or disordered afferent and efferent output in motor neurons impaired by the underlying neuromuscular disease.[1]

Changes in ventilation can be used to evaluate ventilatory drive in subjects with normal lung and respiratory muscle mechanics. However, ventilation is not a good index of respiratory motor activity in subjects with significant respiratory muscle weakness because the thoracic bellows cannot perform increased work of breathing. Decreased ventilatory response to hypoxic or hypercapnic challenge in these patients could indicate abnormalities in afferent information from diseased respiratory muscles, abnormal lung or chest wall mechanics, or upper motor neuron dysfunction, rather than an abnormality in the central control of breathing. In some neuromuscular diseases, degenerative changes in the muscle spindle, impaired afferent stimulation from abnormal stretch reflexes in the muscle spindles, or decreased mechanoreceptor output from tendons may explain the altered breathing pattern.[1]

Measurement of mouth occlusion pressure generated during the first 100 ms of inspiration ($P_{0.1}$) is relatively independent of inspiratory effort and therefore is a more reliable estimate of central ventilatory drive independent of respiratory muscle mechanics.[2] $P_{0.1}$ is maintained or increased in patients with neuromuscular disease despite substantial muscle weakness. The relationship between respiratory mechanics, respiratory muscle strength, and control of ventilation has been examined in patients with neuromuscular diseases in comparison with healthy control subjects. Although patients had 37% and 52% reductions in maximum inspiratory and expiratory mouth pressures, respectively, their $P_{0.1}$ was 66% greater than that of controls.[1]

Similar findings were encountered when normal subjects had acute muscle weakness induced by curarization. After severe muscle weakness was induced, significant increases in $P_{0.1}$ were observed

during hypercapnic challenge.[3] Partial curarization of spontaneously breathing cats also produced a marked increase in phrenic nerve discharge despite a substantial decrease in minute ventilation.[4] These studies indicate that under conditions of substantial respiratory muscle weakness, ventilation is not a reliable measure of central respiratory drive, and that central respiratory drive, at least when measured by $P_{0.1}$, is usually well preserved.

RESPIRATORY MUSCLE FUNCTION

Patients with neuromuscular disease who develop significant respiratory muscle weakness may experience fatigue, dyspnea and impaired control of secretions, recurrent lower respiratory tract infections, acute or chronic presentations of respiratory failure, pulmonary hypertension, and cor pulmonale.

The pattern, prognosis, and degree of respiratory muscle weakness attributable to a neuromuscular disorder are varied. They depend on the level of neuromuscular system impairment, the prognosis of the underlying disorder, and whether therapy is available. Patients with neuropathy, such as GBS, tend to have less severe respiratory muscle weakness than patients with lower motor neuron lesions or neuromuscular junction disorders, such as myasthenia gravis. Even when respiratory muscle dysfunction is observed, not all respiratory muscles are equally impaired, and the course of the underlying neuromuscular disease and degree of respiratory and nonrespiratory muscle impairment can be very different between patients with the same disease. In some neuromuscular disorders, respiratory muscle weakness is the only presentation of an underlying disease (i.e., neuralgia amyotrophy of the diaphragm); in the case of muscular dystrophy, significant respiratory muscle weakness may occur only late in the disease course. Severe, relentless, progressive dysfunction of the respiratory muscles may occur, as in ALS, or be characterized by exacerbations and relapses (e.g., MS). Finally, respiratory muscle weakness may completely reverse with time (phrenic nerve injury after open heart surgery) or with therapy (plasmapheresis in myasthenia gravis).

A significant proportion of patients with severe respiratory muscle weakness were also found in 50% of 30 asymptomatic patients with stable chronic neuromuscular disease. Reductions in inspiratory and expiratory mouth pressures did not correlate with general muscle strength assessment; however, the type of neuromuscular disease and distribution of general muscle weakness both correlated with respiratory muscle impairment.[5] Patients with myopathy, rather than polyneuropathy, whose involvement produced proximal rather than distal limb muscle weakness, were more likely to have significant respiratory muscle weakness. Pulmonary symptoms correlated poorly with evidence of respiratory muscle weakness.

Explanations for the lack of pulmonary complaints in these two studies despite significant muscle weakness are not clear. Patients with chronic and severe neuromuscular disease are usually sedentary and incapable of exertion and, therefore, seldom stress the respiratory system, which may explain their lack of symptoms.

The rapid, shallow breathing pattern found in patients with respiratory muscle weakness may be due to decreased respiratory muscle force generation, but it may also be due to changes in lung and chest wall elastic recoil. A decrease in inspiratory muscle tone may lead to unopposed lung elastic recoil, which reduces lung volume and produces chronic changes in chest wall tone and distensibility. Once inspiratory muscle strength decreases to approximately 30% of normal, abnormalities in gas exchange (manifested primarily by hypercapnia) commonly occur.

Expiratory muscle weakness is also commonly observed in patients with neuromuscular disease. It causes ineffectual cough and impaired secretion clearance, which in some patients lead to recurrent lower respiratory tract infections. In normal persons, dynamic compression of the central intrathoracic airways by large changes in pleural pressure generated by forceful contraction of the expiratory muscles acts to propel secretions proximally, where they can be expectorated. As expiratory muscle weakness progresses, pleural pressures generated during coughing efforts are reduced and airway clearance is impaired.

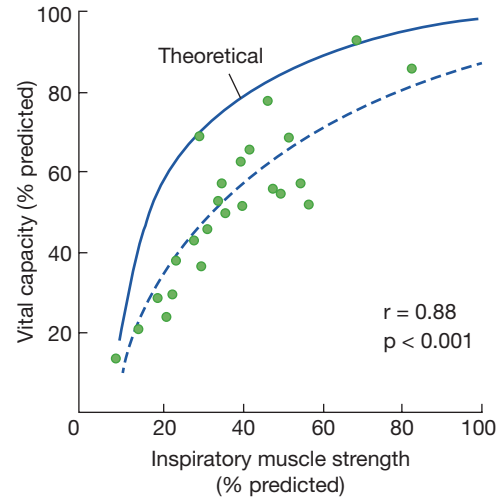

Figure 84-1 The *solid curve* represents the theoretic effect of respiratory muscle weakness on vital capacity (VC) on the assumption that the relaxation pressure–volume characteristic of the lung and chest wall are normal and that the inspiratory and expiratory muscles are uniformly involved. *Dashed curve* is the logarithmic regression calculated in 25 patients with neuromuscular disease *(closed circles)*. Data suggest that loss of lung volume is out of proportion to the degree of inspiratory muscle weakness. *(Data from De Troyer A, Borenstein S, Cordier R. Analysis of lung volume restriction in patients with respiratory muscle weakness. Thorax. 1980;35:603–610.)*

LUNG AND CHEST WALL MECHANICS

A characteristic hallmark of chronic neuromuscular disease is a decreased VC. The VC is reduced because of respiratory muscle weakness, and the decrease in VC parallels the progression of the underlying disease, but the magnitude of the reduction in VC is greater than expected solely based on the reduction in respiratory muscle force. The sigmoidal shape of the pressure–volume curve would suggest that large reductions in pressure initially produce only small reductions in lung volume. In 25 patients with a variety of neuromuscular diseases, De Troyer et al.[6] found that reductions in VC were much greater than expected, solely based on the reductions in inspiratory muscle strength (Fig. 84-1).

It appears that in addition to muscle weakness, alterations in the mechanical properties of the lung and chest wall contribute to the reduced VC. Using the mean deflationary pressure–volume curve of the lung in 25 patients with moderate-to-severe neuromuscular disease, De Troyer et al.[6] found, on average, a 40% decrease in lung compliance (Fig. 84-2). Furthermore, measurements of static lung compliance measured during inspiration in patients with neuromuscular diseases also show marked reductions, suggesting that chronic respiratory muscle weakness changes the elastic properties of the lung itself.[7]

The cause of reduced lung distensibility in patients with neuromuscular disease is unknown. Several causes such as failed maturation of normal lung tissue during childhood or congenital neuromuscular diseases, the presence of micro- or macroatelectasis, increased alveolar surface tension caused by breathing chronically at low tidal volumes, and alteration in lung tissue elasticity have been proposed.

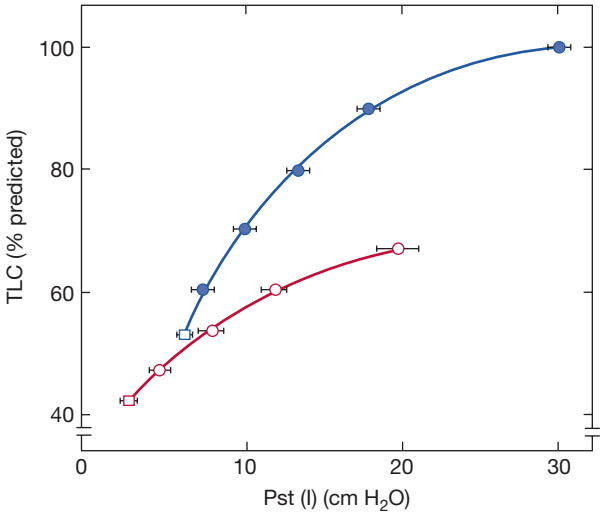

Figure 84-2 Static expiratory pressure–volume curve in patients with neuromuscular disease and respiratory muscle weakness. *Open circles* represent average data in 25 patients. Volume is displayed on the Y-axis as a percentage of predicted total lung capacity (TLC). *Closed circles* represent mean predicted values. In patients, absolute lung volume was decreased for any given transpulmonary pressure. *(Data from De Troyer A, Borenstein S, Cordier R. Analysis of lung volume restriction in patients with respiratory muscle weakness. Thorax. 1980;35:603–610.)*

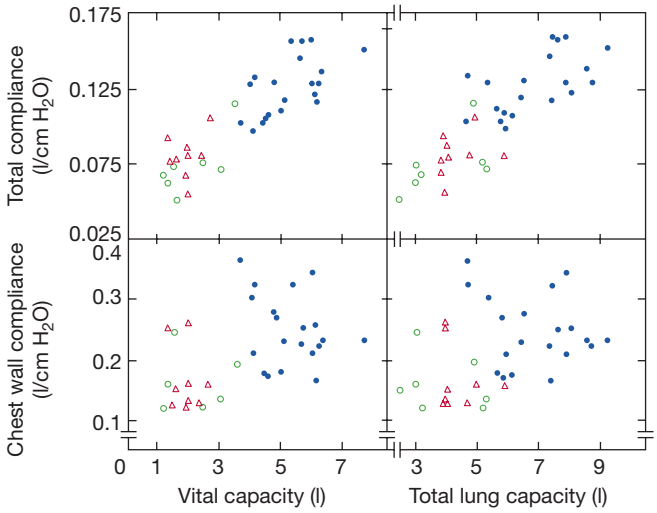

Figure 84-3 Relationships between total respiratory system compliance and VC and TLC (upper panels) and between chest wall compliance and VC and TLC (lower panels) in 16 patients with chronic neuromuscular diseases *(open symbols)* compared to 20 healthy controls *(closed circles)*. *Triangles* symbolize patients who are quadriplegic, *squares* symbolize patients who are paraplegic and four patients had generalized neuromuscular diseases *(circles)*. Compared to healthy controls *(closed circles)*, those with neuromuscular disease had significant reductions in both total respiratory system and chest wall compliance. *(Data from Estenne A, Heliporn A, Dellez L, et al. Chest wall stiffness in patients with chronic respiratory muscle weakness. Am Rev Respir Dis. 1983;128:1002–1007.)*

Impaired lung maturation is unlikely, since patients who develop neuromuscular disease in adulthood also have a reduction in VC that is disproportionate to the magnitude of respiratory muscle weakness. The presence of micro- and macroatelectasis also appears untenable, because most patients who have significant reductions in VC typically do not have alveolar collapse on radiographic imaging. Although rapid and shallow breathing patterns are encountered in patients with chronic severe neuromuscular disease, mechanical hyperinflation of the lung does not restore lung distensibility. Therefore, increased alveolar surface tension is not considered the principal cause of reduced lung compliance in patients with chronic neuromuscular disease.

Theoretically, a reduction in lung tissue elasticity may also contribute to a reduction in lung compliance in patients with neuromuscular disease, but there is no evidence that lung collagen, elastin, and other matrix proteins change in these diseases. Currently, the reason for the reduction in lung compliance in patients with chronic neuromuscular disease is unknown and awaits further study.

Many studies indicate that chest wall compliance is decreased by approximately 30% in patients with chronic neuromuscular disorder. In 16 patients with chronic neuromuscular diseases (e.g., spinal cord injury, Duchenne muscular dystrophy [DMD], and myasthenia gravis), the weighted spirometer technique was used to examine chest wall compliance in comparison with that of 20 healthy control subjects. The weighted spirometer technique delivers an airway pressure that causes an increment in thoracic volumes so as to construct the pressure–volume relationship. In 12 of these patients, chest wall compliance was reduced (Fig. 84-3).[8] Based on the contour of the pressure–volume curve of the normal relaxed chest wall at lower lung volumes, a reduction in functional residual capacity (FRC), as seen in patients with chronic neuromuscular diseases, may in itself reduce static chest wall compliance. However, in other disorders in which FRC is decreased owing to parenchymal lung disease (i.e., pulmonary fibrosis), a reduction in chest wall compliance has not been demonstrated. The mechanism for the reduction in chest wall compliance in patients with chronic neuromuscular disease has not been definitely established, but limitations in respiratory excursions have been proposed to lead to increased rib cage stiffness by decreasing the viscoelasticity of chest wall structures. Regardless of the mechanism, it appears that a reduction in chest wall compliance, along with a decrease in lung compliance, contributes to the marked decrease in VC observation in patients with neuromuscular disease.

Although reductions in VC appear to be clearly established in patients with chronic neuromuscular disease, the effect of chronic neuromuscular disease on FRC and residual volume (RV) are contradictory. FRC and RV have been reported to be unchanged, decreased, or mildly increased. Discrepancies between these studies could be explained by differences in the type of severity, and stages of neuromuscular diseases studied or body positions in which testing were performed. However, in two separate studies, patients with a wide variety of chronic neuromuscular diseases, all studied in a similar seated position, were found to have approximately 20% reductions in FRC but normally predicted values of RV.[9,10] Furthermore, confirmation of these findings was demonstrated in eight patients with myasthenia gravis given pyridostigmine, which acutely decreased FRC by approximately 15% without any significant change in RV.[11] On the basis of the previously mentioned data, it appears that patients with chronic neuromuscular disease have moderate reductions in VC and total lung capacity (TLC) that are associated with a moderate decrease in FRC and a normal RV. The decrease in VC not only is due to respiratory muscle weakness but also appears to result from decreased lung and chest wall compliance. Table 84-2 summarizes the effect of neuromuscular diseases on both lung volumes and central respiratory drive.

SLEEP-RELATED BREATHING DISTURBANCES

Breathing during sleep is often abnormal in patients with neuromuscular disease. Impaired sleep quality and hypopnea and hypercapnia

TABLE 84-2 Characteristic Changes in Respiratory Mechanics in Patients with Neuromuscular Disease

Central drive	Rapid shallow breathing pattern
	Decreased ventilatory response to hypoxic or hypercapnic challenge
	Normal or increased $P_{0.1}$ to hypoxic or hypercapnic challenge
Lung volumes	Decreased vital capacity (VC)
	Decreased inspiratory capacity (IC)
	Decreased functional residual capacity (FRC)
	Decreased expiratory reserve volume (ERV)
	Maintained residual volume (RV)

related to rapid eye movement (REM) sleep are frequent. Patients with chronic neuromuscular disease of various causes have significant and numerous episodes of nocturnal desaturation, which are most prevalent during REM sleep and are characterized by hypoventilation rather than upper airway obstruction (Fig. 84-4).[12] Of six patients, 16 to 22 years of age, with advanced DMD, randomized to breathing either air or oxygen on two consecutive nights, five demonstrated significant oxygen desaturation during REM sleep and approximately 35% reductions in minute ventilation compared to their baseline awake values. Furthermore, the severity of diaphragmatic dysfunction was related to the degree of oxygen desaturation.[13]

Several hypotheses have been proposed to explain nocturnal desaturation. Patients with chronic neuromuscular diseases develop an even more rapid and shallow breathing pattern during REM sleep. A rapid and shallow breathing pattern leads to increased dead space ventilation, which promotes hypercapnia and worsened oxygenation. Reductions in ventilatory drive may be accentuated during sleep in patients with underlying neuromuscular disease, especially in those who have pre-existing abnormalities of ventilatory control, which may further contribute to worsened nocturnal hypoventilation.

It has been hypothesized that patients with neuromuscular disease, especially with diaphragmatic dysfunction, may be more prone to nocturnal desaturation during REM sleep. Intercostal muscle and accessory respiratory muscle activity during REM sleep are depressed, with a greater contribution of the diaphragm required for maintenance of eucapnia and oxygenation. Support for this hypothesis comes from studies that have found diaphragm dysfunction to be highly correlated with the presence and magnitude of REM-related oxygen desaturation. A direct relation has been found between the lowest Sa_{O_2} value measured during REM sleep and the percentage fall in VC measured between the erect and supine positions, using the latter measurements as an index of diaphragm weakness. Similarly, among patients who have paradoxical abdominal movement, signifying a decrease in diaphragmatic contribution to ventilation, a greater oxygen desaturation in both REM and non-REM sleep is observed.[14] In contrast, patients with isolated diaphragmatic dysfunction with intact accessory muscle function are not predisposed to severe nocturnal hypoventilation.[15] Accordingly, severe hypoventilation may become evident only when diaphragmatic weakness is found in the background of global accessory and intercostal muscle weakness, or when ventilatory reserve is severely reduced for other reasons, such as asthma or chronic obstructive pulmonary disease (COPD).

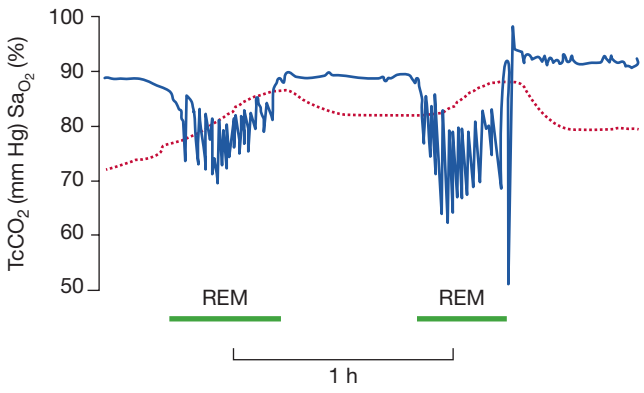

Figure 84-4 Oxygen desaturation and hypercapnia in REM sleep shown from a recording of an all-night sleep study. Transcutaneous carbon dioxide ($TcCO_2$) is shown as the *dashed line*; arterial hemoglobin oxygen saturation (Sa_{O_2}) is shown in the line with sharp deflections. Patients with neuromuscular diseases are often at risk for hypoventilation during REM sleep resulting in a decrease in Sa_{O_2} and increase in TcO_2. *(Data from Bye PT, Ellis ER, Issa FG, et al. Respiratory failure and sleep in neuromuscular disease. Thorax. 1990;45:241–247.)*

Abnormalities in nocturnal gas exchange are harbingers of problems in daytime gas exchange. Hypoventilation during sleep precedes the appearance of daytime hypercapnia, and patients with the most impaired gas exchange during REM sleep have the greatest degree of daytime hypercapnia. Moreover, patients with normal nocturnal gas exchange are unlikely to have abnormal daytime values. Noninvasive (e.g., nasal positive-pressure ventilation, external negative-pressure ventilation) or invasive (e.g., positive-pressure ventilation by tracheostomy) mechanical ventilation improves nocturnal gas exchange and sleep quality, with simultaneous improvement in daytime gas exchange.

Two theories have been proposed to explain the sustained improvements in gas exchange during daytime spontaneous breathing in patients with chronic neuromuscular disease who receive nocturnal ventilatory support. One theory states that nocturnal ventilation rests chronically fatigued respiratory muscles, thereby permitting improved spontaneous ventilation and gas exchange. Although several studies have demonstrated that noninvasive ventilation provides inspiratory muscle fatigue in patients with neuromuscular disease, or that mechanical ventilation consistently increases respiratory muscle strength. However, evidence that inspiratory muscle fatigue is commonly present in patients with neuromuscular disease or that mechanical ventilation consistently increases respiratory muscle strength is lacking. An alternative hypothesis suggests that nocturnal ventilatory support lowers the central respiratory center CO_2 set point and, thereby, sets the central controller to maintain a lower spontaneous daytime CO_2 level. This hypothesis is supported by studies showing that after several weeks of chronic nocturnal ventilation, hypoventilation was less severe in nocturnal studies without ventilation than it had been on baseline nights before chronic intermittent ventilation. Moreover, interruption of successful nocturnal noninvasive ventilation in patients with neuromuscular disease and chronic respiratory failure results in a return of nocturnal hypoventilation and symptoms of impaired gas exchange without evidence of respiratory muscle dysfunction. To date, neither of the previously mentioned theories has been established conclusively, and further investigation is warranted, as one or the other, or both, may be valid in different patients.

ASSESSMENT OF RESPIRATORY FUNCTION

Patients with significant respiratory muscle impairment may range from being totally asymptomatic to having moderate dyspnea at rest or, in some cases, overt respiratory failure. Some patients with neuromuscular disease may have significant weakness of the respiratory muscles and be asymptomatic,[16] whereas others may present with ventilatory failure without an established history of a neuromuscular

TABLE 84-3 Innervation of the Respiratory Muscles

Muscle Group	Innervation	
	Level	Nerve
Upper airway		
Palate, pharynx	IX, X, XI	Glossopharyngeal, vagus, spinal accessory
Genioglossus	XII	Hypoglossal
Inspiratory		
Diaphragm	C3–C5	Phrenic
Scalenes	C4–C8	
Parasternal intercostals	T1–T7	Intercostal

Lateral external intercostals	T1–T12	Intercostal
Expiratory		
Abdominal	T7–L1	Lumbar
Internal intercostals	T1–T12	Intercostal

disease. In the latter patients, the diagnosis of neuromuscular disease may initially be entertained only after difficulty is encountered in weaning the patient from mechanical ventilation. A detailed history and physical examination, coupled with appropriate diagnostic tests, enable the physician to diagnose the presence and type of neuromuscular disease and its effect on the respiratory system. The following section reviews features of the history and physical examination and the diagnostic studies considered useful in the assessment of respiratory function in patients with neuromuscular disease.

In order to provide an organized approach to direct the clinical history taking and physical examination of patients with neuromuscular disease, Table 84-1 characterizes the types of neuromuscular diseases that present at different levels of the neuromuscular system, and Table 84-3 describes the innervation of the different groups of respiratory muscles.

CLINICAL HISTORY

The signs and symptoms of respiratory muscle weakness due to a neuromuscular disease are usually nonspecific and of limited value. Moreover, the clinical manifestations of respiratory muscle dysfunction depend on the specific muscle or muscles affected and the extent of their impairment. In conditions of mild weakness, or in the early stages of neuromuscular disease, the patient may be totally asymptomatic.[16] As respiratory muscle weakness progresses, however, dyspnea on exertion, followed by dyspnea at rest occurs. Disturbances in sleep and daytime hypersomnolence resulting from nocturnal hypoventilation may occur, and if the expiratory muscles are affected, patients may have impaired cough and repeated lower respiratory tract infections. As respiratory muscle weakness becomes more severe, hypercapnia or hypoxemia becomes evident and respiratory failure may ensue, requiring ventilatory support.

The clinical history is invaluable in that it may be the first clue that a neuromuscular disease is the cause of the patient's pulmonary dysfunction. A history is also useful in characterizing the type of neuromuscular disease that is present. Dyspnea and impaired cough with or without recurrent lower respiratory tract infections may be the first clinical clues that a neuromuscular disease is present. Impaired swallowing due to bulbar symptoms and the presence of peripheral limb muscle weakness are indications that one is dealing with generalized neuromuscular disease.

PHYSICAL EXAMINATION

Although the physical examination may yield normal results in patients with early or mild impairment of the respiratory system, patients with more established disease often demonstrate tachypnea at rest. Further clinical information on the nature of the underlying disease and the extent of underlying muscle impairment can be gleaned from the pattern of respiratory muscle contraction in both seated and supine positions. Respiratory rate should be recorded along with any evidence of nasal flaring, intercostal muscle retraction, or palpable evidence of contraction of the sternocleidomastoid and scalene muscles. Furthermore, inward paradoxical motion of the rib cage or abdomen should be sought, as its presence may indicate a respiratory workload that is greater than the patient's respiratory muscle strength, or evidence of severe weakness of the diaphragm as a result of the underlying neuromuscular disease. Besides gross paradoxical movement of the rib cage or abdominal compartments, asynchronous compartmental movements (e.g., one compartment moving faster than the other) may be early evidence of impaired respiratory pump performance.

The hallmark finding of severe diaphragm weakness or paralysis is paradoxical inward movement of the abdomen with inspiration. In the presence of severe diaphragm weakness, the upper abdomen moves inward when the upper rib cage moves outward in stark contrast to the normal pattern of synchronized outward movements of the rib cage and abdominal compartments. Besides paradoxical movement of the upper abdomen, a marked increase in respiratory rate, accompanied by progressive accessory muscle use, and increased dyspnea occur when patients assume the recumbent position due to hypoxemia, hypercapnia, and placing the accessory inspiratory muscles at mechanical disadvantage. Upon reassuming the upright posture, patients may have palpable phasic contractions of the abdominal expiratory muscles. Physiologically, this inward movement of the abdomen on expiration enables passive outward movement of the upper abdomen and diaphragm descent during expiratory muscle relaxation in early inspiration.

Besides a detailed examination of the respiratory musculature and breathing pattern, the physical examination should include a complete neuromuscular examination to exclude systemic involvement. Inspection for atrophy or fasciculations of respiratory and nonrespiratory muscles may point to a lower motor neuron disease. The presence of scoliosis may contribute to the development of restrictive ventilatory pattern.

RADIOGRAPHIC ASSESSMENT

In patients with severe inspiratory muscle weakness or bilateral diaphragm paralysis, maximum inspiration is limited and lung volume appears reduced on chest radiograph. Unilateral hemidiaphragm paralysis produces an elevated hemidiaphragm on the affected side.[17]

Fluoroscopy is often used in the assessment of diaphragm paralysis with the patient making a forceful sniff in the supine position.[17] In unilateral diaphragm paralysis, a positive "sniff" test may demonstrate paradoxical upward movement of the affected hemidiaphragm. However, "sniff" tests have a false-positive rate as high as 6% in normal persons. The use of the "sniff" test to diagnose bilateral diaphragm paralysis is limited by compensatory abdominal muscle contraction. With abrupt cessation of abdominal muscle contraction during early inspiration, the abdominal contents descend caudally. The abdominal wall moves outward and the diaphragm will then appear to descend caudally, at least radiographically. Besides the fact that passive diaphragm descent due to active abdominal muscle contraction is a limitation during fluoroscopy, the fluoroscopic observational field used to examine the diaphragm is limited because of the small visual band that encompasses only the diaphragmatic dome and adjacent ribs. If rib cage rostral movement exceeds diaphragm ascent, the diaphragm will appear to descend lower than the thorax that may falsely suggest the presence of diaphragm shortening.[18]

TABLE 84-4 Two Approaches to Ultrasound of Diaphragm. Taken from the American Thoracic Society Consensus Statement on Respiratory Muscle Testing

Name of Test	Information Provided	Diagnostic Purposes	How to Perform
		Diaphragm	
Dome ultrasound 	Movement of right (or left) dome	Unilateral or bilateral diaphragm paralysis	Ultrasound probes with sufficient penetration (3 or 3.5 MHz) placed over abdomen (A) or over lateral rib cage (B). M-mode
Zone of apposition ultrasound 	Thickness at different lung volumes, relaxed or contracted	Detect contraction during tidal breathing or inspiratory effects Effects of pulmonary or neuromuscular disease, training, and disuse Placement of intramuscular electrodes	High-resolution probe with less penetration (7.5 MHz) over intercostal space, usually in anterior axillary line. B- or M-mode (C) Linear probe in craniocaudal plane over lateral rib cage. B-mode (D)
	Length at different lung volumes	Estimates of diaphragm length and swept volume	Both measurements are usually made on the right side

Although the diaphragm itself is poorly echogenic, ultrasound can be used to assess its function because the parietal pleura and peritoneal membranes lining the diaphragm are brightly echogenic. The two approaches used are the visualization of the dome or measurement of the muscle thickness at the zone of apposition.[2] Craniocaudal movement of the dome of the diaphragm can be measured by placing an ultrasound probe on the upper abdomen or on the lateral chest as shown in Table 84-4. This technique has compared favorably to the traditional fluoroscopic procedures used to assess diaphragm movement. Because the costal portion of the diaphragm is close to the skin, the zone of apposition (Table 84-4) is an ideal area to use ultrasound for assessment of the diaphragm thickness and estimation of length. The thickness of the diaphragm increases with increasing lung volumes and is inversely proportional to its length. Measurement of the zone of apposition will permit the detection of diaphragm contraction during inspiratory efforts when trying to diagnose diaphragm paralysis. As the subject with diaphragm paralysis makes an inspiratory effort there will not be thickening of the diaphragm at the zone of apposition. Measurement of the thickness also allows for the assessment of atrophy or the effect of neuromuscular diseases.

■ ARTERIAL BLOOD GAS ANALYSIS

Arterial blood gas abnormalities usually occur only in patients with severe respiratory muscle weakness. Hypoxemia is usually mild and may occur as a result of macroatelectasis and subsequent intrapulmonary shunting or ventilation–perfusion mismatch. In addition, patients with impaired muscle strength have impaired cough and may retain secretions that further contribute to the development of hypoxemia. Measurement of arterial oxyhemoglobin saturation by pulse oximetry, which has become an extremely common laboratory test for oxygenation, is an insensitive indicator of hypoventilation. In patients with mild-to-moderate respiratory muscle weakness, the value of solely measuring the level of oxygenation is limited and may be misleading.

Hypercarbia is an insensitive measure of respiratory muscle strength. The Pa_{CO_2} does not increase until respiratory muscle strength (measured by maximum inspiratory and expiratory mouth pressures) is less than 50% of predicted. In patients with severe respiratory muscle weakness, however, an elevation in Pa_{CO_2} may be evident. Serum bicarbonate and arterial pH values may help determine whether an acute or chronic respiratory acidosis is present. Because daytime hypercapnia is usually followed by nocturnal hypoventilation, the presence of daytime hypercapnia should prompt investigation of the breathing pattern and gas exchange during sleep, so that appropriate therapy (e.g., nocturnal supplemental oxygen or noninvasive ventilation) can be implemented.

RESPIRATORY MUSCLE STRENGTH

A variety of techniques have been used to assess respiratory muscle strength. Each is discussed below.

■ MAXIMUM MOUTH PRESSURES

Maximum static inspiratory and expiratory mouth pressures, measured at the airway opening during a voluntary contraction against an occluded airway, are the simplest and most commonly performed tests of respiratory muscle strength. Although several methods exist, the technique of Black and Hyatt is still the most widely used.[19] In this technique, mouth pressures are measured using a handheld manometer with the patient seated upright with a nose clip on. During these maneuvers, the patient purses the lips inside a circular wide-bore rubber mouthpiece, which prevents perioral air leakage. This small orifice (2 mm in diameter, 15 mm in length) is placed in the circuit to minimize the contribution of the facial muscles to airway pressure and to keep the glottis open. Maximum inspiratory pressures (PI_{max}) are measured near RV after maximal expiration, while maximal expiratory pressures (PE_{max}) are measured at or near TLC. In each case, efforts are maintained for at least 1 second. Maximum inspiratory and expiratory mouth pressures in normal males and females are listed in Table 84-5. Reported values in normal subjects vary widely and may be due to differences in techniques between different studies or a learning effect in subjects who perform these maneuvers.[20–25]

A major factor affecting PI_{max} is lung volume. PI_{max} is greatest at RV, whereby the inspiratory muscles are at greatest mechanical advantage and the outward elastic recoil of the respiratory system is maximum. On the other hand, measurement of PE_{max} is greatest at TLC because expiratory muscles are at greatest mechanical advantage and inward elastic recoil of the respiratory system is greatest (Fig. 84-5). Only at FRC, where the respiratory system recoil pressures measured at the airway opening are zero, are maximum inspiratory and expiratory mouth pressures solely a function of the pressure generated by actively contracting respiratory muscles (P_{mus}).

TABLE 84-5 Reported Values for Maximum Static Airway Pressures in Normal Adults

Study	Sex	No. of Subjects	Age Range (Years)	PI_{max} (cm H_2O)	PE_{max} (cm H_2O)
Black and Hyatt[20]	Males	60	20–54	124 ± 22	233 ± 42
	Females	60	20–54	87 ± 16	152 ± 27
Ringqvist[25]	Males	100	18–83	130 ± 32	237 ± 46
	Females	100	18–83	98 ± 25	165 ± 30
Leech et al.[22]	Males	325	17–35	114 ± 36	154 ± 82
	Females	480	15–35	71 ± 27	94 ± 33
Rochester Arora[21]	Males	80	19–49	127 ± 28	216 ± 41
	Females	121	19–49	91 ± 25	138 ± 39
Vincken et al.[24]	Males	46	16–79	105 ± 25	140 ± 38
	Females	60	16–79	71 ± 23	89 ± 24
Wilson et al.[23]	Males	48	19–65	106 ± 31	148 ± 34
	Females	87	18–65	73 ± 22	93 ± 17

Values are mean ± standard deviation.

Changes in lung volume due to chest wall or lung pathology may have important effects on the generation of maximum respiratory pressures in patients. For example, patients with COPD and significant hyperinflation have a larger FRC and RV than normal subjects; therefore, PI_{max} performed at FRC or RV usually results in lower values than in age- and sex-matched normal subjects. Likewise, a reduction in TLC due to restrictive ventilatory diseases may result in a reduction in measured values for PE_{max}. Therefore, it is important to realize that in patients with pathologically altered lung volumes, all or part of the reduction in mouth pressures may be due to inspiratory muscle mechanical disadvantage.

Maximum inspiratory and expiratory mouth pressures in patients with neuromuscular diseases range from normal to severely reduced. Patients may have significant respiratory muscle weakness without any pulmonary complaints, and no correlation exists between respiratory muscle strength and the presence of generalized nonrespiratory muscle weakness.[16] When PI_{max} falls below 30 cm H_2O, ventilatory failure commonly ensues.

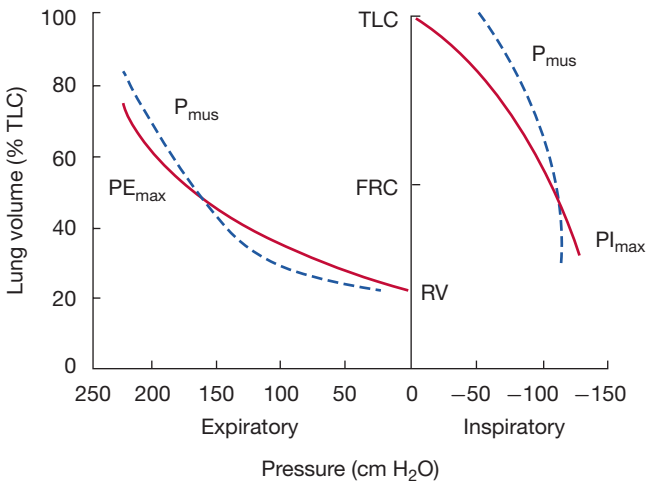

Figure 84-5 The effect of lung volume on maximum respiratory pressures (PI_{max} and PE_{max}) measured at the airway opening displayed by *solid lines*. Both PI_{max} and PE_{max} are made up of two components: the pressure generated by the respiratory muscles (P_{mus}, *dashed lines*) and the recoil pressure of the respiratory system. Only at FRC when recoil pressures are zero are PE_{max} and PI_{max} solely due to P_{mus}.

The assessment of a patient's ability to generate an effective cough is extremely important when managing the pulmonary effects of neuromuscular diseases. Nearly all of these disorders result in weak cough, which puts the individual at risk for aspiration and pneumonia. While a normal PE_{max} ensures that the patient has adequate cough, a low PE_{max} could result from poor effort, bulbar weakness not allowing a tight seal around the mouthpiece or true expiratory muscle weakness. Therefore there is interest in developing a test that will allow the assessment of cough strength in a nonvolitional manner. Measurement of positive pleural pressures with an esophageal balloon during a forceful cough (P_{es} cough) has also been proposed as a measure of expiratory muscle strength. P_{es} cough has been shown to decrease in parallel with PE_{max} when expiratory muscle weakness is induced by progressive curarization. A study examined the use of measurement of gastric pressures during cough (P_{ga} cough) in a group of normal subjects and in those with suspected respiratory muscle weakness from pulmonary and neuromuscular disease. The measurement of P_{ga} cough is theoretically better because it takes into account the abdominal musculature, eliminates the problem of leak around the mouthpiece, and a cough maneuver is easier to perform than the PE_{max} maneuver. In 122 patients with a normal PE_{max}, more than 95% also had a normal P_{ga} cough, but in 171 patients with a low PE_{max} 72 had a normal P_{ga} cough suggesting a high false-positive rate of a low PE_{max}. Conversely, in 105 patients with a low P_{ga} cough only 6 had a normal PE_{max} suggesting a low false-positive rate for a low P_{ga} cough.[31]

Transdiaphragmatic Pressure Measurement

While maximum static airway pressures are useful measures of global respiratory muscle strength, they fail to assess individual respiratory muscle function. Since the diaphragm is the primary muscle of inspiration, and may be susceptible to isolated disease (e.g., phrenic nerve paralysis after open heart surgery or idiopathic diaphragm paralysis), specific testing of diaphragm strength is desirable in some patients. Assessment of diaphragm strength is made by measuring gastric (P_{ga}) and endoesophageal (P_{es}) pressures with balloon-tipped catheters placed in the stomach and midesophagus, respectively. Transdiaphragmatic pressure (P_{di}) is then calculated as the algebraic subtraction of P_{es} from P_{ga} ($P_{di} = P_{ga} - P_{es}$).[2]

Maneuvers to elicit maximum transdiaphragmatic pressures ($P_{di,max}$) have been the subject of intensive study. Earlier studies measured P_{di} during maximum static inspiratory efforts against a closed airway (e.g., Muller maneuver) at FRC or RV. However, this maneuver results in submaximal diaphragm activation, with the degree of activation varying widely from subject to subject. Several studies have demonstrated significant intraindividual variability, with a coefficient of variation as high as 40% in measurement of $P_{di,max}$ during Muller maneuver. When five maneuvers to measure $P_{di,max}$ in 35 subjects (10 normal, 13 with restrictive lung disease, and 12 with COPD) were compared, a combined maneuver of active expulsion with superimposed Muller maneuver yielded the most reproducible and maximal transdiaphragmatic pressure.[32]

Phrenic Nerve Stimulation

A crucial factor in the measurement of diaphragm strength is the ability to consistently obtain maximal activation of the diaphragm during volitional efforts. Electrophrenic stimulation is a method that has been utilized to consistently activate the diaphragm. Besides assessing diaphragm strength, this technique has the added advantage of assessing phrenic nerve conduction and excluding the possibility of phrenic nerve injury in patients with diaphragm weakness of unknown origin.[2]

The phrenic nerve is stimulated in the neck near the posterior border of the sternocleidomastoid muscle, at the level of the cricoid

cartilage, where the phrenic nerves are most superficial. Stimulation may be performed either transcutaneously with surface electrodes (electrical stimulation electrodes), magnetic coil, or percutaneously with needle or wire electrodes. The percutaneous method is rarely used now. Stimulation of the phrenic nerves must be supramaximal with regard to voltage and current. Supramaximal conditions are ensured by increasing the stimulus intensity until maximum diaphragm muscle action potential (DMAP) or P_{di} is achieved. The DMAP is measured by surface electromyography (EMG) electrodes, and the P_{di} is measured by measuring the esophageal and gastric pressures via two pressure transducers as described earlier. The DMAP is then checked periodically throughout the study to ensure that consistent stimulation is maintained.[2,33]

The most commonly used technique of electrophrenic stimulation now employs a frequency of one pulse per second to measure P_{di} during a single unfused twitch contraction (e.g., $P_{di,tw}$). $P_{di,tw}$ has also been used to assess maximal static P_{di} indirectly by the twitch occlusion technique.[2,34] In this method, single twitches are superimposed on progressively stronger voluntary P_{di} contractions. As voluntary effort and P_{di} increase, the increment in P_{di} produced during the twitch (the twitch deflection superimposed on the P_{di}) decreases (Fig. 84-6A). When there is no discernible $P_{di,tw}$ deflection, it is assumed that the diaphragm is maximally activated and voluntary efforts from the inverse linear relationship between the amplitude of the superimposed twitch and P_{di} measured during volitional effort. The extrapolation of the line of this relationship to the X-axis has been interpreted as representing maximum static P_{di} (Fig. 84-6B).

An alternate way to perform phrenic nerve stimulation is via magnetic stimulation.[2,35] In this technique, an electric current is run through a coil thereby producing a magnetic field. The coil is placed over the spinous process of the seventh cervical vertebral body (cervical magnetic stimulation) stimulating the C3 to C5 cervical roots of the phrenic nerve causing the diaphragm to contract. Magnetic stimulation of this area will also stimulate contraction of neck and upper rib cage muscles as well. The advantages of this technique are that it is less painful than the electrical stimulation method, and it is easier to evoke diaphragm contractions. Also it is possible to perform magnetic stimulation of the phrenic nerve while the patient is in the supine position by placing the magnetic coil anterior to the sternum. This would allow for hospitalized bed-bound patients to be evaluated for diaphragm weakness via phrenic nerve stimulation. One of the disadvantages of magnetic stimulation is that it lacks the specificity that electrophrenic stimulation has for the diaphragm and obtaining an EMG_{di} signal can be more difficult with magnetic stimulation. When comparing magnetic stimulation $P_{di,tw}$ to electrophrenic $P_{di,tw}$, the $P_{di,tw}$ tends to be 20% to 25% higher with magnetic stimulation.

In addition to assessing diaphragm strength, phrenic nerve stimulation can be used to assess phrenic nerve function. The EMG_{di} is measured via surface or esophageal electrodes during electric or magnetic phrenic nerve stimulation and the phrenic nerve conduction time can be measured.[2] This measurement is useful when assessing possible injury to the phrenic nerve from thoracic surgery, trauma, or neuropathies (i.e., critical illness polyneuropathy [CIP] or GBS). The normal conduction time via electrical stimulation is 7.5 to 9 ms, but the normal conduction time via magnetic stimulation has not been well defined because activation of the brachial plexus affects the phrenic nerve conduction time. However, Luo et al. demonstrated that if the magnetic coil is placed anteriorly to the cricoid cartilage then the phrenic nerve conduction time was very similar to that obtained by electric stimulation. The authors believe that this occurred because there was more brachial plexus activation in the lower position compared to the higher position.[36]

Because of the relative invasiveness of electrophrenic stimulation of the diaphragm, and the large coefficient of variation in some studies when P_{di} was measured during maximal volitional efforts,

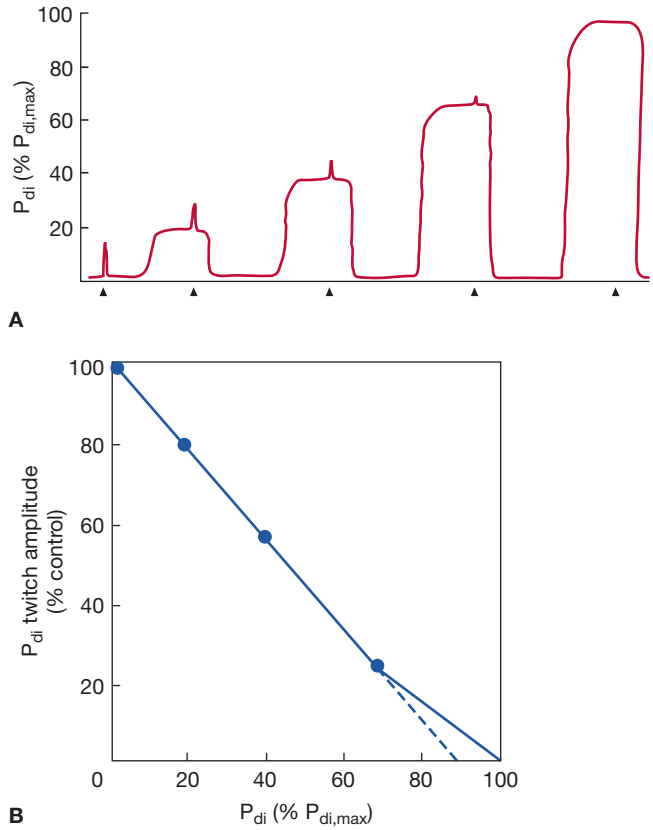

Figure 84-6 **A.** Illustration of a typical P_{di} tracing during twitch occlusion study. As the P_{di} increases during volitional efforts, the superimposed P_{di} deflection during phrenic nerve 1-Hz stimulation (twitch) decreases. At 100% of $P_{di,max}$, the diaphragm is maximally activated and no superimposed twitch is seen. *Arrows* on the horizontal axis mark indicate the phrenic nerve twitches. **B.** Data from A plotted as $P_{di,tw}$ amplitude versus voluntary P_{di}. Using linear regression, $P_{di,max}$ can be extrapolated from results obtained during submaximal efforts. It has been suggested that extrapolation performed from P_{di} values below 70% of maximum may underestimate $P_{di,max}$ by approximately 10% *(dashed line)*.

some investigators prefer measuring maximum inspiratory pressures during a sniff maneuver (Fig. 84-7). In this technique, the subject performs a vigorous sniff against an unoccluded airway. During such an effort, the nose acts as a Starling resistor, thereby generating intrathoracic pressures against an occluded airway. Some investigators argue that this maneuver approaches a more natural respiratory

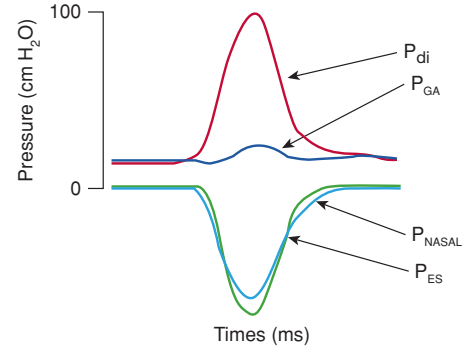

Figure 84-7 Pressure tracing produced utilizing sniff maneuver in a normal individual with gastric and esophageal balloon manometry in place. The noninvasive P_{NASAL} pressure closely mirrors that of the invasive P_{ES}. P_{GA}, gastric pressure; P_{di}, transdiaphragmatic pressure; P_{ES}, esophageal pressure; P_{NASAL}, nasal pressure during sniff maneuver.

effort than other types of maneuvers used to measure maximum inspiratory pressures and thus should be easily mastered by patients and more reproducibly performed by technicians.[37]

Analysis of Rib Cage and Abdominal Motion

During normal tidal breathing, the chest and abdominal compartments move synchronously in an outward direction, owing to diaphragm contraction decreasing pleural pressure and increasing abdominal pressure. In situations where the diaphragm is severely paretic or paralyzed, however, the flaccid diaphragm cannot counterbalance the negative changes in pleural pressure generated by contraction of the inspiratory muscles of the neck and rib cage. Instead of moving normally in a caudad direction the flaccid diaphragm moves paradoxically cephalad into the thorax. This change in diaphragm motion gives rise to a paradoxical inward motion of the upper abdomen indicative of severe diaphragm weakness or paralysis.

Changes in rib cage and abdominal pressure, or volume displacement during respiration, can provide important information about diaphragm strength. Partitioning of respiration can be examined from changes in abdominal and pleural pressures, as proposed by Macklem et al.[38] Changes in abdominal and pleural pressures during inspiration, expressed as the ratio of delta P_{ab}:delta P_{PL} are normally negative as pleural pressure becomes more negative and abdominal pressure becomes more positive. This ratio has a maximum value of +1 when the diaphragm does not contribute to inspiration and is valid only if the expiratory muscles do not contribute significantly to the pressures being generated. Alternatively, the partitioning of ventilation can be noninvasively measured by compartmental changes in rib cage and abdominal volume by respiratory inductance plethysmography or magnetometry. Optoelectronic plethysmography (OEP) is a technique that allows for measurement of chest wall and abdominal motion as well as lung volumes. A series of 89 retroreflective markers are placed on the thorax and abdomen that are monitored by a series of six to eight cameras (Fig. 84-8). The cameras record the distance the markers move in space and using Gauss' theorem the total thoracoabdominal lung volume can be calculated. OEP can differentiate between volume generated by the rib cage (rib cage musculature) and volume generated by the abdomen (diaphragm).[39] OEP can also be used to measure flow and is a nonvolitional test that can be done in any spontaneously breathing individual without regard to the degree of muscle weakness.[39] This technique has been used in patients with DMD to show that with disease progression the proportion of the tidal volume attributable to the abdomen decreases while the tidal volume attributable to the rib cage increases. Furthermore those that had this change in breathing pattern were more likely to have nocturnal desaturation.[40]

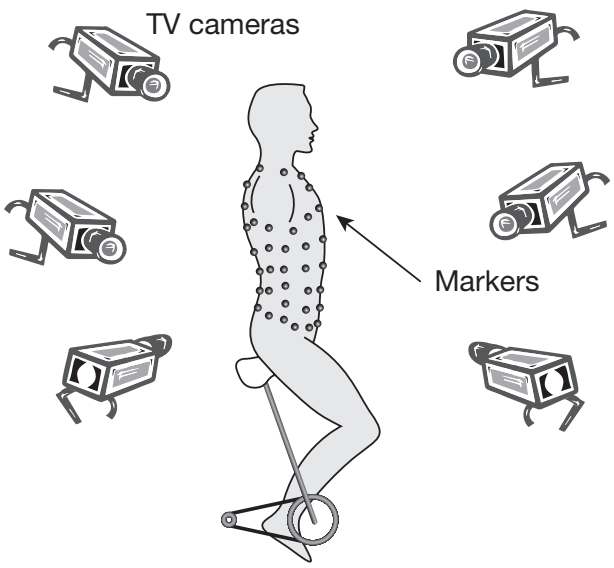

Figure 84-8 An example of optoelectronic plethysmography. A series of markers are placed on the subject's thorax and abdomen. A group of cameras record the distance the markers move in all planes thus permitting calculation of lung volumes during the breathing cycle. *(Reproduced with permission from Vogiatzis et al. Eur J Appl Physiol. 2005; 93(5–6):581–587.)*

SPIROMETRY

Respiratory muscle weakness induced by neuromuscular disease produces a restrictive pattern on spirometric testing with a reduction in VC.[6] As previously mentioned, the reduced VC is commonly out of proportion to the reduction in maximal respiratory muscle force. Reductions in lung and chest wall compliance also probably contribute. Moreover, because of the contour of the pressure–volume curve, large reductions in the respiratory muscle forces have to occur before VC is significantly reduced. A decrease in VC greater than 25% on moving from the upright to supine postures has been used as a sign of diaphragmatic weakness and a greater likelihood of sleep-related hypoventilation.[14,41]

Forced expiratory volume in 1 second (FEV_1) and measurements of midexpiratory flow rates ($FEF_{25–75}$ or FEF_{50}) are often greater than normal predicted values in patients with neuromuscular disease. Further increases in expiratory flow may occur in patients with neuromuscular disease due to increased lung recoil. Two independent studies have shown that partial curarization in normal subjects produces a decrease in peak expiratory flow with an increase in midexpiratory flow rates compared to baseline.[3,42] Moreover, myasthenia gravis patients at their baseline weakness prior to the administration of pyridostigmine have increased midexpiratory flow rates over the range of VC when referenced to absolute lung volumes (Fig. 84-9).[6]

FLOW–VOLUME LOOPS

Changes in the configuration of the flow–volume loop occur in various neuromuscular diseases.[2,43,44] These changes reflect respiratory

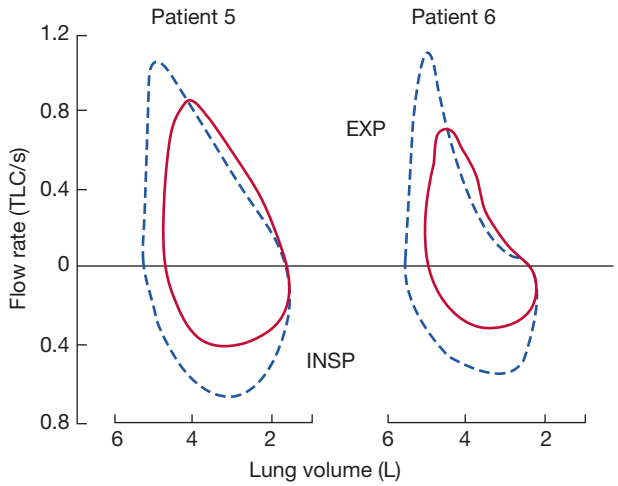

Figure 84-9 Two representative patients with myasthenia gravis and respiratory muscle weakness illustrating the effect of anticholinesterase therapy on maximum flow–volume curves. *Solid curves* represent pretreatment data; dashed curves were obtained following the injection of pyridostigmine. Prior to administration of pyridostigmine the midexpiratory flow rates were greater even though respiratory muscles were weaker and lung volumes were lower. *(Reproduced with permission from DeTroyer A, Borenstien S. Acute changes in respiratory mechanics after pyridostigmine injection in patients with myasthenia gravis. Am Rev Respir Dis. 1980;121(4):629–638.)*

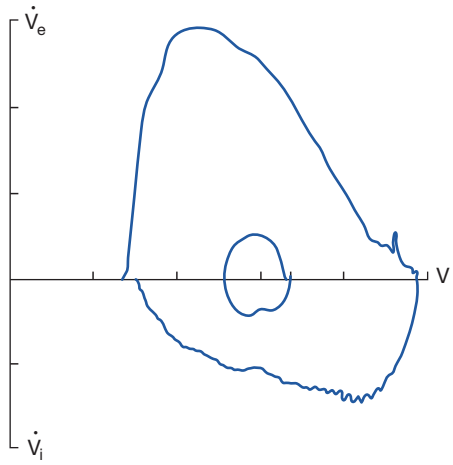

Figure 84-10 Flow–volume loop in a patient with motor neuron disease, showing inspiratory flow oscillation and inspiratory flow limitation. Determinants of respiratory muscle weakness in stable chronic neuromuscular disorders. Am J Med. 1987;82:53–58.)*

muscle weakness or malfunction of upper airway muscles. "Sawtoothing" of the flow contour is seen in extrapyramidal disorders affecting upper airway muscles.[45] Similarly, plateauing of the inspiratory flow waveform indicative of extrathoracic airway obstruction has been described in vocal cord paralysis caused by extrapyramidal neuromuscular disorders. An abnormal flow–volume curve is significantly more common in patients with clinically apparent bulbar muscle involvement (90% vs. 15%, respectively), and the presence of an abnormal, flow–volume loop predicted bulbar and upper muscle involvement by a neuromuscular disease with a high sensitivity and specificity.[46] A characteristic flow–volume contour showing involvement of the upper airway muscles by motor neuron disease is shown in Figure 84-10.

Among patients with stable, chronic neuromuscular disease, the flow–volume loop is significantly more disturbed in those with respiratory muscle weakness, and these abnormalities correlate with reduced mouth pressures. Several features of flow–volume loop configuration correlate with reduced maximum static inspiratory and expiratory mouth pressures; a reduced peak expiratory flow, decreased slope of the ascending limb of the maximum expiratory curve, a drop-off of forced expiratory flow near RV, and a reduction in forced inspiratory flow at 50% of VC (Fig. 84-11). A flow–volume loop score composed of the aforementioned parameters has a high degree of specificity and 90% sensitivity in predicting respiratory muscle weakness.[46]

LUNG VOLUMES

A restrictive ventilatory pattern is demonstrated in patients with neuromuscular disease. A reduced TLC and a normal or reduced FRC are common. The RV is usually elevated and is a sign of expiratory muscle weakness.

MAXIMUM VOLUNTARY VENTILATION

Maximum voluntary ventilation (MVV) is an index of respiratory muscle endurance in the presence of normal expiratory flow rates. This appears to be appropriate in patients with neuromuscular disease, since airway resistance and FRC are usually within the normal range. Values for MVV correlate with respiratory muscle strength and may be even more sensitive than VC in detecting respiratory muscle weakness.[2]

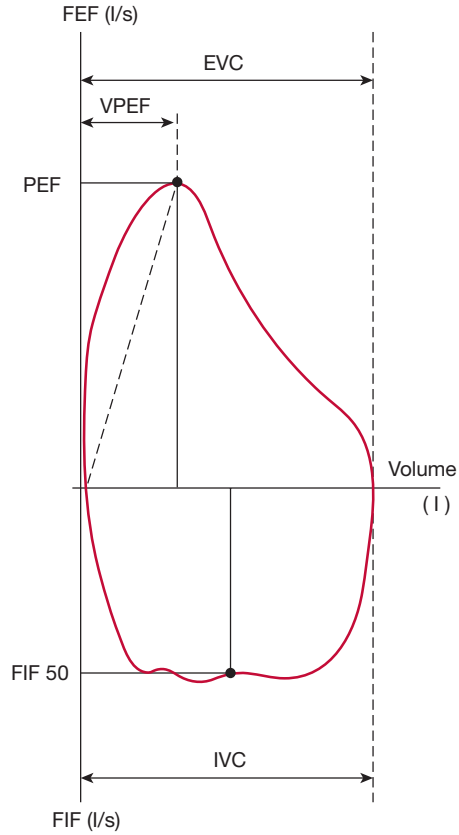

Figure 84-11 Representative flow–volume loop of a patient with chronic neuromuscular disease, showing different volume loop parameters indicative of respiratory muscle weakness. These parameters quantify the effects of respiratory muscle strength on the effort-dependent portions of the flow–volume loop. These four parameters are peak expiratory flow (PEF); ratio of PEF to the exhaled volume at which PEF was achieved, rapid vertical drop of forced expiratory flow at residual volume, and forced midinspiratory flow. *(Data from Vincken W, Elleker MG, Cosio MG. Determinants of respiratory muscle weakness in stable chronic neuromuscular disorders. Am J Med. 1987;82:53–58.)*

SELECTED NEUROMUSCULAR DISEASES

A helpful approach toward understanding how specific neuromuscular diseases affect the respiratory system is to localize the anatomic involvement of the respiratory system. A detailed description of the neuroanatomy of respiration is outside the scope of this chapter and is covered elsewhere in this text. In general, however, neuromuscular disorders can be broken down into disorders that involve the upper motor neuron, the lower motor neuron, or the muscle itself.

Lesions that arise in the cerebral cortex, brainstem, or spinal cord are classified as upper motor neuron lesions and are characterized by an increase in muscle tone or spasticity, the presence of an extensor plantar response, and increased reflex activity. Lesions in the lower motor neuron system demonstrate flaccidity, depressed reflexes, muscular fasciculations, and atrophy. The location and character of the patient's weakness may enable one to identify the exact site of the lesion in the lower motor neuron system (i.e., the anterior horn cell, the peripheral nerve, the neuromuscular junction, or the muscle itself).

The following describes the effect of specific neuromuscular disease on the respiratory system and makes recommendations for treatment.

■ UPPER MOTOR NEURON LESIONS

A variety of disorders in which the primary pathology is centered on upper motor neurons have significant respiratory consequences. Each is discussed below.

Stroke

Hemispheric ischemic strokes reduce chest wall and diaphragm movement on the side contralateral to the cerebral insult. Decreased diaphragm excursion with stroke correlates with diaphragmatic cortical representation identified by transcranial magnetic stimulation. Bilateral hemispheric strokes are also associated with Cheyne–Stokes respiration, which is progressive hyperventilation alternating with hypoventilation and ending in apnea. This breathing pattern may result from increased responsiveness to carbon dioxide as result of interruption of normal cortical inhibition. The significance of Cheyne–Stokes respiration to stroke remains unclear but appears to be more common with bilateral than unilateral insults. Besides its effects on an alteration of breathing pattern, up to 50% of patients with strokes may have signs of pulmonary aspiration due to dysfunction of upper airway muscles that protect the airway.

Spinal cord injury

The degree of respiratory impairment depends on the level and extent of the spinal cord injury. High cervical cord lesions (C1–C3) cause paralysis of the diaphragmatic, intercostal, scalene, and abdominal muscles. Because all respiratory muscle activity is lost except for accessory and bulbar muscle function, high cervical cord injuries almost always require ventilatory assistance. In some patients, spontaneous breathing can be accomplished by glossopharyngeal breathing or diaphragmatic pacing because the phrenic nerve motor neurons (C3–C5) remain intact.

Middle cervical cord (C3–C5) lesions destroy the phrenic motor neurons and prohibit the use of phrenic nerve pacing. Patients with more caudal lesions (i.e., C4–C5 level) have an improved chance to wean from ventilator support compared to those with more cranial lesions (40% of patients with C3 lesions remain ventilator dependent.). Patients with lower cervical (C6–C8) and upper thoracic (T1–T6) cord lesions have intact diaphragm and neck accessory muscle action, but have denervated intercostal and abdominal muscles. These patients usually require ventilatory support only during the period immediately after the injury and rarely require long-term ventilation. Despite this these patients still have increased mortality. In a group of spinal cord injury patients not requiring mechanical ventilation or tracheostomy followed prospectively for a median of 4.5 years, predictors of death included age, cardiac disease, diabetes, smoking history, and lower FEV_1.[47] The decline in FEV_1 and FVC in these patients is related to aging, increasing BMI, smoking, persistent wheeze, and lower MIP.[48] These data suggest that there are modifiable risk factors that can be altered to improve outcomes in those with spinal cord injuries that do not require mechanical ventilation.

In a study of C5 or lower spinal cord–injured patients, inspiratory muscle strength was reduced to approximately 60% of predicted but was dependent on the level of cord injury. In this study, PI_{max} values in low cervical, midthoracic, and lower thoracic–upper lumbar lesions were 61%, 69%, and 75% of predicted, respectively, whereas PE_{max} values were 30%, 32%, and 54% of predicted, respectively. The lower PE_{max} values were explained by a paralysis of abdominal and intercostal muscles resulting in reduced cough and decreased clearance of bronchial secretions. Abdominal muscle paralysis probably accounts for an abnormally compliant abdomen in patients with lower spinal cord injury, which is in stark contrast to the 30% reduction in chest wall compliance believed due to abnormal rib cage stiffness.[8]

Patients with spinal cord injuries also have alterations in thoracoabdominal motion during tidal breathing that is further accentuated by changing from the erect to supine position. In quadriplegic patients with relatively intact diaphragm function, the distribution of respiratory muscle weakness results in paradoxical inward motion of the upper rib cage during inspiration owing to weakness of the parasternal and scalene muscles. This pattern of abnormal thoracoabdominal movement is more marked in the supine than in the upright position. Patients with high quadriplegia (above C3–C5) may be able to sustain short periods of spontaneous respiration because of inspiratory activity of the sternocleidomastoid and trapezius muscles. Phasic inspiratory EMG activity has been observed in the platysma, mylohyoid, and sternohyoid muscles. Analysis of ribcage motion in these patients shows increased upper rib cage diameter, due to the inspiratory action of the neck accessory muscles pulling the sternum cranially and expanding the upper rib cage.

The distribution of muscle paralysis in low cervical cord spinal patients also has a profound effect on the performance of forced expiratory maneuvers. In contrast to healthy normal subjects, in whom VC is moderately decreased on assuming the supine position, in quadriplegic patients there is a paradoxical increase in VC in the supine compared to seated position without a significant increase in TLC. In 14 quadriplegic patients (C4–C7), there was a 16% increase in VC on changing from the upright to supine position and a reduction in RV (29%) and TLC (on average, 6%).[27] The mechanism believed to be responsible for the increase in VC in supine quadriplegic patients is the hydrostatic effect of abdominal contents, causing cephalad displacement and diaphragm lengthening and thereby placing the diaphragm on a more favorable portion of its length–tension curve. The use of elastic binders when quadriplegics assume upright posture has been advocated to prevent the increase in abdominal compliance. Abdominal binding may have physiologic benefit by maintaining diaphragm precontraction length in a more optimum position on its length–tension curve.[49]

It was previously believed that all expiratory muscles were paralyzed in lower cervical cord injuries. However, studies of C5 to C8 quadriplegics indicate that phasic EMG activity of the clavicular portion of the pectoralis major is associated with a marked decrease in the anteroposterior diameter of the upper rib cage.[50] This portion of the pectoralis muscle receives innervation from the C5 to C6 cord level. With the arms placed at the subject's side, contraction of the caudate head of the pectoralis major causes caudal displacement of the manubrium sterni and upper rib cage. This expiratory action has been shown to decrease expiratory reserve volume (ERV) by 60% when the shoulders are held in abduction. After 6 weeks of pectoralis muscle isometric training, patients with low quadriplegia can have a marked increase in maximum pectoralis muscle isometric strength and a significant reduction in ERV.[51] Conceivably, therefore, training of this muscle could improve the effectiveness of cough in patients with low spinal cord injury.

In the months following spinal cord injury, pulmonary function typically improves. In patients with spinal injuries below the C5 level, VC is approximately 30% of predicted in the first week after injury, but increases to 45% of predicted by the fifth week and by the fifth month to approximately 60% of predicted.[52] Improvements in VC have been attributed to spasticity developing in previously flaccid intercostal and abdominal muscles thereby increasing the rigidity of the thorax and abdomen and improving diaphragm force generation.

There is a role for corticosteroid use in the acute management of spinal cord injury. Methylprednisolone given as a bolus 30 mg/kg followed by a 24-hour infusion at 5.4 mg/kg/h has been shown to improve motor function at 6 weeks, 6 months, and 1 year, but only in those received the drug within 8 hours of injury.[53] A subsequent study compared methylprednisolone infusion (5.4 mg/kg/h) for 48 hours to 24 hours after the administration of a bolus (30 mg/kg).[54] There was no difference in functional outcome between the two infusion periods except in those where the bolus dose was given between 3 to 8 hours after the injury. If the methylprednisolone was started between 3 to 8 hours after the injury, then those that received the infusion for 48 hours did have improved motor function at 6 weeks and 6 months.

There were higher rates of pneumonia and sepsis in the 48-hour infusion group but mortality was not different.[54] No trial has shown a mortality benefit, and it should be recognized that the outcome measured was an improvement in the functional independence measure (FIM) score and not a return to normal motor function.

Parkinson Disease

Parkinson disease is due to degeneration of neurons in the substantia nigra and has a prevalence in the United States of approximately 200 cases per 100,000 people. Parkinson disease can be either primary (e.g., idiopathic) or secondary, as in postencephalitic parkinsonism associated with the influenza pandemic, or part of a more generalized disorder, such as multiple system atrophy or drug abuse with MPTP (1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine).

Parkinson disease has been thought to be a purely motor disorder but recently non-motor findings are being associated with Parkinson disease, which can predate motor symptoms.[55] These findings have led to speculation that Parkinson disease could alter respiratory control at the level of the brainstem. A study in 15 subjects with early Parkinson disease and normal respiratory flow and volumes found that 7/15 had an abnormal ventilatory response while 11/15 has an abnormal occlusion pressure response ($P_{0.1}$) to hypercapnic challenge testing suggesting abnormal respiratory control.[56]

Respiratory abnormalities are common in Parkinson disease, with pneumonia being the most common cause of death. A substantial problem with Parkinson disease is glottic muscle dysfunction.[57] An abnormal flow–volume loop contour showing flow oscillations commonly occurs. On direct fiberoptic visualization of the upper airway, these oscillations correspond to rhythmic involuntary movements of glottic and subglottic structures. Physiologic evidence of upper airway obstruction may be present. In addition to the presence of oscillations in flow, a rounding off of the peak of the midexpiratory flow–volume curve, a lowered peak expiratory flow rate, and a delayed appearance of peak expiratory flow have been observed in Parkinson patients. These results have been interpreted as evidence for less coordinated or less "explosive" respiratory muscle contractions.[43,45]

Patients with mild-to-moderate Parkinson disease are able to perform simple single respiratory efforts (e.g., measurements of lung volume and maximum static inspiratory pressures) but have difficulty performing more complex, repetitive ventilatory efforts (i.e., sustaining inspiratory resistive loads to exhaustion and performing maximum unloaded breathing efforts). Performance of repetitive respiratory tasks is associated with an increased work of breathing when compared to that of an age-matched control group. These findings are similar to derangements in task performance exhibited by peripheral skeletal muscle groups in Parkinson patients.[26]

Treatment significantly improves neurologic scores, maximum expiratory pressures, and peak inspiratory flow. A recent meta-analysis has demonstrated that levodopa improves peak expiratory flow and FVC in Parkinson disease.[28] Deep brain stimulation by stereotactically placing electrodes into the suprathalamic nucleus or the globus pallidus nucleus has been shown to be equally effective when treating medically resistant patients.[58] The electrodes produce a low-voltage high-frequency stimulation that results in inhibition of the neurons in the nucleus. Although the effect on respiratory function has not been directly studied, this procedure has been shown to improve motor function and quality of life.[59]

Multiple Sclerosis

MS is a demyelinating disorder of the central nervous system, characterized clinically by remissions and relapses of clinical symptoms due to disseminating CNS lesions. MS is the most common neurologic disease afflicting young adults, with an estimated prevalence of 250,000 to 300,000 cases in the United States in 1990. The cause of the disease is unknown, although epidemiologic evidence points to genetic and environmental factors. Classic clinical symptoms include paresthesia, motor weakness, diplopia, blurred vision, dysarthria, bladder incontinence, and ataxia.

Because MS can cause focal lesions anywhere in the central nervous system, different patterns of respiratory impairment can occur. Impairment of the respiratory centers and the medulla can cause failure of automatic breathing (Ondine's curse), apneustic or neurogenic pulmonary edema. The three most common respiratory manifestations of MS are respiratory muscle weakness, bulbar dysfunction, and abnormalities in respiratory control.

Acute respiratory failure rarely occurs in this disease, but it can occur because of severe demyelination of the cervical cord. Diaphragmatic paralysis resulting in respiratory insufficiency has also been reported. Even with severe disability and impaired respiratory muscle strength, patients with MS seldom complain of dyspnea. This paucity of respiratory complaints may be due to restricted motor activities and greater expiratory than inspiratory muscle dysfunction. Clinical signs that may be helpful in predicting respiratory muscle impairment are weak cough and inability to clear secretions, limited ability to count on a single exhalation, and upper extremity involvement. Advanced MS is frequently complicated by aspiration, atelectasis, and pneumonia.

In a group of 38 patients that were not bedridden or wheelchair bound without bulbar involvement and a diagnosis of MS for 9.2 years, there was a significant decrease in the maximal inspiratory pressure (MIP) and the maximal expiratory pressure (MEP) to 77% and 60% predicted respectively.[60] In a group of 21 ambulatory stable MS patients, the percent predicted MEP was significantly reduced when compared to age-matched healthy controls (69.4% vs. 85.6%, $p = 0.03$). Furthermore, these patients had a greater change in the upright versus supine FVC compared to healthy controls (262 vs. 98 mL, $p = 0.001$).[61] Not surprisingly the MEP had an inverse correlation ($r = -0.47$; $p = 0.04$) with MS functional scores. These data suggest that even in ambulatory MS patients without respiratory symptoms respiratory muscle weakness is present, and should be monitored periodically (particularly MEP). In 60 bedridden MS patients, pulmonary function studies revealed severely decreased MIP (47% predicted), MEP (30% predicted), and VC that was 80% of predicted. In those with a VC below 80% predicted, the MIP and MEP were significantly lower than those with a normal VC.[62] In all of these studies the MEP was more affected than the MIP, and the respiratory muscle weakness directly correlated with the severity of the subject's overall neurologic function. Smeltzer et al. developed a pulmonary dysfunction index for patients with MS and found that it is correlated with MEP measurements. The score assesses the patient's assessment of cough and ability to handle secretions, the examiner's assessment of cough, and how high the patient can count on a single exhalation (Table 84-6). A subject with normal cough efficacy would have a score of 4 while an individual with the most impairment would have a score of 11.[63] Gosselink et al.[29] examined the effect of respiratory muscle training (e.g., three sets of 15 expiratory contractions at 60% of MEP twice daily) on respiratory muscle strength and the subject's pulmonary index score in a group of severe MS patients. At 3 months there was a statistically significant improvement in MIP, and although the MEP improved the p value was 0.07 compared to control patients. The pulmonary index was statistically better at 3 months and 6 months following expiratory muscle training but the FVC was not.[29] A subsequent study in 17 ambulatory MS patients who underwent expiratory muscle training was able to statistically improve MEP but this did not improve pulmonary function or markers of cough effectiveness.[64]

Treatment of MS has traditionally included the use of immunosuppressive agents such as high-dose corticosteroids, cyclophosphamide, and azathioprine. Other treatments have included intravenous immunoglobulin (IVIG), plasmapheresis, and recently medications such as glatiramer, mitoxantrone, and interferon beta (INFβ-1a).[65]

TABLE 84-6 Pulmonary Dysfunction Index for Multiple Sclerosis Patients

Clinical Signs		Score
Patient rating		
1. History of difficulty handling secretions	No	1
	Yes	2
2. Cough	Normal	1
	Weak	2
Examiner rating		
3. Strength of cough when asked to cough voluntarily as hard as possible	Normal	1
	Weak	2
	Very weak/inaudible	3
4. Value reached when patient counts aloud on a single exhalation after a maximal inspiratory effort	>30	1
	20–29	2
	10–19	3
	<9	4

The choice of therapy depends on the clinical situation and whether relapsing–remitting or secondary progressive disease is being treated.

Most of the available data has focused on treating the acute attacks of the relapsing–remitting form of the disease. In one randomized placebo-controlled study, treatment with 10 days of high-dose oral methylprednisolone resulted in improved neurologic function, but there was no difference in the reoccurrence of future acute exacerbations.[30] INFβ-1a has been shown in a multicenter, double-blind placebo-controlled study to decrease the relapse rate after 1 and 2 years of therapy.[66] Both the American Academy of Neurology and the MS Council for Clinical Practice Guidelines recommend the use of INFb for the treatment of acute attacks in relapsing–remitting MS.[65] The use of IVIG has been controversial due to a lack of randomized controlled trials, but it does appear that IVIG can both delay and prevent the occurrences of acute attacks in the relapsing and remitting form of the disease in some patients.[67] Achiron et al.[68] has shown that in patients given IVIG within the first 6 weeks of neurologic symptoms there was a significant reduction in disease activity as measured by MRI imaging and neurologic symptoms. However, there was no significant additional benefit to adding IVIG to methylprednisolone therapy, and a recent study looking at the effect of IVIG use for 27 months in secondary progressive MS failed to show any difference in progression of disability.[69]

■ LOWER MOTOR NEURON LESIONS

The spectrum of disorders of lower motor neurons affecting respiration is considered below.

Poliomyelitis

In the early part of the 20th century, poliomyelitis was the most common cause of lower motor neuron disease in the United States. Paralytic poliomyelitis is the most devastating respiratory presentation of poliomyelitis infection and is preceded by a period of fever and mild illness. After several days of mild fever and myalgia, symptoms disappear; then, 5 to 10 days later, fever reoccurs with signs of meningeal irritation and asymmetric flaccid paralysis. Respiratory motor nuclei may be directly involved, resulting in diaphragmatic or other respiratory muscle dysfunction. In 6% to 25% of paralytic cases, bulbar symptoms may arise, increasing the risk of upper airway obstruction, pooling of pharyngeal secretions, and pulmonary aspiration. Moreover, the central respiratory centers can be directly affected, resulting in irregular respirations.[70]

In contrast to GBS, sensation is intact. Tendon reflexes are significantly diminished or absent. Cerebrospinal fluid analysis shows a pleocytosis associated with mild protein elevation, and electroneuromyography shows widespread patchy denervation.

Fifteen to 30% of adults with paralyzing infection die and treatment overall is supportive. Many patients require aggressive ventilatory and hemodynamic support during the acute phases of their illness. As temporarily damaged nerve cells regain function, recovery begins and may continue for as long 6 months. Paralysis persisting beyond that point is permanent, however, and may be associated with complaints of severe pain, which sometimes recurs years after the illness.

Some patients develop progressive muscle weakness 20 to 30 years after the initial infection. This has been termed "postpolio syndrome."[70] Symptoms vary from mild-to-moderate deterioration of function, with fatigue, joint pain, or weakness that may progress to muscle atrophy. The most common symptom is muscle pain, (typically after exertion) which occurs in 36% to 86% of the patients. The weakness tends to progress slowly, with an average decline in muscle strength of approximately 1% per year. The pathogenesis appears to be due to dysfunction of surviving motor neurons, with slow disintegration of axonal terminals eventually leading to muscle denervation. Although respiratory complaints are common in this disorder, significant hypoventilation with elevated Pa_{CO_2} rarely occurs.[71] Respiratory failure is more common in those that required mechanical ventilation during the acute poliomyelitis phase.

Amyotrophic Lateral Sclerosis

ALS is a chronic, degenerative neurologic disorder characterized by death of motor neurons in the cerebral cortex and spinal cord. The result is a combination of upper and lower motor neuron dysfunction, manifested by spasticity and hyperreflexia muscle wasting, weakness, and fasciculations. It has an incidence of approximately 1 to 2 cases per 100,000 people. Males are more commonly affected than females—by a 2:1 ratio. Most cases are sporadic, but approximately 10% of cases are familial, and there is no difference in response to therapy in those with familial ALS (FALS) or sporadic cases.[72] ALS is now recognized as a multisystem disorder that can initially present as cognitive defects prior to the development of motor symptoms and is known as ALS with frontotemporal degeneration (FTLD). Additionally, some FTLD patients go on to develop motor symptoms consistent with ALS. The main pathologic finding is abnormal accumulation of insoluble proteins in the cytoplasm of motor neurons.[73] Recently, it was discovered that two of these proteins are TAR DNA–binding protein 43 (TDP-43), and fused in sarcoma/translated in liposarcoma (FUS/TLS). Mutations in the genes encoding for these proteins have been found in FALS, SALS, and FTLD, but not in ALS associated with mutations in the superoxide dismutase-1 (SOD-1) gene on chromosome 21.[73] Even in FALS genetic mutations have been discovered in only about 30% of the cases and most remain unexplained.[73]

The usual clinical presentation is progressive weakness of the distal extremities, although severe respiratory muscle weakness, particularly intercostal muscle and diaphragm weakness, has resulted in some ALS patients presenting with respiratory insufficiency as the initial symptom. Respiratory muscle impairment is more evident in the advanced stages of the disease. Abnormalities in pulmonary function are apparent, even in patients with mild extremity weakness. Progression of respiratory impairment is much faster in ALS than in other chronic neuromuscular disorders, and serial lung function studies in ALS patients show progressive reduction in FVC and MVV. In contrast to patients with other neurologic disorders, however, patients with ALS usually have a normal or slightly elevated transpulmonary pressures at FRC, and RV is usually increased

and continues to rise as the disease progresses with maintenance of a normal TLC.[74] These changes are thought to be due to earlier involvement of the abdominal musculature, with preservation of intercostal and diaphragm function. Support for these physiologic findings comes from pathologic studies that show a more pronounced loss of motor neurons in the lumbosacral and lower thoracic spinal segments than in the upper and midthoracic regions.

The use of respiratory muscle testing has been used to help determine the prognosis and help clinicians decide when to initiate ventilatory assistance. The sniff nasal inspiratory pressure (SNIP) test is theoretically easier than the FVC maneuver for the ALS patient, because a tight seal around a mouthpiece is not required. A sniff is a short voluntary inspiratory maneuver, which has been shown to correlate with invasive nonvolitional tests of diaphragm strength. A SNIP <40 cm H_2O was found to predict nocturnal hypoxemia better than FVC. More importantly, a SNIP <40 cm H_2O was associated with a hazard risk for death of 9.1 with a median 6-month survival of 50%. Surprisingly, in those with SNIF <40 cm H_2O 66% had an FVC above 50% and the hazard risk for death was 13.6 in this group.[75] When comparing the two techniques for the ability to predict 6-month mortality, the SNIP test had a sensitivity of 97% and specificity of 79% while the FVC was 58% sensitive and 96% specific.[75] A separate study also has shown that in ALS patients without bulbar involvement SNIP was superior to both VC and MIP in predicting the development of respiratory failure as defined by hypercapnia (Pa_{CO_2} >45 mm Hg) with a specificity of 85% and sensitivity of 81%.[76] In patients with significant bulbar involvement, there was no single test of respiratory muscle function that reliably predicted the development of respiratory failure.[76]

The shape of the flow–volume curve may also pinpoint the subgroup of ALS patients with greater weakness of the expiratory muscles. In patients with severe expiratory muscle weakness, the flow–volume curve near RV shows a sharp drop in flow such that the maximum expiratory curve has a concave appearance. This group of ALS patients usually has lower maximum expiratory pressures, smaller VC, reduced expiratory reserve volume, and a higher RV than do ALS patients with more-normal–appearing flow–volume curves.[74] A prospective study of 55 ALS patients demonstrated that the peak expiratory flow time increased over baseline at a rate of 4.7% per month while the decline in the FVC was only 1.2% per month. The authors concluded that the peak expiratory flow rate can be used as an earlier marker of pulmonary involvement from ALS.[44]

ALS is a progressive and uniformly fatal neuromuscular disease and all patients will eventually develop respiratory failure, which will necessitate the discussion of mechanical ventilation (see Chapter 85). Currently, guidelines from the American Academy of Neurology recommend treatment with noninvasive mechanical ventilation once the FVC is below 50% of predicted, MIP <−60 cm H_2O, SNIP <40 cm H_2O, or have orthopnea.[77] Ventilation with bilevel positive airway pressure has been shown to increase both survival and quality of life in patients with ALS, while those with orthopnea seemed to derive the most benefit.[78–81] A randomized controlled trial of noninvasive ventilation compared to standard of care in 41 patients with ALS that had orthopnea with PI_{max} <60% predicted or symptomatic daytime hypercapnia confirmed these findings. The investigators found that overall survival was prolonged in the noninvasive ventilation group (219 [75–1382] vs. 171 [1–878]) days; $p = 0.006$], with the greatest benefit in those without severe bulbar symptoms.[80] There was also improved quality of life in the noninvasive ventilation group overall but the effect was seen only in those without severe bulbar symptoms.[80]

Due to weakness of both inspiratory and expiratory muscles, ALS patients have diminished cough reflex. Impaired cough becomes even more important when airway secretions are increased during respiratory infections or in those with bulbar symptoms. One group of investigators prospectively followed 53 patients with ALS for 1 year and found that peak cough flow (PCF), peak cough flow/peak velocity time (PCF/PVT), and severity of bulbar symptoms were most predictive of ineffective cough during a respiratory infection.[82] A mechanical insufflation–exsufflation (MI-E) device can be used to augment cough in patients by providing positive airway pressure at 40 to 45 cm (insufflation) for a few seconds and then suddenly switching to 40 to 45 cm of negative pressure (exsufflation). This creates high volume expiratory airflow that can be timed with coughing during exsufflation. MI-E increased PCF by 19% in ALS subjects with bulbar symptoms and 21% in those without bulbar symptoms. Treatment of the other respiratory complications of ALS includes a high index of suspicion for impaired swallowing due to bulbar involvement. Difficulty in swallowing food or even saliva predisposes ALS patients to a markedly high risk for pulmonary aspiration. Special swallowing precautions, earlier placement of enteral feeding tubes, or antisialogues may be required.

Currently, the antiglutamate drug riluzole is the only pharmacologic agent approved for use in ALS. This drug has been shown to induce a significant improvement in median survival from 11.8 to 14.8 months and decrease the rate of deterioration in muscle strength in comparison to a placebo.[83,84]

However, despite any pharmacologic interventions, ALS is a progressive and fatal neuromuscular disease and all patients will eventually develop respiratory failure and ventilatory assistance will therefore need to be considered. In those without bulbar involvement, noninvasive forms of ventilatory support are clearly indicated and will provide both a survival and quality-of-life benefit. Airway intubation may be required because of bulbar dysfunction further impairing cough and the inability to clear secretions. Long-term invasive ventilatory support is infrequently applied in ALS patients, but decisions must be made on an individual basis.

■ DISORDERS OF PERIPHERAL NERVES

Phrenic nerve dysfunction can be a significant cause of respiratory weakness in patients with neuromuscular diseases due to a variety of causes.

Diaphragm Paralysis

Unilateral or bilateral diaphragm paralysis following phrenic nerve injury can result from cardiac surgery, trauma, mediastinal tumors, infections of the pleural space, or forceful manipulation of the neck. Phrenic nerve injury during open-heart surgery is one of the most common causes of unilateral and bilateral diaphragm paralysis and is due either to cold exposure during cardioplegia or to mechanical stretching of the phrenic nerve during surgery. Diaphragm paralysis may also be seen with a variety of motor neuron diseases, myelopathies, neuropathies, and myopathies.

Bilateral diaphragm paralysis is characterized by a severe restrictive ventilatory impairment, with VC being frequently less than 50% of predicted in the upright position and a further reduction of 25% or more in VC in the supine position. TLC is also markedly decreased, as well as FRC and static pulmonary compliance. In most patients with nontraumatic bilateral diaphragm paralysis, the most important clinical feature is orthopnea out of proportion to the severity of the underlying cardiopulmonary disease.[15]

In patients with nontraumatic bilateral diaphragm paralysis, the diaphragm usually goes unrecognized until they present with cor pulmonale or cardiorespiratory failure. A chest radiograph showing elevation of both hemidiaphragms with volume loss and/or atelectasis at the lung bases is common. The diagnosis of bilateral diaphragm paralysis should be considered when any of the following four abnormalities is present: (1) a 40% or greater reduction in VC in the supine compared to upright position; (2) fluoroscopically observed paradoxical movements of both hemidiaphragms during a "sniff" test; (3)

absence of phrenic latency or phrenic nerve conduction velocity tests or lack of EMG evidence of spontaneous diaphragm activity; and (4) transdiaphragmatic pressure two standard deviations below the expected mean for normal subjects with paradoxical inward abdominal motion during maximum inspiratory efforts.[2,17,18,85]

Because in most patients, bilateral diaphragm paralysis occurs in the context of global respiratory muscle impairment, measurements of PI_{max} and PE_{max} may be sufficient to arouse suspicion of diaphragm paralysis as a cause of the patient's complaints. With diaphragm paralysis, a marked reduction in PI_{max} with preservation of PE_{max} should be found, and in general, there is a correlation between maximum inspiratory pressures and $P_{diSNIFF}$. Reductions in $P_{diSNIFF}$ to less than 30 cm H_2O are accompanied by orthopnea, a supine decrease in VC, and the presence of abdominal paradox. In most cases, the presence of severe bilateral diaphragm weakness can be diagnosed from physical examination, measurements of VC in the upright and supine positions, and PI_{max} and PE_{max}. In cases where the diagnosis is uncertain, or when definite documentation is desired, measurement of transdiaphragmatic pressures, phrenic nerve conduction times, EMG activity, transdiaphragmatic pressures during phrenic nerve stimulation, or ultrasound imaging of the diaphragm may be performed.[2] An elevation in Pa_{CO_2}, particularly in the supine position in patients with diaphragm paralysis, has been reported, but is not consistent.

Hemidiaphragm paralysis is more common than bilateral paralysis and is usually diagnosed from unilateral elevation of the hemidiaphragm on chest radiograph. Ultrasound of the diaphragm can be performed to confirm the diagnosis as well.[2] Most disorders reported as causing bilateral diaphragm paralysis have also been reported as causes of unilateral paralysis (e.g., cervical spondylosis, spine cord injury, poliomyelitis, and muscular dystrophy). Other, more specific causes of unilateral diaphragm paralysis are pneumonia, trauma from central vein cannulation, and viral infections of the cervical nerve roots.

Patient complaints and physical examination abnormalities in unilateral diaphragm paralysis are usually the same as with bilateral diaphragm paralysis but are less striking. Orthopnea is a frequent complaint, but it is less dramatic than in patients with bilateral paralysis. Moreover, physical examination findings are nonspecific, but occasionally may show paradoxical inward motion of the paralyzed hemidiaphragm with a reduction in breath sounds at the affected lung base and an increase in percussible dullness. The alveolar–arterial oxygen gradient may be increased with mild hypoxemia due to the reduction in ventilation and perfusion of the lower lobe on the affected side.

Tests of diaphragm function are intermediate between those in patients with bilateral diaphragm paralysis and normal predicted values. VC in the upright posture may be reduced to 74% to 81% of predicted, with a fall in VC also present in the supine compared to erect position, but of lesser magnitude than in patients with bilateral diaphragm paralysis. In patients with right hemidiaphragm paralysis, the fall in VC may be almost twice as great (19% vs. 10%) in comparison with left-sided paralysis, owing to the weight of the liver further encroaching on lung volume. Maximum inspiratory mouth pressures are frequently reduced to approximately 50% to 62% of normal. Similar reductions are also found in maximum P_{di} measured during maximum static voluntary efforts and during maximum sniff.

Treatment of patients with bilateral diaphragm paralysis is similar to that of other patients with chronic neuromuscular diseases. Eliminating nocturnal hypoventilation, especially during REM sleep is warranted, and the implementation of noninvasive ventilation, especially positive-pressure ventilation, may be indicated. In some cases of symptomatic unilateral hemidiaphragm elevation, surgical plication of the affected hemidiaphragm may relieve symptoms and improve FVC and transdiaphragmatic pressure. A series of 22 patients that underwent diaphragmatic plication were followed for an average of 4.9 years, and the investigators found that the percent decline in FVC from seated to supine position improved from 34% (range 10%–47%) preoperatively to 9% (range 0%–21%) postoperatively ($p = 0.004$). There also was an improvement in the transitional dyspnea index (TDI) postoperatively but the TDI did not correlate with the improvement in spirometry.[86] Surgical plication is achieved by placing a series of 6 to 8 U-shaped sutures in the diaphragm, which results in the diaphragm becoming fixed and immovable. This prevents excursion of the diaphragm into the thoracic cavity during inspiration, and permits the accessory muscles of respiration to generate negative intrathoracic pressure.

Guillain–Barré Syndrome

GBS precipitates respiratory failure more often than any other peripheral neuropathy. It is an acute idiopathic polyneuritis with an annual incidence of 0.89 to 1.99 cases per 100,000 people.[87] It usually presents as paresthesia and ascending paralysis of the lower extremities with absent deep tendon reflexes in a symmetrical distribution. Objective findings of sensory loss are variable, and the degree of motor weakness can range from mild paresis to complete paralysis. Maximum weakness of the lower extremities occurs within 2 weeks in 50% of cases, and 90% of cases reach their nadir in weakness by 4 weeks. After the nadir is reached, patients remain at that level for an additional 1 to 4 weeks before recovery begins. Facial, ocular, and oropharyngeal muscles may be impaired as well as the respiratory muscles. Respiratory muscle weakness and, specifically, severe diaphragm weakness may be found in patients with GBS.[87]

The distribution of muscle weakness between respiratory and nonrespiratory muscles is not uniform in GBS, and peripheral muscle strength does not correlate with the presence or absence of respiratory muscle weakness. However, ventilatory failure correlates with diaphragmatic weakness.

The impairment on respiratory tests in GBS is similar to that for other generalized neuromuscular diseases. A decline in FVC and maximum inspiratory and expiratory mouth pressures, impairment in nocturnal gas exchange during REM sleep, and the onset of hypercapnia detected by arterial blood gas analysis have all been reported in symptomatic GBS patients. An FVC of 15 cc/kg is a sign of imminent respiratory failure in GBS.[87,88] Hypercapnia is a late sign of respiratory failure, with the average Pa_{CO_2} at the time of intubation 43 mm Hg when FVC is less than 12 cc/kg.

Respiratory treatment of GBS patients is mainly supportive. Since bulbar involvement, leading to swallowing dysfunction, increases the propensity for pulmonary aspiration, special precautions for feeding and control of upper airway secretions may be required. Primarily because of bulbar dysfunction in those with respiratory failure, noninvasive ventilation has not been used outside of a few case reports. Individual cases without bulbar dysfunction merit special consideration and the use of noninvasive ventilation may be appropriate. Approximately 20% to 30% of GBS patients will require mechanical ventilation. Airway intubation and mechanical ventilation should be initiated when one major criterion or two minor criteria are present (Table 84-7).[87] Earlier intubation and assisted ventilation may be

TABLE 84-7 Criteria for Airway Intubation and Mechanical Ventilation in Guillain–Barré Syndrome

Major Criteria	Minor Criteria
Hypercarbia ($Pa_{CO_2} \geq 48$ mm Hg)	Ineffective cough
Hypoxemia ($Pa_{O_2} \leq 56$ mm Hg)	Impaired swallowing
Vital capacity < 15 cc/kg	Atelectasis

TABLE 84-8 Erasmus GBS Respiratory Insufficiency Score (EGRIS) for Predicting Respiratory Failure in the First 7 Days of Hospitalization

Measure	Categories	Score
Days between onset of weakness and hospitalization	>7 d	0
	4–7 d	1
	≤3 d	2
Facial and/or bulbar weakness on hospitalization	Absent	0
	Present	1
MRC sum score at hospitalization	60–51	0
	50–41	1
	40–31	2
	30–21	3
	≤20	4

Low (0–2)	4	
Intermediate (3–4)	24	
High (5–7)	65	

GBS, Guillain–Barré syndrome; MRC, medical research council.

indicated to avoid complications that arise from progressive respiratory failure, overwhelming pulmonary infections, or both. When indicated, intubation and mechanical ventilation should be initiated early because emergent intubations have been associated with worse outcomes. It is well established that mechanical ventilation is indicated when the VC falls below 15 cc/kg. However, it would be ideal to predict the need for mechanical ventilation at an earlier time. A Dutch group of investigators demonstrated that the most important factors in predicting respiratory failure in the first week of hospitalization were Medical Research Council (MRC) sum score (a muscle strength score), days between onset of weakness and hospitalization, and the presence of facial and/or bulbar weakness at hospitalization.[89] Based on their model the Erasmus GBS Respiratory Insufficiency Score (EGRIS) was made and is shown in Table 84-8. Patients at highest risk for intubation (EGRIS 5–7) should be admitted to the ICU for close observation and timely intubation if required. Evaluation for discontinuation of mechanical ventilation is not different in individuals with GBS, but if the presence of dysautonomia is present at the time of extubation then reintubation rates are exceeding high (73% vs. 26.7%; $p = 0.008$)[90] while an improvement of >4 mL/kg in VC was associated with a 90% positive predictive value for extubation.[90] Aggressive pulmonary toilet, including repeated bronchoscopy, may be needed to decrease atelectasis and the incidence of nosocomial pneumonia.

In a multicenter trial, plasmapheresis (total of four treatments), using either albumin or fresh frozen plasma as replacement fluids, produced short-term benefits in earlier motor recovery, ambulation, reduction in number of patients who required assisted ventilation, and shortened the duration of mechanical ventilation.[91] A subsequent study from the same group showed that two plasmapheresis treatments were better than none in mild disease, but four were better than two in moderate and severe diseases. Giving more than four treatments was not beneficial, even in severe disease. IVIG, given within 2 weeks after the onset of GBS, may also be effective therapy.[92] IVIG has been compared to plasmapheresis and recovery was as effective as plasmapheresis and may have been slightly better. In a study of 150 patients with GBS, 53% of the group treated with IVIG had an improvement of one grade (on a seven point scale) in muscle strength compared to 34% of those treated with plasmapheresis after 4 weeks of therapy.[93] Currently, there is no evidence from randomized controlled trials to support the use of corticosteroids in the treatment of GBS.

Critical Illness Polyneuropathy

CIP was initially described in five patients that had survived sepsis and multisystem organ failure, and the entity is now recognized as a serious complication of critical illness that contributes significantly to morbidity and mortality.[94,95] The disease is common with as many as 68% of patients with sepsis and multisystem organ failure requiring mechanical ventilation having evidence of CIP on EMG/nerve conduction studies. Patients affected by this disorder typically exhibit varying degrees of musculoskeletal weakness, which ranges from mild weakness to near total paralysis with hyporeflexive deep tendon reflexes. Unfortunately, physical examination is unreliable as the sole means of diagnosis, and EMG with nerve conduction studies (EMG/NCS) are required to confirm the diagnosis. EMG studies in these patients show a reduction in the amplitude of the compound muscle action potential without significant prolongation of stimulus latency, suggesting primarily axonal nerve damage rather than a demyelinating process.

Recognition of CIP is important because the disease affects patient management and the prognosis of recovery from the critical illness. Patients that develop CIP tend to require a longer period of mechanical ventilation and longer hospital stays compared to those without CIP. Garnacho-Montero et al. found that in a group of patients with sepsis and prolonged mechanical ventilation that those with CIP required 34 days of mechanical ventilation versus only 14 days for those without CIP. Additionally, the weakness associated with CIP results in an extended rehabilitation period, and there is evidence of persistent neuropathy on EMG/NCS as long as 5 years after discharge from the ICU. Patients that develop CIP appear to have a higher mortality with one study showing a 3.5-fold increase in ICU mortality, and another with significantly higher in hospital mortality.[96]

Although the exact mechanism for axonal damage in this syndrome is unknown, several risk factors for the development of CIP have been described. Two of the most important risk factors are the presence of the systemic inflammatory response syndrome (SIRS) and the APACHE III score. One study looked at 98 patients prospectively and found that 72% of patients with SIRS and an APACHE III score above 85 will develop CIP. Multivariate analysis of associated risk factors from another study found that hyperosmolality, parenteral nutrition, the use of neuromuscular blocking agents, and neurologic failure (GCS <10) were associated with an increased risk of developing CIP.[97] Exactly how these risk factors lead to the development of CIP is not known, but possibilities include nerve toxins released during episodes of multiple system organ failure, antibiotics impairing neuromuscular transmission, protracted use of neuromuscular blocking agents, and hyperglycemia causing nerve ischemia by endovascular shunting.

Because no specific therapy for CIP exists, treatment is purely supportive and includes aggressive rehabilitation, nutrition support and treatment of any medical complications. It should be emphasized to both patient and family that recovery may be prolonged (as long as 5 years).[98]

■ DISORDERS OF THE NEUROMUSCULAR JUNCTION

Disorders of the neuromuscular junction, including myasthenia gravis, Eaton-Lambert syndrome, and botulism, may have profound effects on respiration. Each is discussed below.

Myasthenia Gravis

Myasthenia gravis is an autoimmune disorder characterized by impaired transmission of neural impulses across the neuromuscular junction due to the production of antibodies directed against the

acetylcholine receptor. The prevalence of myasthenia gravis is estimated to be approximately 1 in 10,000 people with 2-to-1 female-to-male predominance. It occurs more often in younger than older adults. The typical myasthenic patient presents with fluctuating muscular weakness, with improvement after rest and the administration of anticholinesterase agents (e.g., edrophonium chloride). Ocular, facial, and neck muscles are commonly affected, but patients who have the most severe respiratory involvement have either acute fulminating or late severe classifications of myasthenia gravis.

In 17 patients with moderate, generalized myasthenia gravis, pulmonary function studies before the administration of edrophonium chloride reveal a mild reduction in VC and moderate reductions in both maximum inspiratory (~54% of predicted) and expiratory (reduced to ~52% of predicted) mouth pressures.[99] Because of increased lung recoil pressure, normal or supranormal values of maximal expiratory flow are seen in relation to lung recoil pressure or absolute lung volume. Although upper airway obstruction due to bulbar muscle involvement is theoretically possible, it has rarely been reported. However, Putman and Wise examined flow–volume loops in myasthenia gravis patients that were adequate for interpretation. They found that in 12/61 patients with myasthenia gravis with reproducible flow–volume loops 7 had either a variable extrathoracic or fixed upper airway obstruction suggesting that upper airway obstruction may be more common than previously thought.[100]

Acute respiratory failure usually occurs in the setting of a myasthenic crisis or cholinergic crisis or as the initial presentation of the disease. A myasthenic crisis refers to worsening of the basic underlying disease, usually precipitated by decreased anticholinesterase medication, surgery, or administration of neuromuscular blocking medication. Clinical parameters useful in predicting the development of postoperative respiratory failure include the severity of the disease (e.g., acute fulminating or late severe categories of myasthenia gravis), a low preoperative VC, and bulbar symptoms.[101] The most common complications of myasthenic crisis are respiratory failure and recurrent pneumonias due to aspiration from bulbar involvement and impaired cough. The mean duration of mechanical ventilation in myasthenia gravis in a series of 22 patients was 8 days, with six patients (32%) requiring tracheostomy for prolonged mechanical ventilation. Of the 22 patients 21 survived and were totally weaned from ventilatory support over 1 to 32 days.[102] Noninvasive bilevel (BiPAP) positive-pressure ventilation is a viable option to treat respiratory failure during a myasthenic crisis until effective therapy is delivered. BiPAP was used in a series of 11 myasthenic crisis events in nine patients. The mean pressures used were 13/5 cm H_2O, and endotracheal intubation was avoided in all but four instances. The only predictor for failure of BiPAP was a Pa_{CO_2} above 50 mm Hg.[103] A subsequent study in 24 patients treated with BiPAP (mean pressure 14/6 mm Hg) had similar findings in that 58% of myasthenia crisis patients avoided intubation, and the best predictor of BiPAP failure was a Pa_{CO_2} >45 mm Hg. Although there was no difference in mortality, those treated with BiPAP had a shorter ICU length of stay (7 vs. 13 days, $p = 0.002$).[104] These data suggest that the use of early noninvasive ventilation prior to the development of severe hypercapnia can reduce intubation rates and ICU length of stay.

The treatment of myasthenia gravis includes anticholinesterase agents, high-dose corticosteroids, thymectomy, and plasmapheresis in patients' refractory to steroid or immunosuppressive therapy. Anticholinesterase agents are the first line of treatment. Most patients improve significantly with anticholinesterase agents, but only a few regain normal function. Remissions can be induced in up to 80% of patients with the use of corticosteroids. However, corticosteroids may cause temporary worsening of muscle weakness, usually on the sixth to tenth day of therapy, and close observation for signs of respiratory insufficiency is advisable.[101] Other immunosuppressive agents (e.g., cyclosporine and azathioprine) may be useful with or without concomitant corticosteroids.

In retrospective studies, thymectomy improves survival and relieves clinical symptoms, even in the absence of thymoma. In patients with thymoma, thymectomy is also indicated because the risk for malignant transformation is high in patients less than 55 years of age. In up to 80% of myasthenia gravis patients without thymoma, clinical improvement after thymectomy occurs during prolonged follow-up.

Plasmapheresis and the use of IVIG produce a temporary reduction in acetylcholine receptor antibody level and may be helpful in patients with respiratory failure not responding to anticholinesterase and immunosuppressive agents. Plasmapheresis and IVIG have been compared and both are equally efficacious. However, IVIG was associated with less severe adverse reactions and therefore is the preferred initial agent in the treatment of myasthenic crisis.

Eaton–Lambert Syndrome

Eaton–Lambert syndrome is a rare myasthenia disorder resulting from a reduction in neurotransmitter release from presynaptic terminals that develops in association with tumors (especially small cell lung carcinoma). Although patients may respond weakly to administration of edrophonium chloride, the disease is differentiated from myasthenia gravis by the predominant involvement of limb and girdle muscles compared to the ocular and bulbar muscle involvement in myasthenia gravis. Respiratory muscle weakness is often detected on pulmonary function tests, but respiratory failure is infrequent.

Botulism

Botulism is a rare disorder caused by the *Clostridium botulinum* toxin. It occurs as a result of eating improperly cooked food, wound contamination by the organism, or, especially in infants, the absorption of toxin from the GI tract. There are eight types of toxins, although human diseases are usually caused by type A, B, or E.

Botulinum toxin binds to the calcium channel in presynaptic terminals, impairing neuromuscular transmission of acetylcholine. GI symptoms predominate early in the disease, followed by neurologic impairment, including descending paralysis of the neck, trunk, and limb muscles. Weakness of the respiratory muscles requiring mechanical ventilation is frequent, especially with botulinum type A toxins. Spirometry usually reveals a restrictive ventilatory defect, and recovery from respiratory muscle weakness may take months, often requiring prolonged mechanical ventilation. The average duration of ventilatory support for type A poisoning is 58 days, in contrast to 26 days for type B botulism. Exertional dyspnea and poor exercise tolerance may persist, even with normal lung function.

■ INHERITED AND ACQUIRED MYOPATHIES

Respiratory function may be significantly affected by a variety of inherited muscle disorders and acquired myopathies (Table 84-9). The inherited muscular dystrophies refer to a heterogeneous group of progressive, degenerative, hereditary skeletal muscle diseases that cause severe muscle weakness, eventually resulting in repeated pneumonias, respiratory failure, and, in some cases, death. Respiratory failure, often accompanied by pneumonia, contributes to death in more than 75% of patients with DMD.

Inherited Myopathies

Duchenne Muscular Dystrophy DMD is the best characterized of these heredofamilial muscle diseases. This disease is transmitted by an X-linked recessive gene, although approximately one-third of cases arise from spontaneous mutation. The disease is due to the mutation of the gene for skeletal protein dystrophin, a subsarcolemma

TABLE 84-9 Myopathies Likely to Produce Respiratory Abnormalities

Inherited Myopathies	Acquired Myopathies
Muscular Dystrophies	Inflammatory (dermatomyositis, polymyositis)
Duchenne	Systemic lupus erythematosus
Myotonic	Endocrine myopathies
Fascioscapulohumeral	Thyroid dysfunction
Limb–girdle	Hyperadrenocorticism
Oculopharyngeal	Acute steroid myopathy
Congenital myopathies	Electrolyte disorders
Nemaline myopathy	Rhabdomyolysis
Centronuclear myopathy	
Metabolic myopathies	
Acid maltase deficiency	
Mitochondrial myopathies	

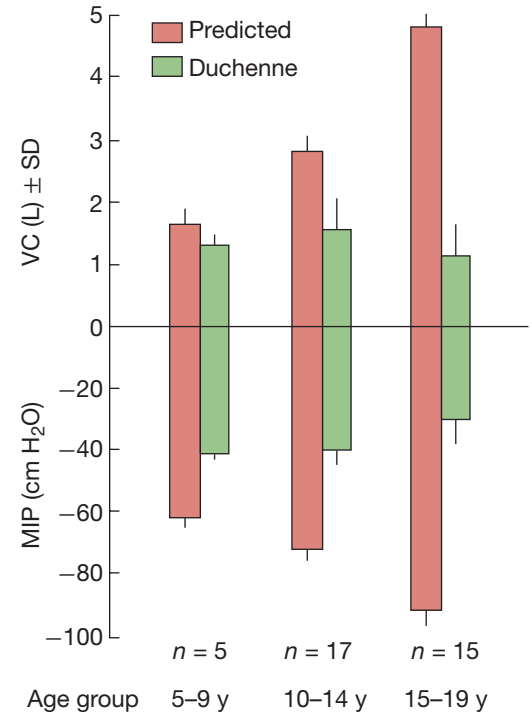

Figure 84-12 Mean vital capacity (VC) and maximum static inspiratory pressures (MIP) in 37 DMD patients in three age groups *(shaded bars)* in comparison to normal predicted values *(unshaded bars)*. MIP decreases gradually as DMD progresses, despite body growth, whereas VC increases until patients reach their early teens. *(Data from Smith PEM, Edwards RHT, Evans GA, et al. Practical problems in the respiratory care of patients with muscular dystrophy. New Engl J Med. 1987;316:1197–1205.)*

protein believed to play a major role in providing structural integrity in the muscle cell surface membrane. Lack of dystrophin leads to a weaker cell membrane that becomes further impaired with muscle contraction. Muscle inflammation, necrosis, and fibrosis subsequently lead to severe atrophy and loss of function. Approximately 30% to 40% of the normal amount of dystrophin must be expressed in order to prevent major myopathic symptoms. The diagnosis is confirmed by demonstrating mutation of the dystrophin gene in DNA from peripheral leukocytes, or an absence or abnormality in dystrophin in muscle biopsy samples.

Symptoms usually present in early childhood. Gait disturbances and delayed motor development are common manifestations, with proximal weakness resulting in an exaggerated lumbar lordosis. Most patients are wheelchair bound by the age of 12 to 15 years, with death occurring around the age of 20 years as a result of progressive respiratory failure and pneumonia. Kyphoscoliosis commonly develops as a result of severe muscle weakness and further contributes to a restrictive ventilatory deficit. Pulmonary symptoms are often minimal early on, despite significant weakness of the respiratory muscles. Maximum inspiratory pressure is reduced at all lung volumes in patients with DMD and declines with time. FVC increases with growth during the first decade and may mask early respiratory muscle dysfunction before it plateaus and progressively decreases about 5% to 6% per year after 12 years of age (Fig. 84-12).[105] Reductions in maximum inspiratory pressure, therefore, occur early in the clinical course of DMD and may precede the reduction observed in VC. In a series of 58 DMD patients, the median decline in FVC was 0.18 L (0.04–0.74 L) per year and once the FVC fell below 1 L the median survival was 3.1 years with a 5-year survival of 8%.[106] Inspiratory muscle weakness does not necessarily parallel the development of expiratory muscle weakness. Maximum expiratory mouth pressures are substantially lower than maximum inspiratory mouth pressures, possibly leading to a marked decrease in the effectiveness of cough. FVC should be measured annually in patients that are able to ambulate and every 6 months in nonambulatory DMD patients. Additionally, PCF, MIP, and MEP should be measured every 6 months in nonambulatory patients.[107,108]

Despite severe and progressive muscle weakness, hypercapnia is uncommon in patients with DMD in the absence of pulmonary infections. The absence of hypercapnia despite severe muscle weakness is believed to be due to relative preservation of diaphragm function until very late in the illness. Once hypercapnia occurs, however, the course is rapidly progressive and mean survival is approximately 10 months.

Since ventilation is heavily dependent on diaphragmatic function in DMD patients, severe nocturnal hypoventilation may occur during REM sleep, when activity of chest wall and neck muscles is markedly attenuated. Indeed, hypoventilation may occur during REM sleep, when activity of chest wall and neck muscles is markedly attenuated, and has been documented in DMD patients with normal daytime gas exchange. The American Thoracic Society has recommended that an annual sleep study be performed when the patient becomes nonambulatory unless symptoms of nocturnal hypoventilation are present.[109] Sleep-related hypoxemia may contribute to respiratory insufficiency and the development of cor pulmonale.

Management of patients with DMD is mainly supportive. Ambulation should be maintained and encouraged as long as possible to retard the development of scoliosis. Surgical correction may attenuate the scoliotic contribution to the fall in VC and improve patient morale and quality of life overall. While the decline in FVC will continue postoperatively, it may be slowed somewhat. In a group of 56 DMD patients that underwent posterior spinal fusion for scoliosis, the decline in FVC decreased from 4% per year preoperatively to 1.75% per year postoperatively ($p < 0.0001$).[110] General physiotherapy may be helpful in preventing contractures. Maintenance of proper nutrition, with an emphasis on weight control, is important. Patients with DMD have a propensity to become overweight through a combination of inactivity, reduced energy requirements, and a misguided desire to improve muscle bulk by overeating. Some authors have emphasized a high-protein (more than 80 g protein daily), low-calorie diet, aiming to achieve a body weight somewhat lower than the ideal weight in patients of a similar height and normal muscle mass.

Inspiratory muscle training (IMT) has been examined as a tool to prevent further decrease in respiratory muscle function in those with DMD, but its routine use remains controversial. Because there is loss of the protective mechanism of nitric oxide release in children with DMD, IMT could potentially be detrimental. Koessler et al.[111] studied the effect of 2 years of IMT on a group of 27 patients with neuromuscular disease (18 DMD and 9 spinal atrophy), and showed a clear increase in PI_{max} and MVV. There was a plateau reached after 10 months of training. Because there is potential for harm and no long-term studies to support its use, ATS guidelines do not suggest the use of routine IMT in this group of patients.[109]

Maintenance of cough and adequate airway clearance is extremely important in attempting to prevent atelectasis and pneumonia in this patient population. A PE_{max} of at least 60 cm H_2O has been shown to be adequate to generate an effective cough in patients with DMD, while a drop below 45 cm H_2O has been associated with ineffective cough.[109,112] Once an ineffective cough is recognized there are multiple treatment modalities. The most studied technique is the use of a manual insuffator–exsufflator, which stimulates cough by providing a positive pressure breath immediately followed by a negative pressure exsufflation. The technique can be used on patients with or without a tracheotomy, and is generally well tolerated. It has been shown to be effective in generating cough and clearing airways in children with DMD, especially once scoliosis has developed.[109] Respiratory tract infections are a serious complication in DMD patients, and must be treated aggressively with physiotherapy, postural drainage, assisted cough techniques, and appropriate antibiotics. All patients, regardless of cough status, should receive vaccination against pneumococcal pneumonia and influenza.

In some patients, assisted ventilation is required once respiratory insufficiency or symptoms of sleep-related breathing disorders are present. Intermittent noninvasive positive-pressure ventilation (NPPV) prolongs survival, improves quality of life, and may attenuate the decline in FVC and MVV. Longer-term follow-up of DMD patients treated with noninvasive ventilation demonstrates that pulmonary function continues to deteriorate 3–4 years after the initiation of noninvasive ventilation, with patients requiring longer periods of ventilation and/or transition to tracheostomy with positive-pressure ventilation.[113] Once patients require the use of NPPV, the pressure should be titrated in the sleep laboratory to eliminate nocturnal apneas and hypopneas. Generally, BiPAP should be used in those with significant daytime or nocturnal hypoventilation, and CPAP should be used primarily in those with obstructive sleep apnea without evidence of hypoventilation.

DMD is a relentlessly progressive disease that eventually will lead to respiratory failure requiring invasive mechanical ventilation (see Chapter 85). End-of-life care and plans for the use of invasive mechanical ventilation should be discussed with the family and the patient well in advance if at all possible. While the institution of mechanical ventilation has been shown to prolong life in the appropriate setting, little is known on the effect on quality of life, and decisions must be made on an individual basis.

There is evidence to suggest that prednisone treatment is beneficial. In a randomized, double-blind controlled 6-month trial of prednisone in 103 boys with DMD, patients were assigned to low-dose prednisone (0.75 mg/kg per day), high-dose prednisone (1.5 mg/kg per day), or placebo. Both prednisone groups showed significant improvements in muscle strength, functional scores, and FVC at 6 months compared to placebo, but there was no difference between low- or high-dose prednisone.[114] A subsequent study found that muscle strength was greater in DMD patients taking 0.75 m/kg compared to 0.3 mg/kg of prednisone for 6 months.[115] The effect of prednisone therapy on respiratory muscle function has been less clear but a case-control study found that steroid therapy for a mean duration of 8.2 years resulted in improved FVC, MIP, MEP, PCF, and FVC compared to those not treated with prednisone.[116] Based on these data expert panels have recommended that corticosteroid therapy be used in DMD patients.[107]

While steroid therapy may improve muscle strength it has not led to improved survival, and most experts believe that gene therapy will be applicable to DMD in the future as a potential cure for the disease. A newer method of gene therapy known as exon skipping is an attractive approach because some DMD mutations result in mRNA, which causes a premature stop in translation of the dystrophin protein. Small oligonucleotides can be developed to bind exons and block them from being incorporated into mRNA which then will allow for translation of a truncated dystrophin protein that will result in some function of the native protein.[117] Traditional gene therapy is limited in DMD by the large amount of skeletal muscle, the large size of the dysmorphin gene, and patient immunity against viral vectors.[118]

Myotonic Dystrophy Myotonic dystrophy is the most common form of hereditary muscular dystrophy in adults, with an estimated incidence of 1 in 8000 people. The gene responsible for the disease is located on the long arm of chromosome 19 and demonstrates an autosomal dominant inheritance pattern. Symptoms usually present during adolescence and in early adulthood, although the syndrome may be recognized as early as infancy.

Respiratory muscle weakness is common and can be severe, despite mild limb muscle weakness. Myotonia of the respiratory muscles contributes to an increased work of breathing by increasing inspiratory impedance. Studies have suggested that the presence of a chaotic breathing pattern may explain the higher prevalence of chronic hypercapnia in patients with myotonic dystrophy than in patients with other forms of muscular dystrophy. Support for these findings came from studies that showed abnormal ventilatory responses to hypercapnic challenges in patients with myotonic dystrophy. However, studies that have used mouth occlusion pressures ($P_{0.1}$) have revealed normal or supranormal responses in $P_{0.1}$ in patients with myotonic dystrophy compared to controls. These data seem to suggest that prior studies showing hypercapnia in patients with myotonic dystrophy underestimated the severity of respiratory muscle weakness by itself as a limitation in the ability to mount a normal ventilatory response. The chaotic breathing pattern observed in some patients with myotonic dystrophy has been suggested to be related to disordered afferent information from diseased muscle spindles.

Patients with myotonic dystrophy are particularly susceptible to development of respiratory failure with general anesthesia and sedatives. Postoperative respiratory monitoring is essential if surgery or the use of these agents is required. Pharyngeal and laryngeal dysfunction increases the risk of aspiration. Sleep-related breathing disturbances are common and may include both central and obstructive forms of sleep apnea. Nocturnal positive-pressure ventilation should be tried when hypercapnia and hypoxemia are present.

Facioscapulohumeral Dystrophy Other inherited adult muscular dystrophies are facioscapulohumeral dystrophy (FSH) and limb–girdle dystrophy. FSH is an autosomal dominant dystrophy that primarily affects muscles of the face and the proximal portion of the upper extremities. FVC is significantly reduced in patients with FSH, although facial weakness complicates spirometric assessment. In 20% of patients with FSH, the disease affects pelvic girdle and trunk muscles, sometimes impairing respiratory function.

Limb–Girdle Dystrophy Limb–girdle dystrophy is a heterogeneous group of autosomal dominant recessive disorders. The disease usually becomes evident in the second or third decade of life. Several case reports have documented the development of chronic hypercapnia

in patients with limb–girdle dystrophy who have severe diaphragm weakness or bilateral diaphragm paralysis as the basis for hypercapnia. However, not all patients with limb–girdle dystrophy develop hypercapnia. Most patients have moderate respiratory muscle weakness with normal gas exchange.

Acid Maltase Deficiency (Pompe Disease) Two metabolic myopathies, acid maltase deficiency and mitochondrial myopathy, have received attention as potential causes of respiratory failure. Acid maltase deficiency is a type I glycogen storage disease due to the deficiency of the lysosomal enzyme responsible for hydrolysis of both the α1 to 4 and α1 to 6 linkages of glycogen. The disease presents in three clinical forms: infantile, childhood, and adult. In adult-onset disease, onset usually occurs after 20 years of age and presents with progressive proximal muscle weakness. The diagnosis may be difficult to establish in some patients, as respiratory failure or sleep-related complaints, secondary to respiratory deterioration during REM sleep, may be the initial presentation. Diagnostic studies include elevated serum muscle enzymes; myopathic changes on EMG, and vacuoles filled with lysosomal breakdown products on muscle biopsy. Enzyme replacement therapy with recombinant human acid maltase, alglucosidase alfa, is now available for both early- and late-onset disease. In a study of 99 patients with late-onset Pompe disease, treated for 78 weeks with biweekly infusions of alglucosidase, the investigators found an improvement in FVC and 6-minute walk distance.[119]

Mitochondrial Myopathy Mitochondrial myopathy represents a heterogeneous group of disorders that affect mitochondrial function and may present as complex multisystem disorders with brain and striated skeletal muscle being the predominant organs affected; (1) Kearns–Sayre syndrome; (2) myoclonic epilepsy, "ragged red fibers," and mitochondrial myopathy; and (3) encephalopathy, lactic acidosis, and stroke-like episodes. The clinical manifestations may be broad and include myalgia and exercise intolerance, proximal muscle weakness, and external ophthalmoplegia with unexplained respiratory failure. All three disorders are characterized by hypoventilation and depressed responses to hypoxia and hypercapnia and, in some cases, unexplained respiratory failure. Skeletal muscle biopsy establishes the diagnosis of mitochondrial myopathy by showing "ragged red fibers," which are accumulations of mitochondria identified with modified trichrome staining. Treatment is supportive. Once identified, patients should be cautioned regarding the use of sedatives, and special attention is required when sedation or surgery is planned.

Acquired Myopathies

A variety of acquired myopathies, outlined in Table 84-9, may affect respiratory muscles. The reader is referred to other sources for detailed discussion.

TREATMENT

Principles in management of respiratory dysfunction in patient with neuromuscular disease include (1) preventative therapies designed to minimize the impact of impaired secretion clearance, alveolar hypoventilation on gas exchange and lower respiratory tract infections and (2) stabilization of patients who develop acute or chronic respiratory failure. Because patients with neuromuscular disease usually have nonpulmonary symptoms and signs before the onset of respiratory problems, preventive actions can be taken to preserve their respiratory status. In neuromuscular disorders causing bulbar dysfunction, swallowing precautions and airway control measures are required. With advanced bulbar symptoms, upper airway control with a cuffed tracheostomy tube may be needed to protect the airway and facilitate suction of lower respiratory track secretions, averting atelectasis and pneumonia. In patients with impaired cough, assisted coughing (e.g., ancillary hand thrust in the substernal location to increase intrathoracic pressure and expel secretions mouthward) may be helpful, along with posture drainage and the use of incentive spirometry. Treatment modalities used for treating pulmonary complications of neuromuscular disease include respiratory muscle training, mechanical ventilation (invasive and noninvasive), and glossopharyngeal breathing, which are all covered extensively in Chapter 85.

DIAPHRAGMATIC PACING

To increase independence from mechanical ventilation, diaphragmatic pacing may be a treatment option in selected patients. Although phrenic nerve pacing by external stimulation has been well documented since the late 1940s, long-term phrenic nerve stimulation did not become a reality until a small implantable electrode and receiver were developed in the late 1960s. Diaphragmatic pacing consists of a radiofrequency transmitter and an antenna that discharges stimulatory signals to a receiver that when activated by radiofrequency waves, transmits electrical impulses in an electrode placed over the phrenic nerve. Surgery is required to implant the electrodes and receiver. Electrode implantation around the phrenic nerves can be achieved by a cervical or thoracic approach; however, the thoracic approach is preferred, to ensure stimulation of all phrenic nerve roots while avoiding the brachial plexus. The subcutaneous receiver is usually placed in the lower anterolateral rib cage to allow it to be superficial, but in an area where soft tissue movement is limited.[120–122] The subject must have intact phrenic nerves in order for the procedure to be successful, and the phrenic nerve is typically assessed by measuring conduction times along the nerve. Electric stimulation is applied transcutaneously in the neck region and surface diaphragm EMG is monitored. The nerve conduction time can then be calculated with normal being around 7.5 to 9 msec.

Diaphragmatic pacing has a number of potential limitations, including its high cost, the potential to fail abruptly, the development of upper airway obstruction, and the induction of diaphragm fatigue. On the other hand, successful implantation allows patients to be independent from ventilatory support for prolonged periods, and to speak more freely.

While implantation of phrenic nerve electrodes has become an accepted procedure, there is ongoing research into placing diaphragmatic electrodes laproscopically, and the technique has been performed successfully in a few centers.[123] This approach would be less invasive, more cost efficient, and have less morbidity than the current approach. Two electrodes are placed on each hemidiaphragm near the motor points of the phrenic nerve. Initially, removable suction electrodes are placed until a location is found that induces maximal contraction of the diaphragm and a large intra-abdominal pressure change both by twitch and high-frequency stimulation. The wires are then brought through the skin and connected to the stimulator. Because patients on chronic mechanical ventilation develop diaphragm atrophy,[124] a reconditioning period is required before the restoration of maximal diaphragm function. Figure 84-13 shows the tidal volume generated gradually increased with time as the muscle is reconditioned and the tidal volume is greatest with bilateral stimulation. In a case series using this technique, 3 of 5 subjects achieved independence from mechanical ventilation. One other was free of mechanical ventilation for 20 hours per day, and the other did not have activation of the diaphragm. This individual most likely did not have intact phrenic nerves.[121] Intact phrenic nerves are required for successful intramuscular diaphragm pacing as evidenced by animal studies showing no diaphragm activation with intramuscular pacing after transection of the phrenic nerves. This probably occurs because the mechanism of intramuscular pacing is by stimulation of phrenic nerve roots in the diaphragm.

Because the intercostal muscles are capable of contributing up to 35% to 40% of the VC they should be able to liberate a subject from

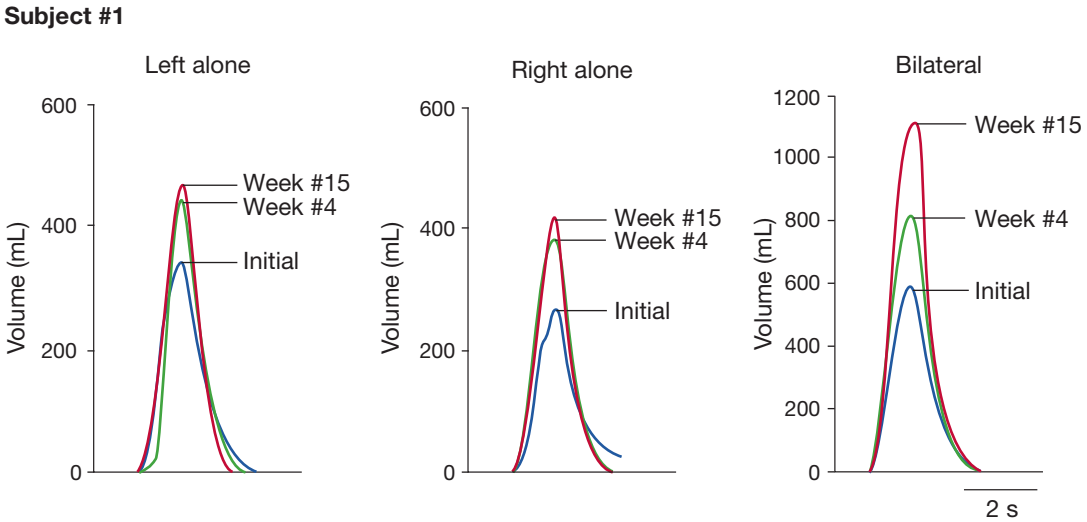

Figure 84-13 Reconditioning of the diaphragm as evidenced by increased inspired volumes initially, at 4, and 15 weeks postoperatively after left and right hemidiaphragm and bilateral diaphragm contraction via diaphragmatic electrode pacing. *(Data from DiMarco AF, Onder BP, Ignagni A, et al. Phrenic nerve pacing via intramuscular diaphragm electrodes in tetraplegic subjects. Chest. 2005;127:671–678.)*

mechanical ventilation if stimulated through pacing. In animal models, stimulation of the ventral surface of T1 to T3 resulted in maximal inspired volumes, and when combined with bilateral phrenic nerve pacing results in tidal volumes that approach the inspiratory capacity. However, when applied to a group of spinal cord injury patients with phrenic nerve damage, very little volumes were generated with stimulation of ventral aspect of T1 to T3, and subjects were unable to breathe without mechanical ventilation for short time periods (20 minutes to 2.45 hours). This discrepancy between animal and human studies may be secondary to the different shape of the human thoracic cage or the reduction in rib cage and lung compliance in those with tetraplegia. Additionally stimulation of T1 to T3 resulted in the movement of several nonrespiratory muscles, which led to hypertrophy of the upper trunk musculature.[121] A follow-up trial combined intercostal pacing with unilateral diaphragm pacing in a small group of patients that had unilateral phrenic nerve injuries in addition to spinal cord injury. All of these patients were able to have significant periods of time free from mechanical ventilation.[125] The main limitation to this approach remains contraction of nonrespiratory muscles, which makes the process metabolically inefficient and can lead to uncontrollable muscle activity.

Patients who appear to benefit from diaphragmatic pacing are ventilator-dependent patients following high cervical cord injury. Approximately one-third of patients with high cervical spinal cord injuries may be suitable for this type of treatment. Although short-term improvements are noted in terms of ventilator independence and improvement in functional status, no long-term studies demonstrating efficacy have been published to date.

CHAPTER 85

Management of Neuromuscular Respiratory Muscle Dysfunction

John R. Bach

INTRODUCTION

Patients with ventilatory impairment due to ventilatory muscle dysfunction are often evaluated and managed according to practices developed for patients with chronic lung diseases. However, pulmonary function laboratories, designed primarily for assessment of lung diseases, do not evaluate lung volume recruitment capacities or cough flows that are important in the assessment of patients with inspiratory and expiratory muscle dysfunction. In the setting of ventilatory muscle dysfunction polysomnograms may be misinterpreted as central or obstructive apneas and hypopneas rather than hypoventilation due to inspiratory muscle dysfunction, and continuous positive airway pressure (CPAP) or nocturnal bilevel positive airway pressure (BiPAP) prescribed. In the context of ventilatory muscle dysfunction CPAP does not increase tidal volumes, and may actually reduce them by causing them to approach maximum lung capacity for these patients with severe pulmonary restriction while BiPAP is often used at pressures inadequate to support alveolar ventilation, provide inspiratory muscle rest, or assist in coughing.[1] In addition, the patients are often treated with supplemental oxygen to correct hypoxemia when efforts to improve oxygenation should be directed at normalizing alveolar ventilation and clearing airway secretions. With advancing inspiratory and expiratory muscle weakness, the common scenario is that respiratory failure ensues and is treated by mechanical ventilation via endotracheal intubation. When ventilator weaning fails, a tracheostomy is performed and mechanical ventilation is continued indefinitely, often in an institution.

Therapeutic modalities commonly used for respiratory diseases can have adverse effects in patients with neuromuscular disorders. Bronchodilator therapy can augment the anxiety and tachycardia that are common in myopathic patients, many of whom have cardiomyopathies. Oxygen therapy increases the risk of pulmonary morbidity, rate of hospitalizations, and mortality by comparison with the use of ventilator assistance or with no treatment at all.[2] As noted earlier, oxygen therapy may obscure recognition of mucus plugging because it alleviates oxyhemoglobin desaturation without attention to the expulsion of airway mucus. Oxygen therapy may also prolong hypopneas and apneas during rapid eye movement (REM) sleep,[3] and it appears to suppress the reflex muscular activity needed for effective noninvasive intermittent positive pressure ventilation (IPPV) during sleep.[4] Translaryngeal intubation, tracheostomy, and tracheal suctioning continue to be used for patients with neuromuscular diseases even though noninvasive IPPV, noninvasive suctioning, and mechanically assisted coughing (MAC) can be more effective and comfortable.

Despite the proven effectiveness of measures to support ventilation noninvasively for long periods even in the absence of respiratory muscle function, these therapeutic modalities have yet to be adopted by many physicians. In Great Britain, 82% of patients with amyotrophic lateral sclerosis (ALS) die receiving morphine and 64% receive benzodiazepines, while few are provided with respiratory muscle aids to prevent respiratory failure.[5] This approach both smoothes and hastens passage to the grave by leading to CO_2 narcosis.[6,7] Often, without consulting the patient, the physician judges the patient's quality of life to be unacceptable and the disease terminal, ignores options that prevent respiratory complications, renders the patient and family hopeless, and biases the family against ventilator use which the physician associates with tracheostomy. Proclaimed as "palliation," the results of this professional point of view are anguish and hopelessness and not infrequently lead patients to seek quack therapies and assisted suicide. Over a recent 5-year period, 12 publications in the New England Journal of Medicine concerned clinical management and assisted suicide for patients with ALS. In none of these reports was prevention of respiratory complications or ventilator assistance by invasive or noninvasive means considered. Failure to consider noninvasive IPPV for full ventilator support continues.[8,9]

PATHOPHYSIOLOGY

Patients with neuromuscular disorders can develop respiratory failure because of some combination of respiratory muscle dysfunction (Table 85-1), that is, dysfunction of inspiratory, expiratory, and bulbar-innervated muscles. These muscle groups will be considered here and the reader is referred to Chapters 84 and 143 for detailed discussions of the physiological disturbances associated with chest wall and neuromuscular disorders that affect ventilation.

Autonomously breathing patients with advanced ventilatory muscle dysfunction develop a rapid, shallow breathing pattern with inability to take deep breaths. If untreated, this can lead to chronic microatelectasis and decreased lung and chest wall compliance.[10,11] Acute respiratory tract infections with pulmonary scarring and the kyphosis and scoliosis that are common in these patients can cause further loss of lung compliance.

In the context of neuromuscular disorders, hypercapnia develops insidiously as a consequence of shallow breathing as respiratory control centers reset and increasing central nervous system bicarbonate levels accommodate and permit it to worsen. Hypercapnia, itself, can decrease respiratory muscle strength,[4] and decreases the effectiveness of its treatment by the nocturnal use of BiPAP or noninvasive IPPV.[4] The risk of pulmonary morbidity and mortality from acute respiratory failure correlates with increasing hypercapnia.[2,4]

Inspiratory muscle weakness, mechanical dysfunction of the chest wall and lungs associated with thoracic deformities, hypopharyngeal collapse or other upper airway narrowing, extreme obesity, abdominal distension, use of improperly fitting thoracolumbar orthoses as well as narcotic and sedative medications, supplemental oxygen, malnutrition and deconditioning, infection, and fatigue can all either cause or exacerbate alveolar hypoventilation and lead to respiratory failure. Oxygen therapy often results in CO_2 narcosis, otherwise hypoventilation is usually first recognized during an intercurrent respiratory infection when bronchial mucus plugging triggers pneumonia and acute respiratory failure due to an ineffective cough and fatigue during acute respiratory infections.[2,7] Ventilatory failure can also develop suddenly or over a period of hours or days in patients with acute cervical myelopathies, Guillain–Barré syndrome, myasthenia gravis, acute poliomyelitis, or exacerbations of multiple sclerosis.

Patients with generalized muscle dysfunction usually also have concomitant expiratory and oropharyngeal (bulbar) muscle weakness that decreases cough peak flows (CPF). When CPF do not exceed 2.7 L/s, cough may be completely ineffective.[12] CPF are

TABLE 85-1 Physical Medicine Respiratory Interventions Benefit Patients with the Following Conditions

Critical care neuromyopathies/deconditioning
Myopathies
Muscular dystrophies
Dystrophinopathies—Duchenne and Becker dystrophies
Other muscular dystrophies—limb-girdle, Emery–Dreifuss, facioscapulohumeral, congenital, childhood autosomal recessive, and myotonic dystrophy
Non-Duchenne myopathies
Congenital and metabolic myopathies like acid maltase deficiency
Inflammatory myopathies such as polymyositis
Diseases of the myoneural junction such as myasthenia gravis, mixed connective tissue disease
Myopathies of systemic disease such as carcinomatous myopathy, cachexia/anorexia nervosa, medication associated
Neurological Disorders
Spinal muscular atrophies
Motor neuron diseases
Spinal cord injuries
Poliomyelitis
Neuropathies
Hereditary sensory motor neuropathies
Phrenic neuropathies–associated with cardiac hypothermia, surgical or other trauma, radiation, phrenic electrostimulation, familial, paraneoplastic or infectious etiology, and with lupus erythematosus
Guillain–Barré Syndrome
Multiple sclerosis
Disorders of supraspinal tone such as Friedreich ataxia
Myelopathies of rheumatoid, infectious, spondylitic, vascular, traumatic, or idiopathic etiology
Tetraplegia associated with pancuronium bromide, botulism
Sleep-disordered breathing including obesity hypoventilation, central and congenital hypoventilation syndromes, and hypoventilation associated with diabetic microangiopathy, or familial dysautonomia
Skeletal pathology such as kyphoscoliosis, osteogenesis imperfecta, and rigid spine syndrome

reduced by airway obstruction caused by tracheal stenosis, laryngeal incompetence, postintubation vocal cord adhesions or paralysis, hypopharyngeal collapse due to bulbar-innervated muscle weakness or spasticity, airway granulation tissue, and obstructive pulmonary disease. The CPF are reduced further when patients cannot take or receive a breath greater than 1.5 L.[13] Thus, the airway secretions that develop during upper respiratory tract infections and after surgical anesthesia often result in pneumonia and acute respiratory failure. Smoking, the presence of an endotracheal cannula that causes bronchorrhea, or bronchorrhea for any other reason increases the tendency to develop mucus plugging that is all too frequently managed by repeated bronchoscopies, intubation, and tracheotomy without trying MAC. Intubation, however, results in a burden of pathogenic bacteria that, even when not causing ventilator-associated pneumonia, exceeds the commonly accepted threshold for diagnosing it.[14]

For patients with ventilatory muscle dysfunction, arterial hypoxemia and hypercapnia occur initially during REM sleep and later extend throughout sleep and eventually throughout the awake hours. Cough reflex is also suppressed during sleep, which is when mucus plugs are most likely to cause sudden and severe hypoxemia. Normocapnic arterial hypoxemia is also common during sleep, most likely reflecting ventilation/perfusion mismatches associated with microatelectasis, scoliosis, airway mucus congestion, and pulmonary scarring.

THE RESPIRATORY MUSCLE GROUPS

The diaphragm is the principal muscle of inspiration. The abdominal muscles are the principal muscles of expiration or coughing. The bulbar-innervated muscles are the muscles of the upper airway. They include the muscles of the mouth, uvula and palate, tongue, and larynx. While these muscles do not have a direct action on the chest wall, they are essential for keeping the upper airway patent; they affect airway resistance and airflow; and they permit glossopharyngeal breathing (GPB).

Decreased inspiratory muscle function results in decreased vital capacity (VC), atelectasis, increased relative work of breathing, and eventually in hypoventilation. Expiratory, inspiratory, and bulbar-innervated muscle dysfunctions result in an ineffective cough. The latter can also affect speech, swallowing, and safe food and saliva management. Fortunately, the inspiratory and expiratory muscles can be substituted for by physical medicine interventions. Indeed, numerous patients with no muscle function below the neck and no measurable VC for over 50 years do not need tracheostomy tubes or develop hypercapnic respiratory failure.

INSPIRATORY AND EXPIRATORY MUSCLE AIDS

Inspiratory and expiratory muscle aids are devices and techniques that involve the manual or mechanical application of forces to the body or pressure changes to the airway to assist or substitute for inspiratory or expiratory muscle function. Negative pressure applied to the airway during expiration assists the expiratory muscles for coughing, just as positive pressure applied to the airway during inhalation (noninvasive IPPV) assists inspiratory function.

A manual thrust applied to the abdomen during expiration, especially when in combination with mild chest compression, assists expiratory muscle function and increases cough flows.[13] The devices that act on the body to enhance inspiratory and expiratory muscle function include body ventilators. The intermittent abdominal pressure ventilator (IAPV) involves the intermittent inflation of an elastic air sac that is contained in a corset or belt worn beneath the patient's outer clothing (Fig. 85-1). The sac is inflated by a positive pressure ventilator. Bladder action against the abdominal wall moves the diaphragm upward, causing a forced exsufflation. During bladder deflation, the abdominal contents and diaphragm return to the resting position, and inspiration occurs passively. A trunk angle of 70 to 80 degrees from the horizontal is ideal for use. The patient who has any inspiratory capacity or is capable of GPB can add autonomous volumes to the mechanical insufflations. The IAPV generally augments tidal volumes by about 300 mL, but volumes as high as 1200 mL have been reported when there is no scoliosis or obesity.[15] Patients with less than 1 hour of ventilator-free breathing ability tend to prefer to use the IAPV rather than use noninvasive IPPV during daytime hours.[15]

Note, CPAP does not assist inspiratory or expiratory muscles and should rarely if ever be used for these patients whose symptoms of sleep disordered breathing are associated with muscle weakness rather than central or obstructive sleep apneas.

CLINICAL GOALS

The goals of management are to optimally inflate the lungs and chest wall to maintain pulmonary compliance, to maintain normal alveolar ventilation around-the-clock, and to maximize CPF.

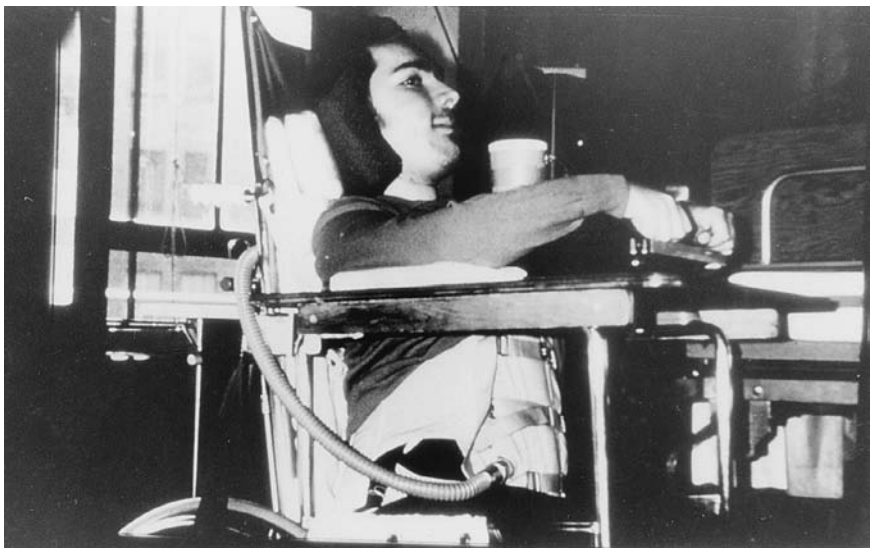

Figure 85-1 The girdle of the intermittent abdominal pressure ventilator (IAPV) with its air sac connected to the tubing of a volume-cycled ventilator. This DMD patient with no measurable vital capacity used the IAPV for daytime ventilator support for 15 years.

MAINTAIN PULMONARY COMPLIANCE AND CHEST WALL MOBILITY

Incentive spirometry can expand the lungs no greater than the VC so it is ineffective as a tool for lung volume recruitment. Like limb articulations, the lungs and chest wall too require regular mobilization.[11] This can be achieved actively by air stacking (Video 85-1),[16] passively by providing deep insufflations for those with an incompetent glottis, or by nocturnal noninvasive ventilation for infants who cannot cooperate with air stacking or passive deep insufflations.[17]

A patient's maximum insufflation capacity (MIC) is the largest volume of air that can be held with a closed glottis. The patient "air stacks" consecutively delivered volumes from a volume-cycled ventilator or a manual resuscitator, holding these volumes with a closed glottis to maximally expand the lungs. The air is delivered via a mouth piece (Video 85-1), nasal or oronasal interface if the lips are too weak to retain the air. This is performed multiple times in three daily sessions. Patients who learn GPB can often air stack consecutive gulps to or beyond the MIC. The difference between the MIC and the VC is a function of bulbar-innervated muscle integrity (force of glottic closure).[13] If the bulbar muscles are too weak for deep active air stacking, single deep insufflations are provided via a mechanical insufflator–exsufflator at 40 to 70 cm H_2O in three daily sessions. Deep insufflations can also be delivered via manual resuscitator with the expiratory valve blocked.

The primary objectives of lung recruitment therapy are to increase voice volume and MIC, maximize CPF, improve pulmonary compliance, prevent atelectasis, and master noninvasive IPPV. Occasionally the VC also increases with increases in MIC. Should the situation arise, the ability to air stack facilitates extubation to noninvasive IPPV (Video 85-1). This is extremely important for avoiding tracheotomy because such patients can be safely extubated without being ventilator weaned.[18]

Video 85-1 A ventilator-dependent patient with amyotrophic lateral sclerosis who failed all spontaneous breathing trials, extubated to full-support noninvasive intermittent positive pressure ventilation via a 15-mm angled mouth piece. He demonstrates lung volume recruitment and increased voice volume by air stacking. *Access at www.fishmansonline.com*

Lung volume recruitment also promotes lung growth and chest wall development in children. While infants cannot air stack, nocturnal use of high span (IPAP [inspiratory positive airway pressures] – EPAP [expiratory positive airway pressures] >10 cm H_2O) BiPAP or a pressure-cycling portable ventilator set at pressures over 16 cm H_2O has been demonstrated to prevent pectus excavatum and promote lung and chest wall growth for infants with spinal muscular atrophy (SMA), all of whom have paradoxical breathing when not using it.[19,20]

MAINTAIN NORMAL ALVEOLAR VENTILATION

Noninvasive Ventilation

BiPAP is not optimal for patients with neuromuscular disorders because one cannot air stack using pressure-cycled ventilators or fully expand the lungs with the machines currently on the market. IPPV from volume-cycled machines can be delivered via lip seals, nasal, or oral–nasal interfaces for ventilator support during sleep. The patients can be trained and equipped in the outpatient and home settings. While inpatient polysomnography can be helpful for adjusting ventilator settings to optimize sleep quality, we have managed over 1500 patients on noninvasive ventilation, many of whom eventually requiring it around-the-clock, without using this expensive intervention.

Patients requiring around-the-clock support use simple 15- or 22-mm angled mouth pieces that are grabbed with the teeth for IPPVs (Fig. 85-2) during the day. To use mouthpiece IPPV, adequate neck

Figure 85-2 A 48-year old with Duchenne muscular dystrophy, continuously dependent on noninvasive intermittent positive pressure ventilation (IPPV) since 23 years of age, seen here using IPPV via a 15-mm angled mouth piece for daytime ventilator support.

Figure 85-3 Brothers with spinal muscular atrophy type 1 (Werdnig–Hoffman disease) who have been continuously noninvasive intermittent positive pressure dependent since 4 months of age using a nasal prongs interface during daytime hours that permits the use of eye glasses. These patients' lips are too weak to use mouth piece; they have had nasogastric tube feedings since infancy; and their vital capacities have been 0 to 10 mL for more than 10 years but they are managed noninvasively.

rotation and oral motor function are necessary to grab the mouth piece and receive IPPV without insufflation leakage out of the mouth or nose. In addition, the patient must open the glottis and vocal cords, dilate the hypopharynx, and maintain airway patency to receive the air.

When the lips are too weak to grab a mouthpiece, the patient can use an IAPV[15] or continue nocturnal nasal IPPV into daytime hours (Fig. 85-3). In the latter case, nasal interfaces are alternated to vary skin pressure. Inconspicuous nasal interfaces that permit the use of eye glasses can also be used.

Although the use of oronasal interfaces is popular in some centers, we have rarely found them to be necessary. Even patients with little or no measurable VC can be safely ventilated day and night by open systems of nasal or oral ventilation. Closed systems are unnecessary provided that ventilatory drive is not blunted by oxygen therapy, sedative medications, or excessive daytime hypercapnia, all of which can result in excessive air leakage out of the nose or mouth when using the open systems of mouth piece/lip seal or nasal ventilation for sleep.[4] If necessary, one can provide an essentially closed system of ventilatory support by using a lip seal device and placing cotton pledgets in the nostrils and sealing the nostrils with a band-aid, or more commonly today, by using a nasal prong system that extends down over the lips, for example, the Hybrid Universal Interface™ (Innomed Technologies, Savannah, Georgia) and the Mirage Liberty™ interface (ResMed Inc., Duncan, South Carolina).

The benefits derived from the part-time, usually nocturnal, use of noninvasive ventilation, appear to be due to some combination of respiratory muscle rest, increasing tidal volumes and alveolar ventilation, and improving blood gases, lung compliance, chemotaxic sensitivity, and possibly ventilation/perfusion matching by reducing atelectasis and small airway closure.[4] To accomplish optimal rest, high volumes or pressure spans are used, that is, assist-control mode at volumes of 800 to 1500 mL or pressures of 18 to 20 cm H_2O for adults and inspiratory-to-expiratory positive airway pressure spans of 13 to 18 cm H_2O for BiPAP users. Patients vary the volume of air taken in from ventilator cycle to ventilator cycle to vary tidal volume, speech volume, and cough flows, as well as to air stack and provide lung expansion.

Complications of noninvasive IPPV include claustrophobia, skin discomfort, abdominal distension, occasional allergy to the plastic or silicone interfaces, mouth dryness, eye irritation from air leakage, nasal congestion and dripping, sinusitis and nose bleeds, gum discomfort and receding, maxillary flattening in children, aerophagia,[21,22] and, as for invasive ventilation, barotrauma. Switching to lip-delivered IPPV can relieve most of the difficulties associated with nasal IPPV, however, it is more difficult to speak when using lip-delivery devices. Abdominal distention can be alleviated by switching to pressure cycling. Distension is often relieved as the air passes as flatus once the patient sits up in the morning or by "burping" of a gastrostomy tube if present. Barotrauma can occur with invasive or noninvasive ventilation but is rare with the latter for patients with neuromuscular disorders.

FACILITATE CLEARANCE OF AIRWAY SECRETIONS

Chest percussion and vibration can help mobilize deep airway secretions, but they are not substitutes for coughing. Cough can be assisted manually or by mechanical means.

Manually Assisted Coughing

Manually assisted coughing requires substantial lung inflation by air stacking or a deep passive lung insufflation especially if the VC is less than 1.5 L.[13] This is followed by an abdominal thrust applied as the glottis opens. Whereas all three respiratory muscle groups are needed for spontaneous coughing, only bulbar-innervated muscle function is required for assisted coughing. This is because airway pressure changes and abdominal thrusts substitute for inspiratory and expiratory muscles but there is nothing noninvasive that can substitute for the function of the glottis.

Manually assisted coughing requires a cooperative patient, good coordination between the patient and care giver, and adequate physical effort and often frequent application by the care giver. When inadequate, and especially when inadequacy is due to difficulty air stacking or diminished strength of the glottis, MAC is required.

Mechanically Assisted Coughing

MAC combines passive mechanical insufflation–exsufflation with an abdominal thrust. Mechanical insufflator–exsufflators deliver deep insufflations followed immediately by deep exsufflations. The MAC cough volumes normally exceed 2 L at flows of 10 L/s. Insufflation to exsufflation pressures of +50 to −50 cm H_2O delivered via oronasal interface or adult tracheostomy or translaryngeal tubes with the cuff inflated are most effective. Machine pressures, however, are secondary. What is important is to fully expand and then fully and rapidly empty the lungs.

Whether via the upper airway or via indwelling airway tubes, routine airway suctioning misses the left main stem bronchus about 90% of the time. This explains high rates of left lower lobe pneumonia. MAC, on the other hand, provides the same exsufflation flows in both left and right airways without discomfort, fatigue, or airway trauma and it can be effective when suctioning is not.

MAC supports or takes the place of the inspiratory and expiratory muscles. Thus, the patients who need it are those whose inspiratory and expiratory muscles are too weak for effective coughing but whose bulbar-innervated muscle function can maintain adequate airway patency but not air stack effectively for assisted CPF over 5 L/s. This is typical of most patients with neuromuscular disease. On the other hand, MAC is usually unnecessary for patients with intact bulbar-innervated muscle function such as those with spinal cord injury, as they can usually air stack sufficiently such that with a properly applied abdominal thrust (assisted) CPF can exceed 6 L/s. MAC becomes ineffective if bulbar-innervated muscle function cannot maintain airway patency during the mechanical exsufflation or if saliva is continually aspirated as often happens in advanced bulbar ALS.

THE OXIMETRY FEEDBACK—RESPIRATORY AID PROTOCOL

This protocol consists of using inspiratory (noninvasive IPPV) and/or expiratory (MAC) aids in combination with pulse oximetry

Video 85-2 This video demonstrates postextubation airway secretion expulsion by mechanical insufflation–exsufflation (MIE) applied via an oronasal interface. A large bolus of mucopurulent material can be seen entering the interface during the exsufflation phase of MIE. *Access at www.fishmansonline.com*

feedback to maintain patients' room air Sa_{O_2} ≥95%. The protocol is most important during respiratory tract infections and when extubating patients with little or no VC (Video 85-2). Noninvasive IPPV and MAC with oximetry feedback has averted hundreds of hospitalizations for patients with Duchenne muscular dystrophy (DMD),[23] SMA,[17] ALS,[24] and other neuromuscular conditions.[25] On the other hand, tracheostomy is indicated when saliva is continuously aspirated and the Sa_{O_2} remains below 95% despite optimal use of noninvasive IPPV and MAC. This essentially only occurs in advanced bulbar ALS. Ninety percent (33 of 35) of these ALS patients whose Sa_{O_2} baseline has decreased below 95% despite noninvasive IPPV and MAC were reported to have been deceased within 2 months unless undergoing tracheotomy.[15,23,24]

NONINVASIVE VERSUS TRACHEOSTOMY IPPV OUTCOMES

In a controlled study in which over a 7-year period all continuously ventilator-dependent DMD patients underwent tracheostomy, 21 survived to a mean age of 28.1 ± 8.3 years of age with 3 still alive. Over the next 21-year period 88 consecutive continuously ventilator-dependent DMD patients used only continuous noninvasive IPPV with none undergoing tracheostomy. These 88 had a 50% survival by Kaplan–Meier analysis to 39.6 years of age ($p < 0.001$).[26] We, too, have reported DMD survival by continuous noninvasive IPPV dependence for 101 DMD with 5 now over age 40 and having required continuous support for over 20 years,[27] and including one to age 48 having used continuous noninvasive support for 25 years.[28] Twenty-two DMD patients unable to pass spontaneous breathing trials were extubated and 8 decannulated to continue full-time noninvasive IPPV.[18]

Considering ALS, although it appears that all patients would eventually lose sufficient bulbar-innervated muscle function to satisfy the Sa_{O_2} criterion for tracheotomy,[24] in one study 22 patients (25%)[29] and in another 41 (42%)[24] became dependent on continuous noninvasive IPPV for means of 8 and 12 months (range to 8 years), respectively, before requiring tracheotomy. In the latter study, 13 became continuously ventilator dependent without developing acute respiratory failure or requiring hospitalization. The difference between the patients who could be spared respiratory failure from those who could not was that the latter had stridor and upper airway spasticity as well as no ability to generate measurable CPF.[24] We have extubated 16 and decannulated 5 ALS patients who could not pass spontaneous breathing trials and who subsequently survived as long as 8 years using continuous noninvasive IPPV before requiring tracheotomy. Once bulbar ALS patients undergo tracheostomy for ventilatory support, survival has been reported to be about 5 years before most patients die from complications related to their tracheostomies.[30]

Infants with SMA type 1 have 70% mortality by 6 months of age and 90% by 24 months of age from respiratory failure unless undergoing tracheotomy. In a recent study of 80 nasal noninvasive ventilation users, all of whom continuously ventilator dependent before 24 months of age, the protocol extubation (Table 85-2) success rate was 87% by comparison to 6% by conventional extubation approaches. Hospitalization rates for the noninvasively managed patients fell from 1.6 per year up to age 3 to 0.04 per year after age 5.[17] Fourteen such typical and severe SMA type 1 patients are currently over 15 years of age, with the oldest being 22 years of age, using nasal ventilation 24 hours a day in some cases since 4 months of age (Video 85-3).[31] Sixty of 63 typical and severe SMA type 1 patients who required intubation for intercurrent chest infections were successfully extubated to continuous noninvasive support despite being unable to pass spontaneous breathing trials.[31] SMA type 1 patients who undergo tracheotomy have also been described to survive into adolescence but tend to die from complications of the tracheostomy tube.[17]

TABLE 85-2 Criteria for Successful Use of Noninvasive Ventilatory Support for Neuromusculoskeletal Disorders

Patient cooperative and no use of heavy sedation or narcotics
No substance abuse or convulsions
Cough flows (with or without manual or mechanical assistance) sufficient to eliminate airway debris and maintain baseline Sa_{O_2} >94%
No mechanical obstacles to using IPPV interfaces (e.g., facial fractures or interfering devices)

Noninvasive IPPV is overwhelmingly preferred by patients over tracheostomy IPPV for speech, sleep, swallowing, comfort, appearance, security, use of GPB, and overall.[32] One study also demonstrated 200% cost savings by using noninvasive support by facilitating community management rather than institutionalization.[33] Despite the benefits of noninvasive management, few clinicians are aware that they can be used instead of tracheostomy IPPV and even fewer are familiar with all of the techniques available.[1] A review of the criteria for successful noninvasive management can be found in Table 85-2.

GLOSSOPHARYNGEAL BREATHING

Both inspiratory and, indirectly, expiratory muscle activity can be assisted by GPB. This technique involves the glottis capturing air and propelling it into the lungs. One breath usually consists of 6 to 9 gulps of 60 to 100 mL each. GPB can permit lung volume recruitment by using the glottis rather than a manual resuscitator or volume cycling ventilator for air stacking (Fig. 85-4). It can provide individuals with no inspiratory muscle function to have normal ventilation throughout daytime hours without using a ventilator and safety in the event of ventilator failure during sleep.[34] The safety and versatility afforded by GPB are key to avoiding tracheostomy or removing one in favor of using noninvasive aids for neuromuscular ventilatory failure. About 65% of patients with functional bulbar-innervated musculature but inadequate respiratory muscle function to sustain respiration have been reported to be able to use GPB instead of respirators in some cases throughout daytime hours.[34,35]

EXTUBATION AND DECANNULATION

Patients in acute distress can be relieved and intubation avoided when Sa_{O_2} can be maintained ≥95% in ambient air by using noninvasive IPPV and MAC. When needed, however, intubation is often

Video 85-3 This video demonstrates postextubation management of a 19-year old with spinal muscular atrophy type 1 who has been continuously dependent on full-support noninvasive intermittent positive pressure ventilation via nasal interface since 2 years of age. Her mother applies the nasal interface and mechanical insufflation–exsufflation. *Access at www.fishmansonline.com*

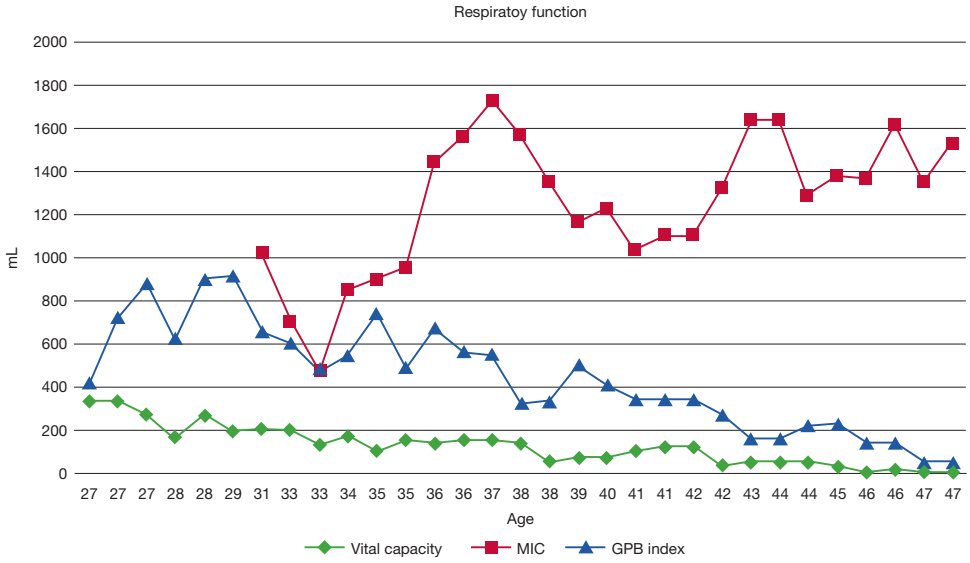

Figure 85-4 A graph of vital capacity (VC), glossopharyngeal maximum single breath capacity (GPmaxSBC), and maximum insufflation capacity (MIC) for the 48-year old with Duchenne muscular dystrophy in Figure 85-2. At age 37, despite having a VC of only 100 mL, he could air stack to 1700 mL to maintain pulmonary compliance and cough effectiveness and his GPmaxSBC was sufficient to permit him ventilator-free breathing.

delayed for fear of inability to ultimately successfully extubate. As for any patient presenting with respiratory distress, patients with neuromuscular disorders conventionally receive supplemental oxygen along with bronchodilators, mucolytics, CPAP, BiPAP, chest physical therapy, and possibly, sedation, but not noninvasive IPPV or MAC. Oxygen therapy, sedation, and BiPAP when used at low spans rather than noninvasive IPPV and MAC, often result in respiratory arrest.

Once intubated, ventilator weaning attempts are conventionally done at the cost of hypercapnia. Because an Sa_{O_2} of 90% to 95% is acceptable for most lung disease patients, patients with neuromuscular disorders are often extubated without concern for their ability to maintain normal Sa_{O_2} in ambient air. An Sa_{O_2} in ambient air less than 95% signals hypoventilation, airway mucus, or residual lung disease and extubation should be avoided. The conventional ventilator weaning parameters including resting minute ventilation, maximum voluntary ventilation, tidal volume, VC, maximum inspiratory pressure, arterial-alveolar oxygen gradient on 100% oxygen, and ratio of dead space to tidal volume, correlate with ability to breathe ("wean") and clear airway secretions and are unnecessary for neuromuscular disease patients who can be safely extubated without functioning respiratory muscles. "Weaning schedules" can cause anxiety when the patient is too weak to breathe or the schedule may be too conservative, delaying respiratory muscle reconditioning. Patients are often extubated to CPAP or inappropriately low span BiPAP and cough aids are not used. However, for these patients the extent of hypercapnia is directly associated with subsequent pulmonary complications and death.[2] Once extubation fails, the clinician feels justified in recommending tracheotomy.

A more appropriate approach for patients with primarily ventilatory impairment is presented in Table 85-3. The strategy is to remove the invasive tube and let the patient "wean" him/herself by using full-setting noninvasive IPPV via a mouth piece and grabbing it less and less as needed (Video 85-1). Thus, "weaning" is done by the patient after extubation when possible or the patient is discharged using continuous noninvasive ventilatory support. It is because of this that tracheotomy can be averted for patients with neuromuscular disease other than advanced bulbar-ALS.[23,34] Postextubation, manually assisted CPF >160 L/min are a sensitive parameter to predict its success because they reflect (glottis) bulbar-innervated muscle integrity and, therefore, the ability to maintain airway patency for effective noninvasive IPPV and MAC (Video 85-2).[12,13]

TABLE 85-3 Protocol for Extubation in Neuromuscular Diseases

Oxygen administration limited to achieve Sa_{O_2} of ~95%, no higher.
Mechanically assisted coughing used via the endotracheal tube up to every few minutes as needed to fully expand and quickly empty the lungs to reverse oxyhemoglobin desaturations due to airway mucus accumulation, when there is auscultatory evidence of secretion accumulation, and on patient demand. Tube and upper airway are suctioned following use of expiratory aids.
Ventilator weaning attempted without permitting hypercapnia.
Extubation whether or not the patient is ventilator weaned when meeting the following criteria:
Afebrile and normal white blood cell count
No supplemental oxygen required to maintain Sa_{O_2} >94% for >24 h
Chest radiograph abnormalities cleared or clearing
Respiratory depressants discontinued with no residual effects from them
Airway secretions normal and suctioning required <1-2×/8 h
Coryza diminished sufficiently to permit use of nasal ventilation
Extubation to continuous high span BiPAP or noninvasive IPPV via mouth/nasal interface, no supplemental oxygen.
Oximetry feedback used to guide the use of MAC, postural drainage, and chest physical therapy to reverse desaturations below 95% due to airway mucus.
With CO_2 retention or ventilator synchronization difficulties, nasal interface leaks are eliminated. For small children with rapid breathing rates who are using high span BiPAP, the inspiratory ramp may need to be shortened or the IPAP decreased. Backup BiPAP rates may need to be set at one-half the child's breathing rate to capture every other breath. Synchrony may also improve by switching to using a more trigger-sensitive volume cycle ventilator. Persistent oxyhemoglobin desaturation despite eucapnia and aggressive MAC can indicate impending severe respiratory distress and need to reintubate.
Following reintubation the protocol is used for a second trial of extubation to nasal IPPV or high span nasal BiPAP. Once extubation is successful and Sa_{O_2} remains >94% in ambient air, the patient weans him/herself to the preintubation regime of ventilator use by taking fewer and fewer mouth piece IPPVs as tolerated and as presented in Figure 85-2.

INSPIRATORY AND EXPIRATORY AIDS AND SURGICAL ANESTHESIA

Prevention or correction of spinal deformities is crucial to maintain quality of life for patients with neuromuscular disorders. Surveys of neuromuscular disease clinics indicated that most children with neuromuscular scoliosis were not undergoing spinal instrumentation and fusion for fear of respiratory complications.[1] As a result, the ability to sit or use an IAPV is often lost. However, respiratory complications are preventable when patients are trained in noninvasive IPPV and MAC pre-op and are extubated to them as described in Table 85-3. We have extubated 17 consecutive pediatric neuromuscular scoliosis patients with pre-op vital capacities less than 40% of normal including those with post-op vital capacities as low as 2% of predicted normal, none of whom could pass spontaneous breathing trials either before or after extubation, to full-setting noninvasive IPPV and MAC with no complications as described.[18] Two of the patients were continuously noninvasive IPPV dependent for several years even before the surgery.

In summary, wider use of noninvasive respiratory muscle aids and approaches would avoid the complications inherent in invasive management and facilitate community disposition rather than lifetime institutionalization and quality of life while greatly diminishing cost.

CHAPTER 86

Asbestos-Related Lung Disease

William N. Rom

INTRODUCTION

Asbestos is a fibrous hydrated magnesium silicate with commercial use due to its indestructible nature, fire resistance, and easy transformability into industrial products from yarn to insulation block to brakes. Asbestos fibers are generally defined as long, thin fibers with a length to width ratio (aspect ratio) of 3:1. There are six commercial forms of asbestos: chrysotile, crocidolite, amosite, anthophyllite, actinolite, and tremolite. Most of the asbestos used in the United States has been chrysotile, a serpentine form of asbestos. Other asbestos types are the amphiboles—notably amosite, mined in South Africa, and crocidolite, mined in the Cape Province of South Africa and in Western Australia. These asbestos fiber types have strikingly different physical characteristics: chrysotile tends to be wavy and long, and occurs in bundles; crocidolite is needle-shaped with many long fibers; and amosite is similar to crocidolite but generally thicker. Asbestos fibers accumulate in the interstitium of the lung and are coated by iron and hemosiderin in a beaded, clubbed fashion referred to as ferruginous or asbestos bodies.

Initially, asbestos was widely used in fireproof textiles and later as insulation for boilers and pipes. Thereafter, asbestos was used in yarn, felt, paper, millboard, shingles, paints, cloth, tape, filters, wire insulation, cement pipes for potable water, gaskets, and in friction materials, including brake linings, and roofing and floor products. Asbestos was extensively used for ship construction during World War II. Occupational exposure to asbestos in the United States now primarily occurs during maintenance activities or remediation of buildings containing asbestos. The Occupational Safety and Health Administration (OSHA) has estimated that 1.3 million workers in general industry continue to be exposed to asbestos, and the National Institute for Occupational Safety and Health (NIOSH) estimates that 44,000 mine workers might be exposed to asbestos fibers or amphibole cleavage fragments, especially tremolite. Although the European Union has banned imports and use of asbestos, approximately 2 million tons are used worldwide. Asbestos is mined in Eastern Europe and Asia where asbestos products are manufactured for use in insulation, roofing, and construction. Globalization has resulted in export of asbestos to developing countries for manufacture and export to other developing countries with concomitant increase in asbestosis and mesothelioma.[1]

TYPES OF EXPOSURE

Primary asbestos exposures occurred in miners and millers. Secondary exposures occurred in manufacturing plants using asbestos in the production of textiles, friction materials, tiles, and insulation materials. Epidemiological studies focused on cohorts in these plants, since asbestos fiber type was often specified and dust measurements were obtained. These studies demonstrated that intensity and duration of exposure play an important role in the prevalence of asbestos-related disease. Common trades with asbestos exposure include sheet metal work, plumbing, pipefitting, insulation, railroad and utility work, and school or building custodians. Prevalence of radiographic opacities in asbestos insulation workers exposed prior to the 1970s reached 50% in long-term workers and was approximately 15% in sheet metal workers. There is a long latency period between exposure and manifestation of asbestos-related disease making identification and intervention difficult.

Although measurements of airborne asbestos fibers were seldom made, the most significant exposures appear to have occurred in the construction trades. These trades included asbestos insulators (called "laggers" in the United Kingdom), who mixed asbestos cement on site to insulate joints and elbows on pipes; boilermakers and sheet metal workers, who worked adjacent to the asbestos workers; and electricians, carpenters, plumbers, and others who worked in the vicinity of work requiring asbestos exposure. These exposures were mainly to chrysotile asbestos, since practically no crocidolite was imported into the United States, and only small amounts of amosite were admixed. Asbestos workers and other construction workers wore their asbestos-covered clothes home, exposing their wives and children when greeting them or while washing their garments. These household contact exposures are often referred to as *indirect exposures,* and those exposed while working near asbestos workers are called *bystander exposures.*

Projected lung cancer deaths range from 55,000 to 76,700 for the 30-year period due to asbestos exposure over 1980 to 2009. The National Occupational Respiratory Mortality System has tracked asbestosis deaths since 1968, peaking at 1400/y since 2004 and mesothelioma deaths peaking at 2700/y since 2005. Asbestosis is the cause of about 11% of deaths in asbestos workers; interestingly, the most important determinant is radiographic profusion score with rates increasing from 2.4% to 10.98% and 35.4% with profusion category increasing from 1 to 3. Profusion of irregular opacities is categorized into four levels ranging from 0 to 3, with 12 subcategories 0/0 to 0/1 to 1/0 up to 3/4 for the most dense fibrosis according to a scale agreed to by the International Labor Organization. Dyspnea, a low FVC, and/or physical examination findings typical of interstitial fibrosis (rales, clubbing or cyanosis) raise the risk of death from asbestosis from two- to sixfold.[2]

NONMALIGNANT PLEURAL MANIFESTATIONS

Pleural disease is the most common manifestation of asbestos exposure. The nonmalignant manifestations of asbestos exposure in the pleural space include circumscribed pleural plaques, diffuse pleural thickening, rounded atelectasis, and asbestos-related pleural effusions.[3]

■ PLEURAL PLAQUES

Important pathogenetic and clinical features of pleural plaques are discussed below.

Pathology

Pleural plaques are the most common manifestation of asbestos exposure. They are focal, irregular, raised white lesions found on the parietal and, rarely, the visceral pleura. The plaques may be small or extensive; commonly they occur in the lateral and posterior midlung zones, where they may follow rib contours and the diaphragm. They commonly enter lobar fissures and can invade the mediastinum or pericardium; rarely do they invade the apices or costophrenic sulci. Histologically, asbestos-related pleural plaques are characterized by a paucity of cells, extensive collagen fibrils arranged in a basket-weave pattern, and a thin covering of mesothelial cells. The parietal pleura is uniformly involved, with minimal thickening of the visceral pleura. The two pleural surfaces are free of adhesions. Pleural calcifications

frequently develop in these fibrohyaline lesions as the length of time from exposure increases. Exposure to asbestos is the most frequent cause of pleural plaques.

Pathogenesis

Two theories have been proposed for the pathogenesis of pleural plaques. The most plausible is based on the direct effects of fibers that reach the pleural space. Asbestos fibers – the short, thin ones in particular – have been shown to be transported by subpleural lymphatics to the pleural space. In the pleural space, it is believed that they scratch, injure, and irritate the pleural surface, leading to hemorrhage, inflammation, and eventually fibrosis. The plaques are submesothelial. Mesothelial cells appear to play an important role in the pathogenesis of these lesions: they internalize asbestos fibers via an integrin receptor that recognizes vitronectin; in vitro pleural mesothelial cells also can synthesize collagens (types I, III, and IV), elastin, laminin, and fibronectin. In keeping with the submesothelial location of the plaques, cultured mesothelial cells can organize these macromolecular connective tissue components into an assemblage of extracellular matrix that is limited to the base of the cell.

Epidemiology and Natural History

Hyaline and calcified pleural plaques have been noted to be an index of exposure to asbestos. In shipyard workers, the frequency of pleural abnormalities was approximately 10 times that of parenchymal disease. The greater the exposure, the more likely the worker was to have extensive calcified pleural plaques as well as parenchymal fibrosis. The intensity of the exposure has been noted to be an important determinant of the prevalence of these abnormalities. For example, among British shipyard workers, 36% of those with continuous exposure as "laggers" developed pleural plaques, while extensive pleural thickening and pulmonary fibrosis were seen in 5% and 7%, respectively. In contrast, those with intermittent exposure had a 6% prevalence of plaques and no pulmonary fibrosis. On average, the latency time for the appearance of plaques is 30 years, but the time can vary greatly. This variation can also be appreciated from studies of British shipyard workers in whom the prevalence of pleural plaques increased from 17% at 10 years after the first exposure to 70% at 30 years among those with continuous exposure; for those with intermittent exposures, the prevalence increased from 1% at 10 years to 16% at 30 years.

All asbestos fibers are equally capable of inducing pleural plaques: Pleural plaques are found in US insulators or shipyard workers exposed to chrysotile or amosite, as well as miners in Western Australia who were exposed to crocidolite.

In addition to occupational exposures, environmental, domestic and residential exposures have been implicated in the production of pleural plaques. Evidence for the latter is the remarkably high rates of pleural calcification (up to 45%) in some rural areas of Greece, Corsica, Cyprus, and Turkey where outcroppings of tremolite asbestos have been used to whitewash houses. Pleural plaques have been noted from environmental exposure to tremolite asbestos fibers contaminating vermiculite mining and milling in Libby, Montana.

Clinical and Physiological Features

In the absence of concomitant asbestosis or obliteration of the costophrenic angle, pleural plaques are usually asymptomatic. Most often they are incidental findings on chest radiographs. In addition, they do not cause significant abnormalities such as pleural rubs, rales, or rhonchi on auscultation of the chest.

Pleural disease has been recognized as a cause of reduced pulmonary function since the 1970s. Among 998 shipyard workers in Groton, Connecticut, who had 15 or more years of asbestos exposure, 17% of those with pleural changes had a forced vital capacity (FVC) under 80% of predicted; for those with normal chest radiographs, 9% had decreased vital capacities. In those with normal chest radiographs, the values were significantly reduced only among smokers and ex-smokers. Recent studies that have applied stepwise regression analysis to data from insulation workers have disclosed a significant inverse relationship between FVC and an integrative pleural index for patients with circumscribed pleural plaques.[4] Even among those with pleuroparenchymal abnormalities, the pleural index was found to make a significant contribution to decrements in FVC, independent of that due to parenchymal abnormalities.

In nonsmoking asbestos workers with circumscribed or diaphragmatic pleural plaques, flow rates (FEV_1, $FEF_{25–75\%}$) have been reported to be reduced. In an epidemiological study of 1211 sheet metal workers, pleural fibrosis was detected in 334 and was related to age, duration of exposure, more pack-years of smoking, and the presence and degree of interstitial fibrosis. After controlling for these confounders, multivariate regression analysis found that both plaques and diffuse thickening were independently associated with decrements in FVC, but not with decrements in the FEV_1/FVC ratio. Furthermore, diffuse pleural thickening was associated with a decrement in FVC twice as great as that seen with circumscribed pleural plaques. After confounding variables such as age, height, smoking status, and the presence of parenchymal abnormality as assessed by chest radiography and gallium scintigraphy were taken into account, there was a significant decrease in FEV_1 and FVC (222 and 402 mL, respectively) among workers who had pleural plaques or diffuse pleural fibrosis.

Radiographic Features

The visualization of plaques on digital chest radiography depends on their thickness, location, and the orientation of the radiographic beam.[5] As a result, they can be viewed in profile along the lateral chest wall or on en face with a rolled or holly-leaf pattern, especially if calcified (Fig. 86-1). Only a modest proportion of plaques detected

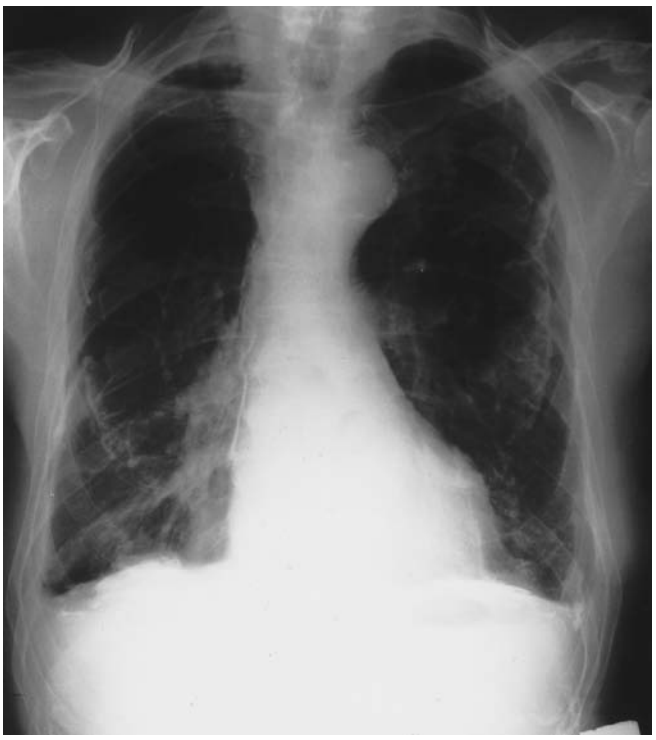

Figure 86-1 Posteroanterior (PA) chest radiograph of a 75-year-old man who worked in a shipyard during World War II insulating ships. The radiograph shows bilateral calcified pleural plaques en face and on top of the diaphragm. The pleura is diffusely thickened bilaterally and the costophrenic angles are blunted. Mediastinal pleural calcification is present on the right. *(Used with permission of Dr. Timothy Harkin.)*

at autopsy can be seen on digital chest radiography. Computed tomographic (CT) scanning increases plaque detection (increase in sensitivity and specificity).

The CT scan can recognize plaques at a much earlier and less well-defined state than digital chest radiography. The CT scan is particularly useful for perivertebral and pericardiac plaques, and high-resolution CT scanning (HRCT) helps to establish the presence of diaphragmatic lesions. In all cases, the CT scan can help to differentiate plaques from extrapleural fat pads and can detect concomitant parenchymal abnormalities that may be difficult or impossible to see on the PA chest radiograph.

Diagnosis

Pleural plaques due to asbestos exposure are usually bilateral (80% of the time), whereas unilateral pleural plaques may be due to trauma, previous tuberculosis, or, rarely, other causes, such as collagen vascular disease. The lesions are usually stable and remain the same size for months. This helps to differentiate plaques from pleural tumors. Histological tissue examination is not necessary for diagnosis the vast majority of the time.

Treatment

No specific treatment is required for asbestos pleural plaques. Since they are markers of asbestos exposure and identify patients at risk for other asbestos-related disorders, medical surveillance, including periodic CT scans and blood biomarkers, are recommended.[6]

■ DIFFUSE PLEURAL THICKENING

Pleural thickening, another common manifestation of asbestos exposure, is discussed below.

Pathology

Pleural fibrosis in persons who have been exposed to asbestos has been well described. The fibrotic responses can be localized or diffuse and either unilateral or bilateral. Macroscopically, the lesions vary in thickness from a whitish discoloration of the lung surface to a thick white peel that can encase significant pulmonary structures. Diffuse pleural thickening is most often seen as a continuous sheet that is 5 to 10 cm in craniocaudal extent, and in 90% of patients it affects the costophrenic angle. Interlobar and interlobular fissures are commonly involved. Whereas pleural plaques predominantly affect the parietal pleura, diffuse pleural fibrosis occurs most commonly as part of a fibrotic process of the visceral pleura and subadjacent interstitium.

Pathogenesis

Diffuse pleural thickening has been proposed to result from three different mechanisms. The first is the confluence of large pleural plaques. This is believed to account for 10% to 20% of the cases. The second is the extension of subpleural fibrosis to the visceral pleura. This probably accounts for 10% to 30% of cases. The most common pathogenic mechanism is thought to be the fibrotic resolution of a benign pleural effusion, producing diffuse pleural thickening. The importance of this mechanism is highlighted by the finding that about one-third of patients with diffuse pleural thickening have had a prior benign asbestos-related pleural effusion diagnosed by thoracentesis or on serial chest radiographs. The pathogenic mechanisms differentiating diffuse pleural thickening from circumscribed pleural plaques are not well defined. However, the fundamental mechanism of asbestos fibers activating macrophages and mesothelial cells to release growth factors and stimulate collagen formation is likely to be important in both. In the case of diffuse pleural responses, these fibers are deposited mainly in the parenchymal subpleural areas of the lung.

Clinical and Physiological Manifestations

Diffuse pleural fibrosis most often occurs long after short-term heavy exposure to asbestos. When mild, diffuse pleural fibrosis can be asymptomatic and discovered as an incidental finding on a chest radiograph obtained for another reason. The diffuse nature of the lesion, however, often leads to pulmonary symptoms, including dyspnea on exertion, chronic dry cough, and chest pain. As noted earlier, diffuse pleural thickening can cause a restrictive physiological abnormality. The degree of physiological abnormality varies with the degree of fibrotic response. On rare occasions, in patients with severe bilateral disease, respiratory insufficiency has occurred. Diffuse pleural fibrosis can increase in severity over time.

Radiographic Features

On the routine chest radiograph, diffuse pleural fibrosis presents as a continuous pleural opacity extending over more than 25% of the pleural surface of a lung, often blunting the costophrenic angle. It can be unilateral or bilateral and seen in the presence or absence of concomitant asbestosis and pleural calcifications. Rarely, the pleural fibrosis will produce a fibrotic pseudotumor with a pleural basis (rounded atelectasis) (see below). CT scanning is particularly useful in delineating the relationship between diffuse fibrosis and other pleural abnormalities and differentiating pleural fibrosis from fat deposits.

Diagnosis

The diagnosis of diffuse pleural fibrosis is usually based on the clinical presentation and chest radiograph. The lesions of diffuse pleural fibrosis are not unique to asbestos-exposed persons and can represent old inflammatory reactions from tuberculosis, thoracic surgery, or hemorrhagic chest trauma. Differentiation among these causes is frequently based on a careful clinical history. Radiographic patterns are also helpful, since bilateral interstitial changes in the lower lung zones in association with pleural plaques or calcifications strongly support a diagnosis of asbestos exposure. A biopsy may be required when the thoracic lesion is progressing or when malignancy is in the differential.

Treatment

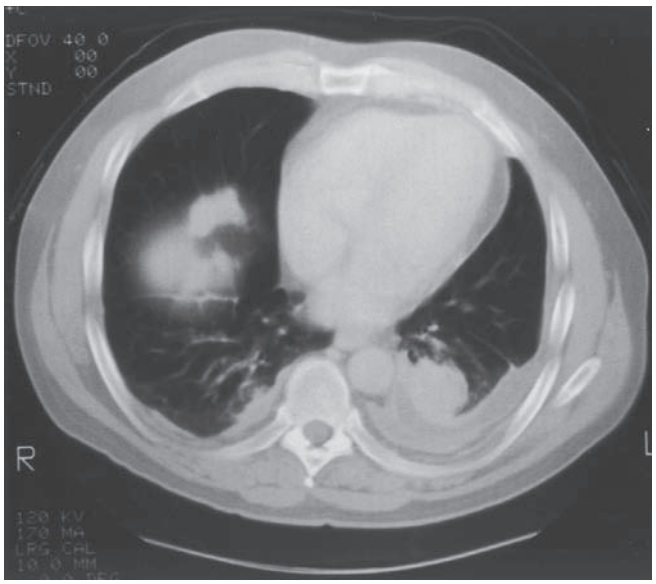
As seen with circumscribed pleural plaques, there are no specific therapies for asbestos-related diffuse pleural fibrosis. Medical surveillance is required to detect disease progression, lung cancer, and mesothelioma.

■ ROUNDED ATELECTASIS

Rounded atelectasis is a rare complication of asbestos-induced pleural disease. It is caused by scarring of the visceral and pari etal pleura and the adjacent lung, with the pleural reaction folding over on itself. The pleural surfaces then fuse to one another, trapping the underlying lung and leading to atelectasis. As a result of this alteration, a mass lesion that mimics lung cancer can be seen on the PA chest radiograph (Fig. 86-2). This lesion is most easily appreciated to be a pseudotumor with use of CT scanning. HRCT can noninvasively demonstrate continuity to areas of diffuse pleural thickening, evidence of volume loss in the adjacent lung, or a characteristic comet tail of vessels and bronchi sweeping into a wedge-shaped mass (Fig. 86-2).

CT scanning can also demonstrate stability over time (from months to years), which supports the diagnosis of a benign lesion, and pleural plaques or parenchymal changes, which support a diagnosis of asbestos exposure. In one clinical series of 74 patients with rounded atelectasis, 64 had significant asbestos exposure, and the lingula or right middle lobe was affected in 49 of the patients.[7] HRCT scans localized most cases of rounded atelectasis to the lower, posterior portion of the lung; moreover, in one-third of the patients, the lesions were multiple. In most patients, rounded atelectasis occurs suddenly on a background of only plaques or a normal chest radiograph. In others, a slowly increasing pleural effusion may precede its appearance.

A



B

Figure 86-2 Rounded atelectasis and other pleural abnormalities in an asbestos worker. The chest radiograph (**A**) shows a left-sided pleural effusion, bilateral pleural thickening, greater on the left than on the right, and a mass in the left midlung field. HRCT (**B**) demonstrates the mass to be rounded atelectasis, with bronchovascular structures entering the trapped lung. It also reveals the pleural effusion, bilateral pleural thickening, and pleural plaques, one of which is on the right hemidiaphragm. *(Used with permission of William M. Rom, MD, MPH.)*

■ ACUTE BENIGN PLEURAL EFFUSIONS

Acute benign pleural effusions are common pleural manifestations in asbestos-exposed persons between 20 and 40 years of age. The latency period for these effusions is shorter than for pleural plaques, malignant mesotheliomas, or pulmonary malignancies. Benign pleural effusions generally occur earlier after exposure than do other asbestos-related processes; the latency is shorter, for example, 12 to 15 years rather than >20 years after the first asbestos exposure compared to pleural plaques or asbestosis.

About 50% of the patients with acute benign pleural effusions are asymptomatic. When patients are symptomatic, the manifestations may be those of a pleurisy (chest pain, chest tightness, dyspnea, cough, and fever). Physical examination reveals the signs of a pleural effusion; a pleural friction rub may be heard. The effusions are exudative and often bloody; glucose concentrations are normal. Mesothelial cells in effusions are found in about 50% of patients. In about 25% of patients, the fluid is eosinophilic. Rarely are asbestos bodies found even though they may be present in underlying lung tissue.

The designation "benign" refers to the lack of evidence of malignancy. The collections may persist for 6 months or more. They frequently clear spontaneously, only to recur on the contralateral side. However, a benign asbestos pleural effusion is a risk factor for the development of pleural thickening, especially diffuse pleural fibrosis. The diagnosis of acute benign pleural effusions is one of exclusion. Thoracentesis is essential. Pleural biopsy is frequently required to rule out other causes of pleural effusions, including mesothelioma. The usual pathological findings are a chronic fibrous pleurisy with minimal cellularity. Diffuse malignant pleural mesothelioma invariably presents as a pleural effusion, but pleural mass lesions are usually seen on CT scan, which are absent in benign asbestos effusions.

ASBESTOSIS

Important pathologic and clinical aspects of asbestosis are discussed below.

■ PATHOLOGY

Asbestosis is the interstitial pneumonitis and fibrosis caused by exposure to asbestos fibers.[3] Early lesions are characterized by discrete areas of fibrosis in the walls of respiratory bronchioles. The septi adjacent to the respiratory bronchioles are often thickened, and the fibrosis sometimes appears to spread outward from the bronchioles. In addition to the peribronchiolar fibrosis, there is an intense peribronchiolar cellular reaction that may narrow and obstruct the airway lumen. Macrophage accumulation is a prominent feature of this cellularity. Proliferation of type II alveolar epithelial cells is enhanced. The interstitium may contain collections of lymphocytes; smooth muscle proliferation may be prominent in areas of remodeling; and buds of loose connective tissue may be seen within the alveoli (Fig. 86-3).[8] Initially, the disease usually involves first-order bronchioles; subsequently, second- and third-order bronchioles are affected. As the disease progresses, the fibrosis becomes diffuse, the architecture of the lung undergoes extensive remodeling, and

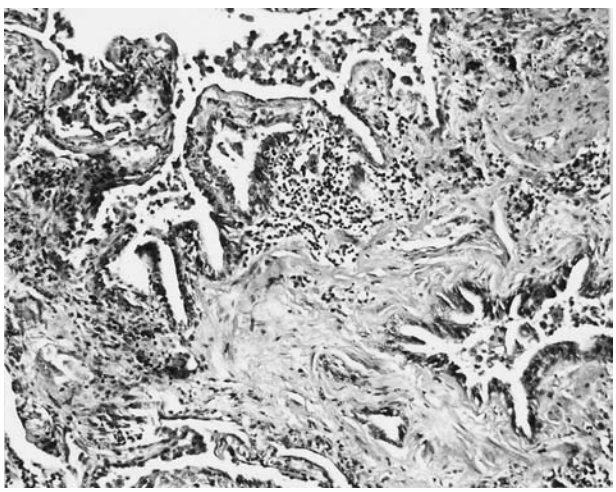


Figure 86-3 Lung tissue from a 64-year-old asbestos insulator with 46 years of exposure to asbestos while insulating pipes. His chest radiograph revealed extensive irregular opacities and bilateral pleural thickening. The figure illustrates peribronchiolar fibrosis, interstitial chronic inflammation, accumulation of macrophages in the airspaces, and proliferation of type II pneumocytes. *(Reproduced with permission from Rom WN, Travis WD, Brody AR. Cellular and molecular basis of the asbestos-related diseases: State of the art. Am Rev Respir Dis.1991;143(2):408–422.)*
