After a patient's medical, physiologic, and psychosocial state have been evaluated, specific goals should be set that are compatible with his or her disease, needs, and expectations. Goals should be realistic in light of the objectives of the program. Family members and significant others should be included in this process so that everyone understands what can and cannot be achieved. Programs should evaluate individual patients to document changes before and after pulmonary rehabilitation with standardized outcome measures of exercise tolerance (e.g., 6-minute walk distance) and symptoms (e.g., dyspnea) or health status (e.g., health-related quality of life).

PROGRAM CONTENT

Comprehensive pulmonary rehabilitation programs typically include several key components: education, instruction in respiratory and chest physiotherapy, psychosocial support, and exercise training (Table 43-2). Often, the various components are provided simultaneously; for example, during an exercise session, a patient may learn and practice breathing techniques for symptom control while being encouraged and supported by staff or other patients. Although there is no consensus regarding the optimal duration of a pulmonary rehabilitation intervention, typical programs last 6 to 12 weeks with 2 to 3 sessions per week, each session including several hours of supervised exercise training and individual or group education and psychosocial interventions.

EDUCATION

Successful pulmonary rehabilitation depends upon an understanding of lung disease and active involvement by patients and important others in providing social support. Education is an integral component; even patients with severe disease can gain a better understanding of their disease and learn specific means to deal with problems. Instruction can be provided individually or in small groups, but it should be adapted to different learning abilities. Topics discussed commonly include normal lung function, chronic lung disease, medications, nutrition, travel, stress reduction and relaxation, reasons to call the physician, and planning a daily schedule. Individual instruction and coaching may be provided on the use of respiratory therapy equipment and supplemental oxygen, breathing techniques, bronchial drainage, chest percussion, energy-saving techniques, and self-care tips. The general philosophy is to encourage patients to assume responsibility for their own care and become partners with their physician in providing the care.[22]

Despite the importance of education, it is unlikely that increased patient knowledge alone will lead to improved health status. It is more difficult to change patient attitudes and behaviors. Patients require specific, individualized treatment strategies, instruction, and reinforcement. Thus, education is a necessary but not sufficient component of pulmonary rehabilitation.

RESPIRATORY AND CHEST PHYSIOTHERAPY TECHNIQUES

Patients with chronic lung disease use, abuse, and are confused about respiratory and chest physiotherapy techniques. In pulmonary rehabilitation, each patient's needs for respiratory care techniques should be assessed and instruction provided in proper use. These techniques may include chest physiotherapy to control secretions; breathing retraining techniques to relieve and control dyspnea and improve ventilatory function; and proper use and care of respiratory equipment, including nebulizers, metered dose inhalers, and supplemental oxygen.[23]

BRONCHIAL HYGIENE

Patients with chronic lung diseases frequently have abnormal lung clearance mechanisms that increase problems with retained secretions and infection. Therefore, rehabilitation programs teach a variety of chest physiotherapy techniques for secretion control (e.g., coughing, postural drainage, chest vibration, and percussion). These are important for patients who experience excess mucus production during exacerbations as well as for those with chronic sputum production. The use of mucolytic agents to reduce viscosity of secretions is of questionable benefit.[24,25]

BREATHING RETRAINING TECHNIQUES

Pulmonary rehabilitation typically includes instruction in breathing techniques, such as diaphragmatic and pursed lips breathing—techniques aimed at helping patients relieve and control breathlessness, improve their ventilatory pattern (i.e., slower respiratory rate and increased tidal volume), prevent dynamic airway compression, improve respiratory synchrony of the abdominal and thoracic musculature, and improve gas exchange.[26] Review of studies evaluating these techniques indicates that improvement in symptoms (e.g., dyspnea) is a more consistent finding than are measurable changes in physiological parameters. The diaphragmatic breathing technique is a maneuver in which the patient consciously coordinates abdominal wall expansion with inspiration and slows expiration through pursed lips. The primary effect is to slow respiratory rate and increase tidal volume. Pursed lips breathing is commonly taught to pulmonary patients, particularly those with COPD. This technique was observed by Laennec as early as 1830 and was advocated as a physical exercise for pulmonary patients in the early part of the twentieth century. As a maneuver assumed naturally by many patients with respiratory disease, pursed lips breathing is characterized by tensing the lips and narrowing the mouth opening during expiration. The aim is to slow expiration and maintain positive airway pressure to "stent the airways open" and prevent collapse.[27]

OXYGEN

When chronic oxygen therapy is required, available delivery methods should be reviewed to help select the best system for the patient's needs. Supplemental oxygen is beneficial for patients with severe resting hypoxemia. Long-term continuous oxygen therapy has been clearly shown to improve survival and reduce mortality and morbidity in hypoxemic patients with COPD.[28,29] The benefits of supplemental oxygen for nonhypoxemic patients or those with intermittent hypoxemia (e.g., during exercise or sleep) are less clearly defined. Although continuous oxygen therapy is feasible and safe, maintaining patients on supplemental oxygen presents several challenges. Handling equipment is particularly difficult for physically disabled and frail patients. Therefore, it is important to assess each person's oxygen needs and provide appropriate instruction.[30]

Several new developments have improved the efficiency of gas delivery systems and patient compliance with continuous oxygen therapy. Liquid oxygen provides more gas with less weight than tanks of compressed gas, particularly in portable systems. Oxygen conserving devices may increase the efficiency of delivery, reducing flow requirements and prolonging the life span of portable gas sources. Transtracheal oxygen delivery may help to improve compliance and avoid problems with nasal catheters; however, patients must be instructed carefully in caring for the catheter.[31]

EXERCISE

Exercise is important in pulmonary rehabilitation.[32,33] Considerable evidence supports favorable responses to exercise training in patients with chronic lung diseases.[3] Benefits are both physiological and psychological. Patients may increase their maximum capacity and endurance for physical activity, even though objective measures of lung function do not usually change. Patients may also benefit from learning to perform physical tasks more efficiently. Exercise training provides an ideal opportunity for patients to learn their capacity for physical work and use and practice methods for controlling dyspnea (e.g., breathing and relaxation techniques). Of all the components in a comprehensive pulmonary rehabilitation program, exercise is probably the most costly and labor-intensive, considering the personnel, equipment, and expertise required. Principles of exercise for patients with lung disease differ from those based on normals or other patient populations because of differences in the limitations to exercise and the problems encountered in training.

Many approaches have been used to train the person with chronic lung disease. To be successful, the program should be tailored to the individual's physical abilities, interests, resources, and environment. For general application, techniques should be simple and inexpensive. As in normals and other patients, benefits are largely specific to the muscles and tasks involved in training. Patients tend to do best with activities and exercises for which they are trained. Walking programs are particularly useful. They have the added benefit of encouraging patients to expand social horizons. In inclement weather, many can walk indoors (e.g., at shopping malls). Other types of exercise (e.g., cycling, swimming) are also effective. Patients should be encouraged to incorporate regular exercise into daily activities they enjoy (e.g., golf, gardening). Since many persons with chronic lung disease have limited exercise tolerance, emphasis during training should be placed on increasing endurance. Changes in endurance with rehabilitation are often greater than changes in maximal exercise tolerance and allow patients to become more functional within their physical limits. Increase in maximum exercise is also possible as patients gain experience and confidence. Resistive training is also used commonly in rehabilitation and can lead to significant increases in muscle strength that are important for many activities of daily living.[34]

EXERCISE PRESCRIPTION

Selecting a training target based upon a predetermined percentage of predicted maximal heart rate or ($\dot{V}_{O_2}$) is a well-established practice for normals or patients without underlying pulmonary disease. However, in patients with chronic lung diseases, the best method of choosing an appropriate training prescription is less clearly defined. Exercise tolerance in pulmonary patients is typically limited by maximal achievable ventilation and breathlessness. Such patients frequently do not reach their limits of cardiac or peripheral muscle performance.

Much controversy exists regarding the appropriate training intensity target for patients with chronic lung disease. Use of a target heart rate has been advocated by some, although it is recognized that such a target may not be reliable for patients with more severe disease.

Many patients with lung disease can be trained at a high percentage of maximal exercise tolerance, with work levels approaching or even exceeding the maximal level reached on the initial exercise test. In a study of 52 patients with moderate to severe COPD, patients were able to perform endurance exercise testing at an average workload of 95% of their baseline maximum.[35] After 8 weeks of training, these patients were training at 86% of the baseline maximum. In fact, many patients with severe COPD were exercising at levels exceeding their baseline maximum. In another study that examined 59 patients with moderate to severe COPD who trained at levels near their ventilatory limits, a mean peak exercise ventilation of 100% of measured maximal voluntary ventilation was achieved after 12 days of training and at 3 months of follow-up.[36] These findings suggest that even patients with advanced disease can be trained successfully at or near maximal exercise levels.

Based on the findings noted previously, some pulmonary rehabilitation programs define exercise targets and progression during training more by symptom tolerance than heart rate, work level, or other physiological measurements. Ratings of perceived symptoms (e.g., breathlessness) help teach patients to exercise to "target" levels of breathing discomfort. A typical approach is to begin training at a level that the patient can sustain with reasonable comfort for several minutes and then to increase the time or exercise level according to symptom tolerance. Patients are encouraged to exercise daily and increase exercise duration up to 15 to 30 minutes of continuous activity. This graduated program helps patients to achieve a goal of improved tolerance for tasks of daily living, which often require a period of sustained activity.

BLOOD GAS CHANGES

A major problem in planning a safe exercise program for patients with lung disease is the potential for worsening of hypoxemia with exercise. Patients who are not hypoxemic at rest may develop changes in arterial oxygenation that cannot be predicted reliably from resting measurements of pulmonary function or gas exchange.[20] Normal individuals do not become hypoxemic with exercise. In patients with obstructive lung disease, Pa_{O_2} changes unpredictably during exercise. In patients with mild COPD, Pa_{O_2} typically does not change with exercise; in fact, it may even improve. However, in patients with moderate to severe COPD, Pa_{O_2} may increase, decrease, or remain the same. Patients with interstitial lung disease commonly develop worsening oxygenation with exercise.

Based on these observations, it is important to evaluate a patient's oxygenation status both at rest and during exercise. Such testing is also used to prescribe oxygen therapy at rest and with physical activity. With the availability of convenient, portable systems for ambulatory oxygen delivery, hypoxemia is not a contraindication to safe exercise training.

OTHER TYPES OF EXERCISE

Exercise programs for pulmonary patients typically emphasize lower extremity training (e.g., walking or cycling). Since exercise conditioning is largely specific to the muscles and tasks involved in training other forms of exercise may be particularly valuable for persons with chronic lung diseases.

Upper Extremity Training

Many patients with chronic lung disease report disabling dyspnea with daily activities involving the upper extremities (e.g., lifting, grooming) at much lower work levels than with the lower extremities. Upper extremity exercise is accompanied by a higher ventilatory demand for a given level of work than is lower extremity exercise. Given the aforementioned muscle specificity of training, upper extremity exercises may be important in helping pulmonary patients cope better with common daily activities.[37]

Ventilatory Muscle Training

The potential role of ventilatory muscle fatigue as a cause of respiratory failure and ventilatory limitation in patients with chronic lung disease has stimulated attempts to train the ventilatory muscles. Techniques of isocapnic hyperventilation, inspiratory resistive loading, and inspiratory threshold loading have been shown to improve function of the respiratory muscles in both normals and patients. In normals, respiratory muscle function does not limit exercise tolerance; therefore, specific respiratory muscle training is unlikely to be of clinical benefit. In patients with COPD, the patient group most extensively studied, improvement in general exercise performance from ventilatory muscle training alone has not been demonstrated consistently. Thus, the role of respiratory muscle training as a routine component of pulmonary rehabilitation has not been clearly established.

PSYCHOSOCIAL SUPPORT

An essential component of pulmonary rehabilitation is psychosocial support, the goal of which is to help patients combat progressive feelings of hopelessness and an inability to cope with chronic, progressive disease.[15] Depression is common in patients with chronic pulmonary disorders, as are anxiety (especially anxiety over dyspnea), denial, anger, and isolation. Patients become sedentary and dependent upon family members, friends, and medical services to provide for their needs. Excessive concern over other physical problems and psychosomatic complaints arise. Sexual dysfunction and fear are common and represent often unspoken consequences of chronic lung disease. Patients may also demonstrate cognitive and neuropsychological dysfunction, possibly related to or exacerbated by the effects of hypoxemia on the brain.

Psychosocial support is provided best by a warm and enthusiastic staff who can communicate effectively with patients and devote the time and effort necessary to understand and motivate them. Family members and significant others should be included in activities so that they can understand the disease and help the patient cope. Support groups are also effective. Patients with severe psychological disorders may benefit from individual counseling and therapy. Psychotropic drugs should generally be reserved for patients with more severe psychological dysfunction.

BENEFITS OF PULMONARY REHABILITATION

A growing body of evidence supports the expected results and benefits of pulmonary rehabilitation in the management of patients with chronic lung disease (Table 43-3). Evidence-based guidelines were

TABLE 43-3 Results of Pulmonary Rehabilitation

Decreases in
Medical resource utilization (e.g., hospitalizations, emergency room visits)
Respiratory symptoms (e.g., breathlessness)
Psychological symptoms (e.g., depression, fear)
Increases in
Quality of life
Physical activity
Exercise tolerance (endurance, maximal level of activities of daily living, strength)
Knowledge
Independence
Return to work possible
No change in lung function
Possible prolonged survival

published by a joint effort of the American College of Chest Physicians (ACCP) and the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR) in 1997 and updated in 2007.[3,38] The 2007 ACCP/AACVPR Panel made and rated 26 recommendations and statements regarding pulmonary rehabilitation. Of these, seven were given the highest rating representing strong evidence and documented benefits. These included improvements in lower extremity exercise training, dyspnea, and health-related quality of life and the decline in benefits over 12 to 18 months from a 6- to 12-week intervention. They also felt that there was high-quality evidence supporting exercise in pulmonary rehabilitation regarding both high and low intensity training, increase in muscle strength and muscle mass from strength training, and upper extremity training. Other benefits with moderate level evidence included greater physiologic benefits from higher exercise training intensity, incorporation of education in pulmonary rehabilitation, and benefits for some patients with chronic respiratory diseases other than COPD. It should be noted that once a patient is stabilized on a standard drug treatment regimen, lung function (e.g., spirometric flow rates, lung volumes) does not change after pulmonary rehabilitation.

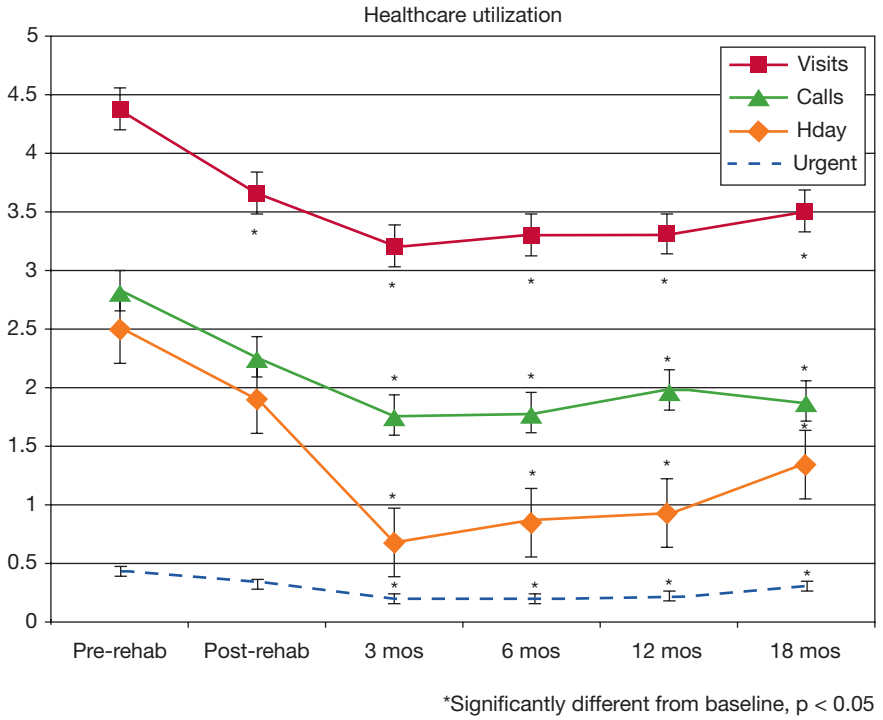

Figure 43-1 Changes in healthcare utilization over 18 months after pulmonary rehabilitation in a collaborative study of 647 patients in 10 centers in California. Results are presented as mean ± SE. *(Reproduced with permission from California Pulmonary Rehabflitation Collaborative Group: Effects of pulmonary rehabfl itation on dyspnea, quality of life and health care costs in California. J Cardiopulmonary Rehabfl. 2004;24:52–62.)*

In addition to the ACCP/AACVPR Guidelines, several other reviews support the benefits of pulmonary rehabilitation. The ATS/ERS Statement of Pulmonary Rehabilitation provides a systematic review and concludes that there is strong and growing evidence for improvement in exercise endurance, dyspnea, functional capacity, and quality of life and reduced healthcare utilization from pulmonary rehabilitation.[2] In a 2006 Cochrane Review, Lacasse et al.[39] analyzed 31 randomized trials in patients with COPD and concluded that rehabilitation forms an important component of the management of COPD. They reported statistically and clinically significant improvement in important domains of quality of life (dyspnea, fatigue, emotions, and patients' control over disease). Improvement in measures of exercise capacity was slightly below the threshold for clinical significance.

Benefits and cost savings associated with pulmonary rehabilitation have been demonstrated not only in highly specialized centers, but also in community-based practice settings.[3,40] A collaborative study of 647 patients in 10 centers in California reported significant improvements in dyspnea and health-related quality of life along with substantial reduction in measures of healthcare utilization over 18 months of follow-up.[41] (Fig. 43-1). Similar findings with a reduction in hospital and intensive care unit days in the year after compared with the year before pulmonary rehabilitation were reported by a consortium of 11 centers in Connecticut and New York in 128 patients.[42] In addition, pulmonary rehabilitation following a hospital admission for acute exacerbation may reduce subsequent hospital admission and mortality.[43]

PULMONARY REHABILITATION AND LUNG SURGERY

In recent years, surgical options for patients with severe, disabling lung disease have been used more frequently. Lung surgery in these patients represents new challenges and may further compromise already reduced lung function. Pulmonary rehabilitation has been found to be a valuable adjunct in preparing the patient for surgery or in postsurgery recovery.

LUNG TRANSPLANTATION

Pulmonary rehabilitation is recommended and used commonly in both the preoperative and postoperative phases of lung transplantation programs.[8,9,44] Although the general strategies of rehabilitation may be similar, the individual and program goals and specific program components differ (Table 43-4).

TABLE 43-4 Goals of Pulmonary Rehabilitation in Lung Transplantation

Pretransplant
Maintain and increase mobility and exercise tolerance
Monitor disease progression
Prevent complications
Provide education about
Underlying disease
Transplantation procedures
Self-care and self-assessment
Provide psychosocial support during waiting period for patients and families
Posttransplant
Improve physical work tolerance
Monitor clinical status and assess symptoms and oxygenation
Prevent complications
Reinforce self-care and self-assessment
Encourage compliance with medical regimen
Provide psychosocial support for adaptation to new demands and expectations

PRETRANSPLANT REHABILITATION

Patients with advanced lung disease who are candidates for lung transplantation are usually evaluated by the transplant team and then referred for pulmonary rehabilitation after their transplant candidacy is approved. Rehabilitation staff evaluate the patient to assess needs and plan an appropriate program that can be maintained throughout a waiting period, which may last months to years. Since these patients have advanced disease with limited life expectancy, the goals in the preoperative period differ from those that typically apply to rehabilitation in chronic lung disease.

The overall goals of pretransplant pulmonary rehabilitation are to maintain function, monitor disease progression, prevent complications, provide education about the underlying lung disease and lung transplantation, and offer psychosocial support for patients and families in coping with the stresses of waiting for a potentially life-saving procedure. Although patients may have some initial improvement in exercise tolerance or endurance as they begin rehabilitation, the primary goal for these patients is to maintain mobility and exercise capacity. Exercise sessions also provide an excellent means to monitor disease progression and to detect, at an earlier stage, problems that commonly occur (e.g., increased breathlessness or reduced arterial oxygenation with exercise).

The goals of education in the pretransplant period are to teach patients about their underlying lung disease, the transplant procedure itself, and expectations following transplantation. Patients can also be taught techniques for self-care and self-assessment that will be useful before and after surgery. The psychosocial stresses of waiting for transplantation are considerable. Many patients feel as though their lives are "on hold." Some may have moved away from family and social support networks to live close to the transplant center. Providing support for patients and families during this time, whether through formal group support sessions or informal contact with supportive staff and other patients, helps patients cope better with these problems.

POSTTRANSPLANT REHABILITATION

After lung transplantation, patients must learn to cope with a new level of function, new expectations, and a new set of problems. Rehabilitation for patients in this phase can facilitate physical reconditioning, help implement self-care and assessment techniques, and facilitate coping with the psychosocial adaptations to a new life-style.

Goals of exercise training after rehabilitation are improved physical work tolerance and continued assessment of symptoms and oxygenation as early warning signs of complications, including rejection and infection. Educational goals are focused on self-care and assessment and the importance of compliance with a new medical regimen. Psychosocial support can assist with adaptation to a new set of stresses related to additional demands and expectations from both patients for themselves and significant others. Patients who are used to being sick, disabled, and cared for by others may now be expected to be well, independent, return to work, and provide support for others.

LUNG VOLUME REDUCTION SURGERY

Pulmonary rehabilitation has been recommended as an important modality in the evaluation for and preparation of patients for this procedure as well as in the postoperative recovery phase.[11,45] Since these patients have severe, disabling chronic lung disease, they are typically good candidates for pulmonary rehabilitation. Enrolling patients in rehabilitation prior to surgery has the advantage of optimizing their functional status, improving physical and psychological symptoms, helping them learn more about their disease and alternative treatment options, and improving their skills for coping and actively co-managing their disease. Patients can then make an informed decision about surgical treatment based upon their optimal level of baseline function. After surgery, similar to the posttransplant period, rehabilitation helps patients to adapt to new levels of function and to reassess symptoms and oxygenation needs.

REHABILITATION AFTER LUNG RESECTION

Patients who undergo pulmonary resection frequently experience a significant increase in symptoms and reduced functional status. This is particularly true for patients with underlying chronic lung disease. Most commonly, surgery is used to treat patients with thoracic neoplasms who are deemed to have resectable disease and are operative candidates. Following resection, these patients with already limited lung function have to learn to adapt to a new, lower level of function.[46,47]

Similar changes may be observed in patients who undergo radiation therapy. Patients in a stable phase of their treatment or in remission may be appropriate candidates for pulmonary rehabilitation. Improvement in health status, physical and psychological symptoms, exercise tolerance, and quality of life – as well as reduced healthcare burdens – are potential benefits. These patients' survival may be as limited by their underlying lung disease as by their treated malignancy.

SUMMARY AND FUTURE OF PULMONARY REHABILITATION

Pulmonary rehabilitation has been well established as a means of improving functional status and reducing the disability and economic burden of the growing number of patients with chronic lung diseases. In adopting a broad rehabilitation medicine perspective, such programs provide interdisciplinary expertise directed toward the needs of the individual disabled patient.

Much of the experience in pulmonary rehabilitation has been in patients with COPD. However, it is clear that similar benefits can result for patients with other disabling pulmonary conditions. Pulmonary rehabilitation may also play an important role in the preoperative evaluation, preparation, and postoperative recovery of patients undergoing surgical procedures, including lung transplantation, lung volume reduction surgery, and lung resection. In many parts of the world, a major challenge for the widespread application of pulmonary rehabilitation to the large number of patients with chronic lung diseases relates to acceptance by health policy makers and health insurers about the benefits and cost savings associated with this treatment. In the United States, for instance, Medicare, the major government sponsored health insurance program that sets standards for many health insurers, recently implemented a national coverage policy for pulmonary rehabilitation.[48] This is a major step forward; however, the current relatively low reimbursement rates have threatened the financial viability of many existing programs. It is hoped that, with time and experience, the benefits of pulmonary rehabilitation as an effective, preventive health intervention that can improve patient outcomes and reduce healthcare costs will be better recognized.

Asthma is characterized by recurrent attacks of breathlessness and wheezing, which vary in severity and frequency from person to person.[1] More than 18 million adults and 7 million children are affected in the United States alone, making asthma one of the most common chronic diseases in this country.[2] Attempts to elucidate the underlying pathophysiology of the disease have led to the realization that asthma truly is a protean disease with various cell types and mechanisms playing variable but important roles in each patient. This degree of mechanistic variation explains the numerous phenotypes of this disease as well as the differences in response to treatment.

By the simplest definition, the pathogenesis of asthma involves bronchoconstriction, airway inflammation, and airway hyperresponsiveness.[3] It is, however, the complex interplay between these factors that defines the disease in general and specifically in an individual patient. A closer examination of the factors involved in each of these components allows a better understanding of this complex disease.

THE ACUTE INFLAMMATORY RESPONSE IN ASTHMA

Perhaps the best illustration of the features of the acute inflammatory response, that is central to the pathogenesis of asthma, is the reaction to the initial and then subsequent exposures to inhaled antigen. While important cellular and molecular mediators will be described later in greater detail, a brief review of the acute inflammatory response serves as a foundation upon which further concepts can be introduced to illustrate the variable but persistent changes that occur in the airway in asthma. When a novel antigen is introduced to the airway of an at-risk individual, it initially becomes trapped in the mucus lining the airway. Here it can be taken up by antigen presenting cells, most notably dendritic cells, which are distributed through the epithelium of the airways.[4,5] After the uptake of allergen, the dendritic cells travel to pulmonary lymph nodes whereby the antigen is presented to naïve $CD4^+$ T cells.[5] Signals derived from the dendritic cell determine which type of $CD4^+$ T cell will be produced. Prior to this event, the dendritic cell is influenced by a complex network of molecular signals that are derived from airway epithelial cells and other local cell types. In allergic inflammation, for example, thymic stromal lymphopoietin (TSLP) and granulocyte–monocyte colony stimulating factor (GM-CSF), which are derived from bronchial epithelial cells, and induce the dendritic cell to promote T_H2 differentiation of naïve $CD4^+$ T cells, thus setting up an environment favorable to the eventual development of allergic inflammation.[5] Upon rechallenge with the sensitizing antigen, these now T_H2 differentiated $CD4^+$ T cells are recruited back to the airway by other signals, such as the chemokines CCL17 and CCL22, secreted by dendritic cells.[6] Upon arrival in the airway, the $CD4^+$ T_H2 cells become key sources of the T_H2 cytokines, namely IL-4, IL-5, and IL-13, which serve as the molecular catalysts to establish a framework for acute allergic inflammation.[6]

After rechallenge with antigen, the local environment of the airways is now rich with T_H2 cytokines, which act on other cell types, either present or recruited to the airway, to propagate the acute allergic inflammatory response. B cells, in the presence of IL-4 and IL-13, are influenced to produce antigen-specific IgE, which binds to high-affinity IgE receptors (FcεRI) on mast cells (MC). When inhaled antigen cross-links the membrane-bound IgE on the mast cells, a variety of preformed and synthesized meditators are released to cause bronchoconstriction, airway edema, and local tissue damage.[7] Mast cells also release chemoattractants such as leukotrienes and cytokines, to recruit a variety of other cells, including eosinophils, basophils, neutrophils, and lymphocytes, which then contribute to the late phase inflammatory response.[7] The eosinophil appears to be, in most cases, the most important and abundant inflammatory cell associated with the late phase response and possibly contributes to the subsequent airflow obstruction.[8] The vast numbers of mediators the eosinophil produces are reviewed later in the chapter. Eosinophil products can cause local tissue damage, mucus hypersecretion, increased vascular permeability, smooth muscle contraction, and a sustained inflammatory response whereby other cell types are recruited to the site of inflammation to perpetuate the reaction.[7,8] The roles of neutrophils and basophils in the pathogenesis of the acute and late-phase allergic inflammatory responses are less well defined.

While the acute allergic response to allergen illustrates the pattern of inflammation seen in asthma, it should be noted that other forms of inflammation can and do play important roles in asthma. Viral respiratory infections, especially with human rhinovirus (HRV), are important triggers for asthma exacerbations.[9] The response to HRV is a primarily T_H1 driven response with increased production of IL-8 and IL-1β and the appearance of airway neutrophilia, as opposed to the strong T_H2 response seen after allergen exposure.[9,10] In asthma, there is evidence that diminished production of the type I and III interferons, antiviral cytokines, may be deficient in some patients with asthma thus leading to increased risk for viral respiratory infections and a greater susceptibility to exacerbations of asthma.[9,10]

This pattern of acute- and late-phase inflammatory response to antigen is, however, a central component of asthma. Chronic inflammation is a later development of the disease and will be described later. Many of the cell types and inflammatory mediators seen in asthma were briefly touched upon in the preceding paragraphs and will now be further developed.

CELL TYPES IN ASTHMA

A study of the pathogenesis of any complex disease begins at the cellular level. The importance of cells of the immune system, including mast cells, basophils, $CD4^+$ T cells, eosinophils, neutrophils, macrophages, dendritic cells, and T lymphocytes, as well as their molecular mediators has long been recognized and appreciated in the development and regulation of inflammation. The contribution of airway smooth muscle cells, especially in relationship to the acute asthmatic response, has also been well documented. More recently, epithelial cells of the airway have become the focus of intense research and emerging importance to both acute and chronic inflammation in asthma. Their role in airway inflammation, and especially in the airway remodeling as is seen in the chronic forms of asthma, is being increasingly cited as a major contributor to the severity of this disease.

CELLS OF THE IMMUNE SYSTEM IN ASTHMA

The contributions of each of the aforementioned immune system cell types in the pathogenesis of asthma are considered below.

Mast Cells

Human mast cells are derived from the same $CD34^+/cKit^+$ hematopoietic stem cell population that also gives rises to eosinophils, basophils, neutrophils, and monocytes.[11] They are resident cells in most tissues of the body and are commonly found in association with blood vessels, nerves, and surfaces that have contact with the external environment.[12] Mast cells exist in two types in humans and are differentiated by their immunohistochemical staining properties.[13] MC_T mast cells contain only the neutral protease tryptase, while MC_{TC} mast cells contain chymase, carboxypeptidase A_3, and cathepsin G-like protease in addition to tryptase.[13–15] In normal lung tissue, mast cells are located in the subepithelium of the bronchi, bronchioles, and alveolar walls and are almost exclusively of the MC_T type.[13] This distribution of mast cell types is also seen in mild asthma. In severe asthma, however, mast cells in the submucosa are decreased in number and are primarily of the MC_{TC} type.[16] MC_{TC} mast cells are also seen in the airway epithelium of severe asthma, a finding not seen in normal lungs or in milder disease.[16] Mast cells increasingly infiltrate airway smooth muscle bundles in asthma where they likely contribute to ongoing bronchoconstriction through release of their mediators.[17]

While mast cells appear to have some importance in nonallergic asthma as well, they are essential components of the allergic (IgE-mediated) response seen in many asthma patients.[18] Antigen-specific IgE molecules bind allergen and cross-link high-affinity IgE receptors (FcεRI) present on the mast cell surface. This results in the release of preformed mediators, such as histamine, tryptase, chymase, and heparin, as well as tumor necrosis factor-alpha (TNF-α) and vascular endothelial growth factor (VEGF) in some cases (Fig. 44-1).[19] Upon activation, mast cells also generate and release newly synthesized mediators, which contribute to the ongoing inflammatory milieu. These include leukotrienes (predominantly LTC_4), prostaglandins (predominantly PGD_2), thromboxane A_2, platelet activating factor (PAF), growth factors including GM-CSF, fibroblast growth factor-2, and VEGF, and various other cytokines including TNF-α, IL-4, IL-5, IL-8, and IL-13 (Fig. 44-1).[19,20]

The effect of mast cell mediator release contributes to numerous features in the asthmatic response.[7] Histamine, leukotrienes, and the various proteases increase mucus production. Prostaglandins, leukotrienes, thromboxane A_2, and histamine cause bronchoconstriction and increase vascular permeability. The various proteases cause local tissue damage and are important in the activation of various protein precursors. Finally, synthesized cytokines contribute to the recruitment, differentiation, and activation of other inflammatory cells, resulting in the propagation of the inflammatory response.

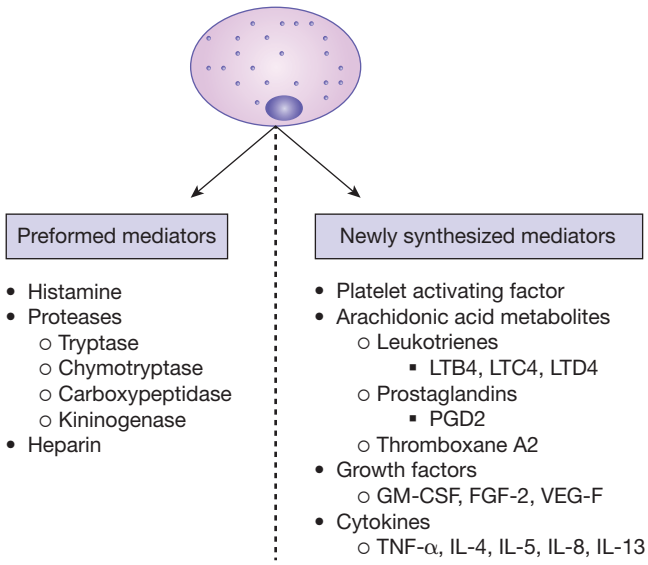

Figure 44-1 The mast cell and its mediators. GM-CSF, granulocyte-monocyte colony stimulating factor; FGF-2, fibroblast growth factor 2; VEGF, vascular endothelial growth factor; TNF-α, tumor necrosis factor alpha.

Basophils

In addition to sharing a common progenitor cell, basophils share many similarities with mast cells, with the exception that basophils are present primarily in the peripheral circulation. Both cells express FcεRI on their cell surface and release both preformed, as well as newly synthesized mediators and cytokines, upon cross-linking by IgE–antigen complexes. The major preformed mediator released from basophils is histamine. Preformed heparin and tryptase are also released, albeit at lower concentrations than mast cells.[21] Basophils synthesize and release LTC_4 upon activation, but unlike mast cells, they do not produce PGD_2.[21] Upon activation, basophils produce large quantities of IL-4 and IL-13, cytokines that play an important role in the T_H2 differentiation, which will be discussed later.[21] More recently, two other roles of basophils in the pathogenesis of asthma have been discovered, both of which also play important roles in T_H2 differentiation. First, basophils can act as antigen presenting cells via their expression of major histocompatibility complex (MHC) class II and co-stimulatory molecules.[22] Second, basophils, along with eosinophils, are also the primary target of IL-33, a potent promoter of allergic inflammation and T_H2 polarization.[23]

Eosinophils

Eosinophils, like basophils and mast cells, are granulocytes derived from $CD34^+$ hematopoietic stem cells. Early eosinophil production is highly dependent upon the presence of GM-CSF and IL-3.[24] Eosinophil precursors are recruited to the airway in asthma as the result of cytokine and chemokine signaling, which involves IL-5, eotaxins, RANTES, macrophage inflammatory protein (MIP)-1α, and macrophage chemotactic factors 2,3, and 4 (MCP-2,3,4).[25] IL-5 is critically important for the terminal differentiation of eosinophils and release from the bone marrow.[24]

Once in the airway, eosinophils are activated and contribute to the inflammatory response through releasing a wide variety of mediators including cytokines (IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, IL-13, IL-16, IL-18, tumor necrosis factor-α [TNF-α] and transforming growth factor-α and β [TGF-α and TGF-β]), chemokines (MIP-1, MCP-2, RANTES and eotaxin), and lipid mediators (PGE_1, PGE_2, thromboxane B_2, PAF, LTC_4) (Fig. 44-2).[26,27] Eosinophils secrete granule proteins, which are important in the eosinophil's primordial role as the primary defender against parasites, as well as in the pathogenesis of asthma.[26,28] Eosinophils contain both primary and secondary granules. The primary granules contain Charcot–Leyden crystal protein, while the secondary granules contain the four principal cationic proteins: major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN), and eosinophil peroxidase (EPO).[26] These cationic proteins play various roles in the pathogenesis of asthma including the induction of mast cell and basophil degranulation (ECP and MBP), increasing airway mucus production (ECP), and formation of reactive oxygen species (EPO) (Fig. 44-2).[26]

Over the past 30 years, the role of the eosinophil in asthma has undergone considerable re-evaluation. Since the discovery of the eosinophil by Ehrlich in 1879 and the later discovery that Ehrlich's cells were present in the sputum of asthmatic patients, the eosinophil has been viewed as the primary effector cell in asthma.[29] Studies have noted that peripheral blood eosinophilia is a characteristic of asthma and often in relationship to disease severity, and that eosinophilic infiltrates were found in the airways of asthma patients at autopsy, regardless of whether asthma was the primary cause of death.[30,31] Later studies detected increased eosinophils and eosinophil products

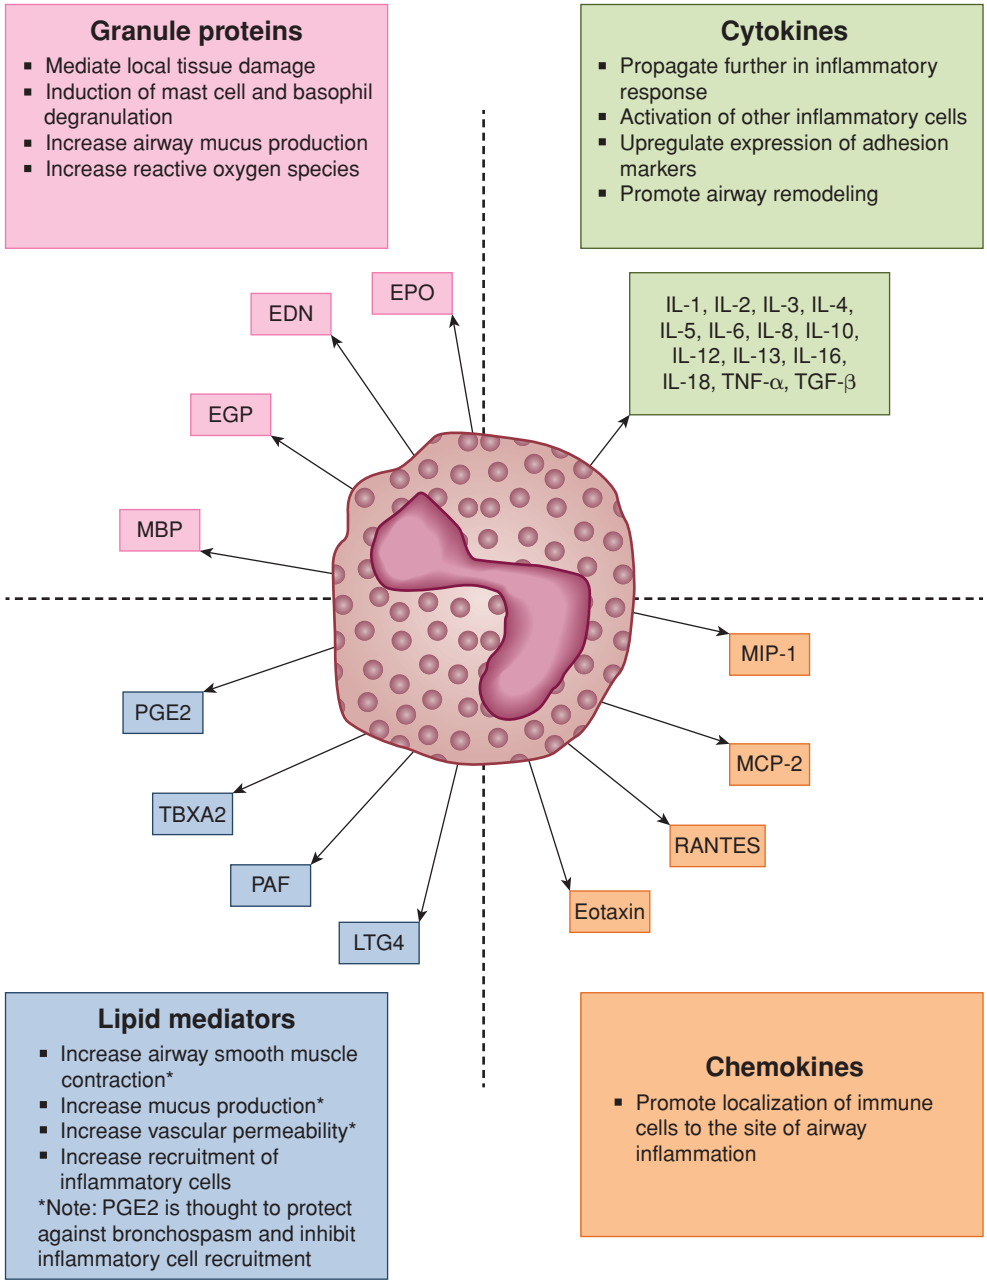

Figure 44-2 Eosinophil products in asthma. EPO, eosinophil peroxidase; EDN, eosinophil-derived neurotoxin; ECP, eosinophil cationic protein; MBP, major basic protein; PGE_2, prostaglandin E2; $TBXA_2$, thromboxane A_2; PAF, platelet activating factor; LTC_4, leukotriene C4; RANTES, regulated upon activation normal T cell expressed and secreted; MCP-2, monocyte chemotactic protein 2; MIP-1, macrophage inhibitory protein 1; TNF-α, tumor necrosis factor alpha; TGF-β, transforming growth factor beta.

in bronchoalveolar lavage (BAL) fluid after antigen challenge.[32] The view that the eosinophil was the principal effector of asthma was largely unchallenged until the new millennium brought new therapies, including monoclonal antibodies to IL-5, into evaluation.

The importance of IL-5 to the differentiation and survival of the eosinophil has been previously noted. Initial studies with monoclonal antibodies to IL-5 in asthma showed a decrease in sputum and peripheral blood eosinophilia, as expected, but failed to demonstrate significant benefit in a wide variety of clinical outcome measures, that is, symptoms or improved airflow obstruction.[33,34] Although this lack of effect on parameters of clinical asthma was a surprise, it led to an increasing interest in the heterogeneity of asthma with the realization that eosinophils may play greater or lesser roles in different patients.

Later studies with anti-IL-5 were conducted in patients who had persistent eosinophilia despite treatment with inhaled corticosteroids (ICS), and in these patients were noted clinical outcomes, the prevention of exacerbations.[35,36] Eosinophils play an important role in a certain subset of asthma, but the contribution of their role appears to be defined by phenotypes and is not necessarily generalizable to the entire asthmatic population. Finally, eosinophils are likely a prime contributor to airway remodeling seen in chronic asthma, and will be discussed in this capacity later in the chapter.

Neutrophils

Neutrophils are granulocytes derived from $CD34^+$ hematopoietic stem cells and are normally present in the bloodstream, as well as in various tissues, including the lung. They contain primary (azurophilic) and secondary (specific) granules, which contain a variety of antimicrobial enzymes, neutral proteases, and acid hydrolases.[37] Neutrophils are attracted to the airway by various cytokines and

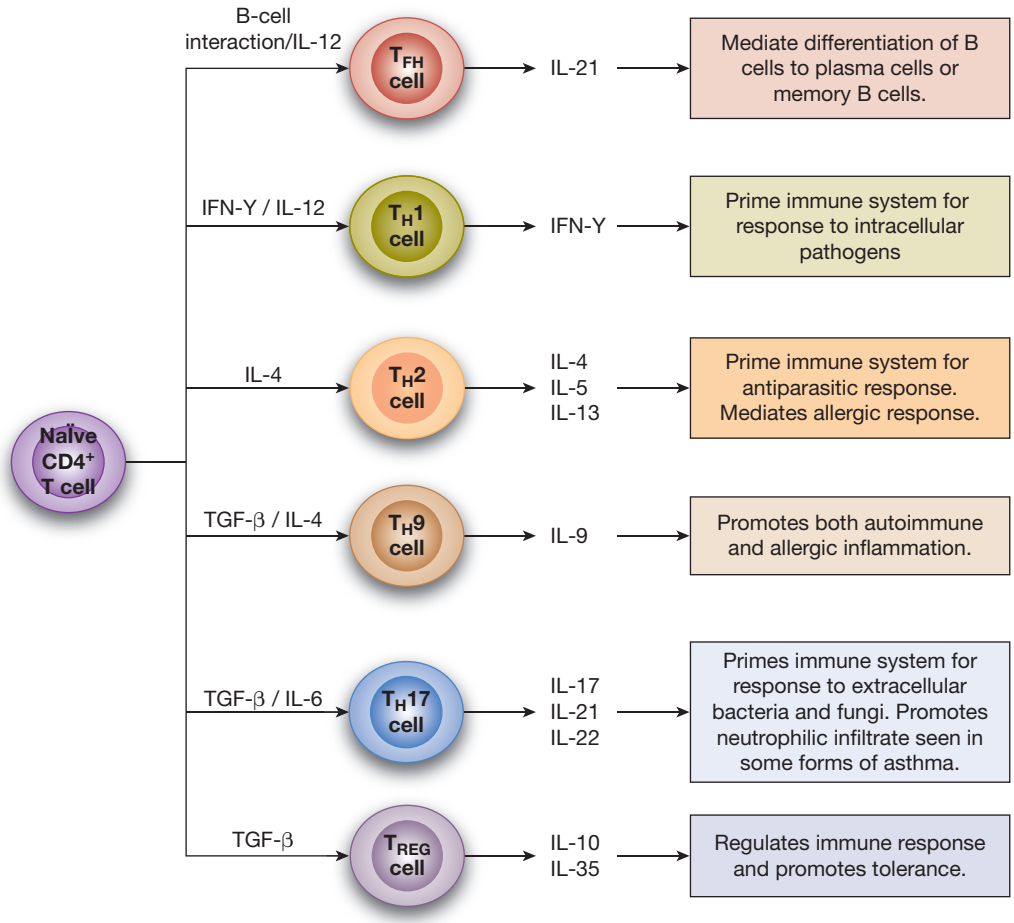

Figure 44-3 $CD4^+$ T Lymphocyte subsets. IFN-γ, interferon gamma; TGF-β, transforming growth factor beta; TFH cell, T follicular helper cell; T_{REG} cell, regulatory T cell.

chemokines including IL-8, IL-17, and granulocyte colony stimulating factor (G-CSF).[38,39] Airway neutrophilia can be seen in many respiratory conditions, viral respiratory infections, COPD, and asthma.[10,39]

The role of neutrophils in response to viral respiratory infections was introduced previously. In response to inoculation with a respiratory virus, such as HRV, dendritic cells, and other mononuclear cells produce proinflammatory cytokines and chemokines, which recruit neutrophils to the airway.[10] Neutrophils contribute to the inflammatory milieu by secreting cytokines such as TNF-α, IL-1, IL-8, and IL-18, to attract other inflammatory cells, upregulate cytokine production, and produce airway inflammation and enhance bronchial hyperresponsiveness.[40] Neutrophil products, such as elastase, can have more direct effects on the airway and cause mucus production.[10] In addition, because neutrophils are found in severe asthma, they are proposed to play a more prominent role in this phenotype.[41] Prominent neutrophilic inflammation has been noted in the sputum of patients with severe asthma exacerbations, in BAL fluid from patients with noninfectious status asthma, and in autopsy specimens from the airway in patients with acute, fatal asthma.[42–44] Other studies have demonstrated subgroups of patients with chronic asthma in whom the primary inflammatory cell type is neutrophils rather than eosinophils.[45,46] These patients are often more difficult to treat and less responsive to treatment with corticosteroids.

Lymphocytes

Unlike the previously discussed cell types, T cells are lymphocytes and derived from the common lymphoid progenitor. Numerous subsets of T cells have been identified and are important contributors to asthma, including $CD4^+$ helper T cells and their subsets (T_H1, T_H2, T_H9, and T_H17), $CD8^+$ cytotoxic T cells, and regulatory T cells (T_{REG}).

$CD4^+$ helper T cells recognize antigens presented to them by antigen presenting cells (APCs) and, in turn, secrete cytokines to influence the inflammatory response. In the airway, the dendritic cell is the most important APC and its role will be described later. A complex series of events involving cytokines and various transcription factors determines whether $CD4^+$ T cells will differentiate into T_H1 cells, T_H2 cells, T_H9 cells, or T_H17 cells (Fig. 44-3).[47]

T_H2 cells are recognized as the primary drivers of inflammation in asthma and allergic disease. When T_H2 cells encounter antigen presented by dendritic cells, they produce IL-4, IL-5, and IL-13, all of which play critical roles in the pathogenesis of asthma and are part of the clinical disease as demonstrated by detection of increased levels of these cytokines in the BAL fluid of patients with asthma.[48,49] IL-4 increases IgE production by plasma cells. As mentioned previously, IL-5 is critical in the terminal differentiation and homing of eosinophils to the airway. IL-13 also increases IgE production and plays a prominent role in airway hyperresponsiveness and tissue remodeling.[50]

The role of T_H1 cells in asthma is not as well defined as T_H2 cells. Although it has been presumed that T_H1 cells counteract the asthma-inducing effects of T_H2 cells, this likely is an over-simplification. T_H1 products have been shown to be increased during asthma exacerbation.[51] Some studies have also suggested that T_H1 cells may play a more prominent role in chronic severe asthma as evidenced by increased levels of the primary T_H1 cytokine, interferon-γ (IFN-γ), in the BAL fluid of patients with severe asthma.[52]

T_H9 cells are a relatively newly defined cell population whose primary cytokine is generation of IL-9. T_H9 cells function similarly to T_H2 cells in that they increase allergic inflammation. Mast cells are the primary IL-9 receptor-bearing cell, and T_H9 cells are important contributors to the previously described increased mast cell activation seen in asthma.[20] Because mast cells also produce VEGF and fibroblast growth factor-2, T_H9 cells likely contribute to airway remodeling seen in chronic asthma.[20]

The role of T_H17 cells in asthma is an area of intense research. With the identification of subphenotypes of asthma patients with primarily neutrophilic inflammation, the role of IL-17 (the primary cytokine produced by T_H17 cells) in asthma has become of considerable interest. Although IL-17 is found to be increasingly expressed in patients with severe asthma,[53] it is, however, also found in high concentrations in patients with mild asthma (FEV_1 >70% predicted) and these values correlate negatively with the PC_{20}.[54] Thus, while T_H17 cells most certainly play a role in patients with primarily neutrophilic asthma, they are also likely important in milder forms of disease as well.

The primary function of $CD8^+$ cytotoxic T cells is the destruction of human cells that are infected with viruses or other intracellular pathogens. $CD8^+$ T cells also likely play a role in asthma, though the extent of their contribution has yet to be fully elucidated.[50] IL-4 and IL-5 producing $CD8^+$ T cells are present in the airways of asthmatic patients.[55] IL-5 production by $CD8^+$ T cells is increased in the presence of a viral respiratory infection, and the overall cytokine production by $CD8^+$ T cells correlates with asthma severity.[56,57] Whether $CD8^+$ T cells function as direct contributors or bystanders in the worsening of asthma has yet to be determined.[50]

T_{REG} cells also appear to play a critical role in asthma development. T_{REG} cells serve to limit inflammatory responses and promote immune tolerance through the production of IL-10 and TGF-β.[50,58] In patients with asthma and other allergic disorders, T_{REG} cells appear to be less effective in limiting T_H2 inflammation.[59,60] However, after allergen immunotherapy, for example, T_{REG} cells increase in the nasal mucosa and may act to promote allergen tolerance.[61] Interestingly, farm exposure early in life is associated with a decreased incidence of allergic disease and asthma, a fact that may be related to increased numbers and function of T_{REG} cells in infants living in this environment.[62]

Natural killer cells (NK cells) are members of the innate immune system and serve as a first line of defense against infections. Their role in the pathogenesis of asthma has yet to be fully elucidated. They obviously appear in response to viral respiratory infections, and NK cells increase during asthma exacerbations.[63] NK cells are capable of producing numerous cytokines including IFN-γ, IL-4, IL-5, and IL-13.[64] NK cells from patients with atopic asthma are skewed toward the production of IL-4 as opposed to IFN-γ upon activation.[64] IFN-γ production by NK cells is also inhibited by prostaglandin D2, a T_H2-promoting lipid mediator produced by mast cells.[65] NK cells may also play a role in "dendritic cell editing" by killing immature dendritic cells, which might influence a certain type of T_H response.[66]

Macrophages and Dendritic Cells

Macrophages and dendritic cells are descendants from the $CD34^+$ hematopoietic stem cell and arise from a common committed precursor cell.[67] Macrophages arise from circulating monocytes and function, primarily, to clear debris and microbes from the airway. They may also function as antigen presenting cells, although this role is likely less important than that of the dendritic cell.[68] Alveolar macrophages may further differentiate into M1 or M2 subsets based on exposure to various cytokines and toll like receptor (TLR) agonists.[67] M1 macrophages are "classic" macrophages, and clear microbes from the airway. They also produce cytokines, such as IL-12, IL-6, and TNF-α, as well as high levels of nitric oxide (NO).[67] M1 macrophages have traditionally been described as suppressing allergic inflammation, primarily through their secretion of T_H1 cytokines such as IL-12; this is not fully resolved.[67]

Differentiation into M2 macrophages is influenced by an environment rich in T_H2 cytokines such as IL-4 and IL-13, thus implicating their role in asthma. When compared with M1 macrophages, M2 macrophages are poor at clearing intracellular pathogens.[67] They release cytokines such as IL-13 and thus are likely contribute to the airway hyperresponsiveness.[67]

Dendritic cells are the lung's primary presenter of antigen to T cells. Their role as the primary APC places the dendritic cell at a critical junction in determining what type of T cell response will be directed toward the antigen (i.e., T_H1, T_H2). Dendritic cells in humans exist in two broad categories: the myeloid dendritic cell (mDC) and the plasmacytoid dendritic cell (pDC). While both types of dendritic cells are present in the human lung, their anatomic localization within the lung is poorly understood. [5] Upon encountering antigen in the airway, dendritic cells migrate to local lymph nodes where they present antigen to T lymphocytes. Both pDC and mDC levels increase in the airway (and coincidently decrease in the blood) after exposure to inhaled allergen.[69–71] Because dendritic cells lie close to the epithelial barrier, they receive numerous signals from epithelial cells, which can influence their effect on T cells. TSLP is produced by epithelial cells and promotes dendritic cells to direct T_H2 differentiation and recruit T_H2 cells to the airway.[5] Other epithelial cell–derived factors, such as GM-CSF, TNF-α, CCL-20, IL-1β, and TNF-related apoptosis-inducing ligand (TRAIL), have similar T_H2 promoting effects.[5] pDC represent the lung's primary source of IFN-α, a potent antiviral cytokine, and they are recruited to the lung during times of viral infections.[72] As viral infections commonly precede asthma exacerbations and may predispose infants to develop asthma, this role of the pDC cannot be understated.[73] The importance of pDC to the development of asthma was illustrated by a recent study which showed that decreased pDC levels in childhood was directly correlated to increased number and severity of viral respiratory infections, increased episodes of wheeze, and increased asthma diagnosis.[74] The function of mDC is not as well known in human asthma, but the role of both dendritic cell types in contributing to the development and propagation of the disease will continue to be an important area of asthma research.

RESIDENT CELLS OF THE AIRWAY

The roles of airway smooth muscle cells and airway epithelial cells in the biology of asthma are considered below.

Airway Smooth Muscle

Given that bronchospasm and bronchial constriction are critical components of asthma, it is intuitive that the cell type responsible for this component, the airway smooth muscle cell, would be a key factor in asthma pathogenesis and pathophysiology. While its importance seems obvious, the details of why airway smooth muscle function is so different in the asthmatic airway compared with the normal airway have been elusive. It has been well documented that the smooth muscle layer surrounding the airway is thicker in asthma compared to nonasthmatic controls. These difference are due to both smooth muscle hypertrophy and hyperplasia.[75] Increased inflammatory cells, including mast cells, can be found within the smooth muscle bundles of asthmatic airways, and the interplay between these cells, the airway epithelium, and the smooth muscle layer, is an important determinant of the asthmatic response.[17] Numerous cytokines, chemokines, and growth factors are involved in this interaction including those produced by the airway smooth muscle cell itself and those produced by other cell types with which the airway smooth muscle cell communicates. Airway smooth muscle cells in asthma are more prolific producers

of these cytokines, and this function likely plays a role in their ability to proliferate more rapidly than those of nonasthmatic subjects.[76]

The treatment of asthma has long focused on preventing or reversing contraction of bronchial smooth muscles. β2-agonists, both short and long acting, have long been key to the treatment of asthma, and these medications act directly on the airway smooth muscle. More recently, debulking of airway smooth muscle, with the use of bronchial thermoplasty, has shown improvement in asthma control, which, in theory, further supports the role that airway smooth muscle plays in asthma pathophysiology.[77,78]

Airway Epithelial Cells

The epithelial lining of the airway is an area of intense research, and its importance, beyond being a simple anatomic barrier, is being increasingly recognized and appreciated. The airway epithelium represents a vast surface area (100 m^2) that is in contact with some 10,000 L of inhaled air daily.[79] As the area of initial contact between the lung and the external airborne environment, functions of the airway epithelium are likely key to determine the body's response to airborne substances.

The airway epithelium is composed of three major cell types: the ciliated columnar epithelial cell, the mucus-secreting goblet cell, and the surfactant secreting Clara cell.[79] Both overproduction of mucus by goblet cells and underproduction of important anti-inflammatory peptides by Clara cells have been noted in patients with asthma.[80,81] The tight junctions between epithelial cells have also been noted to be defective in patients with asthma, which can serve to decrease the ability of the airway epithelium to act as a protective barrier.[79] The airway epithelium in asthma is also less capable of defending itself against reactive oxygen species, a defect that leads to further damage to this airway barrier.[82] Epithelial cells in asthma produce lower amounts of Type I interferon in response to respiratory viruses, which can increase the severity to respiratory infections and promote asthma exacerbations.[83] TSLP promotes T_H2-driven inflammation and is overproduced by epithelial cells in asthmatic patients, thus providing a crucial link between the airway epithelium and the T_H2 type inflammation seen in asthma.[84,85] Finally, epithelial cells are capable of secreting endothelins, which are peptides with significant bronchoconstrictive activity.[86]

MOLECULAR MEDIATORS IN ASTHMA

The above-mentioned cells are able to initiate, perpetuate, coordinate, and regulate the inflammatory process with the synthesis and secretion of several different classes of molecular mediators. These mediators have a variety of functions, as discussed below.

CYTOKINES

Cytokines are small–molecular-weight glycosylated signaling molecules that are secreted by a number of different cell types with autocrine, paracrine, or endocrine directive activities.[87] Cytokine is a broad term and includes many subcategories including interleukins, interferons, and growth factors.[87] Cytokine secretion is usually a brief, self-limited event. It may, however, require new mRNA and protein synthesis, which takes place over a matter of hours rather than seconds or minutes.[88] A variety of cytokines have been implicated in the regulation of airway inflammation and thus in the pathogenesis of asthma (Table 44-1).[89] The support for cytokine involvement in inflammation was first obtained by the detection of these mediators in the airways of patients with asthma, particularly in bronchoalveolar lavage fluid after allergen challenge and in situ hybridization of retrieved cells or biopsy materials.[90,91]

The overall effect of the complex cytokine network in the airway depends on a number of factors, including the relative abundance of the various cytokines, their ability to recruit and perpetuate the actions of inflammatory cells such as eosinophils and lymphocytes, and their ability to amplify or suppress inflammation by interacting with structural cells such as fibroblasts, endothelial cells, and epithelial cells. There is no question, however, that cytokines are key mediators in the pathogenesis of the chronic inflammation characteristic of asthma.

CHEMOKINES

The chemokines are small–molecular-weight proteins, 8 to 12 kD, that are classified into four categories based on the organization of specific cysteine residues in their protein sequence: XC, CC, CXC, CX_3C.[92] The predominant function of chemokines is the recruitment or chemotaxis of inflammatory cells.[92] Some chemokines also have additional signaling function. There are corresponding families of chemokine receptors for each class of chemokines. Notably, there is considerable overlap and redundancy in the chemokines and their target receptors.

Since the localization of inflammatory cells into the airway is dependent to a large extent on chemotaxis via chemokine signaling, the chemokine receptors have become an attractive target for asthma therapy. There are currently chemokine receptor inhibitors for CCR5 as well as others in development as potential therapy for asthma.[93,94]

IgE

The initial association of IgE with asthma was based on several epidemiological studies.[95–97] With the increased understanding of the role of mast cell mediators in the pathogenesis of asthma, the importance of IgE in triggering mast cell activation and the resulting airway inflammation has been underscored. This relationship between IgE levels and asthma, and its function, led to the development of a humanized monoclonal antibody directed to IgE for asthma therapy.[98] This antibody (omalizumab, Xolair®) has been shown to be effective in the treatment of severe asthma, specifically allowing a significant reduction in dosage of corticosteroids and prevention of asthma exacerbation, further supporting a key role of IgE in asthma.[99]

LEUKOTRIENES

The leukotrienes (LT) are a family of lipid compounds generated from the metabolism of arachidonic acid via the lipoxygenase pathway (Fig. 44-4).[100] These compounds are typically not preformed

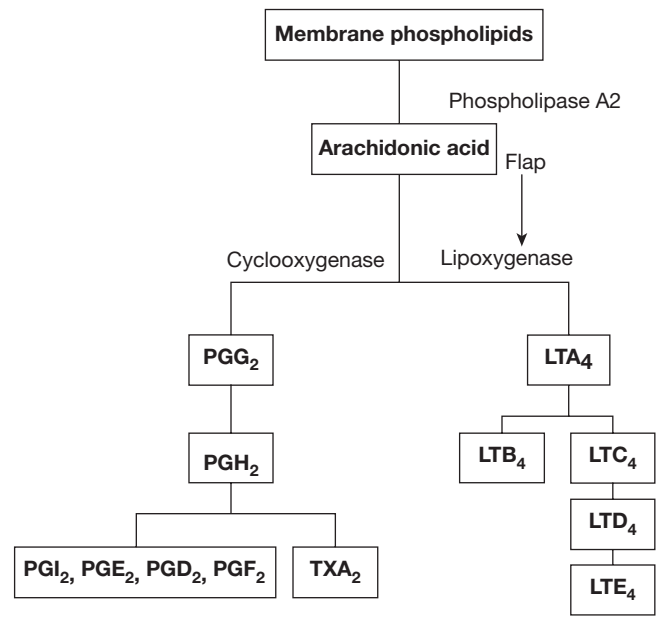

Figure 44-4 Formation of arachidonic acid metabolites. PG, prostaglandin; TXA_2, thromboxane A_2; LT, leukotriene; FLAP, 5-lipoxygenase activating protein.

TABLE 44-1 Cytokines and Lipid Mediators in Asthma

Cytokines		
Cytokine	**Cell Sources**	**Proposed Cell Targets/Functions in Asthma**
Interleukins		
IL-1	DCs, monocytes, macrophages, mast cells, B and T cells, neutrophils, endothelial cells, airway epithelial cells	*Basophils*: Increased production of cytokines and histamine *DCs*: Increased cytokine production, upregulation of MHC and co-stimulatory molecules *Macrophages*: Increased cytokine production *Mast cells*: Increased cytokine production, degranulation, and survival *Neutrophils*: Increased survival and release of proteases *B cells*: Increased antibody production *T cells*: Increased proliferation—especially for T_H2 and T_H17 cells
IL-2	$CD4^+$ T Cells	*T cells*: Increased survival and proliferation, increased T_H2 cytokine production
IL-3	T Cells, mast cells	*Basophils*: Increased survival and release of IL-4, IL-6, and histamine *Eosinophils*: Increased degranulation *Mast cells*: Increased survival and histamine release *Hematopoietic stem cells*: Increased production of mast cells, basophils, neutrophils, eosinophils, macrophages, erythrocytes, megakaryocytes, and dendritic cells
IL-4	T cells, mast cells, basophils, eosinophils	*Airway smooth muscle cells*: Increased airway hyperresponsiveness *Basophils*: Increased recruitment *Eosinophils*: Increased recruitment *Goblet cells*: Increased mucus production *Mast cells*: Increased recruitment, upregulation of FCεRI *B cells*: Increased class switching to IgE, upregulation of FCεRII *T cells*: Increased recruitment, increased T_H2 differentiation, increased production of T_H2 cytokines, decreased differentiation of T_H1 cells, decreased IFN-γ production by T_H1 cells
IL-5	T cells, mast cells	*Basophils*: Increased proliferation, maturation, and functional activation *Eosinophils*: Increased proliferation, chemoattraction, maturation, functional activation, and degranulation
IL-6	Macrophages, DCs, mast cells, neutrophils, B and T cells, endothelial cells, airway epithelial cells	*T cells*: Increased production of T_H2 cytokines, decreased differentiation of T_H1 cells, decreased IFN-γ production by T_H1 cells, promotes differentiation of T_H17 cells, downregulation of T_{REG} cells
IL-7	Bone marrow stromal cells	*Eosinophils:* Increased activation and survival *B cells:* Increased proliferation and survival *T cells*: Increased maturation and survival
IL-8	Airway epithelial cells, neutrophils, eosinophils, monocytes/macrophages	*Eosinophils*: Chemoattraction *Neutrophils*: Chemoattraction
IL-9	T cells	*Mast cells*: Increased recruitment and maturation, increased expression of proteases, upregulation of FCεRI *T cells*: Increased growth and proliferation
IL-10	Monocytes/macrophages, B cells, T cells (specifically T_{REG} cells)	*DCs*: Inhibits expression of co-stimulatory molecules thus inhibiting T_H cell activation *Eosinophils*: Inhibits survival, recruitment, and maturation *Monocytes/macrophages*: Downregulates MHC Class II expression, downregulates inflammatory cytokine production *T cells*: Downregulates IFN-γ and IL-2 production by T_H1 cells and IL-4 and IL-5 production by T_H2 cells
IL-11	Airway epithelial cells, eosinophils, airway smooth muscle cells	*Airway epithelial cells:* Regulate proliferation *Macrophages:* Inhibit production of TNF-α, IL-1, IL-12 *B cells:* Increases immunoglobulin production *T cells:* Inhibits production of TH1 cytokines, Increases IL-4 and IL-10 production
IL-12	Dendritic cells, B cells, macrophages	*NK cells*: Increased IFN-γ production *T cells*: Increased IFN-γ production, increased TH1 differentiation, decreased T_H2 and T_H17 differentiation

TABLE 44-1 Cytokines and Lipid Mediators in Asthma *(Continued)*

Cytokines		
Cytokine	**Cell Sources**	**Proposed Cell Targets/Functions in Asthma**
IL-13	Mast cells, T cells	*Airway epithelial cells*: Increased permeability, increased mucus production, production of inducible nitric oxide synthase *Airway smooth muscle cells*: Increased airway hyperreactivity *Eosinophils*: Promotes migration and survival *Macrophages*: Activation and enhanced MHC Class II expression *B cells*: Increased class switching to IgE and production of IgE
IL-14	T cells	*B cells*: Increased proliferation, suppression of Ig secretion
IL-15	Monocytes/macrophages, DCs	*DCs*: Increased activation and survival, increased production of IFN-γ *Mast cells*: Increased survival *Monocytes/macrophages*: Increased phagocytic activity, increased production of IL-8, IL-12, MCP-1 *Neutrophils:* Increased survival and phagocytic activity, increased IL-8 production *NK cells*: Increased maturation and survival, increased production of IFN-γ, TNF-α, and GM-CSF *T cells*: Increased proliferation of memory $CD8^+$ T cells, Increased proliferation of T_H17 cells
IL-16	T cells, airway epithelial cells, DCs, eosinophils, mast cells	*DCs:* Increased chemoattraction *Eosinophils*: Increased chemoattraction *Monocytes/macrophages*: Increased chemoattraction, upregulation of MHC class II expression *T cells:* Increased migration, maturation, and proliferation
IL-17	T cells, NK cells	*Airway epithelial cells:* Increased production of IL-6, IL-8, G-CSF, PGE_2 *Eosinophils*: Increased chemoattraction *Neutrophils*: Increased production from stem cells, increased chemoattraction
IL-18	DCs, monocytes, macrophages, neutrophils, airway epithelial cells	*Basophils*: Increased production of cytokines and histamine *DCs*: Increased cytokine production, upregulation of MHC and costimulatory molecules *Macrophages*: Increased cytokine production *Mast cells*: Increased cytokine production, degranulation, and survival *Neutrophils*: Increased survival and release of proteases *NK cells*: Increased IFN-γ production. *T cells*: Promotes T_H1 differentiation.
IL-19	Monocytes	*T cells*: Increased production of T_H2 cytokines and downregulation of IFN-γ production
IL-20	Monocytes	Unclear
IL-21	T cells	*B cells*: Increased proliferation of IgA, IgG, IgM producing plasma cells and decrease in IgE producing plasma cells *T cells*: Increased differentiation into T_H17 cells, upregulation of T_H1 cytokine production
IL-22	T cells, NK cells	*Respiratory epithelial cells*: Increased production of antimicrobial peptides
IL-23	DCs	*Macrophages*: Increased TNF-α production *T cells*: Increased IL-17 production, promotion of T_H17 differentiation
IL-24	Monocytes, T cells	Unclear
IL-25	Airway epithelial cells, eosinophils, mast cells	*T cells*: Increased production of T_H2 cytokines
IL-26	Monocytes, T cells	Unclear
IL-27	Macrophages, DCs	*T cells*: Increased differentiation into IL-10 producing T_{REG} and T_H1 cells, decreased development of T_H2 and T_H17 cells
IL-28 (IFN-λ2,λ3)	DCs	Inhibits viral replication *DCs:* Increase ability to stimulate production of T_{REG} cells
IL-29 (IFN-λ1)	DCs	Inhibits viral replication *DCs*: Increase ability to stimulate production of T_{REG} cells
IL-31	T cells	*Airway epithelial cells*: Attenuate proliferation of epithelial cells
IL-32	NK cells, Airway epithelial cells, T cells	*Macrophages*: Upregulation of proinflammatory cytokines *Airway epithelial cells*: Decreased production of proangiogenic factors

TABLE 44-1 Cytokines and Lipid Mediators in Asthma *(Continued)*

Cytokines		
Cytokine	**Cell Sources**	**Proposed Cell Targets/Functions in Asthma**
IL-33	Endothelial cells, airway epithelial cells, dying cells	*Basophils*: Increased production of cytokines and histamine *DCs*: Increased cytokine production, upregulation of MHC and co-stimulatory molecules *Eosinophils:* Increased proliferation, survival, and chemokine production *Macrophages:* Increased cytokine production *Mast cells*: Increased cytokine production, degranulation, and survival *Neutrophils*: Increased survival and release of proteases *NK cells*: Increased IFN-γ and T_H2 cytokines *T cells*: Promotes T_H2 differentiation, enhances release of T_H2 cytokines
IL-35	T_{REG} cells	*T cells*: Decreased production of T_H2 cytokines, suppression of T cell proliferation
IL-36	Airway epithelial cells	*T cells*: Increased T_H1 differentiation
IL-37	Hematopoietic cells	*Macrophages*: Decreased secretion of proinflammatory cytokines *Airway epithelial cells*: Decreased secretion of proinflammatory cytokines
Interferons		
IFN-α	Monocytes/macrophages	*Virus infected cells*: Inhibition of viral replication
IFN-β	Monocytes/macrophages	*Virus infected cells*: Inhibition of viral replication
IFN-γ	T cells, NK cells	*Macrophages*: Differentiation, activation, and expression of Fcγ receptor. Increased cytokine production *T cells*: Increased differentiation to T_H1 cells, increased cytotoxicity of $CD8^+$ T cells
IFN-λ	See above	See above
Growth factors		
bFGF	Endothelial cells	*Fibroblasts*: Proliferation and extracellular matrix formation
G-CSF	Monocytes, fibroblasts, airway epithelial cells	*Neutrophils*: Proliferation and differentiation
GM-CSF	T cells, airway epithelial cells, macrophages	*DCs:* Maturation *Eosinophils:* Increased survival, degranulation *Macrophages*: Differentiation, increased survival, increased cytokine production *Neutrophils*: Increased chemotaxis and survival
M-CSF	Fibroblasts, endothelial cells, macrophages, airway smooth muscle cells	*Hematopoietic stem cells*: Differentiation of monocytes
PDGF	Platelets, monocytes, macrophages	*Fibroblasts*: Proliferation and chemoattraction
SCF	Bone marrow stromal cells, fibroblasts	*Mast cells*: Chemoattraction, induction of histamine release, differentiation, proliferation
TGF-β	Eosinophils, T cells, macrophages, airway epithelial cells, endothelial cells, airway smooth muscle cells	*Fibroblasts*: Chemoattraction and increased conversion to myofibroblasts, increased synthesis of collagen *Macrophages:* Chemoattraction *Neutrophils*: Chemoattraction *T cells:* Increased differentiation of T_{REG}, T_H9, and T_H17 cells, inhibition of T_H1 and T_H2 differentiation
VEGF	Macrophages, airway epithelial cells, T cells, eosinophils	*Airway smooth muscle cells*: Hyperplasia and increased airway hyperresponsiveness *DCs:* Increased proliferation and activation *Endothelial cells*: Increased angiogenesis and vascular permeability *Airway epithelial cells:* Increased proliferation, mucus production *Fibroblasts*: Promotion of subepithelial fibrosis
Other		
TNF-α	Monocytes/macrophages, DCs, mast cells, eosinophils, neutrophils, B and T cells, airway epithelial cells, airway smooth muscle cells, fibroblasts	*Airway epithelial cells*: Upregulation of adhesion molecules *Airway smooth muscle cells*: Increased airway hyperresponsiveness *Endothelial cells*: Upregulation of adhesion molecules *Eosinophils*: Chemoattraction, increased activation *Fibroblasts*: Increased conversion to myofibroblasts *Macrophages*: Chemoattraction *Mast cells*: Increased histamine release *Neutrophils*: Chemoattraction *T cells*: Increased activation and cytokine release

(continued)

TABLE 44-1 Cytokines and Lipid Mediators in Asthma *(Continued)*

Cytokines		
Cytokine	**Cell Sources**	**Proposed Cell Targets/Functions in Asthma**
TSLP	Airway epithelial cells	*DCs*: Increased ability to attract T_H2 cells *Eosinophils*: Induced release of proinflammatory cytokines and chemokines *Mast cells*: Increased production of T_H2 cytokines *T cells*: Increased differentiation to T_H2 cells
Lipid Mediators		
Mediator	**Cell Sources**	**Proposed Cell Targets/Functions in Asthma**
Leukotrienes		
Dihydroxy acid leukotriene (LTB4)	DCs, monocytes/macrophages, neutrophils	*B lymphocytes*: Increased expression of CD23, CD54, and CD105 *DCs*: Recruitment, increased skewing of T_H0 cells to T_H1 type *Eosinophils*: Recruitment *Mast cells*: Recruitment *Monocytes/macrophages*: Increased production of IL-6, TNF-α, MCP-1 *Neutrophils*: Recruitment and activation *Airway smooth muscle cells*: Increased proliferation *T lymphocytes:* Recruitment
Cysteinyl leukotrienes (LTC_4, LTD_4, LTE_4)	DCs, eosinophils, mast cells, monocytes/macrophages	*Airway smooth muscle cells*: Bronchoconstriction *DCs*: Increased migration to lymph nodes *Endothelial cells*: Increased vascular permeability and upregulation of adhesion molecules *Eosinophils*: Recruitment *Goblet cells*: Increased mucus production *Mast cells*: Increased production of IL-5, IL-8, TNF-α, and MIP-1β *Monocytes/macrophages*: Increased production of MCP-1, TNF-α, and MMP-9 *T lymphocytes*: Increased T_H2 immune response
Prostanoids		
PGD_2	Mast cells	*Airway smooth muscle cells*: Bronchoconstriction *Eosinophils*: Recruitment, increased degranulation *Monocytes/macrophages*: Increased cytokine production *Neutrophils*: Inhibition of activation *T lymphocytes*: Recruitment, increased production of T_H2 cytokines, inhibition of IFN-γ production
PGE_2	Airway smooth muscle cells, airway epithelial cells, endothelial cells, macrophages	*Airway smooth muscle cells*: Inhibition of allergen-induced bronchoconstriction *Eosinophils:* Inhibits recruitment *Monocytes/macrophages*: Decreased cytokine production, downregulation of MHC Class II expression *T cells*: Decreased proliferation, decreased T_H2 cytokine production
PGI2 (Prostacyclin)	Endothelial cells, monocyte/macrophages	*Endothelial cells*: Vasodilatation *Eosinophils*: Inhibition of recruitment *T cells*: Increased IL-10 production
Thromboxane A_2	Platelets, endothelial cells, monocyte/macrophages	*Airway smooth muscle cells*: Bronchoconstriction *Eosinophils*: Recruitment

and stored in cells for release upon activation; rather, they are rapidly synthesized following activation of the source cell. LTC_4, LTD_4, and LTE_4 are potent bronchoconstrictors that are produced by several cell types, including eosinophils and mast cells, whereas LTB_4 is a neutrophil attractant.[100] The leukotrienes are also able to increase mucus secretion in the airway and facilitate a plasma leak generating edema in the airway.[100,101] Leukotriene receptor antagonists (e.g., montelukast, Singulair®) are currently used in the treatment of asthma.[102] Although effective in some patients, the leukotriene modifiers have limitations as regards overall potency, thus raising questions as to what are the conditions, or phenotypes, in which leukotrienes dominate.[103]

Prostanoids

The prostanoids (PG) are a family of lipid compounds generated from the metabolism of arachidonic acid via the cyclooxygenase pathway (Fig. 44-4).[104] Most of the prostanoids, that is, PGD_2, PGF_2, and TXA_2, are potent bronchoconstrictors and products of several

cell types including eosinophils and mast cells.[104] However, another prostanoid, PGE_2, has bronchodilatory and anti-inflammatory activity.[105,106] The use of nonsteroidal anti-inflammatory medications to inhibit cyclooxygenase activity has not been shown to have an appreciable effect on airway inflammation. It has been observed that PGD_2 is the predominant prostanoid involved in asthma.[107] Therefore, specific PGD_2 receptor antagonists are currently being considered to ameliorate some of the bronchoconstriction in asthma.[108–110]

NITRIC OXIDE

The role of nitric oxide (NO) in the pathogenesis of asthma remains unclear. NO is continually synthesized at low levels in the airways of normal subjects. Sources of NO in the respiratory tract include airway epithelial cells, smooth muscle cells, sensory nerves, endothelial cells, and macrophages.[111] At low levels, NO is a bronchodilator and vasodilator that antagonizes endothelin and has protective effects in the airway.[111] Higher levels of NO are found in asthma, secondary to increased inducible NO synthase expression, and may be detrimental to airway epithelium.[112] This may be mediated by the ability of NO to react with superoxide anion in inflamed tissue to produce biologic oxidants that contribute to ongoing tissue damage and chronic asthmatic inflammation.[111] The production of NO is also thought to reflect the level or severity of airway inflammation. Thus, exhaled NO measurement has been utilized successfully as a tool to reflect the extent of airway inflammation as a measure of asthma control.[112]

GRANULE PROTEINS

Granulocytes, that is, mast cells, basophils, eosinophils, and neutrophils, are capable of releasing granule proteins, many of which has been proposed to play significant roles in the pathogenesis of asthma.

Insights into the kinetics and importance of mast cell mediators have been obtained from measurements of BAL histamine and tryptase.[113] These studies have demonstrated that mast cell activation is an early event, with elevated BAL histamine and tryptase levels being seen 12 minutes after endobronchial antigen challenge; the levels of tryptase returning to normal 48 hours after antigen challenge.[113] The levels of histamine remain elevated after 48 hours, raising the possibility that non-mast cells (e.g., basophils) are subsequently recruited and activated to produce histamine at these later points or that mast cells generate and continue to release histamine over time following an initial activation.[113] Furthermore, BAL of allergic asthmatic subjects had only moderately elevated levels of tryptase at baseline but higher concentrations of tryptase following antigen challenge.[113]

Histamine is capable of inducing bronchoconstriction, increasing vascular permeability to cause edema, and increasing mucus secretion.[114] The role of tryptase is not well established, although there are data to suggest that it can activate inflammatory cells such as eosinophils, mast cells, and epithelial cells by cleaving a family of protease activated receptors (PARs) on their cell surfaces.

Major basic protein (MBP) is the principal protein constituent of eosinophil granules. It is toxic to epithelial tissues, induces airway hyperresponsiveness, and causes histamine release from basophils.[115] ECP is more cytotoxic to the epithelium than MBP and damages target cells by membrane pore formation.[116] Eosinophil-derived neurotoxin (EDN), as the name implies, damages myelinated neurons.[117] EPO differs from neutrophil and monocyte myeloperoxidases (MPOs); it causes LTC_4 and LTD_4 degradation and causes histamine release from mast cells.[118]

Neutrophil release of MPO and neutrophil elastase enhances host defense functions but is also potentially injurious to normal tissues, including airway epithelium.[119] The primary granules of neutrophils contain MPO and lysozyme as well as hydrolases and proteinases, which are important in tissue penetration by neutrophils.[119] Secondary granules contain lysozyme and collagenases, which can also potentially damage airway tissue.[119] Neutrophil granule proteins are considered toxic to airway epithelium and tissue.

REMODELING IN ASTHMA

As occurs in most chronic inflammatory disorders in which there is an "injury–repair" cycle, tissue remodeling is a key component of asthma. Airway remodeling in asthma involves epithelial changes, increases in smooth muscle mass, increased angiogenesis, increased fibroblast/myofibroblast activity, increased fibrosis, and many other important changes that affect the structure and function of the large and small airways of the lung.[120] Prolonged infiltration of inflammatory cells and the cytokines, chemokines, and growth factors, which they generate, contribute to these structural changes, which help define the features of asthma in some patients.

As mentioned previously, airway epithelium serves not only as an anatomic barrier, but also as a key player in asthma pathogenesis. Defects in airway epithelium are ubiquitous in human asthma and, when injury occurs, the repair process has been likened to a chronic wound, which may not heal normally as a result of repetitive and ongoing insults.[121] As with other types of chronic wounds, the body attempts to heal the epithelial damage by promoting the release of growth factors from the underlying mesenchyme. This, in turn, leads to increased extracellular matrix deposition, fibrosis, and size and number of airway smooth muscle cells.[122] These even have been likened to the function of the epithelial–mesangial trophic unit (EMTU), a key component of early lung morphogenesis, which, in a sense, becomes reactivated in chronic asthma.[122] The consequence of prolonged epithelial injury is a protracted release of proinflammatory cytokines and profibrogenic growth factors such as TGF-β. When these reactions are combined with the inflammatory milieu derived from the immune cells recruited to the airway by this long-term damage, the effects of these morphologic changes are manifested in chronic airflow obstruction, which is often resistant to pharmacologic treatment, and results in permanent airflow obstruction.

PHENOTYPIC CLUSTERS IN ASTHMA

Several recent studies have begun to identify phenotypes, or subphenotypes, of asthma. These studies have confirmed that asthma is a very heterogeneous disease.[123,124] Specifically, studies by Haldar and colleagues in the United Kingdom used sputum eosinophilia, in addition to measurements of atopic status and other characteristics, to identify these subphenotypes.[123] Interestingly, they identified a cluster of patients with symptomatic disease who had very little eosinophilic involvement and lacked evidence of atopic sensitization. Other groups fit a more "classic" pattern of asthma with evidence of eosinophilic involvement and atopic sensitization. Other clusters fell somewhere between the two. This study, and others, are probing the heterogeneity of the disease and discovering the reasons behind differences in disease course and response to conventional asthma therapy.

CONCLUSION

Asthma is a complex disease in which the contributions of many different immune cells, structural cells, molecular mediators, and external factors combine to produce acute and chronic inflammation and airflow obstruction. The study of these different factors has led to a greater understanding and appreciation of the breadth of this disease and a recognition of its complexity and heterogeneity. It has also led to the realization that different phenotypes of asthma exist and treatment of asthma based on the specific phenotype represents an emerging, potentially more specific and effective possibility. Over the last decade, many new advances in therapy have been made that target specific inflammatory mediators in asthma. The fact that these have not been universally successful speaks to the heterogeneity and redundancy of asthma. As research delves further into the pathogenesis and pathophysiology of asthma, many more

targets will emerge, which will hopefully lead to novel therapies to improve the lives of asthmatic patients and with these interventions greater insight into the effects of individual mediators and in whom they may be relevant.

CHAPTER 45
Asthma: Epidemiology

Augusto A. Litonjua
Andrea J. Apter
Scott T. Weiss

Asthma is a clinical syndrome that affects 25 million Americans and accounts for 12.7 million medical visits yearly. One-third of those afflicted with asthma are children under the age of 18 years. It is estimated that roughly half of these children received their diagnosis prior to the age of 6 years. As a result, the origins of asthma are believed to have a clear genomic component that is often manifested in early childhood. The clinical course of this illness is influenced greatly by exposures, including respiratory viruses, indoor allergens, maternal tobacco smoke, and other physical and social aspects of the environment. Thus, this clinical disease has important consequences in childhood and may have important consequences for adult obstructive lung disease.

Asthma is an extremely common clinical problem and the most common cause of hospitalization for children in the United States. The estimated total annual costs of asthma care is rising dramatically and totaled approximately $56 billion in 2007 in the United States,[1] representing a $3 billion increase since 2002. These costs include $50.1 billion per year in medical expenses, $3.8 billion per year in missed school or lost work days, and $2.1 billion per year in premature deaths. The paradox of this illness is that despite important strides in understanding etiologic environmental factors and mechanisms of airway inflammation characteristic of the syndrome, its prevalence and morbidity remain unacceptably high. Although asthma morbidity and mortality rates have been steady over the last few years, the rates are dramatically higher than 25 years ago and continue to be very significant, particularly for urban minority groups, low-income populations, and children.

The purpose of this chapter is to describe trends in asthma epidemiology, specifically prevalence, hospitalization, and mortality. In so doing, we examine potential reasons for these trends, and the recent research on the interactions of genes and environment. We also examine the relationship of the intermediate phenotypes of airway hyperresponsiveness and allergy to the asthma syndrome and consider a variety of risk factors for asthma occurrence. We conclude with a review of asthma natural history and the implications of the current trends.

DEFINITIONS AND PREVALENCE

In 2007, the National Asthma Education and Prevention Program Expert Panel Report 3 (NAEPPR3)[2] defined asthma as

> a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role: in particular, mast cells, eosinophils, neutrophils (especially in sudden onset, fatal exacerbations, occupational asthma, and patients who smoke), T lymphocytes, macrophages, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of coughing (particularly at night or early in the morning), wheezing, breathlessness, and chest tightness. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment.

Because asthma is a clinical syndrome, there is no gold standard for its diagnosis. As such, physicians employ nonstandardized algorithms for making the diagnosis, such as a history of wheezing or a parental history of asthma in conjunction with a favorable response to a bronchodilator to identify the asthmatic patient. Frequently, age, gender, and other patient characteristics such as smoking status or response to allergen may influence a physician's diagnosis. Rarely are tests of airway responsiveness used to investigate symptomatic patients in the clinical setting.

In general, epidemiologic surveys have tended to rely on historical or questionnaire sources to identify patients with asthma. Asthma cases have been identified, either by physicians or surveys of population groups in whom the definition of who is asthmatic has been left to the patients themselves, surrogates, or the report of the diagnosis having been made by the patient's physician. Clearly, each of these methods of identifying asthma patients has inherent weaknesses. One must, therefore, assume that some bias in the reporting of cases is present and that the biases in each method of gathering data are different.

The National Health Interview Survey (NHIS) is an annual random population household interview survey that provides information on asthma prevalence in the United States. Its data demonstrate an almost doubling of asthma prevalence over the last quarter century,

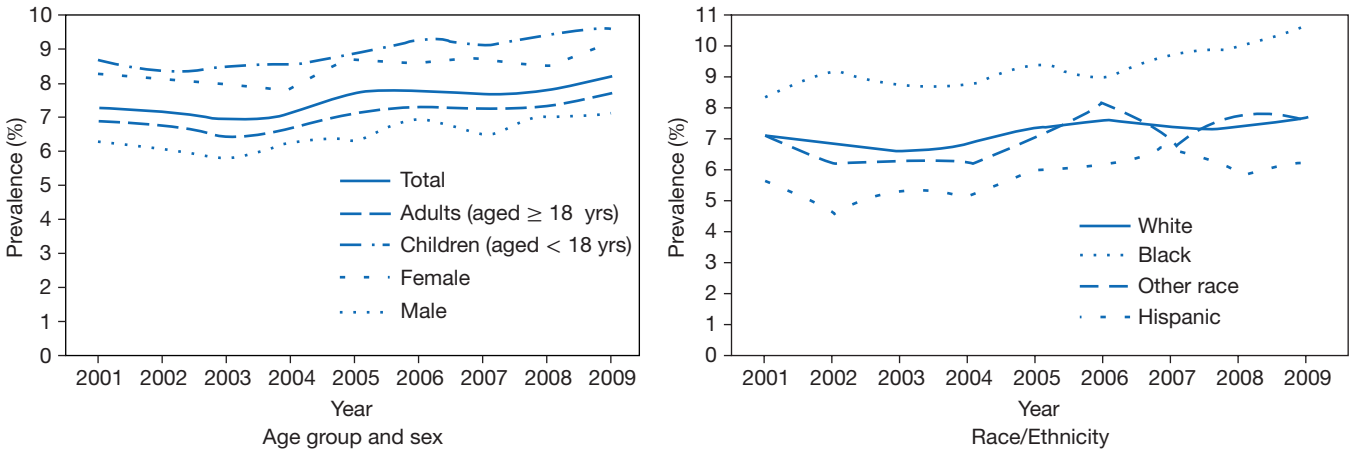

Figure 45-1 Current asthma prevalence figures from the National Health Interview Survey (NHIS), United States, by age group, sex, and race/ethnicity. Prevalence measures include persons who answered "yes" to the questions: "Have you ever been told by a doctor or other health professional that [you/your child] had asthma?" and "Do [you/your child] still have asthma?" *(Reproduced with permission from Vital signs: asthma prevalence, disease characteristics, and self-management education. United States, 2001–2009. MMWR Morb Mortal Wkly Rep. 2011;60(17):547–552.)*

from 3.2 per 100 population in 1981 to 5.5% per 100 in 1996.[3] In 1997 the NHIS questions and methodology were modified, limiting comparisons of prevalence before and after 1997. Instead of asking whether the respondent or a family member had had asthma over the past 12 months the newer version asks, "Have you ever been told by a doctor or other health professional that you had asthma?" (lifetime prevalence). Information about adults can no longer be obtained from a family member or proxy. If the response is affirmative, an "attack" question is asked, "During the past 12 months have you had an episode of asthma or asthma attack?" Beginning in 2001, if the lifetime prevalence response was positive, a point prevalence or "Current" measure was added asking, "Do you still have asthma?" The data from the "Current" question, is most comparable with previous data, but not exactly the same. Most recent data from the CDC, which analyzed data from the NHIS, indicated a plateau in asthma prevalence from 2001 through 2003, but prevalence has continued to rise since then (Fig. 45-1).[4] The prevalence in children under 18 years remains higher than adults, for example, in 2009, 9.6 per 100 compared with 7.7 (Fig. 45-1).

There is a difference in prevalence by racial/ethnic groups. Until 1997 racial groups were classified as black or white with black population having slightly higher 12-month prevalence. Beginning in 2003, racial and ethnic classification was expanded to include Hispanics. The most recent data from 2009 shows that prevalence was 11.1 for black non-Hispanics, 6.3 for Hispanics, and 8.1 per 100 for white non-Hispanics.[4] It is noteworthy that the rate for Hispanics of Puerto Rican descent was 14.2 per 100.[5]

The current data show a significant modification of prevalence by gender, in that males tend to predominate in the younger age group, whereas gender ratios equalize in the pubertal years, and females predominate throughout the rest of the adult life. For example, the current prevalence for males less than 18 years in 2009 was 11.3 per 100 compared with 7.9 for females, but in adults 18 years and older female prevalence (9.7 per 100) is almost twice that for males (5.5 per 100).[4] Thus, age and gender play an important role in modifying disease prevalence. In addition, there also appears to be some regional variation in asthma prevalence rates. Asthma prevalence was highest in the Northeast (9.3%), followed by the Midwest (8.8%), the West (7.7%), and the South (7.5%).[4]

ASTHMA HEALTHCARE USE

Drawing from data from multiple national surveys, the analyses performed by the CDC suggest that hospitalization and emergency

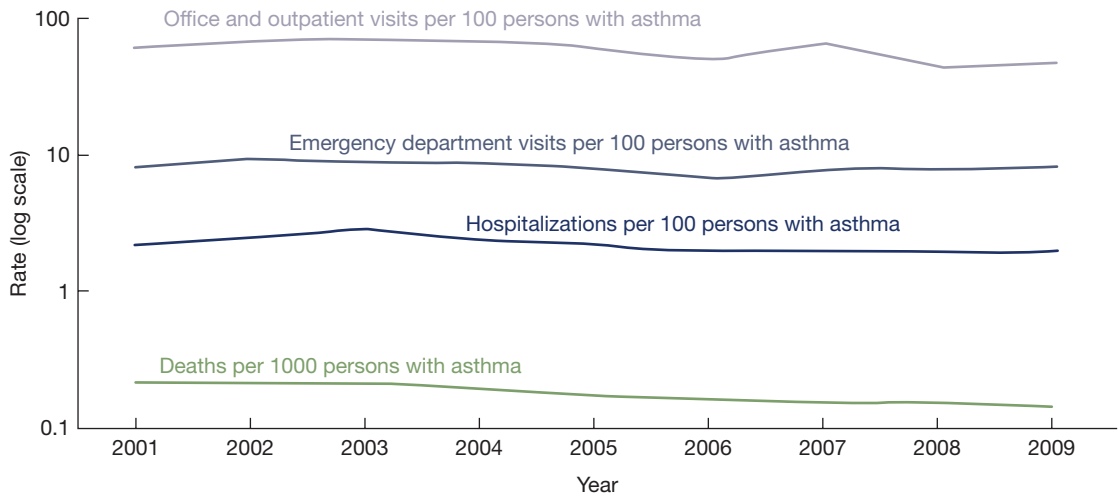

Figure 45-2 Asthma healthcare encounters per 100 persons with asthma, and asthma deaths per 1000 persons with asthma: United States, 2001 to 2009. *(Reproduced with permission from Akinbami LJ, Moorman JE, Bailey C, et al. Trends in asthma prevalence, health care use, and mortality in the United States, 2001–2010. NCHS Data Brief. 2012;(94):1–8.)*

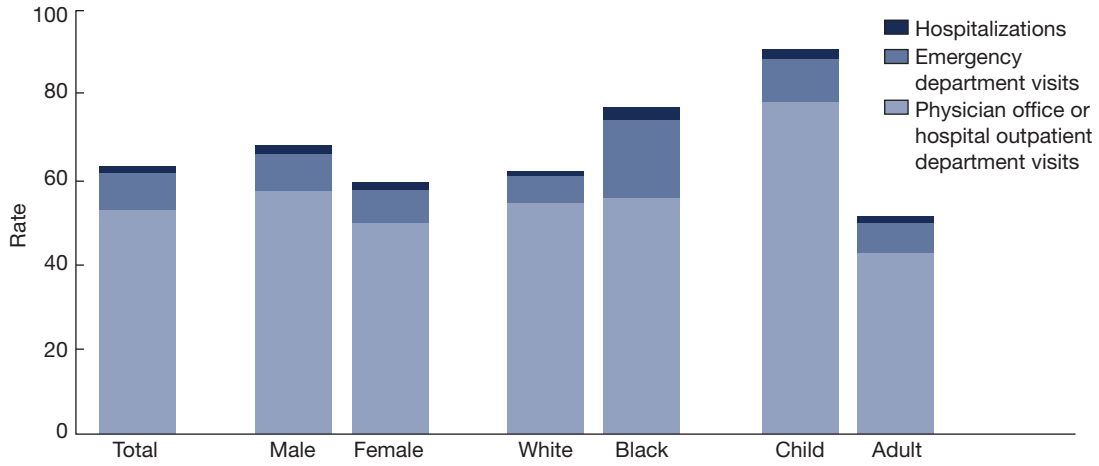

Figure 45-3 Asthma healthcare encounters per 100 persons with asthma: United States, 2001 to 2009. Hospitalizations are three times more frequent and emergency department visits almost five times more frequent among blacks. Healthcare utilization is more frequent in children than adults. *(Reproduced with permission from Akinbami LJ, Moorman JE, Bailey C, et al. Trends in asthma prevalence, health care use, and mortality in the United States, 2001–2010. NCHS Data Brief. 2012;(94):1–8.)*

department (ED) visit rates for asthma have remained stable from 2001 to 2009, a period of rising prevalence (Fig. 45-2).[6] Asthma visits in primary care settings (defined as physician offices and hospital outpatient departments) declined during this period. Asthma healthcare use is known to vary by demographic characteristics. For the period 2007 to 2009, asthma healthcare use across all healthcare settings was greater for children than for adults (Fig. 45-3): outpatient visit rates for children (0–17 years) averaged 78.7 per 100 persons with asthma versus 42.5 for adults; ED visits for children averaged 10.7 per 100 persons with asthma versus 7.0; while hospitalization rates were similar for both groups (2.1 per 100 persons with asthma for children vs. 1.9 for adults).[6] With respect to gender, for the 2007 to 2009 period, males had higher annual average outpatient visit rates than women (57.6 per 100 persons with asthma for men vs. 49.8 for women), while ED visit and hospitalization rates were about the same for both sexes (8.7 ED visits per 100 persons with asthma for males vs. 7.6 for women, and 1.8 hospitalizations per 100 persons with asthma for males vs. 2.0 for women). With respect to race, asthma outpatient visits per 100 persons with asthma were similar for black (54.9) and white (56.0) persons, but ED visits were three times higher in blacks (18.4 per 100 persons with asthma) than whites (6.1 per 100 persons with asthma), and hospitalizations were two times higher in blacks (2.8 per 100 persons) than whites (1.3 per 100 persons).

TRENDS IN ASTHMA MORTALITY

Asthma mortality rates in the United States are quite low. Recent data show that for the period 2007 to 2009, the asthma death rate per 100 persons with asthma was 0.015.[6] Figure 45-4 shows the trends in asthma mortality in the United States between 1980 and 2004.[7] There is an overall decline in deaths since 1998, although 11% of that decline can be attributed to the new coding instituted in 1999. As seen in Figure 45-2, the decline in death rates for asthma has continued through 2009. However, the downward trend in countrywide asthma mortality belies pockets of very high prevalence, morbidity, and mortality in urban minority populations. For instance, in 2009, blacks had a greater likelihood of dying from asthma than whites (Rate ratio = 1.93).[8]

These mortality rates do not represent a public health concern in an absolute sense, as the number of deaths is still very low. However, the rates do represent a clear public health concern because almost all asthma deaths are preventable, and certain urban and minority areas have extremely high mortality rates, suggesting inadequate care practices.

INTERMEDIATE PHENOTYPES

There are two intermediate phenotypes that contribute to the asthmatic syndrome: airway responsiveness and allergy. Both have a genetic component, and both are influenced by environmental factors. We will discuss these phenotypes and their interrelationship to each other and to asthma.

AIRWAY RESPONSIVENESS

Airway responsiveness is measured by quantifying decline in lung function caused by using increasing doses of a bronchoconstrictive stimulus, such as histamine or methacholine (see Chapter 33). When the patient's FEV_1 decreases by 20% from its initial value, or after a maximum stimulus dose has been administered, the test is terminated. The dose at which this drop occurs is called the *provocative dose* (PD_{20}). Individuals who manifest a PD_{20} at a low dose of

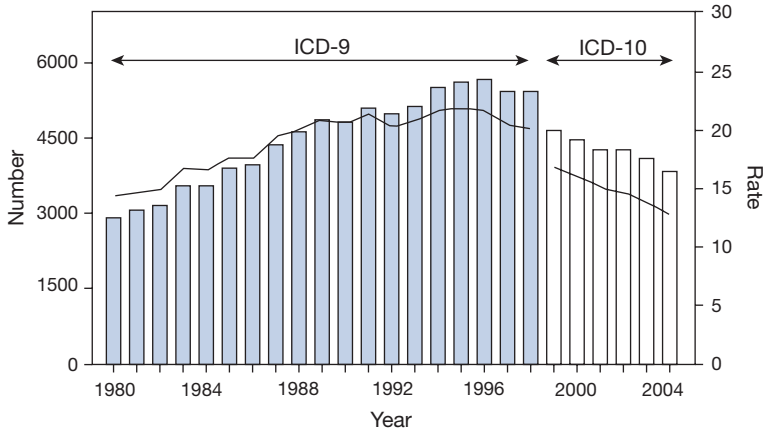

Figure 45-4 Asthma mortality trends, by year and International Classification of Diseases (ICD), United States, 1980 to 2004. Since1980, deaths from asthma rose. Beginning in 1998, both the overall number of deaths and the rate have clearly declined. However, a new mortality coding scheme was implemented in 1999. About 11% of the decline in asthma deaths can be attributed to the new coding scheme. *(Reproduced with permission from Moorman JE, Rudd RA, Johnson CA, et al. National surveillance for asthma–United States, 1980–2004. MMWR Surveill Summ. 2007;56(8):1–54.)*

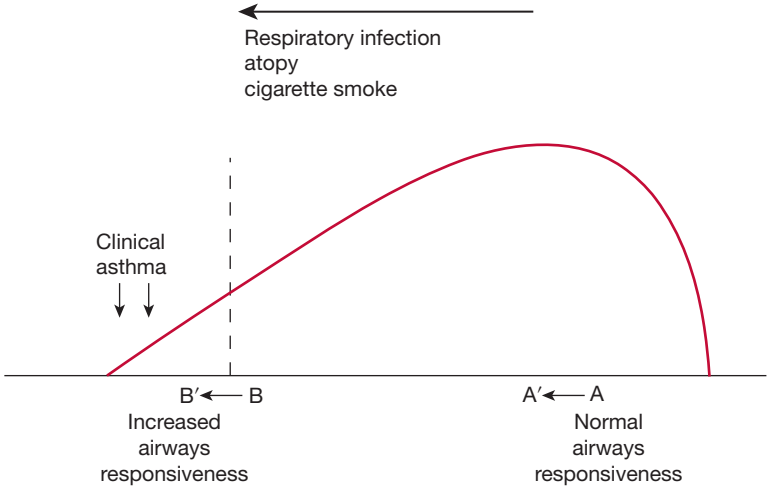

Figure 45-5 The effect of environmental exposures on the population distribution of airway responsiveness acting to move people in a more responsive direction. *(Reproduced with permission from Brown RW, Weiss ST. The influence of lower respiratory illness on childhood asthma: defining risk and susceptibility. Semin Respir Infect. 1991;6(4):225–234.)*

stimulus are said to have increased airway responsiveness and are hyperresponsive to the inhaled agent.

Cross-sectional population-based surveys of children and adults conducted in many different countries and using a variety of techniques for measuring airway responsiveness have shown that the prevalence of airway hyperresponsiveness is upward of 20% in the general population,[9–11] with women having a higher prevalence than men The prevalence of increased airway responsiveness exceeds the prevalence of asthma by two- to fivefold.

These studies have also demonstrated that airway responsiveness is log normally distributed in the general population. An example of this is given in Figure 45-5. In this population-based study of the distribution of histamine airway responsiveness, symptomatic or asthmatic subjects appear at the more responsive end of the distribution, but there is considerable overlap with asymptomatic subjects.[8] Other population-based studies have confirmed that a large number of asymptomatic subjects manifest increased airway hyperresponsiveness to this agent.

It has been well demonstrated in studies of both children and adults that airway hyperresponsiveness antedates and predicts the development of asthma.[12–16] Increased airway responsiveness carries at least twice the risk for the development of asthma in children and young adults. However, increased airway responsiveness is a necessary, but not a sufficient condition for the development of asthma. In all likelihood, subjects who are genetically predisposed have increased airway responsiveness.[15] They then encounter environmental stimuli that generate airway inflammation. The inflammation then moves them in the direction of greater responsiveness and the development of respiratory symptoms. This theoretical paradigm is graphically depicted in Figure 45-5.[17]

A variety of mechanical factors influence airway responsiveness. First, and most important, is the level of lung function. Individuals with lower levels of lung function are more likely to have increased airway responsiveness.[18–20] In part, this is simply a mathematical phenomenon. Since airway responsiveness is expressed as a percent change from baseline, the baseline value will obviously be important in determining the level at which an individual would be considered responsive (i.e., have a PD_{20}). This can be best understood with a simple mathematical example. A man with a 5-L FEV_1 would be required to drop his prechallenge level of lung function by 1 L to achieve a PD_{20} for FEV_1. In contrast, a man with a 500-mL FEV_1 will only need to drop his FEV_1 by 100 mL to achieve a comparable PD_{20} for FEV_1. Other factors, such as the central deposition and distribution of the inhaled aerosol, the fact that airflow is inversely proportional to the fourth power of the airway radius, and baseline bronchomotor tone all contribute to the relationship of lung function to airway responsiveness. For this reason, airway responsiveness is likely to be increased at the extremes of age (i.e., in children and older adults) and reduced in young adults between the ages of 15 and 45 years.[19]

■ ALLERGY

Allergy refers to immediate (Type 1) hypersensitivity to environmental antigens. It is characterized by wheal and flare reactions to skin testing with common environmental antigens, usually with appropriate clinical history. Atopy is the demonstration of allergy and familial aggregation of this trait.

Initially described over 20 years ago by Mosmann and colleagues,[21–23] the Th1–Th2 dichotomy has been helpful in explaining the pathophysiology of the allergic response. This model is also the basis for clinical research seeking to understand the development of asthma. Antigen presenting cells (APCs) display peptide antigens, either allergenic or infectious, on their cell surfaces for recognition by naïve T cells (Th0).[24] Th0 differentiate into Th1 or Th2 cells, depending on the nature of the antigen, the characteristics of the APC, local concentration of cytokines, and other cofactors not fully understood.[25] Th1 cells secrete IFN-γ, while Th2 cells secrete IL-4 and IL-5. (see Chapter 44). For example, activation of APC by microbial products results in production of IL-12 and Th0 cells differentiate into Th1 cells. The presence of IL-4 results in differentiation of Th0 cells into Th2 cells. Th2 cells promote allergic inflammation through the production of cytokines including IL-4, IL-5, and IL-13. IL-4 and IL-13 induce B lymphocytes to differentiate into IgE-producing plasma cells. IL-5 secreted by Th2 cells results in eosinophil production and resistance to apoptosis.[26] A Th1 response results in activation of macrophages and natural killer cells and production of IgG1, which plays a role in complement binding and opsonization. Th1 and Th2 cells cross-regulate each other. That is, IFN-γ inhibits Th2 proliferation and IL-4 inhibits IFN-γ–induced macrophage activation. T-regulatory (Treg) cells are recently characterized cells that inhibit Th1 and Th2 cells.[27] These cells are characterized by their secretion of IL-10 and transforming growth factor (TGF)-β, and, via the expression of Foxp3, lead to suppression or proliferation of other T cells.[28,29] Tregs also suppress effector cells of allergic inflammation (e.g., basophils, eosinophils, and mast cells),[30,31] and regulate IgE production.[32] Thus, it is likely that Tregs play a role in airway tolerance in the prevention of asthma.[33]

Since the initial description of the Th1/Th2 dichotomy, it has become clear that mechanisms involved in asthma and the allergic response are much more complicated. The role of the epithelium and upstream pathways has become clearer (as reviewed in Williams et al.[34]). Initial activation occurs in the epithelium, upon interaction of allergen and/or pathogen (damage)-associated molecular patterns and toll-like receptors. Early response cytokines, including thymic stromal lymphopoietin (TSLP), IL-33, and IL-25 (previously termed IL-17E) are released in the local tissue environment. These set off a cascade of events that include dendritic cell skewing to a phenotype that supports differentiation of Th2 cells, and also expansion of innate immune effector leukocytes secreting IL-4, IL-5, and IL-13 leading to a Th2 inflammatory response. Other cytokines are now recognized to play a role in the acute response and chronic inflammation characteristic of asthma and allergies, including IL-9, IL-17, IL-22, among many others.[26,35]

CLINICAL MARKERS OF ALLERGY

Many clinical allergy markers have been utilized in epidemiologic studies of asthma. Total or allergen-specific IgE, measured by serologic testing, or specific allergen skin testing, assess sensitization as well as exposure to environmental antigens and frequently are used to determine the prevalence of allergic responsiveness. Skin test reactivity depends on at least three separate factors: (1) an intact immune system; (2) the presence of IgE-sensitized mast cells that release mediators when exposed to antigen; (3) and skin that can respond to histamine with the development of an inflammatory response, including erythema and induration. Although these manifestations of an allergic response depend on prior exposure to an environmental antigen, they do not measure or take into account the level of exposure in the environment.

Total serum IgE, although used in epidemiologic studies, has relatively limited value in the diagnoses of atopic diseases, with the exception of allergic bronchopulmonary aspergillosis. Total and specific IgE levels correlate with each other and with skin test results, but no level of total IgE avoids misclassifying a significant proportion of those with and without allergic diseases. The limitations in clinical information imposed by these tests reduce their utility when they are used in epidemiologic studies.

Total and specific IgE measurements appear to be comparable in males and females. Both increase with age and peak approximately at the age of 15 years. After this time, there is a progressive decline, although the decline in skin test reactivity exceeds the reduction in total serum IgE, perhaps related to local factors in the skin.

It is believed that IgE responses to inhalant allergens are commonly set in early childhood. In early life, the immune system is characterized by immature humoral and cellular responses. Initially thought to be unresponsive, in fact, the neonatal response is strongly biased toward a Th2 function.[36–38] As the neonate grows and the immune system matures, there is a shift toward a more balanced immune response in healthy individuals. The process by which this shift comes about is the object of intense research. For example, it is known that potent neonatal Th1 responses can be induced under specific circumstances (e.g., infections).[39–42] Immunomodulatory agents that can promote neonatal Th1 immunity are the subject of current research.[43,44] Thus, sensitization, that is, production of IgE directed at environmental antigens, is not only a function of genetic susceptibility, dose, timing, and duration of allergen exposure, but likely reflects early exposure to other environmental antigens, particularly microbial or viral organisms. One hypothesis of the development of atopic disease, the "hygiene hypothesis," states that the prevention of Th2-mediated disorders is dependent upon early exposure to infectious agents. That is, respiratory or gastrointestinal infections may stimulate macrophages to produce interferon-α and IL-12 that stimulate NK cells to produce IFN-γ, which would inhibit the development of a Th2-type response. The Tucson Children's Respiratory Study, a birth cohort of 1246 subjects, noted that children who had a nonwheezing lower respiratory tract illness before 9 months of age had lower total IgE levels at 9 months and 6 years of age when compared with children who had no lower respiratory illnesses before 9 months of age.[45,46] These children were also less likely to be atopic than those who had no lower respiratory tract illnesses. These investigators also found that children exposed to more siblings at home or to day care in the first 6 months of life, presumably exposed to more infections, were protected from the development of asthma between ages 6 and 13 years.[47] Findings from some other cohorts have shown similar effects of early life exposure to day care or more siblings on asthma risk.[48–50] On the other hand, several other birth cohorts have found either that early day care exposure had no effect on asthma development or that it increased the risk for asthma and asthma-like symptoms in children.[51–54] This research confirms the complexity of environmental influences on the immune system.

RELATIONSHIP OF AIRWAY RESPONSIVENESS AND ALLERGY TO ASTHMA

Atopy and increased airway responsiveness are independent factors, both of which are related to the asthma phenotype. While the prevalence of atopy is higher among asthmatics than nonasthmatics, the association may not be causal. Systematic reviews have shown that at a population level, there is no correlation between the prevalence of atopy and the prevalence of asthma.[55–57] It is likely that there are common factors that raise the risk of both conditions. Studies that have investigated phenotypes of asthma using clustering methods have shown that there are asthma cases that are predominantly atopic with positive skin test reactivity, eosinophilia, and a younger age of onset, whereas there are other clusters that are predominantly nonatopic with neutrophilia and an older age of onset.[58,59]

Atopy and airway responsiveness may also occur together. Studies have shown that individuals who are sensitized to an allergen have bronchospasm when exposed to that allergen,[60,61] but individuals may have airway hyperresponsiveness without atopic manifestations. The introduction of omalizumab, a recombinant, humanized anti-IgE antibody, is helping to elucidate the relationship of airway responsiveness and allergy. Omalizumab lowers total serum IgE and reduces eosinophils in sputum.[62–64] In some studies it has allowed reduction of corticosteroid therapy, but in others it has failed to show reduction in airway hyperresponsiveness, supporting the notion that airway hyperreactivity and allergy have other separate influences.

Since the first report of a longitudinal relationship between exposure to higher levels of dust mite allergen and the development of asthma,[65] researchers have explored the relationship between exposure to allergen and the subsequent development of asthma. A birth cohort design has been used to examine this relationship. Preventing loss of participants to follow-up makes these studies difficult to conduct. It is also difficult to measure exposure to allergen, that is, to quantify inhalation by subjects, while accounting for intermittent and varying exposure over time and place. Nevertheless, most studies have investigated exposure to allergens in house dust early in life. Furthermore, there is an imperfect correlation among skin test reactivity, total serum IgE level, and peripheral blood eosinophil count, such that no single phenotypic marker completely defines the atopic state. These longitudinal studies have shown that exposure to high levels of allergens early in life increases the risk for sensitization and atopy.[66,67] However, the effect on asthma appears to depend on the atopic status of the parents. In children of atopic parents, exposure to high levels of allergen in early life increased the risk of asthma in childhood,[66] whereas in studies where cohorts were not selected for parental atopy, there was no significant effect of exposure to allergens in early life and asthma risk in childhood.[67,68] These studies suggest the theme that asthma and allergies have some common determinants but are likely separate entities, and that genetic susceptibility likely interacts with environmental exposures in determining risk for the development of asthma.

GENETIC SUSCEPTIBILITY AND GENE–ENVIRONMENT INTERACTIONS

Geneticists describe asthma as a complex disease, a disease in which many genes influence the development and phenotype of asthma, each having only a small influence. Since the human genome project was completed in 2000, remarkable advances have been made in identifying asthma genes.

There are two main types of genetic studies: linkage studies and association studies. In an association study, candidate genes are examined to determine a statistical association between polymorphism in the gene and asthma phenotypes; either cases and controls or trios can be used. These studies focus on known pathophysiology. An extension of the candidate gene association study is the genome-wide association study (GWAS). In this case, a panel of

markers, commonly single nucleotide polymorphisms (SNPs) and numbering 500,000 to over 2 million, are genotyped and association analysis is conducted to find associations with asthma phenotypes. This type of association study is hypothesis free and does not focus on known pathophysiology.

Linkage studies start with families with well-characterized phenotypes such as asthma. Genes within families are examined for linkage, the sharing of genes markers that may be located near or at the disease gene. Association studies are then used to follow-up and "fine map" the linkage peak. These studies focus on novel genes.

To date, five genes *ADAM 33*,[69] *DPP10*,[70] *PHF11*,[71] *NPSR1*,[72] and *HLA-G*,[73] have been identified by linkage and fine mapping. One gene *ORMDL3*[74] has been identified by GWAS. Two large meta-analyses of asthma GWAS have been conducted in European and ethnically diverse US populations,[75,76] with surprising consistency in results. In both of these studies, SNPs at or near four loci achieved genome-wide levels of significance in their *p*-values: the 17q21 locus (*ORMDL3/GSDML*), the *IL1RL1/IL18R1* locus, *TSLP*, and *IL33*.

ENVIRONMENTAL RISK FACTORS

Below we present some of the most important environmental risk factors for the development or exacerbation of asthma not discussed earlier.

PERINATAL FACTORS

Prematurity carries an increased risk for the development of asthma. A recent review and meta-analysis showed that infants born at less than 37 weeks' gestation are at greater risk for developing asthma than term infants.[77] Prematurity also is associated with bronchopulmonary dysplasia,[78] a disease characterized by increased airway responsiveness and asthma symptoms. Some investigators have found that low birth weight independent of prematurity has been associated with asthma risk.[79,80] The strength of the association between prematurity and/or low birth weight on asthma or asthma symptoms appears be greatest in very young children, but the effects decrease over time.[81,82] Note that blacks have higher rates of prematurity than whites; thus, prematurity may contribute to racial differences in asthma prevalence and morbidity. Young maternal age (i.e., <20 years) has not been shown to have a consistent independent association with the development of asthma. Despite much research, there is no conclusive evidence that breastfeeding influences atopic sensitization or the development of asthma.[83,84]

Recent studies have focused on maternal diet during pregnancy and its effect on the development of asthma and allergies, with the hypothesis that nutritional deficiency or excess may lead to programming of the fetus for adult disease.[85] These studies have mostly used nutrient intake estimates derived from food frequency questionnaires that assess how often a particular standard serving of a food or drink is eaten. The responses to the questionnaire, in conjunction with a database of nutrient composition of foods, are then used to calculate the amount of a particular nutrient over a specified time period.[86] A few studies have measured the particular nutrient in either maternal or cord blood samples. A meta-analysis found that there was weak support for protective effects of higher maternal intakes of vitamin A, E, and zinc for the prevention of asthma in children.[87]

VITAMIN D

In the strict sense of the word, vitamin D is not a vitamin, since humans are able to produce the compound in the skin upon exposure to the UVA rays from the sun. While the first report of an effect of vitamin D on asthma and allergies appeared in 1934,[88] research into the effects of vitamin D did not begin in earnest until the last decade. There are two opposing hypotheses regarding the role of vitamin D in asthma. Wjst and Dold[89] suggested that fortification of food with vitamin D and the widespread use of multivitamins in childhood contributed to the rise in asthma and allergies. On the other hand, given the documented decrease in the levels of the circulating form of vitamin D in population studies,[90] Litonjua and Weiss hypothesized that the increasing prevalence of vitamin D deficiency led to the increase in asthma prevalence worldwide.[91]

With regard to the development of asthma and allergies, four cohort studies have reported beneficial effects of a higher maternal intake of vitamin D in pregnancy on outcomes in their children.[92–95] However, other studies have not replicated these findings.[96–99] More consistent results have been found with regard to the role of vitamin D in disease severity or treatment. These studies have shown that asthmatics with higher circulating vitamin D levels have greater lung function,[100,101] lower risks for exacerbations,[102,103] and generally more severe indices of disease.[104] Clinical trials of vitamin D supplementation to prevent asthma development and to prevent exacerbations are ongoing.

INDOOR AND OUTDOOR ALLERGENS

Indoor allergen sources include animals (cats, dogs, rodents), insects (mites, cockroaches), and fungi. Allergens are well-known precipitants of asthma exacerbations and increased morbidity.[105,106] There has been some recent investigation as to whether exposure to pets early in life would be useful in preventing asthma,[107–109] but a recent pooled analysis of 11 European birth cohorts did not find any effect of pet ownership on asthma and allergic rhinitis in school age children.[110] It is noteworthy that animal allergens, particularly cat allergen, can be found in settled dust and in circulating air in homes, school classrooms, and other buildings that never housed a cat.[111–113]

House dust mites are ubiquitous in all but very dry climates and exposure and sensitization to mite body and fecal allergens is associated with asthma.[65,66] Mites infest fabrics, including mattresses, bedding, floor coverings, and upholstered furniture. The use of wall-to-wall carpets has increased exposure to mites. Covering mattresses and pillows with vapor-permeable fine weave materials, washing bedding in hot (>30°F) water, vacuuming weekly, and removing carpets, especially from the bedroom, reduce mite levels.[114,115]

Whether reducing exposure results in improvement in asthma outcome has been the focus of several studies,[116,117] with inconsistent results. A Cochrane meta-analysis of 54 trials using varying methods of mite-allergen reduction (physical methods, chemical methods, and a combination) concluded that there was no clinical benefit of dust mite allergen reduction.[118] Adherence to the demanding protocols for control of mite exposure is difficult and may not always result in sufficient reduction in personal aeroallergen exposure. More recent studies have focused on multifaceted intervention programs that target other environmental exposures (e.g., environmental tobacco smoke [ETS]) in addition to allergen avoidance, and may have more promise than single allergen avoidance.[119–123]

Sensitization to cockroach has been shown to be associated with the development of asthma and asthma morbidity.[106,124] Although the presence of this allergen is not limited to low-income homes, it has not been studied in more affluent settings. Removal of this allergen is difficult and more research is needed to evaluate the impact on asthma of allergen removal.[125–127]

Home, school, and workplace dampness and the presence of fungi have been associated with reports of respiratory symptoms.[128] Sensitization to molds has also been shown to be associated with greater asthma morbidity.[129]

Day care establishments may be sources of indoor allergens, including pets, insects, and fungi.[130] They also may be sources of gram-negative bacterial endotoxin and lipopolysaccharides, which induce Th1 activity and have been hypothesized to be protective against the development of allergy and asthma. However, longitudinal studies have not consistently supported this notion. A recent

study of 3963 children found no effect of early day care attendance on the development of asthma symptoms, airway hyperresponsiveness, and allergic sensitization at 8 years of age.[51]

Outdoor allergens include trees, grass, and weed pollen constituents. Susceptible individuals may have increased asthma symptoms at times of pollination.[131] For example, in the Northeast and Midwest grass pollinates in May and June and ragweed in late August and September. Pollens most closely linked to exacerbations of asthma in at-risk individuals are trees such as birch, oak, and Western red cedar; grasses; and ragweed. A recent study, however, suggests that asthmatics react to airborne allergens regardless of their sensitization status.[132] This will require further study.

SMOKING AND ENVIRONMENTAL TOBACCO SMOKE

Maternal cigarette smoking is a major risk factor for the development of asthma in the first year of life. Both a meta-analysis[133] and a pooled analysis[134] showed that the risk of developing asthma ranges from around 40% to 85% greater among children born to mothers who smoked during pregnancy compared to children born to mothers who did not smoke. This effect appears to be strongest in children who developed asthma before 2 years of age.[133]

ETS exacerbates asthma in children of all ages.[135] Wilson and coworkers[136] evaluated a cotinine-feedback behavioral intervention administered to caregivers that successfully reduced ETS exposure and healthcare utilization by children with asthma at 1-year follow-up. However, in a follow-up study, the effect was only seen in children at highest risk for exacerbation.[137] In adults, cigarette smoking is associated with the development of airway hyperreactivity.[138] Whether this hyperreactivity represents asthma or COPD can be difficult to determine. Cigarette smoking in asthma produce a synergistic and accelerated decline in lung function.[139,140] In addition, the response to corticosteroid therapy used for asthma is reduced in active smokers.[139]

OTHER POLLUTANTS

Outdoor pollutants implicated in the development or exacerbations of asthma include ozone, sulfur dioxide, particulate matter, and components of motor vehicle exhaust.[141,142] Measuring exposure to potential pollutants is difficult and correlating exposure with symptoms and exacerbations of disease is very expensive. Most monitoring of pollutants is from fixed external stations. Sometimes proxy measures of pollutant exposure, such as traffic counts, are used. Although potentially more accurate, monitoring of personal exposures is particularly difficult and expensive.[143] Assessing which of the many possible simultaneous outdoor inhalants affects asthma morbidity is also a formidable task. Conclusions drawn from such data may be indirect. An example is the observation that asthma morbidity is highest among low-income individuals who tend to live in less desirable areas, which are frequently those with high traffic volumes and pollution.

There has been much interest in indoor environmental pollutants, such as nitrogen dioxide, sulfur dioxide, volatile organic compounds, and particulate matter, and their possible association with asthma, particularly in inner city homes.[144,145] As with studies of outdoor pollution difficulties in measurement over time, controlling for other exposures such as allergens, infectious agents, and social determinants of health, while linking exposures to symptoms and physical findings makes research challenging.

RACE/ETHNICITY AND SOCIOECONOMIC STATUS

As discussed at the beginning of this chapter, asthma prevalence and especially morbidity and mortality are higher in blacks than whites. Whether these racial differences in asthma prevalence, hospitalization, and mortality are solely due to inadequate treatment and access to medical care remains unclear, but there is indisputable evidence of unequal treatment of minority and low-income groups by health professionals.[146] In addition, environmental factors that are the products of poverty, such as urban crowding, exposure to tobacco smoke or other pollutants or allergens contribute to these findings.[147] A recent line of research to explain some of the racial and socioeconomic disparities in asthma has focused on the effect of stress and violence in the pathogenesis of asthma and morbidity related to asthma.[148,149] These studies have shown that exposure to stress or violence is related to asthma in children, even after adjusting for socioeconomic status.

There is much current debate about the relative importance of social and genetic effects and/or gene–environment interactions that might account for the health disparity seen in asthma and other diseases. In most studies race and ethnicity are not well defined and socioeconomic factors tend to be inseparably linked to ethnicity and race. Perceptions of a person's race influence social experiences including those with the health system. In a recent survey, black and Hispanic women were more likely to report a doctor's diagnosis of asthma and less likely to report a diagnosis of hay fever or eczema. However, these women had higher mean total IgE levels and were more likely to be sensitized to aeroallergens.[150] The investigators concluded that these findings could represent either underdiagnosis by medical personnel (e.g., fewer referrals to an allergist or other specialist) or underreporting of symptoms by patients. They also concluded that it was unlikely that genetics alone could explain the differences in sensitization and that these differences more likely were related to differences in housing and community environmental exposures.

As our cultural and ethnic diversity increases, communication between patient and healthcare provider becomes more complicated and miscommunication more likely. In addition, prior experiences of discrimination or perceived discrimination contribute to distrust of the health system.[151,152] These may result in mistrust of the medical advice, or refusal of treatment and poor adherence and thus contribute to health disparities. One study found patients' beliefs in the risks over the benefits of inhaled steroids to be associated with lower adherence.[153] In focus groups, blacks with moderate or severe asthma who reported their adherence was influenced by reliance on their own assessment of asthma control over that of the health provider. They expressed concern about adverse effects of inhaled steroid therapy and several had misperceptions of their risks. Such misperceptions can be addressed in the patient–provider encounter. Adherence was also adversely affected by the cost of the medication or its copay and insurers' approval policies and restricted formularies.

OBESITY

Obesity has reached epidemic proportions in the United States and has been related to asthma in cross-sectional and longitudinal studies. A number of mechanisms for this relationship have been proposed.[154,155] Some of these mechanisms may begin early in life to confer risk for both disorders.[156,157] A mechanical effect is postulated to be the result of decreased tidal volume and decreased functional residual capacity leading to reduced ability of the smooth muscles to stretch and thus respond to changes in respiration with exercise. Obesity enhances gastroesophageal reflux, a condition associated with asthma. Immune effects also have been postulated. For example, certain inflammatory cytokines such as tumor necrosis factor-α (TNF-α) and IL-6 are expressed by adipocytes. TNF expression is increased in asthma exacerbations and may have a role in amplifying the inflammatory response of asthma. IL-6 stimulates a Th1 response, which may contribute to the inflammation of severe asthma. Leptin, a product of adipocytes, is a member of the IL-6 cytokine family. Whether or not leptin plays a role in asthma is unknown. Because asthma in adults is more common in women and because estrogen is increased in obesity, estrogen has been hypothesized to play a role in a link between asthma and obesity but no such role has been demonstrated.

Since asthma and obesity are both complex diseases, it is possible that some genetic susceptibilities are shared (pleiotropy).[157] There is some evidence for this in that there are regions of the human genome important for both asthma and obesity, such as chromosome 6p, which contains the gene for TNF. Alternatively, it is possible that obesity is related to asthma as an epiphenomenon; that is, there are shared lifestyle or social exposures, for example, physical exercise or diet, that influence both obesity and asthma. Obesity is more prevalent in the same socioeconomic groups in which asthma is more prevalent. No randomized interventional studies have been completed showing that weight reduction ameliorates asthma. Clearly, more research is needed.

■ ACETAMINOPHEN

It has been postulated that acetaminophen use may increase the risk of developing asthma due to its pro-oxidant effects (by depletion of the antioxidant glutathione in lung tissue).[158] Several studies have reported on the association of acetaminophen use, either in pregnancy, in early life, and in adulthood, and the development of asthma.[159–162] However, the issue with studies that investigate over-the-counter medications such as acetaminophen is the possibility of confounding by indication, meaning that these individuals have comorbidities (e.g., respiratory infections) for which they may take the acetaminophen for its antipyretic or analgesic effects. To address this, investigators of the Melbourne Atopy Cohort Study found that when they adjusted for the frequency of respiratory infections, the association between acetaminophen use and asthma at age 6 or 7 years disappeared.[163] Therefore, while more studies need to be done, it is not likely that taking acetaminophen in usual doses is a cause of asthma.

■ RESPIRATORY ILLNESS

Many epidemiologic studies have shown a prominent association between lower respiratory tract viral infections and wheezing illnesses in infancy and increased risk of chronic childhood asthma.[164,165] Respiratory syncytial virus (RSV) has drawn particular attention, since it is the major cause of bronchiolitis in children and RSV infection is associated with IgE production, airway inflammation, and increased airway responsiveness. Human rhinoviruses (HRVs) which are a more common cause of upper and lower respiratory infections than RSV, may also cause bronchiolitis,[166] and have also been associated with asthma onset.[167] This is particularly true of the newly identified type C rhinoviruses. Respiratory tract infections by parainfluenza viruses, influenza virus, and human metapneumovirus during infancy are all associated with childhood wheezing.

It is hypothesized that susceptibility to asthma associated with viral infection in early life results from the interaction of developmental, genetic, and environmental factors. Developmentally, infancy is a time of pulmonary alveolarization and a time when the immune system has not reached full maturity. Several studies have now documented the synergy of allergen sensitization and respiratory infections in the risk for developing asthma. Kusel et al.[168] showed that among sensitized children, the risk for developing asthma by the age of 6 years was almost double that of children who were not sensitized. Jackson and colleagues[167] showed that while HRV was the dominant factor in developing asthma by the age of 6 years, the risk was highest when concomitant allergen sensitization was present.

Atopic status and airway hyperresponsiveness may be important genetically determined characteristics that influence whether RSV, HRV, or other respiratory viral infections increase the risk of developing asthma. Most children who wheezed only during the first 2 years of life had lower levels of lung function when evaluated at the age of 2 and 6 years. In contrast, children who wheezed early in life and who were still wheezing at the age of 6 years had normal lung function, but statistically elevated serum total IgE levels when studied during the first year of life. When restudied at the age of 6 years, they had elevated IgE, but lung function had deteriorated and was below that of individuals who had never wheezed.[45] This has led to the hypothesis that there are two wheezing syndromes associated with lower respiratory tract infection in young children. One occurs in children with small airway caliber who lack airway hyperresponsiveness, and have excellent prognosis. The other syndrome, which represents early-onset asthma, is associated with increased prevalence of allergic markers, bronchial hyperreactivity, and a significant decrease in lung function over the first 6 years of life.

Viral respiratory illnesses trigger asthmatic exacerbations. A number of studies have demonstrated a close temporal relationship at the individual and population levels, between virus infection and asthma exacerbations. These studies have also demonstrated that (1) asthmatics may be more susceptible than normal subjects to viral lower respiratory infections;[169–171] for example, in a surveillance study of 5.3 million children aged 17 years or younger during the 2003 to 2009 influenza seasons and the 2009 pandemic, Dawood and colleagues[170] found that 32% and 44%, respectively, of the children hospitalized had asthma; (2) in contrast to viral infections, bacterial infections are not associated with asthmatic exacerbations, although agents such as *Mycoplasma* and *Chlamydia* may be involved with persistence of asthma;[172] (3) viruses precipitate a high percentage of severe (vs. mild) asthmatic exacerbations; during the 2009 influenza pandemic, a greater proportion of asthmatics required intensive care;[170] and (4) viral infections can induce nonspecific increases in airway responsiveness and airway obstruction.[173–175]

PROGNOSIS

The prognosis of asthma in early childhood has been clarified substantially by data from the Tucson Children's Respiratory Study.[45,46] These investigators followed a cohort of children through the first 6 years of life. They characterized four groups of children: "persistent wheezers," who wheezed both before and after the age of 3 years; "transient early wheezers," who wheezed before the age of 3 years and then stopped; "transient late wheezers," who wheezed after the age of 3 years but not before; and "never wheezers." Totally 40% of all children in the Tucson Children's Respiratory Study cohort wheezed in the first year of life.

Significant predictors of persistent wheezing, and hence children at greatest risk for developing chronic asthma were young maternal age, IgE level at 9 months, parents with asthma, maternal cigarette smoke exposure in utero, abnormal lung function at birth, and male gender. It is likely that early-life wheezing is predominantly a mechanical factor and less due to severe and chronic airway inflammation. It also seems unlikely that allergen exposure predominates as a factor in early childhood.

The characteristics of older children who wheeze are atopy, female gender, and active and passive cigarette smoking. By preadolescence, atopy and environmental allergen exposure are important risk factors for wheezing in children.

In roughly half of all childhood asthmatics, symptoms decrease or disappear by late adolescence and early adulthood. Characteristics that suggest a good prognosis include male gender, precipitation of attacks by viral respiratory illness, and children with airway parenchymal desynapsis (i.e., large lungs but small airways). These children are predominantly male, and, although often atopic, still are likely to outgrow their asthma. In a longitudinal study of children from East Boston, initially 5 to 9 years of age followed over a 13-year period, the effect of asthma on lung growth was different for boys than girls.[176] Boys with asthma had larger growth in vital capacity than boys without asthma and tended to have mild disease. This was associated with fewer hospitalizations for asthma, despite somewhat greater prevalence than in girls. Asthmatic girls, however, had persistent reductions in FEV_1 and were more likely to be hospitalized

for asthma, despite an initially reduced prevalence relative to the boys. These data are consistent with asthma being milder in boys in that the boys are more likely to "outgrow" their asthma. In contrast, the Childhood Asthma Management Program (CAMP) followed lung function of 1041 children (420 girls and 621 boys) with mild to moderate persistent asthma, who participated in a clinical trial of asthma treatment.[177] The authors used lung function data of 5415 nonasthmatic children from the Harvard Six Cities Study for comparison. In children of both sexes aged 6 to 18 years, the FEV_1/FVC ratio was significantly lower and FVC was significantly higher for asthmatic children, compared to nonasthmatic children. In contrast to the East Boston study, boys had lower FEV_1 between the ages of 10 to 18, whereas there were no significant differences in girls. Taken together, these studies suggest that asthma that starts in early life (i.e., by the age of 6 years) leads to decrements in lung function that are persistent through adolescence. These patterns have been borne out in other longitudinal studies (reviewed by Grad and Morgan[178]).

In both adolescents and adults, airway responsiveness predicts the development of asthma[12–16] and antedates and predicts accelerated decline in lung function.[179,180] Both persistent symptoms[181] and active smoking[140] conferred more rapid rates of lung function decline in longitudinal studies. The severity of adult asthma is clearly predicted by the severity of childhood asthma, and the persistence of symptoms in childhood and early adulthood is associated with reduced lung function and more severe disease later in adult life.

IMPLICATIONS OF CURRENT TRENDS IN PREVALENCE, MORBIDITY, HOSPITALIZATIONS, AND MORTALITY

Although prevalence, morbidity, and hospitalizations have remained stable recently, these absolute levels remain unacceptably high, particularly for certain minority groups and low-income populations. Risk factors such as obesity, prematurity, young maternal age, and cigarette smoking are all associated with these same patient groups, speaking about social and healthcare disparities. There are many vulnerable groups for which no data on asthma prevalence and morbidity yet exist. Certainly, genetic differences exist from patient to patient. These differences must be better characterized. Understanding the influence of gene–gene and gene–environment interactions is crucial. Gene–environmental interactions must be carefully studied for all exposures, and particularly for the exposure of socioeconomic status and cultural groups.

CHAPTER 46

Asthma: Clinical Presentation and Management

Omar S. Usmani
Peter J. Barnes

ASTHMA—A HETEROGENEOUS DISEASE

Asthma is a chronic inflammatory disorder of the airways characterized by marked variability in airflow obstruction that is often reversible, either spontaneously or with treatment.[1] This inflammation presents clinically in susceptible patients with recurrent symptoms of wheezing, chest tightness, cough, and, occasionally, dyspnea and contributes to the heightened airway hyperresponsiveness to specific and nonspecific stimuli; a pathognomonic feature of asthma. Increased airway hyperresponsiveness manifests in patients as intolerance to smoke, dust, air pollution, and strong odors, where exposure to such agents in healthy individuals does not induce such symptoms. Asthma is not a single disease entity with a unique pathogenesis, but rather recognized to be a clinical syndrome and heterogeneous disease;[2] that is, asthma comprises multiple endotypes that manifest common symptoms, but have distinct and probably different pathophysiologic and etiologic mechanisms with an interplay between genetic and environmental factors. This phenotypic heterogeneity in the expression of asthma is multidimensional and includes variability in pathologic, clinical, and physiologic parameters among different patients.[3]

RISK FACTORS FOR ASTHMA

Several risk factors for asthma are considered below.

■ ATOPY AND ALLERGENS

The most important factor predisposing to asthma is atopy (Table 46-1). Asthma has been classified as *atopic* (extrinsic) *or nonatopic* (intrinsic) depending on the suspected role of allergens as etiologic factors. Atopic asthma involves an exaggerated immune response characterized by immunoglobulin E (Ig-E) activation and mast cell degradation. Atopy can be clinically elicited with a positive skin prick test or specific antibodies to IgE in serum against common aeroallergens such as house dust mite, grass and tree pollens, cat and dog fur, rodents (in laboratory workers), and cockroaches (in inner city populations). House dust mite is recognized as a significant cause of asthma throughout the developed world, although the relative importance of different indoor allergens may vary among populations. Patients with atopic asthma commonly suffer

TABLE 46-1 Risk Factors and Triggers Involved in Asthma

Endogenous Factors	Environmental Factors	Triggers
Atopy	Allergens–indoor	Allergens (especially house dust mite, animal dander, cockroach, indoor fungi, perennial allergens, and seasonal pollens)
Airway hyperresponsiveness	Allergens–outdoor (fungi, pollens)	Changes in the weather (cold air, thunderstorms)
Ethnicity	Obesity	Drugs (angiotensin-converting enzyme inhibitors, aspirin, β-blockers, NSAIDs)
Gender	Occupational sensitizers	Exercise and hyperventilation
Genetic predisposition	Parasitic infections	Extreme emotional expression (laughing, stress)
	Respiratory infections (early childhood, viral)	Irritants (household sprays, paint fumes)
	Socioeconomic status	Respiratory infections
	Tobacco smoking (active and passive)	Sulfur dioxide and pollutant gases
		Tobacco smoking

from other atopic diseases, including allergic rhinitis that may be seasonal (hayfever), and may be found in over 80% of asthmatic patients; allergic conjunctivitis; and atopic dermatitis (eczema). Nonatopic asthmatic patients (approximately 10%) have a negative skin prick test, normal serum IgE concentrations, and usually show later onset of disease (adult-onset asthma). In this group, their asthma is more severe, persistent, there is more sensitivity to aspirin and commonly they have concomitant nasal polyps. This classification, although appropriate from a pathologic perspective, does not readily help clinicians as it does not aid in establishing an etiologic diagnosis nor does it help in defining treatment strategies.[4] There is a high prevalence of atopy among nonasthmatics and a large percentage of skin prick sensitive persons report no allergic symptoms. Around 50% of asthma can be attributed to atopy in the developed world and the prevalence of atopy among asthmatics is mainly determined by the general prevalence of atopy in the population.[5,6] In addition, the immunopathology in bronchial biopsies and sputum in patients with nonatopic asthma appear to be identical to that found in atopic asthmatic patients. Therefore, the finding that an asthmatic is atopic does not imply that the disease is allergic in nature or, that atopy is causing asthma. Moreover, respiratory tract viruses have emerged as the most frequent triggers for exacerbations in both children and adults and may play a more prominent role than allergens as triggers of acute exacerbations in most patients.[7] House dust mites are the most common indoor allergen, where particles excreted from the digestive tract contain the principal allergen *Dermatophagoides pteronyssinus*. Other main sources of inhaled indoor allergen are cat and dog fur, and cockroaches (Table 46-1). Although asthmatic symptoms often improve when the allergen is removed, rigorous allergen avoidance has not shown any evidence for a reduced risk of developing asthma.

Although allergens are often triggers of acute exacerbations of asthma, allergens themselves may induce subclinical airway inflammation that may lead to enhanced airway responsiveness and greater susceptibility to the provocative effects of other triggers such as respiratory viral infections and exercise. In this regard, it is important to understand the distinction between triggers and etiologic risk factors. A trigger is any agent capable of inducing or exacerbating asthma and whereas triggers may lead to symptoms, they do so only in susceptible persons who already possess the underlying asthmatic diathesis.

VIRAL INFECTIONS

Acute upper respiratory tract viral infections are the commonest triggers of exacerbations of asthma and most are due to rhinovirus infections. Viral infections not only give symptoms of the common cold and cause acute inflammatory rhinitis, but may also play a role in asthma development and potentially, airway remodeling through increasing inflammation in the lower airways.[8] Asthma is recognized to be more common in children who have had croup or lower respiratory tract infections in early life, although viral infections in the absence of atopy do not appear to be risk factors for the development of asthma.[9] Other viruses commonly implicated in acute exacerbations of asthma are respiratory syncytial virus, influenza virus, and parainfluenza virus. Bacterial infection with species of *Mycoplasma* and *Chlamydia* are also associated with exacerbations of asthma, whereas other bacterial infections are not.

OCCUPATIONAL EXPOSURE

Occupational asthma accounts for approximately 5% of all adult cases of asthma, and the disease can often be classified according to its etiology. In these circumstances, not only is the specific agent that triggers the symptoms known, but the same agent is usually the underlying cause of asthma.

EXERCISE-INDUCED ASTHMA

Many asthma patients have worsening of symptoms on or after physical exercise and another category of asthma is exercise-induced, where exercise per se is not the cause of, but rather one of many nonimmunologic triggers that produce symptoms in patients who already have the disease. In this condition, the trigger is thought to be the drying of the airway mucosa as a result of hyperventilation that leads to osmotically induced mast cell mediator release and bronchospasm.

OBESITY

Obesity is a major risk factor for asthma where abdominal obesity (waist circumference) and general obesity (BMI) both show a strong correlation with the risk of new-onset asthma.[10]

DRUGS

Drugs that may worsen asthma control include β-blockers, occasionally angiotensin-converting enzyme (ACE) inhibitors, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs).

CLINICAL PRESENTATION AND DIAGNOSIS

Asthma is a clinical diagnosis made on the basis of a medical history of typical symptoms, consideration to provocative factors, and supported with objective confirmation of variable airflow obstruction. As the disease is heterogeneous in its presentation and severity, the clinical features of asthma show great variability both between individual asthmatics, and also within the same patient over time. It is also important to recognize that asthma is often associated with different comorbidities including allergic rhinitis, atopic dermatitis, rhinosinusitis, gastroesophageal reflux disease, diabetes, depression, obesity, all of which may affect the clinical expression and severity of the disease.[11] The following clinical features and laboratory assessments are important in the consideration of the diagnosis of asthma.

MEDICAL HISTORY

The typical symptoms of asthma are paroxysmal wheezing, cough, breathlessness, and chest tightness, which may temporally be related to exposure to triggers or exercise. Cough may be productive of clear or yellow/green discolored sputum, where the latter may be tenacious and difficult to expectorate and reflect the underlying airway inflammation rather than a respiratory infection. Indeed, cough may be present in isolation to other symptoms and as the sole manifestation of an episode of asthma.[12] Breathlessness may occur as a result of the dynamic lung hyperinflation that accompanies acute asthma episodes and patients may report the sensation of difficulty in "getting air in" their lungs. Exertional symptoms may not be apparent if the patient's ability to exert themselves is limited by other health conditions such as rheumatologic or cardiac disease and, therefore, asthma may be underdiagnosed in the elderly. No single symptom is specific or more significant for asthma, although wheezing is a useful sign, as nonasthmatics rarely report frequent wheezing. In younger patients, the symptom of chest tightness is helpful, since it occurs more often in association with asthma than with other pulmonary or cardiac disorders. The pattern of symptom occurrence, the precipitating or aggravating factors, and the profile of a typical exacerbation are important elements in the clinical evaluation.

In patients with poorly controlled asthma, symptoms may temporally evolve slowly over days or weeks, or present abruptly. The severity and frequency with which symptoms occur varies greatly within the asthmatic population. The recurrent paroxysmal nature of symptom presentation is characteristic of asthma and symptoms improve, sometimes rather spontaneously, although usually with treatment. Nocturnal episodes are common in adult asthmatics and typically patients awake in the early hours of the morning with symptoms.

Distinguishing whether nocturnal symptoms are due to asthma, angina, or gastroesophageal reflux may be difficult, but early-morning asthma symptoms are usually relieved with administration of inhaled bronchodilators, in contrast to cardiovascular symptoms which occur at any time during the night and, gastroesophageal reflux which tends to usually cause symptoms soon after the patient reclines at night.

Chest symptoms that vary by season and are accompanied by symptoms of irritation of other mucus membranes, such as conjunctivitis and rhinitis, are typical of allergic asthma. Triggers such as indoor allergens of house dust mite, cockroach, and animal dander proteins are more likely to result in perennial symptoms, whereas pollens and some mold spores are likely to provoke seasonal symptoms. The presence of rhinosinusitis, nasal polyps, conjunctivitis, or eczema, coupled with a family history of asthma or atopy, may further support the diagnosis of asthma. Symptoms after heavy exertion, especially in the cold air, are highly suggestive of exercise-induced asthma and typically, patients experience symptoms at the end of exercise, rather than during its performance. Excessive coughing after exercise in the absence of wheeze may also be a sign of asthma. Premenopausal women with asthma may experience a deterioration of asthma control perimenstrually.[13] The medical history should elicit risk factors for asthma (Table 46-1), and special consideration should address symptoms induced by aspirin or those associated with the patient's occupation.

■ ASTHMA AND ASPIRIN SENSITIVITY

The association of asthma and sensitivity to aspirin or other NSAIDs is well established.[14] Aspirin-sensitive asthma affects approximately 5% of all asthmatics, although it is more common in patients with severe asthma (~20%) and in those frequently hospitalized for their asthma. This subtype of asthma is usually characterized by a tetrad of asthma, nasal polyps, chronic hypertrophic eosinophilic sinusitis, and aspirin intolerance. Classically, perennial rhinitis is the first symptom in this syndrome, preceding the development of aspirin sensitivity, and then followed much later by nasal polyps that are usually bilateral and originate from the turbinates and the paranasal sinuses. Even in small doses, aspirin typically causes wheezing, facial flushing, rhinorrhea, and conjunctival irritation. Although aspirin-induced asthmatic episodes often resemble allergic reactions, there is no evidence that immunolglobulin (Ig)-E–related mechanisms are at work. Aspirin-induced asthma is due to blockade of cyclooxygenase 1 by nonsteroidal anti-inflammatory drugs and has been associated with enhanced leukotriene production and mast cell activation, but the cellular pathways responsible for these events remain unclear. The diagnosis of aspirin sensitivity is made on the basis of the clinical history and can be confirmed by a provocative aspirin challenge, although this test carries a potential health risk of anaphylaxis for the patient.

Aspirin-sensitive asthma usually responds to standard therapy with inhaled corticosteroids (ICSs), although the condition is associated with severe asthma, who are a group of patients often refractory to treatment with inhaled and oral CS. Potentially, antileukotriene therapy should be efficacious in these patients, but have been found to be no more effective compared to their use in patients with allergic asthma. Aspirin desensitization may sometimes be needed, and should only be performed in specialized centers. In all asthmatic patients with aspirin sensitivity, the nonselective cyclooxygenase (COX) inhibitors should be avoided, but when an anti-inflammatory analgesic is needed, the selective COX-2 inhibitors are usually safe to use.

Occupational Asthma

Occupational asthma is asthma arising de novo that is initiated as a consequence of exposure to a specific etiologic agent in people without prior asthma. In contrast, work-exacerbated asthma is defined as the worsening of asthma, that is already pre-existing or concurrent, triggered by nonspecific irritants in the workplace.[15] Occupational asthma may be classified into (i) that caused by a sensitizing agent in the workplace (sensitizer-induced asthma) where the specific sensitizing agent causes asthma through an identified underlying immunologic mechanism and (ii) asthma caused by exposure to irritant compounds (irritant-induced asthma) where the exposure agent is not considered to be sensitizing.[16] Table 46-2 highlights the causes of both sensitizer-induced occupational asthma and the common agents responsible for irritant-induced occupational asthma. The diagnosis of occupational asthma is based on a demonstrable link between asthma symptoms and workplace exposure, showing work-related variability in measurements of lung function made serially.[16] Classically, a typical history of asthma-like symptoms during the working week and improvement over the weekend or on vacation are elicited and symptoms may occur either during exposure to the etiologic substance, or they may be delayed until the evening or night after the work day. Early detection and avoidance of occupational asthma is important where, if the patient is removed from exposure within the first 6 months of symptoms, there is usually complete recovery.

TABLE 46-2 Causes of Occupational Asthma

Sensitizing Agent-Induced Asthma	
Agent	**Workers at Risk**
Acrylate	Dental workers; adhesive handlers
Anhydrides	Workers using epoxy resin for plastics
Animal protein allergens	Veterinary workers; animal handlers
Cereals (grains)	Bakery workers; grain workers; farmers
Dyes	Textile workers
Enzymes	Pharmaceutical workers; bakery workers; laboratory workers
Formaldehyde, glutaraldehyde	Hospital and healthcare workers
Gums	Carpet makers
Isocyanates	Installers of insulation; manufacturers of plastics; rubbers and foam; spray painters
Latex	Healthcare workers; rubber workers
Persulfate	Hairdressers
Seafoods	Seafood handlers and processors
Wood dusts	Forestry workers; sawmill workers; carpenters

Common Agents Responsible for Irritant-Induced Asthma
Acids (acetic, hydrochloric, sulfuric)
Alkaline dust
Ammonia
Bleach
Chlorine
Cleaning agents
Diesel exhaust
Endotoxins
Formalin
Mustard
Oxide (calcium)
Paints (heated)

■ PHYSICAL EXAMINATION

The most typical physical finding in asthma is wheezing on auscultation, which is usually caused by turbulent airflow through narrowed

airways. Wheezing may be heard throughout the chest and is classically polyphonic, present to a greater extent during expiration, although it may also be heard during inspiration. The quality and character of wheezing is not specific to asthma or to the severity of the underlying disease. There may be no abnormal physical findings when asthma is under control yet conversely, in cases of very severe airway obstruction, breath sounds and wheezing may be absent. Examination of the upper respiratory tract may reveal clinical signs of rhinitis, sinusitis, or nasal polyps.

During an acute exacerbation of disease, physical signs of increased ventilation may be observed with the use of accessory muscles of respiration and chest signs of hyperinflation. A sign of severe airway obstruction is pulsus paradoxus, which is the exaggerated decrease in systolic blood pressure during inspiration by >10 mm Hg. As ventilatory effort can be diminished with respiratory muscle fatigue, pulsus paradoxus may be absent, but its absence does not preclude severe airway obstruction. Stridor is a high-pitched inspiratory sound and indicates airflow turbulence in the upper airways. In the acute setting, stridor should prompt a review of causes such as epiglottitis or foreign body, and in chronic presentation conditions such as upper airway tumors, tracheal–bronchial stenosis, vocal cord dysfunction/paralysis, and airway narrowing due to thyroid enlargement should be excluded.

LABORATORY INVESTIGATION

The diagnosis of asthma is usually apparent from the medical history with symptoms of variable and intermittent airway obstruction and objective measurements of lung function and spirometry support the diagnostic process. Similarly, the clinical history provides relevant information regarding the relationship between symptoms and allergen exposure, but skin prick testing and serology may be useful in identifying specific allergic triggers of asthma. Radiologic examination of the thorax, blood tests, and body plethysmography are not routinely indicated, unless there is some uncertainty in the diagnosis, where these tests may be used to exclude other conditions that may mimic asthma or complicate its clinical presentation.

LUNG FUNCTION TESTS

Peak flow meters are portable devices, readily available for patient use, that measure the peak expiratory flow (PEF). Serial readings of PEF that vary by more than 20% either spontaneously or in response to treatment are supportive of a diagnosis of asthma. Twice-daily PEF measurements, morning and evening, may also demonstrate diurnal variation, which is a typical feature of asthmatic patients.

Spirometry measures the expiratory volume and flow of air using forced maneuvers from full lung inflation, as a function of time. Simple spirometry is important for objectively demonstrating airflow obstruction, confirming the diagnosis of asthma, establishing the severity of the disease, and monitoring the response to therapy. Patients with asthma typically show a reduced forced expiratory flow in 1 second (FEV_1), reduced PEF, preserved forced vital capacity (FVC), and an FEV_1/FVC ratio of 0.7 or greater, but with worsening disease, FEV_1 less than 60% predicted the FEV_1/FVC ratio is more usually <0.7.[17] Home PEF monitoring may be of diagnostic use, confirming the diurnal variations in airflow obstruction, especially in patients who demonstrate normal spirometry during clinic visits. Spirometry also allows the assessment of the flow–volume loop, which shows a reduced maximum expiratory flow.

Bronchodilator reversibility is a measure of the magnitude of airway smooth muscle relaxation. A postbronchodilator increase in FEV_1 of >12% and 200 mL is often considered evidence of reversible airway obstruction, where measures are taken 15 minutes after an inhaled short-acting β_2-agonist (SABA). However, this level of increase is arbitrary and lacks sensitivity or specificity for detecting asthma. In addition, bronchodilator reversibility is diminished in well-controlled asthmatic patients, so it is not a good measure of asthma severity or response to therapy. In some patients, bronchodilator reversibility may be demonstrated by a 2- to 4-week trial of oral corticosteroids (prednisone or prednisolone 30–40 mg daily). Bronchodilator reversibility may also occur in patients with chronic obstructive pulmonary disease (COPD), and although asthma and COPD are distinct diseases, an "overlap syndrome" is described between the two conditions.[18–20]

BODY PLETHYSMOGRAPHY

Whole-body plethysmography is rarely required to establish a diagnosis of asthma in family practice, but may help in patients where there is diagnostic uncertainty. In stable asthma, measurement of the lung volumes may reveal an increase in residual volume, which reflects airway closure at a lung volume that is higher than normal. Air trapping is typically seen in patients with severe asthma. Airway resistance is characteristically increased and, during acute episodes of disease exacerbation, functional residual capacity and total lung capacity may also be observed to be increased. Measurement of the diffusing capacity of the lung (D_{LCO}) may also differentiate patients with COPD from those with asthma. In stable asthma, D_{LCO} is usually normal, but there may be a small increase in some patients. In contrast, patients with COPD typically have a reduced D_{LCO}, which reflects alveolar septal destruction and loss of pulmonary capillary volume—characteristic features of emphysematous patients.

BRONCHIAL CHALLENGE TESTING

Assessing bronchial hyperresponsiveness (BHR) is a sensitive tool that, although not routinely undertaken in clinical practice, may be helpful in diagnosing asthma, particularly when there is diagnostic uncertainty in the context of normal pulmonary function tests and unexplained chest symptoms (see Chapter 33).[21] Bronchial challenge tests assess the abnormally increased airway hyperresponsiveness observed in patients with asthma, by detecting the exaggerated response to inhaled bronchoprovocative agents. The provocation agents can be classified into two categories: direct and indirect. Direct stimuli such as histamine and methacholine, which are normally used in the clinic, act on airway smooth muscle receptors, whereas indirect stimuli act through intermediate pathways that include the release of mast cell mediators, and/or through local and central neurologic reflexes. Indirect stimuli include adenosine monophosphate (AMP), mannitol, exercise, hypertonic saline, and isocapnic hyperventilation.

Increased BHR is typically defined as the inhaled concentration of the bronchoprovocative agent that reduces FEV_1 by 20% (PC_{20}). This criterion for the test has maximal sensitivity but not maximal specificity and thus, when a diagnostic PC_{20} threshold of ≤8 mg/mL is used, pharmacologic challenges are sensitive tests with a high negative predictive value, that is, a PC_{20} >8 mg/mL excludes a diagnosis of asthma with a high degree of accuracy. Similarly, a positive result, although consistent with is not diagnostic for asthma. False-negative results can be obtained in patients who experience only intermittent symptoms and are tested when they are asymptomatic. The prevalence of abnormal responsiveness in nonatopic, nonasthmatic subjects who have no history of prior respiratory problems ranges between 5% and 10%. Knowledge of family history, personal atopy, and comorbidities clearly improves the prediction that abnormal airway responsiveness predisposes to the subsequent development of asthma.[22]

Technical factors related to the test procedure must be strictly controlled and follow standard operating procedures that include: the aerosol generation, the method of inhalation (intermittent versus continuous), and the measurement and calculation of the response. Medications such as β_2-agonists, theophylline, long-acting muscarinic antagonists, and CSs may influence the test and decrease

airway responsiveness. Measuring BHR may have additional utility in the management of asthma. Patients whose disease is considered to be clinically controlled, may still have BHR and underlying airway inflammation and studies have shown that using AHR to guide treatment with ICSs, leads to an additional improvement in symptoms, lung function, and airway biopsy findings, compared with conventional assessment.[23]

Exercise testing of patients using cycle, treadmill, or free running challenges is occasionally undertaken to show postexercise bronchoconstriction if there is a suggestive history of exercise-induced asthma.[24] In professional athletes, asthma may be both under- or overdiagnosed and objective confirmation by appropriate lung function testing with bronchodilator or exercise challenge is often needed. Allergen challenge is rarely utilized in the routine management of patients with asthma and should only be undertaken by a specialist center if a specific causative or occupational agent is to be identified, such as aspirin.

BLOOD TESTS

Blood tests are usually not helpful in establishing the diagnosis of asthma. The eosinophil count in the peripheral blood film may be raised in atopic conditions and eosinophilia may support a diagnosis of asthma; however, a normal level does not rule out atopy or exclude asthma. In patients receiving CSs, eosinophilic counts may be normal or low. Because of their poor sensitivity and specificity, blood eosinophil counts are not recommended in the routine monitoring of asthma severity or as a barometer of airway inflammation. Markedly high levels may be present in disorders such as tropical parasitic eosinophilia, allergic bronchopulmonary aspergillosis (ABPA), Churg–Strauss syndrome, and Loeffler's syndrome as discussed elsewhere in this volume. In these hypereosinophilic conditions, clinical suspicion may warrant additional blood tests directed to ruling out vasculitis or ABPA, which are uncommon causes of asthma symptoms.

Total serum immunoglobulin E (IgE) may be measured in patients. Epidemiologic studies demonstrate an association between asthma and total serum IgE levels, standardized for sex and age. There is also a relationship between total serum IgE and asthma in patients with negative skin tests. Importantly, total IgE levels are used to calculate the dose of the anti-IgE antibody therapy, omalizumab, when it is used for asthma treatment as discussed below in Anti-IgE Monoclonal Antibodies. Blood tests of specific IgE to inhaled allergens, radioallergosorbent testing (RAST), and immunoCAP may help identify or confirm allergy to specific allergens, such as house dust mite, cockroach, *Aspergillus* species, pollens, or animal dander.

In acute exacerbations of disease, arterial blood gases may reveal hypoxemia and the arterial Pa_{CO_2} may be reduced due to hyperventilation. With a severe exacerbation, the arterial Pa_{CO_2} may rise due to respiratory muscle fatigue and an inability to maintain the required alveolar ventilation.

SKIN TESTS

If the clinical history suggests specific aeroallergens are important triggers or when asthma symptoms in a patient are accompanied by other symptoms typical of allergic disease, such as conjunctivitis or rhinitis, skin prick tests may be helpful to determine whether the patient is allergic, and to investigate the role of specific allergens as a cause of asthma. Sensitivity to a particular allergen such as house dust mite, cockroach, *Aspergillus* species or animal dander can be verified by skin tests or in vitro serum antibody studies (see above). Antihistamines and antidepressants should be avoided when undertaking testing as these drugs can interfere with the response. Positive responses on skin prick testing may help encourage patients to undertake allergen avoidance measures or, in selected cases, may help develop immunotherapy regimens.

CHEST IMAGING

Chest radiography is usually unremarkable and normal in patients with mild-to-moderate asthma; however, in more severe disease, nonspecific findings such as hyperinflation, prominent hilar vessels, and bronchial wall thickening may be seen. In patients with an exacerbation of their symptoms, chest radiography may be useful to exclude a pneumothorax. Consolidation shadowing in the lung usually indicates pneumonia or eosinophilic infiltrates in patients with ABPA. High-resolution computed tomography (HRCT) of the chest may identify atelectasis, bronchial wall thickening, or areas of bronchiectasis in patients with severe asthma, but these changes are not diagnostic of asthma. Emphysema is absent. Multidetector computed tomography (MDCT) undertaken in inspiration and expiration provides additional information concerning the tracheobronchial tree during the entire respiratory cycle.

EXHALED NITRIC OXIDE

The measurement of fractional nitric oxide gas in the exhaled breath (FeNO) of patients is being utilized as a noninvasive test to assess intrapulmonary eosinophilic inflammation.[25] Portable, compact hand-held devices allow FeNO measurements to be undertaken at the bedside and in family practice. Typically, asthmatic patients have elevated FeNO levels compared with healthy subjects, which correlate with the amount of eosinophils in sputum. ICSs and oral leukotriene receptor antagonists have been shown to decrease FeNO levels. These observations suggest a possible role for FeNO as an index of asthma disease severity, as a test of treatment efficacy and, in the assessment of patient adherence with asthma therapy. Measurements of FeNO have also been used successfully to titrate inhaled steroids without any loss of asthma control; thus, FeNO may be used as a tool in conjunction with other clinical measures to optimize asthma management as recommended by guidelines, that is, achieving disease control using the lowest doses of medications possible. In the research environment, FeNO can be partitioned into that arising from the central bronchial/conducting airways, or to that generated in peripheral alveolar regions, allowing an assessment of the site of intrapulmonary inflammation.[26,27] Patients with severe refractory asthma have shown greater alveolar NO concentrations compared to those with mild asthma.

SPUTUM EXAMINATION

The sputum differential count may be helpful. Induced sputum eosinophil counts have been used as an endpoint in clinical trials of therapeutic agents targeted at patients with eosinophilic lung diseases like asthma.[28] Research studies have shown sputum eosinophilia predicts clinical outcomes, particularly asthma exacerbations, when CSs are withdrawn. Induced sputum eosinophil counts have also been shown to guide anti-inflammatory treatment in patients with asthma in a management strategy that minimizes eosinophilic inflammation.[23] However, induced sputum remains a research tool as it is rather an unpleasant procedure for the patient and further studies are needed before measurement of sputum eosinophils can be widely used as a biomarker to monitor patients in clinical practice.

DIFFERENTIAL DIAGNOSIS

There are a number of conditions to consider in the differential diagnosis of asthma and these are listed in Table 46-3. Usually, it is not difficult to differentiate asthma from other conditions causing wheeze and dyspnea. The degree of diagnostic accuracy is probably dependent on the age of the patient, where the diagnosis in young adults is usually not difficult since there are few other conditions that mimic asthma or confound its clinical presentation. With increasing age, cardiovascular disease and other forms of chronic lung disease are more common, and the differential diagnosis of episodic chest symptoms is broader.

TABLE 46-3 Differential Diagnosis of Asthma

Upper Airway	Pulmonary	Cardiac	Other
Foreign body	Allergic bronchopulmonary aspergillosis (ABPA)	Angina	Anemia
Postnasal drip	Bronchiectasis	Left ventricular failure	Carcinoid
Upper airway obstruction	Churg–Strauss syndrome	Mitral valve disease	Functional
Vocal cord dysfunction	COPD		Gastroesophageal reflux
Tracheobronchomalacia	Cystic fibrosis Interstitial lung disease Lung cancer Pneumonia Pneumothorax Sarcoidosis		Hyperventilation Mastocytosis Obesity

Patients with upper airway obstruction can mimic severe asthma, and typically these patients present with localized wheeze and stridor of the large airways. Assessing the flow–volume loop in such patients will reveal a reduction in inspiratory flow as well as expiratory flow, and bronchoscopy can demonstrate the site of narrowing in the upper airways. Vocal cord dysfunction can be assessed using nasoendoscopy, which allows the observation of abnormalities in the movement of the vocal cords, and is most helpful when adduction of the cords is detected in the presence of the patient's symptoms.[29] Persistent wheezing auscultated in a localized area of the chest wall may indicate endobronchial obstruction due to lung cancer or a foreign body. Eosinophilic pneumonias and systemic vasculitis, including the Churg–Strauss syndrome and polyarteritis nodosa may be associated with wheezing and their systemic clinical manifestations may help in their identification.

COPD is usually easy to differentiate from asthma. The symptoms in patients with COPD are more persistent, show less variability, are progressive, and usually exhibit minimal reversibility to bronchodilator agents. The literature highlights an "overlap syndrome," where COPD patients have features of asthma with increased sputum eosinophils and a response to oral corticosteroids; these patients probably have both diseases concomitantly.[20] Important cardiologic causes to consider include left ventricular failure, where usually bibasal lung crackles are present in contrast to the scattered polyphonic wheeze in asthma. Anemia should always be thought of as a cause of dyspnea, especially in elderly patients. The symptoms of gastroesophageal reflux disease (GERD) may be mistaken for those of asthma; however, it is important to recognize that GERD is common in patients with asthma and has been identified as a potential trigger for asthma symptoms.[30]

TREATMENT OF ASTHMA

Treating asthmatic patients is generally straightforward; with effective and safe drugs, most asthmatics are now managed by family doctors. The successful management of asthma requires an appreciation of the heterogeneity of the disease with respect to etiology, clinical presentation, severity, natural history, and response to therapy. It is unlikely that a single management approach will work for all patients and hence, treatment should be tailored to the individual patient. It will also be recognized that symptom severity in patients varies over time with periods of remission that are interspersed with acute exacerbations, and thus the patient should be monitored regularly and treatment should be modified on an ongoing basis to meet the patient's current needs. There are several aims in the management of patients with asthma (Table 46-4) and although prominence has been placed on drug therapy, there are important patient-orientated approaches that focus on correct inhaler usage, emphasize self-management action plans, and address environmental control.

TABLE 46-4 Aims of Asthma Therapy

Control symptoms
Prevent (or minimize risk of) exacerbations
Eliminate emergency visits
Maintain lung function as close to as normal levels as possible
Decrease diurnal variation, especially nocturnal
Maintain normal levels of daily activities, including exercise
Eliminate or minimize adverse effects from medicine

INHALER DEVICES

Drug delivery to the lungs via the inhaled route remains the cornerstone of therapy for patients with asthma. Inhaled therapy targets drug directly to the lungs and allows a distinct therapeutic advantage over systemic therapy with the use of smaller drug doses, a more rapid onset of therapeutic action, and decreased adverse effects. There are several types of inhaler device and drug delivery systems used in clinical practice for the management of asthma and these include the pressurized metered-dose inhaler (pMDI), spacers, dry powder inhalers (DPIs), and nebulizers.[31] There are potentially over 250 device drug combinations available and this leads to confusion in prescribing among healthcare practitioners. Indeed, studies have shown that not just patients, but healthcare workers are uncertain about the correct use of inhaler devices and physician's knowledge, in particular, remains poor and may be related to a lack of education and instruction about inhaler usage during their training.[32] It has been shown that training and counseling patients in their inhalation technique can increase their adherence to device usage, and patients may be assessed with respect to their suitability for a particular inhaler device by using portable handheld meters that assess inhalation flows. Evidence-based guidelines from the American College of Chest Physicians,[33] recommend the following points for healthcare practitioners to consider when choosing an inhaler for their patient; the clinical condition and disease severity; availability of the inhaler device for the drug prescription; the patient's ability to use the selected device correctly; consideration given to using the same device type for all drugs; the setting and convenience of outpatient and inpatient use; the time required for drug administration; cost and reimbursement; and the inhaler preference of the patient as well as the prescriber. The advantages and disadvantage of the common inhaler device types are shown in Table 46-5.

PRESSURIZED METERED-DOSE INHALERS

The pMDIs contain the drug as a liquid suspension or solution with propellant in a sealed canister and, other formulation ingredients may be present such as ethanol, chemical preservatives, flavoring agents, and surfactant. Most inhaler therapies are now free of chlorofluorocarbon (CFC) propellants having being replaced by non–ozone-depleting propellants such as hydrofluorocarbons (HFCs). Upon actuation of the pMDI canister, there is quick vaporization of the propellant and this provides the force to aerosolize and propel the liquid drug out of the canister at high velocity. Vaporization of the

TABLE 46-5 Advantages and Disadvantages of Inhalation Devices

	Advantages	Disadvantages
Pressurized metered-dose inhaler (pMDI)	Compact and portable	High oropharyngeal deposition
	Multi-dose	Difficulty in hand–mouth coordination
	Quick treatment time	Propellants may cause "cold Freon" effect and affect climate change
	Drug in sealed canister	Difficult to assess empty canister
	Inexpensive	
Dry powder inhaler (DPI)	Compact and portable	Need adequate inhalation flow to disperse drug
	Quick treatment time	High oropharyngeal deposition
	Breath-actuated function removes need for coordination	Humidity can cause drug degradation
		Patients may be intolerant to additives, e.g., lactose
Nebulizers	Large doses of drug can be given	Bulky, cumbersome, and expensive
	Can be used with relaxed tidal breathing	Wasted drug in nebulizer reservoir
	Suitable for young, old, and acutely ill patients	Variation in aerosol output performance between models
	Many drug solutions can be aerosolized	Time consuming
		Need for power source
		Regular cleaning and maintenance

propellant also causes cooling of the drug aerosol which can sometimes give rise to the "cold Freon effect," which is the sensation experienced by some patients of cold aerosol hitting the back of their oropharynx, which can stop them from inhaling the drug and sometimes cause paradoxical bronchospasm. Some of the formulation ingredients added to pMDIs described above, have been shown to cause bronchospasm, wheeze, and cough in asthmatic patients. pMDIs are compact, portable, and inexpensive devices. Recent advances in the technologic design of pMDIs include the addition of a dose counter.

Optimal clinical efficacy with a pMDI is obtained when the device is actuated at the start of a deep and slow inhalation lasting for 5 seconds followed, at the end of inspiration, by a breath-hold pause of 10 seconds. Failure to inhale slowly and deeply with pMDIs is a more common mistake than the actual patient coordination between inhalation and actuation. However, the latter problem is more pertinent in elderly patients and add-on spacer attachments, device-holding adaptors, and breath-actuated pMDIs have been developed to overcome this. Breath-actuated metered-dose inhalers utilize the patient's inspiratory force to trigger and activate the inhaler device, although it has been shown breath-actuated pMDIs offer no advantage over patients with good conventional pMDI inhaler technique. In contrast, breath- "coordinated" devices are different from breath-"actuated" metered-dose inhalers in that they do not depend upon the patient's inspiratory flow for actuation and help patients achieve coordination with aerosol inhalation.

SPACERS

Spacer devices are used with pMDIs and are designed to assist in the delivery of inhaled drug to the lungs by promoting ease of pMDI use, and reduce oropharyngeal deposition by slowing the high velocity of the emitted aerosol cloud. The plastic walls of the spacer trap the large dug particles and this decreases oropharyngeal impaction, which may lead to a decrease in local unwanted side effects, particularly with CSs, and also a reduction in systemic adverse effects by minimizing the amount of drug absorbed via the gastrointestinal tract. In addition, increasing the distance the aerosolized drug travels (by using the spacer as an extension attachment to the pMDI device), slows the emitted aerosol cloud and allows more evaporation of the propellant, leading to relatively smaller drug particles that have a greater potential to deposit within the lungs. Spacers include valve-holding reservoir chambers with a one-way inhalation valve in the mouthpiece only allowing airflow through the chamber when the patient inhales; simple extension devices that are nonvalved add-on products that require a reasonably good amount of coordination; and reverse-flow devices where the aerosol spray is actuated away from the patient into a collapsible reservoir chamber or bag through which outside air is entrained to provide the airflow stream for inhalation.

Spacer devices each differ in their design characteristics and should be prescribed only with the pMDI they are compatible with, as each spacer–inhaler combination has distinct aerosol output characteristics.[34] To reduce the electrostatic charge in spacers which can significantly contribute to decreased drug available to be delivered to the lungs, spacers should be primed with the pMDI prior to use, and one-dose actuation at a time from a pMDI into the spacer device should be employed as opposed to simultaneous multiple-dose administrations. Spacers should be washed with ionic detergent and air dried. Antistatic spacer devices are available and can be used.

DRY POWDER INHALERS

DPIs are propellant-free devices that contain finely milled powdered drug particles bound into loose aggregates or, drug particles associated with larger carrier molecules such as lactose. DPI devices are breath-actuated in their operation, and critically rely on the patient's inspiratory effort to deaggregate the drug from its carrier particle to achieve optimal delivery and deposition within the lungs. Studies have shown that DPIs are highly dependent on the patient's inspiratory flow for therapeutic success, and have observed that patients with asthma and those with COPD use suboptimal inspiratory flows from DPIs leading to low pulmonary deposition.[35]

DPIs can be classified into single-dose delivery systems that either require drug to be individually loaded into the inhaler prior to use or where individual doses are dispensed from punctured gelatin capsules. In contrast, multiple-dosing delivery DPIs avoid the inconvenience associated with repeated drug loading and can be divided into "multi-dose" or "multi–unit-dose" systems. Multi-dose systems deliver drug that is metered from a powder reservoir, whereas multiple–unit-dose devices either contain drug sealed in individual foil blisters, or drug sealed in pockets on a moving strip. Deterioration of the drug may occur in damp and humid conditions, and so all these devices should be stored in a dry environment.

A newer generation of DPIs have been developed that rely less on the patient's inspiratory effort, requiring either lower inhalation flows to aerosolize the drug or, in some circumstances, deliver the drug wholly independent of the patient's breathing maneuver.

NEBULIZERS

The main types of nebulizer commonly used in clinical practice can be divided into two categories: ultrasonic and jet nebulizers.[36] Ultrasonic nebulizers utilize the vibration from a piezoelectric crystal at a high frequency to produce aerosol clouds for inhalation from the liquid drug. Ultrasonic nebulizers are smaller and less noisy compared to jet nebulizers, but are usually less robust, more expensive, and not as effective in nebulizing liquid suspensions of drug. Jet nebulizers use either compressed gas or an electrical compressor to generate aerosolized particles. High-velocity air streams are generated and directed through a narrow Venturi opening, across the liquid drug solution/suspension, to produce aerosolized droplets within the nebulizing chamber.

Nebulizers require tidal breathing at rest for effective use and do not require much patient coordination. However, it is recognized that there is great variation in the aerosol output generated from each of the different nebulizer devices, and the inhalation maneuver will affect drug delivery to the lungs that can be greatly reduced with crying, as may occur with children, or when there are shallow and rapid inhalations.[37] Consideration should be given to the nebulizer–facemask combination as incorrect mask insertion into the nebulizer may give rise to unwanted deposition of drug onto the face and eyes, particularly in children. Generally, nebulizer devices are large, lack portability, and have a longer treatment time than conventional inhalers.

There are now a newer generation of nebulizer devices that offer a marked improvement in the efficiency and precision of pulmonary drug delivery.[38] These devices are more costly as units compared to conventional nebulizers, but may be cost-effective by decreasing drug loss from the nebulizer chamber particularly during exhalation, and overall by delivering a reduced drug dose to the lungs but more effectively. Nebulizer systems have also been developed that control the patient's inhalation maneuver so as to minimize the variability in dose delivery that occurs during use, and there are systems that provide feedback to the patient and allow an assessment of patient compliance.

THERAPEUTIC DRUGS

A wide variety of agents are used in the management of asthma.

BRONCHODILATORS

Bronchodilators reverse the bronchoconstriction of asthma, principally by acting to relax airway smooth muscle, and this results in the rapid relief of symptoms. Bronchodilators are not adequate enough to control asthma in patients with persistent symptoms, as they have little effect on the underlying airway inflammation. The classes of bronchodilators in current clinical use include β_2-adrenergic agonists, anticholinergics, and theophylline, where β_2-agonists are the most efficacious.

β_2-Adrenergic Agonists

Inhaled β_2-adrenergic agonists are the drugs of choice for relief of respiratory symptoms due to acute airway obstruction.

Mode of Action β_2-Agonists activate β_2-adrenergic receptors resulting in an increase in intracellular cyclic AMP, which leads to relaxation of airway smooth muscle cells. β_2-Agonists act as functional antagonists; that is, they prevent and reverse the contraction of airway smooth muscle cells by bronchoconstrictors, and it is this action that mainly accounts for their efficacy as bronchodilators in asthma. These drugs also have nonbronchodilator effects that include the inhibition of mast cell mediator release, the inhibition of sensory nerve activation, and a reduction in plasma exudation, which may be clinically useful.[39]

Clinical Use SABAs, such as albuterol and terbutaline, have a rapid onset of action and a 3- to 6-hour duration of activity. This pharmacodynamic characteristic of a rapid onset of bronchodilation allows these drugs to be used as quick-relief medications or "relievers" on an as-needed basis. As a matter of caution, increasing use of SABA indicates that asthma is not controlled and patients should be reviewed. At recommended doses, inhaled β-agonists have few adverse effects, although when used at higher doses by nebulizer, patients may experience short-lived side effect. Long-acting β_2-agonists (LABAs) include formoterol and salmeterol. Both drugs are given twice daily by the inhaled route and have a duration of action of over 12 hours. In particular, formoterol has an onset of action as rapid as albuterol and can be used as a "reliever" component in fixed-dose combinations of LABA with ICS medication. LABA should not be used as monotherapy for the control of asthma of any severity and should not be given in the absence of ICS therapy as they do not control the underlying inflammation. However, fixed-dose combinations of LABA with ICS are now increasingly used in the management of asthma and have proved to be highly effective in improving the control of asthmatic patients, reducing disease exacerbations, and allowing asthma to be controlled using lower doses of CSs.[40] Studies have also shown the clinical benefits of LABA/ICS fixed combinations compared with the monocomponents administered using two separate inhalers. Interestingly, the combination of formoterol and budesonide, and recently formoterol and beclomethasone dipropionate, have been demonstrated to be effective when used as both a controller and reliever agent, and thus provides the advantage of a single device used for both purposes.[41]

Adverse Effects The commonest adverse effects of β_2-agonists are palpitations and muscle tremors, which are unusual with the inhaled route and seen more commonly with high-dose nebulizer therapy and in elderly patients. The safety of β_2-agonists has been an issue of concern. An association has been demonstrated between the amount of SABA used and asthma deaths, but thorough analyses demonstrate that the increased use of rescue SABA implies poor asthma control, which itself is a risk factor for asthma death. A slight increase in deaths from asthma has been observed with the use of LABA, but this is most likely related to the lack of use of parallel ICS, as the LABA therapy on its own fails to suppress the asthmatic airway inflammation, and this highlights the need to always use ICS when LABA are given which can most suitably be achieved by using a combination ICS/LABA inhaler.[42] Patients should also be reminded to avoid β-adrenergic receptor–blocking drugs, including those contained in topical ophthalmic preparations, as they can precipitate severe and sometimes life-threatening asthmatic episodes. Accordingly, β-blockers are contraindicated during acute asthma exacerbations and the risk–benefit ratio should be considered before they are used in stable patients with asthma. Some patients experience deterioration in their asthma control following inhaled β-agonist treatment and possible mechanisms and contributory factors include paradoxical bronchospasm, increased BHR, and tolerance to the drug. With prolonged exposure to a drug, down-regulation of the β-receptor may occur and this can limit therapeutic efficacy; that is, lead to tachyphylaxis to treatment. Indeed, β-receptor mutations and gene polymorphisms have been implicated in influencing the response to inhaled β-agonists.[43]

Anticholinergics

Anticholinergic agents are another class of drugs to be considered in asthma management.

Mode of Action Muscarinic receptor antagonists, such as ipratropium bromide, induce airway smooth-muscle relaxation by blocking

muscarinic receptors on airway smooth muscle, inhibiting vagally mediated cholinergic tone and preventing mucus secretion.[39]

Clinical Use In general, the anticholinergic drugs are not as efficacious compared to the β_2-agonists as bronchodilator agents. Anticholinergics prevent the cholinergic reflex component of bronchoconstriction, whereas in contrast, β_2-agonists inhibit all bronchoconstrictor mechanisms. Hence, anticholinergics tend only to be used as add-on bronchodilator treatment in asthmatics who remain uncontrolled on other inhaled therapy. In the treatment of acute severe asthma, high doses of anticholinergic therapy may be given by nebulizer, but should only be given following β_2-agonist treatment as anticholinergics do not have such a fast onset of bronchodilation. A combination preparation of albuterol and ipratropium bromide is available for nebulization therapy. It has recently been shown that the long-acting anticholinergic drug tiotropium may be as useful as an asthma treatment, as it is in patients with COPD, although the drug is currently not licensed for the treatment of patients with asthma.

Adverse Effects Adverse effects are usually not a concern with anticholinergics as there is minimal absorption into the systemic circulation, but the most commonly experienced side effect is dry mouth, and in elderly patients, glaucoma and urinary retention can occur.

Theophylline

Oral theophylline was primarily used as an adjunct bronchodilator treatment, but due to its narrow therapeutic index and adverse effect profile, together with the availability of safer and more effective alternatives, theophylline is now infrequently used in patients with asthma.[44]

Mode of Action Theophylline inhibits phosphodiesterases in airway smooth muscle cells, which increases intracellular cyclic AMP and this leads to a bronchodilator effect. However, the doses required for bronchodilator activity commonly cause adverse effects, which are mainly a consequence of direct phosphodiesterase inhibition. Theophylline has been shown to exhibit anti-inflammatory effects, which are likely to arise through different molecular pathways; for example, theophylline has been shown to stimulate a key nuclear enzyme, histone deacetylase-2, which is an important intracellular mechanism for switching off inflammatory genes that have been activated.

Clinical Use Theophylline is normally administered as an oral slow-release formulation either once or twice a day, as this results in more steady plasma concentrations compared to standard theophylline tablets. In severe asthmatic patients, theophylline may be used as an add-on bronchodilator treatment, although plasma concentrations of 10 to 20 mg/L are typically needed, and these levels are usually associated with adverse effects. In contrast, the anti-inflammatory effects of theophylline seem to occur at plasma levels below the traditional therapeutic range of 10 to 20 mg/L, and at low doses, the drug is better tolerated. Low-dose theophylline has additive effects to ICS and is particularly helpful in severe asthmatic patients, where withdrawal of theophylline may result in clear worsening of asthma control. Intravenous aminophylline is now seldom used for the treatment of asthmatic patients, only very rarely in those with acute severe asthma exacerbations.

Adverse Effects The adverse effects of theophylline are directly related to drug levels in the plasma and are infrequently observed at concentrations below 10 mg/L. The measurement of plasma theophylline may be useful in determining and guiding the correct clinical dose. Headaches, nausea, and vomiting are the commonest adverse effects, which arise from the inhibition of phosphodiesterase. Palpitations and diuresis may be troublesome, and with higher plasma concentrations, epileptic seizures, cardiac arrhythmias, and death may occur due to adenosine A_1-receptor antagonism. Oral theophylline is well absorbed through the gastrointestinal route and is largely inactivated in the liver by the enzyme CYP450 and so, drugs that inhibit CYP450 activity such as allopurinol and erythromycin may increase plasma levels of theophylline with consequently, a greater potential for adverse effects.

CORTICOSTEROIDS

Corticosteroids (CSs) are potent anti-inflammatory agents and when administered by the inhaled route are the most effective therapy available for treating and controlling asthma, and have greatly contributed to a reduction in asthma mortality in the Western world.[45]

Mode of Action

CSs reduce the number and activation of inflammatory cells in the airways. The reduction in eosinophils, activated T lymphocytes, and surface mast cells in the airways contribute to the lessening in the airway hyperresponsiveness that is seen with CS therapy. There are several molecular mechanisms underlying the action of CS on airway inflammation and the main pathways center on the inhibition of transcription factors NF-κB and AP-1, which switch off the transcription of multiple activated genes encoding inflammatory proteins such as cytokines, chemokines, inflammatory enzymes, and adhesion molecules. Another key mechanism in the action of CS is the inhibition of the recruitment of histone deacetylase-2 to the inflammatory gene complex, which reverses the histone acetylation associated with increased gene transcription. CSs increase the expression of β_2-receptors and this may contribute to the complementary clinical effects observed when CS are combined with LABA.[46] Transcriptional activation is responsible for most of the endocrine and metabolic adverse effects of CS.

Clinical Use—Inhaled Corticosteroids

CSs are usually administered by the inhaled route for maintenance controller therapy in patients with asthma. ICS have been shown to prevent the symptoms of asthma, reduce severe exacerbations rates, improve lung function, and reduce airway hyperresponsiveness. Early and timely treatment with ICS appears to avert the irreversible changes in airway function that occur with chronic asthma. Patients with persistent asthma stabilized on ICS experience increased exacerbations when treatment is withdrawn, indicating that ICS suppress symptoms and inflammation, but do not cure the underlying disease. ICS are beneficial in treating asthmatic patients of any age and at any stage of disease severity. They are first-line therapy for patients with persistent asthma and are usually administered twice a day, although ICS may be effective given once a day in some patients with mild symptoms. The dose–response curve of ICS is relatively flat, meaning that higher doses are only incrementally better than low-to-medium doses. If low-to-medium doses of ICS do not control persistent asthma symptoms, it is usual practice now to add a LABA, preferably as a combination of the two drugs delivered from a single inhaler device.

Clinical Use—Systemic Corticosteroids

Oral CSs are reserved to treat acute exacerbations of asthma. Typically prednisolone or prednisone 30 to 45 mg is given once daily for 5 to 10 days and on finishing the course of treatment, no tapering of the dose is required. Some asthmatic patients, especially those with more severe disease, require maintenance treatment with oral CS and in these patients it is important to determine the lowest dose necessary to maintain asthma control in light of the greater potential for adverse effects with higher doses. CSs may also be administered intravenously (methylprednisolone or hydrocortisone) for the treatment of acute severe asthma, although studies show oral CSs are as equally efficacious and easier to take.

Adverse Effects

ICS may give rise to local oropharyngeal adverse effects such as oral candidiasis, dysphonia, and hoarseness, but these may be lessened with the use of a spacer device. There exist concerns about the systemic adverse effects of ICS from swallowing of the oropharyngeal dose and lung absorption, but these depend upon the individual pharmacokinetic properties of the different CS and overall, studies show that ICS have minimal systemic adverse effects.[47] At higher drug doses, ICS may suppress plasma and urinary cortisol levels, and in prepubertal children it has been shown that the initial decrease in attained height from ICS persists as a reduction in adult height, but is not progressive or cumulative and is approximately a loss of 1 cm. Most importantly, ICS allow the effective control of asthma symptoms and disease, and maintenance therapy may decrease the need and number of prescribed courses of oral CS, and thus, reduce the total-body systemic exposure to CS in general.

Oral CS gives rise to greater systemic adverse effects than ICS, with a greater potential in those on chronic maintenance therapy. Adverse effects include bruising, diabetes, truncal obesity, osteoporosis, duodenal and gastric ulceration, hypertension, mood and behavioral changes, proximal myopathy, and cataracts. It is important to assess and monitor bone density if patients are administered chronic oral CS therapy so that preventive treatment for osteoporosis with bisphosphonates or estrogen in postmenopausal women may be initiated if levels of bone density are borderline or low. If CS adverse effects are a considerable problem, steroid-sparing agents may occasionally be considered.

■ ANTILEUKOTRIENES

Leukotriene pathway inhibitors are a group of compounds that alter the pathophysiologic effects of leukotrienes derived from the 5-lipoxygenation of arachidonic acid. Two classes of agents are available: inhibitors of the 5-lipoxygenase enzyme (zileuton) and cysteinyl-leukotriene receptor type-1 antagonists (montelukast, zafirlukast, and pranlukast).[48]

Mode of Action

Cysteinyl-leukotriene receptor type-1 antagonists inhibit the smooth muscle bronchoconstriction, microvascular leakage, and eosinophilic airway inflammation that occur through activation of cys-LT_1-receptors. These agents predominantly act on the inflammatory mediators produced by mast cells in asthma, and also to a lesser extent on mediators produced by eosinophils.

Clinical Use

Antileukotrienes have less effect on airway inflammation and provide modest clinical benefit compared to ICS. ICSs are more effective anti-inflammatory agents and clinically superior in controlling asthma than antileukotrienes. Antileukotriene treatments may be useful as add-on therapy to selected mild asthmatic patients on low-dose ICS, although these agents are less efficacious than add-on therapy with LABA. Antileukotrienes may be helpful when CS use is poorly tolerated or not desired by the patient, or there is concomitant rhinosinusitis. These drugs are usually given orally once or twice a day.

Adverse Effects

Antileukotrienes are usually well tolerated, but can sometimes give rise to gastrointestinal upset, hepatotoxicity, and hypersensitivity reactions including anaphylaxis and angioedema.

■ CROMONES

Cromolyn sodium and nedocromil sodium are classified as asthma-controller drugs. Their main mechanisms of action seem to be to inhibit sensory nerve and mast cell activation, and therefore they are effective in blocking trigger-induced asthma such as allergen- or exercise-induced symptoms. However, these drugs have a short duration of action, requiring up to four times a day inhalation, and consequently have somewhat little benefit in the long-term control of asthma. They are popular in the treatment of children with asthma because they are remarkably safe, although they are inferior to ICS with respect to most relevant clinical outcomes, and low-dose ICSs are now favored in children as they are more efficacious and have an established safety profile.

■ CORTICOSTEROID-SPARING TREATMENTS

Some patients experience serious adverse effects with CS therapy, especially oral CS therapy in those with severe asthma, and in an attempt to minimize CS exposure and reduce patient requirement, various immunomodulatory treatments have been tried. Many agents have been utilized as steroid-sparing therapies including azathioprine, colchicine, cyclosporin A, gold, methotrexate, and intravenous gamma globulin; but none of these treatments have shown long-term efficacy and importantly, each has been associated with a high-risk adverse effect profile and cannot be recommended to be used in lieu of CSs.

■ ANTI-IGE MONOCLONAL ANTIBODIES

Omalizumab is a monoclonal antibody to IgE that inhibits IgE-mediated reactions by neutralizing serum IgE without binding to cell-bound IgE. It is used as an adjunctive agent for atopic asthmatic patients who are dependent on CS therapy.[49] Studies in patients with moderate-to-severe CS-dependent asthma show an improvement in asthma control, a reduction in the number of disease exacerbations, and a significant steroid-sparing effect. However, anti-IgE treatment is very expensive and appropriate only for specific patients who have a high circulating IgE within a precise range and are not controlled on maximal doses of inhaled and/or oral CS therapy. Omalizumab is usually given as a subcutaneous injection every 2 to 4 weeks and is relatively safe with few significant adverse effects, although anaphylaxis has occasionally been reported. A 3- to 4-month trial of therapy should be undertaken to ascertain any objective benefit with this treatment.

■ IMMUNOTHERAPY

Allergen immunotherapy is of benefit in highly selected patients with defined allergic triggers.[50] Asthmatic patients with a single specific allergic trigger and concomitant nasal symptoms derive the greatest benefit than patients with multiple allergic triggers. Allergen-specific immunotherapy (ASIT) involves the repeated administration of allergen products to induce immunologic and clinical tolerance to the specific allergen. ASIT may be given subcutaneously and studies have supported efficacy by this route of administration, but there is a risk of adverse effects including anaphylaxis. In contrast, sublingual ASIT has recently been shown to be an effective and safe alternative in patients with seasonal allergy, although data for perennial allergies related to asthma is lacking.

■ NONPHARMACOLOGIC MANAGEMENT

Alternative therapies may be popular and more acceptable with some patients and include acupuncture, breathing control, chiropraxy, homeopathy, hypnotherapy, and yoga; but placebo-controlled studies show these treatments lack efficacy and they should not be clinically recommended.[51] The concern with these therapies is that they may lead to discontinuation of effective drug therapy and destabilize asthma control in patients. However, as these therapies are considered not to be harmful, patients may utilize them as an adjunct to their conventional pharmacotherapy.

■ FUTURE TREATMENTS

Although current asthma therapy with CSs and β_2-agonists are effective in controlling disease symptoms in the majority of patients, poorly controlled asthma still remains a problem in a considerable

proportion of patients.[52] Poor adherence to prescribed controller therapy contributes to poor asthma control, and the use of combination LABA/ICS therapy delivered by a single inhaler device and/or the use of combination LABA/ICS therapy as both a controller and reliever agent, may partly address this problem. Indeed, the majority of current inhaler devices target their treatment to the large airways of the lung and research is ongoing to assess the clinical implications of targeting inhaled therapy to the peripheral lung regions, where they may be ongoing untreated inflammation additionally contributing to the patient's clinical state.[53] Asthma continues to remain an unmet need as the life-long treatments currently used only address the clinical symptoms and have little effect on the underlying structural alterations associated with asthma. There is also pressing need for the development of novel therapies for patients who have side effects with systemic CSs.[54]

Ultra–long-acting bronchodilators with once-daily dosing have been approved for COPD but not for asthma, and these treatments have allowed the production of several combination therapies incorporated with once-daily CS are in development.

CS resistance is a particular problem in patients with severe asthma, and several molecular mechanisms have been elucidated that may lead to novel therapeutic approaches, including the reversal of this resistance by drugs such as theophylline and nortriptyline. New treatments have been developed to control disease in very select groups of asthmatic patients. In patients with severe eosinophilic asthma (<5% of all asthmatic patients) despite treatment with high doses of CSs, blocking antibodies against interleukin-5 have been shown to reduce disease exacerbations. In contrast, anti–TNF-α antibodies have not been shown to be effective in patients with severe asthma. Several other blockers of specific mediators such as prostaglandin D(2), IL-9, and IL-13 are in clinical trials in patients with subtypes of severe asthma. New broad-spectrum anti-inflammatory treatments are in clinical development and include phosphodiesterase-4, NF-κB, and p38 MAP kinase inhibitors, but these drugs act on signal transduction pathways that are common to many immune cells, and present the risk of troublesome adverse effects particularly by the parenteral route and hence, there is ongoing research into their delivery by the inhaled route.

Studies of the steroid-sparing effects of macrolide antibiotics in asthma management have yielded discordant results. Macrolides might benefit some patients with infection by atypical bacteria, but recent results are not encouraging, although there could be an effect in patients with predominant neutrophilic asthma.

Bronchial thermoplasty has recently been advocated in selected patients with severe asthma and may be of benefit, and clinical studies although limited have demonstrated improved outcomes.[55]

MANAGEMENT OF CHRONIC ASTHMA

Management guidelines in asthma now focus on the control of asthma symptoms using a stepwise approach to drug therapy.[1] There has been a shift away from treatment based on disease severity with the realization that asthma does not necessarily remain in the same category permanently, but may change over months or years and that patients may move up or down in their asthma severity based on factors such as the presence of allergens, the incorrect/correct use of medications and treatments, and lack of adherence to the prescribed treatment regimen. If control at a particular step is not adequate, then treatment should be increased to the next level. The principles of therapy embody the fact that effective treatment should lead to better asthma control and allow the patient to move to a less severe category, and therefore for ongoing management of asthma, classification by level of control may be more relevant and useful. The aims of chronic therapy in asthma are highlighted in Table 46-2.

The Global Initiative for Asthma (GINA) stratifies patients into four categories of the level of asthma control; controlled (where therapy is maintained or stepped down); partly controlled (where consideration is given to stepping up therapy); uncontrolled (where treatment is stepped up until symptom control is achieved); and exacerbation (where patients are treated according to the exacerbation algorithms).[1] The characteristics that contribute to determining the level of control involve an assessment of the following: daytime symptoms experienced in the last week; limitations in activities of daily living; nocturnal symptoms or awakenings the need for rescue reliever medication during the week; lung function; and the number of exacerbations (if any) in the last week and last year.

STEPWISE TREATMENT

The stepwise approach to asthma management is a description of the levels of treatment required to achieve good asthma control.[1] Some patients may experience acute worsening of asthma control, such as those with a concomitant upper respiratory tract infection, and may need to step up more than one step at a time.

Step 1

For all asthma patients, a SABA delivered by a metered-dose inhaler is all that is required and gives relief of acute symptoms. The increasing use of a reliever medication more than three times a week, or triggering of symptoms from exercise, provide an indication that controller therapy is needed. An important, but often overlooked part of asthma management relates to measures to control environmental triggers. Recognized triggers that worsen asthma control in the patient such as aeroallergens or occupational agents should be avoided, although this is not always possible. Patients with asthma may also have several triggers; therefore the impact of avoiding a single trigger will vary considerably between patients. However, complete removal from exposure to house dust mite has been shown to reduce asthma severity and airway hyperresponsiveness.

Guidelines recommend that influenza vaccination should be administered in adult asthmatics. However, where studies suggest it is unlikely to induce asthma exacerbations, there is no conclusive evidence regarding the efficacy of vaccination on influenza-related asthma complications or a reduction in exacerbations of asthma. Asthmatic patients, especially the elderly or those with comorbid conditions that increase the risk of death from influenza infection, should receive inactivated influenza vaccine if there are no other contraindications. The CDC recommends a single dose of Pneumovax for adults from 19 to 64 who have chronic illnesses, including asthma.

Steps 2–3

When patient symptoms are no longer intermittent, the addition of a long-term controller medication on a scheduled daily basis is recommended, and the treatment of choice for all patients is an ICS to alleviate the underlying airway inflammation. It is usual to start with a low-to-intermediate dose of ICS twice daily (e.g., 200 μg beclomethasone dipropionate (BDP) or equivalent BID) and if symptoms are controlled after 3 months the dose should be stepped down. However, if symptoms persist and are not controlled, a LABA should be added as a fixed combination drug with an ICS delivered from a single inhaler device, as studies show a clinical advantage compared with the monocomponents administered using two separate inhalers. Indeed, low-dose ICS with LABA therapy has been shown to be as efficacious at high-dose ICS treatment.[56] The dose of the ICS should be adjusted up or down accordingly to the need for rescue inhaler treatment and to the control of the patient symptoms. Alternative add-on therapies to ICS that can be considered include low doses of slow-release oral theophylline or an antileukotriene, but these are less effective than the LABA/ICS combination.

Step 4–5

In patients with worsening symptoms, the addition of low-dose slow-release oral theophylline to high-dose LABA/ICS may be

helpful. Recently, it has been shown that the addition of the inhaled long-acting anticholinergic tiotropium bromide to LABA/ICS treatment in patients with poorly controlled asthma, significantly decreases asthma exacerbations and improves bronchodilator lung function.[57] In patients with severe asthma who fail to achieve symptom control, maintenance therapy with systemic oral CSs may be indicated, and there should always be an aim to titrate down to the lowest possible daily (or every other day) dose that maintains asthma control. Occasionally, anti-IgE therapy with omalizumab may be tried in patients who are CS dependent and continue to remain uncontrolled, but this treatment is only suitable for highly selected patients. Allergen-specific immunotherapy may be considered in this group; however, the risk of severe events including death is highest in patients with severe asthma.

STEP-DOWN TREATMENT

Once asthma patients achieve stable symptoms and have stable peak flow readings, it is important to slowly decrease therapy to find the optimal dose to control symptoms. Indeed, asthma severity may fluctuate and improve with time, owing to improved disease management, changes in environmental exposure, or because of the natural history of the disease, and most asthma guidelines recommend a step-down approach once patients are controlled.[1] Overtreatment of patients, particularly with ICS, can cause significant morbidity and adverse effects, especially in moderate-to-severe asthmatics. It may also be unnecessarily costly. Unfortunately, in such patients there is a tendency to maintain a static treatment regimen, even after symptoms are controlled and clinical stability is achieved. Studies have now supported the notion that stable asthmatic patients on high-dose ICS may be overtreated and that reductions in the inhaled dose can be achieved without significant increases in asthma exacerbations, visits to the family practitioner, or recourse to oral CS use.[58] A gradual reduction in medications starting with the treatment with the greatest toxicity should be attempted once stability is achieved and sustained for several months, and symptoms should be monitored on a long-term basis using both objective lung function and subjective symptom measures. Most patients should be maintained on an ICS, and this treatment should not be stopped as this provides anti-inflammatory protection. In those asthmatic patients that needed admission to hospital and/or ventilatory support, a longer period of stability on maintenance therapy may be justified before consideration of a step-down treatment approach.

MANAGEMENT OF REFRACTORY ASTHMA

Most asthmatic patients are controlled with appropriate stepwise therapy, but approximately 5% of asthmatics are difficult to control, do not remain symptom free despite maximal inhaled therapy, and may require maintenance treatment with oral CSs. In this group of patients, a thorough investigation of factors aggravating or contributing to poor asthma control should be undertaken. It is important to check adherence with medication and inhaler technique, particularly if the patient's disease is unstable despite the maximal recommended dose of therapy. Nonadherence with medication remains an important factor for the poor control of asthma and may be particularly manifest with ICS, as patients may be concerned about adverse effects or describe lack of immediate clinical benefit from this treatment. Monitoring adherence to ICS therapy in the clinic is difficult as there are no useful plasma measurements that can be made, however in contrast, the measurement of plasma cortisol suppression and absolute plasma drug concentrations may be useful in monitoring adherence to oral CSs. Evidence suggests nonadherence may be commoner in those with psychosocial problems or depression and these conditions should be actively sought and addressed during the clinical assessment. A detailed review of factors such as exposure to environmental allergens, unidentified occupational agents, or drugs that worsen asthma control such as aspirin or β-blockers should also be undertaken. Asthma may coexist with a number of disorders that can affect lung function, and the successful management of asthma often requires treatment of these associated conditions that are thought to aggravate asthmatic symptoms. Rhinosinusitis and gastroesophageal reflux disease are the most common of the disorders associated with poorly controlled asthma.

The relationship between rhinosinusitis and asthma is well established as described in the "united airway disease hypothesis," where treating the inflammation of allergic rhinitis in the upper airways has been shown to translate into improved asthma control.[59,60] It has also been postulated that poor asthma control may arise as a result of the inability of current inhaler devices to target drug therapy to the ongoing inflammation in the peripheral lung regions, and possibly treatment of this lung compartment with targeted anti-inflammatory therapy may result in improved symptoms.[53] In spite of the lack of data from meta-analyses which fail to show a consistent effect of antireflux therapy on asthma symptoms and lung function, many clinicians will assess and treat the possibility that gastroesophageal reflux disease may be aggravating asthma.[61]

As discussed earlier, patients with vocal cord dysfunction may present with wheeze and stridor and an escalation in asthma therapy. This disorder can be assessed using nasoendoscopy to observe abnormalities in the movement of the vocal cords, and if confirmed patients should be weaned off CSs. Speech therapy intervention may be helpful. Bronchoscopy or MDCT to exclude tracheobronchomalacia may be considered. A reconsideration of the potential differential diagnoses should be explored in the refractory asthmatic patient and this may require specialist referral (Table 46-3).

Patients who require high doses of oral CSs to maintain asthma control are referred to as CS-"dependent" asthmatics. In contrast, patients with complete CS-"resistant" asthma show a failure to respond to high-dose oral CS therapy, but this is very uncommon affecting less than 1 in 1000 patients. Several molecular mechanisms have been implicated in CS resistance and the impairment of their anti-inflammatory action, and this has led to the identification of new drug targets for future therapies.[62] There is evidence that in asthmatic patients who smoke (approximately 20% of the population), smoking itself hinders the anti-inflammatory action of CSs leading to relative CS resistance with the need for higher drug doses to achieve asthma control. It is recognized that smoking asthmatics compared to nonsmoking asthmatics have a faster decline in lung function, more severe asthma, more frequent hospital admissions, and a higher risk of death. Smoking cessation should be strongly pursued in this group as this intervention has been shown to reduce CS resistance and improve lung function.

Some asthmatic patients have unstable disease with rapid variations in lung function that may lead to recurrent and severe attacks of asthma, despite appropriate treatment for the disease.[63] These patients may be divided into type I brittle asthma, where there is a sustained pattern of chaotic peak flow variability on a daily basis or; type II brittle asthma, where asthma symptoms and lung function are well controlled, but there are abrupt and unpredictable falls in peak flow that may be catastrophic and result in sudden death. These patients are difficult to treat as they do not usually respond to maximal high-dose CS therapy but rely and need subcutaneous epinephrine injections. The assessment of treatment adherence and education on allergen avoidance is particularly important in these patients and they should wear an identification bracelet of their condition. The importance of carrying a portable epinephrine autoinjector at all times and being taught to self-administer this treatment should be a central part of their management.

ASTHMA EDUCATION AND MONITORING

Asthma education and training is important as patients need to understand the disease, its management, how to use inhalers properly, adverse effects of treatment, and importantly when to use reliever and controller treatments. Education may improve adherence to treatment recommendations and also engage the patient in self-management strategies particularly in terms of recognizing their symptoms, identifying and avoiding asthma triggers, objectively measuring any deterioration in their asthma control, and treating exacerbations of asthma at their earliest stages by stepping up their therapy. Educating the patient in the self-administration of oral CSs and access to healthcare advice are also important elements in a management program, which are designed to reduce emergency hospitalizations and patient morbidity. Studies have shown that written personal patient action plans result in better asthma control, reduced emergency room visits and hospitalizations, and decreased morbidity in both adults and children. Written plans are particularly useful and recommended in patients with unstable disease who have frequent exacerbations. The additional provision of a program of educational sessions (one-to-one or in small groups) with a knowledgeable healthcare professional has been shown to be more effective than written materials alone. Like drug therapy, the educational program and the method and frequency of reinforcement should be tailored to the patient's individual needs. Patients should be reassured that with proper treatment, their symptoms and occasional exacerbations can be minimized, and in most cases a normal lifestyle and life expectancy can be anticipated.

Home monitoring of asthma symptoms and control is an important aspect of self-management programmers. PEF measurements allow patients to be monitored on a long-term basis with relative ease using hand-held, compact, portable devices. Asthma treatment guidelines recommend patients use PEF measurements not only to monitor the course of the disease, but also to dictate self-administered treatment regimens.[1] Indeed, studies show improvements in measures of asthma control when peak flow measurements are used by patients (in relation to their personal best peak flow) to adjust medication usage. However, despite the advantages of written plans highlighted above, the US Centers for Disease Control and Prevention (CDC) analyzed asthma data from adults and children between 2001 and 2009 in a national health interview survey and showed that only one-third of patients with asthma reported being given a written asthma action plan, and just over two-thirds of patients had been taught the appropriate response to symptoms of an asthma attack.[64] It should be recognized that not all patients are capable of comprehending and executing complicated treatment plans. There are also concerns that peak flow–guided self-management may lead to overtreatment with medication, and hence the potential for increased morbidity due to adverse effects. Similarly, patients with severe asthma in whom self-management plans are more readily recommended, may tend to use more oral CSs where it may be unclear whether the increased use is appropriate or medically warranted (although the increase in medication may be initially viewed as a potential benefit of peak flow monitoring). Action plans should be written using clear, simple language and individualized based on patients' understanding of their asthma, its severity, and their demonstrated ability to comply with instructions.

MANAGEMENT OF ACUTE SEVERE ASTHMA

Asthma is characterized by exacerbations of disease, which can lead to substantial morbidity, occasional mortality, and considerable medical and economic costs. Patients with asthma fear disease exacerbations as they can be life-threatening and exacerbation-prone patients seem to be at increased risk for attacks of near-fatal asthma. Analysis of asthma mortality data identifies that patients experience worsening symptoms and deterioration in asthma control of a period of several hours to several days, before the event.[65] Indeed, life-threatening episodes can develop in any asthmatic patient, but particularly those patients with severe and poorly controlled disease; those who frequently access the emergency room; or patients who are hospitalized, are all recognized to be at high risk of life-threatening events. The importance of educating all patients with asthma should not be underestimated, as well as their carers, and in particular healthcare professional should identify and closely monitor such at-risk patients.

CLINICAL FEATURES

Patients with a moderate exacerbation of their disease notice a deterioration in their asthma control by an increase in daytime and nocturnal symptoms of cough, chest tightness, wheeze, and dyspnea, that do not respond to their usual maintenance therapy and require more reliever drug. A history of prodromal symptoms may be elicited that precede an asthma attack, such as itching under the chin, discomfort between the scapulae, or inexplicable fear (impending doom). A fall in home peak flow recordings also signify a worsening of asthma and the GINA guidelines classify exacerbations based on the peak flow into mild (PEF >80% predicted), moderate (PEF between >60% and 80% predicted), and acute severe (PEF between <60% predicted).[1] Patients may become so breathless in acute severe exacerbations that they become exhausted, unable to talk freely in complete sentences, and show life-threatening features of confusion, agitation, and cyanosis. Clinical examination usually shows an increased respiratory rate, hyperinflation, and tachycardia. In acute severe asthma, pulsus paradoxus (the accentuated decrease in systolic blood pressure [>10 mm Hg] during inspiration), may be present. Life-threatening signs are a silent chest, bradycardia, and hypotension. Investigations will show a marked fall in PEF and spirometric values; hypoxemic saturations on air and arterial blood gases may reveal a low Pa_{O_2}, and initially a low Pa_{CO_2} usually due to hyperventilation. In life-threatening situations the PEF will be <30% of predicted, oxygen saturation (Sa_{O_2}) measured by pulse oximetry <92% and, arterial blood gases on air will show a Pa_{O_2} <60 mm Hg (8 kPa) and a rising Pa_{CO_2} will indicate impending respiratory failure and requires immediate monitoring and therapy. A chest radiograph is not routinely recommended in the absence of a suspected pneumothorax, pulmonary consolidation, failure to respond to treatment satisfactorily, or a requirement for ventilation.

PHARMACOLOGIC TREATMENT

The cornerstone of therapy for worsening asthma control requires the escalation of both ICSs and quick-relief inhaled β_2-agonists.[1] Exacerbations of asthma should never be treated by escalating bronchodilators alone and asthma fatalities usually result when patients fail to promptly seek medical attention. Studies have shown patients dying from asthma commonly self-medicate with escalating doses of reliever bronchodilator medication in the preceding days to an asthma attack. A short course of oral CS therapy for at least several days may be needed to control and prevent a mild–moderate exacerbation and tapering of the dose should be undertaken with close outpatient follow-up. Very mild or subacute exacerbations in asthmatics with mild persistent disease may be managed in some cases by escalating the dose of ICSs in cases in which patients are taking low-doseCS. In less severe exacerbations, patients who promptly respond to treatment in the emergency department may be discharged but close outpatient follow-up is essential.

In patients with an acute severe exacerbation presenting to the emergency department, oxygen at high concentrations and high flows should be given continuously by face mask to achieve oxygen saturations (Sp_{O_2}) of between 94% and 98%. Hypoxemia is to be avoided at all costs, as patients die from hypoxemia in acute asthma and oxygen therapy is critical to prevent death in severe acute asthma, so continuous monitoring of oxygen saturation is needed until there is a meaningful response to treatment.

High doses of inhaled SABA given either by nebulizer (oxygen-driven) or via a pMDI with a spacer should be the first-line agents in acute asthma and be administered as early as possible. While generally well tolerated, occasionally nebulized bronchodilators cause arrhythmia and continuous electrocardiogram monitoring is required. In those patients in whom inhaled therapy cannot be used reliably, or in severely ill patients with impending respiratory failure, intravenous β_2-agonists may be given. In patients not responding, nebulized anticholinergic treatment (ipratropium bromide) may be added as they provide additional bronchodilation. Systemic CSs should be given in adequate doses in all cases of acute severe asthma for at least 5 days or until recovery and should be tapered after this response over a 2-week period, particularly in cases of severe asthma exacerbations. In patients unable to take oral CSs, intravenous therapy (e.g., hydrocortisone) should be administered in the emergency department.

A single dose of intravenous magnesium sulfate for patients has been shown to be effective when added to inhaled β_2-agonists. It is relatively well tolerated and can be considered in patients with acute severe asthma who have not had an initial good response to inhaled bronchodilator therapy, or in those with life-threatening features.

Patients should be referred to the intensive care unit for intubation and ventilation if they have acute severe or life-threatening asthma that is failing to respond to therapy indicated by: a deteriorating PEF, worsening hypoxemia, a normal or rising Pa_{CO_2}, poor respiratory effort, and exhaustion or confusion. Intravenous aminophylline may be used, but the risks of toxicity are much greater than when inhaled β_2-adrenergic agonists are used. Sedatives should never be given as they may depress ventilation, and antibiotics should not be routinely administered, unless there are clinical or radiologic signs of pneumonia.

ACKNOWLEDGMENT

CHAPTER 47

Aspirin- and Exercise-Induced Asthma

Jose L. Gomez
Geoffrey L. Chupp
Gregory P. Geba

Asthma is well known to be triggered by specific immune factors such as aeroallergen exposures. There are, however, several important nonallergic triggers for the development of asthmatic bronchial obstruction. Two of the most important are aspirin and related nonsteroidal anti-inflammatory drugs (NSAIDS) and exercise. Both can provoke airway responses in the setting of established symptomatic aeroallergen-induced asthma or in isolation. These two nonspecific triggers may also share pathophysiologic mechanisms, including mast cell and leukotriene-related pathways, and may be related to vascular response–mediated airway narrowing.

ASPIRIN-INDUCED ASTHMA

The first report of aspirin-induced asthma (AIA) was that of Hirschberg in 1902. Six decades later, the association between aspirin sensitivity, asthma, and nasal polyps was documented in a classic paper by Samter and Beer.[1] In 1928, the clinical importance of sensitivity to aspirin was highlighted by van Leewen, who challenged 100 asthmatics with aspirin, provoking bronchoconstriction in 16. Several others[2,3] have made similar observations, documenting a prevalence of aspirin sensitivity in asthmatics that ranges from 5% to as high as 30%, depending on the characteristics of the asthmatics studied (severity increases risk) and the criteria applied to make the diagnosis.

Aspirin was originally recognized as the first drug capable of precipitating asthma. With the development of chemically related analgesic and nonsteroidal anti-inflammatory drugs (NSAIDs) after 1950, other agents were found to exacerbate asthma. In a study of 781 asthmatics observed over a period of 2 years, drugs were noted to provoke asthmatic airway responses in 10.5% of patients.[4] Reactions to NSAIDs were thought to be responsible for 77% of all cases, with aspirin accounting for two-thirds of the reactions to NSAIDs, or nearly 50% of all cases of drug-induced asthma. Therefore, although aspirin is the most common drug to induce asthma and the most common NSAID to cause asthma, other NSAIDs are responsible for an important number of these reactions.

CLINICAL PRESENTATION

Reactions to aspirin take two distinct forms: Cutaneous—most commonly characterized by urticaria and angioedema,[5] and respiratory—characterized by rhinoconjunctivitis and bronchospasm.[6] The cutaneous reactions that develop after the ingestion of NSAIDs include hives with or without angioedema, may develop in individuals with a history of chronic urticaria or healthy individuals, and are the result of exposure to a single drug in this class or to one of multiple NSAIDs.[5] The wide spectrum of underlying variables suggests that the pathogenic processes leading to these clinical presentations are diverse. The fact that a great majority of patients were able to tolerate the same NSAIDs before the development of the urticarial process, suggests that the NSAIDs interact with an underlying urticarial tendency but do not directly and independently cause the hives. This explains why the avoidance of NSAIDs does not eliminate the urticarial symptoms in all patients. However, the identification of the reaction as one provoked by a single or by multiple NSAIDs is fundamental to develop a therapeutic plan in these subjects, to provide guidance with respect to the restriction of exposure to the inciting agent in this therapeutic class.

The respiratory manifestations of aspirin sensitivity involve both the upper (nasal) and lower airway (asthma), and are generally temporally linked. Sometimes, upper respiratory symptoms, typically rhinitis, precede the development of lower respiratory reactions to these agents. AIA can occur on a background of established asthma or can appear de novo without previous asthma symptoms. This observation has led to the use of more accurate descriptors for this condition including, aspirin-induced asthma (AIA) or aspirin-exacerbated respiratory disease (AERD), the latter a more inclusive term that extends beyond the lower airway manifestations (asthma), to include the upper airway (nasal and sinus mucosa).

The typical presentation of this syndrome is characterized by an initial complaint of upper respiratory symptoms, similar to those caused by a viral illness. The syndrome peaks in the third decade of life. Upper respiratory symptoms become persistent and extend to involve the nasal mucosa and paranasal sinuses. Marked eosinophilia is often observed in the setting of chronic rhinitis, and nasal polyps. A detailed history documenting a relationship between the ingestion of aspirin and/or NSAIDs and the upper and lower respiratory symptoms helps to establish the connection between these agents and the development of nasal polyps. Typically, though symptoms may improve, the inflammation persists despite substantially reduced or absent exposure to aspirin or NSAIDs.

In addition to Samter's classical description of nasal polyps, asthma, and aspirin sensitivity,[1] the documentation of sinusitis involving one or several paranasal sinuses at some point in the disease in almost all patients is an additional feature of the syndrome.[7] The nasal and sinus inflammation is often accompanied by anosmia, recurrent sinus infections often leading to recurrent surgeries to remove polyps to provide relief for the chronic sinus congestion. Opacification of one or more sinuses on plain radiographs can be seen in 90% of these patients, while sinus CT has a higher sensitivity to detect mucosal thickening resulting from chronic hyperplastic eosinophilic sinusitis, and air fluid levels.

Atopy does not seem to be the main pathogenic mechanism in AIA. This observation is based on evidence from multiple sources and includes the observation that many patients with AIA are not atopic; with a rate of positive aeroallergen skin testing between 30% and 60%, a substantial proportion exhibit negative skin tests and IgE levels in the normal range. The documentation of NSAID-specific IgEs has not been successful, and the peripheral blood eosinophilia, complement activation, and serum histamine elevation seen after acute aeroallergen challenge of atopic asthmatics, are absent after acute aspirin challenge. Thus, the term, pseudoallergy has been used to describe some of the AIA reactions.

In contrast, the typical reaction after aspirin ingestion in these patients is the slow development (within ½ to 4 hours, mean 50 minutes) of nasal congestion with profuse rhinorrhea, cutaneous flushing involving the head and neck, conjunctivitis, and bronchial obstruction, the latter usually manifested as wheezing. A typical reaction provoked by an oral challenge under laboratory conditions is illustrated in Figure 47-1. In severe reactions, headache, nausea and vomiting, and acute hypercarbic respiratory failure culminating in death can occur. Life-threatening responses with faster kinetics have also been reported with systemically administered NSAIDs such as ketorolac.[8]

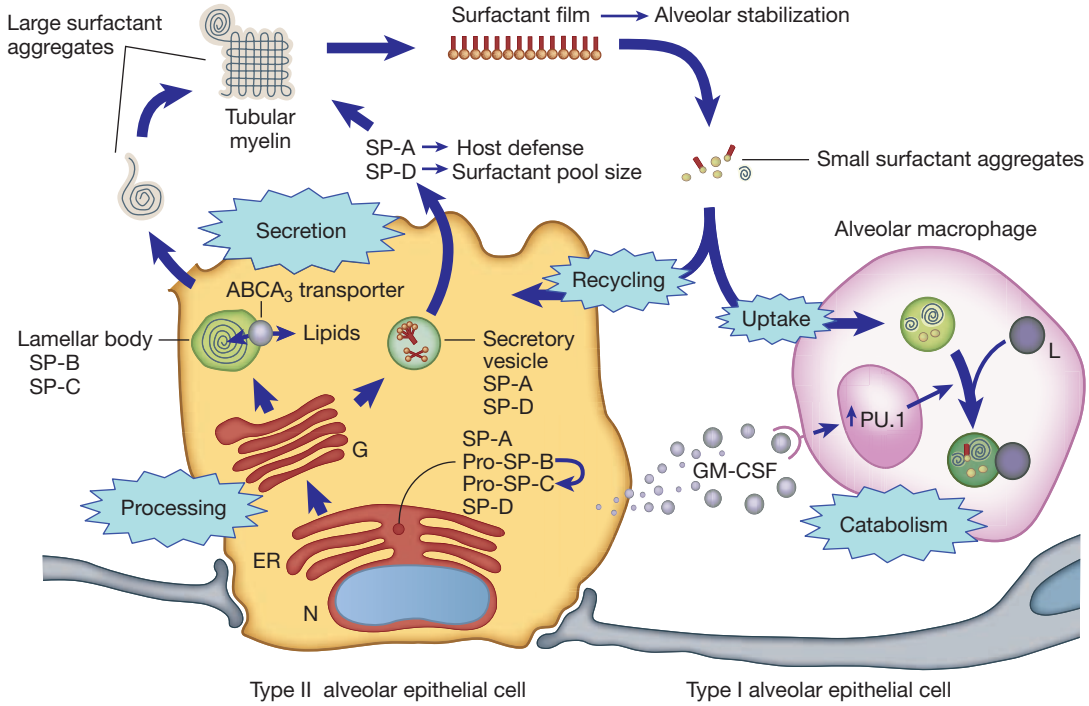

Figure 47-1 Typical reaction to aspirin in AIA. The timeline illustrates the kinetics of respiratory compromise and nasoocular symptoms after graded aspirin or placebo challenge. IPPB, intermittent positive-pressure ventilation with β-adrenergic agonist bronchodilator. *(Data from Stevenson DD, Simon RA. Aspirin sensitivity: Respiratory and cutaneous manifestations, in Middleton E Jr, et al (eds). Allergy: Principles and Practice. St. Louis, CV Mosby. 1993;1747–1767.)*

Combined cutaneous and respiratory reactions (i.e., true urticarial eruptions in association with asthma) occur in <3% of cases.[9]

■ GENETICS

In contrast to classic atopic asthma, which patients develop during childhood and adolescence, AIA typically occurs in individuals in the third to fourth decade of life. An original report by Lockey describing a consanguineous family suggested an autosomal recessive pattern.[10] However, a subsequent report by Von Maur indicated an autosomal dominant pattern.[11] The late onset of the disease points to important environmental influences that may play a significant role in the development of the syndrome. Both genders are affected by the disease; however, the prevalence is higher in women than men.

Notwithstanding the lack of familial association in most cases, one study did show an increase in the expression of *HLA-DQW2* in a group of patients.[12] A later study showed increased expression of *HLA-DPB1*0301* (Odds ratios: 4.4 and 5.3) and decreased expression of *DPB1*0401* (OR: 0.42 and 0.48) in AIA versus normals and nonaspirin-sensitive asthmatics, respectively, among Europeans.[13] Korean investigators confirmed a higher risk of AIA in patients carrying *HLA-DPB1*0301*, while those carrying *HLA-DRB1*1302* and or *DQB1*0609* exhibited a higher risk of aspirin-induced urticaria.[14]

Several genes in the arachidonic acid pathway have been associated with molecular defects responsible for aspects of the pathogenesis of the disease. The single nucleotide polymorphism (SNP) rs730012 (A-444C) in the Leukotriene C4 synthase *(LTC4S)* gene was associated with higher gene expression in blood eosinophils and higher relative risk of AIA (2.62; 95% CI: 1.38, 4.98) in Europeans with AIA.[15] An additional study from the same group showed a functional and gender association of the rs20417 SNP (G-765C) in the *COX-2* promoter region in AIA patients with more severe disease.[16] A Japanese group found an association between the rs4794067 SNP in the *TBX21* gene, the human analogue for the *T-bet* gene in mice, that, when absent, had previously been shown to result in airway eosinophilia and hyperresponsiveness. The rs4794067 polymorphism was in linkage disequilibrium with a synonymous coding 390A-G SNP in exon 1 and was significantly associated with AIA.[17] Another study showed heightened transcription or polymorphisms in the 5-lipooxygenase activating protein *(ALOX5AP)* gene in AIA.[18] New insight may result from the recent observation of selective expression in AIA patients of cysteinyl leukotriene type 2 receptor, but not type 1 receptor, expressed by infiltrating inflammatory cells of the upper airway, not observed in aspirin-sensitive patients with chronic allergic rhinitis and normal controls.[19]

The number of genetic studies in AIA has increased significantly over the last decade, with the advent of high throughput technologies. The majority of studies have used a candidate gene approach, with some positive associations. The interpretation of the evidence suggests that the development of AIA is the result of the interaction between multiple polymorphisms and the environment; however, some of these findings in specific populations may not be generalizable to all individuals with disease due to different allelic frequencies and individual environmental risk factors that modify the AIA phenotype.

Gene expression profiling of nasal polyps of individuals with AIA has shown higher levels of periostin expression;[20] this observation is particularly relevant for both the upper and lower airway, since periostin is also secreted by bronchial epithelial cells and is associated with TGF-β stimulation and increased extracellular matrix deposition in the airway of asthmatics.[21]

■ CROSS-REACTIVITY

Cross-reactivity of aspirin with other NSAIDs was first recognized in 1967 by Vanselow and Smith.[22] This report was followed by others of reactions to structurally unrelated NSAIDs, which suggested that these reactions were not atopic in nature. It was subsequently shown that the ability of these drugs to provoke asthma in susceptible patients was related to their ability to inhibit cyclooxygenase (COX), and that the degree of cross-reactivity with aspirin was related

to the degree to which these agents inhibited COX in vitro.[23,24] Subsequently, the discovery of isoforms of COX has revealed that the dominant form that is inhibited by low doses of aspirin and is capable of eliciting airways responses in AIA is COX-1. Drugs that are less potent inhibitors of COX-1, but are structurally related to aspirin (e.g., sodium salicylate), at clinical doses, do not provoke AIA.

The association of AIA with the COX-1 isoform of the enzyme has been strengthened by studies with specific inhibitors of COX-2, which, at clinical doses, nearly completely spare inhibition of COX-1. Two separate studies have shown convincingly that selective inhibitors of COX-2 (celecoxib and rofecoxib) do not provoke airway changes typical of AIA in patients known to have the disorder, or in those who were challenged in the laboratory de novo in the process of diagnosing the disease.[25,26] In individuals challenged with celecoxib, including high doses, no reaction was seen (Fig. 47-2).[27,28] The increased risk of thrombotic cardiovascular events with rofecoxib and celecoxib, has limited the evaluation of these effects in larger populations of individuals with AIA. A list of NSAIDs reported to provoke AIA and those not associated with AIA is given in Table 47-1.

Curiously, although at least two studies involving nearly 100 subjects showed that a later generation, highly specific COX-2 inhibitor, etoricoxib, did not provoke acute responses with doses up to 120 mg,[29,30] another study showed a small, though detectable risk of cutaneous reactions after challenge with etoricoxib.[31] In one case report involving a single patient, challenge with etoricoxib was associated with a reduction of FEV_1 and development of rhinorrhea 30 minutes after a 60 mg dose. Thus, although the vast majority of patients with ASA may not develop symptoms when administered COX-2 inhibitors, confirmation of ability to tolerate these agents with formal testing may be the most conservative approach.

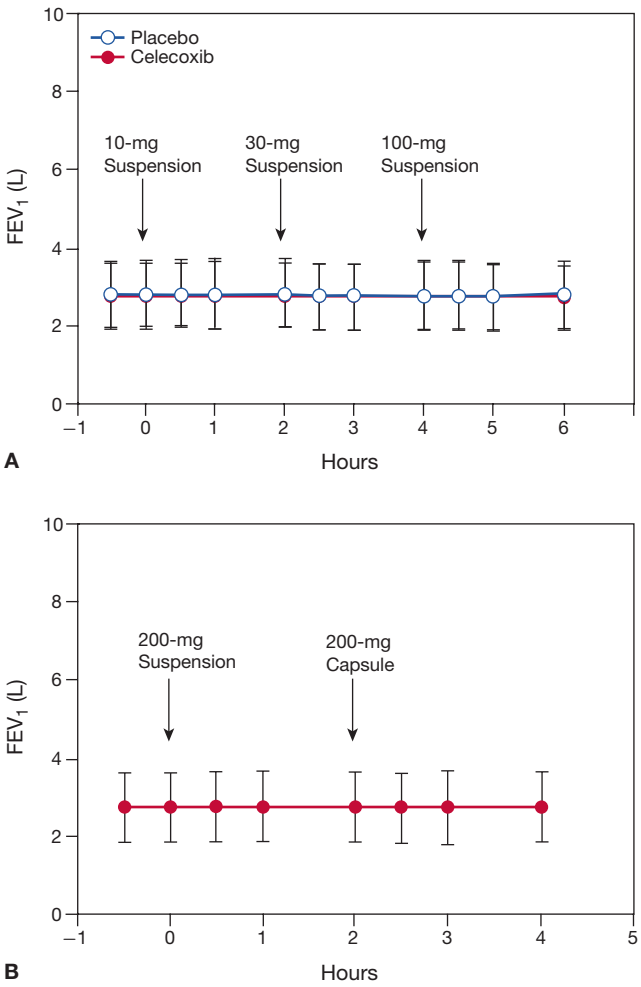

Figure 47-2 Lack of airway bronchoconstriction to increasing doses of a COX-2 inhibitor in aspirin-sensitive asthmatics. FEV_1 measured before and after oral challenge. **A.** Double-blind crossover challenge. **B.** Open label challenge. *(Reproduced with permission from Gyllfors P, et al. Biochemical and clinical evidence that aspirin-intolerant asthmatic subjects tolerate the cyclo-oxygenase 2-selective drug celecoxib. J Allergy Clin Immunol. 2003;111(5):1116–1121.)*

TABLE 47-1 NSAIDs in Aspirin-Induced Asthma (AIA)

NSAIDs that Can Provoke Airway Narrowing in AIA
Carboxylic acids
Salicylates
Acetylsalicylic acid (aspirin, Easpirin, Zorpin)
Acetic acids
Indomethacin (Indocin)
Sulindac (Clinoril)
Tolmetin (Tolectin)
Diclofenac (Voltaren)
Ketorolac (Toradol)
Zomepirac (Zomax)
Propionic acids
Ibuprofen (Motrin, Advil, Nuprin)
Naproxen (Naprosyn)
Fenamates
Meclofenamate (Meclomen)
Mefenamic acid (Ponstel)
Enolic acids
Piroxicam (Feldene)
NSAIDs and Analgesics that Appear to Be Well Tolerated in AIA
Sodium salicylate
Choline salicylate
Salicylamide
Dextropropoxyphene
Acetaminophen in low doses
Selective COX-2 inhibitors

A number of other analgesics have long been considered to be well tolerated in patients with AIA. They are also listed in Table 47-1. However, some analgesics, formerly considered safe for use by these patients, were subsequently shown to be capable of provoking bronchospasm if given in large doses. For example, doses generally greater than 1000 mg of acetaminophen, and salicylate, at doses of 2000 mg or greater, can provoke significant declines in FEV_1 in some aspirin-sensitive asthmatics. Reactions to high doses of these drugs, when they occur, tend to be milder than those seen with aspirin. A similar phenomenon has been observed with meloxicam and nimesulide, drugs that inhibit COX-2 somewhat more than COX-1. At typical clinical doses they are generally well tolerated in patients with AIA; however, at high doses, cross-reactions may be observed.

The documentation of NSAID-specific IgE antibodies and anaphylactic reactions to NSAID after a period of sensitization is much less common than non–IgE-mediated reactions, which tend to occur after first exposure. However they must be considered in the

differential diagnosis in the appropriate clinical situation. Avoidance of the specific NSAID involved prevents relapses.[32]

An interesting association of AIA with sensitivity to hydrocortisone has been made. After several case reports of the association, two studies[33] demonstrated that a small percentage of patients with aspirin-induced asthma may experience acute bronchospasm (15–30 minutes) after the intravenous or intramuscular injection of hydrocortisone. The vehicles and diluents used in the hydrocortisone preparations could not be linked to the reactivity. One of these studies showed no bronchoconstrictor response to methylprednisolone, dexamethasone, or betamethasone when given intravenously, indicating that these potent anti-inflammatory steroid preparations, related to hydrocortisone but with different side chain chemical structure, could be used safely.[34] The mechanism of this reaction is not known, though corticosteroids can reduce phospholipase PLA2 activity (generally decreasing eicosanoid production) and broadly inhibit isoforms of COX, especially COX-2.[35]

PATHOGENESIS

The combination of epidemiologic data, genetic and genomic information, with the observation that COX-2 inhibitors exhibit a relatively safe profile in individuals with AIA has pointed to key aspects of the pathophysiology of AIA. The main theory supports an alteration in the balance between leukotrienes and prostaglandins generated by the lipooxygenase- and COX-dependent pathways of arachidonic acid metabolism (Fig. 47-3). Other attempts to explain the spectrum of symptoms are based on the release of other mediators, most likely from mast cells, basophils, or platelets. These theories include upregulation of mast cell–basophil mediator release by substances not yet identified that affect mast cell membranes, increased histamine production by basophils of patients with aspirin-induced asthma in comparison to normal subjects, decreased production of prostaglandin E2 (PGE2) with enhanced production of leukotriene B4 (LTB4) by AIA basophils, and enhanced aspirin-induced release of serotonin and other mediators by AIA platelets.[9,36] It has been proposed that complement activation may be important in these processes.[37] However, the role of complement activation in AIA has been questioned by data showing no significant changes in CH50 and C4 levels in patients experiencing an asthma exacerbation after acute oral aspirin challenge.[38]

Alterations in arachidonic acid metabolism appear to play a central role in AIA. The major pathways of COX and lipooxygenase metabolism of arachidonic acid are illustrated in Figure 47-3. Arachidonic acid is derived from membrane phospholipid by phospholipase A2. It is then metabolized via the COX pathway to prostaglandins (COX-2 > COX-1) and thromboxanes (COX-1 > COX-2) or via the lipooxygenase pathway to sulfidopeptide (cysteinyl) leukotrienes. The leukotrienes have a variety of effects, including the induction of contraction of bronchial smooth muscle. In contrast, the prostaglandins, in particular PGE2, act as bronchodilators and may inhibit T cell–mediated inflammatory responses in the lung. Aspirin and the other NSAIDs that cause AIA inhibit COX-1 activity. A shift occurs after the administration of aspirin or appropriate doses of these other agents, shunting approximately 90% of the arachidonic acid metabolism to the 5-lipooxygenase pathway, decreasing prostaglandin and thromboxane production, and increasing leukotriene generation. In comparison to normal controls, patients with AIA generate leukotrienes in exaggerated quantities after aspirin challenge. Discovery that AIA patients produce less of the anti-inflammatory mediators lipoxins and 15-epimer lipoxin might enhance effects of this shift.[39] AIA patients may also be more sensitive than normal subjects to the bronchoconstrictor properties of leukotrienes (particularly LTE4) and more susceptible to the loss of the bronchodilating and potentially anti-inflammatory effects of PGE2. The data supporting these conclusions are briefly summarized below.

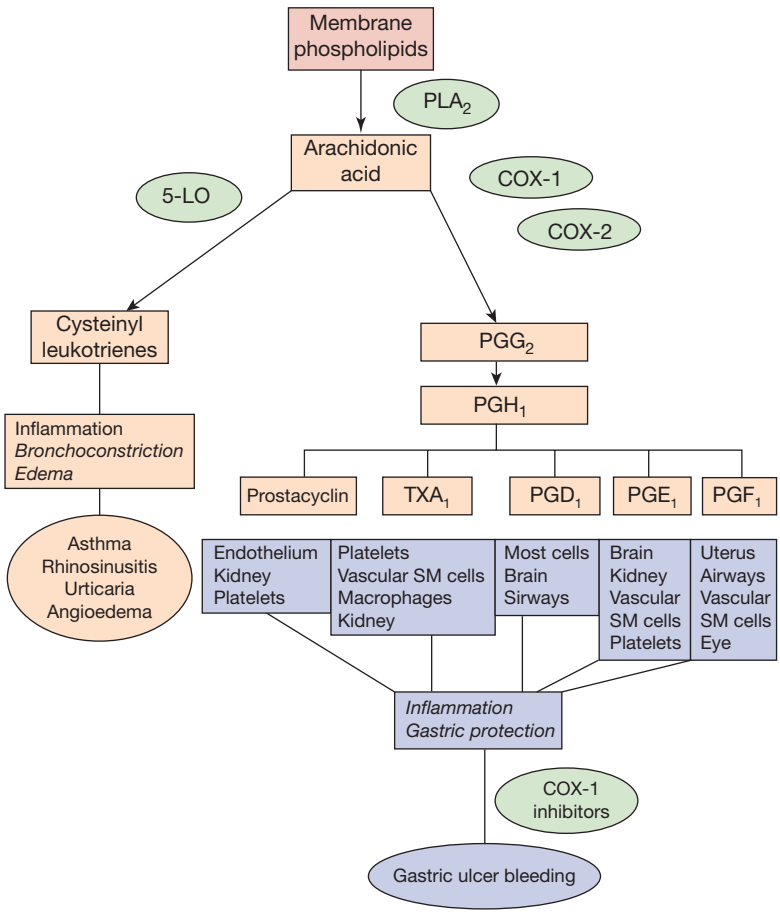

Figure 47-3 Enzymatic pathways of arachidonic acid metabolism. *(Reproduced with permission from Sanchez-Borges M, et al. Cutaneous reactions to aspirin and nonsteroidal anti-inflammatory drugs. Clin Rev Allergy Immunol. 2003;24(2):125–135.)*

Several groups have analyzed the nasal lavage fluid from aspirin-sensitive and control patients and found inducible levels of cysteinyl leukotrienes and plasma proteins when patients with AIA received oral or nasal aspirin challenges.[40,41] One study found that LTC4 and LTD4 levels were not significantly induced in normal subjects, but could be induced to some degree in patients with allergic rhinitis and in those with isolated nasal polyps (rising 93% and 69% above baseline levels, respectively).[41] Similarly, although histamine levels rose significantly in the AIA group (greater than threefold increase in total protein) they did not rise significantly in the control groups. Analysis of the nasal lavage fluids showed impressive increases in lactoferrin and lysozyme, suggesting that submucosal glands are stimulated in this process.

In a follow-up study, the cellular source of these nasal abnormalities was investigated by analysis of nasal lavage fluid after induction by aspirin challenge for the presence of mast cell tryptase and eosinophil cationic protein (ECP).[40] Significant increases in nasal tryptase, histamine, and cysteinyl leukotrienes were observed after AIA was provoked in these patients. ECP levels at baseline were variable and did not

increase significantly after challenge. A similar study before and after intranasal challenge with aspirin revealed changes in the vascular permeability of patients with AIA, an associated influx of eosinophils coupled with increased ECP, and an associated increase in tryptase suggestive of mast cell activation.[42] These findings are consistent with earlier work[8] that documented similar increases in blood tryptase (4 hours) and urinary LTE4 levels (6 hours); the decreases in blood eosinophil counts demonstrated could be associated with eosinophil recruitment at the tissue level after aspirin challenge.

The metabolism of arachidonic acid in the lung has not been studied as extensively. The available data show both similarities and differences with findings in the nose and circulation. For example, bronchoalveolar lavage fluid (BALF) obtained 30 minutes after inhalation of threshold doses of lysine–aspirin contained decreased levels of COX-dependent mediators (PGE2, PGD2, thromboxane B2 [TXB2], and PGF2α). However, only small increases in LTE4 and 5-hydroxyeicosatetraenoic acid (HETE) levels were noted. Lysine–aspirin inhalation also did not produce a significant rise in tryptase levels in BALF and led to a significant fall in ECP levels despite baseline eosinophil and ECP levels, which were higher in the AIA group than in placebo-treated nonasthmatic individuals.[43] The authors postulated that the altered pulmonary eicosanoid production might be related to eosinophilic inflammation in the airways of patients with AIA.

Additional understanding of the mechanism of bronchospasm in AIA has been gained by other investigators who used inhibitors of leukotriene effector function. One study administered a specific sulfidopeptide leukotriene receptor antagonist via inhalation and noted that it attenuated aspirin-induced asthma in five of six subjects by 43% to 74%.[44] This was followed by a double-blind, placebo-controlled, crossover study that showed that a specific leukotriene receptor antagonist given as a single oral dose 1 hour before perithreshold lysine–aspirin inhalant provocative challenge could almost completely block the development of aspirin-induced bronchospasm.[45] This was achieved without evidence of any direct bronchodilatory effect of the drug before lysine–aspirin challenge, confirming that leukotriene receptor antagonist was effective in preventing analgesic-induced (dipyrone) bronchospasm.

The effects of leukotrienes in the lung can also be modulated by blocking 5-lipooxygenase activation. The efficacy of this approach was demonstrated in a randomized, double-blind, crossover study in which the 5-lypooxygenase inhibitor zileuton (600 mg orally, four times a day, for 6–8 days before aspirin challenge) led to a greater than 70% reduction in baseline urinary LTE4 excretion, a greater than 60% reduction in mean maximal urinary concentration of LTE4 after aspirin challenge, and almost complete suppression of subthreshold and threshold oral aspirin-induced bronchospasm.[46] In addition, nasoocular, gastrointestinal, and cutaneous manifestations were reduced to the levels of symptoms produced by placebo challenge. Similar data have been generated with the cysteinyl leukotriene receptor antagonists montelukast and zafirlukast.[44,45,47]

Analysis of mast cells isolated from patients with AIA shows that the overproduction of cysteinyl leukotrienes by these cells is very sensitive to the regulatory role of PGE2, suggesting an additional molecular mechanism to account for the excess sensitivity to the COX inhibition associated with NSAIDS in AIA.[48] Altered cellular cross talk involving platelets and leukocytes has been recently recognized as a potential source of excess cysteinyl leukotrienes in individuals with AIA through a biologic mechanism known as transcellular biosynthesis.[49]

In summary, although the mechanism of AIA remains incompletely understood, there appears to be a clear role for lipooxygenase products in the pathogenesis of the disorder. The available data also suggest that mast cells, stimulated by aspirin directly or indirectly, discharge their leukotriene mediators in large amounts into nasal secretions, but may not play the same role in the lung. The presence of increased numbers of eosinophils and altered eosinophil phenotype may be more relevant to the pathophysiology in the lung and may be linked to the airway inflammation that characterizes this disorder. This probably reflects their recruitment secondary to the release of mast cell–derived mediators, including leukotrienes and cytokines.

DIAGNOSIS

Despite the characteristic clinical features of AIA, diagnostic evaluation is fundamental, given the presence of false positive and negative diagnosis based on clinical history alone.[27] Several *in vitro* assays have been described in individuals with AIA; however, their standardization and availability as diagnostic tests has not materialized. This ranges from cellular assays, to biomarkers in serum, induced sputum, and exhaled condensate, to assays performed on saliva and on urine.[36,50] The use of provocation tests with aspirin or NSAIDS for persons suspected to have this disorder (Table 47-2) is used in the diagnosis of AIA employing protocols using single-blind or double-blind approaches.

A traditional protocol begins with a 3 mg dose of aspirin, although higher initial doses (30 mg) have been recently advocated.

TABLE 47-2 Diagnosis of Aspirin-Induced Asthma (AIA): Aspirin Challenge Protocols

Single-Blind Oral 3-Day Aspirin Challenge			
	Test Days		
Time	1	2	3
0	Placebo	ASA 30 mg	ASA 100–150 mg
3 h	Placebo	ASA 45–60 mg	ASA 150–325 mg
6 h	Placebo	ASA 60–100 mg	ASA 325–650 mg
Double-Blind Oral Aspirin Challenge			
Both tester and patient are blinded to eliminate potential bias.			
Bronchial Challenge with Lysine–Aspirin			
Time (min)	Challenge (Lysine–Aspirin in mg/mL)		
0	Placebo		
45	Placebo		
90	11.25		
135	22.5		
180	45		
225	90		
270	180		
315	360		
350	360 (10 breaths)		
Patients receive four breaths of all doses of lysine–aspirin unless otherwise indicated.

Sensitivity to aspirin and nonsteroidal antiinflammatory drugs, in Middleton E Jr, Reed CE, Ellis EF (eds). Allergy: Principles and Practice. St. Louis, CV Mosby, 1993; Phillips GD, Foord R, Holgate ST. Inhaled lysine-apirin as a bronchoprovocation procedure in aspirin-sensitive asthma: Its repeatibility, absence of a late-phase reaction, and the role of histamine. J Allergy Clin Immunol. 1989;84:232–241.

If reactions occur at this dose, patients are easily treated. The dosage is then increased to a maximum of 650 mg over a 3-day period. Due to concerns regarding the safety of the protocol, the use of leukotriene antagonists to decrease the rates of severe lower respiratory tract reactions during provocation tests has gained popularity.[51] The improvement in the safety profile for the oral aspirin challenge has also allowed reduction in the time needed to complete the protocol from 3 to 2 days. Spirometric pulmonary function is monitored serially during the challenge to assess the degree of bronchial obstruction. Airway reactivity to methacholine is not a viable surrogate for spirometry, since aspirin does not consistently alter methacholine sensitivity. Aspirin challenge should probably be reserved for use in centers experienced in its application and adverse effects. An alternative to oral challenge, used in some centers in Europe and elsewhere for the diagnosis of AIA, is the inhalation of stabilized lysine–aspirin, followed by serial lung function measurements, or nasal provocation with aspirin or lysine–aspirin followed by serial rhinomanometry or acoustic rhinometry.[52] Since lysine–aspirin is not available for clinical use in the United States, intranasal ketorolac challenge has been advocated as an alternative.[53]

TREATMENT

Given the particular pathophysiologic characteristics of AIA, optimal treatment of patients with AIA requires knowledge of the best approaches to treat acute aspirin-induced bronchial symptoms and associated nasal and sinus pathology. No specific therapy has emerged which can be recommended for the routine treatment of acute bronchospasm provoked by NSAIDs. Corticosteroids are not effective after acute aspirin ingestion, and theophylline and cromolyn sodium play no definite role.[9] Treatment of symptoms after acute ingestion, therefore, relies mainly on β-adrenergic agonists to reverse bronchospasm, and topical vasoconstrictors for both nasal congestion and eye symptoms. Frequent applications of these agents usually are necessary to maintain nasal and airway potency over the 2- to 6-hour reaction duration. On a chronic basis, the treatment of AIA depends on the correct diagnosis and avoidance of aspirin and other COX inhibitors that could cross-react to induce acute bronchospasm. Patients should be instructed that many over-the-counter medications contain aspirin or other NSAIDs, and they should carefully read package inserts before using any medication.

Drug treatment of AIA should focus on treating the underlying asthma and the strict avoidance of aspirin and cross-reacting NSAIDs. Currently, there also appears to be no role for systemic corticosteroids or theophylline in the prevention of AIA. Some investigators have found that antihistamines such as clemastine and mast cell stabilizers such as ketotifen, cromolyn, and nedocromil can have prophylactic efficacy.[54–56] However, not all subjects on these drugs are protected against bronchoconstriction after aspirin challenge. 5-lipooxygenase inhibitor zileuton was not found to be effective in preventing FEV_1 decline or nasoocular reactions to direct aspirin challenge,[57] although it had been previously shown to improve chronic asthma symptoms when added to conventional therapy in another study.[58] In contrast, experience with the cysteinyl leukotriene receptor antagonists has been variable, but mostly positive[56,59,60] and may be more effective in those who carry the variant C allele of LTC4S than in noncarriers.[61] Pretreatment with inhaled or systemic steroids or long-acting β-agonist (salmeterol) was shown to at least partially attenuate aspirin-induced respiratory lung function declines. The failure of tacrolimus (0.1 mg/kg), (a drug which could potentially affect both T cell generated cytokine responses and prevent release of mast cell histamine and leukotrienes) to prevent aspirin-induced respiratory reactions in patients with AERD on aspirin challenge in another study[62] suggests that this agent cannot be relied upon to prevent reactions from aspirin and cannot be used to facilitate "silent" aspirin desensitization of the patient with AERD.

In cases in which aspirin (or cross-reacting NSAIDs) cannot be avoided (i.e., in the setting of cardiovascular prophylaxis) or the efficacy of prophylactic measures cannot be assured, aspirin "desensitization" can be considered. Protocols are available for selected patients (Fig. 47-4).[63] These methods can effectively protect many from experiencing symptoms on exposure to aspirin or NSAIDs and will maintain this level of desensitization as long as aspirin is ingested indefinitely at doses of 325 to 650 mg a day. In a study of 25 aspirin-sensitive asthmatics, such therapy was shown to reduce nasal symptoms by 67% and asthma severity by 48%.[63,64] In the largest study of its kind, 172 patients with AERD were desensitized,

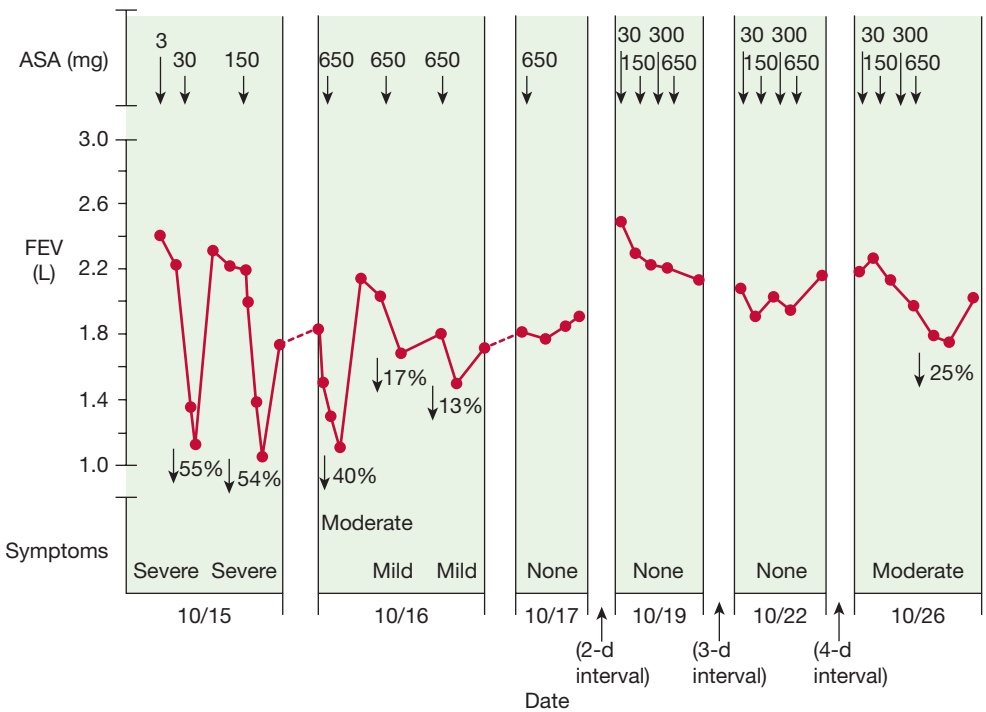

Figure 47-4 Airway desensitization to aspirin challenge in AIA. Timeline of respiratory function and overall symptoms after serial aspirin dosing. The reappearance of respiratory compromise and symptoms after 4 days without aspirin shows the need for continuous aspirin administration to maintain desensitized state. *(Data from Pleskow WW, et al. Aspirin desensitization in aspirin-sensitive asthmatic patients: Clinical manifestations and characterization of the refractory period. J Allergy Clin Immunol. 1982;69:11–19.)*

treated with 1300 mg of aspirin each day and followed for 1 to 5 years.[65] Clinical improvements were noted over the first 6 months, including reduction in dose of systemic corticosteroid and improvement in global assessments, which were maintained, but not further enhanced, during the remainder of the study. Approximately 67% (115 of 172) improved, 16 failed to improve, 24 discontinued because of aspirin-related side effects, and another 17 dropped out for other reasons.

It is interesting to note that although there are some reports of increased methacholine reactivity developing in patients soon after aspirin challenge,[44] baseline methacholine responsiveness does not seem to be successfully downregulated by aspirin desensitization. Also, there is no firm evidence that aspirin desensitization leads to abatement in skin disease in those with aspirin–urticaria syndrome.

Inhaled PGE2 was shown to prevent bronchoconstriction in a high proportion of patients challenged with inhaled L-lysine–aspirin in two small studies. In two studies[66] using misoprostol, a stable analogue of PGE1, prior to challenge with L-lysine–aspirin (400 μg 1 hour before) or predetermined threshold dose of aspirin (400 before, followed by then 200 μg with the provocative dose of aspirin), evidence was provided of some protection in 7 of 11 patients ($p = 0.024$) and in 6 of 7 patients (statistically only significant at time points 3 hours after challenge), respectively. To test whether asthma symptoms might improve on treatment with misoprostol, another group performed a double blind crossover study that showed that misoprostol, given for a period of 6 weeks (at dose of 800–1600 μg per day) led to a small improvement in nasal symptomatology without any effect on asthma control in 17 patients with proven AIA.[66] Thus, evidence of a specific method to control AIA apart from desensitization methods described above, has not been proven to be reliable. Fortunately, for those who require aspirin to prevent disease, such as those on low-dose aspirin, given for cardiovascular prophylaxis, the threshold needed to provoke airway and skin reactions is above that of the dose required for cardiovascular prophylaxis.

The potential contribution of chronic sinusitis to asthma exacerbations is well established. Aspirin sensitivity, chronic sinusitis, and nasal polyposis are well documented to coexist in AIA. Thus, the presence of these upper airway disorders must be considered in patients with AIA and effective treatment instituted if they are identified. High-dose topical intranasal corticosteroids can shrink polyp tissue and prevent obstruction of nasal passageways. In the setting of chronic sinusitis, standard approaches – including topical vasoconstrictors, antihistamines, and antibiotics – should also be utilized. Surgery to drain sinuses and remove polyps has been shown to be effective in the short term; however, polyps can regrow and the sinusitis often recurs.[2] The initial approach to nasal polyps in AIA is medical management, with aspirin desensitization playing an important role to decrease symptoms and improve postoperative outcomes in those requiring endoscopic sinus surgery, however, there is limited data on long-term follow-up in patients with nasal polyposis and AIA.[67] In selected cases where aspirin predominantly provokes nasal symptoms, administration of intranasal lysine–aspirin at increasing weekly doses successfully desensitized such patients and prevented regrowth of polyps.[68] A more recent and larger (though, due to drop-outs, under-powered randomized clinical trial) employed a crossover design after withdrawal of intranasal steroids. Lower doses of lysine–aspirin were administered more frequently (16 mg intranasally every 48 hours).[69] Results showed encouraging immunohistochemical changes characterized by a decreased expression of CysLT1 receptor on nasal submucosal inflammatory cells from turbinate tissue, but no clinical (diary scores of nasal and chest symptoms) or objective improvement on rhinometry. Two US studies that piloted the use of intranasal ketorolac administration with a modified aspirin challenge have shown the ability of ketorolac to induce nasal and lower respiratory reactions as part of the diagnostic element of the challenge. In addition, the administration of ketorolac prior to the modified aspirin challenge has the ability to decrease the severity of the FEV_1 decline, the frequency of laryngospasm and other extrapulmonary reactions. The rate of partial to complete desensitization was estimated at 77% for the intranasal portion of the protocol.[53] An additional advantage was the shortening in the duration of the desensitization.[70]

Despite aspirin desensitization and careful treatment of commonly associated sinusitis, a significant proportion of AIA patients do not achieve complete control of asthma or nasal symptoms. It is postulated that this may reflect permanently remodeled airways or residual allergic triggers that require specific allergy control measures and anti-inflammatory therapy. Evaluation of the effect of strict allergen avoidance, specific allergen immunotherapy, more intensive local management of the inflamed nasal mucosa and anti-IgE treatment in this scenario may better clarify the role of atopy in persistence of symptoms after aspirin desensitization.

EXERCISE-INDUCED ASTHMA

The first report of exercise-induced asthma (EIA) is attributed to John Floyer in 1698.[71] Nearly 300 years later, interest in this subject grew when it was recognized that exercise or hyperventilation could provoke asthma attacks. EIA can be defined as a condition in which vigorous physical activity triggers acute airway narrowing in persons with heightened airway reactivity.[72] It appears that EIA is always associated with the asthmatic diathesis, although EIA can be seen before other characteristic features of asthma emerge. Various reports indicate that EIA is common, affecting between 50% and 90% of all asthmatics[73] and 40% of patients with allergic rhinitis without known asthma.[74] Some have suggested that all asthmatics can be shown to manifest airway narrowing to thermal provocations of sufficient intensity, whether induced by exercise or hyperventilation. Other susceptible persons are first degree relatives of asthmatics, atopic "nonasthmatics," and patients with cystic fibrosis. Approximately 10% of pediatric patients can be found to have EIA, a higher prevalence than that of clinical asthma.

Elite athletes may be more predisposed to developing EIA.[75] Surveys conducted of athletes at the Atlanta (summer) and Nagano (winter) Olympic Games, showed a prevalence of 16% to 17%. The prevalence may actually be higher in those who are regularly exposed to high minute ventilation of cold, dry air typical of winter sports. In some studies the prevalence of EIA reported in figure skating (35%), and ice hockey (35%)[75] may be responsible for driving the overall incidence of EIA in winter sports to as high an estimate as 23%.[76]

CLINICAL PRESENTATION

Several societies have adopted a definition of EIA as clinical asthma where exercise triggers symptoms.[77] This is important given the recognition of exercise-induced bronchoconstriction (EIB) in individuals without asthma. Patients with EIA generally manifest a series of fairly predictable symptoms and alterations in pulmonary function that can be assessed by laboratory testing (Fig. 47-5). Normal persons and asthmatics generally first respond to exercise with bronchodilation, probably mediated by the release of catecholamines.[78,79] This response is short-lived, peaking at midexercise, and is followed by return of normal baseline airway tone at the end of exercise. In patients with EIA, the transient bronchodilation and reversal are followed by bronchoconstriction coincident with

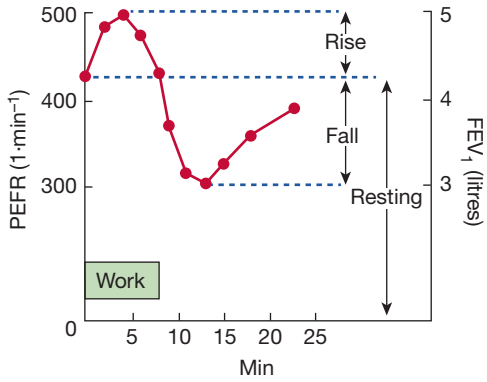

Figure 47-5 Typical pulmonary function changes induced by exercise in EIA. Transient bronchodilation during exercise and bronchospasm after exercise are noted. *(Data from Anderson SD. Is there a unifying hypothesis for exercise-induced asthma? J Allergy Clin Immunol. 1984;73:660–665.)*

symptoms of cough, wheezing, dyspnea, and chest tightness typical of asthmatic attacks. Typically, when they are provoked with a brief, intense exercise period in the laboratory, maximal bronchoconstriction occurs 5 to 10 minutes after the cessation of exercise and lasts for 30 to 60 minutes (Fig. 47-4). Rarely does this form of bronchoconstriction result in ventilatory failure, although it can limit the performance of trained athletes.

In addition to asthma after exercise, many athletes describe dyspnea during exercise. If these athletes are able to continue to exercise despite the initial airway obstruction and increase their level of activity, relief of bronchoconstriction often occurs. This is associated with symptomatic improvement that is described as "running through the attack." The development of dyspnea during exercise is ostensibly related to the development of bronchoconstriction at lower work intensities (simulating a postexercise state), which is reversed by interval training at higher intensities (simulating an exercise state). This has been taken as evidence that airway function during exercise reflects a balance between bronchoconstrictor and protective bronchodilator influences, and that this balance can be influenced by rapid changes in exercise intensity.[75,78]

The reproducibility of EIA is highly dependent on the specific characteristics of the stimulus- and patient-related factors. The net influence of exercise intensity, the temperature and humidity of the inspired air, the presence of allergens and pollutants in the environment, and the patient's baseline airway reactivity are fundamental in determining whether exercise will lead to bronchoconstriction. If asthma is better controlled at baseline, EIA may be more difficult to provoke. If climatic conditions vary, even though asthma is not well controlled, EIA may fail to develop. Classic work has shown that for a fixed minute ventilation, cold, dry air inspired during exercise is more likely to provoke EIA than warm, humid air.[79,80] Thus, EIA is more likely to occur with jogging outdoors during the winter than with swimming indoors. A recent study in children showed that exercise-induced wheeze was associated with an increased rate of urgent medical visits independently of asthma severity or socioeconomic factors, suggesting that EIB may be a surrogate marker of poorly controlled asthma rather than a distinct asthma phenotype.[81]

It is interesting to note that about 50% of patients with EIA will not manifest a bronchoconstrictive response if rechallenged with the same stimulus within 60 minutes and thus appear to be in a "refractory state." Neither baseline airway obstruction nor the degree of obstruction provoked by exercise can be used to determine who will be refractory to repeated exercise challenges. Furthermore, after 3 hours, even patients who were refractory to repeated challenge will regain ability to bronchoconstrict with exercise.

PATHOPHYSIOLOGY

The heterogeneity of responses present in EIA and bronchoconstriction, are influenced by the fundamental differences in the types of exercise and the environmental aspects of specific disciplines. Despite the attempt to categorize EIA as a unique entity the truth is that this is almost impossible. Two pathogenic schemas have been proposed for the bronchoconstriction seen in EIA. The two theories focus on the roles of (1) heat exchange, water loss, and airway rewarming; and (2) airway inflammation. The role of inflammation as a reaction to these stimuli or as an enhancer of the effects of these two pathophysiologic pathways is likely tied to leukotrienes and related lipooxygenase products.

Heat Exchange and Water Loss

During tidal breathing, heat (via conduction and evaporation) and water (via evaporation) are transferred from the mucosa of the upper airways to the entering air. Since exercise requires marked increases in minute ventilation, surpassing the volume of air that can be inspired through nasal structures, air enters directly through the mouth, bypassing the normal warming and conditioning function of the nose. The lower respiratory mucosa then attempts to compensate for the function of the bypassed nose. Heat and water fluxes first occur. The lower airways are cooled and dried and are subject to rewarming by warm blood carried by the bronchial circulation.

In the late 1970s, a number of investigators postulated that EIA was the result of increased heat loss in the airway. This was based on the observation that cold, dry air caused a greater fall in FEV_1 than did hot, dry air[82] and on correlations between heat exchange and the degree of bronchoconstriction. Others, however, showed that the temperature of the inspired air was not crucial to inducing bronchoconstriction, and that temperatures of dry inspired air that varied by as much as 60 degrees could still provoke airway narrowing.[80,83] This suggested that airway evaporative water loss might be more important than airway cooling. The water loss was predicted to change the osmolarity of the cellular and extracellular components of the airway wall, stimulating increased bronchial blood flow to increase the delivery of water.[80] In addition, bronchial wall hyperosmolarity was hypothesized to increase the release of proinflammatory mediators from resident airway immune cells such as mast cells.[82] This concept was supported by work that demonstrated that changes in the humidity of inspired air, and not temperature, determine the magnitude of EIA. Further support for this construct came from studies using cold gas mixtures with different water-carrying capacities, which showed a significant correlation between evaporative heat loss but not total heat loss or temperature gradient on the airway response.[84]

In apparent contrast to these data is the considerable body of work that does not support the concept that osmolar changes precipitate EIA. The most important of these showed that increasing minute ventilation at constant humidity increases the severity of EIA.[74] The combination of overlapping mechanisms including airway cooling, airway dehydration and osmolar changes account for the pathogenic features responsible for EIA, rather than a single mechanism.[114]

Airway Rewarming

An important theory that also remains to be unequivocally proven is that offered by McFadden, who proposed that the process of airway rewarming is active in the pathogenesis of the airway narrowing that occurs in EIA.[85] This theory postulates that loss of heat associated with exercise transiently leads to decreased bronchial blood flow.

At the end of exercise, the bronchi undergo reactive hyperemia characterized by vascular engorgement. This leads to airway caliber compromise and airway wall edema. The strongest support for this theory arises from studies showing that the severity of EIA could be controlled by regulation of the thermal gradient during exercise and the rate of rewarming after exercise. The presence of an elevated airway permeability index in individuals with EIA is associated with the severity of EIB,[86] suggests that individuals with abnormal vascular permeability may be more susceptible to larger fluid shifts and airway physiologic changes associated with exercise. Sodium ingestion also seems to affect vascular volume and increase airway inflammation in the setting of exercise.[87]

In summary, there is evidence that associates exercise-induced bronchoconstriction with a sequence of events that includes heat loss, water loss, and airway rewarming. The degree to which these temperature and water alterations contribute to the pathogenesis of EIA is still, however, a topic of debate and investigation.

Inflammation and EIA

Theories postulating a role for inflammatory mediators in the pathogenesis of EIA have recently received new support and are being harmonized with the already considerable evidence supporting a role for inflammation in the pathogenesis of other forms of asthma. New information in exercise suggests that those predisposed to EIA, specifically elite athletes, may manifest a degree of airway inflammation that had not been previously appreciated. Instead of demonstrating a lower rate of EIA, allowing a potentially higher level of exercise performance, which might be expected on the basis of selection of those best equipped to excel in sports, elite athletes appear to exhibit a paradoxically higher incidence of EIA and a higher degree of airway inflammation without necessarily manifesting a higher prevalence of underlying clinical asthma.

Older data on the role of inflammation in EIA did not necessarily support this link. One study analyzing the characteristics of bronchoalveolar lavage (BAL) fluid from patients with EIA 12 minutes after exercise failed to find evidence for mast cell mediator release since BAL histamine, tryptase, LTC4, and PGD2 levels were not altered. Similarly, studies performed 1 hour and 25 hours after exercise did not reveal significant differences in BAL cellularity or in histamine or tryptase levels.

In contrast, one group studying elite cross-country skiers, found elevated airway T lymphocytes and eosinophils compared to controls.[88] Several others have demonstrated changes in exhaled NO, which generally decreased with exercise, suggesting a high basal level and ventilatory clearance of this gas associated with airway inflammation,[75] while another observed increases in plasma adenosine after exercise.[89] A different group documented the presence of a late phase airway response after exercise that was demonstrable in 50% of competitive athletes studied.[90] Most importantly, the new concept that these changes might be provoked by exercise, rather than be a reflection of underlying inflammation in those who manifest EIA, is supported by Helenius,[91] who showed that athletes who stopped high-level training and modulated the amount of exercise they subsequently pursued, experienced reduced asthma symptoms and diminished bronchial responsiveness to histamine. Additional observations using exhaled breath condensate (EBC) have shown elevations of cysteinyl leukotrienes,[92] RANTES and eotaxin,[93,94] after exercise. RANTES has also been found to be elevated in the EBC of asthmatic children with EIB after exercise challenge.

Leukotrienes in EIA To determine whether leukotrienes play a role in the pathogenesis of EIA, LTD4 receptor antagonists and 5-lipooxygenase inhibitors have been employed. Studies using an intravenous LTD4 receptor antagonist 20 minutes before exercise demonstrated significant attenuation of the maximal provoked bronchoconstriction and mean time to recover from bronchoconstriction (8 minutes for the treatment group vs. 33 minutes for placebo).[95] Similar results were noted by others using oral or inhaled leukotriene antagonists. In general, although the protection was relatively small, it was significant and equivalent in potency to inhaled cromolyn.

The results obtained with peptidoleukotriene antagonists are consistent with those obtained when the effects of a 5-lipooxygenase inhibitor on bronchoconstriction induced by cold, dry air were evaluated. In the most important study of this kind,[96] a 5-lipooxygenase antagonist was an effective as cromolyn or terbutaline in augmenting respiratory heat exchange. Thus, leukotrienes may well mediate the airway inflammation and contribute to the pathogenesis of EIA.

GENETICS AND GENOMICS

Little information is available on the potential genetic underpinnings of EIA, however, some of the observations from genetic and genomic studies are summarized here. Using microarray analysis, a group demonstrated enhanced transcription of 5-lipooxygenase (ALOX5) and 5-lipooxygenase activating protein (ALOX5AP) genes.[18] A more recent study examined the transcriptional profile of induced sputum after an exercise challenge and identified the upregulation of transglutaminase 2 (TGM2), a molecule associated with an increase in the activity of secreted phospholipase A2, the rate-limiting step on eicosanoid formation.[97] The same investigators described the predominant role of airway MUC5AC expression during exercise challenge in a similar setting.[98]

Other investigators have provided evidence of leukotriene C4 synthase (A-444C) promoter polymorphisms in association with greater severity of EIA in studies conducted in a large cohort of Korean children with asthma.[99] However, these polymorphisms are not associated with montelukast responsiveness in a subsequent pharmacogenomics study of the same population.[100] These observations suggest the potential existence of disease-modifying genes in exercise-induced bronchospasm.

DIFFERENTIAL DIAGNOSIS

The diagnosis of EIA is most accurately established by employing validated exercise protocols coupled with pulmonary function testing. However, patients are commonly given a presumptive diagnosis based on their history and physical examination. Important points in the clinical history include the level and type of exercise that provokes asthma, the timing of symptom onset, situations that modify symptom onset, environmental conditions and the precise symptoms experienced. Many of the symptoms of EIA can mimic other conditions that would require an entirely different therapeutic approach (Table 47-3). For example, chest

TABLE 47-3 Differential Diagnosis of Exercise-Induced Asthma

Cardiac Disease	Functional Abnormalities
Coronary ischemia	Vocal cord dysfunction
Mitral valve prolapse	Panic disorders
Atrial myxoma	General
Cardiomyopathy	Deconditioning
Arrhythmias	Anemia
Lung Disease	
Fixed airway obstruction	
Interstitial lung disease	
Exercise-induced cough	

tightness with exercise should be unequivocally distinguished from coronary ischemia. Other cardiac disorders that can mimic EIA are arrhythmias, cardiomyopathies, atrial myxoma, and mitral valve prolapse, all of which can manifest with dyspnea and wheezing. The presence of a murmur, click, or other findings on physical examination should help to identify patients with these conditions. Exercise-induced anaphylaxis can also mimic EIA but will generally exhibit skin manifestations (urticaria), and respiratory symptoms will be less prominent. Two other conditions that have been reported to mimic EIA are fixed glottal and tracheal obstruction, which become noticeable with the increased ventilation of exercise and exercise-induced vocal cord/arytenoids dysfunction, not present at rest. Some have also suggested that panic disorders and the excessive tachypnea associated with deconditioning can be confused with EIA. Symptoms due to these other conditions generally are greatest during exercise provocation rather than afterward, when airflow limitation due to EIA usually reaches its peak.

Exercise-induced cough is another phenomenon that can mimic EIA. Both may be induced by changes in the osmolarity of the airways reflecting water loss from the respiratory tract during exercise, the inhalation of humid air also prevents both phenomena. However, EIA and exercise-induced cough respond differently to β-adrenergic agonists, suggesting that they are mediated by different underlying mechanisms. It is postulated that exercise-induced cough is the direct result of the osmolarity changes provoked by airway drying, whereas EIA is due to the mediator release that results from the process of airway drying. Therefore, although nearly all patients with EIA cough with exercise provocation, there are patients who have exercise-induced cough without bronchospasm, and thus do not have EIA.

■ PHYSIOLOGIC DOCUMENTATION

Because a simple history or cough or wheezing may not reliably predict EIA, especially in those in whom a trial of preventive measures has not been successful, formal exercise testing may be required.[75] The clinician needs to document airflow obstruction that reaches a peak just after provocation, during the recovery period. In athletes, the presence of EIA and EIB has major implications in their exercise performance and management. In addition, societies and committees have created practice guidelines to assist in the documentation of EIA.[77,101,102] Bronchial provocation tests (BPT) are used to identify airway hyperresponsiveness and they can be classified as indirect and direct. Indirect tests include exercise, the inhalation of dry air (isocapnic hyperventilation [ISH], also known as eucapnic voluntary hyperpnea), hypertonic saline, and mannitol. The direct methods include methacholine, histamine, carbachol and AMP inhalation.

Indirect methods trigger airway hyperreactivity through different mechanisms that affect the release of inflammatory mediators and cause bronchoconstriction. Exercise provocation, whether performed on an ergometer or a treadmill, leads to significantly greater increases in heart rate, metabolic rate, and oxygen consumption. Exercise, but not ISH, is accompanied by increased numbers of circulating basophils and increased circulating catecholamines and cAMP. The differences in the last two parameters probably explain why the bronchodilatory response that characterizes exercise is not provoked by ISH. The bronchoconstriction induced by ISH is similar to that induced by exercise in terms of magnitude, time course, and refractory period. Two main advantages over exercise include the ease with which the ISH protocol can be standardized and the finding that oxygen consumption and heart rate are not increased with ISH. As a result, ISH is useful in differentiating EIA from occult cardiac disease and is especially valuable when elderly or cardiac patients are being evaluated.

The most commonly used ISH protocol for the diagnosis of EIA in the United States is that published by O'Byrne et al.[103] and modified by Philips et al. (Fig. 47-6).[104] This is accomplished by registering changes in pulmonary function in response to varying rates of ventilation using dry air with a fixed CO_2 content of 4.9% to maintain isocapnia. Each ventilatory challenge is performed for 3 minutes, with spirometry performed at intervals thereafter (usually 2, 5, and 10 minutes after the end of hyperventilation). Serial increase in hyperventilation is performed until maximal voluntary ventilation is reached. If the FEV_1 falls greater than 10% after provocation, the test is considered positive, confirming the diagnosis of EIA. Although some have pointed out that it is not necessary to condition air to subfreezing temperatures to perform the test, Scandinavian investigators showed that assessing bronchoconstrictor responses to whole-body exposure to very cold air significantly increased the number of asthmatic patients who experienced bronchoconstriction. Others have pointed out the need to assess athletes in the field performing in the sport in which they compete, since they may not have a significant drop in FEV_1 symptoms during in the laboratory during challenge.[75]

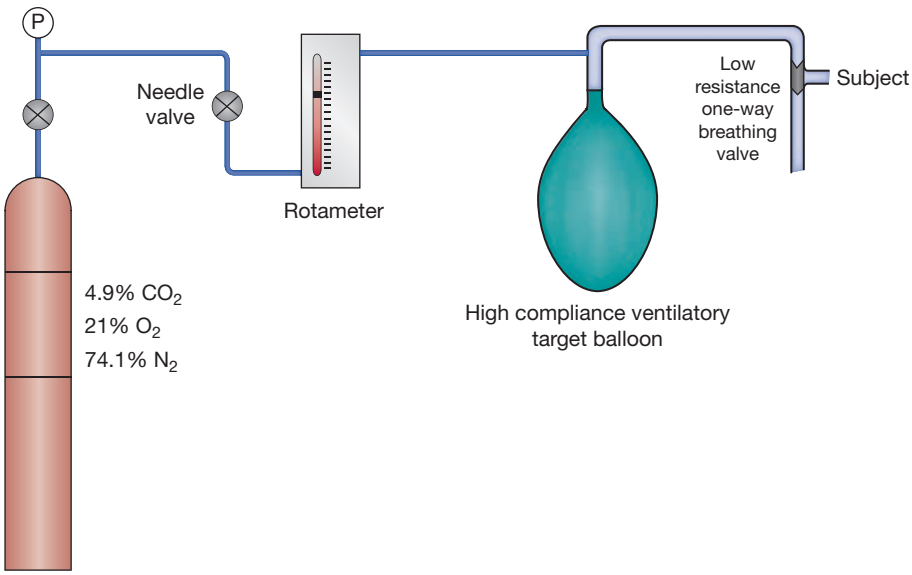

Figure 47-6 Apparatus for isocapnic hyperventilation challenge to diagnose EIA. *(Data from Phillips YY, et al. Eucapnic voluntary hyperventilation of compressed gas mixture: A simple method for bronchial challenge by respiratory heat loss. Am Rev Respir Dis. 1985;131:31–35.)*

To optimize the validity, repeatability and practicality of exercise testing for the diagnosis of EIA, a variety of testing protocols have been pursued. Unfortunately, the criteria used to define a positive test in these studies are different, making standardization difficult. Although the optimal diagnostic algorithm for the assessment of EIA is still lacking,[72,75] data reported on athletes from the 2002 Olympic Winter Games,[105] compared eucapnic voluntary hyperventilation (EVH) with exercise testing outdoors in the cold (20°C and 45% humidity). The EVH test for 6 minutes with cold dry air was determined to perform best in assessing the presence of EIA.

The mannitol inhalation test relies on the airway fluid changes to incremental doses of this hyperosmolar dry powder. This bronchial provocation agent was approved by the FDA in 2010 and is available for adults and children older than 6 years of age. A decline in FEV_1 equal to or larger than 10% is considered positive. In a similar fashion, the inhalation of hypertonic saline (4.5%) takes advantage of the same physiologic principle to evaluate for the presence of bronchoconstriction. The most popular direct challenge method is the methacholine challenge test, supported by its standardization and reproducibility; it has been approved by the International Olympic Committee Medical Commission.

In addition to the difficulties inherent in the standardization of the challenge protocol, the clinician must be aware of situations that can lead to false-negative evaluations. Specifically, it is important that all drugs that can potentially attenuate bronchoconstrictor responses – such as calcium channel blockers, methylxanthines, cromolyn, and β-adrenergic agonists – be discontinued for a sufficient period before the evaluation.

TREATMENT

A variety of nonpharmacologic and pharmacologic approaches have been employed in treatment of EIA.

Nonpharmacologic Treatments

The treatment of EIA is influenced by the underlying process driving this response. In patients with asthma who experience EIA, optimization of the asthma therapy is the first step. Inhaled steroids attenuate the development of EIA during laboratory provocation and increase the threshold for the development of EIA clinically. Prophylactic measures to prevent EIA include avoiding exercises that expose the patient to cold, dry air and favoring those in which the patient breathes humid air during exercise. Patients can reduce the severity of their EIA by breathing through the nose rather than through the mouth during exercise. Face masks (e.g., 3M Cold Weather Mask) can be effectively used by the many people who find it impossible to breathe through the nose during intense exercise.

It is still unclear whether physical training and improvement in work capacity can relieve symptoms of EIA. Training ought to be useful, at least theoretically, since a better-trained athlete may require a lower mandatory minute volume—which may lead to less water loss from the airways and less severe EIA. Pre-exposure of patients with EIA to air high in ozone in two studies performed in Los Angeles and Toronto showed that EIA was not enhanced. This suggests that choosing a day to exercise on the basis of ozone will not help prevent EIA. A series of repeated short sprints has been shown to be effective in inducing the refractory state, which might then allow the athlete to maximally exercise without developing EIA.[106] A warm up period to induce the refractory period has been advocated by some to improve performance in the competitive athlete.[107] A high-intensity interval warm-up in recreational athletes prior to an exercise challenge resulted in improved FEV_1, and this protective effect was increased when used in combination with salbutamol.[108] A systematic review of the effect of warming-up prior to exercise found that interval and variable-intensity protocols are effective short-term strategies to prevent EIB.[109]

A low sodium diet has also been advocated as a nonpharmacologic intervention in individuals with EIA, based on the observation that those with a low sodium diet had smaller declines in FEV_1 with exercise compared to those ingesting normal or high amounts of sodium.[110]

TABLE 47-4 Treatment of Exercise-Induced Asthma (EIA)

Treatment Immediately Before Exercise (10–20 min before)	Treatment of Underlying Disease (Days Before)
β-Adrenergic agonists	Goal: Improved asthma control
Cromolyn sodium	Inhaled corticosteroids
Nedocromil	Systemic corticosteroids
? Anticholinergics	? Theophylline
? Inhaled furosemide	
Leukotriene receptor antagonists	

Pharmacologic Treatment

Several classes of drugs have been shown to prevent EIA if administered just before (10–15 minutes) exercise. The list includes β-adrenergic agonists, cromolyn sodium, anticholinergics, and possibly rapid-release theophylline (Table 47-4).[75,103] β-Adrenergic agonists are the most effective drugs for use against EIA and, therefore, are the mainstay of therapy. They have a rapid onset of action and are 90% effective in preventing EIA when used just before exercise. They are especially useful if the patient has some reversible airway obstruction, since they also improve lung function before exercise. Long-acting β-adrenergic agonists (LABA) have also been found to be effective in preventing EIA. The duration of protection they confer may approach 10 hours or more. It is interesting to note that the cough so often associated with EIA appears to occur independent of the bronchospasm provoked by exercise. Although exercise-induced airway narrowing is prevented by the inhalation of β-adrenergic agonists before exercise, the cough is not.

Cromolyn sodium also has been shown to attenuate bronchoconstriction in most patients with EIA. This medication is not a bronchodilator and, therefore, does not reverse bronchoconstriction. Cromolyn does, however, have two advantages over other agents. First, it does not contribute to tachycardia and is therefore useful in elderly patients or patients with cardiac compromise. In addition, cromolyn has been shown to prevent the late bronchoconstrictor response to exercise. Related drugs (including nedocromil, minocromil, and oxatomide, but not ketotifen) have been shown to be similarly effective against EIA. Anticholinergics, such as ipratropium bromide, prevent airway narrowing after exercise in a high percentage of patients with EIA. They are especially useful in those who experience a rapid bronchodilating effect of the drug. The slower onset of action for most patients, however, limits their utility after bronchodilation has occurred.

Theophylline has weak bronchodilatory effects, high side-effect profile, and slow onset of action and is not recommended for routine use as pretreatment for EIA. However, it has been shown to confer protection against EIA if 100 to 200 mg is taken 2 hours before exercise. Other orally administered drugs that are not commonly used, but have the potential to be helpful in preventing EIA, are terbutaline, albuterol (2 hours before exercise), some alpha adrenergic agonists, and verapamil if taken 1½ hour before exercise as well as

the inhaled antihistamine clemastine.[78] In addition, terfenadine was shown by one group to prevent EIA.[111]

For athletes, organizations including the World Anti-Doping Association and International Olympic Committee, have developed standards that incorporate physiologic documentation of bronchial hyperresponsiveness, including bronchoprovocation tests, permitting use of certain medications, particularly short acting β-agonists.[112] Due to concerns related to doping, all practitioners involved in the management of athletes should review the specific guidelines developed by the appropriate governing bodies. Some of these agencies include the World Anti-Doping Agency (WADA; http://www.wada-ama.org/), International Olympic Committee (IOC; http://www.olympic.org/ioc), National Collegiate Athletic Association (NCAA; http://www.ncaa.org/), and US Anti-Doping Agency (www.usantidoping.org), among others.

Despite the observation that inhaled furosemide can prevent EIA in adults and children, their use for this indication has not evolved as standard therapy. Leukotriene antagonists have been advocated by some and shown to be effective, especially if treatment with short acting β-agonists in insufficient.[75] Because of their low side-effect profile, leukotriene antagonists would appear to be well suited as single agents for use against EIA. However, additional head-to-head studies showing efficacy during exercise need to be conducted before these agents can be recommended over inhaled β-adrenergic agonists in routine prophylaxis against EIA. A recent study showed that the combination of inhaled budesonide and montelukast, was superior to either agent alone, shortening the duration of EIB.[113]

Management needs to be tailored to individual needs and response to therapy. Despite the mechanistic differences seen in EIA and EIB, an approach that optimizes underlying asthma control is key, since the two syndromes are associated with impaired airway function. In individuals with chronic asthma, EIB seems to be a marker of suboptimal control, and an increase of controlling agents is advocated.[77,114]

CHAPTER 48

Allergic Bronchopulmonary Aspergillosis (Mycosis) and Severe Asthma with Fungal Sensitivity

Geoffrey L. Chupp

INTRODUCTION

Allergic bronchopulmonary aspergillosis (ABPA) is an idiopathic inflammatory disease of the lung, characterized by an allergic inflammatory response to colonization of the airways by *Aspergillus fumigatus* or other fungi. The entity was first described in 1952 by Hinson et al., and then again in 1967, when Scadding recognized an association between the disease and proximal bronchiectasis in areas previously affected by infiltrates (predominantly in the upper lobes).[1,2] The first adult case of ABPA was reported in the United States in 1968.[3] Although most cases entail hypersensitivity to *Aspergillus* spp. (especially *A. fumigatus*), the finding of a virtually identical clinical syndrome associated with immune sensitivity to *Candida albicans* (most commonly), *Helminthosporium*, *Alternaria, Curvularia lunata, Drechslera hawaiiensis, Stemphylium languinosum, Saccharomyces cerevisiae*, or *Pseudallescheria boydii* has led some to use the term *allergic bronchopulmonary mycosis* to describe the syndrome.[4] However, since the predominant causative organism is *A. fumigatus* and the commercially available laboratory testing is for this organism, ABPA is primarily designated as the diagnosis. In addition, a new entity has been recently recognized that appears to be on the continuum between fungal allergy, at one end, and ABPA at the other: severe asthma with fungal sensitivity (SAFS).[5]

The precise prevalence of ABPA is unknown, in part due to variability in diagnostic criteria used in various studies, the lack of distinction between ABPA and mold-sensitive asthma, and delays in the diagnosis of patients with long-standing disease; however, it is clear that ABPA is a relatively common entity. Estimates are that true ABPA complicates approximately 7% to 14% of cases of chronic steroid–dependent asthma and approximately 7% to 15% of cases of cystic fibrosis (CF).

Most cases of ABPA are recognized in the third to fifth decade of life, but they may present during childhood. In some patients, it is likely that ABPA starts early in life and continues, unrecognized, until adulthood. Interestingly, familial cases have been reported, suggesting that genetic factors underlie development of ABPA.[6,7] The spectrum of disease is broad. Patients may be asymptomatic, have mild-to-moderate asthma, or have severe and debilitating disease, leading to lung transplantation. However, if recognized early and managed aggressively, ABPA is treatable and may remit indefinitely; progressive lung damage can be avoided.

For the purposes of this discussion, the focus is on ABPA. However, clinicians should be cognizant that diagnostic testing for other fungi needs to be pursued when organisms other than *Aspergillus* spp. are suspected. In addition, the newly defined form of asthma noted previously, SAFS, is discussed and differentiated from ABPA.

PATHOGENESIS

Although the pathogenesis of ABPA is poorly understood, it is believed to be the result of an exaggerated immunologic reaction to chronic airway colonization by *Aspergillus* (or other relevant fungal) species.[8] *Aspergillus* spp. are globally ubiquitous, thermotolerant fungi that reside in decaying organic matter and colonize most domestic environments, including carpets and air duct systems.

In humans, airborn *Aspergillus* spores or conidia that are inhaled are immunologically inert, and in normal individuals are cleared by innate immune system mechanisms to maintain airway homeostasis. However, in susceptible individuals, conidia colonize airways, germinate into somatic hyphae that stimulate a chronic allergic inflammatory response that results in tissue injury and, ultimately, dictates the clinical features of ABPA. In contrast to a true infection in which fungal hyphae invade the lung parenchyma, colonization of the airways with germinating fungal spores represents an abnormal state that contributes to the exaggerated Th2 inflammatory response without clear tissue invasion. While a detailed understanding of the mechanisms that drive this process remains poorly understood, it appears that susceptibility to *Aspergillus* colonization and development of clinical disease depend on host factors, such as genetic background, T-cell responsiveness to *Aspergillus* antigens, the magnitude of tissue response to *Aspergillus*, and the level of environmental exposure to this ubiquitous fungus.

Investigations into the genetic risk factors associated with ABPA have identified several candidate genes, suggesting that the pathogenesis of ABPA requires both host and environmental factors.[9] Best characterized is the association between gene mutations in the CF transmembrane conductance regulator (CFTR) and the pathogenesis of ABPA.[10,11] CFTR mutations are more common among patients with ABPA compared with the general population or with individuals with severe asthma without sensitivity to *A. fumigatus*. Another genetic link to ABPA is that Th2-type T-cell reactivity to selected *Aspergillus* antigens is determined by the presence of MHC Class II DR2 or DR5 alleles, which may predispose patients to the disease, whereas the MHC DQ2 allele may be protective.[12,13] In addition, investigators have determined that there is an increased prevalence of polymorphisms in the promoter region of the pathogen associated molecular pattern receptor, Toll (TLR) 9, in individuals with ABPA compared with controls or patients with SAFS.[14] We recently determined that children with severe asthma and ABPA are more likely to carry the Chitotriosidase 1 (CHIT1) exon 10 mutation.[15,16] Individuals with the exon 10 mutation have lower levels of, or lack, chitinase activity in serum and are unable to degrade chitin, a structural polysaccharide in the cell wall of lower life forms such as *A. fumigatus*.[17–19]

At the microscopic level, ABPA is characterized by an intense eosinophilic and mononuclear cell inflammatory response, leading into areas of parenchymal scarring, airway remodeling, and bronchiectasis.[20,21] Immunologic studies demonstrate the presence of a type I hypersensitivity reaction, with elevated serum levels of total IgE and *A. fumigatus*-specific IgE in individuals with ABPA. In addition, patients have evidence of an exaggerated Type III hypersensitivity reaction, indicated by the presence of *A. fumigatus-specific* IgG antibodies (classically called "precipitins" or precipitating antibodies) and circulating immune complexes during disease exacerbations. A type IV cell-mediated immune reaction may also be at work, based on the finding of dual (immediate and delayed) cutaneous reactions and *in vitro* lymphocyte transformation to *A. fumigatus* antigen stimulation in some patients.[22,23]

A substantial amount of work has been done on the immune response in ABPA, demonstrating that several cell types and pathways are involved in the pathogenesis of this destructive variant of

asthma.[17,18] A pathogenetic role for helper T lymphocytes is suggested by a number of findings, including the presence of increased numbers of airway Th2 cells and elevated levels of soluble interleukin 2 receptors (suggesting T-cell activation) in the circulation of persons with active ABPA[24]; the derivation of *A. fumigatus*-specific T-cell clones with T helper–2 (Th2) patterns of cytokine production from the blood of patients with ABPA[25,26]; positive correlations between activated T-cell number, levels of the T-cell–derived cytokines IL-4 and IL-5, and number of airway eosinophils in the disease; the critical role IL-5 plays in murine models of ABPA[27–34]; and increased reactivity of Th2 cells to *A. fumigatus* antigens among patients with ABPA as compared with patients with asthma and skin reactivity to *Aspergillus*.

In addition to lymphocytes, eosinophils and basophils may contribute to local airway injury, and neutrophils likely play a role in airway inflammation and tissue damage in ABPA, as evidenced by the fact that sputum IL-8 levels correlate with sputum neutrophilia, matrix metalloproteinase levels, and FEV_1 among patients with ABPA.[35,36]

It is also clear that the fungus itself contributes substantially to the pathogenesis of disease. *A. fumigatus*-derived proteases likely cause epithelial cell injury and protective barrier disruption, triggering immune hypersensitivity by inducing inflammation or by allowing increased penetration of fungal antigens into the airway wall.[37] *Aspergillus*-derived proteases may also stimulate proinflammatory cytokines, such as IL-8, and release of growth factors; proteases may also cause tissue damage, leading to bronchiectasis.[36]

A variety of other *Aspergillus*-derived antigens (including cytotoxins and heat shock proteins) with demonstrated ability to bind IgE and IgG derived from the blood of patients with ABPA have also been shown to drive both the IgE (hypersensitivity) and IgG immune responses. *A. fumigatus*-derived proteases with antibody-binding capacity may also amplify the inflammatory response. *A. fumigatus* antigens, such as Aspf1 (a cytotoxic protein), Aspf2 (a fibrinogen binding protein), Aspf5 (a metalloprotease), Aspf6 (manganese superoxide dismutase), Aspf8 (a ribosomal protein), Aspf13 and Aspf18 (serine proteases), as well as Aspf3 and Aspf4, have all been implicated in these processes. Finally, host response to *Aspergillus fumigatus* antigens includes surfactant proteins (SP) A and D, which may play a protective role against ABPA by interfering with binding between *A. fumigatus* antigens and IgE. Notably, however, SPD levels do not correlate with acute exacerbations of ABPA in humans.[38–40]

CLINICAL FEATURES

Although ABPA typically presents in patients with a history of difficult-to-control asthma, the spectrum of presentation is highly variable and should be considered in any patient with difficult-to-control asthma and hypersensitivity to *A. fumigatus* (Table 48-1).[40] Typical presenting complaints are often nonspecific and include dyspnea, wheezing, poor asthma control, cough (sometimes productive of thick, brown mucus plugs), malaise, low-grade fever, and occasionally, hemoptysis. There may be an antecedent history of recurrent asthma exacerbations in conjunction with pneumonias without a culture-identified bacterial source. In addition, atopy with rhinitis, drug allergy, and/or allergic conjunctivitis are also common. It is often not until a patient has been repeatedly ill over weeks to months and unresponsive to standard treatments that the diagnosis is considered.[41] As patients with SAFS have the same clinical presentation, differentiation from ABPA is based on interpretation of laboratory testing and radiographic studies.[40]

DIAGNOSTIC GUIDELINES

In general, the diagnosis of ABPA is based on appropriate clinical features in combination with supporting radiologic and serologic findings. While there are no absolutely specific diagnostic criteria, similar guidelines have been proposed by multiple expert panels to aid clinicians in the diagnosis of ABPA (Table 48-1).[20,42] These guidelines have evolved over time and have been recently updated by several societies. Although there is no agreement on clinical criteria that should trigger screening for ABPA, in most asthma centers, all asthmatics with difficult-to-control asthma are screened by checking an eosinophil count, total IgE, and radioallergosorbent test for 22 aeroallergens, including *A. fumigatus and Alternaria.*

TABLE 48-1 Criteria for the Diagnosis of ABPA

Seropositive ABPA (ABPA-S)
History of asthma (almost always difficult to control)
Elevated total serum IgE (usually >1000 IU/mL)
Immediate skin test reactivity to *Aspergillus fumigatus* OR elevated specific serum IgE to *A. fumigatus*
Presence of serum precipitins (by gel diffusion) or elevated specific serum IgG to *A. fumigatus*
ABPA central bronchiectasis (ABPA-CB)
Above criteria are positive
Central bronchiectasis by high-resolution CT scan or CXR
Other supportive clinical findings
Peripheral blood eosinophilia (often absent, especially if patient is on oral or inhaled corticosteroids)
Patchy, fleeting infiltrates (often absent, especially if patient is on oral corticosteroids)
Expectoration of brown mucus plugs
Mucoid-impacted bronchi evident on radiographic studies
Sputum culture positive for *A. fumigatus*

Using the Patterson criteria (Table 48-1), ABPA may be considered to exist in two different forms: ABPA-seropositive (S) and ABPA-central bronchiectasis (CB).

Patients with ABPA-S usually display all of the following diagnostic criteria proposed by Greenberger and Patterson: (1) history of asthma; (2) total IgE >1000 IU/mL; (3) elevated serum anti-*AF* IgE and IgG (twofold higher than *A. fumigatus* allergic asthma controls); (4) positive immediate hypersensitivity skin test to *A. fumigatus*; and/or (5) serum anti-*A. fumigatus* IgG antibodies to *A. fumigatus*. The last criterion is considered positive when either the double gel diffusion, enzyme-linked immunoassay (ELISA), or fluorescent enzyme immunoassay (FEIA) are positive for anti-*AF* IgG antibodies.[43]

Patients with ABPA-S have normal chest radiographic studies, with no evidence of bronchiectasis. In contrast, patients with ABPA-CB have the classic features of advanced disease (expectoration of mucus plugs or sputum culture positive for *A. fumigatus*) and are positive for all of the criteria of ABPA-S listed earlier. Patients with ABPA-CB also have central bronchiectasis on high-resolution CT scanning or chest X-ray.[44,45] Patients with ABPA-S tend to have fewer symptoms, lower IgE levels, less severe airflow obstruction, and fewer exacerbations than do persons with ABPA-CB. Although IgE levels fluctuate with disease activity, a normal IgE level in a symptomatic, untreated patient with asthma virtually excludes the diagnosis.[46] It remains unclear whether ABPA-S is a milder form of the disease (e.g., representing a different host response) or an earlier stage of illness. Identification of *Aspergillus* (or other relevant fungus) in the sputum and dual (immediate and delayed) cutaneous reactions to challenge with *Aspergillus* (by prick test or intradermal) are also common clinical features of ABPA. Rare cases lacking a history of asthma, but meeting the other major diagnostic criteria, have been reported.[41]

TABLE 48-2 Criteria for the Diagnosis of Severe Asthma with Fungal Sensitivity (SAFS)

1. History of poorly controlled asthma (>500 μg/d of fluticasone or the equivalent, near continuous oral corticosteroids for >6 mo, or >2 oral steroid tapers per year)
2. Total serum IgE <1000 IU/mL
3. Positive immediate skin test reactivity to *Aspergillus fumigatus* OR elevated specific serum IgE to *A. fumigatus*
4. Absence of serum precipitins (by gel diffusion) and elevated specific serum IgG to *A. fumigatus*
5. No radiographic evidence of bronchiectasis or infiltrates

SEVERE ASTHMA WITH FUNGAL SENSITIVITY

The broad spectrum of clinical, laboratory, and radiographic abnormalities evident in patients with asthma with fungal allergy has led to the description of additional diagnostic categories of allergic fungal disease. The most relevant of these diagnoses is based on studies that demonstrate that antifungal therapies are effective in patients with poorly controlled asthma that have some of the criteria for ABPA-S, but do not reach the threshold for diagnosis. These patients have been designated as having SAFS.

Whether SAFS is a unique disease or is on the continuum from asthma to ABPA remains unclear. However, the primary distinction is that patients with SAFS have a milder allergic reaction and lack the exaggerated IgG response that is typical of patients with ABPA. Therefore, patients with SAFS are difficult to distinguish from patients with ABPA, and especially ABPA-S, as the clinical features are identical between the two entities and both lack radiographic abnormalities.

The diagnosis of SAFS is based on the interpretation of *Aspergillus*-specific immunologic studies. The diagnostic criteria for SAFS (Table 48-2) overlap substantially with ABPA-S and include: (1) severe uncontrolled asthma (treatment requirement of >500 μg/d of fluticasone or the equivalent, need for near continuous oral corticosteroids for 6 months or >2 oral steroid tapers per year); (2) positive skin prick test or RAST for *A. fumigatus* or other fungi; (3) total serum IgE (<417 IU/mL or <1000 ng/mL)); and (4) absence of IgG against *A. fumigatus* (by ELISA, gel diffusion, or FEIA).

In general, patients with SAFS typically have normal radiographic studies and a milder immunologic response that may be identified in patients with milder asthma. Although it remains unclear whether these patients are on the continuum from asthma to ABPA or are at risk of progressing to frank ABPA, the importance of identifying such patients is based on several studies indicating that antifungal therapies may significantly improve asthma control and reduce oral corticosteroid exposure.[47–49]

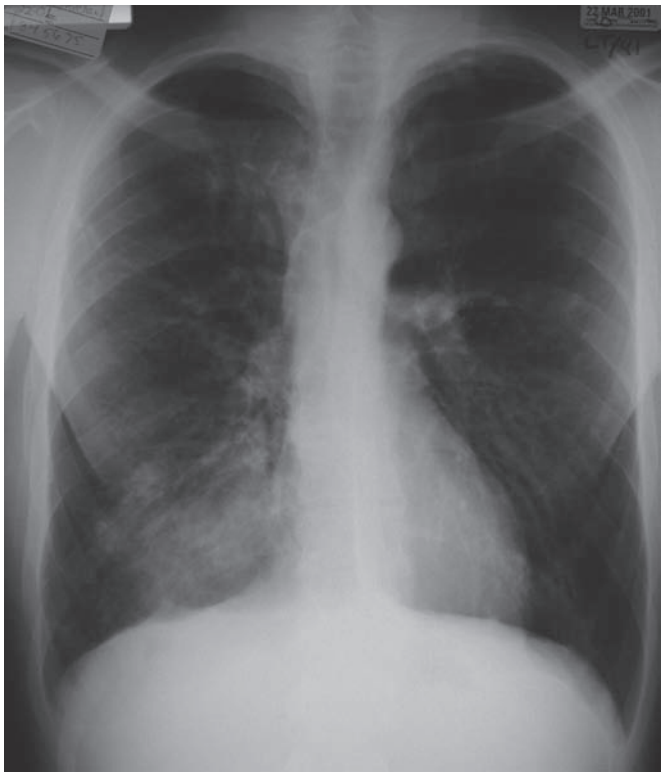
The differential diagnosis of ABPA is broad and includes corticosteroid-dependent asthma without ABPA, SAFS, chronic obstructive pulmonary disease (COPD), chronic necrotizing aspergillosis, tuberculosis, parasitic infections, hypersensitivity pneumonitis, Churg–Strauss syndrome, acute eosinophilic pneumonia (including drug-induced pneumonitis), chronic eosinophilic pneumonia, lymphoma, idiopathic hypereosinophilic syndrome, autoimmune disease, crack cocaine use, CF, and other causes of bronchiectasis. In addition, the diagnosis of ABPA in patients with mold-sensitive asthma and CF poses particular diagnostic challenge. This is especially true in asthmatics, since, by definition, bronchiectasis is absent; furthermore, serum precipitins to *Aspergillus* spp. may be present in up to 10% of patients with positive immediate skin tests to *Aspergillus* and in up to 25% of asthmatics, making distinction from ABPA-S difficult.

Persons with mold-sensitive asthma or ABPA may have peripheral blood eosinophilia and/or elevated serum total IgE levels. However, most persons with ABPA have 2- to 20-fold higher serum levels of *Aspergillus*-specific IgE and total IgE than do mold-sensitive asthmatics without ABPA. A more confusing diagnostic conundrum occurs when considering the diagnosis of ABPA in patients with CF, because patients with CF alone may manifest chronic airflow obstruction, recurrent exacerbations with infections and/or bronchoconstriction, underlying bronchiectasis, pulmonary infiltrates, chronic sputum production, *Aspergillus* colonization of the airways, and positive serum precipitins.

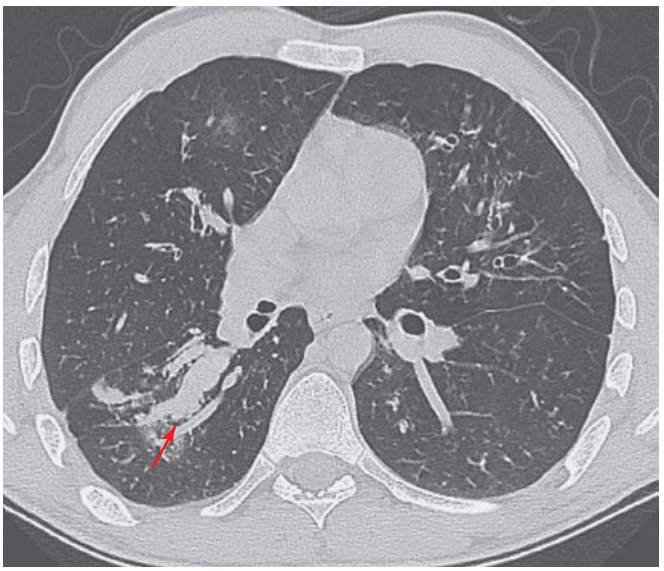
Distinguishing ABPA in patients with CF is critical, because infectious CF exacerbations and the presence of ABPA require different treatments. The steroid treatment required for ABPA may be detrimental in the setting of infection, yet antibiotics alone given for infection may be inadequate to control the inflammation associated with ABPA. Among patients with CF, factors associated with the risk of ABPA include adolescent age, atopy, severe lung disease, and colonization with *Pseudomonas aeruginosa*. ABPA should be suspected in patients with CF who develop clinical deterioration, exhibit a greater than fourfold increase in total serum IgE (especially >1000 IU/mL), have immediate cutaneous reactivity to *Aspergillus* or increased *Aspergillus*-specific IgE or IgG, and show a change in baseline CXR. Annual screening of total serum IgE is recommended; if the level rises >500 IU/mL, immediate cutaneous hypersensitivity testing for reactivity to *A. fumigatus* or testing for serum anti-*A. fumigatus* IgE is recommended.[11,50] The presence

TABLE 48-3 Clinical Stages of ABPA

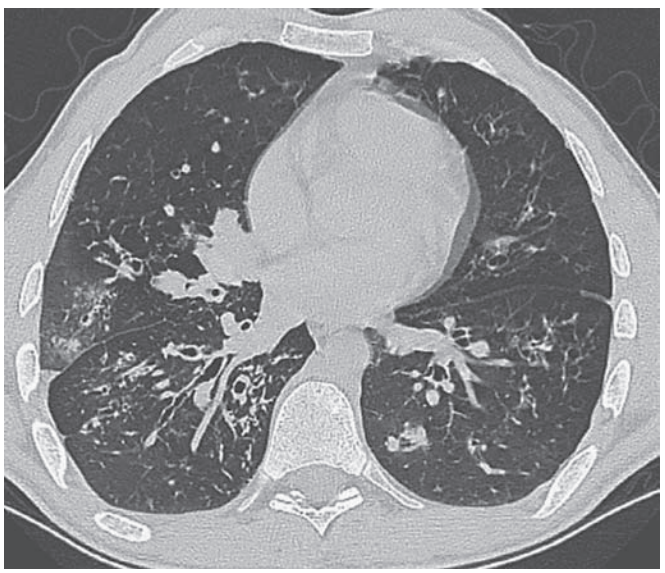
Stage I: Acute
Acute asthma symptoms
Elevated serum IgE (>1000 IU/mL)
Peripheral blood eosinophilia (may be absent in patients treated with oral corticosteroids)
Fleeting infiltrates on chest X-ray (may be absent in patients treated with oral corticosteroids)
Positive specific IgE, IgG, skin test reactivity, or precipitins to *Aspergillus fumigatus*
Responds to steroids/antifungal therapy
Stage II: Remission
Resolution of symptoms
Resolution of pulmonary infiltrates
Improvement in eosinophilia and *A. fumigatus* specific blood abnormalities
Stage III: Exacerbation/Recurrence
Recurrence/worsening of clinical symptoms
Recurrent pulmonary infiltrates
Rising IgE levels
Stage IV: Steroid-Dependent Asthma
Refractory steroid-dependent asthma
Persistently elevated serum IgE levels
Persistently elevated *A. fumigatus*–specific blood abnormalities
Stage V: Fibrotic Lung Disease
Refractory steroid-dependent asthma
Fibrotic lung disease (irreversible obstructive and restrictive defects with impaired diffusing capacity)
Chronic bronchiectasis symptoms (sputum production, frequent infections)



A



B



C

Figure 48-1 A 27-year-old man with a history of moderate asthma, recurrent bronchitis, and mild hemoptysis. Serologic studies were consistent with ABPA (IgE, 9490 IU/mL) and radiographic studies were consistent with bronchiectasis. **A.** PA chest X-ray shows hyperinflated lungs, bronchial dilatation, and right lower lobe opacity consistent with mucoid impaction. **B.** High-resolution CT scan image of impacted bronchus *(arrow)* and chronic inflammatory changes. **C.** Dilated central bronchus consistent with cylindrical/central bronchiectasis.

of IgE reactive against the purified *Aspergillus* allergens Aspf3 and Aspf4 may be useful in distinguishing patients with ABPA and CF or *Aspergillus*-sensitive asthma from patients without ABPA.[10]

■ CLINICAL STAGING OF ABPA

Five clinical stages of ABPA have been recognized, based on clinical, serologic, and radiographic characteristics (Table 48-3). A modified version proposed by the International Society for Human and Animal Mycology (ISHAM) has not been widely adopted.[20,51]

Using the classic staging system, Stage I, the *acute* stage, is characterized by symptoms of moderate-to-severe asthma, elevated total IgE (typically >1000 IU/mL), elevated anti-*A. fumigatus* IgE or hypersensitivity skin test to *A. fumigatus*, infiltrates on chest radiograph (with or without proximal bronchiectasis), peripheral blood eosinophilia (frequently >2000/mm^3), and positive precipitating or anti-IgG antibodies to *A. fumigatus* (up to fivefold concentration of serum may be required for detection of the precipitating antibodies).

Patients with stage II ABPA have disease that is in *remission*. This stage is characterized by the resolution of symptoms, radiographic clearing, and decreased stabilization of total IgE levels. Remissions are of varying length, may last several months to years, or may be permanent, allowing corticosteroid treatment to be tapered or discontinued.

Patients with stage III ABPA have *recurrent* disease or disease *exacerbations* (Fig. 48-1). This stage of ABPA is common and is characterized by development of new pulmonary infiltrates and, usually, a substantial increase in total IgE. Elevation of IgE may precede clinical or radiologic worsening during this stage; an isolated increase in the severity of bronchospasm does not constitute an exacerbation

Figure 48-2 Representative CT image of the lungs of a 41-year-old woman who presented with Stage-V ABPA after a long history of mild asthma (IgE, 1500 IU/mL). Pulmonary function studies demonstrated severe combined obstructive and restrictive defects. CT shows bilateral upper lobe scarring and emphysematous changes.

in the absence of a change in biomarkers. Although a majority of disease exacerbations are associated with a concomitant increase in symptoms, exacerbations may occur in the absence of any increase in symptoms. Indeed, since up to one-third of patients with radiographic infiltrates may be asymptomatic, evolving progressive lung damage may remain unrecognized. Total serum IgE levels should be monitored every 1 to 2 months for at least a year after diagnosis, and chest radiographs should be performed intermittently. *Aspergillus*-specific IgA levels may also be elevated in the acute or exacerbation stages of disease. Exacerbations are more likely to occur during seasons or in environments when mold counts are high.

Stage IV ABPA is defined as *steroid-dependent asthma*. In stage IV disease, total IgE, *Aspergillus* precipitins, and *Aspergillus*-specific IgE and IgG typically remain elevated, despite chronic steroid therapy. The frequency of exacerbations may increase.

Stage V is defined as *pulmonary fibrosis*. Stage V patients have prominent symptoms of dyspnea; are often steroid dependent because of persistent bronchospasm; frequently have chronic sputum production, recurrent respiratory infections, and irreversible pulmonary function abnormalities (obstruction, restriction, and/or gas exchange abnormalities), and may have cyanosis or clubbing. The serologic profile of patients with stage IV disease persists during stage V. Stage V disease is generally thought to be the consequence of longstanding, often unrecognized, disease, but it may occur occasionally among patients with little prior clinical evidence to suggest the diagnosis (Fig. 48-2).

DIAGNOSTIC STUDIES

In addition to the blood abnormalities described earlier, analysis of BAL fluid from patients with ABPA often reveals a moderate eosinophilia (especially in steroid-naive patients) and increased levels of *Aspergillus*-specific IgE and IgA, but not IgG. On bronchoscopy, mucoid impaction may be evident, and bronchial brushings may reveal mucus that contains aggregates of eosinophils, fungal hyphae, and eosinophil-derived Charcot–Leyden crystals. The finding of hyphae-filled mucus plugs is considered pathognomonic for ABPA. Pulmonary function tests typically reveal an obstructive ventilatory defect (due to bronchospasm or mucus impaction of the bronchi) during Stages I, III, IV, and often, V and may not correlate with the duration of ABPA or asthma. Patients with Stage V disease typically also have a restrictive ventilatory defect and a reduced D_{LCO} (Fig. 48-2).

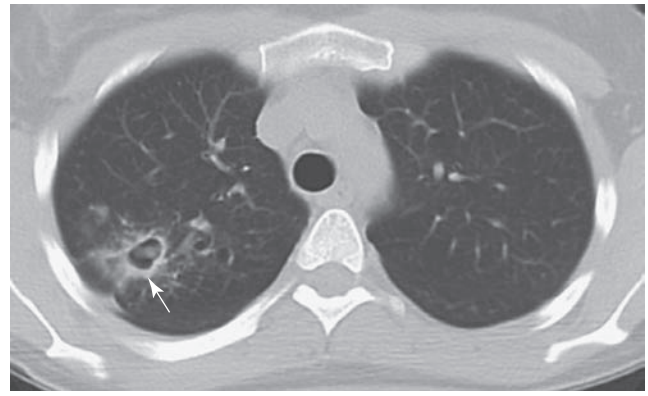


Figure 48-3 A 21-year-old woman with ABPA, who responded to treatment with oral corticosteroids and chronic antifungal therapy, developed an aspergilloma and hemoptysis *(arrow)*. Amphotericin paste injection failed and the patient ultimately underwent a right upper lobe lobectomy.

The typical radiographic manifestations of ABPA include parenchymal infiltrates and bronchiectasis (Figs. 48-1–48-3). The infiltrates are often irregular and transient (1–6 weeks). They have a predilection for upper lobes, although all lobes may be affected. The bronchiectasis is classically cylindric and proximal (central), occurring within the proximal two-thirds of the lung (Fig. 48-1B). Mucoid impaction in dilated bronchi leads to a characteristic (but nonspecific) radiographic appearance of ABPA termed the "finger in glove" opacity. "Tramline shadows" (parallel linear shadows extending from the hilum in bronchial distribution and reflecting longitudinal views of inflamed, edematous bronchi), "toothpaste shadows" (representing mucoid impaction of the bronchi), "ring shadows" (dilated bronchi with inflamed bronchial walls seen on end), local consolidation, or lobar collapse are also common features. Involvement of the small airways may lead to centrilobular nodules and branching tree-in-bud opacities (Fig. 48-1). Less common radiographic findings include bullous changes, pneumothorax, pleural effusion, cavitating nodular lesions, aspergilloma (Figs. 48-2 and 48-3) and migratory parenchymal opacities, some of which have a ground-glass appearance. High-resolution CT scanning is the most reliable noninvasive means of detecting proximal bronchiectasis.

Open-lung biopsy is usually not required to establish the diagnosis of ABPA. Histopathologic findings include intense bronchocentric inflammation with prominent eosinophilia, as well as lymphocytes, plasma cells, and monocytes. Bronchi may be filled and/or impacted with copious mucus plugs containing fibrin, Charcot–Leyden crystals, Curschmann spirals, and fungal hyphae. Bronchiectasis of segmental and subsegmental bronchi may be evident. Regions of bronchocentric granulomatosis, eosinophilic pneumonia, eosinophilic microabscess, lymphocytic or desquamative interstitial pneumonitis, proliferative or obliterative bronchiolitis, lipoid pneumonia, or interstitial fibrosis may also be seen.

TREATMENT

The goals of treatment for individuals with ABPA consist of controlling symptoms, preventing exacerbations, and preserving normal lung function.

Systemic corticosteroids are the mainstay of therapy for ABPA. Without treatment, ABPA may cause significant irreversible lung damage due to bronchiectasis and pulmonary fibrosis. Therefore, initiation of appropriate treatment early in the course of disease is essential. Although most data are derived from small uncontrolled trials, and definitive proof that corticosteroid therapy prevents the development of central bronchiectasis is lacking, retrospective

studies suggest that early therapeutic intervention using corticosteroids may prevent progression to lung fibrosis.

Therapy for Stage I or III disease should include prednisone, 0.5 to 1 mg/kg a day for 2 weeks, followed by 0.5 mg/kg every other day for 6 to 8 weeks. A subsequent taper (by 5–10 mg every 2 weeks) over the ensuing 3 months may then be tried. The duration of treatment must be guided by activity and severity of disease, with an aim of minimizing cumulative exposure to systemic corticosteroids. A low maintenance dose (e.g., 5.0–7.5 mg/d) may be required long term to control the disease and prevent recurrence in some patients.

Corticosteroid therapy leads to relief of symptoms and decreases in airflow obstruction, decreases (>35%) in serum IgE, reductions in peripheral blood eosinophils, and resolution of pulmonary inflammation and infiltrates. IgE levels should be monitored within a few months of an acute episode or exacerbation and should be followed every 2 months thereafter since levels may rise, reflecting disease activity, prior to an exacerbation or in the absence of clinical symptoms. Escalation of steroid therapy should be considered if IgE levels rise more than 100%. The CXR should be monitored within the first year of an acute episode or exacerbation and may be followed yearly thereafter if the disease is quiescent. Pulmonary function testing should be followed closely as well.

Although treatment of acute exacerbations is believed to be helpful in preventing fibrotic complications of ABPA, it is not known if early detection and treatment of disease flares has any effect on disease progression. Therefore, high-dose systemic corticosteroid treatment of asymptomatic individuals is not recommended. Patients with CF and ABPA flares may derive symptomatic or functional improvement from steroid treatment. However, patients with CF who are on steroids should be followed closely for development of invasive aspergillosis. It is unclear whether development of ABPA alters the course of CF disease progression.

Although not advocated as primary treatment, inhaled corticosteroids are useful for control of bronchospasm and may help minimize the dose of systemic steroid necessary to control wheezing. They have been used occasionally as a steroid-sparing agent for the treatment of symptomatic exacerbations and pulmonary infiltrates, and they may help maintain stability of lung function. In addition, adjuvant treatment with bronchodilators and antibiotics also helps control bronchospasm and secondary respiratory infections.

In the last decade, development of oral antifungal agents has brought new hope to patients with ABPA.[52,53] Even though the current concept is that ABPA is not a classic "infection," evidence is mounting to support use of the antifungal agent, itraconazole, in patients with ABPA. Presumably, the agent minimizes the degree of fungal colonization.

In one randomized controlled study, itraconazole (200 mg twice daily for 16 weeks) led to significant reductions in corticosteroid dose, decreased IgE levels, greater resolution of pulmonary infiltrates, and gains in exercise tolerance or pulmonary function.[54] Several clinical studies have demonstrated that treatment with itraconazole also reduces *Aspergillus* antibody titers and eosinophilia compared with placebo.

Itraconazole treatment (200 mg/d or every other day) is generally recommended for patients with ABPA who are steroid dependent, have frequent relapses, and in whom the cost and risks are thought not to outweigh the potential benefits. Itraconazole also has demonstrated utility in ABPA associated with CF. If itraconazole is used, steady-state blood levels can be checked after 1 to 2 weeks, 4 hours after the dose is given, to assess drug absorption.[55]

Since itraconazole interferes with the hepatic metabolism of several medications, including cyclosporine, oral hypoglycemics, tacrolimus, terfenadine, cisapride, and midazolam, particular caution should be exercised with its use among patients taking any of these medications. In addition, physicians must be mindful of adrenal insufficiency associated with itraconazole treatment among patients with ABPA using inhaled corticosteroids, as itraconazole may cause reduced steroid clearance and/or possible direct suppression of adrenal steroid production. Interval screening for adrenal insufficiency should be considered among such persons. In contrast, the efficacy of itraconazole in ABPA may be less among persons taking agents that raise gastric pH, as an elevated gastric pH may dramatically reduce drug absorption.

Other antifungal agents, including nystatin, amphotericin B, miconazole, clotrimazole, and natamycin, are generally ineffective in controlling ABPA. Ketoconazole may be effective, but its utility is limited by hepatotoxicity. Efficacy of voriconazole has not yet been studied in ABPA, but anecdotal reports from our center and others suggest similar results to itraconazole.[56–59]

Finally, the new biologically engineered antibody directed against IgE, omalizumab, is an intriguing consideration for use in ABPA, but the agent has not been extensively studied in large randomized trials. Given that the recommended dosing of this biologic is based on patient weight and serum IgE level, many patients with ABPA are outside of the dosing nomogram. However, multiple case reports and small series indicate that at conventional doses (up to 375 mg subcutaneously every 2 weeks), administration may improve disease activity and spare oral corticosteroid dosing.[60–69]

In addition to medical therapy, all patients with ABPA-related bronchiectasis should be prescribed standard airway clearance treatments, including hypertonic saline and mucus clearance valves or percussion vests, depending on the severity of disease. In addition, patients with ABPA should avoid areas and environmental conditions associated with high mold counts, such as decomposing organic materials and moldy indoor environments. One should consider the use of HEPA filters if such exposures are unavoidable.

PROGNOSIS

With appropriate treatment, long-term control of ABPA is feasible, and durable remissions are common. Treatment of Stage I disease using corticosteroids typically results in decreased sputum production, improved control of bronchospasm, >35% reduction in total IgE within 8 weeks, clearing of precipitating antibodies, and resolution of radiographic infiltrates. IgE levels typically do not completely normalize, but rather, they decrease by approximately one-half of peak levels seen in the acute stage. Progression of Stage IV disease to pulmonary fibrosis may be prevented if patients are maintained on low-dose steroids; most patients with Stage V disease have a stable course over several years. Persons with an FEV_1 persistently <0.8 L have a worse prognosis.

In addition to severe airflow obstruction and pulmonary fibrosis, long-term complications of ABPA occasionally include the development of an aspergilloma (Fig. 48-3), chronic or recurrent lobar atelectasis, allergic *Aspergillus* sinusitis, or *Aspergillus* tissue invasion and semi-invasive *Aspergillosis*. Transplantation has been undertaken successfully among patients with ABPA. However, post-transplant recurrence of ABPA has been reported.

SECTION 10 Other Obstructive Disorders

CHAPTER 49

Upper Airway Obstruction in Adults

Christine Won
Gaetane Michaud
Meir H. Kryger

INTRODUCTION

The upper airway is conventionally described as being made up of all the structures that conduct air between the carina and the nares and includes the trachea, larynx, pharynx, nasal airway, and oral airway. Upper airway structures may change their physiologic function in response to pressures around them, and anatomic structures near them. Thus, physiologically, the segments of the upper airway behave differently when they are subject to pleural pressures (anatomically intrathoracic) or ambient pressures (anatomically extrathoracic). Furthermore we now know that extrathoracic airway function may change with posture, sleep/wake state, and the function and anatomy of tissues surrounding the airway.

The upper airway evolved anatomically in humans to subserve several important functions including swallowing, breathing, and vocalization.[1] The multifunctionality of the upper airway increases the risk of certain diseases (e.g., aspiration and sleep apnea).[2] These functions require that different segments of the airway have differing properties. The trachea receives some support by the tracheal rings, the nasal airway is surrounded by rigid structures, and the oral airway has a rigid boney roof, the hard palate. On the other hand, the pharyngeal airway does not have rigid structures supporting it. It is a collapsible tube whose patency is maintained by muscles whose function is affected by arousal state (sleep/wake, and more specifically during sleep, the stage of sleep), the structures around it, and posture. Thus, the pharyngeal airway is divided anatomically and physiologically into the nasopharynx, retropalatal oropharynx, retroglossal oropharynx, and hypopharynx.

Clinically significant obstruction in adults may occur anywhere within the upper airway. Common etiologies of upper airway obstruction (UAO) include neoplasia, scar formation, skeletal facial malformations, infection, inflammatory disorders, trauma, extrinsic compression related to pathology of adjacent structures, and functional changes related to posture and sleep/wake state. Airway obstruction may be classified as extrinsic, intrinsic, or mixed (Fig. 49-1).

UAO can be acute and life-threatening, or chronic and resulting in significant symptoms, some of which may not even relate to the respiratory system. Initial management of acute UAO focuses on securing the airway and stabilizing the patient. Often the intervention is surgical. Some diseases require bypassing the obstruction using translaryngeal intubation or tracheostomy. Definitive long-term management depends on the underlying etiology and physiology, and may include both medical and surgical interventions. The still evolving fields of imaging and interventional pulmonology offer new diagnostic and management modalities. This chapter provides an overview of acute and chronic UAO in adults and focuses on clinical presentation, assessment, etiology, and management. Obstructive sleep apnea is covered in Chapter 99 of this volume.

HISTORICAL PERSPECTIVE

Acute UAO can be so distressing to the patient and to those around him/her that it is not surprising that tracheostomy has been used as a treatment for at least 3000 years, as described in ancient Egyptian tablets and Greek and Roman writings.[3] Tracheostomy was considered dangerous because it might lead to catastrophes (e.g., laceration of the carotid artery) or infections that may not be controlled. Even Hippocrates warned about the dangers of tracheostomy. By the mid-16th century, the tracheostomy had been performed to relieve UAO caused by a pharyngeal abscess.

Although the procedure was already widely known within the medical profession in the 18th century, it was seen as potentially very dangerous. The first president of the United States, George Washington, died of acute UAO likely caused by epiglottis while his doctors (who were familiar with tracheostomy) treated him with blood letting.[4] During the 19th century, the procedure was used to treat UAO caused by croup and diphtheria.

By the early 20th century, nonsurgical treatments were used to treat UAO; for example, rigid bronchoscopy was used to remove foreign bodies from the trachea.[5] The flexible fiberoptic bronchoscope was introduced in 1966, and the next four decades saw the introduction of many diagnostic and therapeutic modalities including: Nd:YAG laser, video

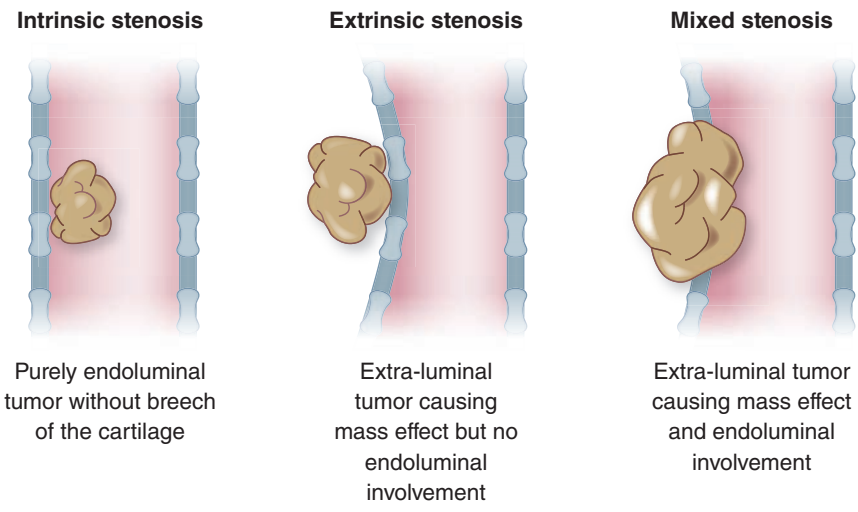

Figure 49-1 Classification of airway tumor involvement. **A.** Intrinsic stenosis. Purely endoluminal tumor without breech of the cartilage. **B.** Extrinsic stenosis. Extraluminal tumor causing mass effect but no endoluminal involvement. **C.** Mixed stenosis. Extraluminal tumor causing mass effect and endoluminal involvement.

bronchoscopy, airway stenting, endobronchial ultrasonography, endobronchial electrocautery, cryotherapy, argon laser coagulation, thermal laser therapy, photodynamic therapy (PDT), brachytherapy, and percutaneous tracheostomy.[6]

There are newly described causes of UAO and novel imaging techniques, both radiographic and endoscopic, which are in evolution to detect and quantify UAO. Treatment strategies are continuously advancing. The incidence of malignancy and related obstruction of the upper airway has increased due in part to tobacco use and exposure to modern environmental toxins. It is estimated that 20% to 30% of lung cancer patients present with symptomatic airway obstruction. The exact prevalence, however, is unknown as a result of the nihilistic view of lung cancer, particularly in the setting of advanced disease. Complications of endotracheal intubation and tracheostomy have become well-recognized causes of benign upper airway stenosis and malacia. Again, it is likely that this pathology is underreported and many people are inappropriately treated for asthma or other chronic peripheral airway diseases. Improvement in pharmacologic agents to treat infectious, inflammatory, and malignant etiologies, as well as developments in radiation oncology, have influenced the management of UAO. More recently, advances involving anesthetic agents and anesthesia techniques, along with development of sophisticated surgical procedures for reconstruction of the larynx, trachea, and bronchi, have had a considerable impact on the management of this condition. Development of new endoscopic and imaging techniques and introduction of interventional pulmonology also have proved useful in the management of UAO.

In the mid-1960s it became apparent that UAO occurred in some patients only during sleep and until the mid-1980s the only effective treatment was tracheostomy, which was used to bypass the segment of the airway obstructing during sleep.[7] Up to that era, the main focus of the laboratory diagnosis of pulmonary disease was for patients with obstructive intrathoracic disease and soon the importance of being able to diagnose UAO became apparent.[8] Soon the notion of using positive airway pressure to overcome UAO was established.[9]

CLINICAL FEATURES

Upper and lower airway obstruction may present with similar symptoms (e.g., shortness of breath, noisy breathing) and physical findings (e.g., wheezing, diminished breath sounds). Asthma and chronic obstructive pulmonary disease, common causes of lower airway obstruction, are often incorrectly assumed to be causing the patient's symptoms.

Significant UAO may be asymptomatic for a prolonged period of time, resulting in delayed presentation, diagnosis and possibly a catastrophic outcome. When UAO develops or worsens acutely, asphyxia and death may result within minutes to hours. When UAO develops slowly, diagnoses may be delayed or incorrect, and, in the case of malignancy in the upper airway, may lead to incurable disease.

Dyspnea and noisy breathing, the most common symptoms of UAO, are often prominent during exercise and also may be intensified or relieved by a change in body position. The patient may indicate that breathing is labored while supine and may experience sleep disordered breathing in the forms of obstructive sleep apnea or upper airway resistance syndrome (see Chapter 99). Therefore, daytime somnolence may be a prominent feature of UAO. In severely affected patients, peripheral edema as a result of cor pulmonale may be present as a consequence of chronic hypoxemia and hypercarbia during sleep and wakefulness.

In most cases, significant anatomic obstruction precedes the development of symptoms. By the time dyspnea on exertion occurs, the airway diameter at the site of obstruction is likely to be reduced to about 8 mm. Shortness of breath at rest often develops when the airway diameter is about 5 mm, and stridor is now often present. Stridor is a loud, musical sound of constant pitch that usually indicates the presence extrathoracic airway obstruction most often affecting the larynx or upper trachea.

Unlike wheezing, which is a feature of diffuse peripheral airway obstruction and occurs primarily during expiration, stridor usually occurs during inspiration and is loudest in the neck. The sound can usually be appreciated without using a stethoscope. Although one would expect to be able to distinguish stridor from wheezing coming from lower airways, sound recordings from the neck and chest have shown that the sounds from the asthmatic wheeze and stridor have similar frequencies. Hence there may be errors in diagnosis and a UAO caused by a tumor or foreign body may be mistakenly treated as asthma.

Breathing maneuvers that increase inspiratory airflow, such as forced inspiration or voluntary hyperventilation, accentuate the intensity of stridor. Neck flexion may change the loudness of stridor. When the obstructing lesion is fixed, both inspiratory and expiratory stridorous sounds may be heard. At times, the character of a patient's voice may be a clue to the presence of UAO. Hoarseness may be a sign of a laryngeal abnormality. Muffling of the voice may be present when vocal cords are paralyzed.

LABORATORY ASSESSMENT

Just as UAO must be quite advanced before development of symptoms, physiologic abnormalities do not become apparent on lung function testing until severe obstruction occurs. Studies of subjects breathing through tubes of varying diameters suggest that UAO must narrow the airway lumen to less than 8 mm in diameter to produce abnormalities on a flow–volume loop. This corresponds to an obstruction of more than 80% of the normal median diameter of the tracheal lumen. The forced expiratory volume in 1 second (FEV_1) remains above 90% of control until a 6-mm orifice is created. Therefore, spirometry, which is often the first screening test for pulmonary symptoms, may not be an effective way to detect upper airway abnormalities. The peak expiratory flow rate (PEFR) and maximal voluntary ventilation (MVV) are more sensitive than the FEV_1 in detecting UAO. Of note, a noncritical airway may become so with a lesser degree of obstruction in the context of airway secretions, edema, or bleeding.[10]

The flow–volume loop, which is a recording of maximal inspiratory and expiratory flows at various lung volumes, is an important tool for the diagnosis of UAO. The configuration of the normal flow–volume loop is shown in Figure 49-2. During a forced expiratory maneuver from total lung capacity (TLC), the maximal flow achieved during the first 25% of the forced vital capacity is dependent on effort, that is, an increase in driving pressure (effort) may result in increased flow. During the remaining 75% of the forced vital capacity maneuver, flow is determined by the mechanical properties of the lungs and is not effort dependent. During this portion of forced exhalation, a linear deceleration of flow is caused by dynamic compression of the intrathoracic airways (Fig. 49-3A). An increase in effort and therefore pleural pressure causes further compression of the intrathoracic airways and a further limitation of airflow. At higher lung volumes, flow may be limited by a UAO. At low lung volumes, flow may not be affected by a UAO, since measurement of flow in this effort-independent portion of the curve represents the function of the peripheral airways. Since the FEV_1 reflects a large portion of flow at these lower lung volumes, it is not a sensitive test for UAO. Because the PEFR reflects flow at higher lung volumes, it may be abnormal when the FEV_1 is not.

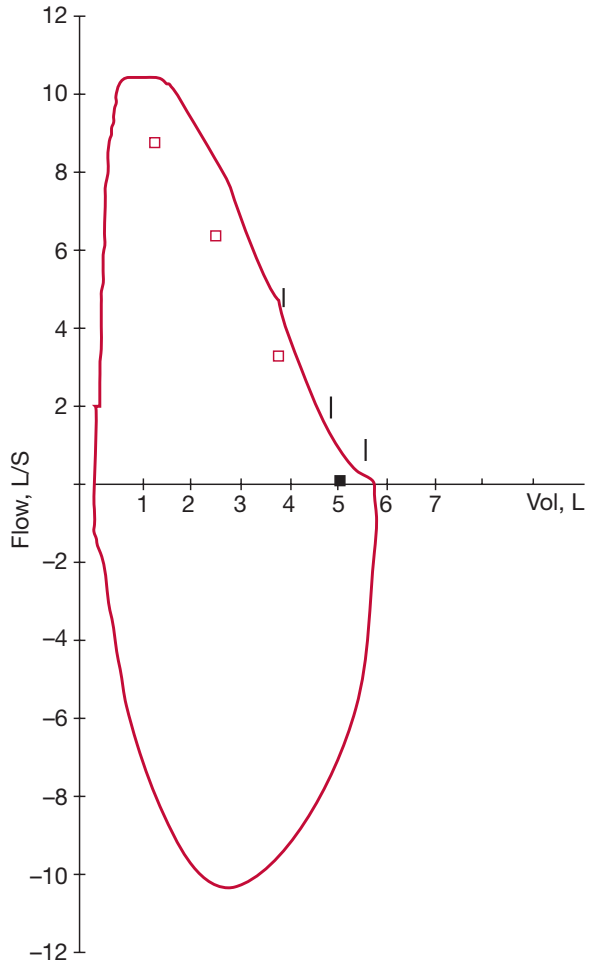

Figure 49-2 Normal flow–volume loop following maximal expiratory *(above)* and inspiratory *(below)* effort. Small vertical lines denote seconds.

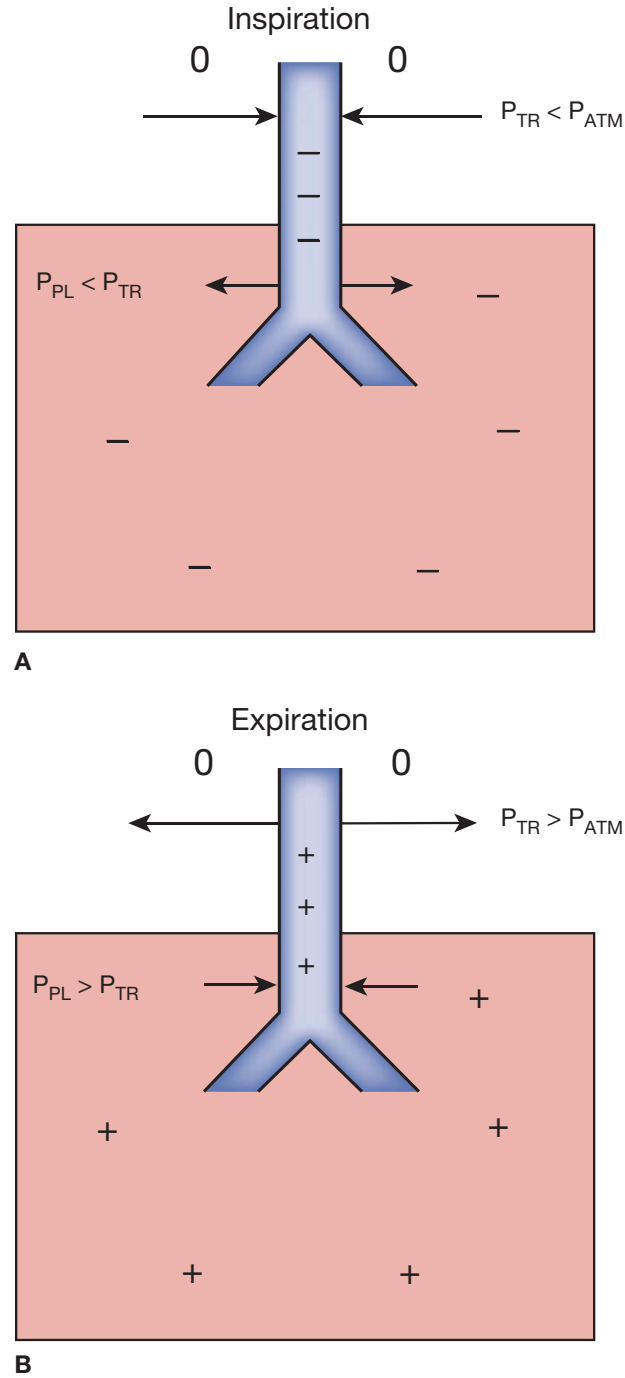

Figure 49-3 Forces acting on intra- and extrathoracic airway walls during inspiration and expiration. 0, atmospheric pressure; +, positive pressure; −, negative pressure. **A.** During inspiration, extrathoracic tracheal pressure (P_{TR}) falls below atmospheric pressure (P_{ATM}), favoring narrowing of the lumen *(arrows)*. Intrapleural pressure (P_{PL}) becomes negative, favoring airway enlargement *(arrows)*. **B.** During expiration, the extrathoracic tracheal pressure (P_{TR}) becomes positive and, therefore, greater than P_{ATM}, favoring enlargement of the lumen *(arrows)*. Intrapleural pressure (P_{PL}) is positive, causing dynamic compression of the intrathoracic trachea *(arrows)*.

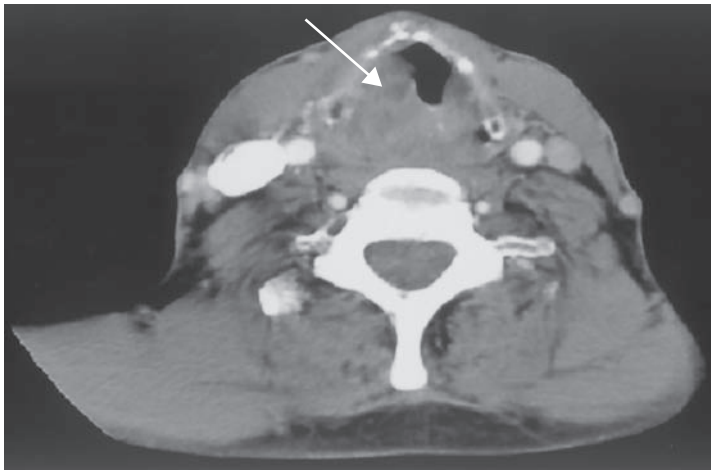
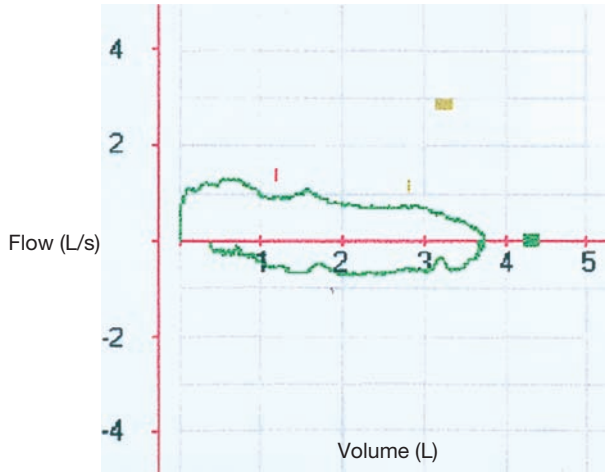
In generating the flow–volume loop, forced inspiratory flow is limited by effort during the entire inspiratory maneuver. Flow increases from residual volume to near the midportion of the curve, where it becomes maximal at the peak inspiratory flow rate. Flow then declines until TLC is reached. The pressure surrounding the extrathoracic portion of the upper airway is atmospheric. The turbulent nonlaminar airflow, which occurs during forced inspiration and causes airway pressure to fall in this portion of the airway, favors slight narrowing of the extrathoracic airway (Fig. 49-3B). Peak inspiratory flow, therefore, is less than peak expiratory flow in normal subjects. Because of the dynamic compression of the intrathoracic airways that occurs during exhalation, flow during the middle of inspiration, that is, the forced inspiratory flow at 50% of the forced vital capacity ($FIF_{50\%}$), is usually greater than flow during the middle of forced expiration, that is, the forced expiratory flow at 50% of the forced vital capacity ($FEF_{50\%}$). Typical patterns of the flow–volume loop may be seen, depending on whether the obstruction to flow is "fixed" or "variable," and whether the site of the obstruction is above or below the thoracic outlet or suprasternal notch.

Fixed obstructions of the upper airway are those in which the cross-sectional area does not change in response to transmural pressure differences during inspiration or expiration. A fixed obstruction may occur in either the intrathoracic or extrathoracic airways. Irrespective of the site of the obstruction, a fixed lesion results in the flattening of the inspiratory and expiratory phases of the flow–volume loop. A *variable obstruction* is one that responds to transmural pressure changes, eliciting varying degrees of obstruction during the respiratory cycle. Since the stresses on the intrathoracic and extrathoracic airways are different, changes seen in the flow–volume loop vary according to the site of the obstruction.



A



B

Figure 49-4 **A, B.** Flow–volume loop in fixed upper airway obstruction due to laryngeal abscess in a 56-year-old man who developed persistent wheezing, hoarseness of voice, and intermittent stridor for 3 months after a brief intubation for asthma exacerbation. Computed tomography scan of the neck (**A**) shows a laryngeal abscess with significant impingement on the laryngeal inlet. The flow–volume loop (**B**) demonstrates a plateau of flow during inspiration and expiration; the $FEF_{50\%}/FIF_{50\%}$ ratio is near 1.

A number of conditions have been associated with nondistensible narrowing of the upper airway and fixed airway obstruction. Benign strictures and malignancy are common examples. Maximal inspiratory and expiratory flow–volume loops with fixed obstruction show constant flow, represented by a plateau during both inspiration and expiration (Fig. 49-4A,B). On the expiratory curve, the plateau effect is seen in the effort-dependent portion of the curve near TLC; very little change is noted in the effort-dependent portion near residual volume. Since the inspiratory curve is similar in appearance, the ratio of $FEF_{50\%}$ to $FIF_{50\%}$ is normal (close to 1). The forced inspiratory volume in 1 second (FIV_1) and FEV_1 are nearly the same in fixed UAO.

Unilateral vocal cord paralysis is a common cause of variable extrathoracic obstruction. A variable extrathoracic airway obstruction increases the turbulence of inspiratory flow, and intraluminal pressure falls markedly below atmospheric pressure. This leads to partial collapse of an already narrowed airway and a plateau in the inspiratory flow loop (Fig. 49-5A,B). Expiratory flow is not significantly affected, since the markedly positive pressure in the airway tends to decrease the obstruction. The ratio of $FEF_{50\%}$ to $FIF_{50\%}$ is high (usually greater than 2). Similarly, the FEV_1 is greater than the FIV_1.

A variable obstruction in the intrathoracic airways reverses the situation. A predominant reduction in maximal expiratory flow is associated with a relative preservation of maximal inspiratory flow. This association occurs because intrapleural pressure becomes decidedly positive during forced expiration and causes dynamic compression of the intrathoracic airways. The obstruction caused by an intrathoracic lesion is accentuated and a plateau in expiratory flow occurs on the flow–volume loop (Fig. 49-6A,B). A plateau of flow suggests that the lesion has caused the airway lumen to reach its minimal size. A flow peak may precede the plateau, suggesting that the obstruction may not affect flow until a certain lung volume is reached. During inspiration, intrapleural pressure is markedly negative; therefore, the obstruction is decreased. The ratio of $FEF_{50\%}$ to $FIF_{50\%}$ is very low and may approach 0.3. Similarly, the FEV_1 is considerably lower than the FIV_1. Although the flow ratios are similar to those seen in patients with COPD and chronic asthma, these disorders are distinguished from UAO by the appearance of the flow–volume loop. Thus, the expiratory curve in patients with COPD and asthma is primarily altered in the effort-independent portion of the curve, leading to a characteristic shape unlike the plateau configuration of a UAO (Fig. 49-7).

Figure 49-6 Variable intrathoracic obstruction due to squamous cell carcinoma of the trachea. **A.** Computed tomography of the chest shows a tracheal lesion *(arrow)*, which was not readily apparent on plain chest radiograph. **B.** Superimposed flow–volume loops show a plateau of expiratory flow preceded by a peak of flow at higher lung volumes. The forced inspiratory flow is preserved in comparison to expiratory flow, but it is also reduced. $FEF_{50\%}/FIF_{50\%}$ is 0.4.

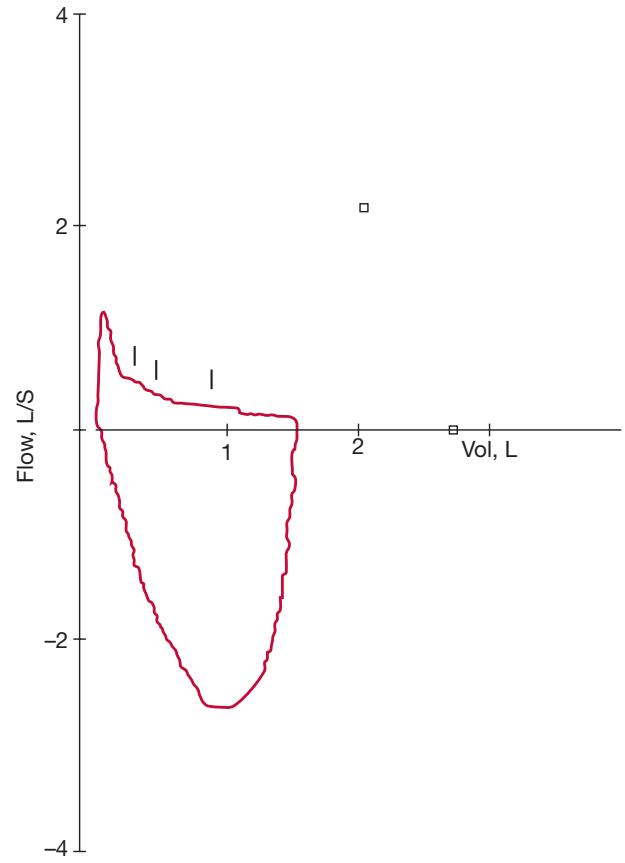

Figure 49-7 Flow–volume loop typical of chronic obstructive lung disease. Very low $FEF_{50\%}/FIF_{50\%}$ and typical curvilinear shape are noted.

When a hospital laboratory or physician's office is not equipped to perform flow–volume loops, results of other tests, such as routine spirometry, may be helpful. If the forced spirogram shows that the PEFR is reduced disproportionately to the reduction in FEV_1, a UAO should be suspected. Other findings that suggest the diagnosis include a ratio of less than 1.0 for the inspiratory flow between 25% and 75% of the inspired vital capacity ($FIF_{25–75\%}$) and a value of less than 1.0 for the expiratory flow between 25% and 75% of the expired vital capacity ($FEF_{25–75\%}$). Another indication is an FEV_1 that is decreased to the same degree as the $FEF_{25–75\%}$. The MVV may also be a useful test, since it measures both inspiratory and expiratory flows. A ratio of MVV to FEV_1 of less than 25% is often found with UAO. Whenever the MVV is reduced in association with a normal FEV_1, a diagnosis of UAO should be considered.

In contrast to the situation in patients with diffuse obstructive disease of the lower airways (e.g., COPD, asthma), the distribution of ventilation in the lungs is normal, and ventilation–perfusion mismatch does not occur. Hypercarbia is not seen unless the degree of obstruction is very severe, although nocturnal hypercarbia may occur while daytime levels of P_{CO_2} are normal. Hypoxemia is also not present except during exercise and with severe airflow limitation, when it may accompany increases in the level of P_{CO_2}. In contrast to asthma and many instances of COPD, the airflow obstruction caused by an upper airway lesion does not resolve following the inhalation of a bronchodilator unless there is also a component of small airway disease that is often the case.

IMAGING

When acute airflow obstruction occurs as a result of an abnormality of the extrathoracic airway, roentgenographic studies of the soft tissues of the upper chest and neck in the emergency setting may be helpful (Fig. 49-8). However, computed tomography (CT) has afforded the most important approach to imaging of the extrathoracic airways (Fig. 49-9). The standard chest roentgenogram is often not helpful in detecting the presence, or the cause, of UAO. Occasionally, in patients with chronic airway obstruction, generalized hyperinflation of the lungs may occur; in the absence of asthma or COPD this finding may raise suspicion of occult disease in the central airways. The trachea is usually well visualized on the posteroanterior (PA) and lateral views in chest roentgenograms of good quality. It is located in the midline and is moderately deviated at the level of the aortic arch. However, many standard roentgenograms are underpenetrated so that the trachea may become a "blind spot." In one study, only 13 of 53 tracheal tumors were evident to the radiologist on the standard PA roentgenogram. The use of digital imaging techniques may avoid such pitfalls. However, thoracic CT studies have become the procedure of choice for imaging the upper airway.

The sensitivity of CT scanning for detecting upper airway disease surpasses that of the routine chest roentgenogram (97% vs. 66%, respectively). Helical CT (HCT) scanning minimizes artifacts due to respiratory motion and provides imaging of the whole thoracic volume during a single breathhold.[11] The technique represents

Figure 49-8 Acute epiglottitis. Lateral soft tissue radiograph of the neck of a patient with stridor shows swelling of the epiglottis *(large arrow)* and loss of normal convexity of the edematous aryepiglottic folds *(small arrows)*.

Figure 49-9 Computed tomography scan of the neck demonstrating a large laryngocele compressing the lateral wall of the larynx *(arrow)* causing positional air flow obstruction.

Figure 49-10 **A.** Computed tomography scan of the chest demonstrating marked narrowing of the trachea with intraluminal calcified nodular projections in a patient with tracheopathia osteoplastica. **B.** Computed tomography scan of the chest demonstrating multiplanar reformation of the trachea in the sagittal plane of the same patient.

an improvement over conventional CT scanning in that it allows detection of intraluminal, submucosal, and extraluminal lesions (Figs. 49-10A,B and 49-11). Since the early 1990s, HCT has become the preferred noninvasive modality for evaluation of the central airways. The use of HCT using multidetector technology and thin collimation provides high-resolution images of the entire thorax, improved special resolution, greater speed of image acquisition, and

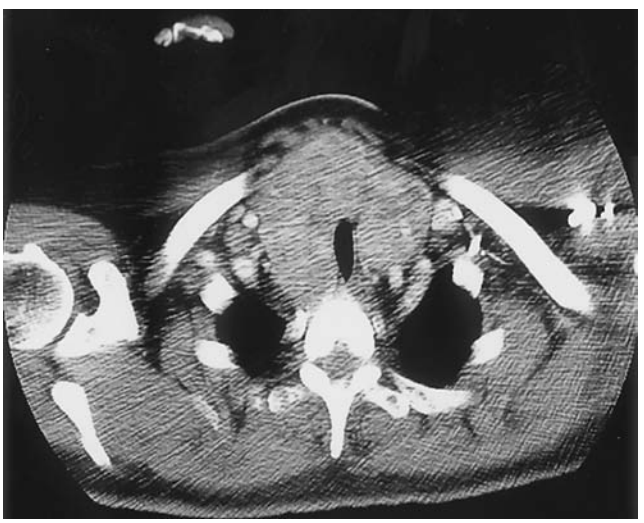

Figure 49-11 Computed tomography scan of the chest demonstrating marked extraluminal compression of the trachea caused by intrathoracic goiter.

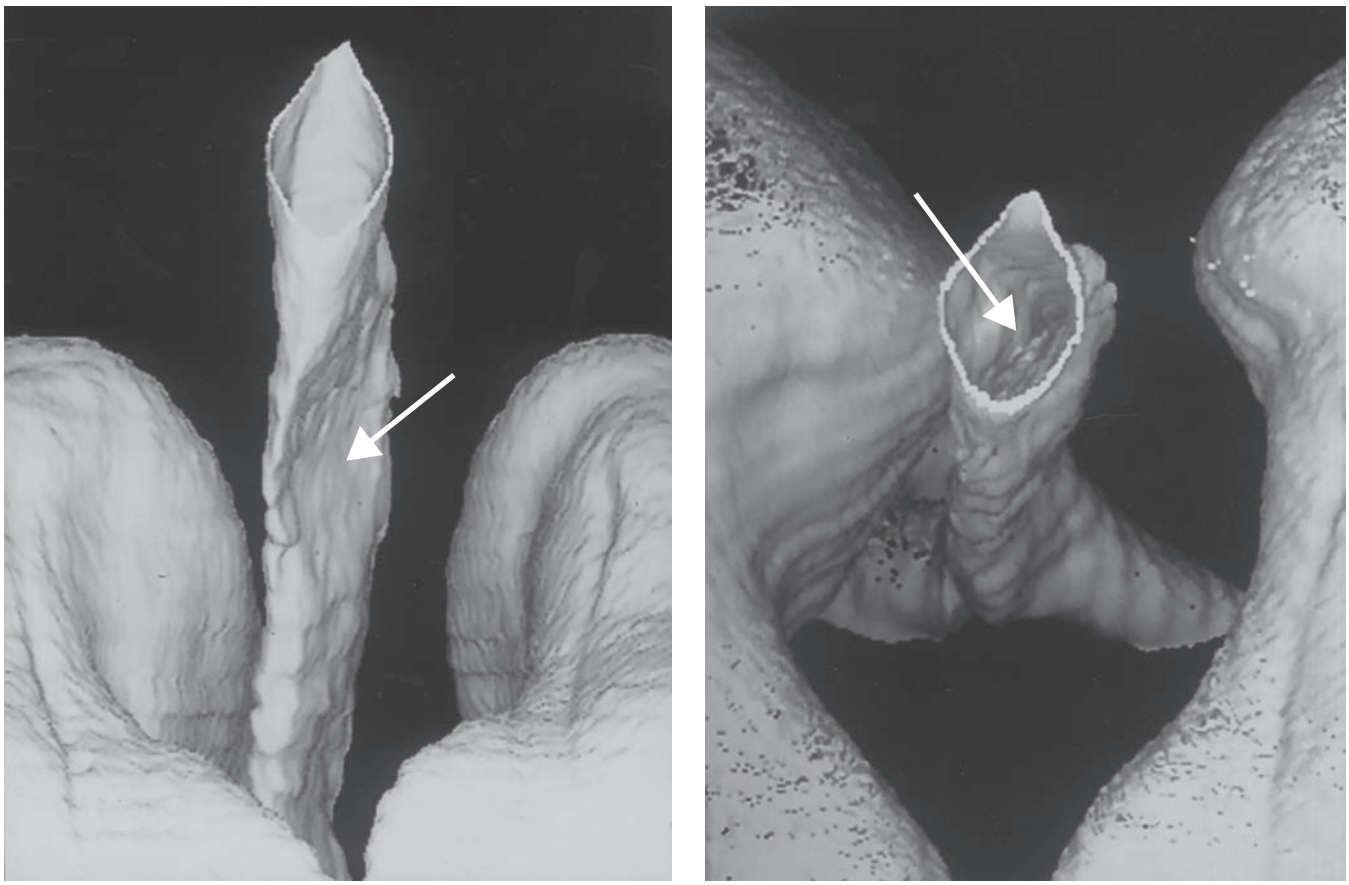

A B

excellent contrast enhancement. HCT techniques using multiplanar and three-dimensional reconstruction can provide virtual images of the thorax that enhance the perception of local and diffuse anatomic lesions of the upper airways (Fig. 49-12). The images may demonstrate the degree of tracheal widening or narrowing, show the location and longitudinal extent of abnormalities, assess tracheal wall thickness, and demonstrate associated extratracheal diseases.

The use of paired inspiratory dynamic and expiratory multislice HCT has proved helpful for the diagnosis of tracheomalacia. Because the maximal degree of collapse in tracheomalacia usually occurs during exhalation rather than at end expiration, dynamic expiratory imaging is preferable to end-expiratory imaging. If complete collapse is not demonstrated during expiration, then one should confirm the diagnosis by quantitatively measuring the degree of airway luminal narrowing during expiration. Tracheomalacia is generally defined as a reduction in cross-sectional area of greater than 50% on expiratory images; however, this cut point may not be discriminatory enough to detect clinically significant tracheomalacia.[12]

Another novel CT-based imaging technique is virtual bronchoscopy. The use of volumetric imaging allows for an intraluminal three-dimensional reconstruction of the airways and surrounding tissues. The technique has been used with a high degree of accuracy in assessing the width, length, and contour of fixed airway lesions, but it has not been effective in defining dynamic airway lesions, such as excessive dynamic airway collapse.

Magnetic resonance imaging (MRI) is another modality that may be used to assess the central airways and surrounding mediastinal structures. MRI provides a multiplane image of the chest without the need for contrast material. However, the technique is best used to investigate vascular structures surrounding central airways, such as vascular rings or aneurysms that may compress the trachea, rather than the airways themselves, which are better visualized using CT scanning.

ENDOSCOPY

Bronchoscopy and direct laryngoscopy provide a real-time morphologic and functional evaluation of the upper airway. Imaging techniques are often limited by their inability to document the dynamic nature of many airway lesions and may underestimate the extent of an obstruction.

With respect to laryngeal disease, endoscopy allows the operator to determine whether the vocal cords are mobile or fixed in abduction or adduction or alternatively moving paradoxically. This valuable information can help guide management. In cases of traumatic or thermal injury to the airways, edema, laryngeal fracture, or carbonaceous materials can be readily identified.

CAUSES OF UPPER AIRWAY OBSTRUCTION

UAO may be observed in a wide variety of settings, including infections, trauma (including iatrogenic), vascular disorders, and a wide variety of benign and malignant tumors. Each is discussed below.

INFECTION

A broad variety of infections may eventuate in UAO.

Deep Cervical Space Infections

Deep cervical space infections occur in potential spaces bounded by the deep cervical fascia. The cervical fascia is divided into a

superficial and, a more complex, deep layer. This configuration and complexity divides the neck into functional units. Infection can spread along the planes formed by the cervical fascia. Infections affecting the deep neck tissues may result in life-threatening UAO.

Patients with deep cervical space infections may present with sore throat, odynophagia, neck swelling, pain, fever, and dyspnea. Stridor and profound respiratory difficulty are signs of significant UAO. Parapharyngeal, peritonsillar, submandibular, and retropharyngeal abscesses appear to be common locations in adults. The bacteriology and initiating event of deep cervical infections appear to have changed over time.

Mixed infections caused by aerobic and anaerobic infections are common and have been reported in up to two-thirds of cases.[13] *Streptococcus viridans* and *Klebsiella pneumonia* are common pathogens. *Staphylococcus aureus, Staphylococcus epidermidis, Streptococcus pneumoniae, Escherichia coli*, and *Haemophilus influenzae* are other agents that are commonly reported. Alpha and beta hemolytic *streptococci* appear to have significantly declined in frequency. Overall, an odontogenic origin is probably most common, with upper respiratory tract infections as an important etiology in children. Intravenous drug abuse, mandibular fractures, iatrogenic and noniatrogenic traumatic injury to the upper airway, underlying malignancy, and poor underlying immune status are associated conditions. Ludwig's angina – an infection of the submandibular space and the floor of the mouth – is potentially lethal and is commonly associated with significant UAO. This entity is usually a cellulitic process and can affect the submandibular spaces bilaterally. Many cases with true Ludwig's angina require tracheostomy.

Treatment of deep cervical infections involves maintenance of oxygenation and ventilation by securing an adequate airway, administration of appropriate antibiotics, and when indicated, use of surgical drainage. Complications of deep cervical infections include UAO, Lemierre's syndrome (see next paragraph), distant infection, septic embolization, carotid artery rupture, pulmonary embolism, direct extension of infection resulting in mediastinitis and empyema, and rupture of the abscess during intubation or other interventions.[14]

One particularly virulent cervical infection, known as Lemierre's syndrome, arises from a nasopharyngitis or peritonsillar abscess. This lateral pharyngeal space infection results in suppurative thrombophlebitis of the internal jugular vein, septicemia, and metastatic abscess formation, particularly in the lungs and joints. *Fusobacterium necrophorum* is usually the causative agent and has been cultured from blood in over 80% of cases. Symptoms begin with a sore throat, fever, and painful swelling in the neck, followed by tender lymphadenopathy and tenderness along the sternocleidomastoid muscle (representing thrombophlebitis of the internal jugular vein). Dysphagia, trismus, and UAO may occur as a result of swelling of the lateral pharyngeal space. Contrast-enhanced CT scan of the neck is most useful in establishing the diagnosis of thrombosis of the internal jugular vein and may demonstrate soft tissue abscesses, fasciitis, and myositis, which may require extensive surgical debridement. Without the use of early and appropriate antibiotics, such as high-dose penicillin with metronidazole, or monotherapy with clindamycin, the mortality rate approaches 100%.

Epiglottitis

Epiglottitis is an infectious process that causes variable degrees of inflammation and edema of the epiglottis and supraglottic structures. Supraglottitis may be more appropriate term in adults, since the supraglottic structures usually are involved with variable involvement of the epiglottis. This condition can be life-threatening. Its prevalence is 0.18 to 9.7 cases per million adults; the mortality rate may be as high as 7.1%. Clinical presentation includes odynophagia, with inability to swallow secretions, sore throat, dyspnea, hoarseness, fever, tachycardia, and stridor. In one review, 44% of the patients had a normal routine oropharyngeal examination.[15]

Fiberoptic laryngoscopy is necessary to make the diagnosis. The procedure is safe in adults with suspected epiglottitis and should be done without delay. Radiographic studies can be helpful in ruling out other etiologies with similar presentations and in evaluating potential complications. However, the airway must be secured, and radiographic studies should not delay diagnosis or management.

Supraglottitis may involve the base of the tongue, uvula, pharynx, and false vocal cords. The disease may be increasing in prevalence among adults and declining in children, perhaps, reflecting introduction of *Haemophilus b* conjugate vaccines. Young adult males are commonly affected. The disorder appears to be more prevalent in colder, winter months and in smokers. Blood cultures are positive in less than one-third of cases. Although *Haemophilus influenzae* is the most common organism isolated in children, adult supraglottitis may be caused by a variety of organisms, including *Haemophilus influenzae, pneumococci*, group A *streptococci, S. aureus, Streptococcus viridans*, a variety of anaerobic organisms, mycobacteria, fungi, and viruses. Throat cultures can be helpful in diagnosis and management; however, treatment should not be delayed while awaiting culture results.

Illicit drug use may be associated with epiglottitis, with inhalation of heated objects (e.g., metal pieces from a crack cocaine pipe or the tip of a marijuana cigarette) causing thermal injury to supraglottic structures. Signs, symptoms, and roentgenographic and laryngoscopic findings are similar to infectious epiglottitis.

Initial antibiotic therapy using a third-generation cephalosporin or extended-spectrum penicillin is reasonable. The prevalence of resistant organisms should be taken into account when choosing empiric antibiotic coverage. Corticosteroids often are used in management of acute epiglottitis despite lack of evidence to support their use. Based on anecdotal case reports, epinephrine is also used.

Patients should be observed closely and experienced staff should be available immediately to secure the airway by intubation or surgical approach, if needed. Securing the airway is extremely important in patients who develop stridor and other signs of significant airway obstruction. Mortality in this group has been reported to be as high as 17.6%.[16]

Laryngotracheobronchitis and Bacterial Tracheitis

Laryngotracheobronchitis, often called croup, is commonly seen in children who present with hoarseness, barking cough, shortness of breath, and stridor. This is an acute viral illness characterized by narrowing of the subglottic area. Adult croup is a rare condition. Rare instances of diphtheric croup have been described in adults. Noninfectious membranous tracheitis related to trauma also has been reported.

Acute bacterial tracheitis refers to involvement of the subglottic trachea by bacterial infection and usually follows an episode of viral laryngotracheobronchitis. Thick, purulent exudates and mucosal edema may cause symptoms of UAO. *S. aureus* appears to be the predominant organism. Prompt antibiotic therapy, close observation with attention to airway compromise, and frequent suctioning are important. Data to suggest effectiveness of steroids or epinephrine in adults are lacking.

Rhinoscleroma is a chronic, progressive granulomatous infection of the upper airway that may cause airflow obstruction. This disorder affects primarily the nose and paranasal sinuses, but also may involve the nasopharynx, larynx, trachea, and bronchi. The causative organism is *Klebsiella rhinoscleromatis*. Rhinoscleroma is endemic in Africa, Asia, and South America and is rare in North America. About 5% of patients have diffuse narrowing of the trachea.[17] Prolonged antibiotic therapy with trimethoprim/sulfamethoxazole is effective.

Tuberculosis

The incidence of laryngeal tuberculosis may be on the rise due to the epidemic caused by the human immune deficiency virus. This form of the infection is relatively uncommon, accounting for less than 1% of tuberculosis cases. Laryngeal tuberculosis may present as progressive hoarseness and ulceration or a laryngeal mass. In the appropriate clinical context, a positive purified protein derivative (PPD) skin test and acid-fast bacilli in sputum may suggest the diagnosis. However, a biopsy from the laryngeal abnormality usually is required. Biopsy features include granulomatous inflammation, caseating granulomas, and acid-fast bacilli. The true vocal cords and epiglottis are the areas most affected. Treatment with antituberculous medications is usually adequate and should be instituted promptly, since the disease is highly contagious. Surgical interventions, including tracheostomy, are reserved for airway obstruction and long-term complications and, in one report, were required in 12% of the cases.[18]

Endobronchial tuberculosis may result in significant airflow limitation that is related to the initial lesion or subsequent stricture formation. A barking cough and sputum production are common findings. The diagnosis of tuberculosis can be delayed while the diagnosis of malignancy is being entertained. Early diagnosis and treatment with antituberculous medications should decrease the development of fibrostenosis and resultant airflow limitation. The role of steroids in reducing the incidence of fibrostenotic complications remains unclear and controversial. Management may require endoscopic or surgical approaches.

UPPER AIRWAY TUMORS

Both head and neck cancers and tracheal tumors may cause UAO.

Head and Neck Cancer

The great majority of cancers that impact the upper airway are squamous cell carcinomas, and the incidence of oropharyngeal cancer appears to be increasing in some countries (Fig. 49-13).[19] Other less common cancers occurring in the oropharynx include salivary gland carcinomas, lymphomas, and lymphoepitheliomas. Tobacco and alcohol abuse represent the most significant risk factor for the development of head and neck cancers. Other risk factors may include a diet poor in fruits and vegetables,[20] and infection with the human papillomavirus (HPV), especially HPV-type-16.[21–23] A 23% decline in head and neck cancers has been observed in the United States over the last three decades. The reported incidence was 10.8 cases per 100,000 per year from 2005 to 2009, as compared with 14.6 cases per 100,000 per year from 1976 to 1983.[24,25]

Figure 49-13 Laryngeal squamous cell carcinoma.

The clinical manifestations of head and neck cancer depend on the location and stage. Cancers at the base of the tongue and pharyngeal walls are insidious. These cancers grow either in an infiltrative or exophytic pattern. Because of the lack of pain fibers at the base of the tongue, these tumors are often asymptomatic until they are far advanced. The most common location of a primary tumor of the oropharynx is the anterior tonsillar pillar or tonsil. Symptoms of these cancers include hoarseness, hemoptysis, sore throat, dysphagia, referred otalgia due to cranial nerve involvement, and trismus due to pterygoid muscle involvement. Life-threatening UAO may be seen. Five percent of newly undiagnosed laryngeal cancers (a subcategory of head and neck cancers) present with severe dyspnea or stridor and may require emergency laryngectomy or tracheostomy. Patients who have had head and neck surgery for cancer have a very high prevalence of obstructive sleep apnea.[26]

TRACHEAL TUMORS

Tumors that originate in the trachea are uncommon, and make up only about 2% of all tumors that form in the upper airway. Although rare, when they do occur, approximately 80% of tracheal tumors are malignant. Primary tracheal cancers are rare with a reported incidence of 0.1 per 100,000 per year.[27] Adenoid cystic carcinoma and squamous cell carcinoma comprise the majority of primary malignant tracheal tumors. Squamous cell carcinoma is almost always associated with cigarette smoking. These tumors grow quickly, and in nearly half of cases, they are often too large to be removed by the time they are discovered. Adenoid cystic carcinoma grows much more slowly, and has not been found to be related to smoking. Men and women have the same risk for this type of cancer, and it is commonly diagnosed around the age of 40 years. Dyspnea, cough, hemoptysis, wheeze, and stridor are frequent presenting symptoms. Surgery remains the most effective management. Emergency treatment with procedures to recannulize the airway, including airway stenting, may be necessary pending definitive surgery. Postoperative radiation therapy appears useful for primary tracheal malignancies, particularly when surgical margins are positive. Palliative radiation is used for local control when surgery is contraindicated. Five-year survivals for adenoid cystic and squamous cell carcinomas are reported at 52% and 39%, respectively.[28] Favorable prognostic factors include negative airway margins at the time of resection and adenoid cystic histology.

More commonly, malignancies found in the trachea result from direct extension of primary lung cancer or regional extension to the lymph nodes (Fig. 49-14). Metastases to central airways

Figure 49-14 Squamous cell carcinoma of the lung.

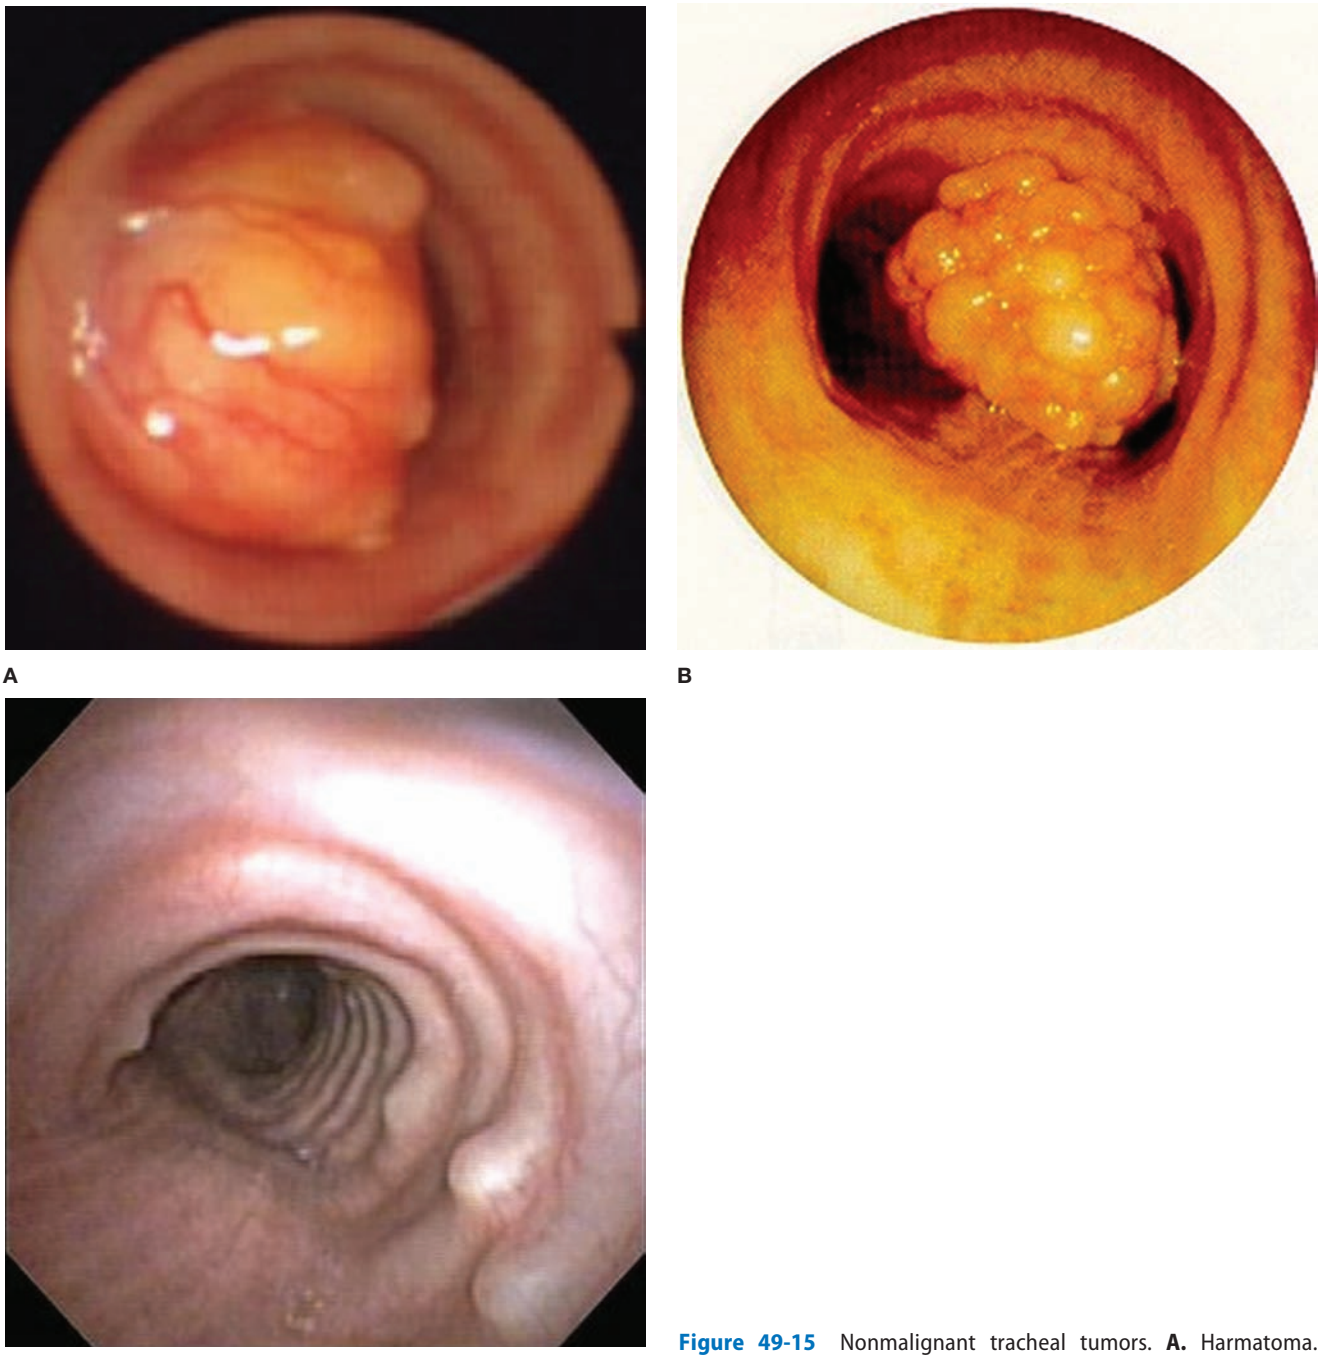

Figure 49-15 Nonmalignant tracheal tumors. **A.** Harmatoma. **B.** Papillomatosis. **C.** Chondromas.

from nonpulmonary malignancies are uncommon, although endobronchial metastases from breast, colorectal, renal, ovarian, thyroid, uterine, testicular, nasopharyngeal, and adrenal carcinomas, as well as sarcomas, melanomas, and plasmacytomas have been described. In an autopsy series of over 1300 patients with solid tumors, metastatic disease to central airways occurred in 2%.[29] The mediastinal lymph nodes are also a common site for disease involvement from hematologic malignancies such as lymphoma.

Nonmalignant tracheal tumors include papillomas, chondromas, and hemangiomas (Fig. 49-15). Chondromas are the most common type of benign tracheal tumor. It is formed from the cartilage rings of the trachea, and has the potential to become malignant over time. Recurrent respiratory papillomatosis in adults, caused by human papilloma virus types 6 or 11 (or, much less commonly, types 16 or 18) may result in UAO and death. Although the larynx is most commonly affected (Fig. 49-16), the tracheobronchial tree may be involved, with a predilection toward areas with prior mucosal injury, including tracheostomy sites and tracheal injuries. Lesions tend to progress down through the tracheobronchial tree. Pulmonary parenchymal involvement is rare, but it may be severe, and bronchiectasis, pulmonary nodules, and abscess formation may occur. Malignant transformation is also possible. The course of the disease is difficult to predict. Recurrent endoscopic interventions (debulking), with attendant risk of airway stenosis, are often required. It is important to minimize intervention unless clinically relevant obstruction exists due to concerns regarding extension secondary to airway injury. No controlled trials on the role of antiviral therapy have been conducted. Available data suggest beneficial effects of intralesional cidofovir. Favorable effects also have been reported with the use of interferon-A. Chemotherapy, radiation therapy, and

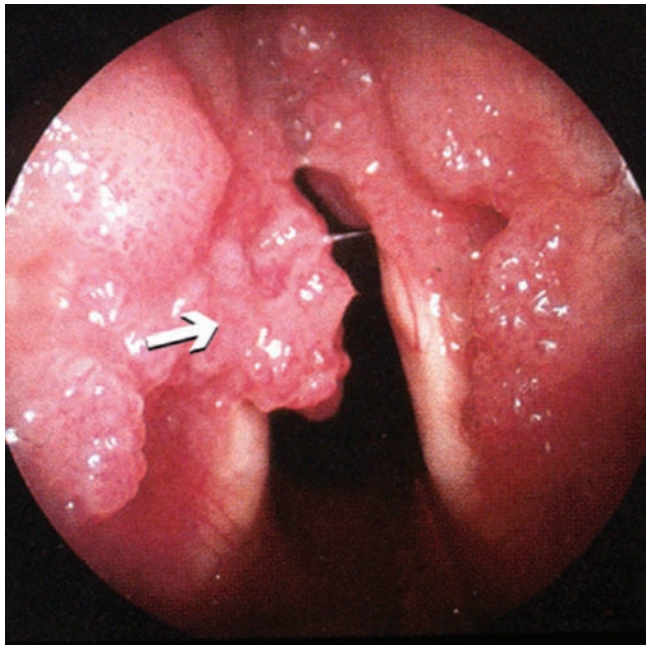

Figure 49-16 Recurrent laryngeal papillomatosis *(arrow)*.

Figure 49-17 Posttracheostomy stenosis.

targeted surgical resection are utilized for confirmed malignant transformation.

■ LARYNGEAL AND TRACHEAL STENOSIS

Common causes of laryngeal and tracheal stenosis include prior intubation and tracheotomy. However, many other causes have been reported.

Postintubation and Posttracheotomy

Concentric scar formation in the larynx or trachea may lead to narrowing and obstruction to airflow. Significant stenosis, defined as obstruction exceeding 50% of the lumen, can lead to serious symptoms and functional limitations.

Endotracheal intubation, tracheostomy, and prior laryngotracheal instrumentation account for most cases of laryngotracheal stenosis. The reported frequencies of tracheal stenosis following tracheostomy or laryngotracheal intubation vary widely (0.6–65%) (Figs. 49-17 and 49-18).[30,31] Although injury to the laryngotracheal airway is common following intubation or tracheostomy, the incidence of symptomatic stenosis, demonstrated by radiographs or bronchoscopy, appears to be much lower (<2%). A recent 8-year retrospective review from Lahey Clinic identified certain patient demographics associated with an increased incidence of postintubation and posttracheostomy stenosis. These included female gender (75%), obesity (66%), diabetes mellitus (35.4%), hypertension (51.6%), and cardiovascular disease (45.1%) and current smoker (38.7%).[32]

Tracheal stenosis in the region of the tube cuff is related to pressure-induced ischemic injury of the mucosa and cartilage and its risk can be minimized by use of large-volume, low-pressure cuffs. The duration of translaryngeal intubation also affects the frequency and severity of laryngotracheal stenosis.

Stenosis following tracheostomy may be above the stoma, at the level of the stoma, at the cuff site, or at the tip of the cannula. Damage to the cartilage above the stoma is a common cause of tracheal stenosis after tracheostomy. In addition to ischemic mucosal injury and ischemic chondritis, anterior and lateral tracheal wall damage, with "buckling in" fractures of the cartilage, is an important factor. The fractures can be minimized by avoiding excessive pressure on the cartilage during the procedure, selecting the appropriate size and length of the tracheostomy tube, avoiding infection, and using the lowest possible cuff pressure.

Percutaneous tracheostomy is growing in popularity as an alternative to the standard procedure. The ideal anatomic site for percutaneous tracheostomy is between the second and third, or the first and second, tracheal rings (not the subglottic space). The incidence of symptomatic tracheal stenosis following percutaneous tracheostomy is comparable to the incidence that occurs after open techniques. When symptomatic tracheal stenosis and tracheomalacia are included as long-term complications, the incidence has been reported to be less than 2.5%.[33]

Other Causes of Tracheal Stenosis

Other causes of laryngeal and tracheal stenosis are uncommon. They include airway trauma, including external injury; inhalational burns, irradiation; tracheal infections, including bacterial tracheitis, tuberculosis, and diphtheria; granulomatosis with polyangiitis

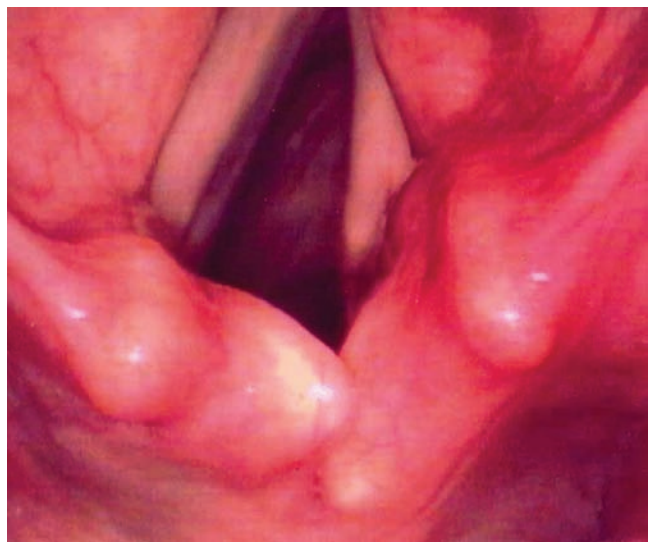

Figure 49-18 Postintubation trauma.

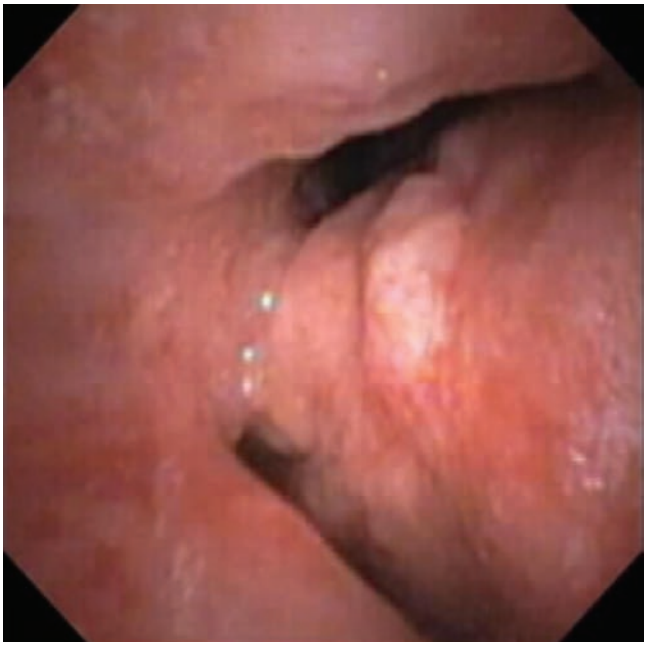

Figure 49-19 Airway sarcoid.

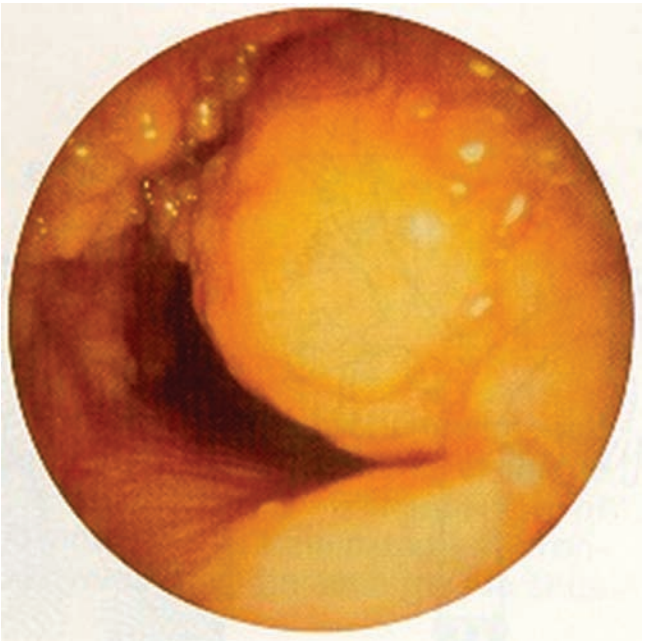

Figure 49-20 Amyloid pseudotumor.

(formerly known as Wegener granulomatosis); sarcoidosis; amyloidosis; collagen vascular diseases, including relapsing polychondritis, polyarteritis; inflammatory bowel disease; and congenital disorders.

Granulomatosis with polyangiitis may present with significant subglottic stenosis, a complication reported in 16% to 23% of patients. Subglottic stenosis may be the only manifestation of Wegener's granulomatosis and have a clinical course distinct from other manifestations of the disease. Endoscopic biopsy of suspected sites of involvement is positive in only 5% to 15% of cases.

Sarcoidosis may be associated with granulomatous infiltration and obstruction of the upper airways (Fig. 49-19). Laryngeal involvement is more common, but tracheal stenosis has been described. Radiographs may show diffuse tracheal stenosis, which progresses despite corticosteroid therapy. Bronchoscopy may reveal extensive tracheal narrowing.

Pulmonary amyloidosis includes tracheobronchial manifestations. The chest roentgenogram may show diffuse narrowing and wall thickening involving a long tracheal segment. Involvement is diffuse and circumferential, often with ossification of the amyloid deposits (Fig. 49-20). Bronchoscopy demonstrates multiple plaques on tracheal walls or localized tumor-like masses.

Relapsing polychondritis is a rare systemic disease characterized by recurrent episodes of inflammation of cartilaginous structures. Respiratory manifestations are often severe and may be life-threatening. Inflammation occurs in all cartilage types, including the elastic cartilage of the ears and nose, hyaline cartilage of all peripheral joints, and axial fibrocartilage. The most common presenting symptom is pain in the external ear due to auricular chondritis. Respiratory tract involvement may develop years after the first occurrence of auricular chondritis. Symptoms include hoarseness, aphonia, and choking. Tenderness over the thyroid and laryngeal cartilages may be present. When the trachea is involved, endoscopic examination shows inflammation and stenosis. CT demonstrates major airway collapse caused by destruction of cartilaginous rings or airway narrowing due to inflammatory edema and fibrosis. CT findings also include diffuse, smooth thickening of the trachea and proximal bronchi; thickened, densely calcified cartilaginous rings; tracheal wall nodularity; and diffuse narrowing of the tracheobronchial lumen. The posterior tracheal membrane is spared.[34]

Tracheopathia osteoplastica is a rare, benign disease of the trachea and major bronchi in which cartilaginous or osseous nodules project into the airway lumen, often causing considerable airway deformity. The posterior membranous portion of the tracheal wall is spared. The disorder may begin just below the larynx, but most often it affects the lower two-thirds of the trachea. Extension into the proximal portions of the major bronchi may be noted. The condition usually occurs over the age of 50 years and may cause severe airflow obstruction. Its etiology is unknown.

On rare occasion, inflammatory bowel disease produces tracheobronchial stenosis and severe airflow obstruction. The associated airway mucosal inflammation may be steroid responsive early in the course of illness. If fibrosis ensues, medical management has limited success.

Laryngopharyngeal reflux may contribute to subglottic stenosis and, when documented, merits treatment.

Idiopathic progressive subglottic stenosis may be diagnosed in the absence of a clear, underlying etiology. Since most affected patients are females, a hormonal etiology has been proposed. However, estrogen receptors have not been demonstrated in specimens studied.[35]

In addition to medical management, repeated rigid and flexible bronchoscopy-based interventions aimed at reestablishing airway patency may be necessary, particularly in those who are not considered to be surgical candidates or in those with simple web-like stenoses. In cases of web-like stenosis, radial incisions sparing the posterior membrane are made and then the airway dilated either using a balloon or the rigid bronchoscope barrel. With respect to more complex stenosis, endoscopic intervention is generally considered a bridge in patients considered good operative candidates with potentially resectable disease. There exists concern on the part of many experts that repeated endoscopic intervention may result in extension of the area of scar rendering potentially resectable stenoses no longer amenable to surgical intervention.[36] Unfortunately resection and reanastomosis is limited by the length of trachea to be resected.[37,38] A multidisciplinary approach incorporating medical and surgical specialists as described by Brichet is utilized in many centers.[39]

Figure 49-21 Bronchoscopic view of tracheomegaly or Mounier-Kuhn syndrome.

TRACHEOMALACIA

Tracheomalacia refers to loss of tracheal rigidity and resulting susceptibility to collapse. Tracheomalacia may be diffuse or localized to a tracheal segment. The affected portion may be intrathoracic, in which airway obstruction is accentuated during expiration. Less common is extrathoracic obstruction resulting from cervical malacia, in which airway obstruction is most marked during inspiration. Tracheobronchomalacia is the term used to describe the condition when the mainstem bronchi are involved.

Tracheomalacia in adults may be classified as congenital or acquired. The congenital form, described more extensively in children, is related to a variety of congenital disorders and associated syndromes. The disorder may persist into adult life and is referred to as "idiopathic giant trachea," "tracheomegaly," or the "Mounier-Kuhn syndrome" (Fig. 49-21). Bronchiectasis and recurrent respiratory infections are common. Tracheal diverticuli have been reported in more advanced disease. Although atrophy of the longitudinal elastic fibers and muscularis layer has been described, the etiology of these changes is unclear. The diagnosis is made when the diameters of the trachea or right or left mainstem bronchi exceed the upper limits of normal by 3 or more standard deviations. In a recent article by O'Dell, patients with tracheobronchomalacia attributable to Mounier-Kuhn were found to benefit symptomatically from airway stenting and tracheobronchoplasty.[40]

Acquired or secondary tracheomalacia in adults may be related to a variety of conditions.[41] Tracheostomy and endotracheal intubation are probably the most common etiologies. Usually, limited, focal weakness of the trachea and excessive dynamic airway collapse are present. Tracheomalacia may be caused by conditions that are associated with chronic pressure on the tracheal wall, inflammation of the cartilaginous support or mucosa, interference with tracheal blood flow, or chronic infection. Traumatic injury to the central airways or surgical interventions also may lead to tracheomalacia.

Symptoms of tracheomalacia include dyspnea, a seal-barking paroxysmal cough, recurrent pulmonary infections, and respiratory failure in a small subset.[42] Many of these patients will also have decreased exercise tolerance and in severe cases impaired quality of life.

Tracheomalacia is diagnosed by using direct bronchoscopic visualization to confirm significant narrowing of the tracheal lumen during regular, forced expiration. Assessment of the central airways using end-expiratory, dynamic, three-dimensional CT images is useful. Application of continuous positive airway pressure (CPAP) has been reported as beneficial as pneumatic splint for the airways. Tracheobronchoplasty may be useful in selected patients and has been shown to improve quality of life and exercise tolerance.[42] Optimal medical management includes treatment of associated infections and of distal airway disease.

EXTRINSIC COMPRESSION OF THE CENTRAL AIRWAY

The upper airway is subject to extrinsic compression by a variety of pathologies that involve adjacent structures. The compression may affect the intrathoracic trachea or extrathoracic trachea and upper airway.

Mediastinal Masses and Lymphadenopathy

Rarely, mediastinal masses present with serious limitation to airflow that develop either acutely or indolently. Common symptoms include chest pain, fever, dyspnea, and cough. Based on one large series, approximately 40% of mediastinal masses are malignant; 25% are cystic. The anterosuperior compartment is the most common site of mediastinal malignancies. Thymic neoplasms and lymphoma are the most common malignancies, followed by neurogenic tumors and teratomas. Both Hodgkin and non-Hodgkin lymphomas may be manifested by severe respiratory compromise due to airway compression. A similar syndrome may be due to a metastatic tumor to the mediastinal lymph nodes arising from bronchogenic or other carcinomas.

Patients with large mediastinal masses present a challenge during the perioperative period because of the potential for development of acute UAO and other respiratory complications. In adults, complete airway obstruction during induction of anesthesia is rare. Serious pulmonary complications develop intra- and postoperatively in about 4% and 7% of patients, respectively. Complications may occur while the patient is placed in the supine position, during induction, or following extubation. Patients with severe symptoms, including stridor, and those with greater than 50% airway obstruction appear at high risk for respiratory complications; asymptomatic patients are at significantly less risk. Patients with reduced peak expiratory flow and mixed obstructive–restrictive patterns on pulmonary function testing also appear to be at increased risk for postoperative complications.

Middle mediastinal masses include benign cysts that are bronchogenic, enterogenous (duplication), pericardial, pleural, and thymic in origin. Most bronchogenic cysts are asymptomatic. However, some evoke cough, chest pain, and dyspnea. Severe respiratory distress and compressive symptoms can occur. Usually, cyst contents appear to have the density of water on CT or MRI. Mucoid contents may give the impression of solid appearance on CT. Surgical resection and transthoracic or transbronchial drainage are options for management. Surgical intervention appears to be the preferred treatment in patients who are symptomatic. The role of interventions, including surgery, in asymptomatic patients is controversial. Enterogenous cysts are usually removed surgically.

Enlarged mediastinal lymph nodes that compress the airway may arise from infectious and noninfectious benign etiologies. One notable example is fibrosing mediastinitis, defined as the presence of excessive mediastinal fibrous tissue that tends to invade and destroy normal structures. The entity is thought to represent a reaction to an infectious granulomatous disease, especially histoplasmosis. The incidence in populations exposed to histoplasmosis remains low. Constriction of the central airways and vessels and the resulting cardiopulmonary limitations may develop several years after the initial infection. Hemoptysis is common, as are cough, dyspnea, and chest

pain. CT imaging shows mediastinal fibrosis, calcification, and compression of mediastinal structures. Bronchoscopic findings include concentric airway narrowing and mucosal edema with hyperemia. Unfortunately, hemoptysis tends to be recurrent, and the disease does not respond to corticosteroids or antifungal agents. Surgical intervention is generally ineffective and may be hazardous.

Neck and Thyroid-Related Causes

Retrosternal extension of a diffuse goiter may cause extrathoracic or intrathoracic airway obstruction. Up to 90% of patients with substernal goiter report respiratory symptoms. A choking sensation occurs in about one-third of patients with diffuse thyroid enlargement and 14% in patients with solitary thyroid nodules. Orthopnea is prevalent when the goiter is intrathoracic and may be enhanced by obesity. Flow–volume loops show evidence of UAO in one-third of patients. Lack of correlation has been reported between symptomatic obstruction and CT findings.[43]

Laryngoceles and saccular cysts, which are abnormal dilatations of the laryngeal saccule (ventricle), are uncommon. Saccular cysts usually are filled with mucus. Laryngoceles communicate with the laryngeal lumen, resulting in air-filled structures noted on radiographic studies. Laryngoceles may be internal (i.e., confined to the larynx), external (i.e., extending into the thyrohyoid membrane superiorly), or combined. Most are asymptomatic. Hoarseness, dysphagia, pain, or signs of airway obstruction or infection may occur. A neck mass during the valsalva maneuver may be detectable. Pyocele formation (i.e., infection in the laryngocele) may result in airway obstruction, aspiration pneumonia, or infection of the lateral pharyngeal space. The incidence of laryngeal carcinoma in association with laryngoceles makes close evaluation necessary. Endoscopic and surgical approaches may be employed in management.

Parathyroid cysts may be located in the neck or mediastinum. Fifty percent are accompanied by clinical hyperparathyroidism. Paroxysmal symptoms of airway obstruction can develop. Surgical excision is the treatment of choice; results are generally good.

Cervical osteophytes, common in the elderly, are related to either degenerative spinal arthritis or more generalized idiopathic skeletal hyperostosis; the osteophytes may be associated with dysphagia. In addition, airway narrowing and ulcerations due to osteophytes have been reported. The airway compression may make even elective endotracheal intubation difficult, despite adequate preoperative evaluation.

Finally, significant upper airway compression may arise from cervical lymph node involvement with infectious or malignant disorders, hematomas or pseudoaneurysms (related to trauma, surgical interventions, central line placement, or coagulation abnormalities), abscess formation, or other expanding lesions in the soft tissue of the neck.

Diseases of the Esophagus

Involvement of the trachea, glottis, or vocal cords by advanced esophageal cancer is common and associated with a poor prognosis; estimated 1-year survival is less than 10%. Airway obstruction requiring stent placement is associated with a median survival of 1 to 4 months after the placement. Tracheal obstruction may develop if an esophageal stent is placed in the setting of significant tracheal compromise. Development of tracheoesophageal fistula represents a devastating complication.

Placement of stents simultaneously in the trachea and esophagus is effective palliation for a tracheoesophageal fistula.[44] If such double stenting is anticipated for a fistula or for simultaneous esophageal and tracheal obstructions, the tracheal stent is placed first to ensure patency of the airway, followed by the esophageal stent. Palliative external or local radiation therapy, chemotherapy, or other treatment modalities (e.g., PDT) may be effective with or without accompanying airway interventions. The risk of esophageal disruption and rupture should be considered if stenting is performed after these local measures are employed.

Achalasia may cause a variety of pulmonary complications, including cough, aspiration with pneumonia or abscess formation, and rarely UAO. Tracheal compression by a dilated megaesophagus is the usual etiology. Ensuring patency of the airway and decompressing the esophagus are necessary in urgent management.

Vascular Abnormalities

Vascular rings, defined as anomalies of the aortic arch or its branches that compress the trachea or esophagus, are rare in adults (incidence <0.2%). Respiratory symptoms are common.

Right-sided aortic arch occurs in less than 0.1% in adults and may be associated with complete vascular rings, while double aortic arch and right-sided aortic arch with aberrant left subclavian artery appear to be the most common etiologies of vascular rings in adults.

The right-sided aortic arch usually crosses over the right mainstem bronchus and descends on either the right or the left side. The vascular ring is usually completed by the ligamentum arteriosum arising from the descending aorta, an aberrant left subclavian artery, or an aortic diverticulum. With a double aortic arch, the left arch crosses over the left main-stem bronchus and joins the descending aorta to complete the ring; the ligamentum arteriosum does not contribute to the vascular ring. Symptoms, resulting from malacia of the compressed airway and resultant dynamic airway obstruction, may be misdiagnosed as exercise-induced asthma. An increase in aortic diameter due to rising blood pressure during exercise, intravenous fluid administration, or anatomic changes with aging may contribute to symptoms. Surgical intervention is indicated in symptomatic patients.

Pulmonary artery sling with anomalous origin of the left pulmonary artery from the right pulmonary artery is very rare in adults. In neonates, the condition is symptomatic and can be fatal without surgical intervention. However, in adults the condition is usually diagnosed incidentally on imaging a patient who has no significant symptoms. This disorder may be associated with a complete tracheal ring, forming the "sling-ring" complex. This condition may present with a right paratracheal mass noted on the chest radiograph.

Compression of the trachea by large aortic or innominate artery aneurysms or pseudoaneurysms may occur and complicate management in the perioperative period. Surgical repair is indicated to relieve symptoms.

FOREIGN BODY ASPIRATION

Foreign body aspiration, more common in children than adults (in whom the peak incidence is in the sixth decade), is usually recognized from the patient's history. Foreign bodies commonly lodge in the bronchi after migrating through the trachea. In adults, food products are the most commonly aspirated material. The penetration syndrome, defined as the sudden onset of choking and intractable cough after aspirating a foreign body, with or without vomiting, is often followed by persistent cough, fever, chest pain, dyspnea, and wheezing. Impairment of the normal protective airway mechanisms is common; among the frequent associations are neurologic disorders, trauma with loss of consciousness, sedative or alcohol use, poor dentition, and advanced age. Emergency measures, entailing a food extractor or the Heimlich maneuver, can be life-saving. Flexible bronchoscopy is usually successful in removing foreign bodies, although back-up rigid bronchoscopy should be available and is preferred as the primary procedure at some centers. A complicating chemical bronchitis from aspiration of vegetables or nuts may affect visualization and management of the foreign body. Certain nut oils also cause a significant foreign body mucosal reaction resulting in the development of granulation tissue that may be misdiagnosed as endobronchial tumor.

TRAUMA

A variety of traumatic injuries may eventuate in UAO.

Facial Trauma

Emergency access to the airway is necessary in up to 6% of cases of facial trauma complicating motor vehicle accidents and other causes of crush injuries. If intubation is difficult or impossible due to the injury or related airway obstruction, emergency cricothyroidotomy or tracheostomy must be considered.

Laryngotracheal Injuries

Blunt and penetrating injuries to the laryngotracheal airway are rare. Without a high index of suspicion, clinicians may miss the diagnosis. The incidence of penetrating injuries appears to be increasing.

Stridor, wheezing, dysphonia, hemoptysis, and general neurologic deficits are common. Cervical crepitus and subcutaneous emphysema also may be present. Cervical ecchymoses and hematomas, pneumomediastinum, and pneumothorax should prompt consideration of a laryngotracheal injury.

Management includes prompt securing of the airway, but blind endotracheal intubation should be avoided, since it carries the risk of complete airway obstruction. Some experts recommend tracheostomy as the primary airway management strategy. Awake fiberoptic intubation can be useful. Flexible fiberoptic laryngoscopy, rigid or flexible bronchoscopy, and CT imaging may be helpful in assessing the degree of injury. Unfortunately, the mortality of laryngotracheal injuries remains high (20%–40%). Thoracic injuries and closed head injuries are commonly associated pathologies that can influence management and prognosis.

Inhalation Injuries

Thermal and chemical injuries to the upper respiratory tract may lead to serious consequences, including airway obstruction. Unfortunately, the mortality rate increases significantly when burns are accompanied by inhalational injury. Symptoms can be delayed in becoming manifest, making early recognition and intervention vital in the management of patients with inhalational injuries. The presence of cough, dyspnea, hoarseness, or loss of consciousness, or the findings of singed nasal hairs, carbonaceous sputum, or burns involving the face indicate a high likelihood of inhalation injury.

Early flexible bronchoscopy remains important in evaluation and management of patients with inhalation injuries, enabling the assessment of the extent and severity of the injury, procurement of samples for bacteriologic studies, and bronchoscopic intubation, as necessary. Translaryngeal intubation is the standard method of securing the airway in inhalation injury; early tracheostomy is used in some centers. A role for prophylactic corticosteroids or antibiotics is currently not supported by published reports. Significant tracheal stenosis may develop in patients who survive the initial insult, especially when translaryngeal intubation or tracheostomy is necessary.

ENDOTRACHEAL TUBE–RELATED TRAUMA

Postextubation stridor due to glottic edema, laryngospasm, or laryngotracheal stenosis is a serious event. Reintubation rates for UAO due to endotracheal tube–related trauma in critically ill patients have been reported to range from 4% to 33%. An "acceptable" rate is considered to be 5% to 15%. The cuff leak test does not accurately predict success or failure of extubation. Although the efficacy of corticosteroids or racemic epinephrine in the management of postextubation stridor is not substantiated, both are used extensively in clinical practice.

Translaryngeal intubation may also produce vocal cord paralysis, accounting for 10% to 15% of all cases. Paralysis may be unilateral or bilateral. Affected patients may present with hoarseness or airway obstruction. Findings may occur immediately after extubation or be delayed. Prolonged intubation, use of a large endotracheal tube (number 8 or larger), placement of the tube cuff close to the vocal cords, or use of excessive cuff pressure are risk factors. The condition usually resolves spontaneously within 10 weeks.

Vocal cord (contact) granuloma may develop 4 to 6 weeks after intubation. Symptoms include prolonged hoarseness, exertional dyspnea, and stridor. Management, using antireflux medications, inhaled and systemic corticosteroids, antibiotics, botulinum toxin injection, speech therapy, smoking cessation, and rest of the voice are usually successful. Surgical intervention is reserved for cases that fail conservative management.

On occasion, dislocation of the arytenoid cartilages occurs during intubation. Rheumatoid arthritis that affects the cricoarytenoid cartilage is a risk factor for this condition. Rigid bronchoscopy or surgical interventions may be needed to reduce the dislocation. Other disorders that may cause complications during intubation include hyperostosis of the cervical spine due to ankylosing spondylitis and cricoarytenoid joint disease due to systemic lupus erythematosus.

NEUROMUSCULAR DISORDERS

Neuromuscular disorders may affect the bulbar muscles, many of which surround the upper airway (Fig. 49-22). When this occurs, resistance to airflow is increased, and the flow–volume loop often shows an inspiratory flow plateau typical of variable extrathoracic UAO. In addition, a pattern of flow oscillations during inspiration ("sawtooth pattern") may be seen.[45] The abnormal flow pattern, first noted in patients with sleep apnea,[46] is commonly seen in extrapyramidal disorders, myasthenia gravis, and motor neuron disease; it may also be seen in patients who have functional stridor and wheezing (see Vocal Cord Dysfunction section). In extrapyramidal disorders, the flow oscillations correspond to vocal cord tremor. In motor neuron diseases, muscle denervation causes irregular muscle fasciculation, resulting in tremor of upper airway muscles.

Upper airway symptoms may be seen in Shy–Drager syndrome with extrapyramidal involvement and in Parkinson disease.[47,48] Patients may present with symptoms of chronic dyspnea or with stridor and respiratory failure relieved by endotracheal intubation or tracheostomy. Bilateral vocal cord paralysis may also occur with familial bulbar spinal muscle atrophy, postpoliomyelitis syndrome,

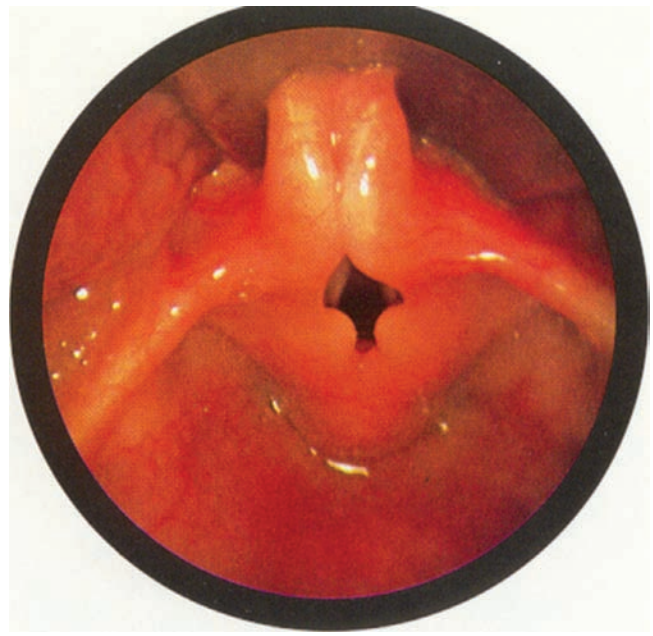

Figure 49-22 Laryngomalacia.

Figure 49-23 Bilateral vocal cord paralysis.

Parkinson disease, multiple sclerosis, acute poliomyelitis, amyotrophic lateral sclerosis, Guillain–Barré syndrome, brain stem stroke, and large cerebral hemisphere stroke. Dystonic extrapyramidal reactions due to neuroleptic medications (e.g., haloperidol) may cause significant UAO. The usual reactions to these medications are akathisia, dyskinesia, dysarthria, and dystonic reactions, such as torticollis. Laryngeal–pharyngeal dystonia may cause severe upper airway dysfunction, and if not reversed, symptoms can last for days or lead to respiratory arrest.

BILATERAL VOCAL CORD PARALYSIS

Bilateral vocal cord paralysis is a serious condition resulting in nocturnal stridor, oxygen desaturation, sleep disruption or, in extreme cases, acute respiratory failure (Fig. 49-23). Thyroidectomy is the most common cause of bilateral recurrent laryngeal nerve injury, with its consequent bilateral vocal cord paralysis.[49] As mentioned earlier, bilateral vocal cord paralysis may occur with numerous neurologic conditions. Nonneurologic causes include endotracheal intubation injury, laryngeal trauma, infection, and thoracic aortic aneurysm. Bilateral vocal cord paralysis results in abnormalities of inspiratory flow and a distinctive flow–volume loop.

Spontaneous recovery of vocal cord motility is rare after surgical injury of the recurrent laryngeal nerve. For those patients showing no spontaneous functional recovery, several surgical techniques to achieve a glottic space enlargement are available. CO_2 laser endoscopic surgery has led to shorter hospitalization and higher patient compliance.[50,51] Endoscopic surgeries include arytenoidectomy with or without posterior true and false cord cordectomy. Surgeries aim to improve breathing with minimal deglutition impairment and improve quality of voice. Restenosis of the glottis space is the main problem that leads patients to reoperations.

VOCAL CORD DYSFUNCTION

The glottis plays an active role in adjusting airflow, both voluntarily and through reflex control from laryngeal and lung receptors. During a normal respiratory cycle, the vocal folds widely abduct during inspiration and slightly adduct during expiration. Occasionally, the glottis can become dysfunctional in the absence of organic disease. The disorder, most commonly called vocal cord dysfunction or paradoxical vocal fold motion, is characterized by paradoxical closure of the vocal cords intermittently during inspiration. The glottis angle formed by the true vocal folds can become acute and cause airflow obstruction during inspiration and/or expiration. The mechanism is unknown, but likely multifactorial. Laryngeal hypersensitivity has been associated with reflux, upper respiratory tract infections, postnasal drip, irritants, exercise, as well as psychogenic factors.

Signs and symptoms of vocal cord dysfunction resemble those of laryngeal edema, laryngospasm, vocal cord paralysis, or asthma. Wheezing or stridor and shortness of breath are typical and are often so dramatic that they suggest acute asphyxia and respiratory failure. Intubation and other emergency measures are used frequently. However, symptoms are often brief and may remit without intervention. Distinguishing physical examination findings include tracheal localization of wheezing or stridor with absent peripheral airway expiratory wheezing; however, it should be understood that this might also occur during severe asthma attacks.

On pulmonary function testing, patients with vocal cord dysfunction typically have normal spirometry without evidence of obstructive ventilatory defect. Some may demonstrate a pattern of variable extrathoracic airway obstruction, resulting in an increase in the ratio of $FEF_{50\%}$ to $FIF_{50\%}$. Some patients show a pattern of "sawtoothing," or fluttering of the inspiratory limb of the flow–volume loop, representing fluctuations in the abnormal cord motion (Fig. 49-24). Often, attempts to perform the flow–volume loop maneuver generate variable results from test to test. A normal alveolar–arterial oxygen gradient and absence of bronchial hyperresponsiveness are other clues to the diagnosis.

The diagnosis of vocal cord dysfunction is confirmed during direct visualization of the vocal cords during an attack. The anterior

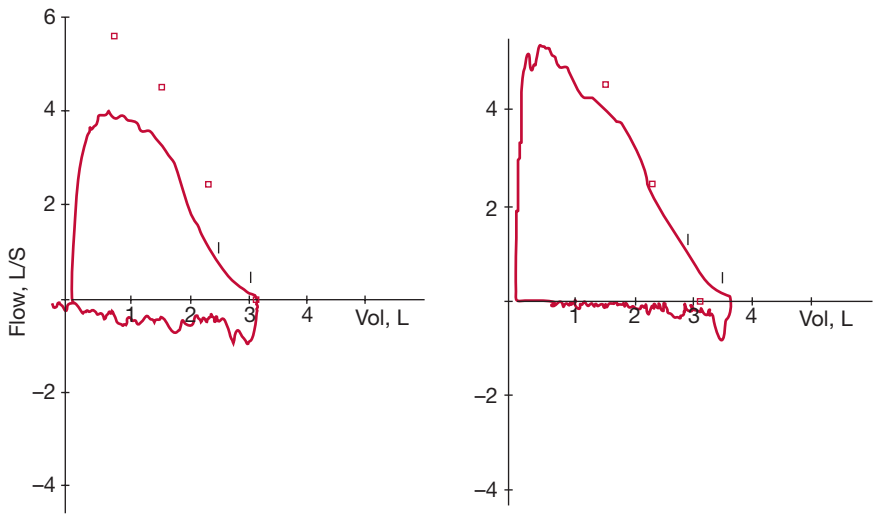

Figure 49-24 Variable extrathoracic obstruction due to vocal cord dysfunction. Two consecutive flow–volume loops from a young woman with inspiratory stridor. Variable effort accounts for the differences in configuration. $FEF_{50\%}/FIF_{50\%}$ in each is very high. The inspiratory loop is flat and demonstrates a sawtooth pattern. This pattern has also been associated with sleep apnea syndrome and various neuromuscular disorders.

two-thirds of the vocal folds adduct and give the presence of a posterior diamond-shaped chink in the folds during inspiration.[52]

The true prevalence of the disorder is unknown because it is often mistakenly diagnosed as asthma, and many patients in fact have both vocal cord dysfunction and asthma. Patients without asthma are predominantly women who have been misdiagnosed as having asthma for an average of 5 years. Typically, patients have been treated with large doses of oral corticosteroids, and have experienced frequent emergency room visits, hospitalizations, and endotracheal intubations.

Psychiatric disorders are common in these patients. Major psychiatric disorders, personality disorders, and sexual and physical abuse are commonly uncovered. Whereas many patients are unaware of their self-induced wheeze or stridor, others appear to derive secondary gain from their symptoms and manifest factitious illness. A high index of suspicion is warranted when the adventitious sounds are loudest over the neck in a patient who presents with wheezing, stridor, or both. Despite their respiratory distress, patients often have little difficulty completing full sentences and can hold their breath; the laryngeal-induced sounds disappear during a panting maneuver.

Treatment includes discussion of the diagnosis with the patient, discontinuation of unnecessary medications, and referral to a speech therapist or psychotherapist. The response to bronchodilator therapy is usually poor. Administration of an inhaled helium–oxygen mixture may alleviate symptoms during an acute attack.

ANGIOEDEMA

Angioedema is characterized by well-demarcated swelling of the face, lips, tongue, and mucus membranes of the nose, mouth, and throat. When the larynx is involved, UAO may occur and is fatal in as many as 25% of patients. In most instances, the cause of angioedema is unclear; prior exposure to common allergens, such as drugs, chemical additives, and insect bites should be suspected.

Contrary to what might be thought, the most common causes of angioedema are not IgE initiated. They include reactions to histamine-releasing drugs, such as narcotics and radiocontrast materials, to aspirin and other nonsteroidal anti-inflammatory drugs, and to angiotensin-converting enzyme inhibitors. Hereditary angioedema, a rare cause of UAO, is an autosomal-dominant trait that occurs in all races. The underlying mechanism is a deficiency in production or function of C1 esterase inhibitor, a serum protease inhibitor that regulates the complement, fibrinolytic, and kinin pathways. Hereditary angioedema is characterized by painless nonpitting edema of the face and upper airway. The disorder usually begins in childhood and becomes more prominent in adolescence. Swelling progresses over many hours and then resolves spontaneously over 1 to 3 days. Despite the slow progression, death may occur from laryngeal obstruction. Physical stimuli (cold, heat, stress) and circulating immune complex diseases (e.g., due to serum sickness or systemic lupus erythematosus) are also known to cause angioedema.

Emergency management includes foremost securing the airway. Epinephrine is used for allergic angioedema. Administration of corticosteroids and antihistamines are often used, although current evidence suggests that such a therapy is rather ineffective in kinin-induced angioedema.[53] Thus, symptom-related medical care should be provided until the swellings have disappeared. Approaches targeting the kallikrein–kinin system, such as kallikrein inhibitors[54] and bradykinin type-2 receptor antagonists[55] may improve pharmacotherapy. It is probable that these drugs may also be beneficial in patients with bradykinin-mediated drug-induced angioedema.

MISCELLANEOUS ETIOLOGIES

Postpneumonectomy syndrome refers to compression of the left main bronchus between the aortic arch and left pulmonary artery following a right pneumonectomy. The syndrome also may be seen following a left pneumonectomy, sometimes in the setting of a right-sided aortic arch. Mediastinal repositioning prostheses, with or without additional fixation methods, may be useful in selected patients.

Mucus ball formation related to transtracheal oxygen catheters has been described. Although transtracheal oxygen delivery decreases supplemental oxygen flow requirements by approximately 50% during rest and 30% during activity, development of symptomatic mucus balls (occurring in up to one-third of patients) remains a major disadvantage of the technique. Death and life-threatening events secondary to airway obstruction have been reported.

MANAGEMENT OF UPPER AIRWAY OBSTRUCTION

Key elements in the management of UAO include general principles, securing the airway, and specific interventions.

GENERAL MANAGEMENT

The primary goals in management of any patient with UAO are assurance of adequate oxygenation and ventilation and management of the underlying condition. If airway obstruction is partial, and the patient's condition is stable, close monitoring and diagnostic studies are appropriate. Depending upon the underlying etiology, temporary measures may include close observation in an intensive care unit, elevation of the head of the bed, administration of humidified oxygen, use of a helium–oxygen inhalation mixture (see next paragraph), systemic corticosteroids, and inhaled racemic epinephrine, pending definitive medical or surgical management.

A helium–oxygen gas mixture (heliox) may be useful in management of UAO when the obstruction is temporary and reversible. The physiologic rationale for heliox is based upon a reduction in work of breathing achieved through administration of a low-density gas. In particular, heliox has a lower density than does oxygen, room air, or a mixture of the two, resulting in conversion of the predominantly turbulent flow at the site of obstruction to a more laminar pattern. Furthermore, since laminar flow requires a smaller pressure gradient than turbulent flow to achieve the same flow rate, the accompanying work of breathing is less (see Chapter 10). The major limitation of the modality is an inability to deliver gas with an inspiratory fraction of oxygen ($F_{I_{O_2}}$) of more than 40%. Despite physiologic evidence and clinical reports of efficacy, prospective, randomized studies demonstrating improved outcome in patients receiving heliox are lacking, as are data supporting use of corticosteroids or inhaled epinephrine in airway obstruction from a variety of causes.

SECURING THE AIRWAY

Although under controlled circumstances, a significant portion of the so-called difficult airways and intubations may be identified in the course of a thorough preoperative assessment, the patient with impending airway obstruction presents a challenge. Under such circumstances, a critical first concern is deciding whether an artificial airway is needed emergently.[56] Regardless of the airway utilized, emphasis is placed on ensuring adequate oxygenation and ventilation.

Airways judged unsafe for routine management may be addressed according to the "difficult airway algorithm" recommended by the American Society of Anesthesiologists (see also Chapter 146).[57] A difficult airway is defined as a clinical circumstance in which a conventionally trained anesthesiologist experiences difficulty using face mask ventilation, endotracheal intubation, or both.

Airway access in emergency situations may be challenging because the patient frequently is critically ill and can deteriorate quickly. The likelihood of a difficult intubation can be estimated by using the Mallampati score or a modification of the score to assess potential laryngeal exposure and prospects for adequate airway visualization.

A number of parameters, such as mouth opening distance, jaw size, thyromental distance, and cervical range of motion, have been

incorporated into airway assessment scoring systems; each parameter has limited sensitivity and specificity. Combining scoring systems provides better accuracy of prediction. The "rule of threes," which is a useful, simple bedside tool, predicts successful direct laryngoscopy if the examiner can place three finger breadths (~6 to 7 cm) between the upper and lower teeth, the mandible and hyoid bones, and the thyroid cartilage and sternal notch. In the emergency setting of UAO, the most experienced physician available should secure the airway. Appropriate equipment and monitoring, along with back-up resources for alternative and invasive airway management, should be available.

A variety of invasive and noninvasive techniques are available as alternatives to standard, laryngoscopy-guided orotracheal intubation. Invasive methods include surgical and/or percutaneous tracheostomy, surgical and percutaneous transtracheal (needle) cricothyrotomy, translaryngeal guided or "retrograde" intubation, fiberoptic endotracheal intubation, and use of a rigid ventilating bronchoscope. Noninvasive techniques include use of specialized laryngoscope blades, Glidescope™, guiding and lighted stylets, directional tip control tubes, and esophageal–tracheal (Combitube) or laryngeal mask airways. In selected circumstances, tactile intubation, nasotracheal intubation, or blind orotracheal intubation may be employed.

CRICOTHYROIDOTOMY

Cricothyroidotomy (either surgical or based on Seldinger technique) has a long history of use in emergency access to the airway when more conservative approaches fail or are contraindicated. Currently, surgical cricothyroidotomy is performed by surgeons, anesthesiologists, and intensive care specialists. In early reports, a high incidence of laryngeal stenosis during intermediate and long-term follow-up was noted, perhaps related to the presence of infectious laryngeal disease or the use of large-bore tubes. In addition, the risk of subglottic stenosis also appears high in patients with prolonged prior intubation. Hence, although the procedure is useful for short-term airway control, tracheostomy should be considered if prolonged airway access is required.

TRACHEOSTOMY

Most tracheostomies are performed on intubated patients in the intensive care unit. Percutaneous tracheostomy is rapidly becoming the method of choice in the intensive care unit and is associated with acceptable intraoperative and postoperative complication rates. Advantages of the technique over the traditional procedure include low cost, short procedure time, low complication rate, and elimination of the need to transport critically ill patients to the operating room. Adaptation of percutaneous techniques for emergency situations also has been described.

In a review of over 1100 patients who underwent tracheostomy, 76% were performed in patients who required prolonged ventilation, 6% for UAO, 7% for extensive maxillofacial trauma, and 11% as an adjunct for head and neck or chest surgeries; only 0.26% were performed as emergency procedures. Overall mortality was 0.7%.[58]

INTERVENTIONAL BRONCHOSCOPIC TECHNIQUES

Interventional bronchoscopy is discussed in chapter 36. Use of these techniques for managing UAO is well established and is briefly summarized in the following paragraphs.

Rigid bronchoscopy allows oxygenation, ventilation, and application of various diagnostic and therapeutic interventions, including debridement of obstructing lesions, control of bleeding, and removal of foreign bodies. Complications include anesthetic risks, barotrauma, damage to teeth, lips or gums, airway perforation, bleeding, and mucosal injury.

Thermal modalities may be used to devitalize tissue prior to mechanical debridement or to cauterize the base of lesions following debulking. Electrocautery, laser (Nd-Yag, CO_2, i.e., Yap), argon plasma coagulation, and cryotherapy can be applied through rigid or flexible bronchoscopy. Side effects include bleeding, perforation, airway fire and damage to cartilage.

Photodynamic therapy is based on the principle of targeted tissue apoptosis after local activation of a systemically injected photosensitive chemotherapeutic agent. In essence, PDT creates a phototoxic cell reaction when nonthermal laser light is applied by bronchoscopy and activates a drug trapped in these target cells. The major disadvantage of this technique is that the tissue necrosis occurs within 48 to 72 hours and as such the ability to debride the airway is delayed for several days. Bleeding and obstruction from necrotic tumor and edema are potential immediate complications. PDT may also result in airway perforation.

Standard cryotherapy, based on repeated freeze–thaw cycles to achieve cell necrosis and tissue damage is used in benign and malignant disorders of the upper airway. Cryotherapy has excellent hemostatic effects; the incidence of perforation or bleeding is low. Due to the delayed beneficial effect, cryotherapy is not usually used under emergent conditions. In recent years a cryobiopsy technique has been developed in which the tissue is simply frozen to the probe and then sheared from the surface, obviating the thaw cycle. Applied in this fashion, cryotherapy can be used for the immediate treatment of airway obstruction. In addition, cryotherapy has the advantage over other thermal modalities in that cartilage is cryoresistant.

Finally, external beam radiation and brachytherapy are useful modalities for palliative management of airway obstruction and hemoptysis. For external beam radiation, unwanted exposure of adjacent structures is a limiting factor, while hemorrhage, radiation bronchitis, and fistulae with surrounding structures are known complications of radiotherapy. The maximal effect of all radiation techniques is delayed days to weeks and there is a risk of worsening of obstruction during therapy due to airway edema.

AIRWAY STENTS

Airway stents are used in the palliative management of both benign and malignant airway obstruction.[59] Available tracheal stents include expandable metal, silicone, and hybrid prostheses. Major complications include stent migration, granulation tissue formation, and stent interference with mucociliary clearance. In a series of over 1500 patients who had stents placed for UAO due to benign or malignant disorders, stent migration was reported in 9.5%, granulation tissue formation in 7.9% and obstruction in 3.6%. Due to concerns regarding stent fracture, the FDA posed a warning on the use of metallic airway stents for benign disease. Currently, metallic stents are only recommended in benign disease for patients who are not candidates for or have failed a trial of silicone stent placement.

CHAPTER 50

Cystic Fibrosis

Judith A. Voynow
Maria Mascarenhas
Andrea Kelly
Thomas F. Scanlin

Cystic fibrosis (CF) is a common inherited disease that has a high frequency in Caucasians. The disorder affects all exocrine glands, with symptoms involving the lungs and pancreas usually dominating the clinical picture. Even though the gene responsible for CF and its gene product, an integral membrane glycoprotein, have been identified, two aspects of the disease make CF particularly difficult to both diagnose and manage. First, there is tremendous variability in the degree and pattern of involvement of organs in different persons. In addition, we lack information about the precise details of the molecular and cellular pathogenesis of the disease. This chapter focuses on the pathophysiology and management of CF. Our current understanding of the genetics and underlying molecular biology is highlighted. Complications of the disorder are addressed, and a brief discussion of relevant psychosocial and reproductive issues is provided. Finally, potential future directions in treatment are described.

GENETICS

CF demonstrates an autosomal-recessive pattern of inheritance. In the United States, the incidence of the disease is approximately 1 in 3000 in Caucasians, 1 in 6000 in Hispanics, and 1 in 10,000 in African Americans. The frequency of unaffected heterozygote carriers of a CF mutation is estimated to be 1 in 26 in persons of Northern European ancestry.

CF is caused by mutations in a single gene named the *cystic fibrosis transmembrane conductance regulator* (CFTR). This gene was identified with an approach known as positional cloning, which permitted mapping of the gene, without prior knowledge of the biochemical defect, through use of polymorphic DNA markers. The first genetic marker that was found to be linked to CF was paraoxonase. In 1985, the demonstration of the linkage of CF to two DNA markers, D7S15 and D7S8, and to the *met* oncogene established the localization of the CF gene to the long arm of chromosome 7. Following a series of molecular cloning experiments, which included "chromosome walking" and "jumping," a candidate gene was identified. This was proved to be the CF gene in 1989, largely through the discovery of a frequent mutation.[1,2]

The CF gene spans approximately 230 kb of DNA and contains 27 exons. The mRNA is 6.5 kb and is detected in a variety of tissues, including lungs, pancreas, and sweat glands, which are predominantly affected in pathogenesis of the disease. The deduced polypeptide was predicted to be an integral membrane glycoprotein containing 1480 amino acids (Fig. 50-1) (see "Pathogenesis" below). Several major and minor splicing variants in the transcripts have been described in individuals with and without CF. In most cases, however, the significance of the alternative splicings is not clear.

The most common CF mutation, and the first to be described, is a three-base deletion in exon 10 that causes a deletion of phenylalanine from position 508 (ΔF508 or F508del) of the CFTR glycoprotein. This mutation accounts for 66% of CF mutations.[3] However, more than 1900 CF mutations have now been reported, and the list continues to grow. In addition, a number of benign sequence variations have been described. A listing of the most common mutations and their relative frequency is included in Table 50-1. The large number of mutations makes accurate detection of a satisfactory percentage of carriers extremely difficult, and carrier screening for the general population has not been recommended or implemented. Testing for 32 of the most common mutations is widely available; such testing will detect approximately 90% of the carriers in Caucasians of Northern European descent. In families with an affected individual and known mutations, prenatal diagnosis and

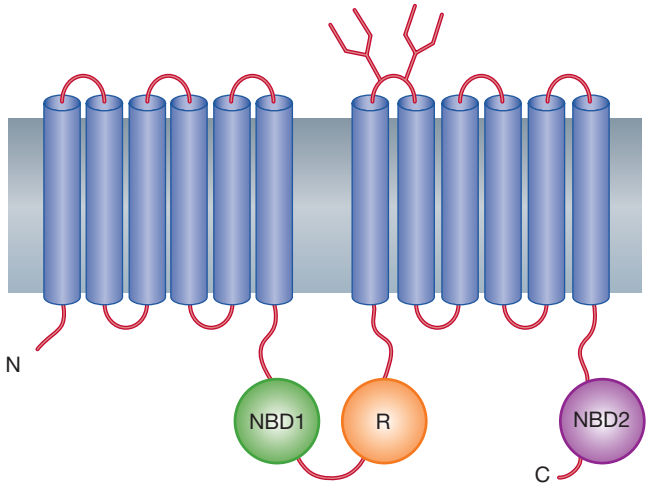

Figure 50-1 Domain model of the cystic fibrosis transmembrane conductance regulator (CFTR). Based on hydrophobicity plots, CFTR has 12 transmembrane-spanning domains, two nucleotide (N) binding domains (NBD 1 and NBD 2), and a regulatory (R) domain. The 12 transmembrane domains form the ion channel "pore." In the closed state, the "R" domain is believed to obstruct the channel. Channel opening requires binding of two adenosine triphosphates (ATPs) to the nucleotide binding domains. This model is similar to other ATP-binding cassette transporter proteins that bind ATP and transport ions or micronutrients. *(Modified with permission from Riordan J, Rommens JM, Kerem B, et al. Identification of the cystic fibrosis gene: Cloning and characterization of complementary DNA. Science; 245(4922):1066–1073.)*

carrier testing using direct detection of mutations is accurate and available. In families with a member diagnosed as having CF, but with undetected mutations, sequencing of the complete CFTR coding region and critical intronic regions is now also available to detect rare mutations.

PATHOGENESIS

Discovery of the gene responsible for CF and description of its product, CFTR, have provided the necessary foundation for understanding the pathogenesis of the disorder at the molecular and cellular levels. CFTR is an integral membrane glycoprotein of approximately 170 kD that is expressed in epithelial cells of affected organs. CFTR contains 1480 amino acids, which are arranged in 12 transmembrane domains, two nucleotide binding domains, and a putative regulatory domain (Fig. 50-1). The most common mutation, F508del, is a three-base deletion that causes deletion of phenylalanine from position 508, located in the proposed first nucleotide-binding domain. The original structural model, which was based on hydrophobicity plots, has proved to be essentially correct in its main features. CFTR shares many structural features with the "adenosine triphosphate (ATP)-binding cassette" transporter family, which includes P glycoproteins, as well as a number of bacterial transporters. CFTR has been clearly shown to function as an apical chloride channel in airway epithelial cells.

The localization of CFTR to the apical aspect of airway epithelial cells, to the ciliated duct of submucosal gland cells, and to submucosal serous cells, and the role of CFTR as an apical chloride channel fits nicely with the simplest hypothesis to account for the pathogenesis of pulmonary disease in CF. Decreased secretion of chloride and water by airway epithelial cells results in dehydrated mucus (Fig. 50-2). However, CFTR may have other functions, such as regulation of other ion channels, including the epithelial sodium channel. Loss of CFTR causes increased reabsorption of sodium; increased epithelium sodium channel activity alone alters regulation of ions and water, resulting in mucus obstruction of airways. CFTR transports bicarbonate; loss of CFTR function may result in acidification of the small intestinal lumen and, possibly, the airway lining fluid. Alternatively, CFTR may also function in *intracellular* membranes (e.g., endoplasmic reticulum, endosomes, phagosomes, and clathrin-coated vesicles). A consequence of the altered function of CFTR in intracellular membranes may explain abnormalities of CF glycoproteins: Increased sulfation of respiratory mucins, with decreased sialylation and increased fucosylation of both secreted and membrane glycoproteins. Altered glycosylation of airway glycoproteins may significantly impact

Data based on the most frequent mutations found overall in the United States. Source: Adapted with permission from Bobadilla JL, Macek M Jr., Fine JP, et al. Cystic fibrosis: A worldwide analysis of CFTR mutations-correlation with incidence data and application to screening. Hum Mutat. 2002;19(6):575–606.

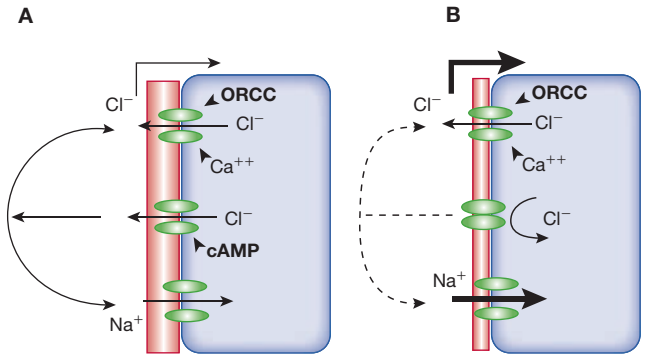

Figure 50-2 Simplified model of ion transport in airway epithelium. **A.** Normal airway cell with multiple apical ion channels. At the top, two different chloride channels are represented, the outwardly rectifying chloride channel (ORCC) and the Ca^{++}-gated chloride channel. In the center, cyclic adenosine monophosphate (cAMP)-gated cystic fibrosis transmembrane conductance regulator (CFTR) is shown. The apical sodium channel is depicted at the bottom. Experimental data suggest that CFTR interacts with the other channels, although the type of interaction is not clear *(solid arcs)*. **B.** CF cell with nonfunctioning cAMP-gated apical chloride transport. The function of the other channels is affected in an unknown manner *(dashed arc)*. The net result of ion channel activity on the pericellular fluid composition *(hatched area)* is under investigation. Many questions remain concerning the function of CFTR and ion transport in the airway.

bacterial–epithelial interactions and innate immune functions in the lung.[4]

In addition to the effect of CFTR on epithelial ion channels and glycoprotein processing, loss of CFTR function negatively impacts innate immunity and accentuates inflammation. Absence of CFTR function is associated with impaired bacterial killing in vitro and defective function of antimicrobials including human β-defensin 1 and lysozyme. Absence of CFTR is also associated with increased interleukin-8 (IL-8) production and decreased IL-10 in vitro. In the CF airway, excessive neutrophil elastase cleaves complement and immunoglobulins, interfering with bacterial opsonization. CF airways have increased oxidant stress due to neutrophilic inflammation and reduced antioxidants such as glutathione. Together, these factors synergistically increase the inflammatory milieu in the airways in CF.

A long-standing impediment to progress has been the absence of a completely suitable animal model. A number of mouse models of CF have been developed and while these have been useful in understanding some features of the disease such as the regulation of inflammation, a drawback has been the absence of spontaneous development of lung disease.[5] Two recently developed animal models in the ferret[6] and pig[7] have shown promise in developing some features of the early lung disease of CF.

CFTR mutations have been grouped into five classes,[8] depending on the effect of the mutation on the expression, processing, and function of the protein (Fig. 50-3). The most common mutation, F508del, is a processing mutation in which very little of the mutant protein reaches the apical surface. If the mutant protein escapes normal intracellular processing, however, F508del protein functions normally in the apical membrane. Furthermore, only 25% of normal CFTR transcripts are properly processed and transported to the cell surface. The remaining 75% are degraded before being processed. These data suggest that one therapeutic strategy to overcome the defect in CF is to disrupt normal intracellular processing mechanisms. A phase III clinical trial is in progress to test a therapeutic small molecule which is based on this concept.

PATHOPHYSIOLOGY

In CF, all exocrine glands appear to be affected primarily, albeit to varying degrees. Because exocrine glands perform highly specialized functions in a variety of organs – for example, in the skin, respiratory tract, gastrointestinal tract, and reproductive system – the number of possible symptoms and complications in CF is large. Table 50-2 highlights the complications and symptoms of CF according to the age groups in which they most often occur.[9] Obstruction of exocrine ducts by viscous secretions appears to play a cardinal role in the pathogenesis of almost all manifestations of the disease. In 10% to 20% of patients, the initial manifestation is often *meconium ileus* – that is, obstruction of the intestine by thick, viscous meconium stool. Chronic pulmonary disease, pancreatic insufficiency, and focal biliary cirrhosis progress gradually throughout the course of the disease, albeit at different rates in different patients. Progressive obstruction of exocrine ducts is a regular feature of the disease except in sweat glands, where obstruction of ducts has not been implicated in pathogenesis.

RESPIRATORY TRACT

In the lungs, hypersecretion of viscid mucus and chronic bacterial infection combine to produce a progressive and distinctive type of

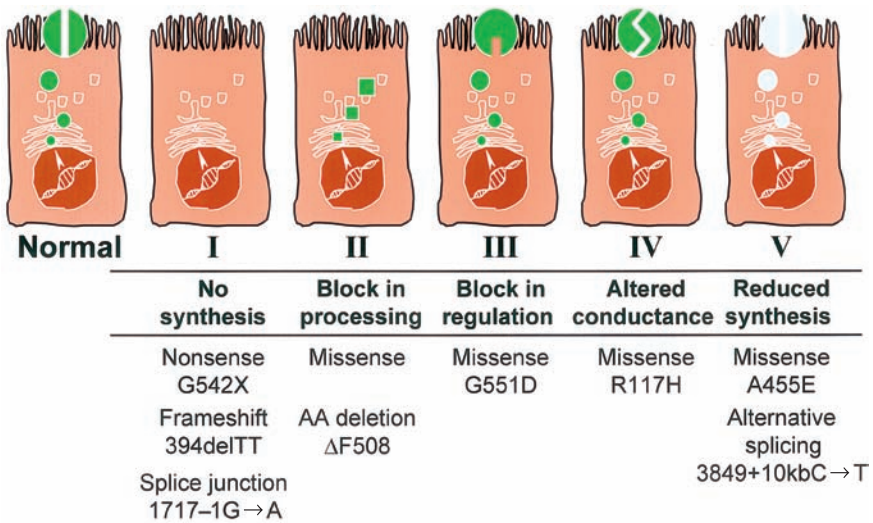

Figure 50-3 Classification of cystic fibrosis transmembrane conductance regulator (CFTR) mutations by molecular and biochemical abnormalities. This schematic depicts the effect of different classes of CFTR mutations on expression and function in the cell. Class I mutations block mRNA transcription. Class II mutations prevent normal CFTR protein processing and localization. Class III mutations permit CFTR localization at the apical membrane but inhibit chloride channel conductance. Class IV mutations result in partial chloride channel conductance. Class V mutations affect transcription, translation, or protein processing resulting in reduced CFTR expression at the apical membrane. Examples of mutations in each class are depicted below the cell models. Epithelial cell models with finger-like projections depict cilia at the apical surface. Fully processed CFTR protein is depicted by the *gray circles* embedded among the cilia at the apical surface of the cells. *(Adapted with permission from Zielenski J1, Tsui LC. Cystic fibrosis: genotypic and phenotypic variations. Annu Rev Genet. 1995;29:777–807.)*

Infancy	Childhood	Adolescence/Adult
Positive prenatal test for CF mutations or hyperechoic bowel on ultrasound	Pulmonary infection with *Staphylococcus* and *Pseudomonas*	Chronic bronchitis with bronchiectasis
Positive CF newborn screen	Malnutrition with steatorrhea and pancreatic insufficiency	Pansinusitis
Meconium ileus	Heat prostration with hypoelectrolytemia and metabolic alkalosis	Hemoptysis
Obstructive jaundice	Atypical asthma with clubbing and/or bronchiectasis	Recurrent pancreatitis
Edema with hypoproteinemia and hypothrombinemia	Esophageal varices and/or hyperplenism	Cholelithiasis
Failure to thrive	Nasal polyps	Chronic abdominal pain and constipation
Salty taste and/or salt loss syndrome		Obstructive apnea
Rectal prolapse		CF-related diabetes
Intestinal obstruction with or without intussusceptions/volvulus		Osteopenia
Recurrent pneumonia/bronchiolitis		Chronic respiratory failure

chronic obstructive airway disease that eventually leads to diffuse, severe bronchiectasis. The earliest pathologic lesions are found in the distal bronchioles. Whether the viscid secretions are primary or are secondary to chronic bacterial infections remain unsettled. In favor of a primary disturbance is the demonstration of mucus obstructing submucosal gland ducts in the airways of neonates with CF, who have not yet developed any evidence of bacterial infection or chronic colonization of the airways. With the use of sophisticated culture methods, bacterial pathogens can almost invariably be isolated from the respiratory tract of patients with CF. The most common pathogens isolated from sputum cultures are *Staphylococcus aureus* and *Pseudomonas aeruginosa*. Less commonly found are *Escherichia coli, Klebsiella,* and *Haemophilus influenzae*. In later stages of the disease, *Pseudomonas* usually predominates. By adulthood, more than 80% of patients are colonized with *P. aeruginosa*. Chronic infection with *P. aeruginosa* elicits an anaerobic milieu within mucus plugs in the CF airway.[10] Using anaerobic culture conditions, large numbers of anaerobes, particularly *Prevotella, Veillonella*, and *Propionibacterium*, were detected in CF sputum but not in induced sputum from healthy volunteers.[11] There is a correlation between *P. aeruginosa*–positive cultures and presence of the anaerobes. Multidrug-resistant organisms (MDROs) are detected in CF sputum cultures with higher prevalence and chronicity apparently associated with acute and chronic administration of antibiotics to suppress *P. aeruginosa*. These pathogens include *Stenotrophomonas maltophilia, Achromobacter xylosoxidans*, and *Burkholderia cepacia complex*. Other opportunistic pathogens including *Aspergillus* and nontuberculous mycobacteria have also been detected more commonly in CF sputum cultures. There is still controversy concerning whether these MDRO are actively contributing to CF lung disease or are commensal pathogens present in bronchiectatic airways.

Neutrophil-dominated lower airway inflammation also plays a primary role in the pathogenesis of the characteristic central bronchiectasis of CF.[12] Bronchoalveolar lavage fluid (BALF) demonstrates increased neutrophils and various cytokines, especially IL-8, even in infants whose BALF is sterile.[13,14]

Typically, respiratory secretions increase when a patient with CF, already chronically colonized with *Pseudomonas,* develops a viral respiratory tract infection. In turn, the increase in secretions leads to a gradual increase in cough and sputum production and then to an exacerbation of the pulmonary disease, usually manifested by increase in respiratory rate; retraction of the chest during inspiration; and diffuse, coarse inspiratory crackles. Leukocytosis is common. The chest radiograph demonstrates worsening hyperinflation. Both peribronchial thickening and nodular or cystic densities are more marked than usual. Pulmonary function tests show a worsening over baseline. Usually, residual volume (RV) increases; forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1) decrease; the forced expiratory flow between 25% and 75% of the exhaled vital capacity ($FEF_{25–75\%}$) also decreases. Treatment using antibiotics and chest physiotherapy generally succeed in restoring most indices of pulmonary function to, or almost to, baseline. However, *Pseudomonas* and *Staphylococcus* persist in sputum cultures.

The most attractive hypothesis to account for the pattern of response to treatment is that therapy reduces the number and, probably, virulence of organisms. Despite the virtual return to baseline after an exacerbation, however, the cumulative effect of repeated episodes is progressive bronchiectasis or atelectasis, or a combination of the two, accompanied by a gradual and irreversible decrease in pulmonary function. The striking degree of airway destruction and relative sparing of the pulmonary parenchyma at autopsy are shown in Figure 50-4. A simplified scheme illustrating the evolution of the process is shown in Figure 50-5.

GASTROINTESTINAL TRACT

Although pancreatic function may be either normal or abnormal at birth, it gradually becomes increasingly abnormal in most patients with CF as the pancreatic ducts become progressively obstructed by thick, viscous secretions from the exocrine portion of the organ; pancreatic enzymes that are trapped within the ducts lead to autodestruction of the pancreas. A cycle of destruction and obliteration of the ducts is set into motion, leading to cystic dilatation of ducts proximal to sites of obstruction and fibrosis of the body of the pancreas. In advanced stages of the disease, pancreatic fibrosis sometimes causes obliteration of the islets of Langerhans and, consequently, diabetes. This concept has been challenged by the notion that CFTR may have a direct effect on β-cell dysfunction as, discussed in the next section.

The liver and biliary tract are also affected in CF. Here too, the primary mechanism appears to be obstruction of small intrahepatic bile ducts by abnormally viscid secretions, leading to accumulation of toxic bile acids, depletion of hepatic antioxidants, and subsequent liver injury. CFTR is localized to the apical surface of the bile duct epithelium and not in the hepatocytes. Risk factors for liver disease appear to be male sex, meconium ileus, PiZ heterozygous state, and transforming growth factor-β1 (TGF-β1) polymorphisms. Elevated liver enzymes can be seen intermittently in 40% to 50% of patients with CF. Hepatic steatosis is frequently seen and may be related to malnutrition, essential fatty acid, choline and carnitine deficiency. Focal biliary cirrhosis, multilobular cirrhosis, and portal hypertension are also seen. Some newborn infants with CF develop the *inspissated bile syndrome,* characterized by prolonged obstructive jaundice starting at 2 to 8 weeks of age. The jaundice often clears

Figure 50-4 Section of lung from autopsy of a patient with CF, demonstrating remarkable dilation of large airways and preservation of intervening pulmonary parenchyma. *(Used with permission of Dr. S. Moolten.)*

without therapy. Gall bladder anomalies may be seen in about 24% to 50% of patients and include microgall bladder, gall stones, and gall bladder dysfunction.[15] The most striking pathologic change in the intestines is hyperplasia of the mucus glands and goblet cells. Biochemical abnormalities in intestinal mucins may contribute to malabsorption of specific nutrients and bile acids. Much of the malabsorption in CF can be corrected by administration of pancreatic enzyme replacement therapy (PERT). However, the abnormal mucins may lead to slowing of intestinal transit time; the slowing, combined with maldigestion of food substances, sometimes causes fecal impaction in the terminal ileum and ileocecal area, a condition referred to as *meconium ileus equivalent* or distal intestinal obstruction syndrome. The fecal impaction, in turn, occasionally causes volvulus or intussusception of the bowel (Fig. 50-6).

■ ENDOCRINE INSUFFICIENCIES

Important CF-associated endocrine disorders are discussed below.

Cystic Fibrosis–Related Diabetes

Diabetes mellitus is a common comorbidity in CF and increases in frequency with increasing age. According to data from University of Minnesota where annual cystic fibrosis–related diabetes (CFRD) screening is recommended for all patients ≥6 years, CFRD affects 2% of children, 19% of adolescents, and 40% to 50% of adults.[16]

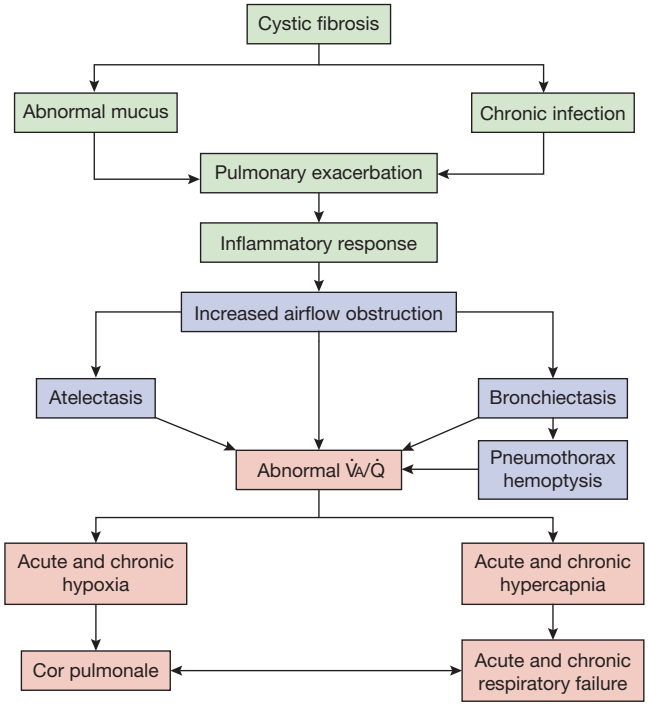

Figure 50-5 Simplified scheme for pathogenesis and progression of pulmonary disease in CF.

Similarly, CFRD was found in over a third of 775 patients of age ≥6 years undergoing CFRD screening over a 15-year period.[17]

Underscoring its relevance, CFRD has been associated with decreased survival,[18–24] worse pulmonary function, and lower BMI.[23] Declines in pulmonary function and nutritional status have been observed even prior to the CFRD onset.[22,25] Moreover, less significant glucose impairments are associated with greater declines in nutritional status over the previous year in children[25]; these findings suggest more subtle glucose abnormalities may be clinically relevant in CF. Microvascular complications, such as retinopathy, nephropathy, and neuropathy also occur in CFRD but may be limited to those individuals with fasting hyperglycemia (FH).[17]

Fortunately, early identification and treatment of CFRD appear to curb the impact of CFRD upon survival.[16] Insulin treatment of adults with CFRD without FH improves BMI,[26] and small studies have found insulin treatment improves weight in children even prior to development of CFRD.[27–29]

As described above, CFRD is considered an insulin-deficient state. In fact, delayed and blunted insulin secretion in response to a glucose load or meal prevails even in the setting of "normal" glucose tolerance in CF,[30–32] and these abnormalities progress with worsening glucose intolerance.[30,32,33] This progressive decline in insulin secretion has traditionally been considered a product of "collateral damage" extending from obstructive damage to the exocrine pancreas.

This "bystander" model has been challenged in more recent years. Animal models suggest CFTR may play a direct role in β-cell dysfunction.[34,35] For instance, CFTR knockout ferrets demonstrate glucose abnormalities and insulin secretion defects as newborns.[35] Moreover, the T2DM GWAS-implicated gene, *TCF7L2*, which may contribute to the defective insulin secretion that underlies T2DM, confers an even stronger risk of CFRD. In addition, disturbances in secretion/function of incretins, gut-secreted hormones that potentiate insulin secretion, have been described in CF[36] and in T2DM.[37–40,44–47]

Osteoporosis/Vitamin D Deficiency

Low bone mineral density occurs in as many as 85% of adults with CF. The origin of osteoporosis in CF is multifactorial and is attributed to

A

B

C

Figure 50-6 Distal intestinal obstruction syndrome (DIOS). **A.** Presenting Gastrografin enema of a child who had crampy abdominal pain and a right lower–quadrant mass. pancreatic insufficiency and malnutrition and poor growth, CFRD, deficiencies in vitamin D, vitamin K, and calcium levels, elevated inflammatory cytokines, pubertal delay, diabetes, and exposure to glucocorticoids.[41] Bone histology in clinically stable CF adults is significant for decreased cancellous bone volume and decreased connectivity.[42] Importantly, the sequelae of low bone density in CF patients include increased risk of vertebral and rib fractures, approximately twice as great as the general population, and increased risk of kyphosis.

■ REPRODUCTIVE ORGANS

Except for an increase in viscosity and an abnormal midcycle fern-ing pattern in cervical mucus, no consistent pathologic changes occur in the female reproductive tract in patients with CF. In the male reproductive tract, however, the vas deferens is either atretic or absent at birth. Although the pathogenesis of this lesion is not certain, viscous secretions may contribute to obstruction in utero, followed by failure of development of the vas deferens. Spermatogenesis and testicular development are otherwise normal. Because of either partial or complete obstruction of the vas deferens, approximately 98% of males with CF are aspermic.

■ SWEAT GLANDS

The sweat glands of patients with CF manifest no distinctive histologic changes. Nonetheless, their function is abnormal. Micropuncture experiments have shown that the precursor solution secreted by the sweat glands is isotonic to plasma, both in CF patients and in normal subjects. In normal persons, as the sweat flows along the duct of the gland, sodium and chloride are reabsorbed, so that by the time the opening at the skin surface is reached, sweat is hypotonic to plasma with respect to both sodium and chloride concentrations. In CF, the relative impermeability to chloride ions is thought to be responsible for the elevated chloride and sodium concentrations which are the basis for the diagnostic test, the quantitative pilocarpine iontophoresis sweat test, and are also responsible for the characteristic increase in potential differences across isolated, perfused sweat glands from CF patients.

DIAGNOSIS

The diagnosis of CF requires the demonstration of abnormally high concentrations of sodium and chloride in the sweat of a person who has the characteristic history and symptoms of CF. The most prominent clinical features are chronic pulmonary disease and pancreatic insufficiency. The most compelling family history for the diagnosis is CF in a sibling. If the clinical picture and/or the family history support the diagnosis, and if two sweat tests using the quantitative pilocarpine iontophoresis method are clearly positive, the diagnosis of CF can be made with assurance. Identification of two pathologic mutations, in addition to the characteristic clinical picture, is accepted as a criterion for the diagnosis. However, CF is a complex syndrome (Table 50-2) whose clinical manifestations are sometimes subtle. In addition, the family history is not always straightforward. Therefore, a high index of suspicion, coupled with a battery of clinical tests, is sometimes required to establish the diagnosis, especially in adolescents or young adults.

Since CF occurs with a high frequency in the general population, the diagnosis should be considered routinely in a broad array of differential diagnoses. Although Table 50-2 categorizes symptoms according to the age at which they most often occur, symptoms at any age should prompt consideration of the diagnosis of CF.

The most consistent feature of CF is an abnormally high concentration of sodium and chloride in sweat. Measurement of the chloride concentration is recommended for clinical testing. The only reliable sweat test is based on iontophoresis of pilocarpine, followed by quantitative determination of the concentration of chloride in an adequate, measured volume of sweat. Guidelines for the proper performance of a sweat test have been published.[43] In children, concentrations of chloride of less than 40 mEq/L are usually regarded as normal. However, the average of values for sodium and chloride concentrations is about 20 mEq/L for normal subjects and 95 mEq/L for those with CF. In children, values between 40 and 60 mEq/L are traditionally considered borderline elevated; such values call for further evaluation. As a result of recent experience with CF newborn screening, it has been suggested that sweat chloride values above 30 mEq/L may be diagnostic in the first few months of life.

The concentration of sodium and chloride in sweat increases gradually with age. Conditions other than CF in which the concentrations of sodium and chloride in sweat are abnormally high include malnutrition, adrenal insufficiency, hereditary nephrogenic diabetes insipidus, ectodermal dysplasia, and fucosidosis. Except in some instances of malnutrition, these conditions are readily distinguished from CF.[44] The finding of abnormal concentrations of sodium and chloride in sweat should automatically prompt evaluation of the patient to determine if, and to what extent, other organs are affected.

Genetic analysis can be used to confirm the diagnosis of CF. In patients with minimal symptoms, the diagnosis of CF can be made with certainty if two CF-associated alleles are present. As mentioned previously, screening for 32 of the most common alleles yields an overall sensitivity of 90% due to undetected alleles. Therefore, a negative mutation analysis does not rule out a diagnosis of CF, and atypical patients should be followed carefully.

Newborn screening is now standard practice in the United States.[45] The initial stage of screening often uses the neonatal blood spot to determine the concentration of immunoreactive trypsinogen. If this is elevated, secondary screens vary in individual states from repeat immunotrypsinogen determination to F508del or 25 to 32 mutation screen. The screening programs have a sensitivity ranging from 87% to 99%. Risks versus benefits and the relative costs of the screening programs are being evaluated to determine the best approach. Infants with positive newborn screens for CF are referred to CF centers for sweat test confirmation. It has been proposed that infants who have a positive newborn screen, but do not otherwise fulfill the criteria for a diagnosis of CF,[45] should be termed as having "CFTR metabolic syndrome"[46,53] and at a minimum they should be followed in a CF center until their status can be clarified.

CLINICAL EVALUATION

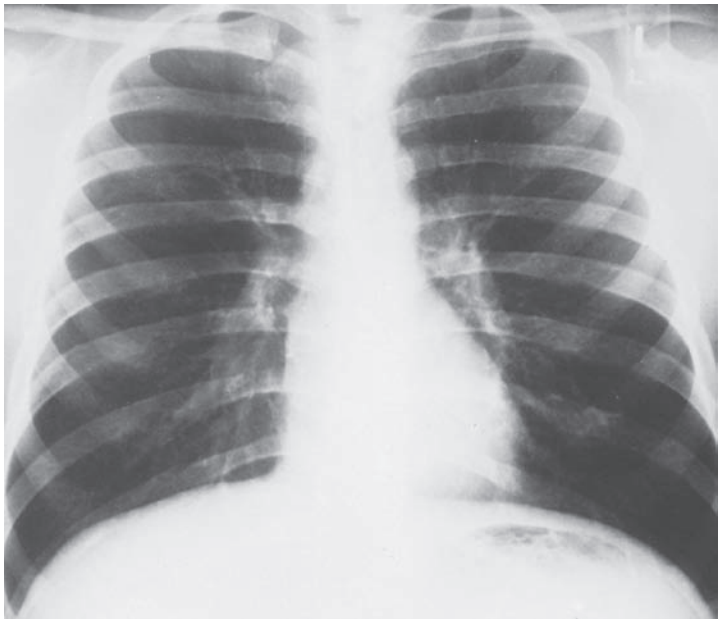
The evaluation of patients with CF includes chest radiography, tests of pulmonary performance, sputum culture, and assessment of pancreatic, endocrine, hepatic, and reproductive functions. Each is described below.

■ PULMONARY ASSESSMENT

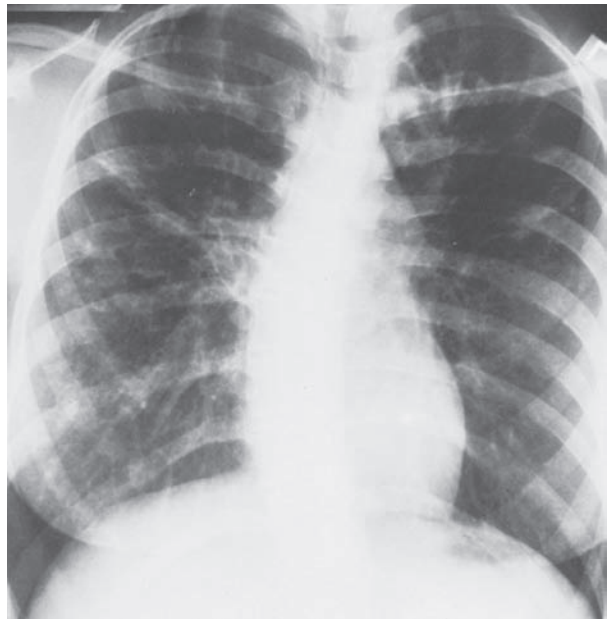
Pulmonary assessment includes chest radiography; measurement of pulmonary function, including that of small airways; and evaluation of gas exchange.

Chest Radiography

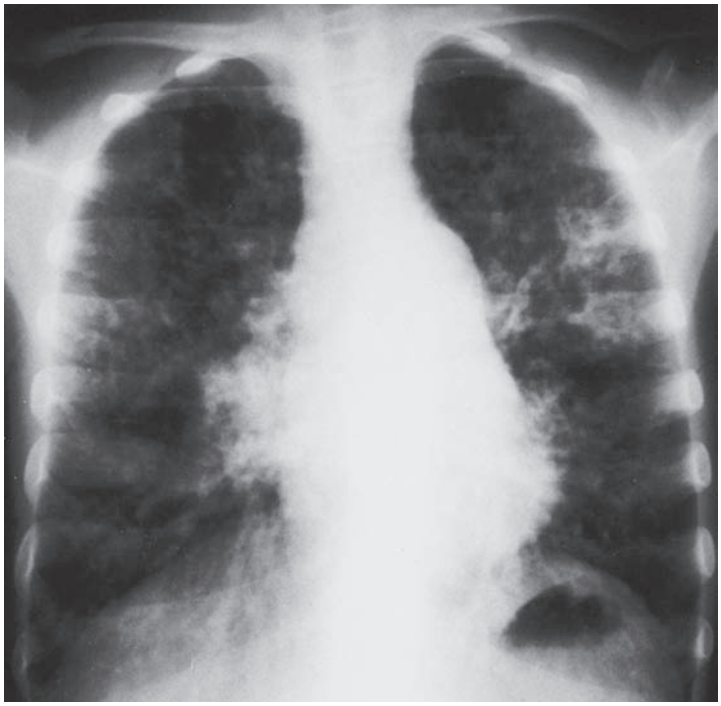
Rarely is the chest radiograph completely normal in CF. In the person with minor pulmonary symptoms, the manifestations may be questionable (e.g., mild hyperinflation and minimal peribronchial thickening). However, the radiographic findings become more distinctly abnormal as the disease increases in severity. Peribronchial thickening, which is often most prominent in the upper lobes of the lungs early in the course of the disease, usually progresses to affect all lobes. In the advanced stage of pulmonary involvement, ring shadows, cystic lesions, and nodular densities are increasingly apparent, as are areas of bronchiectasis and atelectasis. The central pulmonary artery often enlarges in the middle stages of the disease, but the cardiac silhouette remains within normal limits until the disease is far advanced. The variability in the chest radiograph is illustrated in Figure 50-7 for three siblings with CF when each was 17 years old.



A



B



C

Figure 50-7 Chest radiographs of three siblings with CF taken when the patients were 17 years of age. **A.** Mild hyperinflation; otherwise normal. Patient is now 32 years old and has been hospitalized once for treatment of electrolyte depletion. **B.** Diffuse peribronchial thickening, mild hyperinflation, and cystic changes in both upper lobes. The patient was hospitalized seven times for pulmonary exacerbations, once for diabetes, and once for hemoptysis. She died at age 34 following complications from lung transplantation. **C.** Severe hyperinflation, diffuse peribronchial thickening, multiple infiltrates, and increased pulmonary vascular markings and heart size. The patient died 1 month later from respiratory failure complicated by congestive heart failure.

High-resolution computed tomography (HRCT) scans are more sensitive than plain radiographs. The most common abnormalities described are bronchiectasis, peribronchial thickening, mosaic perfusion, air trapping, and mucus plugging.[47] Early bronchiectasis is easily detected on the CT scan, even when routine chest radiographs are normal, as seen in Figure 50-8. CT scan abnormalities may be detected prior to a change in pulmonary function tests. Chest CT scan abnormalities have been detected in asymptomatic newborn infants diagnosed by newborn screening.[48] Currently, there are no standard recommendations for CT use due to the radiation exposure incurred by these studies.

Pulmonary Performance

The lungs of patients with CF are usually morphologically and functionally normal at birth. Over time, accumulation of tracheobronchial secretions and recurrent infections progressively impair pulmonary function in almost all patients. In the fully developed clinical syndrome, all the pulmonary function abnormalities seen in chronic bronchitis, emphysema, and asthma may occur. However, one complicating regular feature of CF – bronchiectasis – modifies pulmonary performance. Chronic, local infection and airway damage increase the compliance of bronchiectatic airways, resulting in airway collapse during rapid expirations or cough. The usefulness of pulmonary function testing in CF is twofold: Tracing the natural history of the disease and assessing the value of therapeutic interventions.

The earliest stages of the pulmonary disorder are the most difficult to quantify. In infants, tests are limited almost entirely to those that do not depend on the patient's understanding and cooperation. A variety of methods to measure infant pulmonary function have been devised; one method, the raised volume rapid thoracoabdominal compression technique, requires sedation of infants but provides values most similar to standard spirometric values, and has detected reduced

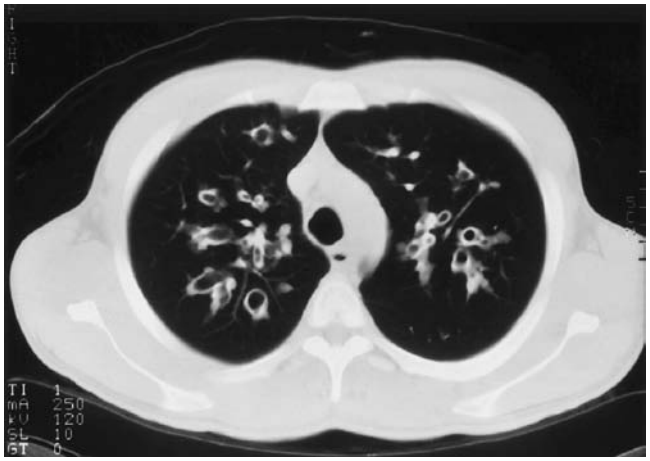


Figure 50-8 High-resolution chest computed tomography scan from a patient with CF. Marked bronchiectasis with peribronchial thickening is shown in the upper lobes.

pulmonary function in infants with CF[49] Nitrogen multiple breath washout or lung clearance index, can be performed in preschool age children and detects early ventilation inhomogeneity that correlates with airflow obstruction by spirometry.[50] After age 6, pulmonary function tests originally designed for adults may be performed quite readily on children. Changes in pulmonary performance throughout the natural history of CF can be described with confidence.

Obstruction in Small Airways

The small airways – that is, the bronchioles – are vulnerable to obstruction early in the course of CF. At this stage, as in cigarette smokers, results of tests for small airway disease are apt to be abnormal, while those of tests for obstruction of large airways are still normal. Three factors interact in causing the obstruction: (1) Intrinsic disease of the smaller airways, often in association with bronchiectasis in the proximal, larger airways; (2) viscid secretions, impaired ciliary action, and impaired cough; and (3) progressive decrease in lung elastic recoil.

The progressive reduction in lung elastic recoil in CF is predominantly a function of overinflation due to intrinsic airway disease, rather than loss of pulmonary parenchyma. This mechanism differs from that in chronic bronchitis and emphysema, in which the combined effects of parenchymal destruction and overinflation are responsible for the decrease in elastic recoil. Emphysema is not a regular feature of CF. In some patients, emphysema occurs only late in the course of the disease (Fig. 50-4).

Airway smooth muscle tone increases only slightly in CF. Exercise elicits bronchodilation, followed shortly thereafter by bronchoconstriction. Both the bronchodilation and bronchoconstriction are far less impressive in CF than in asthma. Indeed, exaggerated bronchomotor responses in CF raise the possibility of superimposed asthma. In distinguishing between contributions to airway obstruction by intrinsic airway disease caused by CF and asthma, maximal expiratory flow–volume curves are sometimes helpful.

Because of the bronchiolar locus of the early lesions in CF, abnormalities in breathing frequency–dependent tests (e.g., dynamic lung compliance), in volume-dependent tests (e.g., closing volume), and in maximal expiratory flow ($\dot{V}E_{max}$) at low lung volumes are demonstrable, even though results of tests of large airway function (e.g., FEV_1 and airway resistance) are still normal.

Change in Lung Volumes

As with chronic bronchitis, emphysema, and asthma, RV in CF increases. Thereafter, an increase in functional residual capacity and, sometimes, in total lung capacity is seen. As CF lung disease progresses, air trapping increases in severity and is manifest as an elevated ratio of RV to total lung capacity. This change decreases the compliance of the lung and increases the work of breathing.

Abnormalities in Gas Exchange

Early in the evolution of the pulmonary abnormalities in CF – that is, when tests of small airway function alone are abnormal – ventilation–perfusion abnormalities usually result in widening of the alveolar–arterial oxygen gradient and an increase in the ratio of dead space to tidal volume (V_D/V_T). These abnormalities portend increasing inhomogeneities in alveolar ventilation and blood flow as the affected child grows to adulthood. The diffusing capacity for carbon monoxide ($D_{L_{CO}}$) is low at rest and does not increase normally during exercise. This observation is difficult to reconcile with the preservation of the gas-exchanging surface of the lungs (in the absence of emphysema) until late in the course of the disease (Fig. 50-4).

As obstructive disease of the airways progresses and exaggerates the imbalances between alveolar ventilation and blood flow, arterial hypoxemia develops; pulmonary hypertension, cor pulmonale, and right ventricular failure follow, in turn. Late in the course of the disease, hypercapnia and respiratory acidosis contribute to the final picture of respiratory failure. At this juncture, the ventilatory response to inhaled CO_2 is depressed. Bouts of infection punctuate the course of the illness; during each episode, pulmonary function deteriorates, but it usually returns toward baseline, except in the preterminal stages of the disorder.

■ SPUTUM CULTURE

The unique respiratory flora isolated from sputum or oropharyngeal cultures from patients with CF is helpful in establishing the diagnosis and in guiding the antimicrobial therapy for acute exacerbations. In many patients with CF, *P. aeruginosa* and *S. aureus* are found alone, or in combination with other organisms, in the sputum. There is growing evidence of correlations between different organisms and CF lung disease progression. The presence of mucoid *Pseudomonas* is important because acquisition of mucoid *Pseudomonas* predicts more rapid progression of CF lung disease.[51] Similarly, acquisition of methicillin-resistant *S. aureus* is associated with a decline in pulmonary function[52] and worse survival.[53] Infection with *B. cepacia complex* organisms may be aggressive with rapid deterioration of clinical status or may have an indolent course; the presence of mucoid-positive organisms appears to be protective.[54] Chronic antibiotic therapy to suppress *Pseudomonas* has improved clinical outcomes but has also led to a greater number of MDROs identified in sputum, including *S. maltophilia* and *A. xylosoxidans*. Chronic colonization with *S. maltophilia*, induces a serologic response and independently correlates with progression in airflow obstruction.[55]

In addition to bacteria, sputum cultures for detection of molds and nontuberculous mycobacteria are helpful to guide therapy for patients with acute exacerbations unresponsive to antibiotic therapy, or for patients with unexplained progression of lung disease. Allergic bronchopulmonary aspergillosis (ABPA) complicates CF lung disease,[56] and recent evidence suggests that *Aspergillus fumigatus* may also be associated with airway infection or allergy-triggered asthma in the absence of ABPA.[57] The prevalence of nontuberculous mycobacteria ranges from 7% to 24% with the most frequent species identified as *Mycobacterium avium complex* and *Mycobacterium abscessus*.[58]

■ PANCREATIC FUNCTION

The evaluation of pancreatic function is an important part of establishing the diagnosis of CF, since almost 90% of patients have pancreatic insufficiency. Infants with pancreatic insufficiency due to CF can present with failure to thrive and loose or frequent stools.

However, visual appearance does not always correlate with the degree or presence of fat malabsorption. Currently the diagnosis of pancreatic insufficiency can be made by measuring fecal elastase (FE)-1 levels and assessment of the degree of malabsorption is best accomplished by the determination of the coefficient of fat malabsorption. The FE-1 test is performed on a random single stool sample. It is easy to obtain and in patients with CF, a human enzyme-linked immunosorbent assay (ELISA) for FE has a sensitivity of 98% to 100% and a specificity of 93% to 100%, even while patients are taking pancreatic enzyme supplements.[59] Also available is a polyclonal assay that detects human as well as porcine elastase and should not be used to diagnose pancreatic insufficiency in patients already on pancreatic enzyme supplementation. There is some debate as to the value used for the diagnosis of pancreatic insufficiency.[60] The coefficient of fat absorption is performed by collecting stools for 72 hours while the patient is ingesting a high-fat diet (documented on a 3-day diet record) and analyzing the stool fat content. A malabsorption coefficient of greater than 7% is usually considered abnormal. Patients with CF usually have a malabsorption coefficient around 20% to 30%. The test is not popular with families who find the stool collections very unappealing. Pancreatic stimulation tests are the most accurate measurement of pancreatic function but are invasive, cumbersome, and at this time are not clinically available.

Cystic Fibrosis–Related Diabetes

Because the onset of CFRD is generally insidious, and FH tends to be a late manifestation, annual CFRD screening with an oral glucose tolerance test (OGTT) starting by age 10 is recommended.[61,62] Based upon the fasting, 1-hour, and 2-hour plasma glucose (PG0, PG1, and PG2) during the OGTT, the following glucose tolerance categories are defined.

- Normal glucose tolerance (NGT) = PG1 <200 mg/dL and PG2 <140 mg/dL
- Indeterminate = PG1 ≥200 mg/dL but PG2 <140 mg/dL
- Impaired glucose tolerance (IGT) = PG2 ≥140 and <200 mg/dL
- CFRD = PG2 ≥200 mg/dL
  Without FH = PG0 <126 mg/dL
  With FH = PG0 ≥126 mg/dL

Contrary to what one might expect, isolated impaired fasting glucose (PG0 100–125 mg/dL) is not associated with worse survival, nutritional status, pulmonary function, or progression to CFRD.[63] Over 10 years, FH occurs in 60% of patients with CFRD without FH at baseline.[17] At least in children, increased plasma glucose at 1 hour during the OGTT predicts increased risk of progression to CFRD.[64]

Additional CFRD screening measures include fasting and postprandial glucose measurements during hospitalizations for acute illness.[61,62] Home glucose monitoring should also occur periodically during and after continuous overnight enteral feeds as well as during intercurrent illnesses, intravenous antibiotic therapy, and glucocorticoid treatment.[65] While an elevated hemoglobin A1C (>6.5%) is consistent with CFRD, the HbA1C tends to underestimate overall glucose intolerance in CF patients and is not generally recommended for CFRD screening.

Osteoporosis/Vitamin D Deficiency

Patients with CF are at risk for vitamin D deficiency and osteoporosis. Annual serum 25-hydroxy vitamin D levels should be monitored. In addition, in all adults and children greater than 8 years with risk factors for osteopenia including malnutrition, chronic glucocorticoid use, moderate-to-severe airway obstruction (FEV_1 <50% predicted), or history of fracture or delayed puberty, a DXA scan should be obtained to monitor bone mineral density.[41]

LIVER FUNCTION

Evaluation of liver function (transaminases, bilirubin, gamma glutamyl transferase [GGT]) is an important part of the evaluation of CF. Transient elevations of serum transaminases can be often seen and may be related to intercurrent illnesses and medications. However, these tests can often be relatively normal, even in patients with mild or moderate focal biliary cirrhosis. The prothrombin time is sometimes prolonged, owing to a combination of malabsorption and decreased synthesis of clotting factors by the liver. Obtaining a level of protein induced by vitamin K absence-II (PIVKA-II) to assess vitamin K status can be helpful in these instances. A liver ultrasound with Doppler should be performed in patients with persistently elevated liver function tests. Fatty liver, cirrhosis, splenomegaly, varices, and reversal of portal blood flow can be seen on ultrasound. Occasionally, patients present with bleeding esophageal varices from advanced cirrhosis and an upper endoscopy is helpful diagnostically and therapeutically.

SEMEN ANALYSIS

Occasionally, a man who is found to have aspermia during the course of an evaluation for infertility is found to have CF. In men with CF, a complete semen analysis is part of the evaluation. Azoospermia is found in more than 98% of men with the disorder.

MUTATION ANALYSIS

There are currently over 1900 mutations associated with CF (http://www.genet.sickkids.on.ca/cftr/). A new initiative, The Clinical and Functional TRanslation of CFTR (CFTR2) (www.cftr2.org), funded by NIH, the US CFF, and Sequenom, is a website dedicated to publishing the functional implications of CFTR mutations. Patients homozygous for the most common mutation, F508del have pancreatic insufficiency; patients with CF who have pancreatic insufficiency tend to have a worse prognosis. F508del is one of the major mutations classified as disease causing; other mutations are associated with CF-related disorders, and yet other mutations have no known clinical importance or unknown significance. Several mutations, including R117H, are associated with pancreatic sufficiency and a mild phenotype. Interestingly, the phenotype of R117H is linked to the expression of the polyT and polyTG intronic domains found 5' to exon 9. A T5 polymorphism expressed with R117H results in congenital bilateral absence of the vas deferens (CBAVD) or idiopathic pancreatitis, and may be complicated by mild lung disease. In contrast, R117H associated with T7 or T9 may have no manifestations of CF or CF-related disease.[66]

Certain alleles associated with CF (e.g., 3849+10kbC→T) are associated with nasal polyposis and bronchiectasis but normal sweat test results. The diagnosis of CF can be made with confidence in these patients. More problematic are persons with atypical presentations, normal sweat test results, and at least one CF-associated mutation. More extensive genotyping should be attempted for all patients with a high clinical suspicion for CF (see "Genetics") because mutation analyses will be used to determine eligibility for mutation-specific protein-correcting therapies. For example, therapy for CF patients with the G551D mutation with the CFTR potentiator ivacaftor® results in astonishing improvements in respiratory tract symptoms, weight gain, and shift from positive to borderline sweat chloride values (see "Therapy," "Genetics," and "Future Directions").[67]

Patients with the same genotype may have dramatically different phenotypes, supporting the concept that modifier genes play an important role in determining the CF phenotype. Three large GWAS consortia are collaborating to define modifier genes associated with lung disease severity[68] and with specific disease manifestations such as CFRD,[69] liver disease,[70] and meconium ileus.[71] Investigations using these large well-characterized cohorts recruited by the consortia have identified chromosomal regions of interest but have not yet confirmed gene targets or polymorphisms that confer increased risk of severe lung disease. Using a hypothesis-driven

approach, several potential candidate modifier genes for severity of lung disease were identified, including α_1-antitrypsin, HLA antigens, nitric oxide synthase, mannose-binding lectin, TGF-β, tumor necrosis factor-α (TNF-α), and β_2-adrenergic receptor. However, none of these genetic polymorphisms were validated as gene modifiers by GWAS analysis in the combined consortia.

ATYPICAL CLINICAL PRESENTATIONS

Atypical clinical presentations confound the diagnosis of CF in adults; a high index of suspicion is required to establish the diagnosis. Approximately 6% of all CF is diagnosed after age 18. Late presentations of CF tend to occur in persons with pancreatic sufficiency; indeed, overweight or well-nourished persons may have CF. Recovery of unusual gram-negative organisms, mucoid *Pseudomonas* species, or *S. aureus* from sputum of asthmatics with persistent sputum production, chest radiographic abnormalities, or clubbing should prompt referral for sweat testing. Recurrent sinusitis and nasal polyposis may be the only manifestations of CF in a mildly affected person. Isolation of *P. aeruginosa* from deep nasal cultures should raise the suspicion of CF. Frequently, the sinus findings on CT mimic fungal sinusitis, demonstrating concentric, inhomogeneous material. Occasionally, persistent inflammation produces bony destruction that is mistaken for previous surgical intervention. Sweat testing and referral to a CF center should be considered for men with azoospermia or CBAVD. The clinical entity, "CFTR-related disease" has recently been defined by an international working group. CFTR-related disease encompasses patients with evidence of CFTR dysfunction who do not meet the criteria for CF disease (e.g., only one CFTR mutation, a normal sweat test, and single organ involvement). CFTR-related diseases include CBAVD, idiopathic pancreatitis, and diffuse bronchiectasis.[72]

TREATMENT

Intensive, comprehensive CF treatment programs designed to deal with particular symptoms, correct deficiencies, and prevent progression and complications of the disease have led to a dramatic increase in the median age of survival. Although the value of comprehensive treatment is beyond question, far less certain are the utility of each component of the treatment plan and the level of each component necessary in a given patient. At present, the best approach still appears to be determination of the type and degree of abnormality in individual patients and design of a treatment program that will improve or maintain function of the organ systems affected. Two recent reviews highlight the evidence supporting each component of CF therapy.[73,74] To ensure that the treatment regimen meets the needs of the individual patient, that necessary treatment is not omitted, or that side effects of prescribed treatments do not go unnoticed, it is often desirable to hospitalize the patient for diagnosis and evaluation. Hospitalization also provides an excellent opportunity for counseling the patient, parents, and family about the diverse aspects of the diagnosis, treatment, prognosis, and inheritance pattern of CF. Hospitalization provides the opportunity to monitor the response of individual patients to each component of the therapeutic program.

An important aspect of the care of patients with CF is the network of more than 100 CF centers that exist throughout the United States and the larger network throughout the world. CF centers use a team approach to the care of patients. A CF care team usually includes physicians, nurses, respiratory therapists, physical therapists, nutritionists, social workers, and genetic counselors.

■ MANAGEMENT OF PULMONARY DISEASE

Management of CF-related pulmonary disease focuses on chronic respiratory management and treatment of acute exacerbations.

Chronic Maintenance Therapy

More than 90% of the patients with CF die from respiratory failure or pulmonary complications. The goals of treating the pulmonary disorder in CF are to prevent and treat the complications of airway obstruction and infection. Although management of the pulmonary disorder consists of many components applied in combination,[75] the individual components of therapy are discussed separately below.

Chest Physiotherapy

Almost all treatment programs for CF include a strategy intended to clear pulmonary secretions to prevent complications arising from airway plugging by viscous secretions. Chest physiotherapy – that is, "percussion and postural drainage" – performed regularly, is the most widely prescribed method. In infants and young children, chest physiotherapy is generally performed routinely, twice daily. Percussion and postural drainage technique has been modified to exclude head-down positioning which increased the risk of GE reflux and increased the duration of acute exacerbations of cough in infants.[76] In addition to manual chest percussion and postural drainage, there are several other effective modalities for chest physiotherapy. These alternative measures include the high-frequency chest-wall oscillation (HFCWO) vest; the flutter device, a small pipe–like device that produces an oscillating resistance during a forced expiratory maneuver; the acapella device that produces both positive expiratory pressure (PEP) and an oscillating resistance during forced expiratory maneuver; PEP mask; intrapulmonary percussive ventilation; autogenic drainage and active cycle of breathing; and exercise.[77]

Overall, due to the difficulty in designing unbiased, well-controlled trials with sufficient power to unequivocally distinguish efficacy between treatments, evidence does not exist to demonstrate superiority of one airway clearance mechanism over another. Therefore, the recommendations based on expert opinion are that airway clearance should be initiated in asymptomatic infants because they develop signs of lung disease within the first few months of life, and that patients should be offered and instructed in a variety of methods so that they can select the methods that they deem provides the most subjective benefit.[78] Some form of physiotherapy that is effective in mucus clearance is required daily because without chest physiotherapy, pulmonary function deteriorates.[79] At present, most CF centers recommend that all patients with CF attempt to maintain clearance of pulmonary secretions with a method that is applied regularly (e.g., twice daily). An additional recommendation is that chest physiotherapy be applied more often during an exacerbation of the chronic pulmonary infection. Unfortunately, the recommendation of chest physiotherapy on a regular basis – a time-consuming and often arduous form of treatment – is difficult to implement without considerable support and encouragement from family and health professionals.

Mucolytics and Inhaled Hypertonic Saline

A number of mucolytic agents have been tried over the years. One that has endured is *N*-acetylcysteine. In the test tube, this agent is quite effective in dissolving mucin components and in decreasing the viscosity of sputum from patients with CF.[80–82] Although some centers who have outstanding pulmonary outcomes, have used this agent as a standard part of the chronic regimen as an adjunct to airway clearance therapy in CF, others have been reluctant to use it because of a lack of randomized controlled trials.[83] One CF center which has a track record of outstanding CF outcomes recommended using *N*-acetylcysteine in combination with sodium cromolyn and albuterol (W. Warwick, personal communication). We continue to recommend its use to our CF patients. Interestingly, *N*-acetylcysteine was found to activate CFTR Cl^- conductance in cultured epithelial cells.[84]

In 1994, Pulmozyme, a DNA-cleaving enzyme, was approved for use in patients with CF following a large phase III multicenter trial.[85] More than 900 patients were enrolled for a 6-month period. Three dosing regimens were employed: Placebo, 2.5 mg inhaled once

daily, and 2.5 mg inhaled twice daily. The treatment groups showed a 5% improvement in FEV_1 over placebo, as well as a slightly lower relative risk of exacerbation of lower respiratory tract infection after 6 months. There was no difference between the once- and twice-daily treatment groups. A second study revealed that Pulmozyme, inhaled once daily over 96 weeks, maintained pulmonary function and decreased the relative risk of respiratory tract exacerbations in young CF patients with normal FEV_1 (≥85%).[86] Currently, this drug is in fairly widespread use for CF. However, questions regarding patient selection and timing and duration of use of this expensive drug remain unanswered.

Abnormal homeostasis of airway surface fluid results in dehydrated secretions and impaired mucociliary clearance. As a strategy to improve airway surface hydration and airway clearance, inhaled hypertonic therapy was evaluated. Patients with CF, age 6 years and older, inhaled 7% hypertonic saline twice daily following a bronchodilator for 48 weeks; results revealed only a modest improvement in FEV_1, but a significant reduction in the number of pulmonary exacerbations and days lost from school or work.[87] Inhaled 7% hypertonic saline did not decrease the frequency of pulmonary exacerbations in CF infants and children less than 6 years of age,[88] and therefore did not meet the primary outcome for approval as a maintenance therapy in this age group. However, in a subset of infants tested, infant pulmonary function testing revealed an improvement in $FEV_{0.5}$ in the hypertonic saline group suggesting that this therapy may be useful and considered on an individual basis.

Bronchodilators and Anti-Inflammatory Agents

Bronchodilators are often used in treating the pulmonary manifestations of CF. Their use should be individualized. For example, in many patients, bronchospasm that is reversible with bronchodilators at one point in the course of the illness may prove refractory a short time later. Some patients undergo deterioration in pulmonary function following use of bronchodilators. In infants who are audibly wheezing, a bronchodilator can be tried. In older patients, pulmonary function testing provides a more objective and quantitative measure of bronchodilator effectiveness.

Corticosteroids have been used with good results in infants with severe obstructive airway disease that does not respond to antibiotics and bronchodilators and in patients with CF in whom the pulmonary disease is complicated by severe asthma or allergic bronchopulmonary aspergillosis (ABPA). Preliminary observations initially suggested that patients with CF would benefit from long-term administration of alternate-day corticosteroids, based on the presumption that corticosteroids would decrease the airway inflammatory response. However, in a large, placebo-controlled, multicenter trial of alternate-day corticosteroids administered in two dosage regimens (1 mg/kg and 2 mg/kg), the development of many side effects precluded a general recommendation for long-term corticosteroid treatment in CF.[89] Subgroup analysis led to the suggestion that patients with moderately severe obstructive airway disease and those with chronic *Pseudomonas* infection might benefit from treatment for periods of less than 1 year. Beneficial effects were sufficient to prompt further studies of anti-inflammatory agents in CF. A controlled 4-year trial of high doses of ibuprofen in 40 patients with CF showed improvement in the rate of decline of pulmonary function in children.[90] Questions remain whether side effects that might accrue with continued therapy will justify the gains. In concert, these two studies suggest that future development of a lung-specific anti-inflammatory agent with fewer systemic side effects may offer a promising approach.

Antibiotics

Two major innovations using antibiotics have been implemented as part of the regimen of maintenance therapy for CF. First, inhaled therapies have been demonstrated to successfully eradicate initial *Pseudomonas* infection and postpone chronic colonization in three large prospective trials of patients with CF in North America and in Europe.[91–93] Second, chronic inhaled and/or oral antibiotic therapies successfully decrease the progression of lung disease related to chronic *Pseudomonas* infection. In addition to these therapies, it is important to emphasize that person-to-person transmission of *P. aeruginosa* and other opportunistic microbes is another source for chronic colonization. In healthcare facilities for CF patients, contact isolation precautions are recommended.[94]

Chronic airway colonization/infection with *P. aeruginosa* promotes progression of lung disease. Hoiby et al. championed early treatment of *P. aeruginosa*–positive sputum cultures with inhaled colistin and oral ciprofloxacin, even in the absence of symptoms, as a modality to prevent chronic colonization.[95] The EPIC trial[91] tested four randomized regimens: Cycled therapy versus culture-driven therapy; and 28 days of inhaled tobramycin inhalation solution (TIS) in the presence or absence of 14 days of oral ciprofloxacin. Approximately 80% of patients remained free of *P. aeruginosa* for the duration of the study (18 months) with no difference concerning time to first pulmonary exacerbation attributed to regularly cycled therapy or the addition of ciprofloxacin. The ELITE study[92] was an open label randomized study comparing 28 to 56 days of inhaled TIS which revealed approximately 90% eradication at the end of therapy with 66% to 69% of patients having *Pseudomonas*-free cultures at the end of the 27-month study. In addition, a trial comparing inhaled colistin and oral ciprofloxacin to inhaled TIS and oral ciprofloxacin showed no difference between regimens in eradication with approximately 62% to 65% of patients with *Pseudomonas*-free cultures at 6 months.[93] Therefore, although the evidence from these three studies supports antibiotic eradication of new *Pseudomonas* infection, there is no consensus yet for a specific therapeutic regimen.

Another approach that has been advocated is suppression of chronic *Pseudomonas* colonization by alternating monthly cycles of inhaled antibiotics. Inhaled, preservative-free TIS, 300 mg twice daily for 28 days on and 28 days off, improved pulmonary function (FEV_1 increased by 10%) at the end of the third treatment cycle (20 weeks) compared to placebo.[96] Recently, inhaled aztreonam, 75 mg three times per day, was tested in an open label study of cycling monthly regimen for patients with chronic *P. aeruginosa* infection.[97] Patients reported improved symptoms and pulmonary function during on-therapy months with sustained weight gain over the 18-month duration of the study. Currently, prospective clinical trials are evaluating the efficacy of continuous alternating inhaled antibiotics compared to on–off cycling inhaled antibiotics.

Another antibiotic which has been studied as a chronic therapy in CF is azithromycin. Azithromycin, 250 mg or 500 mg thrice weekly, was evaluated in CF patients colonized with *P. aeruginosa*. After 6 months of therapy, patients on azithromycin had a modest improvement in FEV_1 (6.2%), increased weight gain, and decreased rates of pulmonary exacerbations.[98] Although macrolide antibiotics have been reported to have anti-inflammatory properties,[99] there is no direct evidence of azithromycin-induced anti-inflammatory activity in CF. One concern about inhaled tobramycin, inhaled aztreonam, and oral azithromycin as chronic therapies is the risk of bacterial resistance and selection for growth of MDRO. In addition, questions regarding selection of patients and timing and duration of treatment remain unanswered.

CFTR Potentiators and Correctors

The most exciting breakthrough in CF therapies was announced in 2011 with the proof-of-concept demonstration that an oral drug, ivacaftor®, corrected the physiologic impact of a CFTR mutation, G551D. The G551D mutant CFTR protein is expressed at the cell surface but does not conduct chloride or regulate other ion channels. Ivacaftor® was discovered using a high throughput screening approach.[100] In a

phase III randomized, placebo-controlled, double-blind trial for CF patients with at least one copy of G551D mutation, ivacaftor®, administered orally, 150 mg twice per day for 48 weeks, increased FEV_1 percent predicted by 10.6%, decreased risk of pulmonary exacerbations by 55%, improved CF quality of life (CFQL) respiratory symptom scores by 8.6 points, decreased sweat chloride values by 48 mmol/L, and was associated with an average 2.7-kg weight gain.[67] Currently, other mutations similar to G551D are being tested as potential ivacaftor® targets. Importantly, other compounds that potentially correct F508del CFTR are being tested. One lead compound, VX-809 has been reported to decrease sweat chloride values in a dose-dependent manner.[101] VX-809 will be combined with ivacaftor® for complementary combined therapy to enhance both processing and functioning of F508del-CFTR in homozygous patients.

Management of Acute Exacerbations of CF Bronchitis

During the past few decades of treatment of CF, antibiotics have proven to be the key element responsible for increased survival. A reasonable approach balances the dangers of overzealous administration of antibiotics against progressive airway damage and bronchiectasis resulting from untreated infection. The approach is based on sputum culture at the time of diagnosis and at regular intervals thereafter.

When signs and symptoms herald an exacerbation of pulmonary infection (i.e., increased cough or sputum production, dyspnea, decreased exercise tolerance, decreased appetite) or new abnormalities on the physical examination (i.e., increased respiratory rate, use of accessory muscles, changes on auscultation of the chest including decreased breath sounds, new crackles or wheezes, weight loss), new abnormalities on the chest radiograph, or a decline in pulmonary function tests, chest physiotherapy is increased and appropriate antibiotics are given orally, or for severe exacerbations, intravenously.

Currently useful agents for treating staphylococcal infections include dicloxacillin, cephalexin, the third-generation penicillin–clavulanic acid combinations, and macrolides. Early in the course of the pulmonary disease, a small fraction of *Pseudomonas* strains may be sensitive to tetracycline, trimethoprim/sulfamethoxazole, or chloramphenicol. Occasionally, even *Pseudomonas* strains considered resistant according to laboratory sensitivity tests apparently respond to these antibiotics. A mechanism that has been proposed to account for this phenomenon is that even though the antibiotic is not bactericidal, it may inhibit either growth of the organism or its production of exotoxin and proteases. Ciprofloxacin, a quinolone derivative that can be given orally, is initially effective against many strains of *Pseudomonas* and has gained widespread use in the outpatient management of CF. A major disadvantage in its use is that resistance often develops after a few courses of treatment.

For treatment of a severe pulmonary exacerbation of CF caused by methicillin-resistant *Staphylococcus*, vancomycin or linezolid are indicated. For *Pseudomonas,* a combination of an aminoglycoside given intravenously and a semisynthetic penicillin is generally used. This combination is presumed to act synergistically on *Pseudomonas*, and the *Pseudomonas* is less likely to become resistant to either antibiotic.

The most popular antibiotic combination currently in use is tobramycin and ceftazidime. To achieve high levels of antibiotics in the airways and in secretions, the aminoglycoside is generally administered in higher doses, 10 mg/kg/d instead of 7.5 mg/kg/d. A recent randomized trial comparing once-daily versus three-times–daily regimens of tobramycin revealed that once-daily IV therapy provided equivalent efficacy with less nephrotoxicity in children.[102] Dosing should be titrated for serum peak levels of 20 to 30 mg/L and trough levels of 1 mg/L or less.

Third-generation penicillins and cephalosporins, piperacillin, and ceftazidime; carbapenems, imipenem and meropenem; and the latest β-lactam, aztreonam, are also quite effective against *Pseudomonas.* When given alone, resistance often develops quickly. Usually, these agents are used in combination with an aminoglycoside. Because the sensitivity and resistance patterns of the *Pseudomonas* often change, various combinations are tried at different times, with clinicians relying on sensitivities from recent isolates to determine which is most effective for the particular strain of *Pseudomonas.* For other resistant gram-negative organisms, such as *B. cepacia, S. maltophilia,* and *Achromobacter xylosoxidans,* other antibiotic combinations are indicated, including ceftazidime, meropenem, ciprofloxacin, minocycline, aztreonam, chloramphenicol, or trimethoprim/sulfamethoxazole.

Staphylococcus, Pseudomonas, and other gram-negative organisms, such as *B. cepacia, A. xylosoxidans,* and *S. maltophilia*, once found in the sputum, are rarely eradicated. However, most other manifestations of an exacerbation of pulmonary disease abate during a 2-week course of antibiotics administered intravenously; for example, the densities seen on the chest radiograph decrease, the white blood cell count decreases, fever and respiratory rate decrease, and pulmonary function test results, which often deteriorate at the start of an exacerbation, return to their previous baseline. Although many patients begin to show improvement after 5 to 7 days, most CF centers continue antibiotics intravenously for at least 2 weeks to decrease the relapse rate and to avoid a decrease in the interval between exacerbations. Indeed, some centers routinely recommend a 3- to 4-week course of intravenous antibiotics to treat an exacerbation of a pulmonary infection. In the occasional-hospitalized patient who experiences a relapse or manifests an increase in symptoms shortly after administration of intravenous antibiotics is stopped, long-term intravenous administration of an aminoglycoside can be continued with use of a heparin lock. This technique may be helpful in allowing the patient to return home while still receiving effective doses of aminoglycosides.

Nutritional Support

Patients with CF should have a detailed nutrition assessment at diagnosis and annually as per the CFF guidelines.[60] Nutritional status should be screened at every visit. Patients are prescribed a high-calorie balanced diet. The CFF recommends that for infants and young children (0–2 years) weight for length be maintained at the 50th percentile and that children and adolescents (2–20 years of age) have their BMI percentile at the 50th percentile. Although it is true that pulmonary function is the predominant factor in determining morbidity and mortality in CF, it is becoming increasingly clear that overall patient status is closely tied to nutritional status. Importantly, achieving and maintaining normal nutritional status is associated with maintenance of lung function in young children and adults. Calorie goals are often 110% to 120% of usual calorie requirements. At these caloric intakes, protein intake is often adequate to meet needs. Patients are encouraged to achieve calorie goals by the ingestion of calorically dense foods. If this is hard to achieve, calorie boosters (vegetable oils, butter, and cheese) are recommended followed by the use of high-calorie supplements (shakes). Calorie needs may be increased in patients with chronic lung disease, malabsorption, and chronic liver disease. Nocturnal nasogastric feeds may be used in the short term for aggressive nutritional rehabilitation, and patients who need long-term support have placement of a gastrostomy tube for ease of care. Typically standard formulas are used but some patients with feeding intolerance and poor weight gain benefit from hydrolyzed formulas. Intravenous or parenteral nutrition is rarely used, but may be required in patients who have had GI surgery.

Pancreatic status (insufficiency or sufficiency) should be determined and monitored as needed. The mainstay in managing the pancreatic insufficiency of CF is PERT which consists of enteric-coated capsules containing amylases, proteases, and lipases. PERT should be ingested before meals that contain protein, fat, or complex

carbohydrates. Dosing guidelines have been developed by the CFF. Fibrosing colonopathy or the development of colonic strictures is a complication that appears to be related to high PERT doses exceeding 10,000 lipase units/kg/d and was first noted following the introduction of high-potency pancreatic enzymes.[103] Most patients can be managed with pancreatic enzyme doses within the published guidelines. Patients who require higher pancreatic enzyme doses should be evaluated by a dietitian and a pediatric gastroenterologist.

Patients with pancreatic insufficiency are at risk for fat-soluble vitamin deficiency. Guidelines also exist for vitamin supplementation and CF-specific vitamin products are available.[60] It is recommended that fat-soluble vitamin status be monitored annually and additional supplements (Vitamin D) may be required if levels are still low. It is very unusual for patients with CF to be vitamin A deficient if they are on a CF-specific vitamin preparation. Supplemental salt is needed by patients to prevent salt depletion. Salt is added to infant formula and children and adults are encouraged to salt their foods liberally and to take salt-containing liquids and snacks during hot weather and periods of increased physical activity.

MANAGEMENT OF CYSTIC FIBROSIS–RELATED DIABETES

Insulin is the treatment of choice for CFRD, and ideally the regimen is customized to fit the needs of the individual patient. Combinations of basal (long-acting) and bolus (rapid-acting) insulins are used in the treatment of CFRD with FH. In the absence of FH, premeal rapid-acting insulin is the main treatment approach. Frequent meals, snacking, and "grazing" are not uncommon in CF, and the requirement of multiple daily injections can be prohibitive for some individuals. The insulin pump offers flexibility and can negate the need for frequent injections.[104] Moreover, calories are not restricted in CFRD although either avoidance of foods of low nutritional value (sugared soda or confection) or their consumption in combination with complex carbohydrates, protein, and fats is useful in avoiding excessive hyperglycemia. Pancreatic enzyme replacement also appears to improve meal-related glucose excursion.[36] The role of treatment of prediabetes and early insulin deficiency in preserving pancreatic β-cell function, pulmonary function, and nutritional status has yet to be defined.

NATURAL HISTORY AND PROGNOSIS

A comprehensive treatment program for CF has unequivocally improved overall survival of patients. Fifty years ago, the median survival was only a few years of age. For the 5-year period from 2007 to 2011 the median predicted survival was 36.8 years of age (CF Foundation Patient Registry, 2011 Annual Data Report, Bethesda, MD). However, because CF is a complex disorder that affects different organs to different degrees, it is difficult to describe a "typical course" for a patient with CF. Some patients die in childhood or adolescence, while others survive well beyond age 40.

An important determinant of the natural history of CF is the severity of the pulmonary disease and the rate at which it progresses. Although most patients' condition improves in response to therapy, skillful management does less to influence the course of the severely affected than that of the mildly affected patient.

A variety of scoring systems have been devised for CF. The clinical scoring system devised by Shwachman and Kulczycki and the chest radiograph scoring system devised by Brasfield and associates are widely used. However, although these and more elaborate scoring systems are useful in categorizing patients according to the severity of illness, none has proved useful in prognosticating the course of an individual patient.

Because CF is a genetic disease, the question of a familial pattern of severity is often raised. Figure 50-7 shows chest radiographs of three siblings with CF; the radiographs demonstrate mild, moderate, and severe disease in individuals in the same family. The capsule histories, which are included in the figure legend, also illustrate the variability in courses experienced.

Patients with CF can be categorized not only with respect to severity of illness, but also with regard to survival. For example, more than half of patients with CF who underwent surgery for meconium ileus before 1965 died in the first 2 months of life. Although this situation had improved markedly by 1976, the survival rate for patients with meconium ileus was still not as good as for all other patients with CF. In addition, the survival rate was much lower for females than for males, especially in adolescents. In recent years, differences between the patients in these groups have declined or disappeared. Because of improvements in the collection of mortality statistics, comparison of current data with those from previous years may be somewhat misleading, but 50% survival age has not been increasing as rapidly in recent years as in the 1970s and 1980s. Furthermore, there is a difference in outcomes among individual CF centers.

COMPLICATIONS

The course of CF is often characterized by a gradual decrease in pulmonary function, punctuated by further abrupt declines during exacerbations. Malnutrition, when present despite therapy, usually correlates best with the severity of the pulmonary disease. However, the course of CF may be suddenly altered by certain complications of the disease.

HYPOELECTROLYTEMIA AND METABOLIC ALKALOSIS

Hypoelectrolytemia and metabolic alkalosis are serious complications that are especially apt to occur during periods of hot weather, when losses of sodium and chloride increase. Electrolyte depletion may be life-threatening, especially in infants and young children (Table 50-3). Prompt fluid replacement with isotonic saline is critical.

INTESTINAL OBSTRUCTION

Intestinal obstruction in patients with CF may be related to distal intestinal obstructive syndrome (DIOS), volvulus, intussusception, and adhesions from prior surgery. Acute or chronic crampy abdominal pain can be seen in patients with CF with pancreatic insufficiency and pancreatic sufficiency. This is most often due to DIOS which is related to intestinal dysmotility, poor hydration of intestinal contents, and malabsorption. Typically the pain is in the right lower quadrant of the abdomen and is related to a buildup of stool in the terminal ileum, cecum, and ascending colon. Treatment consists of adequate fluid and electrolyte intake, use of polyethylene glycol solutions, and treatment of malabsorption. If the obstruction is incomplete and manifested solely by a tender right lower–quadrant mass, then the above-described measures are used. Nasogastric infusion of polyethylene glycol solutions is also used successfully in the hospitalized patient. If these measures are unsuccessful or the patient has an obstruction, then hyperosmolar contrast enemas are administered by a radiologist

after hospitalization is required. It is important that patients are well hydrated, that the terminal ileum is cleared of stool and that an abdominal x-ray is performed to document clearance of stool prior to the patient being discharged from the hospital. Adherent stool/mucus may serve as the leading edge for a volvulus or intussusception (Fig. 50-6) and surgical consultation may be required. Careful pre- and postoperative management is essential to avoid the deterioration in pulmonary function that may follow the use of anesthesia.

LIVER DISEASE

Liver disease is often asymptomatic and can be detected by evaluation of liver function tests on routine yearly studies. Assessment of liver status (synthetic function) and anatomy (abdominal ultrasound with Doppler) are important in the diagnosis of cirrhosis and portal hypertension. Only a small percentage of patients with significant liver disease will need liver transplantations unlike other chronic liver diseases seen in children. Liver biopsy is recommended in patients in whom an etiology other than CF liver disease needs to be established.[105] It is recommended that other causes of liver disease be ruled out and that patients receive hepatitis A and B immunizations. There is a paucity of data to support the routine use of ursodeoxycholic acid in patients with CF-related liver disease. However, this medication is often used in doses of 10 to 20 mg/kg/d as a choleretic agent to improve bile flow.[59] Persistent hepatomegaly or splenomegaly, or complications of portal hypertension establish significant liver involvement. Patients may develop esophageal varices as a result of portal hypertension and present with upper gastrointestinal bleeding. Once bleeding has been identified as due to varices and hemoptysis has been excluded, therapeutic endoscopy (sclerotherapy or band ligation) is required. For patients with complications of portal hypertension, transjugular intrahepatic portosystemic shunting or surgical portosystemic shunts can effectively decompress esophageal varices by decreasing portal pressure as a bridge to liver transplantation.

Liver transplantation is another option for many patients with CF who have end-stage liver disease. Indications include significant synthetic dysfunction, unresponsive or recurrent esophageal varices with recurrent upper GI bleeding, ascites, and encephalopathy. Patients need to be evaluated by a hepatologist. Ideal candidates are those with an FEV_1 of at least 50% of predicted. Colonization with a multidrug-resistant or panresistant strain of *Pseudomonas* is a relative contraindication to transplantation. In patients in whom poor pulmonary function or drug-resistant pulmonary infection is an issue, double organ (liver and lung) transplantation may be considered. Despite concerns about worsening airway infection during transplant-associated immunosuppression, liver transplantation in patients with CF does not worsen their pulmonary status.[106]

ATELECTASIS

Atelectasis of a lung segment or lobe sometimes occurs in CF. Acute atelectasis is generally associated with few symptoms (Fig. 50-9A). If it is untreated, however, the end result of atelectasis is a severely bronchiectatic segment or lobe (Fig. 50-9B). Vigorous chest physiotherapy, in conjunction with antibiotics, is often successful in reexpanding the affected lung region. Bronchoscopy is occasionally helpful. As a rule, however, bronchoscopy is no more effective than chest physiotherapy and pulmonary pharmacotherapy. Resection of a persistently atelectatic or bronchiectatic lobe is undertaken only when the remaining areas of the lung are in relatively good condition, overall pulmonary function is good, and the evidence convincing that the affected segment is responsible for intolerable symptoms (fever, cough, or sputum production).

PNEUMOTHORAX

Recurrent pneumothorax is common in CF, particularly in older patients (Fig. 50-9C). Tension pneumothorax occurs in up to 30% of patients with CF who develop pneumothorax. Tube thoracostomy is indicated when the pneumothorax occupies more than 10% of the area of the hemithorax seen on the posteroanterior chest radiograph. Because the frequency of recurrence of pneumothorax is high, attempts are often made at the time of the initial event to achieve chemical or surgical pleurodesis. Surgical pleurodesis is more effective at preventing recurrence of a pneumothorax and is no longer considered a contraindication to lung transplantation.

HEMOPTYSIS

Expectoration of a small amount of blood-streaked sputum is a fairly common occurrence in CF and is generally managed by intensifying home therapy for pulmonary infection. In contrast, hemoptysis (the expectoration of at least 30–60 mL of fresh blood) requires hospitalization, even with a chest radiograph that is virtually unchanged (Fig. 50-9D). The probable mechanism underlying most instances of hemoptysis in CF is the erosion of an area of localized infection into a bronchial vessel. Massive hemoptysis (blood loss of 240 mL) is uncommon in CF. However, it represents a potentially life-threatening situation. Bronchoscopy, and sometimes thoracic surgery, may be required to control the hemorrhage. Bronchial artery embolization has been used successfully in patients with CF and is now the treatment of choice when a physician experienced in the procedure is available.[107]

INFECTION WITH UNUSUAL ORGANISMS

CF produces central bronchiectasis, even though the disease initially is in the small bronchioles. Bronchiectatic airways are frequently colonized with unusual organisms, including *Aspergillus* and atypical mycobacteria. As is the case with pathogenic bacteria, eradication of these organisms from the airways is virtually impossible. The focus of therapy is directed toward verifying that the organisms are resulting in worsening of the disease and controlling the infection, rather than effecting a microbiologic cure.

Mycobacteria

The prevalence of infection with atypical mycobacteria in CF mandates surveillance for these organisms in sputum cultures at least annually.[108] When atypical mycobacteria are cultured, antimicrobial sensitivities should be obtained. A decision about therapy for isolation of atypical mycobacteria is based on the likelihood that the organism is contributing to airway infection and a decline in pulmonary function. Isolation of the same organism on several occasions, positive smears, presence of progressive chest radiographic changes, further decline in pulmonary status despite vigorous antipseudomonal (or antistaphylococcal) therapy, persistent night sweats, and fever are clinical clues that the atypical mycobacteria are contributing to disease. Demonstration of tissue infection with transbronchial lung biopsy is rarely recommended. A clinical database has been established by the CF Foundation to track results of treatment for atypical mycobacterial infections in patients with CF. The current standard for therapy is treatment with several antimicrobials for synergy and to prevent development of resistance.

Aspergillus

In an analogous fashion, molds, especially *Aspergillus,* are occasionally isolated from patients with CF. Approximately 5% to 15% of patients have ABPA. The diagnosis of ABPA in CF is difficult because of overlapping symptoms between the two disorders. Diagnostic criteria for ABPA are (1) reversible airway obstruction, (2) proximal bronchiectasis, (3) history of pulmonary infiltrates, (4) skin test positivity to aspergillus antigens, (5) precipitating serum antibodies to *A. fumigatus*, (6) elevated total serum immunoglobulin E (IgE), (7) elevated specific serum IgE and serum immunoglobin G (IgG) to *Aspergillus,* and (8) peripheral eosinophilia. A negative skin test for *Aspergillus* effectively rules out the diagnosis of ABPA. During the

Figure 50-9 Chest radiographs of patients with pulmonary complications of CF. **A.** Atelectasis of the right upper lobe in a 4-month-old boy. The atelectasis resolved with antibiotics and chest physiotherapy. **B.** The same patient at 9 years of age with mild hyperinflation, central bronchiectasis, resolving right upper lobe infiltrate. The diagnosis of allergic bronchopulmonary aspergillosis was made, and the patient improved after treatment with prednisone. **C.** Pneumothorax of the right lung *(arrows)* in a 13-year-old boy. The pneumothorax resolved after tube thoracostomy and tetracycline sclerosis. The patient died 3 years later from respiratory failure with congestive heart failure. There were no recurrences of the pneumothorax. **D, E.** A 43-year-old man showing hyperinflation and diffuse peribronchial thickening. The radiograph was taken during an episode of significant hemoptysis, and no acute changes were seen on the radiograph.

active phase of ABPA, elevations in total IgE and eosinophil count are seen. Rises in *Aspergillus*-specific titers (IgE and IgG) are more specific for ABPA than are serum precipitins. ABPA in patients with CF is treated with corticosteroids and itraconazole. The level of total IgE is used to follow the activity of the disease.

Gram-Negative Bacteria

In the late 1970s and early 1980s, the importance of *B. cepacia* (formerly *Pseudomonas cepacia* [PC]) was recognized. *B. cepacia* is a gram-negative, oxidase-positive rod that is uniformly resistant to polymyxin and, frequently, panresistant. Isolation of *B. cepacia* requires plating on special oxidative fermentive polymyxin B bacitracin lactose (OFPBL) or PC agar plates to retard growth of other gram-negative rods and enhance growth of *B. cepacia.* The plates must be maintained for a minimum of 4 days. *B. cepacia* colonization has been associated with septicemia, which is very rarely seen with *P. aeruginosa.* The clinical course after acquisition of *B. cepacia* may be fulminant, with death occurring in a matter of months. However, most patients' disease follows a more benign course. Carefully controlled epidemiologic studies are needed to better define risk factors and to establish the true virulence of *B. cepacia.* Experimental evidence exists that at least one strain of *B. cepacia* may be transmitted in an epidemic fashion. The combination of a poor clinical course after acquisition of *B. cepacia* and the evidence supporting epidemic transmission has led to cohorting or isolation of patients with CF infected with *B. cepacia,* as recommended by the CF Foundation and the Centers for Disease Control (CDC).

In addition to being colonized with *Pseudomonas* and *Burkholderia* species, patients with CF may be colonized with other gram-negative, oxidase-positive organisms, such as *S. maltophilia, Pseudomonas oryzihabitans,* and *A. xylosoxidans*. These are pathogenic organisms, similar in importance to *P. aeruginosa*. Antibiotic therapy should be directed toward these bacteria when they are isolated from the patient with CF who is experiencing an acute exacerbation. The prolonged, prophylactic, aggressive use of antibiotics in CF has led to emergence of resistant organisms. A multiply resistant *Pseudomonas* is an organism that is resistant to all agents in at least two different classes of antibiotics. Resistance to oral fluoroquinolones occurs after about 3 weeks of therapy; if the agent is withheld, the organism occasionally becomes sensitive again.

■ RESPIRATORY FAILURE

As the pulmonary disease of CF progresses and the degree of hypoxia increases, patients are at risk to develop pulmonary hypertension and cor pulmonale. An increase in hypoxia often occurs during exacerbations of the pulmonary disease. During the acute episode, antibiotic treatment for the underlying pulmonary disorder is intensified and supplemental oxygen is added. Expectant monitoring and aggressive treatment of nocturnal hypoxemia (maintaining $Sa_{O_2} \geq 95\%$) prevent the onset of cor pulmonale. When respiratory failure develops in CF, that is, hypercarbia (Pa_{CO_2} at least 55 mm Hg) in addition to hypoxemia, management becomes extremely difficult. Noninvasive mechanical ventilation using bilevel positive airway pressure has been used successfully in patients with end-stage CF awaiting lung transplant; it improved oxygenation, reduced respiratory rate, and was successfully transitioned to home nocturnal use.

Mechanical ventilation is generally instituted when an acute episode, such as viral pneumonia or status asthmaticus, thrusts the patient into acute respiratory failure. This approach is particularly indicated in the patient who has had good pulmonary function before the acute episode. Mechanical ventilation is less apt to be successful if the patient has previously experienced a bout of respiratory failure. When respiratory failure marks the end of a chronic course of progressive pulmonary insufficiency despite adequate medical therapy, mechanical ventilation is usually unhelpful. None of the indications or contraindications for mechanical ventilation is absolute; however, and the clinical outcome depends, to a large extent, on the availability of a dedicated and skilled intensive care team experienced in caring for patients with CF.

■ COMPLICATIONS RELATED TO LUNG TRANSPLANTATION

Lung transplantation has emerged as an option for patients with end-stage CF.[109] Despite initial concerns about immunosuppression in patients with suppurative lung disease, the outcome for those with CF who undergo lung transplantation is among the best reported for this procedure. Timing for lung transplantation has changed with the adoption of a Lung Allocation Score (LAS) which takes into consideration parameters to predict 1-year survival, with a transplant versus without a transplant, and medical urgency. The impact of this organ allocation system is a dramatic decrease in the number of patients on the waiting list for transplantation and a significant shortening of wait times for transplantation.

One major complication postlung transplantation for CF patients is the risk of infection due to resistant organisms. Colonization with *B. cepacia complex*, or rapidly growing mycobacteria such as *M. abscessus*, has been reported to negatively impact survival.[110] *Aspergillus* may cause invasive infections in the parenchyma or the anastomosis site. Other complications, not specific to CF patients, include acute and chronic graft rejection. Acute graft rejection is associated with a humoral immune response to donor HLA antigens and complement activation.[111] Importantly, acute graft rejection is a negative prognostic factor for chronic graft rejection. Chronic allograft rejection is characterized by obliterative bronchiolitis following transplantation. Obliterative bronchiolitis is a progressive occlusion of the bronchiolar lumina by inflammatory cells and submucosal fibrosis. Transient improvement in airflow is seen following augmentation of immunosuppression. About 50% of transplant patients develop obliterative bronchiolitis after the second year following the procedure. The disease pursues a relentless downhill course, with a median survival of about 2 years following the initial diagnosis.

The poor prognosis associated with obliterative bronchiolitis has several important implications for patient selection and timing of referral for transplantation. First, the main reason for seeking lung transplant is to improve the quality of life, rather than to improve survival. Second, the timing of referral for lung transplantation needs to be calculated to optimize the candidate's fitness for transplant yet delay transplant until absolutely necessary considering the risk of developing obliterative bronchiolitis.

Results from clinical studies may aid with proper timing of referral for lung transplantation in CF. CF patients with severe airflow obstruction as indicated by FEV_1 less than 30% of predicted have a 50% 2-year mortality. Other important clinical parameters useful in determining the timing of transplantation are the presence of hypoxemia (Pa_{O_2} under 55) and hypercarbia (Pa_{CO_2} above 50). Of interest, in both single and multivariate analyses, female gender is associated with an increased relative risk, suggesting that for female patients, referral for lung transplantation should be considered at an even earlier stage.

Because CF is a multisystem disorder, both management and proper selection of patients are more complicated than for other diseases managed with lung transplantation. Among the most difficult challenges presented by patients with CF before transplantation is the microbiology of their lower airways. As discussed previously, colonization with multidrug-resistant *B. cepacia*, specifically the genotype, genomovar III, has been associated with a poor clinical outcome. For poorly understood reasons, patients with CF metabolize drugs differently from those without CF, complicating the dosing of medications, including cyclosporine. The difficulties in achieving an optimal drug dose may be related to malabsorption or enhanced excretion of the drug. Nutritional issues also complicate the posttransplantation management of patients with CF. About

50% of all patients with CF over 30 years of age are overtly diabetic, and administration of corticosteroids induces diabetes in another 10%. Maintenance of proper nutrition is important in CF, especially for rapid postoperative recovery. Finally, gastroesophageal reflux may negatively impact pulmonary outcomes following transplantation. Despite all the special challenges to successful lung transplantation posed by patients with CF, their actuarial survival is quite good. The median survival is 7.1 years, reinforcing the tenet that lung transplantation is done principally to improve quality of life.

PSYCHOSOCIAL ISSUES

A number of psychosocial issues are important in the management of patients with CF. Special circumstances should be recognized for adults with the disorder.

GENERAL

Careful attention to the emotional, social, and financial well-being of the patient with CF and his or her family has considerable value in favorably influencing the course of the disease. At the time of diagnosis, it is important to strike an optimistic note while educating the patient about the illness and its management. As part of the early encounter with the patient, the importance of identifying and reinforcing the emotional and financial strengths of the family, as well as weaknesses that will need buttressing, should be recognized. Medical care for CF patients is costly, especially if hospital admissions are required. Many states have programs for children with disabilities that provide support for patients and families. Several states have also established special programs for adults with CF.

As the disease runs its course, counseling and feedback about disease progression are essential. As the patient and family go about setting educational, career, and family goals, they need guidance in realistic planning. It is vital that the physician develop and maintain a positive attitude. The patient who gives up hope is liable to undergo rapid deterioration. Conversely, even patients with severe pulmonary disease can continue to function well and be productive. At the stage when medical therapy is of no further avail, however, the patient and family require considerable emotional support to accept the inevitable. In recent years, many CF centers have allowed patients to die at home, rather than in the hospital. The family requires specific instructions about how to provide physical and emotional comfort for the patient in the home. Usually, home visits by some members of the CF team are required. Not all families have the strength or resources to care for the patient dying at home.

SPECIAL CONSIDERATIONS IN ADULT PATIENTS

In the 5-year period spanning 2007 to 2011, the median life expectancy for patients with CF was about 37 years (CF Foundation Patient Registry, 2011 Annual Data Report, Bethesda, MD). Managing a chronic illness becomes more complicated when patients must also begin to manage their independence and make life decisions regarding education, marriage, children, careers, insurance, and self-care. Intense support for both patients and their families is required. Patients with a relatively mild clinical course of disease form healthy and satisfying relationships in a manner similar to that of their healthy, age-matched peers. With advanced disease, patients with CF have more difficulty in forming intimate relationships. Disturbances in body image, decreased mobility, and lack of opportunity to meet suitable partners are cited as reasons for the decreased ability to form intimate relationships in the severely affected young adult with CF.

The adult patient with CF faces unique problems with self-care. Families of patients with CF provide a tremendous amount of care that is expensive and time-consuming to replace for the independently living adult. When the disease flares, patients must "step up" their level of care at precisely the time when they are least able to do so. Judicious use of hospitalization and home care must be provided if the patient is to recover. The trend toward home management of a pulmonary exacerbation using intravenous antibiotics alone ignores the obvious contributions of nutrition, airway clearance, and rest toward resolution of the problem.

REPRODUCTIVE ISSUES

More than 98% of male patients with CF are sterile, secondary to bilateral absence of the vas deferens. Microsurgical epididymal sperm aspiration (MESA), coupled with in vitro fertilization, has been successful in producing pregnancies in a few carefully selected patients. Not all males with CF are sterile, however. In addition to counseling, these men should be offered semen analysis.

Pregnancy for women with CF is increasingly common, and several important issues remain unsolved. In 2004, 191 women with CF were pregnant (CF Foundation Patient Registry, 2004 Annual Data Report, Bethesda, MD). This stands in marked contrast to the total of 13 pregnancies in 10 patients recorded from 1960 to 1966 (data from the 1994 CF Foundation Data Registry).

Maternal clinical status before pregnancy is the most important prognostic factor of maternal outcome. In a study of 25 women with 38 pregnancies, no significant difference was seen between pre- and postgravid gas exchange or nutritional status. A small, but statistically significant, decline in spirometry was noted. However, the decline was not outside the range of expected decline for the natural progression of the disease. More severely affected women suffered an irreversible decline in clinical status during pregnancy. Without an appropriately matched control group of nongravid women with CF, it was not possible to determine whether pregnancy per se was responsible for the decline or whether the decline is a reflection of the natural history of the disease. Comparison of matched groups of pregnant and nonpregnant and CF women from a registry suggested that there was no difference in the rate of decline between these groups. However, the pregnant women received a greater number of therapies and more intense monitoring of their health.[112]

Recommendations about pregnancy for women who are either mildly affected or severely affected is straightforward. For the woman with moderately compromised pulmonary status (i.e., FVC under 50%–60% of predicted), an overall assessment of the clinical situation is recommended, although no firm guidelines can be given. Increased incidence of fetal prematurity is noted in women with a pregravid FVC below 50% of predicted, lending additional weight against recommending pregnancy to women with moderate-to-severe airflow obstruction. In any woman with CF who is contemplating pregnancy, thorough evaluation and treatment of nutritional deficiencies and pulmonary exacerbations are required. Frequent use of antibiotics is unavoidable, and the teratogenic risk of many antibiotics is unknown. Despite this theoretical risk, good maternal and fetal health depends on aggressive management of pulmonary exacerbations, including use of antibiotics. Management of the gravid patient with CF is best accomplished in a CF center that has a program in high-risk obstetrics. A European consensus panel has published detailed guidelines for the management of pregnancy in women with CF.[113]

For men with CF who opt for MESA and for women with CF who are contemplating pregnancy, all offspring are obligate heterozygotes for CF. These offspring need to be counseled that their risk of having a child with CF is about 1 in 50 if the genotype of the spouse is not known. Although genetic testing of children from affected parents is not recommended, they should receive genetic counseling on reaching adolescence. Parents with CF also need to consider the ethical issues of a premature parental death and its effect on the family. If the spouse of an individual with CF is a known carrier of a CF mutation, the availability of in vitro fertilization with preimplantation genetic testing provides a method to avoid having a child who is affected with CF.

Discovery of the CF gene in 1989 led to the hope that prenatal diagnosis might eventually decrease the incidence of the disease. There is a suggestion that this may in fact be occurring.[114]

FUTURE DIRECTIONS

To further enhance survival in CF, physicians must look into insights gained from basic research. Although much work needs to be done, much has already been accomplished, warranting a realistic expectation that major breakthroughs will soon occur in the treatment of the disorder.

Progress toward cure of CF will require a multidisciplinary approach. Management of the lung disease in CF will probably be based on combined methods. However, the momentum gained from recent improvements in our understanding of the molecular details of CFTR structure and function provides a basis for realistic optimism that specific therapy will result in better outcomes for patients with CF. As described above, specific single molecule therapy has already become a reality for CF patients who have the G551D mutation. A phase III trial of the combination of two small molecules for the most common CF mutation, F508del, is underway. Newer compounds that are based on a better understanding of the structure and function of CFTR[115–117] are already progressing from the bench to bedside.

CHAPTER 51 Bronchiolitis

Gary R. Epler

DISEASES OF THE BRONCHIOLES

Diseases of the bronchioles occur throughout the bronchiolar structures, from bronchiolar airways to alveolar ducts and alveoli (Table 51-1). Acute and chronic bronchiolitis are seen from near the bronchi, all the way to the respiratory bronchioles; constrictive bronchiolitis is seen in the midbronchioles, while diffuse panbronchiolitis occurs from the distal bronchioles to the respiratory bronchioles, and smoker's bronchiolitis involves the respiratory bronchioles. Bronchiolitis obliterans organizing pneumonia (BOOP) includes both the terminal bronchioles and alveoli and is discussed in Chapter 57.

New bronchiolar disorders continue to be described, including diffuse panbronchiolitis and smoker's bronchiolitis. New causes of bronchiolitis obliterans have also been described, including lung transplantation, pulmonary microcarcinoids, *Sauropus androgynous* vegetable drink, and food-flavoring. This chapter includes a discussion of the pathological, clinical, radiographic findings, and treatment of the bronchiolar airway disorders.

BRONCHIOLAR ANATOMY

Bronchioles are noncartilagenous small airways which are usually 1 mm or less in diameter; they have been called the bridge between the bronchi and alveoli.[1] The bronchioles have cartilage and mucus glands that are commonly found in the bronchi, but bronchioles also contain ciliated epithelium, smooth muscle, and Clara cells.[2] Clara cells are columnar cells with apical surfaces capable of secreting proteins and surfactant. Neuroendocrine cells are common in the proximal bronchioles.

More distal in the airways are approximately 30,000 terminal bronchioles that have an average diameter of about 0.6 mm. These bronchioles have circular smooth muscles in the their walls; the surface cilia gradually disappear distally. Terminal bronchioles branch into 224,000 respiratory bronchioles that differ from the bronchioles: respiratory bronchioles have two to three alveolar structures in the walls containing columnar cells with cuboidal type II cells and squamous type I cells. These structures terminate in 13.8 million alveolar ducts and 300 million alveoli.

TABLE 51-1 Clinical Classification of the Bronchiolar Diseases

Airway diseases
• Acute and chronic bronchiolitis
• Respiratory bronchiolitis
• Follicular bronchiolitis
• Diffuse panbronchiolitis
• Bronchiolitis obliterans
Interstitial diseases
• Respiratory bronchiolitis-interstitial lung disease (RB-ILD)
• Bronchiolitis obliterans organizing pneumonia (BOOP)

THE CLINICAL SPECTRUM OF THE BRONCHIOLAR DISEASES

The wide variety of bronchiolar diseases that may be seen in clinical practice are discussed below.

■ ACUTE AND CHRONIC CELLULAR BRONCHIOLITIS

Acute and chronic cellular bronchiolitis is characterized pathologically as acute or chronic inflammation of the bronchioles without a fibrotic component.[3] The inflammation may be submucosal, mural, or peribronchiolar. Clinically, this is a common respiratory illness in children that is caused by several infectious agents, including *Mycoplasma*, adenovirus, influenza, parainfluenza, herpes virus, and adenoviruses. In the adult, bronchiolitis is rare and caused by similar viruses. Symptoms include a flu-like illness with persistent nonproductive cough of several weeks duration. There is generally no wheezing and no airflow obstruction. The chest x-ray is normal. The illness usually subsides over time. Cough suppressants may be utilized. Sometimes, a brief course of corticosteroid therapy is given for a severe, relentless cough. If symptoms are not responsive to corticosteroid therapy or if symptoms worsen, the illness may be fibrotic constrictive bronchiolitis – a disorder with a different clinical course and prognosis.

■ RESPIRATORY BRONCHIOLITIS

Respiratory bronchiolitis is sometimes called smoker's bronchiolitis, as cigarette smoking is almost always the cause of this lesion.[3] The characteristic histological feature is the accumulation of tan-brown macrophages in the lumens of respiratory bronchioles and adjacent alveoli-often seen as an incidental finding in cigarette smokers. For example, respiratory bronchiolitis was found in 70 of 79 (88.6%) smokers who underwent surgery for spontaneous pneumothorax.[4] There are usually no clinical symptoms associated with this type of respiratory bronchiolitis. Treatment is smoking cessation.

In some situations, respiratory bronchiolitis may extend into the interstitium and is referred to as respiratory bronchiolitis-interstitial lung disease (RB-ILD). Affected individuals have shortness of breath, bilateral crackles, reticulonodular opacities on chest radiography, decreased vital capacity, and decreased diffusing capacity. Treatment is smoking cessation, but often a course of corticosteroid therapy is needed for resolution.

■ FOLLICULAR BRONCHIOLITIS

Follicular bronchiolitis is characterized by hyperplastic lymphoid aggregates forming 1- to 2-mm peribronchiolar nodules.[3] Follicular bronchiolitis is often limited to a pathological description with no clinical counterpart. It occurs in the connective tissue disorders, such as rheumatoid arthritis. In some patients, there may be cough, sputum production, and small linear radiographic opacities.[5]

■ DIFFUSE PANBRONCHIOLITIS

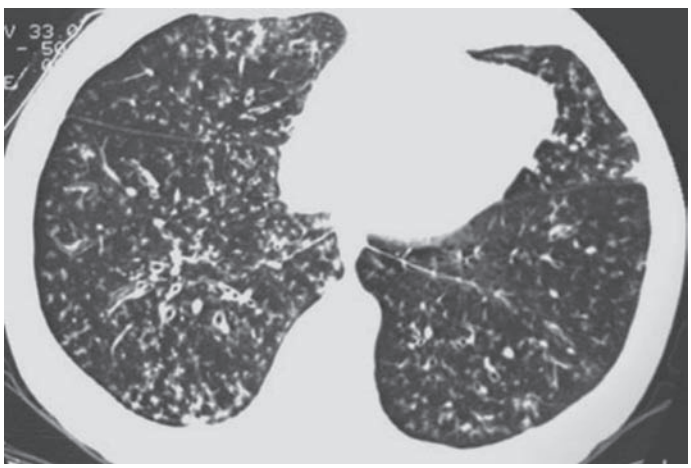
Diffuse panbronchiolitis was first described in the 1960s and is characterized by chronic inflammation and lymphofollicles of the respiratory bronchioles and adjacent centrilobular regions, with infiltration of histiocytosis, plasma cells, and lymphocytes.[6] There is also an interstitial accumulation of foam cells in the walls of respiratory bronchioles and adjacent alveolar ducts and alveoli (Fig. 51-1). The disorder is largely restricted to the Asian countries, but diffuse panbronchiolitis has been reported in the United States, Australia, Canada, and Spain.[7–10] The disorder has been reported in Kartagener syndrome.[11] In recent years, there appears to be a major decrease in the incidence and prevalence of diffuse panbronchiolitis in Japan.[12]

Symptoms include chronic cough, sputum production, shortness of breath, and almost all individuals have chronic paranasal sinusitis. Rhonchi and crackles are common. Radiographic findings show hyperinflation and diffuse small nodular opacities bilaterally. Pulmonary function testing shows airflow obstruction with decreased forced expired volume in one second (FEV_1) and FEV_1 to forced vital capacity (FEV_1/FVC) ratio. Hypercapnia and cor pulmonale occur late. There is often an associated increase in the cold-hemagglutinin titer. There appears to be a major susceptibility gene located between the HLA-A and HLA-B loci on the short arm of chromosome six.[13]

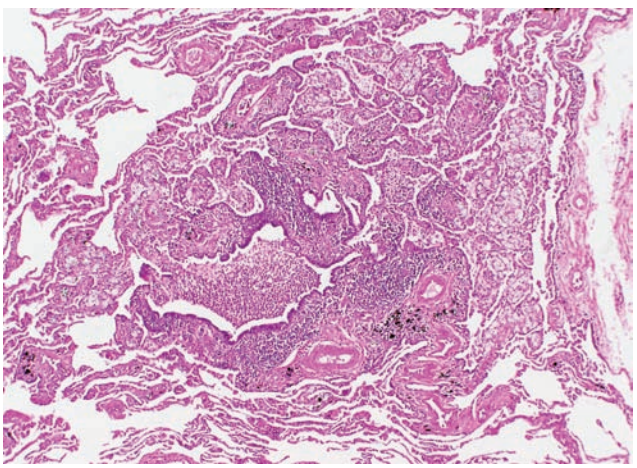
The disorder is progressive. In the past, diffuse panbronchiolitis was a fatal disease with a 10-year survival of less than 20% in patients with *Pseudomonas aeruginosa* infection. However, the introduction of low-dose, long-term erythromycin and other macrolides has resulted in a dramatic improvement in survival. Among Chinese patients, Li et al.[14] showed azithromycin, 500 mg once daily, for 3 months and 500 mg three times weekly for 6 to 12 months, resulted in complete cure in 27.5% of patients, elimination of symptoms in 70.6%, and a 5-year survival of 94.1%. The macrolides may prevent influx of neutrophils into the alveoli, decrease interleukin-8, and interfere with the pathological potency of *P. aeruginosa*.[15]

■ BRONCHIOLITIS OBLITERANS

Bronchiolitis obliterans is an important lesion because it can be severely disabling and deadly. Traditionally, bronchiolitis obliterans



A



B

Figure 51-1 Diffuse panbronchiolitis. **A.** The chest CT scan shows bilateral centrilobular nodules with branching showing "tree-in-bud" pattern. **B.** The pathology micrograph shows chronic inflammation of the respiratory bronchioles, with interstitial accumulation of foam cells in the walls of the respiratory bronchioles, adjacent alveolar ducts, and alveoli. *(Used with permission of Dr. Kenneth W. Tsang, Queen Mary Hospital, Hong Kong, China; and Dr. Thomas V. Colby, Lung Pathology, Mayo Clinic Scottsdale.)*

TABLE 51-2 Pathological Findings of Bronchiolitis Obliterans

Constrictive bronchiolitis
• Concentric fibrotic lesion of the mid to distal bronchioles
• The lesion surrounds the lumen, causing extrinsic narrowing and obliteration
• Distortion of the lumen and mucostasis
• Muscle layer hypertrophic early, atrophic late, and replaced by fibrotic tissue in end-stage disease
• May be patchy and focal
• Late stage includes traction bronchiectasis and bronchiolectasis
Proliferative bronchiolitis
• Intraluminal polypoid myxoid fibroblastic tissue arising with the bronchiole wall.
• May be organized polypoid granulation tissue from the bronchioles to the respiratory bronchioles including the alveoli
• No disruption of the lung architecture
• No traction bronchiectasis

has been used as a clinical term to describe irreversible fibrosis of the bronchiolar airway that is idiopathic or occurs after accidental toxic fume inhalation or a viral pneumonia. However, pathologists may see two distinctive lesions that, in turn, have a different clinical course and response to treatment.

Histologically, the two lesions are *proliferative bronchiolitis* and *constrictive bronchiolitis* (Table 51-2). Depending on severity, obliteration of the bronchioles, the obliterans term, may or may not occur with these lesions. The histological distinction between these two lesions is that constrictive bronchiolitis arises in a concentric fashion outside the bronchiole walls as a fibrotic lesion, and proliferative bronchiolitis arises from within the bronchiole walls as an inflammatory lesion.

The term *bronchiolitis obliterans* is used in this chapter, as it has been used by clinicians for more than a hundred years and almost always reflects the fibrosing, constrictive, pathological lesion.[16] The proliferative lesion is often self-limiting and less severe, or responds to corticosteroid therapy with complete resolution; it usually does not result in the clinical label of bronchiolitis obliterans.

Proliferative bronchiolitis is an inflammatory bronchiolitis characterized by intraluminal polypoid connective tissue masses of myxoid fibroblastic tissue which resembles granulation tissue that arises from within the bronchioles.[1] Central clusters of mononuclear inflammatory cells may be found in these polypoid masses. This type of bronchiolitis includes organized polypoid granulation inflammatory tissue in the distal bronchiole airways, respiratory bronchioles, alveolar ducts, and alveoli in the form of BOOP[17] Additional distinctive histological findings with proliferative bronchiolitis associated with BOOP include no disruption in the lung architecture, interstitial fibrosis, absence of traction bronchiectasis, or histological honeycombing (Fig. 51-2).

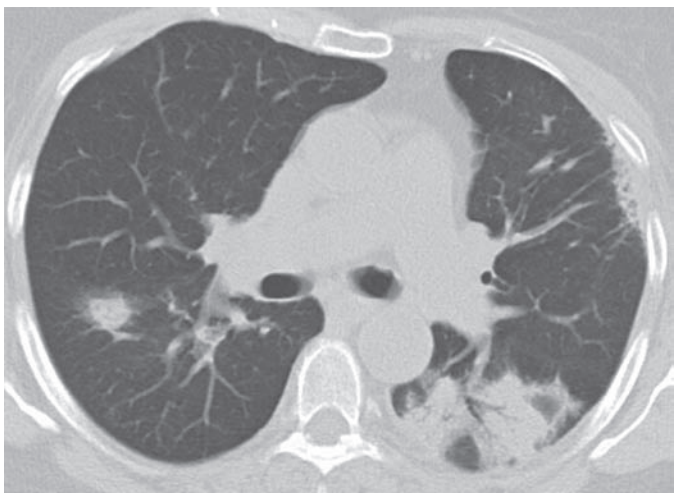
Constrictive bronchiolitis is a fibrotic, concentric bronchiolitis lesion with or without complete obliteration (Fig. 51-3). This lesion is usually seen in the mid to distal area of bronchioles and does not extend into the respiratory bronchioles or alveoli. The lesion is characterized by a peribronchiolar fibrotic process that surrounds, rather than fills, the lumen, resulting in extrinsic compression and obliteration of the airway.[3] There is mural thickening by submucosal collagenous fibrosis with progressive concentric narrowing associated with luminal distortion, mucus stasis, and chronic inflammation.[18]

Constrictive bronchiolitis was called "fibrosing bronchiolitis" in the German pathology literature.[19] The lesion preferentially involves membranous bronchioles and is characterized by fibrosis of the stroma and narrowing the lumen in a concentric fashion. The muscle layer may be hypertrophic in early lesions, atrophic in late stages, and replaced by fibrotic tissue at the end stage. Visscher and Myers noted that constrictive bronchiolitis is often patchy and focal, making the diagnosis difficult from a transbronchial biopsy; advanced cases may be especially inconspicuous because of lack of active inflammation and disappearance of bronchioles.[20]

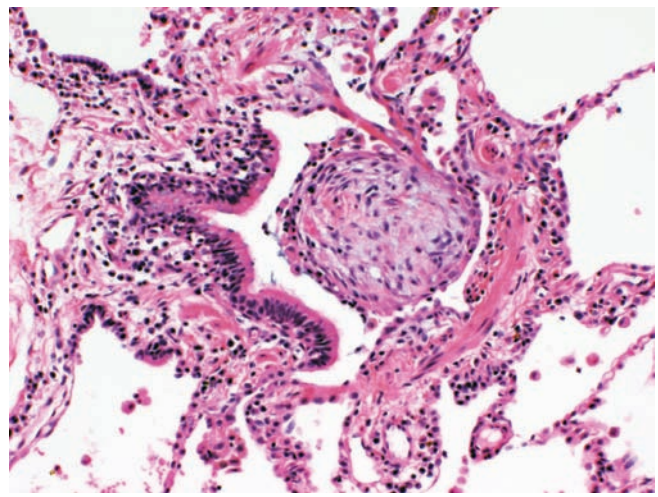
There are several causes of bronchiolitis obliterans and associated systemic disorders (Table 51-3).

Idiopathic Bronchiolitis Obliterans

Idiopathic bronchiolitis obliterans occurs among individuals who have no obvious inciting agent or associated systemic disorder,

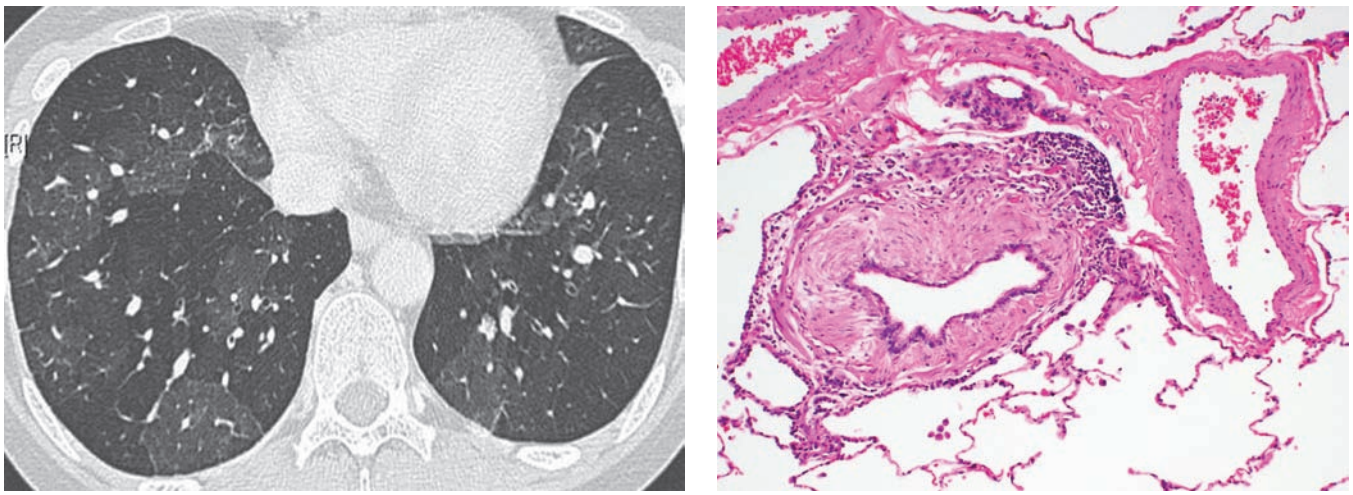


A



B

Figure 51-2 Bronchiolitis obliterans organizing pneumonia. **A.** The chest CT scan shows bilateral patchy ground-glass opacities, air bronchograms, and peripheral-based triangular infiltrates. **B.** The pathology micrograph shows organized polypoid granulation tissue filling the distal bronchiole and extending into the alveoli. *(Used with permission of Dr. Ritu R. Gill, Chest Radiology, Brigham and Women's Hospital, Boston, and Dr. Thomas V. Colby, Lung Pathology, Mayo Clinic Scottsdale.)*



A B

Figure 51-3 Constrictive bronchiolitis. **A.** The expiratory chest CT scan shows the mosaic pattern of air trapping seen from obliterated bronchioles. **B.** The pathology micrograph shows extrinsic fibrosis of the bronchiolar wall in a concentric manner constricting and obliterating the bronchiolar lumen. *(Used with permission of Dr. Ritu R. Gill, Chest Radiology, Brigham and Women's Hospital, Boston, and Dr. Thomas V. Colby, Lung Pathology, Mayo Clinic Scottsdale.)*

and who have airflow obstruction and constrictive bronchiolitis histologically. This disorder continues to be exceedingly rare. Symptoms begin with a nonproductive cough, and shortness of breath develops later. Physical examination shows no wheezing but may demonstrate an unusual finding of early inspiratory crackles. The crackles occur early because of the scarring around the midbronchiole airways, causing snapping closure of the airways and resultant crackling sound.

TABLE 51-3 Clinical Classification of Bronchiolitis Obliterans

Idiopathic
Toxic fumes
Post-respiratory infections
Connective tissue disorders
Drug-related
Organ transplantation

Primary biliary cirrhosis
Miscellaneous diseases
• Ataxia-telangiectasia
• IgA nephropathy
• HIV
• Paraneoplastic pemphigus and paraneoplastic autoimmune multi-organ syndrome (PAMS)
• Swyer–James syndrome
• Inflammatory bowel disease

Pulmonary function studies show irreversible decrease in the FEV_1 and FEV_1/FVC with no improvement after bronchodilator inhalation. The diffusing capacity is highly variable, from increased, to normal, to markedly decreased.

The chest roentgenogram is often normal or shows hyperinflation. High-resolution chest CT scans during inspiration and expiration can be helpful for establishing a diagnosis (Fig. 51-1). For example, a 65-year-old woman with idiopathic bronchiolitis obliterans had a normal chest CT scan in the inspiratory study, but the expiratory study showed extensive lobular air trapping.[21] These expiratory images show low-attenuation areas in the secondary pulmonary lobules, resulting in a typical mosaic pattern with scattered areas of low attenuation. Additional thin-section CT findings include constriction of the pulmonary vessels within the low-attenuation areas, expiratory air trapping, bronchial dilation, and sometimes, centrilobular nodules or branching linear densities.[22]

Treatment consists of high-dose corticosteroids such as prednisone with an initial dose of 60 mg daily, followed by lower-dose therapy for usually one year in patients who respond. For those who do not respond by three months, corticosteroids are discontinued and employed for life-threatening exacerbations. Immune-suppression treatment can be utilized and lung transplantation for individuals with life-threatening and severe disease.

Patients who survive the initial episode may stabilize for several years or progress to end-stage airflow disease and cor pulmonale.[23] For example, a 43-year-old woman had idiopathic bronchiolitis obliterans for 24 years and showed relentless progression of airway obstruction with 19 admissions for respiratory failure.[24] The autopsy in this patient showed complete obliteration of smaller airways. The FEV_1 decreased from 1.06 L to 0.40 L terminally.

Myong et al.[25] described three women aged 41 to 54 who developed cough and progressive shortness of breath during 6 months to 10 years; lung tissue showed constrictive bronchiolitis with bronchiolar airway obliteration. The thin-section CT scans showed low-attenuation changes of the mosaic pattern. None responded to corticosteroid treatment. One woman died 8 months after the diagnosis from lymphoma and the other two were stable.

Toxic Fume Bronchiolitis Obliterans

Toxic fume bronchiolitis obliterans is a three-phase response disease. The exposure usually occurs from an accidental explosion

resulting in nose, throat, and eye irritation with no major respiratory symptoms. Phase one is an asymptomatic latency period of 6 to 12 hours after exposure. Phase two begins suddenly with acute-onset respiratory failure and acute respiratory distress syndrome. Successful treatment results in another asymptomatic latency period of 7 to 10 days. Phase three then occurs as constrictive bronchiolitis with irreversible airflow obstruction, progressive shortness of breath, and chronic respiratory failure.

This disorder occurs after accidental exposures to sulfur dioxide fumes, nitric acid fumes, and nitrogen dioxide in freshly filled corn silos. Unusual accidental exposures to toxic fumes may cause this lesion. For example, two workers in a lithium battery factory were accidentally exposed to thionyl chloride, and one of them developed findings consistent with bronchiolitis obliterans.[26] This acidic compound is used in the manufacturing process and produces sulfur dioxide and hydrochloric acid fumes when in contact with water.

Smoke inhalation bronchiolitis obliterans was described in a 23-year-old man who was in a fire while sleeping in his newly constructed house.[27] He was unconscious when rescued. There was cough and mild dyspnea after recovery. He returned 3 years later because of persistent dyspnea. He had finger clubbing, an FEV_1 of 0.90 L, and an FEV_1/FVC of 34%. The burning synthetic structural materials used to build his house produced gases containing acrolein, formaldehyde, acetaldehyde, nitrogen dioxide, and sulfur dioxide.

There has been a report of bronchiolitis obliterans from mustard gas occurring from a chemical warfare attack in a 37-year-old man who had cough, sputum production, shortness of breath, and airflow obstruction for 14 years after the exposure.[28] Later, investigators[29] used high-resolution chest CT scan findings for the diagnosis of bronchiolitis obliterans in a group of individuals exposed to the same mustard gas attack. They treated 18 individuals with bronchodilator treatment and 18 with interferon gamma-1b and 7.5 mg of prednisolone. Patients had baseline FEV_1 values of 49.3% and 48.7% predicted, respectively. Both groups improved after 6 months of treatment; however, the group treated with interferon gamma had a significantly higher posttreatment FEV_1 of 66.3% compared to 57.3% for the group treated with bronchodilators ($p = 0.001$).

King et al.[30] reported constrictive bronchiolitis among 38 US soldiers returning from Iraq and Afghanistan and found a common exposure to a sulfur-mine fire in 2003 among 28 of them.

A 42-year-old police officer exposed to the dust in the cloud from the New York City World Trade Center disaster of September 11, 2001 developed decreased FEV_1 and FEV_1/FVC in April 2002.[31] The lung biopsy showed regions of constrictive bronchiolitis. He was treated with oral corticosteroid therapy and azithromycin. By April 2003, pulmonary function studies had returned to normal values.

An unusual radiographic appearance of scattered lung cysts has been reported in a 49-year-old woman with severe airflow obstruction and constrictive bronchiolitis.[32]

Diacetyl appears to be a common exposure among artificial butter flavoring workers who developed constrictive bronchiolitis. A report of nine microwave popcorn factory workers showed airflow obstruction among the mixers, and biopsy of some individuals showed constrictive bronchiolitis.[33] Investigators[34] have reported that four workers at a cookie factory who were exposed to diacetyl developed severe and persistent airflow obstruction, with FEV_1 ranging from 25% to 44%. Lung biopsy showed constrictive bronchiolitis and bronchiolar airway distortion.

Post-Respiratory Infection Bronchiolitis Obliterans

Post-respiratory infection bronchiolitis obliterans may occur after adenovirus pneumonia, influenza or parainfluenza pneumonia, or after *Mycoplasma* pneumonia.[35] Cough develops several days after the initial infection. Chest radiographs may show diffuse reticulonodular opacities early but are normal or show hyperinflation late. Expiratory, high-resolution chest CT scans show low-attenuation mosaic pattern. Tissue shows constrictive bronchiolitis with extensive scarring that obliterates many of the bronchioles, corresponding clinically with severe airflow obstruction. At this stage, the lesion is not responsive to corticosteroid medication. Lung transplantation has been utilized for severe post-*Mycoplasma* pneumonia bronchiolitis obliterans.[36]

Connective Tissue Bronchiolitis Obliterans

Connective tissue bronchiolitis obliterans occurs most commonly in rheumatoid arthritis and has been reported in scleroderma, lupus erythematosus, and Sjögren's syndrome.[37,38]

Rheumatoid arthritis-related constrictive bronchiolitis often has a poor prognosis. Among 25 individuals with rheumatoid arthritis and bronchiolitis obliterans, most had severe airflow obstruction, often with an FEV_1 less than 1 L, and the process was not responsive to corticosteroids.[39] The outcome was poor, as chronic respiratory failure occurred in 40% of the patients; four patients died.

Drug-Related Bronchiolitis Obliterans

Drug-related bronchiolitis obliterans has been reported with penicillamine and gold used for treatment of rheumatoid arthritis. The penicillamine-related bronchiolitis obliterans has a poor prognosis, sometimes requiring lung transplantation for management.[40] Fatal bronchiolitis obliterans has been reported in a 12-year-old girl with juvenile rheumatoid arthritis after a 6-month course of intramuscular gold.[41] Although cause and effect are difficult to confirm for both of these agents, patients receiving these medications who develop unexplained cough or dyspnea need to be evaluated for the possibility of bronchiolitis obliterans.

Bone-Marrow Transplantation Bronchiolitis Obliterans

Bone-marrow transplantation bronchiolitis obliterans occurs much less frequently as allogeneic stem-cell transplantation has become so common; however, bronchiolitis obliterans may occur in up to 9% of allogeneic bone-marrow recipients.[42] Bronchiolitis obliterans occurs only after graft-versus-host reaction, and therefore, is rarely seen after autologous bone-marrow transplantation. As complications of chronic graft-versus-host develop after 100 days, bronchiolitis obliterans is usually seen 6 to 12 months after transplantation. Donor type-2 T-helper lymphocytes appear to be the primary mediators. The pathological lesion is concentric bronchiolar fibrosis typical of constrictive bronchiolitis. There is generally a poor response to corticosteroid therapy; mortality ranges from 40% to 100%.[42] Living donor lobar lung transplantation has been used successfully for bone-marrow transplant-related bronchiolitis obliterans.[43]

Stem-Cell Transplant Bronchiolitis Obliterans

Stem-cell transplant bronchiolitis obliterans has replaced bone-marrow transplantation-associated bronchiolitis obliterans as allogeneic hematopoietic stem-cell transplantation has become more widespread (see Chapter 95). The prevalence of bronchiolitis obliterans ranges from 2% to 3% among all allogeneic recipients to 6% among those who develop chronic graft-versus-host disease (cGVHD).[44] These data underestimate the incidence of bronchiolitis obliterans (26%) when using an annualized rate of decline in FEV1 of 5%. Those with cGVHD had a rate of 30%, but more importantly, they had a mortality rate of 40% at 10 years. cGVHD is the major risk factor for bronchiolitis obliterans, as high as 80% of patients with bronchiolitis obliterans are preceded with cGVHD. Other risk factors include low IgG levels, use of peripheral blood stem cells, poor pretransplant lung function, and respiratory infection during the first 100 days. Biopsy specimens performed early show bronchiolitis, fibrous obliteration of the respiratory bronchioles, and inflammatory cell infiltrates; later lesions show constrictive bronchiolitis with circumferential fibrosis. The mechanism of bronchiolitis

obliterans is based on chronic rejection that may involve donor cytotoxic T cells.

Preventive treatment of stem-cell transplantation bronchiolitis obliterans consists of early and aggressive treatment of respiratory infections and cGVHD. Treatment includes high-dose systemic corticosteroids and immunosuppression with calcineurin inhibitors, sirolimus, azathioprine, and anti-thymocyte globulin. Prognosis continues to be poor despite treatment and supportive care, with an overall survival rate of 44% at 2 years and 13% at 5 years.[44]

In a study of 2087 allogeneic stem-cell transplantation recipients from 1994 to 2005, there were 57 (2.8%) who developed bronchiolitis obliterans.[45] The time interval between transplantation and bronchiolitis obliterans ranged from 83 days to 907 days with a median time of 335 days. Acute graft-versus-host disease was not found to be a risk factor, whereas cGVHD was a significant risk factor. The development of bronchiolitis obliterans was related to the stem-cell source, with related peripheral blood stem-cell transplantation (3.83%) the highest. Unrelated bone-marrow transplantation (2.91%) and cord-blood transplantation (2.65%) were lower, with related bone-marrow transplantation (1.62%) the lowest. The outcome among these 57 patients showed that 8 (16.7%) improved, 10 (21.7%) showed no change, and 28 (60.9%) died; the cause of death was respiratory failure in 17 (60.7%).

The high-resolution chest CT findings in bronchiolitis obliterans among patients receiving allogeneic stem-cell transplantation shows geographic hypoattenuation and air trapping with subpleural predominance.[46] In some patients, the geographic hypoattenuation involved more than half of both lungs.

Extracorporeal photodynamic therapy has been used for the treatment of cGVHD and bronchiolitis obliterans.[47] The role of this treatment in the management of bronchiolitis obliterans in stem-cell transplantation recipients has not yet been established. Some patients have improved pulmonary function.

Mesenchymal stem-cell treatment was used for one patient. A 38-year-old patient received peripheral blood stem cells from her sibling and developed bronchiolitis obliterans 8 months later with an FEV_1 <0.7 L.[48] She was treated experimentally with human bone marrow–derived mesenchymal stem cells from her sister on day 275 and on day 305, resulting in disappearance of symptoms and improved pulmonary function. This may be an effective treatment on a case-by-case basis, but at this time, there are too many unknown variables involved to advocate its use (e.g., absence of large scale studies, availability of a standardized source of mesenchymal cells, and an understanding of potential carcinogenic effects).

Lung Transplant Bronchiolitis Obliterans

Lung transplant bronchiolitis obliterans has emerged as the most important clinical complication among lung transplant recipients since the mid-1980s and has continued to plague thoracic surgeons and patients, with minimal change in occurrence and mortality (see Chapter 107).

The terminology has become the bronchiolitis obliterans syndrome (BOS), which is a clinical classification based on FEV_1. The classification was developed because BOS is a common problem among lung transplantation recipients. The approach eliminates the need for low-yield transbronchial biopsy or other invasive procedure to establish a definitive diagnosis of bronchiolitis obliterans. A clinical severity classification has been used.[49] A National Institutes of Health (NIH) diagnostic classification of BOS in cGVHD[50] has also been developed (Table 51-4).

Many years after the initial description of bronchiolitis obliterans occurring in lung transplant recipients, BOS remains a common process with devastating consequences.[51] At least one-half of lung transplantation recipients surviving 5 years will develop airflow obstruction. BOS has not declined significantly in incidence, and no totally effective treatment is available.

TABLE 51-4 Bronchiolitis Obliterans Syndrome (BOS) Classifications

BOS clinical severity classification	
BOS 0	FEV_1 >90% of baseline and $FEF_{25–75}$ >75% baseline
BOS 0-p	FEV_1 81–90% of baseline and/or $FEF_{25–75}$ ≤75%
BOS 1	FEV_1 66–80% of baseline
BOS 2	FEV_1 51–65% of baseline
BOS 3	FEV_1 50% or less of baseline
NIH chronic graft-versus-host BOS classification	
1. FEV_1 <70% predicted or FEV_1/FVC <70%	
2. Expiratory HRCT showing air trapping, small airway thickening or bronchiectasis, residual volume >120% predicted, or constrictive bronchiolitis by pathology	
3. Absence of respiratory infection	

The frequency and severity of acute cellular rejection continues to be the major risk factor. For example, a study showed that lung transplant recipients who had more than three episodes of acute rejection in any 12-month period eventually had a 100% incidence of bronchiolitis obliterans.[52] Both types of acute rejection are involved, including acute vascular rejection and lymphocytic bronchiolitis.

Primary graft dysfunction (PGD) is a term used for a process that occurs during the initial postoperative phase characterized by pulmonary edema and acute respiratory failure. This process has been associated with high perioperative mortality and is a risk factor for the subsequent severity of bronchiolitis obliterans.[53]

A classification system for PGD (Table 51-5) has been established based on oxygenation and the presence of pulmonary edema.[54]

Daud et al.[55] found that among 334 lung transplant recipients, 130 (39%) had grade-one PGD, 69 (20%) had grade-two, and 70 (21%) had grade-three. All grades were associated with increased risk of bronchiolitis obliterans, with a risk ratio ranging from 1.73 for grade-one to 2.53 for grade-three. This risk was independent of acute rejection.

Innate immunity may play a role in development of postlung transplant bronchiolitis obliterans. There are several risk factors that activate this innate system, including prolonged ischemic time, cytomegalovirus (CMV) pneumonia, *Aspergillus* colonization, PGD, gastroesophageal reflux disease (GERD), and community respiratory virus infections.[51]

Autoimmunity as a mediator in BOS has been proposed as a biphasic rejection.[56] The first phase is recurrent tissue injury from airway insults, and the second phase is sequestered self-antigens and fragments released into the lung, triggering autoreactive T-cell proliferation and autoantibody production.

TABLE 51-5 Classification of Primary Graft Dysfunction (PGD)

PGD grade 0: $Pa_{O_2}/F_{I_{O_2}}$ >300 mm Hg
PGD grade 1: $Pa_{O_2}/F_{I_{O_2}}$ >300 mm Hg and pulmonary edema
PGD grade 2: $Pa_{O_2}/F_{I_{O_2}}$ 200–300 mm Hg and pulmonary edema
PGD grade 3: $Pa_{O_2}/F_{I_{O_2}}$ <200 mm Hg and pulmonary edema

$Pa_{O_2}/F_{I_{O_2}}$: Arterial oxygen (mm Hg) to the fraction of inspired oxygen.

Eberlein et al.[57] found that an oversized allograft can be associated with improvement, including higher expiratory airflows, and less frequent occurrence of BOS. Circulating fibrocyte levels correlated with BOS after lung transplantation.[58] Levels of KL-6, a high–molecular-weight human MUC1 gene mucin, are increased and correlated with the level of FEV_1 decline in lung transplantation recipients.[59] Bourdin et al.[60] showed that donor Clara cell secretory protein polymorphism is a risk factor for BOS. Gastroesophageal reflux, a cause of bronchiolitis obliterans, occurs in as many as 50% of lung transplant recipients, and early fundoplication may improve rates of bronchiolitis obliterans and survival.[61]

Chronic productive cough and shortness of breath were commonly reported as symptoms in early reports, but bronchiolitis obliterans is now diagnosed earlier than in the past, and these symptoms may not be present. Gradual onset of progressive shortness of breath is the most common symptom. Early inspiratory crackles may be heard. The decreases in FEV_1 may be mild to severe and life-threatening.

The chest x-ray is often normal; however, the combination of newly decreased FEV_1 and the expiratory high-resolution chest CT scan showing mosaic pattern have virtually become diagnostic.[62]

Management of lung transplantation bronchiolitis obliterans begins with early and aggressive treatment of acute organ rejection, including both the acute vascular rejection and lymphocytic bronchiolitis. Treatment of bronchiolitis obliterans generally includes a calcineurin inhibitor, a purine synthesis inhibitor, and a corticosteroid.

The calcineurin inhibitor tacrolimus has become an alternative to cyclosporine, with evidence for similar survival and a decrease in episodes of acute rejection with use of tacrolimus.[63] In addition, compliance with tacrolimus appears to be better than cyclosporine. New-onset diabetes after transplantation is a major complication of tacrolimus, and there is an increased risk of infections.

Mycophenolate mofetil (MMF) has generally replaced azathioprine[64] as the purine synthesis inhibitor. Both alloimmune and nonalloimmune mechanisms are involved in development of bronchiolitis obliterans; therefore, vigorous treatment of infections is needed at all times during the posttransplant period.

Extracorporeal photopheresis (ECP) appears to be effective for early treatment of BOS. It consists of the patient's white blood cells being exposed to ultraviolet light in the presence of 8-methoxypsoralen in a photoactivation chamber.[65,66] In a study of 60 lung transplant recipients, ECP treatment decreased the rate of the FEV_1 decline and improved FEV_1 actual value by 25% in patients. In addition, the rate of decline in lung function was sustained over both the 6- and 12-month period.[65] In a study of 1012 lung transplant recipients, 194 developed BOS and 51 received ECP.[66] There were 31 (61%) who responded to the therapy and showed sustained stabilization of the FEV_1 for at least 6 months. Responders showed significantly greater survival and less need for re-transplantation. Treatment was more effective when given soon after the diagnosis of BOOP.

The macrolides, such as erythromycin, appear to be an effective treatment in a subset of patients with BOS. The finding of bronchoalveolar lavage neutrophils may distinguish responders from nonresponders.[67] The process in the responders is referred to as neutrophilic reversible allograft airway dysfunction (NRAD).[68] An additional important finding about azithromycin is that this agent may reduce gastroesophageal reflux in lung transplant recipients, further decreasing the risk of constrictive bronchiolitis.[67] Early treatment resulted in responders having more lower-grade BOS.[69] A thin-section CT study showed patients with NRAD had more centrilobular nodularity at the beginning of treatment, and they had improved bronchus dilation, consolidation, and air trapping.[70]

The six-minute walk test can be useful for monitoring lung transplant recipients with bronchiolitis obliterans. In a 2009 study, patients who walked farther than 330 m had a median survival of 1178 days, compared to 263 days for lung recipients who walked less.[71]

A 2011 study of traffic air pollution as estimated by the proximity of the home to a major road showed that lung transplant recipients living near a major road within 171 m were 2.06 times more likely to develop BOS and 2.20 times more likely to die than patients living far away.[72]

Aspiration Bronchiolitis Obliterans

Aspiration bronchiolitis obliterans was first reported in 1908 occurring in a 2.5-year-old child who aspirated a prune pit that eventually caused respiratory failure and death.[73] Activated charcoal used for management of a medication-related suicide attempts has been reported as a cause of bronchiolitis obliterans.[74] Massive gastroesophageal reflux has been reported as a cause of bronchiolitis obliterans in a patient who later underwent a gastrojejunostomy that relieved the symptoms and prevented recurrent aspiration, accompanied by a corresponding improvement in the FEV_1.[75]

Neuroendocrine Hyperplasia-Related Bronchiolitis Obliterans

Neuroendocrine hyperplasia-related bronchiolitis obliterans has been reported to occur among six patients who developed shortness of breath and fibrotic bronchioles.[76] In a case report of a 65-year-old man who had 20 years of shortness of breath and a severely decreased FEV_1 of 19% predicted, neuroendocrine hyperplasia with fibrotic narrowed bronchioles was observed.[77] In addition, in another report of two women who had airflow obstruction and unexplained cystic lung disease, biopsies showed showed diffuse idiopathic neuroendocrine cell hyperplasia.[78]

Carcinoid-Related Bronchiolitis Obliterans

Carcinoid-related bronchiolitis obliterans has occurred in patients with multiple tumorlets and microcarcinoids located within the bronchioles, resulting in bronchiolitis obliterans and airflow obstruction.[38,79]

Sauropus Androgynus Bronchiolitis Obliterans

Sauropus androgynus bronchiolitis obliterans has been reported among women who consume this leafy vegetable. It is cultivated in India, Malaysia, Indonesia, China, and Vietnam. The leaves are boiled and blended with pineapples or guavas to make a mixed vegetable-fruit juice which is consumed for its alleged effects of body weight reduction and blood pressure control. The leaves contain the alkaloid papaverine. Among 194 patients in Taiwan, the obstructive ventilatory defect was irreversible and resulted in progressive deterioration in some patients resulting in lung transplantation.[80] In a report of five patients in Japan, the illness occurred 6 months after ingestion; four were mothers and daughters, and none improved with corticosteroid treatment.[81]

Stevens–Johnson-Related Bronchiolitis Obliterans

Stevens–Johnson-related bronchiolitis obliterans has been described in a woman who developed progressive dyspnea 12 days after developing diffuse oral erythematous lesions and blisters after antibiotic therapy.[82] She developed progressive respiratory failure and died 2 months later. Autopsy showed constrictive bronchiolitis with obliterated bronchioles.

Primary Biliary Cirrhosis Bronchiolitis Obliterans

Primary biliary cirrhosis bronchiolitis obliterans has been reported in a 39-year-old woman.[83] Early there was improvement from corticosteroid therapy, but later deterioration and death. Lung tissue showed concentric submucosal fibrosis and scarring, constricting the lumen of the airway, consistent with constrictive bronchiolitis and bronchiolar airway obliteration.

Paraneoplastic Autoimmune Multi-Organ Syndrome Bronchiolitis Obliterans

Paraneoplastic autoimmune multi-organ syndrome bronchiolitis obliterans, also referred to as paraneoplastic pemphigus-related bronchiolitis obliterans, has been reported in several patients.[38,84–86] A patient with myasthenia gravis died from bronchiolitis obliterans after surgical resection of a Castleman tumor.[84] Another patient had this paraneoplastic syndrome and developed constrictive bronchiolitis.[85] In a 2009 report from Mayo Clinic of three patients, all had severe airflow obstruction, with FEV_1 <1 L.[86] Two of them died and the third had stable chronic respiratory failure. A case report describes a 44-year-old woman with Castleman tumor and paraneoplastic syndrome; autopsy showed partial obliteration of the bronchiolar lumen by fibrolymphocytic tissue and dense inflammatory infiltrates surrounding the bronchioles. The oral mucosa, skin and bronchioles showed similar immunophenotypes.[87]

Swyer–James Syndrome Bronchiolitis Obliterans

Swyer–James syndrome bronchiolitis obliterans is not congenital in origin but is secondary to respiratory infection occurring during infancy.[38,88] Respiratory infections that can cause this syndrome include measles, whooping cough, tuberculosis, *Mycoplasma* pneumonia, influenza A, and adenovirus types 3, 7, and 21.

Miscellaneous Systemic Disorders Associated with Bronchiolitis Obliterans

Bronchiolitis obliterans has been reported in four patients with *ataxia-telangiectasia* who died from respiratory failure secondary to bronchiolitis obliterans.[89] Another report describes an elderly man with renal failure from *IgA nephropathy* characterized by diffuse crescentic glomerulonephritis who died from progressive respiratory failure and bronchiolitis obliterans.[90] *HIV-related bronchiolitis obliterans and* [91] *inflammatory bowel disease bronchiolitis obliterans* have been reported.[38]

SUMMARY

In summary, the bronchiolar airway diseases include acute and chronic bronchiolitis, follicular bronchiolitis, diffuse panbronchiolitis, and bronchiolitis obliterans. Acute bronchiolitis is usually transient, whereas diffuse panbronchiolitis responds to macrolide therapy. Postlung transplantation bronchiolitis obliterans continues to be a major problem, with minimal change in frequency or response to treatment.

CHAPTER 52

Bullous Disease of the Lung

Fernando J. Martinez

DEFINITION

A *bulla* is an air-containing space within the lung parenchyma that arises from destruction, dilatation, and confluence of airspaces distal to terminal bronchioles and is larger than 1 cm in diameter (Fig. 52-1).[1] Its walls are composed of attenuated and compressed parenchyma. Bullae occur in various clinical contexts: (1) with emphysema ("bullous emphysema"); (2) with pulmonary fibrosis, as in the late stages of sarcoidosis or complicated pneumoconiosis; (3) in so-called "vanishing lung," in which the parenchyma is rapidly replaced by multiple bullae; and (4) in lungs that are otherwise normal ("bullous lung disease") and, therefore, likely secondary to a mechanism different from that of bullae occurring in conjunction with emphysema (Table 52-1).[2,3]

Distinctions are drawn between bullae, blebs, and cysts (Table 52-2).[2] A *bleb* is an accumulation of air between the two layers of the visceral pleura that arises when the thin covering of the bleb ruptures and permits entry of air (Fig. 52-1). *Cysts* are epithelial-lined cavities that may resemble bullae on radiographs.[3] Many fall into the category of developmental anomalies and include mixtures of mesenchymal and epithelial components that are normally present in the lung. The pathologic nature of these cystic lesions is reflected

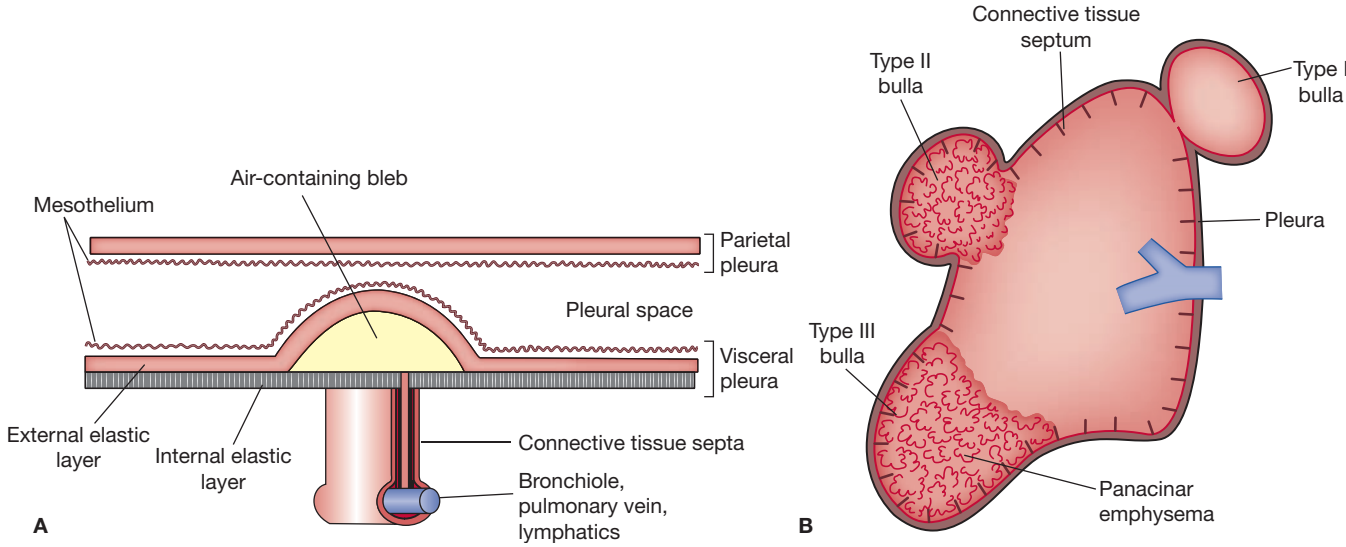

Figure 52-1 Blebs and bullae. **A.** Development of a bleb. A bleb is an accumulation of air within the pleura that is not confined by connective tissue septa within the lung. Air that escapes within the substance of the lungs makes its way to the surface, separating the internal from the external elastic layers on the visceral pleura. **B.** Different types of bullae. In contrast to a bleb, a bulla is confined by connective tissue septa of the lung and is deep to the internal elastic layer of the visceral pleura. Three different types of bullae are shown arising from a lung that has been removed from within the chest wall. A type I bulla is shown at the apex, a type II is in the middle zone, and a type III is arising at the base. The short *dark lines* denote connective tissue septa. Panacinar emphysematous parenchyma is present within the types II and III bullae. *(Adapted with permission from Reid L. The Pathology of Emphysema. Chicago: Year Book; 1967:211–240.)*

in their names: "cystic adenomatoid malformations," "peripheral bronchogenic cysts," "congenital polycystic disease," and "atypical bronchopulmonary sequestration."[1]

The term *bullous disease* is reserved for multiple bullae in lungs that are otherwise normal.[2] This entity is different in etiology and pathogenesis from that in which bullae occur in conjunction with underlying chronic obstructive pulmonary disease (COPD). Confusion occasionally arises between the two entities because some pathologists regard bullous disease as a subset of panacinar emphysema.[1] However, this view is not useful as (1) panacinar emphysema tends to occur in the lower lobes, whereas bullous disease favors the upper lobes; (2) the natural history of the two disorders is quite different; and (3) panacinar emphysema has certain distinctive features not shared by bullous disease. Bullae may occur not only as part of obstructive lung disease, but also as a complication of fibrotic lung disease (Table 52-1).

TABLE 52-1 Classification of Bullae

Primary
Vanishing lung syndrome
Single giant bulla
Bullous lung disease
Secondary
Emphysema
Paraseptal
Panacinar
Centriacinar
Pulmonary fibrosis
Sarcoidosis
Idiopathic pulmonary fibrosis
Progressive massive fibrosis
Conglomerate silicosis
Fibrotic tuberculosis
Other fibrotic lung disorders
Familial disorders
α_1-antitrypsin deficiency
Ehlers–Danlos syndrome
Salla disease
Marfan syndrome
Fabry disease
Cutis laxa

ETIOLOGY

Bullae may originate in a variety of clinical and pathogenetic settings: (1) with emphysema of distal acini; (2) in the setting of cigarette smoking; (3) in conjunction with scar tissue formation, which "traps" areas of normal lung, enlarges airspaces by traction on surrounding intact alveoli, or produces retraction or shrinkage of intact walls of adherent alveoli; (4) in the setting of intravenous drug abuse; (5) as a result of chronic inflammation and destructive

TABLE 52-2 Characteristics of Blebs, Bullae, and Cysts

	Bleb	Bulla	Cyst
Site	Within visceral pleura	Arises within secondary lobule	Lung parenchyma or mediastinum
Size	1–2 cm	1 cm to 75% of a lung	2–10 cm
Lining	Elastic laminae of the pleura	Connective tissue septa	Epithelium
Associated condition	Spontaneous pneumothorax	Bronchogenic carcinoma	Respiratory infection

changes in terminal and first-order respiratory bronchioles, resulting in airspace distention from delayed emptying; and (6) with α_1-antitrypsin deficiency.[2,4,5]

CLASSIFICATION

Bullae are classified anatomically into three main types (Fig. 52-1B).[1,2] Type I bullae are characterized by a narrow neck that connects the bullae with the pulmonary parenchyma. This type of bulla may be caused by overinflation of a volume of flawed lung tissue. The walls of type I bullae are thin, and their interiors are empty. Type I bullae are usually found at the lung apices and along the edges of the lingula and middle lobes. They often occur in association with paraseptal emphysema. Scanning electron microscopy has demonstrated that the thin neck is a consistent feature and that pleural mesothelial cells on the external surface are either reduced in number or completely absent; bundles of collagen fibers lie naked and separated from one other by small pores or crevices.

Type II bullae arise from the subpleural parenchyma and are characterized by a neck of panacinar emphysematous lung tissue. The interior of these airspaces consists of emphysematous lung in which blood vessels are still present. In contrast to type I bullae, the outer wall is formed by pleura covered with intact mesothelial cells. Although connective tissue septae are present within the bullae, they are not found in the wall. Type II bullae may occur anywhere in the lung, but they are most frequent in the upper lobe, at the anterior surface of the middle lobe, and over the diaphragm.

Type III bullae consist of slightly hyperinflated lung connected to the rest of the lung by a broad base extending deep into the parenchyma. This type is believed to represent an atrophic form of emphysema.

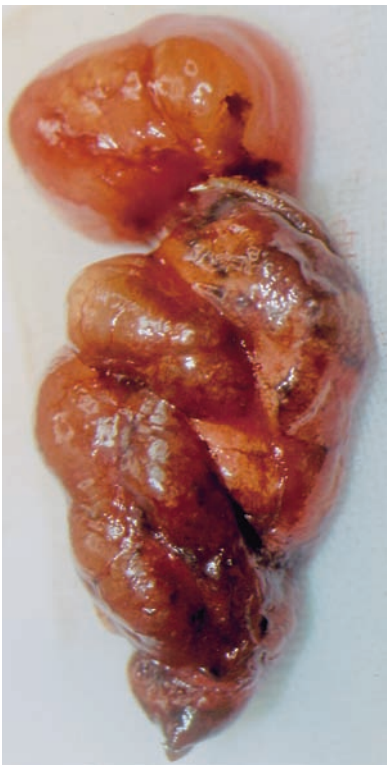
PATHOGENESIS

Several hypotheses have been proposed over the years for how bullae develop, although none have been proved.[1,2,3,6] These include (1) weakness of the alveolar walls predisposes to the formation of bullae, particularly at the apices of the lungs, where pleural pressures are most negative. This theory underscores the proclivity of bullae for the upper lobes and stresses the influence of mechanical forces acting upon flawed tissue. (2) Inflammatory disease of a bronchiole leads to progressive air trapping and "tension airspaces." (3) Disordered collateral ventilation produces the findings. (4) The same mechanisms responsible for generalized emphysema are operative in the formation of bullae. (5) Underlying paraseptal emphysema produces bullous disease.

Of all the hypotheses, that of underlying paraseptal emphysema is the most popular.[1,2] The hypothesis envisages destruction of alveoli adjacent to connective septae or the pleura. The pattern relates to the fact that capillaries in alveolar walls that abut connective tissue septa are less numerous than elsewhere because of a sparse network of arterioles and arteries in peripheral alveoli. Consequently, these regions of the acinus have less vascularity and greater compliance.

Dynamic computerized tomography and intrabulla pressure measurements have raised questions about the theory that bullae are formed by positive pressure within the airspace.[1,7] The lung surrounding a bulla is less compliant than the bulla itself; accordingly, the pressure necessary to inflate the surrounding lung is greater than that necessary to inflate the bulla. The pressure within a giant bulla has been found to be the same as pleural pressure. Therefore, when a bulla and its surrounding lung are exposed to the same negative pleural pressure, the bulla fills preferentially and completely like an inflated paper bag, prior to the surrounding lung inflating. Further inspiration increases the elastic recoil pressure, thereby exerting a greater retractive force on the lung parenchyma and enlarging the airspace. Nevertheless, bullae can be removed from within the lung while still maintaining their volume, indicating a positive intrabulla pressure.

Bullae within the intact chest are molded and compressed to fit adjacent anatomic configurations. However, if the lung is released from these constraints (e.g., when removed from the chest cavity), bullae project as shiny bubbles at the lung surface (Fig. 52-2).



A

B

Figure 52-2 **A.** Surgically resected specimen with a bulla projecting from the lung surface. **B.** A bulla is shown projecting through a previous chest tube insertion site onto the surface of the skin.

Within the thoracic cavity, large bullae cause crowding of adjacent lung parenchyma, and structures such as bronchi are displaced, stretched, and narrowed over the bullae surfaces. Very large airspaces can expand across the midline or even extend into the neck. Bullae represent more than just overexpanded alveoli, because the remnants of bronchioles and their accompanying vessels sometimes persist as trabeculae within the bullae. Interlobular septae can be incorporated into the wall as the airspace expands from within the secondary lobule.

Two important risk factors for bullous emphysema are cigarette smoking and α_1-antitrypsin deficiency. Many patients with bullous emphysema are cigarette smokers, and most bullous lesions are associated with paraseptal or centriacinar emphysema. Although bullous emphysema is typically found in young males, elderly patients with α_1-antitrypsin deficiency who are lifelong nonsmokers may develop bullous changes in later life. A hereditary predisposition to bullous emphysema is also suggested by its association with a variety of rare familial disorders, including Fabry disease, Salla disease, cutis laxa, Ehlers–Danlos syndrome, and Marfan syndrome.[1] Giant bullous emphysema has also been reported with histologic changes of placental transmogrification—a rare, benign lung disease of unknown etiology in which the lung shows bullous changes or, rarely, cysts or nodules.[8,9] Lung pathology demonstrates papillary structures similar to placental villi surrounding the pulmonary epithelium. The tight skin mouse, which has a dominant mutation for the elastase gene and is characterized by multiple connective tissue abnormalities, serves as a unique model for bullous emphysema.[10]

DISTRIBUTION OF BULLAE

As noted previously, the tendency for bullae to occur in the upper lobes is usually attributed to the greater mechanical stresses imposed on the lung apices than bases. Because intrapleural pressure near the lung apices is more negative than at the bases, apical alveoli are subjected to greater expanding stresses than are basal alveoli. Radioactive gas studies and in situ freezing techniques have demonstrated that alveoli in the upper lung zones are considerably larger than those in the lower zones. Gravity also plays a role, as the upright lung behaves like a coiled spring, which, when allowed to dangle in the upright position, shows larger gaps between coils at the top than the bottom.

Engineering techniques used to study the distribution of stresses in aircraft have been applied to the analysis of stresses on the lung.[1] These have shown that the larger expanding stresses at the apices are directed primarily in a vertical direction, and to a lesser extent, laterally. The stresses tend to increase with expansion of the lung, but they are present also when the lung volume decreases below functional residual capacity (FRC). The increase in apical stress at low lung volumes has been attributed to an increase in the rigidity of the lungs as residual volume is approached.

EVALUATION AND DIAGNOSIS

In asymptomatic individuals, bullae may be detected in the course of routine chest radiography. Small bullae rarely become visible on the chest radiograph but are usually easily visible by computed tomography (CT). As a rule, small bullae usually produce no symptoms, signs, or discernible alterations in pulmonary function.[11] However, rupture of one or more bullae may lead to spontaneous pneumothorax (see below). In some patients bullae give rise to progressive dyspnea or chest pain (Fig. 52-3A,B).[12] On occasion, a patient with bullous lung disease develops sudden, severe breathlessness secondary to development of a spontaneous pneumothorax[13] or sudden increase in bulla size due to air trapping. In patients with known bullous disease infection in a bulla can occur (see below). Radiographically, infection is usually identified by the appearance of an air–fluid level (Fig. 52-4A).[4–6] The physical findings in a patient with one or more bullae usually reflect the overall state of the lungs. Only infrequently do giant bullae reach a size sufficient to cause a localized decrease in regional air entry, with absent breath sounds and increased resonance to percussion.

LABORATORY

Routine laboratory testing in the evaluation of bullae includes the measurement of hemoglobin and hematocrit to identify if anemia is contributing to respiratory symptoms and to assess for possible secondary polycythemia due to chronic hypoxemia.[1,12] Measuring an α_1-antitrypsin level should be obtained to diagnose α_1-antitrypsin deficiency.[14] Finally evaluation of arterial blood gases, performed while the patient is breathing room air if possible, is generally indicated in patients with severe respiratory insufficiency and those being evaluated for possible bullectomy.[12] As noted in Table 52-3, a Pa_{CO_2} greater than 45 mm Hg is considered a relative contraindication for bullectomy.[15]

IMAGING

Imaging techniques used in the evaluation of bullous lung disease include chest radiography, computed tomography, and nuclear medicine-based studies.

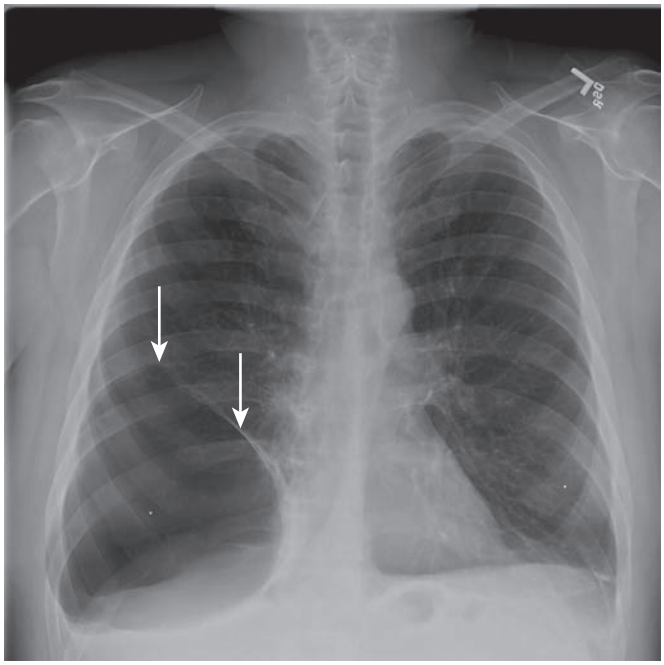
Chest Radiography

Although routine chest radiography is the most practical method for identifying the presence of bullae, the technique generally discloses less than 50% of bullae identified on CT.[16,17] In a given patient, serial radiographs taken over years are invaluable in tracing evolution of the disease.[11] The presence of the condition is suggested by areas of increased radiolucency that are sharply delineated by fine radiopaque lines representing the walls of the bullae. These lines, or "hairline shadows," are composed of compressed and fused interlobular septae or pleura.[10,18] Because the hairline shadows appear incomplete on the chest radiograph, they delineate only segments of the bulla wall (Fig. 52-3A). Distinction between hairline shadows produced by a bulla, and thicker, sometimes irregular, walls of a cavity is usually not difficult. More difficult is distinguishing bullae from cysts. The presence of other radiologic signs of emphysema or fibrotic lung disorders suggests that the cystic structure is a bulla.[13] Similarly, distinguishing between a large bulla and pneumothorax may be challenging.[12,19] In general, the pleural line associated with a large bulla is usually concave relative to the lateral chest wall, whereas the pleural line associated with a pneumothorax is convex relative to the lateral chest wall.[12] Similarly observation of "the double-wall sign" (i.e., the presence of air on both sides of the bulla wall) may be helpful in identifying the findings as due to a bulla.[18]

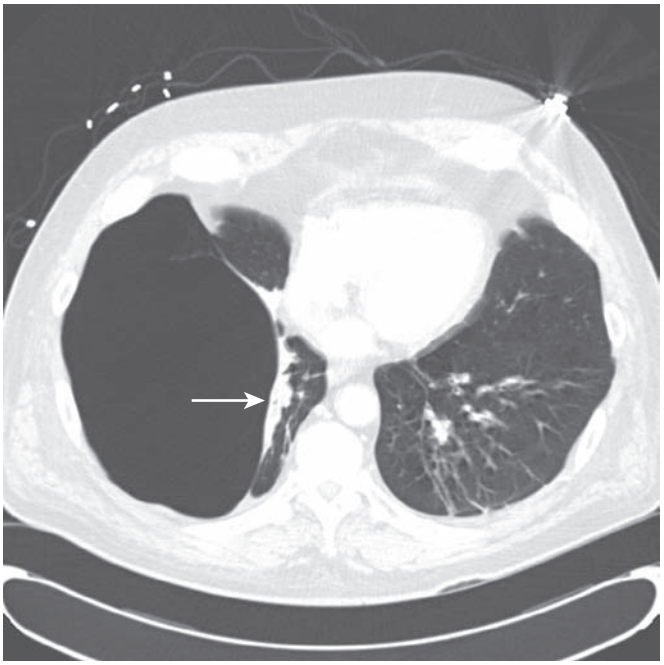
A chest radiograph obtained after forced expiration is sometimes helpful in demonstrating the presence of bullae: air trapping during the expiratory maneuver accentuates their outline by preventing a decrease in their size as the surrounding lung empties.[3] Large bullae sometimes displace the mediastinum contralaterally and may even compress the opposite lung.

Computed Tomography

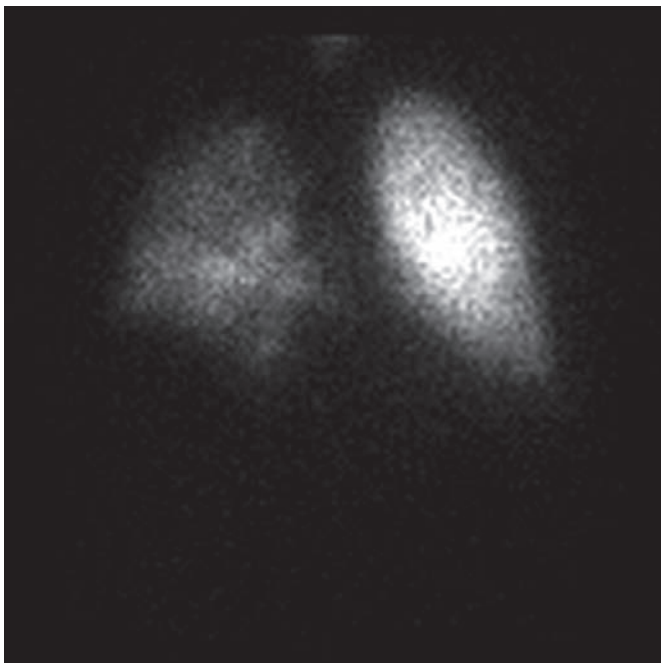
CT provides valuable anatomic information about the size, number, and relationships of bullae, as well as crowding of adjacent lung and disposition of the pulmonary vasculature (Fig. 52-3B).[20–22] Bullae are identified as areas of radiolucency that usually do not contain blood vessels and that are confined by visible walls. High-resolution computed tomography (HRCT) shows that large bullae are frequently associated not only with distal acinar (paraseptal) emphysema, but also with centriacinar emphysema—the type of emphysema usually associated with cigarette smoking.[20]



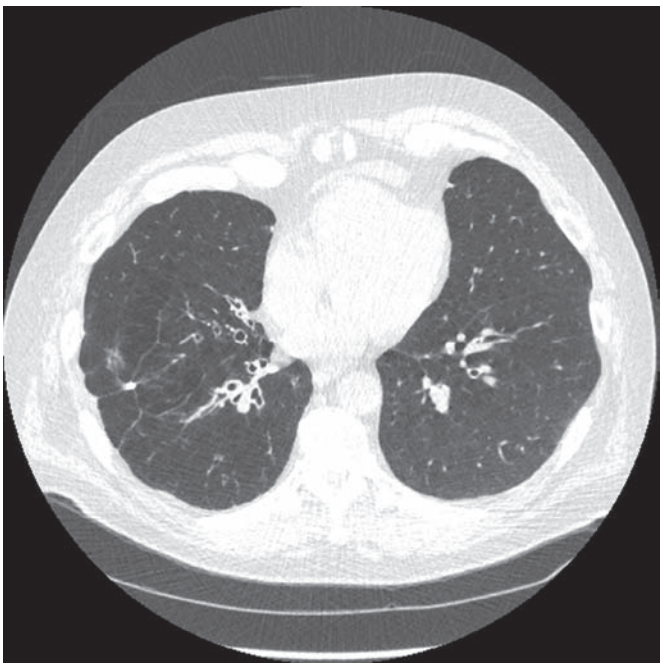
A



B



C



D

Figure 52-3 **A.** Chest radiograph demonstrating a right lower lobe bulla. Note the demarcating lines, or "hairline shadows" *(arrows)*. **B.** CT image of the lungs demonstrating the right lower lobe bulla with compressed lung *(arrow)*. **C.** Perfusion scintigraphy demonstrating decreased perfusion to the right lower lung zone. **D.** CT image of the lung following surgical resection of the right lower lobe bulla.

These observations are consistent with the hypothesis that peripheral airspaces in paraseptal emphysema may coalesce to form larger bullae that may crowd normal adjacent lung. In addition, CT has shown that when bullae occur in the context of generalized emphysema, the extent of bullous emphysema correlates poorly with measurements of pulmonary function, and that the main determinant of respiratory function is the severity of emphysema in the bullous-free parts of the lung.[23]

On chest CT, giant bullae are predominantly located in the upper lobes and are generally subpleural.[12] However, in patients with α_1-antitrypsin deficiency, bullae are most commonly located at the lung bases. Approximately half of the patients have bilateral bullae (Fig. 52-4), and, occasionally, deviation of the mediastinal structures to the contralateral side may be noted.[12] CT has been used to create three-dimensional reconstructions of bullae, which can then be used to calculate bullae volumes (Fig. 52-5).

Nuclear Imaging

Lung scanning using radionuclide-based techniques may provide useful preoperative information in evaluating patients with bullous lung disease.[24] A lung perfusion scan provides a semiquantitative assessment of regional blood flow (Fig. 52-3C); results of ventilation

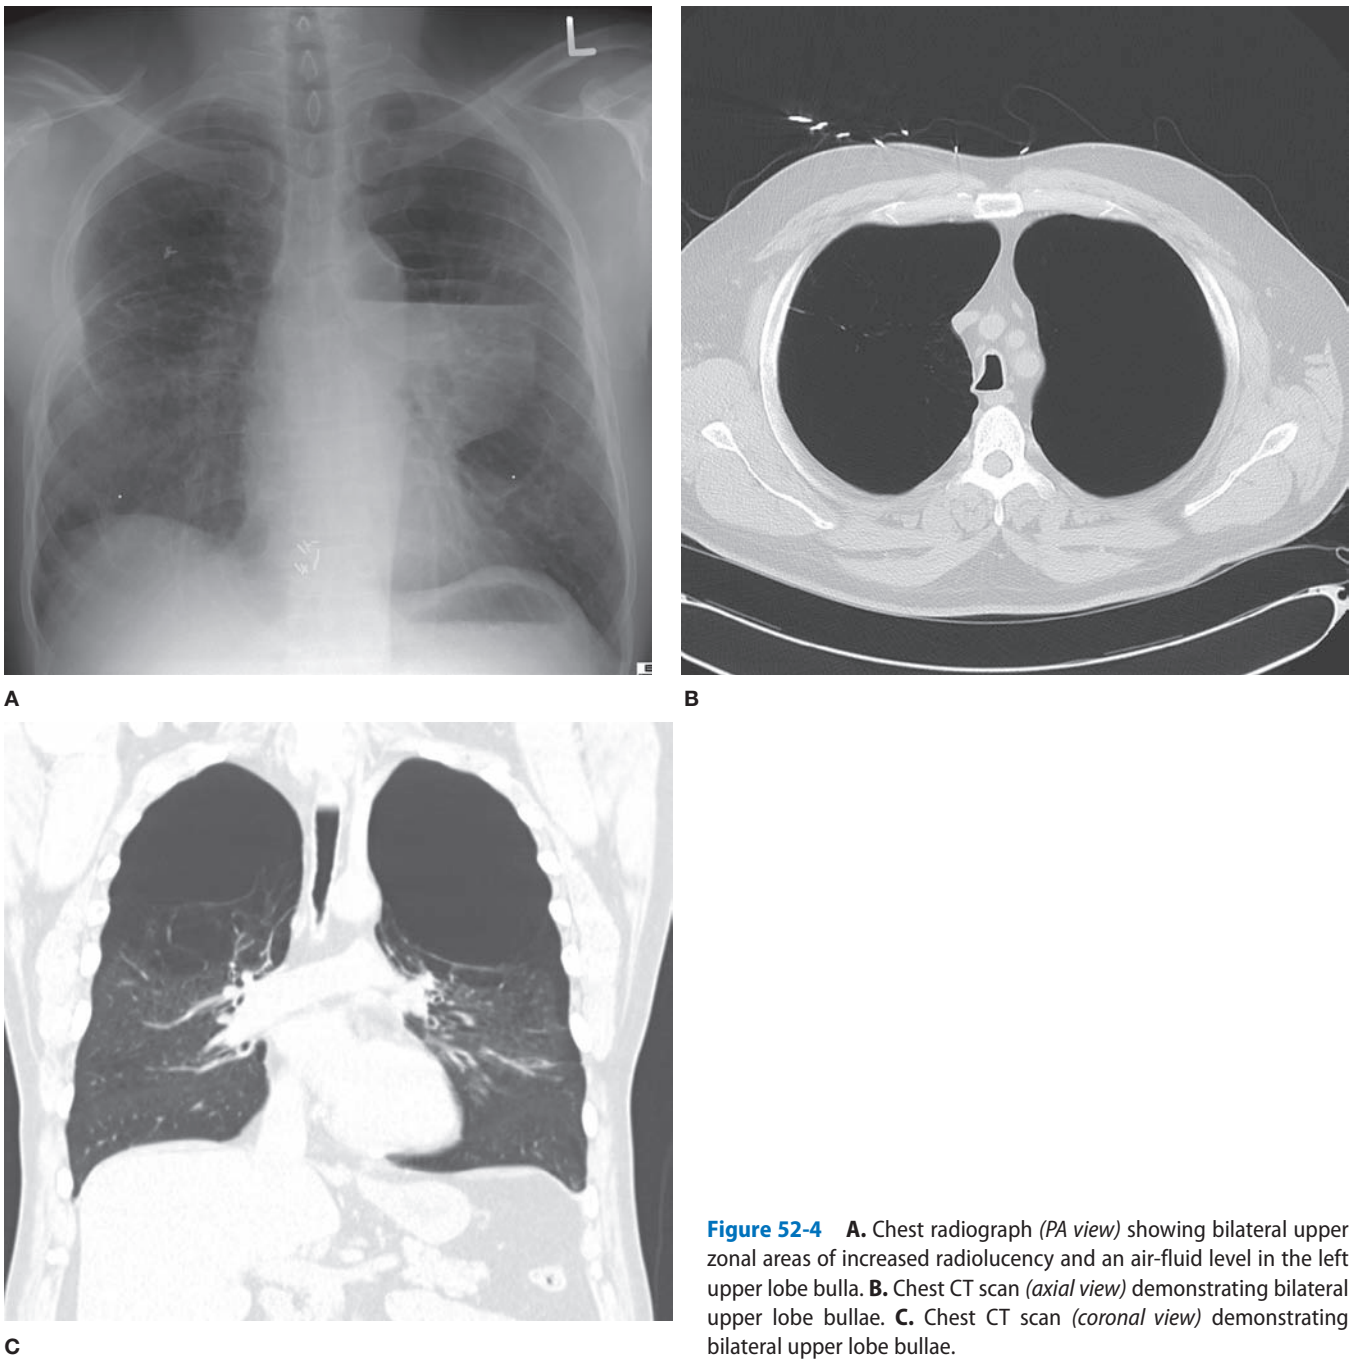


Figure 52-4 **A.** Chest radiograph *(PA view)* showing bilateral upper zonal areas of increased radiolucency and an air-fluid level in the left upper lobe bulla. **B.** Chest CT scan *(axial view)* demonstrating bilateral upper lobe bullae. **C.** Chest CT scan *(coronal view)* demonstrating bilateral upper lobe bullae.

scans vary with the technique. A single-breath scan using ^{133}xenon often fails to demonstrate ventilation of a bulla, whereas a continuous ventilation scan often shows slow filling and emptying of the structure.[24,25] Complete lack of communication between the airways and bulla is reflected in the absence of filling during all phases of the continuous ventilation scan.

■ PULMONARY PHYSIOLOGY

Clinical evaluation of bullous lung disease is aided by assessment of pulmonary function, pulmonary mechanics, exercise performance, and the pulmonary circulation.

Pulmonary Function Tests

Pulmonary function tests have considerable practical value in distinguishing between individuals with localized bullae in whom intervening lung is normal (bullous disease), and those in whom localized bullae are part of obstructive airways disease (bullous emphysema) (Table 52-4).[12] The distinction is important, since those with obstructive airways disease are generally poor surgical candidates because of impaired pulmonary function.

In individuals with bullous disease, the volume of air in the lungs can be estimated using plain radiography, CT, body plethysmography, or other pulmonary function test methods for determining lung volume, including closed circuit (helium dilution) and open circuit (nitrogen washout) techniques.[12,15] The volume of air trapped in a bulla can be determined as the difference between the functional residual capacities determined plethysmographically and by open or closed circuit methods (Table 52-4). This difference is due to the relative inability of the inert gas used in the circuit methods to enter the bulla.

Pulmonary Mechanics

Distinction between widespread obstructive airways disease with concomitant bullae and bullous lung disease has practical

TABLE 52-3 Potential Indications and Contraindications for Classical Bullectomy[a]

Parameter	Indications	Contraindications
Clinical	Young age (<50 y)	Age >50 y
	Rapid progressive dyspnea despite maximal medical therapy	Comorbid illness
	Ex-smoker	Cardiac disease
		Pulmonary hypertension
		>10% weight loss
		Frequent respiratory infections—chronic bronchitis
		Ongoing tobacco use
Physiologic	Normal or slightly ↓ FVC	FEV_1 <35% predicted
	FEV_1 >40% predicted	"Low" trapped gas volume
	Little bronchoreversibility	Decreased D_{LCO}
	"High" trapped lung volume	
	Normal or near-normal D_{LCO}	
	Normal Pa_{O_2} and Pa_{CO_2}	
Imaging	*CXR*—bulla >1/3 hemithorax	*CXR*—vanishing lung syndrome
	CT—large and localized bulla with vascular crowding and normal, compressed pulmonary parenchyma around bulla	Poorly defined bullae
		CT—multiple ill-defined bullae in underlying lung
	Angiography—vascular crowding with preserved distal vascular branching	*Angiography*—vague bullae; disrupted vasculature elsewhere
	Isotope scan—well-localized matching defect with normal uptake and washout for underlying lung	*Isotope scan*—absence of target zones, poor washout in remaining lung

[a]*Data from www.thoracic.org/copd.*

significance, since surgical lung resection in generalized emphysema offers a less certain therapeutic response than does resection of giant bullae in the absence of widespread obstructive lung disease (Table 52-3).[12] As large bullae expand, they initially cause relaxation of adjacent elastic lung tissue; with continued expansion, adjacent lung is compressed. Relaxation of the surrounding pulmonary parenchyma results in a decrease in radial traction on airways, thereby increasing airflow resistance. The effects of bullectomy on respiratory mechanics are inconsistent. Generally, resection of a large bulla increases lung static elastic recoil (by allowing for decompression of elastic lung parenchyma) and decreases airways resistance.

The diffusing capacity (D_{LCO}), rather than lung elastic recoil, is usually determined to aid in distinguishing between widespread emphysema and localized bullae, as more widespread loss of alveolar surface area in emphysema reduces the D_{LCO}; indeed, the D_{LCO} correlates better with morphologic estimates of emphysema than do most other tests.[12,15] Although the combination of a decreased D_{LCO} and reduced static elastic recoil pressure favors the diagnosis of widespread emphysema rather than localized bullae, both measurements may also be decreased by bullae that compress adjacent normal lung (Table 52-3).[3] Respiratory muscle strength, assessed by measurements of maximal inspiratory and transdiaphragmatic pressures, improves after bullectomy in some patients with bullous emphysema.[26]

Exercise Testing

In patients with a few circumscribed bullae and otherwise normal lungs, exercise testing reveals that the alveolar–arterial difference in Pa_{O_2}, ratio of dead space to tidal volume, D_{LCO}, and arterial oxygenation remain normal or near normal with exercise.[11] On the other hand, in patients in whom bullae are associated with panacinar emphysema, the alveolar–arterial difference in Pa_{O_2} is widened at rest and during exercise.[27] The latter group of patients also may develop arterial hypoxemia during exercise. The Pa_{O_2} tends to hover around the upper limit of normal at rest and during exercise, and the ratio of dead space to tidal volume is higher than in patients with normal intervening lung. The steady-state D_{LCO} is also reduced and fails to increase normally during exercise.

Patients in whom bullae are associated with chronic bronchitis also show a widened alveolar–arterial difference in Pa_{O_2} and an increase in the ratio of dead space to tidal volume at rest. However, in these patients the decrease in Pa_{O_2} during exercise is modest, even though the Pa_{O_2} at rest is abnormally high and increases further during exercise (indicating progressive alveolar hypoventilation).[2]

Pulmonary Circulation

In general, resting pulmonary arterial pressure and blood flow are within normal limits in patients with bullous lung disease (i.e., the bullae act like "amputated" segments of lung); the volume of the vascular bed available for recruitment as cardiac output increases is limited.[1,2] However, in patients in whom bullous disease has severely reduced the extent of the pulmonary vascular bed, pulmonary arterial pressure may be elevated at rest and during exercise; in a few instances, pulmonary and cor pulmonale may be observed.[1,2] Exercise in bullous lung disease is generally associated with an excessive increase in pulmonary arterial pressure as increases in pulmonary blood flow are not effectively accommodated by the restricted vascular bed.[2] Underlying pulmonary disease further exaggerates the increase in pulmonary artery pressure during exercise.

COMPLICATIONS

The major complications of bullous lung disease are fluid accumulation (including infection) in the bulla, spontaneous pneumothorax, bronchogenic cancer, chest pain, and hemoptysis.

■ FLUID ACCUMULATION

The determination that an air–fluid level is within a bulla and not in a newly formed cyst or cavity is generally based on the new appearance of fluid in a previously known bulla or the presence of other bullae (Fig. 52-6).[12] CT of the chest is indicated to assure that the air–fluid level is within a bulla and to identify any surrounding pneumonia, adjacent pulmonary nodule, or an increase in wall thickness of the bulla. The latter aids in differentiating an air–fluid level within a bulla from other disorders such as tuberculosis, fungal disease, lung abscess, or cavitary bronchogenic lung cancer. These processes typically have substantially thicker cavity walls.

The presence of a fluid level within a bulla, especially if the bulla is located subpleurally, occasionally prompts the mistaken diagnosis of a loculated hydropneumothorax. CT is helpful in separating these two conditions.

Benign, Sterile Bullous Fluid

Benign, sterile fluid accumulations in a bulla can result from adjacent pneumonia or from poorly functioning bronchial communications with inadequate drainage of normally accumulating fluid.[28] In asymptomatic patients who have a thin-walled bulla without

chest CT evidence of an adjacent pneumonitis or nodule, continued observation without specific therapy is appropriate.[4] Close radiologic evaluation is typically performed at 6- to 12-week intervals to ensure that an infection or bronchogenic carcinoma is not present. In patients with clinical and radiographic evidence of adjacent pneumonia antibiotic therapy is indicated.[29] The air–fluid level may persist for weeks to months after resolution of active infection.

Infected Bulla

A superinfection within a bulla can occur with clinical manifestations including fever, cough, purulent sputum production, dyspnea, and pleuritic chest pain. Laboratory findings may include leukocytosis and positive sputum cultures. When clinical and radiographic findings suggest an infected bulla, empiric antibiotics should be initiated based on a regimen similar to that used for community-acquired pneumonia in a patient with COPD.[4,12] Bacterial species that have been identified from infected bullae include methicillin-resistant *Staphylococcus aureus* (MRSA), Bacteroides, *Pseudomonas aeruginosa*, and mycobacteria.[30–32] Treatment is sometimes prolonged and may require parenteral or intrabulla administration, since poor drainage of the bulla inevitably slows resolution of the disease process.[33] The course of the infection should be followed by interval chest radiographs, in part as bulla infection has been associated with bronchogenic cancer.[34] If a patient does not improve with empiric antibiotics percutaneous aspiration of bullous fluid can be performed under CT guidance to confirm the presence of infection and to identify the antibiotic sensitivities of the infecting organism.[4,30] It should be recognized that percutaneous aspiration carries an increased risk of pneumothorax and empyema.[12] Tube thoracostomy[35] and endoscopic drainage have also been utilized.[36]

■ PNEUMOTHORAX

Spontaneous pneumothorax may be a complication of paraseptal emphysema, particularly in patients who continue to smoke. The typical presentation is a sudden onset or worsening of dyspnea with or without pleuritic chest pain. Ultrastructural assessments suggest the possibility of air leaking through the wall of the bullae with sloughling of mesothelial cells,[37] while lung density measures suggest a valve like effect with air trapping.[38] A few case reports have described a pneumothorax occurring when a bronchogenic carcinoma eroded through the wall of a bulla.[39]

Tube thoracostomy drainage of pleural air is often required; this depends on the size of the pneumothorax and the degree of respiratory impairment.[12,40,41] Patients with ruptured bullae also tend to have prolonged air leaks, along with pleural and parenchymal infections. Subsequent management is directed at preventing recurrence. For patients with a bulla and a secondary spontaneous pneumothorax, pleurodesis using mechanical abrasion of the pleura via video-assisted thoracoscopic surgery (VATS) can be considered.[39,41,42] For patients with minimal surrounding diffuse emphysema, a bullectomy can be performed at the time of pleurodesis; for those with diffuse bullous emphysema, pleurodesis is often performed without bullectomy.[12]

■ BRONCHOGENIC CANCER

Primary lung cancer has been reported to be associated with bullous lung disease.[43–46] Presenting manifestations include pneumothorax and hemoptysis.[46] The increased incidence of lung cancer may be due to the fact that lung cancer occurs more frequently in fibrotic lungs that are, themselves, predisposed to development of bullae.[1] Other explanations for the increased incidence of malignancy include dystrophic changes in lung parenchyma caused by bullous disease or persistence of carcinogens in poorly ventilated bullae.[1] The CT appearances for bronchogenic cancer complicating bullae include a nodule or mass extruding from the wall of the bulla, a nodule or mass confined within the lumen, a soft tissue density thickening the wall of the bulla, a pneumothorax, and an air–fluid level.[37,47–50]

■ CHEST PAIN AND HEMOPTYSIS

Chest pain may occur with a bulla and is attributed to overdistention of the structure.[12] The pain is angina-like and located retrosternally. The symptom is sometimes so severe as to constitute an indication for surgical intervention. Hemoptysis, which is occasionally massive, can result from rupture of blood vessels within the walls of bullae.[51]

TREATMENT

Many patients with bullous lung disease can be managed medically.[52] Because the natural history of a bulla is unpredictable, patients with bullous disease should be monitored by chest radiography at regular intervals to ensure that the disease is stable. Occasionally, bullae enlarge suddenly and rapidly for no apparent reason; alternatively, they may shrink or disappear.[50,53,54]

■ MEDICAL MANAGEMENT

The finding of a bulla in an asymptomatic patient calls for reassurance, a recommendation for annual chest radiography, advice to stop smoking, and an alert to the need for a prompt visit to a physician should symptoms develop. Activities that promote rupture of bullae (e.g., contact sports and scuba diving) should be proscribed.[1,14] Chronic bronchitis, asthma, or emphysema associated with bullae require treatment in their own right. For patients with α_1-antitrypsin deficiency augmentation therapy with antiproteases may be appropriate.[14] Endobronchial therapy with endobronchial valves (see Chapter 36) has been recently reported.[55–57]

■ SURGICAL MANAGEMENT

Although randomized trials of giant bullectomy have not been performed, the potential benefits of elective bullectomy have been described in a number of case series.[15,58,59] In general, significant symptomatic and functional improvements have been reported for 5 or more years in 60% to 90% of patients.[15,58,59] Patients with diffuse emphysema tend to deteriorate faster than patients without diffuse emphysema.[59] A systematic review of bullectomy reported that hypoxemia was more likely to improve compared with spirometric parameters or D_{LCO}.[59] Patients with radiographic evidence of compressed lung were the most to likely experience improved oxygenation.[59] Perioperative mortality ranges from 0% to 7% for bullectomy via open thoracotomy; patients with diffuse emphysema seem to experience a higher mortality rate.[59] Causes of death include pneumonia, respiratory failure, pulmonary embolism, and cardiovascular complications.

■ INDICATIONS

The most common indication for bullectomy is severe dyspnea due to a bulla occupying 30% or more of the hemithorax or spontaneous secondary pneumothorax.[22,60,61] A key challenge for the clinician is selecting the optimal patient for bullectomy. A key factor suggesting that bullectomy may be beneficial is a bulla that occupies greater than 50% of the hemithorax with radiographic evidence that the bulla is compressing adjacent normal pulmonary parenchyma (Table 52-3; Fig. 52-3A,B).[15,58] An overall enumeration of criteria reported to define patients who are most likely to benefit from bullectomy is presented in Table 52-3.

As noted in Table 52-3 physiologic data have been reported to provide valuable information in guiding the decision to perform bullectomy. The majority of patients who undergo bullectomy have an FEV_1 less than 80% predicted but greater than or equal to 40% predicted; these thresholds have been supported by case series.[60]

Similarly, patients likely to benefit have physiologic evidence of air trapping (e.g., total lung capacity [TLC] >100% predicted, residual volume [RV] >150% predicted).[62] Some have suggested that the difference in lung volume measured by body plethysmography versus helium dilution techniques can be compared to estimate the volume of nonventilated lung. A larger nonventilated volume suggests a more favorable response to bullectomy.[15,58]

CONTRAINDICATIONS

As noted in Table 52-3 features associated with a less favorable result following bullectomy include older age, ongoing cigarette smoking, significant comorbid disease, lower pulmonary function (FEV_1 and D_{LCO}), hypercapnia, poorly defined bullae on chest imaging, and pulmonary hypertension.[59,60,62–68] Similarly, patients with chronic sputum production or frequent lung infections have been suggested to be less likely to improve.[58,59]

PREOPERATIVE EVALUATION AND MANAGEMENT

The preoperative evaluation for bullectomy includes pulmonary function testing and imaging as noted earlier. Underlying COPD should be treated aggressively with an appropriate combination of inhaled medications and pulmonary rehabilitation.[58] Preoperative cardiac evaluation is appropriate given the increased risk of cardiovascular comorbidity among patients with COPD.[69]

ANESTHETIC MANAGEMENT

Standard monitoring during the procedure includes blood pressure, pulse oximetry, capnography, core temperature, and continuous electrocardiography.[70] Arterial and central venous pressure monitoring are not mandatory but frequently utilized.[58] Bullectomy is typically performed under general anesthesia.[70] Short-acting anesthetic agents are preferred over longer-acting agents to facilitate early extubation.[70] Intravenous agents are typically used for induction of anesthesia, as severe bullous disease may make the uptake and distribution of inhalational agents erratic.[70] A thoracic epidural catheter is usually placed for administration of epidural anesthetic agents during and/or after surgery.[70]

After anesthetic induction, appropriate positioning, and sterile draping, an endotracheal tube that allows isolation of ventilation to one lung is placed to administer single lung ventilation to the nonoperative lung and to enable deflation of the operative lung.[70] Immediately postoperatively patients are assessed for anemia, cardiac ischemia, electrolyte abnormalities, hypercapnia, hypoxemia, and inadequate lung reexpansion.[70] If these factors are acceptable, the patient may be extubated; in the majority of cases this occurs in the operating room.[71]

OPERATIVE APPROACH AND TECHNIQUES

Although many surgeons prefer an open approach for bullectomy there is increasing application of VATS techniques.[62,72–74] When an open thoracotomy is performed, the posterolateral approach is generally used for unilateral bullous disease, while median sternotomy is often utilized for resection of bilateral bullae.[62] The amount of lung resected in addition to the main bulla is dependent on a balance between removing diseased tissue to optimize reexpansion of compressed tissue while avoiding resecting healthy lung tissue and minimizing prolonged air leak around the suture line.[22,59] For a single bulla that is well-demarcated and has a clear, narrow pedicle, a simple stapled excision is adequate. When the bulla is broad based or when numerous bullae merge indistinctly, a broad stapled wedge resection is usually necessary.[71] Lobectomy and segmentectomy may be utilized in unusual settings.[61,62,75]

Ablation or excision of bullae can be achieved by a variety of surgical methods, including plication, laser ablation, and excision with a stapler.[22,58] The latter is the most frequently utilized. Numerous approaches are utilized to minimize postoperative air leaks, including applying exogenous materials to buttress staple sutures (e.g., bovine pericardial or polytetrafluoroethylene strips), fibrin sealant to areas of air leak intraoperatively, and creating a "pleural tent."[76–80] The Brompton technique, or modified Monaldi procedure, utilizes a limited thoracotomy to visualize the bulla, insufflation of the bulla with iodized talc, and drainage of the bulla for several days with a Foley catheter under water seal.[66,81,82] Talc is subsequently instilled into the pleural cavity to achieve pleurodesis.

The postoperative approach includes careful attention to respiratory status, pain control, minimizing bronchoconstriction and hyperinflation, monitoring for development or worsening of a pneumothorax, and prevention of thromboembolic disease.[58] Attention to the proper function of chest tubes is key to minimize the negative implications of pneumothorax. Thoracostomy tubes are generally left in place until the lung is fully expanded and there is no evidence of air leak. In those patients with persistent slow air leaks a minichest tube with a unidirectional flutter valve (e.g., Heimlich valve) can be used to facilitate discharge of the patient. The management of postoperative pain to ensure early mobilization of the patient and effective cough is crucial to minimize complications.[71]

SUMMARY

Recognition of bullous lung disease and its causes, classification, and underlying pathophysiology have important clinical implications. Careful clinical, radiographic, and physiologic assessment allows identification of patients whose dyspnea may be substantially improved through a variety of medical, surgical, and bronchoscopic interventions.

CHAPTER 53
Bronchiectasis

Alan F. Barker
Steven L. Brody

Bronchiectasis (*broncos,* airways; *ectasia*, dilatation) is a morphologic term used to describe abnormal, irreversibly dilated and thick-walled bronchi. This is an anatomic definition that evolved from Laennec's original description in 1819 of ectatic bronchi in pathologic specimens. Bronchiectasis represents the end stage of a variety of pathologic processes that cause destruction of the bronchial wall and its surrounding supporting tissues. Etiologies include prior lung infection, systemic inflammatory disorders, and genetic disorders of host defense, however, bronchiectasis is considered to be idiopathic in up to half of the affected individuals. The clinical manifestations include chronic cough and copious mucopurulent expectoration.[1] Bronchiectasis shares many features with chronic bronchitis, including inflamed and easily collapsible airways, airflow obstruction on spirometry, and frequent exacerbations.

PREVALENCE

Bronchiectasis was a common disabling and fatal condition in the pre-antibiotic era and remains more common in medically underserved regions of the world. Overall, it is an important cause of suppurative lung disease with a significant impact on the quality of life of affected individuals and on the health system as patients utilize many medical care resources including frequent clinic visits, hospitalizations, diagnostic imaging such as high-resolution computed tomography scan (HRCT) of the chest and parenteral antibiotics.[2] In the United States, the overall prevalence has been estimated to be 52 per 100,000, but varies by age. In persons aged 18 to 34 years the prevalence is approximately 4.2 per 100,000 but in those who are 75 years old or it is estimated to be greater than 272 per 100,000. There are an estimated 110,000 affected individuals in the United States.[3] In most series, 60% of affected individuals are women. The incidence is higher in some ethnic groups living in isolated regions including the native peoples in Alaska, Maori populations in New Zealand and the Pacific, and Aboriginal groups in Central Australia. In North America and Europe, improved health care has decreased the incidence, thus bronchiectasis due to cystic fibrosis (CF) and other genetic diseases now significantly contribute to the fraction of affected adults.

PATHOPHYSIOLOGY

The pathogenesis of bronchiectasis is not known in many cases, and in others may vary with etiology, so that the pathophysiology often remains descriptive. Gross pathology reflects chronic changes so that initial changes of injury proposed to lead to initial airway obstruction are not often observed. The abnormal bronchial dilatation in bronchiectasis principally affects the medium-sized bronchi, but typically extends to the distal bronchi and bronchioles. On gross examination of surgically resected or autopsied lungs, the affected bronchi and bronchioles are so prominent as to be visible all the way to the pleural surface. These dilated and ectatic bronchi are commonly filled with purulent secretions. The affected bronchi show transmural inflammation, mucosal edema, cratering, ulceration, and neovascularization. The bronchial epithelium may show a polypoidal appearance due to underlying granuloma formation and lymphoid aggregates, ridging due to bronchial smooth muscle hypertrophy, and pitting due to the dilated bronchial mucus glands. Severe cases may show denudation of epithelial lining, with destruction of underlying elastic laminae, smooth muscle, and cartilage with fibrotic changes replacing these structures. Dilated and tortuous bronchial arteries may be seen secondary to the development of extensive bronchial-pulmonary anastomoses.

Microscopically, bronchiectasis is associated with airway epithelial remodeling characterized by mucus cell metaplasia, and decrease in ciliated cells. In other regions, cuboidal and squamous metaplasia predominate. Intense infiltration of the bronchial wall with neutrophils, lymphocytes, and monocytes is common. Hypertrophy of bronchial glands, and lymphoid hyperplasia are also seen.

Various explanations have been advanced for the phenomenon of bronchiectasis after bronchial obstruction. Following bronchial obstruction, airways proximal to the collapse are exposed to strong dilating forces caused by the difference in the atmospheric pressure in the bronchi and the negative pressure in the pleural space. Over time, these forces acting on weakened, inflamed airways may result in permanent and pathologic airway dilatation. The presence of surrounding lung fibrosis, atelectasis, and loss of lung volume leading to regional increases in local retractile lung forces may also play a role. Animal experiments suggest that obstruction may facilitate the development of bronchiectasis by interfering with bronchial clearance and promoting bacterial infection, bronchial wall inflammation, and weakening.

It has long been recognized that the pathologic changes are associated with chronic bacterial infection, independent of the initial cause of bronchiectasis. The concept of the "vicious cycle" of recurrent infectious and inflammatory insults proposed by Peter Cole et al.,[4] 37 years ago has largely been accepted. The cycle is initiated by an infection and an airway insult in a host at genetic risk. This vicious cycle theory proposed that chronic bacterial endobronchial infection and inflammation damage or destroy mucociliary defenses, leading to secretion stasis, which in turn propagates furthers bacterial infection, and increases airway inflammation and bronchial dilatation. Specific primary defects in innate host defense (e.g., IgG deficiency) have been identified as causative.[5] Furthermore, acute bacterial infection and chronic biofilm formation in the airways alone are not sufficient to produce true bronchiectasis. Impaired airway epithelial cell function, immune response, or other systemic inflammatory conditions resulting in insufficient airway clearance are additionally required. Once injury ensues, the appearance of *Pseudomonas aeruginosa* in the respiratory tract of bronchiectasis patients on a chronic or recurring basis has been associated with worsening airway clearance and airway obstruction, resulting in impaired health-related quality of life (HQOL) and worsened lung function.[6] This may be due to the ability of this organism to release virulent exotoxins, form biofilms on tissue surfaces, and easily develop hypermutable *P. aeruginosa* strains resistant to antibiotics, all factors perpetuating and propagating bronchial damage.

Specificity biochemical and molecular markers of non-CF bronchiectasis are not established and robust animal models of bronchiectasis have not been developed. Early biochemical changes are proposed related to infection and reflect a stereotyped host immune response. Later in disease, neutrophils, macrophages, and monocytes, along with their products are abundant. At both stages, cytokines such as tumor necrosis factor-a (TNF-a) and interleukin-8 may be elevated, providing a sustained signal for inflammatory cell recruitment.[7] Neutrophil- and macrophage-derived elastases and proteases isolated in large quantities in sputum have been proposed to contribute to airway injury and subsequent chronic bronchiectasis pathology.[8]

CLINICAL FEATURES

The classic clinical manifestations of bronchiectasis are daily cough and mucopurulent sputum production. Cough is invariably present and often may be the only symptom for years. Purulent, tenacious sputum production, frequently worse in the morning (having accumulated during recumbency in sleep) is present in most patients. Sputum production may be intermittent, being affected by recurrent infections, bronchial plugging, and antibiotic therapy. "Dry bronchiectasis" presenting as cough, minimal sputum expectoration, and/or hemoptysis is occasionally described. Hemoptysis may be seen in 40% to 70% of patients and may vary from blood streaks to large clots. Increasing cough, dyspnea, and volume and darkening of sputum color, fever, hemoptysis, and chest pain are hallmarks of acute exacerbations. Often patients give a history of recurrent chest infections, although single episodes of severe pneumonia, tuberculosis, or pertussis with secondary pneumonia may also result in bronchiectasis.

On physical examination chest auscultation usually reveals findings of early and midinspiratory crackles as well as diffuse rhonchi and prolonged expiration. Bronchial breath sounds may be heard in severe cases or patients with a complicating pneumonia. Digital clubbing and hypertrophic pulmonary osteoarthropathy, although common in the pre-antibiotic era, are rarely seen now. In advanced cases, there may be evidence of respiratory insufficiency and cor pulmonale.[9]

PREDISPOSING OR ASSOCIATED CONDITIONS

Previously bronchial damage secondary to childhood respiratory tract infections such as pneumonia, pertussis, complicated measles, and tuberculosis were implicated as common causes of bronchiectasis. However, with the early use of antibiotics and childhood immunizations, the focus has shifted from postinfectious to intrinsic host defense causes. Often regarded as a condition in which extensive investigation is unlikely to yield treatable causes, recent studies have shown results to the contrary (Table 53-1). Most series from referral centers identified an association or contributing cause in approximately 50% of patients. Careful investigation and the identification of the genetic basis for immune and other disorders of innate airway defense have reduced the number of idiopathic cases and increased the number of individuals that may considered for specific therapy. The overall impact of these efforts is a bimodal distribution in the age of adult patients with bronchiectasis composed of those with genetic causes first presenting in childhood and an elderly population, typically composing the idiopathic group.

INFECTION

A number of pulmonary infections have been associated with the development of bronchiectasis. Complicating secondary infections with adenovirus, herpesvirus, and bacteria such as *Staphylococcus aureus*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa* contribute to the severity of a necrotizing bronchopneumonia. *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella* infections typically do not cause bronchiectasis, but may be chronically present within bronchiectatic airways. Necrotizing pneumonias secondary to chronic aspiration or bronchial obstruction are often complicated by parenchymal destruction and bronchiectasis. Tuberculosis can result in bronchiectasis by several mechanisms. Bronchiectasis may be a consequence of tuberculous bronchitis, postobstructive bronchial damage secondary to posttuberculous bronchial wall stenosis, and extraluminal bronchial obstruction by enlarged tuberculous lymph nodes.

The association of nontuberculous *Mycobacterium (NTM)* with bronchiectasis is well documented. CT scan of the chest in such cases is relatively specific, showing small irregular nodules in the middle lobe or lingula, but other parts of the lung may be affected. While traditionally considered a secondary pathogen in an abnormal host or a colonizer in damaged lungs (bullous emphysema, cavitary lung disease) it is now recognized that NTM can cause bronchiectasis in apparently normal hosts. A recent study of individuals with idiopathic bronchiectasis infected with NTM demonstrated shared features with primary ciliary dyskinesia (PCD) (slow cilia beat frequency, low nasal nitric oxide) suggesting the presence of either an underlying genetic or acquired defect.[14] One phenotype for NTM-associated bronchiectasis seems to involve predominantly slender white women 50 to 70 years old with kyphoscoliosis. An underlying primary lung disease or immune defect has not been identified in this subpopulation.[15]

BRONCHIAL OBSTRUCTION

Localized bronchiectasis may also been seen in middle-lobe syndrome, and is usually caused by intraluminal or extraluminal obstruction

secondary to tumor, enlarged lymph nodes, or abnormalities of bronchial structure and branching. Endobronchial adenomas, fibromas, chondromas, and lower respiratory tract papillomatosis causing partial airway obstruction and bronchiectasis have been described.

■ ASPIRATION/INHALATION AIRWAY INJURY

Aspiration or inhalation of foreign matter, such as noxious fumes or particulates into the airways, may result in bronchiectasis. This may involve aspiration of oropharyngeal secretions containing microaerophilic and anaerobic bacteria, leading to a necrotizing pneumonia. Refluxed material from the esophagus or stomach containing food particles, gastric, biliary, and pancreatic secretions, and gut microbes may enter and damage airways, especially if the aspiration events are large and repeated. Depressed sensorium (stroke, alcohol and drug use, seizure, postanesthetic), neuronal or spinal cord dysfunction (amyotrophic lateral sclerosis, multiple sclerosis, syringomyelia), defective laryngeal function (postsurgery, postirradiation), esophageal disorders (dysmotility, achalasia, tracheoesophageal fistula), and gastric disorders (gastric outlet obstruction) influence the likelihood and frequency of aspiration. Bronchiectasis may present years after foreign body aspiration (aspiration is often unrecognized), although bronchiectasis has been seen to occur in animals as soon as 2 to 8 weeks after experimental foreign body introduction into the bronchial tree. GERD is the most common condition in this category contributing to the risk of bronchiectasis CCDC.

■ CYSTIC FIBROSIS

CF is a common cause of bronchiectasis in the United States and other developed countries (see Chapter 50). This is an autosomal recessive, monogenic disorder that presents most commonly in childhood as a multisystem disease. However, 3% to 7% of patients with CF are diagnosed in adulthood, and due to improvements in therapy, there are now more adults over 18 years old with CF than younger individuals. CF is caused by a genetic deficiency in the Cystic fibrosis transmembrane conductance regulator (CFTR). Approximately 2000 mutations in the CF gene have been identified. Clues suggesting CF as a cause of bronchiectasis include upper lobe radiographic involvement and sputum cultures showing mucoid *P. aeruginosa* or *S. aureus*. The diagnosis of CF rests on a combination of clinical criteria accompanied by sweat chloride values above 40 to 60 mmol/L. However, intermediate or normal sweat chloride values may be seen in patients with clinical manifestations of CF and genetically confirmed CF. Screening for other mutations in the CFTR gene may be necessary in these circumstances. Measurement of the electrical potential difference across the nasal epithelium, available in specialized centers, is sometimes used to corroborate the diagnosis.

■ PRIMARY CILIARY DYSKINESIA

PCD is a genetically heterogeneous syndrome caused by defect in motile cilia. The true prevalence is unknown but estimated to affect 1:20,000 to 1:100,000 people.[16] The tissue-specific location of cells with motile cilia reflects the clinical features including chronic otitis media, rhinosinusitis, bronchiectasis, infertility, and laterality defects including situs inversus. PCD has an autosomal-recessive inheritance pattern and has been ascribed to mutations in over 30 genes to date that are estimated to account for approximately 60% of all cases. The involvement of many genes in this syndrome is consistent with the knowledge that over 2000 proteins are involved with cilia assembly, structure and function. The ciliary axoneme contains nine outer and two inner pairs of microtubules that are connected to dynein motor proteins forming characteristic structures of motor complexes called inner and outer dynein arms that can be observed by transmission electron microscopy of preparations of cilia from respiratory epithelial cells. Known causative genes in PCD encode proteins for dynein motors (e.g., DNAI1, DNAI2, DNAH5, DNAH11), cilia motor regulation and structural assembly (e.g., RSPH4 A, RSPH9, CCDC39, CCDC40) and motor complex preassembly (e.g., DNAAF1, DNAAF2, HEATR2).[16]

In 1933 Kartagener described the PCD syndrome, as the triad of situs inversus, bronchiectasis, and either nasal polyps or recurrent sinusitis, while the description by Afzelius in 1976 of the defects in the ultrastructure of ciliary dynein arms revealed the basis of this condition.[17,18]Thus, clinical findings include, respiratory distress in neonates, recurrent respiratory tract infections, bronchiectasis, situs inversus, infertility, and heterotaxy in approximately 50%. Laterality defects are the result of motile cilia defects in the embryonic node, a midline structure transiently present during early development that contains cilia. Directional movement of fluid in the node activates downstream programs that establish left and right sidedness of organs. In the absence of flow, *situs solitus* (normal left-right), *situs inversus* (fully reversed right-left, functional organs), or intermediate states may occur resulting in cardiac defects. Thus, individuals with congenital heart disease may also have cilia dysfunction, complicating exacerbation of pulmonary disease in heart failure.[19] Hydrocephalus due to dysfunction of the motile cilia of the brain ventricles is exceedingly rare.

In a study of 94 patients from 68 families, Noone et al.[20] showed that cough was seen in 100% of patients, bronchiectasis (98%), sinusitis (47%), otitis media (92%), and situs inversus (46%). Although most patients with PCD are identified in childhood, this disorder may not be accurately diagnosed until adulthood. Like CF, bronchiectasis occurs in children and is progressive, however in contrast to CF, lung disease is not as severe and lifespan is usually normal.

Accurate testing for PCD is technically demanding and should be performed in specialized centers.[21] Nasal nitric oxide (NO) is emerging as the most sensitive screening test, with levels of NO being characteristically low, a feature that can be shared with CF.[20] Once CF is excluded (e.g., by sweat test), then nasal NO together with clinical features provides high specificity for diagnosis. Ciliated epithelial cells obtained from the inferior or middle turbinate using a sterile cytology brush may be studied for ciliary beat pattern and frequency using digital high-speed video imaging. This requires experienced observers. Abnormalities in ciliary beat have been correlated to ultrastructural defects, but normal ciliary motion cannot fully exclude PCD since some mutations are associated with near normal beat frequencies. Axonemal structure of respiratory cilia may be visualized by transmission electron microscopy and defects in dynein arms, peripheral and central tubules, radial spokes, and basal bodies may be seen. These studies are technically challenging and no structural abnormalities may be found in cases of PCD,[22] particularly when mutations involve regulatory proteins. Genetic testing is available in some research centers.

■ COPD AND BRONCHIECTASIS

Cigarette smoking causes COPD but is probably not an etiology for bronchiectasis although there is overlap in clinical characteristics that have prognostic and management implications. The phenotype includes frequent exacerbations requiring medical attention in an urgent care setting,[23] HRCT scans that have both emphysema and bronchiectasis portend a reduced prognosis,[24] obstructive impairment on pulmonary function, and sputum microbiology that contains *P. aeruginosa*.[6,25,26]

■ ALPHA-1 ANTITRYPSIN DEFICIENCY (AATD)

Unimpeded neutrophil elastase contributes to the alveolar destruction of emphysema in AATD. Abundant elastin in airways could also be subject to destruction. There may be a spectrum of disease with heterogeneous lung conditions rather than simply pure emphysema in patients with AATD. Small case series have identified

bronchiectatic changes in patients with AATD. Cuvelier et al. measured AAT alleles in patients with known bronchiectasis and healthy blood donors. They did not find any significant differences in AAT alleles between patients with bronchiectasis and control individuals except in those patients with both emphysema and bronchiectasis. There were more abnormal alpha-1 alleles in those patients with coexisting emphysema and bronchiectasis. They concluded that bronchiectasis might be a consequence of emphysema.[27] In a study of 74 patients by Parr et al. with AATD (PiZ phenotype), 70 out of 74 were found to have bronchiectasis on HRCT scan. They defined clinically significant bronchiectasis as patients with regular sputum production and HRCT findings of bronchiectasis affecting four or more lobes.[28] Fifty-seven patients had bronchiectasis in four or more bronchopulmonary segments. Twenty (27%) met the criteria for clinically significant bronchiectasis. In general, those with more severe bronchiectasis had more severe emphysema. Whether there is a common pathway that contributes to both emphysema and bronchiectasis in patients with AATD or whether emphysema predisposes to bronchiectasis is still unknown.[28]

■ ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

Allergic bronchopulmonary aspergillosis (ABPA) is a hypersensitivity lung disease caused by the ubiquitous fungus *Aspergillus fumigatus* and usually occurs as a complication of persistent asthma or CF. The excessive mucus production and impaired mucociliary clearance in these conditions allow the inhaled conidia of *Aspergillus* to persist and germinate, releasing exoproteases and other fungal products that further compromise clearance, breach epithelium, and activate immune responses. ABPA is characterized by a marked local and systemic eosinophilia, an elevated level of *A. fumigatus*—specific IgG and IgE antibodies, as well as a nonspecific elevation of total IgE. Clinically, ABPA manifests as difficult-to-control or recurring episodes of asthma, pulmonary infiltrates, and central bronchiectasis that may progress to fibrosis. Criteria have been established for the diagnosis of ABPA in the non-CF as well as the CF population.[29]

■ INFLAMMATORY DISORDERS

Inflammatory and fibrotic processes affecting large and small airways may be seen in several rheumatic diseases and autoimmune states. Significantly higher frequencies of bronchiectasis (20%–35%) have been found in *rheumatoid arthritis* (RA) patients undergoing HRCT, both in symptomatic (30%) and asymptomatic (8%) patients, and was independent of smoking status. Bronchiectasis may precede or follow the development of RA, and the coexistence of both conditions is considered to portend a reduced survival.[30] *Sjögren syndrome* may also be complicated by bronchiectasis presumed to be secondary to the effects of inspissated bronchial secretions causing atelectasis and bronchial wall destruction.[31] *Relapsing polychondritis* may be complicated by bronchiectasis in regions of recurring pneumonia as well as regions free of infection. It is not clear whether the chondritis itself or the recurrent infections predispose to bronchiectasis. Inflammatory bowel disease such as *chronic ulcerative colitis* is associated with bronchiectasis. The pathogenesis remains unknown, although autoimmune and immune complex deposition theories have been proposed. This variant of bronchiectasis does not respond to colectomy and has been known to appear and progress after colectomy. Bronchiectasis seen in sarcoidosis is usually traction bronchiectasis secondary to parenchymal and peribronchial fibrosis. Endobronchial sarcoid may result in localized bronchiectasis secondary to obstruction, atelectasis, and bronchial wall destruction.[32]

■ IMMUNE DEFICIENCIES

Bronchiectasis is associated with defects in both cellular and humoral immunity. Bronchiectasis is found in HIV and HTLV-1 infected individuals.[33] It is also associated with acquired immunodeficiencies associated with stem-cell transplant and chemotherapy.[5,12] Recurrent sinopulmonary infections and bronchiectasis are associated with defects in humoral immunity and hypogammaglobulinemia. Several forms of antibody deficiency have been linked with the development of bronchiectasis, including X-linked agammaglobulinemia, common variable immunodeficiency, IgA deficiency, and IgG subclass deficiency (usually IgG-G2 and IgG-G4).[34] The issue of subclass deficiency (in the presence of normal or near-normal levels of total IgG) as a cause of bronchiectasis is controversial due to the wide range of values in normal individuals and the difficulties involved in accurately measuring these levels. An immunizing challenge with common humoral bacterial antigens, such as capsular polysaccharides of *H. influenzae* and *S. pneumoniae* followed by measurement of antibody titers 4 to 6 weeks later, may help establish the presence of such a deficiency. The lack of an antibody response is suggestive that humoral deficiency is present.[35] Early diagnosis of these conditions and replacement with intravenous immunoglobulin significantly reduces infections and prevents bronchiectasis, although the efficacy of this treatment in patients with selective IgM, IgA, and IgG subclass deficiency remains controversial. Standard doses in adults of 300 mg/kg by intravenous infusion every 4 weeks have been proved to reduce rates and severity of respiratory infections, but higher doses of 600 mg/kg appear more efficacious in reducing respiratory exacerbations and preserving pulmonary function in some patients.[36] Hyper-IgE syndrome is accompanied by recurrent lower respiratory infections leading to bronchiectasis and cystic lung destruction. Respiratory infection with *Pseudomonas* is a contributor to mortality.[37]

DIAGNOSIS OF BRONCHIECTASIS

The diagnosis of bronchiectasis is based on history, clinical features, and radiologic demonstration of bronchiectatic airways. The diagnostic evaluation in these patients is largely aimed at identifying potentially treatable underlying causes of bronchiectasis (Table 53-2). After confirming the diagnosis with chest imaging, CBC with differential

TABLE 53-2 Clinical Approach to the Patient with Suspected Bronchiectasis

History	Recurrent lower and/or upper respiratory tract infections, pneumonia
	Daily mucopurulent sputum production
Initial studies	CBC with differential
	Chest x-ray
	Immunoglobulins IgG, IgM, IgA
	Sputum: bacterial culture and sensitivity, mycobacteria, fungi
Confirms diagnosis	Chest CT (non-contrast)
Other studies	Sweat chloride and/or genetic panel for CFTR alleles
	Allergic bronchopulmonary aspergillus panel (IgE, precipitins, or skin test)
	Bronchoscopy (for cultures, obstruction)
	Nasal nitric oxide
	Alpha-1 antitrypsin level; phenotype
	Pulmonary function (spirometry pre- and postbronchodilator)
	Serum antibody response to bacterial antigen challenge, e.g., pneumococcal vaccine

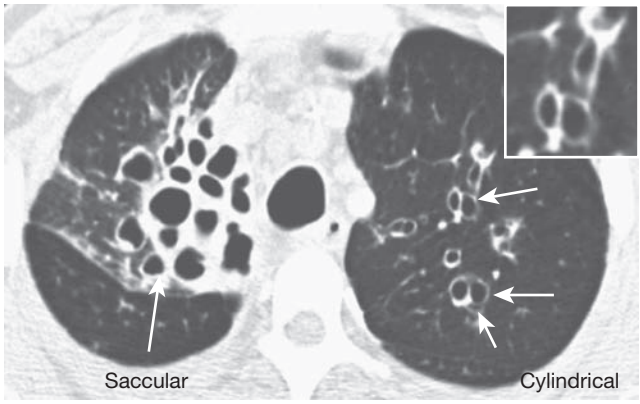

Figure 53-1 Chest computed tomography. *(Left chest) Cylindrical* bronchiectasis: dilated and thickened airways *(arrows and insert). (Right chest) Saccular* or cystic bronchiectasis: very dilated airways clustered into saccules, cysts, or grapelike clusters *(arrow)*.

for eosinophils, serum immunoglobulins IgG, IgA, and gM, sweat chloride or genetic CF testing, sputum culture for bacteria, mycobacteria, and fungi are productive starting tests. Subsequent testing will depend on clues from the history and likelihood of other conditions.

CHEST RADIOGRAPH

The chest x-ray may be abnormal and show the presence of increased pulmonary markings, ring-like structures, atelectasis, dilated and thickened airways (tram lines), and mucus plugging (finger-in-glove) appearance; however, the chest radiograph may be normal even in the presence of bronchiectasis.

HIGH-RESOLUTION COMPUTED TOMOGRAPHY

HRCT is now the defining test for the diagnosis of bronchiectasis. HRCT can accurately diagnose bronchiectasis, localize, and describe areas of parenchymal abnormality, and identify bronchiolar abnormalities and mucus plugging. It also can identify focal areas of air trapping as an indicator of small airway disease (mosaic attenuation).

Airway dilatation can be gauged when seen in cross section. A luminal diameter more than 1.5 times the adjacent vessel is indicative of bronchiectasis (Figs. 53-1 and 53-2). Other findings include bronchial wall thickening and small airway plugging with debris (tree-in-bud) (Figs. 53-2 and 53-3). The distribution and pattern of

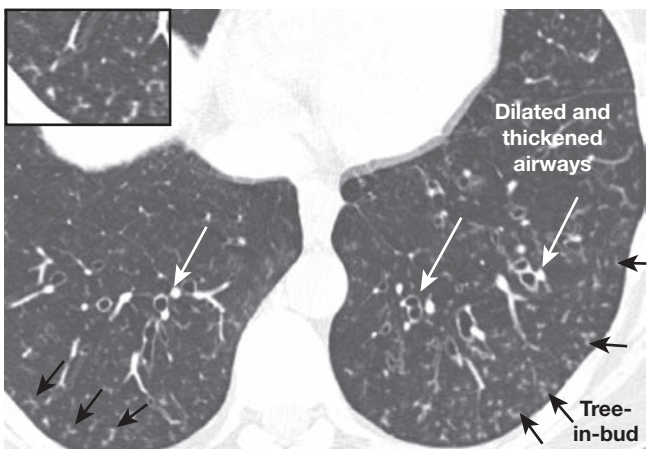

Figure 53-2 Chest computed tomography. Extensive peripheral branching opacities of tree-in-bud *(black arrows)*. Dilated and thickened airways *(white arrows)*.

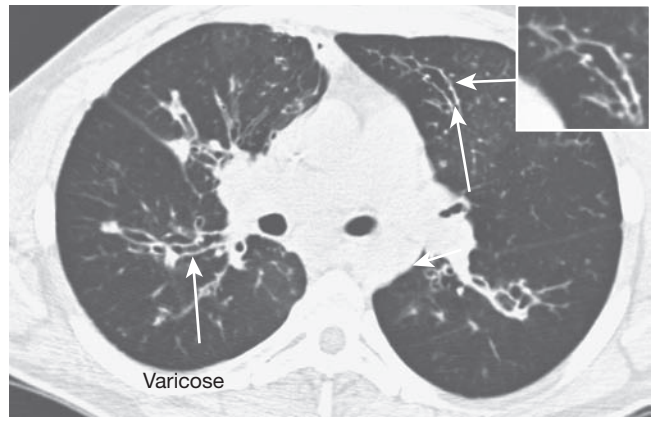

Figure 53-3 Chest computed tomography shows *varicose* bronchiectasis: dilated airways with irregular thickened mucosa *(arrows)*.

bronchiectasis may implicate a specific cause. Cartier et al.[38] found that bilateral predominantly upper lobe bronchiectasis is seen most commonly in CF, ABPA, and sequelae of tuberculosis. A middle-lobe distribution with irregular ground glass nodules is very characteristic of NTM.[15] A lower lobe predominance is seen in most other causes. HRCT scoring systems for CF have been developed to identify disease at an early stage, grade severity, monitor disease progression, and utilize as endpoints in clinical trials. With similar CT findings in bronchiectasis, these scoring systems may be applicable for non-CF bronchiectasis.[39] PCD children have been assessed with one of these scoring systems and correlated with pulmonary function and compared to age and gender-matched CF children and adults.[40]

Bronchiectasis may be classified by pathologic features and radiographic appearance. Reid[41] described a correlation between pathologic and bronchographic findings in bronchiectasis; since then, this has been the most widely used classification. In *cylindrical* bronchiectasis, the bronchi are regularly outlined (tubular), dilated in diameter, with straight walls, often coming to a straight abrupt end instead of a tapering end due to obstruction of the peripheral bronchial tree by secretions, casts, and inflammatory wall edema. *Varicose* bronchiectasis (illusion to varicose veins) is marked by the presence of irregular dilatations, outpouchings, and tortuosity of the airways. *Saccular* (cystic) bronchiectasis is characterized by the presence of cystic distortion of the distal airways that may be focal or more generalized, resulting in saccules that appear as a cluster of grapes (Fig. 53-1 *arrows and inset*). Traction bronchiectasis, a term used to describe the dilated airways seen in diffuse pulmonary fibrosis secondary to fibrous tissue traction and elevated negative intrathoracic pressure, should be distinguished from usual bronchiectasis, because of the lack of intrinsic airway pathology and paucity of sputum expectoration. Congenital bronchial cysts (central and peripheral) are developmentally abnormal cystic bronchial structures, often filled with mucus and lined with respiratory epithelium. While usually lacking connection with the parent bronchus and distal alveoli, if infected they may communicate and mimic localized bronchiectasis. Intralobar bronchopulmonary sequestration too may become infected and communicate with the bronchial tree, mimicking localized bronchiectasis.

PULMONARY FUNCTION

Pulmonary function is usually abnormal. The degree of impairment depends not only on the nature and extent of the morphologic abnormalities of bronchiectasis, but also on the presence or absence of associated COPD. Thus, patients with mild localized bronchiectasis and no chronic bronchitis may have normal lung function tests. Spirometry will often show a pattern of airflow obstruction, with normal or reduced forced vital capacity (FVC), reduced forced

expiratory volume in 1 second (FEV_1), and reduced FEV_1/FVC ratio. In some patients with accompanying atelectasis and/or parenchymal and pleural scarring, restrictive or mixed/obstructive and restrictive physiology may be seen with reduced FVC and normal FEV_1/FVC ratios. The Lung Clearance Index (LCI; multiple breath nitrogen washout) is another method to detect airflow obstruction. The LCI has been used to detect early airflow obstruction in CF and may be more sensitive than changes in spirometry. In bronchiectasis the LCI is reproducible and correlates better with abnormalities on chest CT than FEV1.[42]The diffusing capacity for carbon monoxide is initially normal but may decrease with progressive disease. Impaired oxygenation is highly variable, most likely due to heterogeneity among patients in anatomic disease distribution.

MICROBIOLOGY

The sputum of patients with bronchiectasis is frequently found to be colonized with potentially pathogenic microorganisms (Table 53-3). The most frequent microorganisms isolated are *H. influenzae*, *S. pneumoniae*, and *P. aeruginosa* and are often implicated as the cause of exacerbations. Sequencing of lung microbiota in patients with bronchiectasis demonstrates both diversity of communities and a predominance of *Haemophilus*, *Pseudomonas*, and *Streptococci* in stable patients and during exacerbations.[43,44] Colonization with *P. aeruginosa*, in particular, has been associated with more severe impairment of lung function, more intense inflammatory response, and more extensive lung disease independent of the cause of bronchiectasis.[6] Instances of airway colonization with other potential pathogens that may require specific treatment include *Nocardia asteroides*, *A. fumigatus*, and nontuberculous mycobacteria. Anaerobic bacteria are identified in genomic surveys of airway microbiota of individuals with non-CF bronchiectasis; however, there is no direct implication for therapy.[43,44]

TREATMENT

The management of bronchiectasis is aimed at treating underlying conditions, controlling infection, reducing inflammation, improving bronchial hygiene, and surgical resection of focal bronchiectasis or severely affected segments or lobes. With few quality clinical trials for guidance, treatment often has to be tailored to the specific needs, tolerances, and preferences of individual patients.

CONTROL OF INFECTION

Since infection plays a major role in the causation and perpetuation of bronchiectasis, reducing the microbial load and associated inflammatory mediators remains a cornerstone of therapy. Antibiotics are indicated to treat an acute exacerbation. Antibiotics are directed at commonly isolated pathogens such as *H. influenzae* and *P. aeruginosa*. Oral fluoroquinolones are often used as initial antibiotic choices for treatment durations of 10 to 14 days. In the face of failure to respond to treatment or the occurrence of frequent exacerbations over short periods of time, sputum cultures and sensitivity tests should be performed to help define antibiotic selection and/or aid in alternative diagnoses, for example, atypical mycobacteria or fungus. Severe exacerbations due to *P. aeruginosa* require the intravenous administration of antipseudomonal antibiotics and potential hospitalization.

The role of prophylactic/suppressive antibiotics remains controversial. Several approaches to the prescription of suppressive antibiotics exist, including daily antibiotics, antibiotics given for 1 to 2 weeks each month, as well as more prolonged courses lasting weeks to months.

The use of daily, twice weekly, and thrice weekly macrolides (erythromycin, azithromycin) as biologic response modifiers in CF and diffuse panbronchiolitis has generated considerable interest regarding a role in the treatment of bronchiectasis. In the EMBRACE and BAT trials, azithromycin was associated with a decrease in exacerbations compared with placebo. However, no significant difference was noted in lung function.[11,46] In the BAT trial gastrointestinal intolerance and macrolide resistance was common. Similarly, in the BLESS study, erythromycin decreased the number of exacerbations and ameliorated the decline in lung function but with a consequential development of macrolide resistance.[47] Macrolides have been shown to have several biologic effects not related to their antibacterial properties. These include effects on nuclear transcription factors with downregulation of proinflammatory cytokines, suppression of iNOS, reduced adhesion molecule expression, reduced neutrophil chemotaxis and degranulation, cytoprotection against phospholipids, improvement in mucus rheology, reduction in bronchial hyperreactivity, effects on *Pseudomonas* biofilm production, and quorum sensing function.[48]

Administration of antibiotic aerosols (chiefly tobramycin 300 mg nebulized twice daily and aztreonam 75 mg three times daily) are effective in CF. Pilot studies of non-CF bronchiectasis have demonstrated a reduction in *Pseudomonas* density and even eradication of *Pseudomonas* in some patients, although side effects were also noticed, including increased cough, wheezing, dyspnea, tinnitus, voice alteration, and tobramycin resistance.[49] The effects of other aerosolized antibiotics, such as colistin, ciprofloxacin,[50]

and gentamicin[51] alone, or in rotation with tobramycin need to be assessed for efficacy and side effects.

NTM-associated bronchiectasis should be considered in patients not responding to antibacterial therapy. The diagnosis requires two or more separate expectorated sputum collections with positive cultures for NTM or one positive culture from a bronchial wash and radiologic evidence of progressive infiltrates, multiple nodules, or cavitation on chest imaging. American Thoracic Society guidelines provide treatment guidance for the individual NTM species.[52]

ABPA responds to oral prednisone in doses of 0.5 to 1 mg/kg per day. The addition of antifungal azoles (itraconazole 400 mg/day for 2 months; then 200 mg/day; or voriconazole 300 mg twice daily)[53] may confer additional benefits in terms of reducing fungal burden, steroid dose, and exacerbations. Early and appropriate therapy for ABPA may prevent or delay permanent airway destruction. Because of its relapsing course, monitoring of clinical, radiographic, and serologic responses (IgE) is necessary.

BRONCHIAL HYGIENE

Airway mucus clearance is a problem in bronchiectasis. Chest percussion and postural drainage have been the traditional method of facilitating mucus clearance. The onerous and labor-intensive nature of physical therapy procedures such as chest wall percussion and postural drainage, and potential issues of hypoxemia and chest discomfort may result in poor patient compliance. These issues have led to a search for alternative therapies. Autogenic drainage, mechanical vibration with ultrasonic devices, positive expiratory pressure, and flutter valve devices have been shown to achieve good airway clearance provided the patient has motivation, breath control, and the neuromuscular function to perform. An intrapulmonary percussive ventilation device and vibratory vest help provide mucus clearance in patients unable to perform the other techniques.[54] Studies document increased sputum expectoration using all these methods, with no method being demonstrably more effective or preferred. Thus, it is recommended that patients should choose their modality based on ability, motivation, preference, needs, and resources.

MUCUS CLEARANCE

Mucus hypersecretion is a prominent feature of bronchiectasis and little is known about the effects of current therapies, because of the difficulties in quantifying mucus hypersecretion in clinical studies, both at baseline and in response to treatment. Maintenance of hydration with oral and/or intravenous fluids is considered useful in preventing inspissated sputum retention. Humidification of inhaled air or oxygen as an adjunct to airway clearance techniques has been shown to significantly increase the wet weight of sputum produced. The use of nebulized normal or hypertonic saline may be considered as adjuncts to bronchial hygiene, although bronchospasm may be associated with the use of these agents. A randomized multicenter study evaluating the efficacy of aerosolized DNAse in non-CF bronchiectasis did not find it efficacious in this group of patients.[55] Rather it was associated with increased pulmonary exacerbation rates, hospitalizations, antibiotic use, and a fall in FEV_1 and FVC. The antiosmolar agent, mannitol, has shown efficacy to stabilize pulmonary function and reduce exacerbations.[56]

BRONCHODILATORS

Bronchodilators, such as beta agonists or anticholinergics, are used in patients with bronchiectasis, since these patients show signs of airflow obstruction and hyperreactivity. Formoterol in addition to budesonide has been shown to reduce symptoms and improve scoring on an HQOL questionnaire as compared to budesonide alone.[24]

Anti-inflammatory Therapy Persistent endobronchial inflammation is known to play a significant role in the pathogenesis of bronchiectasis, and anti-inflammatory therapy may be beneficial. The role of inhaled steroids (fluticasone) in bronchiectasis was evaluated by Tsang et al.,[57] who found reduced sputum volume and purulence, and reduced rates of exacerbations.

SURGERY

Bronchiectasis is usually a diffuse disease and surgical extirpation of affected areas is often not feasible. However, in selected cases surgical resection of the most severely affected segments, bleeding segments, or areas harboring resistant tuberculosis or atypical mycobacteria may confer significant benefits in terms of symptom control, reduction of tenacious sputum production, elimination of large-volume bronchial bleeding, reduction of acute infective episodes, and improved quality of life. The surgical approach varies according to the centers offering this treatment, with some preferring a video-assisted thoracoscopy approach, while others recommend the lateral thoracotomy approach. The complications associated with surgery include spread of infection, bleeding, prolonged air leak, and poor lung expansion following surgery.[58]

Lung transplantation is now considered a viable option in advanced cases, when earlier the risks of persistence of infection in the face of prolonged immunosuppression seemed prohibitive. The outcomes of patients receiving lung transplantation in non-CF bronchiectasis were reported from the United Kingdom. Fifty-four patients underwent bilateral lung transplantation between 1997 and 2007. The mean age was 54 and the median transplant list waiting time was 309 days. The median survival time for transplant recipients was 8 years.[59]

MISCELLANEOUS

While not evaluated specifically for bronchiectasis, vaccinations against *S. pneumoniae* and influenza should be considered in these patients. Smoking cessation should be emphasized as a matter of routine. Patients with advanced bronchiectasis with evidence of exercise and/or nocturnal desaturation should be considered for oxygen supplementation to delay the onset of pulmonary hypertension and cor pulmonale and improve exercise tolerance. Pulmonary rehabilitation and inspiratory muscle training may be considered, as these modalities have been documented to improve exercise tolerance.[60]

CHAPTER 54

Interstitial Lung Disease: A Clinical Overview and General Approach

Danielle Antin-Ozerkis

INTRODUCTION

Commonly, interstitial lung disease (ILD) presents with dyspnea on exertion, diffuse bilateral infiltrates on chest imaging, and restriction with diffusion impairment on physiologic testing. When tissue is obtained, the lung parenchyma may contain any combination of abnormalities, including inflammation, fibrosis, and granulomas. While many forms of ILD are extremely rare, there are some, such as idiopathic pulmonary fibrosis (IPF) and sarcoidosis that are seen commonly in general pulmonary practice. Masqueraders of ILD such as infection, pulmonary edema, and malignancy will be encountered in the assessment of an abnormal chest radiograph, and distinguishing these from true ILD is crucial.

ILD refers to a heterogeneous collection of more than one hundred distinct lung disorders that tend to be grouped together because they share clinical, radiographic, and pathologic features. These disorders are sometimes called diffuse parenchymal lung disease (DPLD) to make the point that the interstitium is not the only compartment of the lung affected. Entities such as organizing pneumonia or pulmonary alveolar proteinosis may cause an alveolar filling process. Respiratory bronchiolitis and chronic hypersensitivity pneumonitis may center on the airway, involving this compartment as well. Occasionally, purely airway-centered diseases like bronchiolitis obliterans may be initially identified as an ILD because of overlapping radiographic findings. A structured approach is necessary since treatments may vary considerably depending on the diagnosis.

Diagnosis is based upon a comprehensive history, a careful physical examination, as well as review of laboratory data, physiologic studies, radiography, and in some cases, pathologic tissue obtained from lung biopsy. Multidisciplinary review is an important part of the process and can have a significant impact on diagnostic and management decisions. For each patient, decisions regarding diagnostic approach and therapy must be individualized based upon the patient's respiratory status, comorbid medical conditions, and personal approach to medical care.

DIAGNOSTIC APPROACH TO ILD

Several classification schemes for ILD have been proposed, which include histopathologic and clinical characteristics.[1] The American Thoracic Society (ATS)/European Respiratory Society (ERS) consensus panel classification system was published in 2001 and has recently been revised.[2] One approach is given in Figure 54-1.

It is often helpful in the case of any individual patient to incorporate a combination of historical, clinical, radiographic, and pathologic features. Distinguishing those patients who have a known cause for their ILD (e.g., connective tissue disease, occupational or environmental exposure, or drug toxicity) from those who do not (e.g., IPF, sarcoidosis) is an important first step. Clinical features, such as acuity of onset, may help to classify disease as well. For example, the subacute time course of a patient with organizing pneumonia will be quite different than the insidious onset of dyspnea in IPF. The radiographic pattern of IPF will be characterized by bibasilar traction bronchiectasis and honeycombing, while sarcoidosis may demonstrate upper lobe-predominant nodular opacities with retraction and volume loss. Histopathologic characterization may range from acute inflammation to granulomatous involvement, or fixed fibrosis and collagen deposition.

It is important to note that the names used to describe the clinical entities themselves must be distinguished from the radiographic and

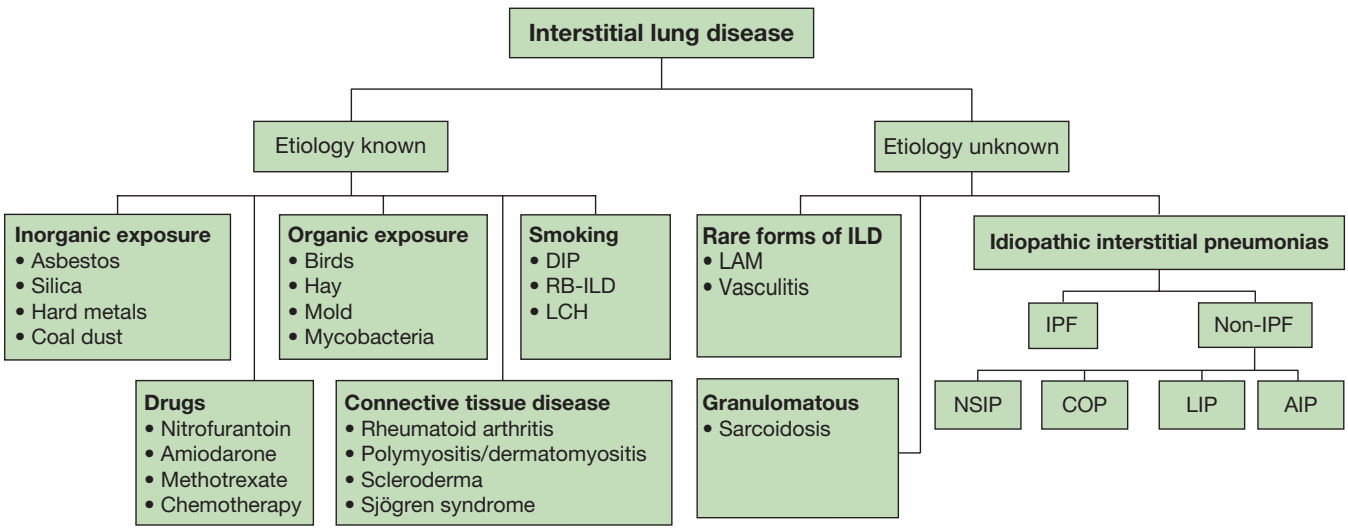

Figure 54-1 An overview of ILD classification. DIP, desquamative interstitial pneumonia; RB-ILD, respiratory bronchiolitis interstitial lung disease; LCH, Langerhans cell histiocytosis; LAM, lymphangioleiomyomatosis; IPF, idiopathic pulmonary fibrosis; NSIP, nonspecific interstitial pneumonia; COP, cryptogenic organizing pneumonia; LIP, lymphocytic interstitial pneumonia; AIP, acute interstitial pneumonia. *(Data from ATS/ERS classification, 2001.)*

TABLE 54-1 Time Course of Disease Onset

Acute
Cryptogenic organizing pneumonia
Acute eosinophilic pneumonia
Acute hypersensitivity pneumonitis
Diffuse alveolar hemorrhage
Acute interstitial pneumonia
Acute exacerbation of idiopathic pulmonary fibrosis or other ILDs
Subacute to Chronic
Connective tissue disease–associated ILD
Idiopathic pulmonary fibrosis
Sarcoidosis
Chronic hypersensitivity pneumonitis
Occupational lung disease
Nonspecific interstitial pneumonia
Desquamative interstitial pneumonitis
Respiratory bronchiolitis interstitial lung disease
Lymphocytic interstitial pneumonia
Chronic eosinophilic pneumonia

pathological terms used to describe the findings. For example, IPF is the clinical entity associated with a usual interstitial pneumonia (UIP) pattern on chest CT and on pathology. However, the finding of a UIP pattern alone does not ensure a diagnosis of IPF, as this may also be seen in other entities, such as the connective tissue diseases.

CLINICAL HISTORY

The typical presentation of ILD is nonspecific and may include vague pulmonary complaints, such as dyspnea on exertion or cough, and an abnormal radiograph. In some cases the time course of the disease may suggest certain forms of ILD (Table 54-1). The acute forms of ILD must be distinguished from respiratory infections and pulmonary edema due to congestive heart failure.

It is important to consider key features of the patient. For example, the differential diagnosis for dyspnea and diffuse infiltrates on chest radiograph will vary markedly between immunocompetent patients and those who have undergone organ or bone marrow transplantation, are neutropenic from recent chemotherapy, or who have advanced HIV disease. In the immunocompetent host, it is often after a lack of response to antibiotics or diuretics that ILD is suspected. Other clinical features may affect the presentation as well. In elderly or disabled patients, musculoskeletal issues may limit mobility and dyspnea may be a late symptom. In a patient with other cardiopulmonary disease, relatively minor ILD may cause an earlier onset of disabling dyspnea and the discovery of ILD for this reason. It is helpful to attempt an objective quantification of the degree of dyspnea, such as the distance the patient walks before becoming breathless or the number of steps climbed before a rest must be taken.

Often a persistent cough after a respiratory infection leads to the initial chest radiograph. While other respiratory symptoms are less common, they may help focus the differential diagnosis. For example, a history of wheezing may suggest an airway-centered process such as hypersensitivity pneumonitis, eosinophilic pneumonia, or sarcoidosis.[3] Substernal chest pain is commonly described by patients with sarcoidosis.[4] Pleuritic chest pain may herald serositis in a patient with connective tissue disease, or pneumothorax in cystic lung diseases such as lymphangioleiomyomatosis (LAM) and Langerhans cell histiocytosis (LCH).[5–7] Hemoptysis may suggest diffuse alveolar hemorrhage, though it is not present in most cases.[8]

SYSTEMIC SYMPTOMS

Connective tissue disease is a frequent cause of ILD, and patients may come with a pre-existing diagnosis. However, most will not and it is incumbent on the physician to search carefully for suggestions of underlying autoimmune disease, as the pulmonologist may be the first to make such a diagnosis, prompted by the onset of ILD. In some cases, nonspecific systemic symptoms such as night sweats, fever, fatigue, or weight loss suggest an underlying inflammatory condition. In others, one can arrive at a specific diagnosis by merely performing a thorough review of systems. For example, careful questioning regarding dermatologic symptoms may lead to the discovery of dermatomyositis as demonstrated by a heliotrope rash, Gottron's papules, or "mechanic's hands," all of which may be relatively specific features that do not bother the patient. Patients with underlying systemic sclerosis (scleroderma) may give a history of skin tightness and thickening, telangiectasias, Raynaud's phenomenon, or digital pitting. Papular eruptions, lupus pernio, and erythema nodosum may be seen in sarcoidosis.[9] Patients with systemic lupus erythematosus (SLE) may describe malar rash, photosensitivity skin reaction, or hair loss.

Gastrointestinal symptoms may be indicative of underlying esophageal motility problems related to connective tissue disease such as systemic sclerosis and polymyositis, or may be the root cause of the ILD itself. In particular, symptoms suggestive of acid reflux (chest burning or pressure, cough after meals, regurgitation of food) should be sought. Chronic, intermittent aspiration can lead to progressive fibrotic lung disease from recurrent lung injury. Patient descriptions of coughing or choking while eating or noting food "going down the wrong pipe" are suggestive of frank aspiration and could lead to a discovery of progressive neuromuscular diseases such as amyotrophic lateral sclerosis (ALS), cerebrovascular accidents, or other causes of oropharyngeal and laryngeal dysfunction.[10] Other gastrointestinal complaints, such as bloating and diarrhea, may suggest inflammatory bowel disease or bacterial overgrowth due to bowel dysmotility in systemic sclerosis.

Musculoskeletal complaints can be helpful in identifying underlying connective tissue disease as well. In particular, arthralgias, morning stiffness, joint swelling and erythema, and deformities may be evidence of an underlying inflammatory disorder such as rheumatoid arthritis, Sjögren syndrome, or mixed connective tissue disorder. Swollen fingers ("sausage digits") may be observed in systemic sclerosis and polymyositis. Raynaud's phenomenon manifests as either blue/purple discoloration or whiteness of the digits (fingers or toes) in the cold. In some cases this may be quite profound and can even be associated with digital ulcerations and, rarely, digital gangrene. This finding is most suggestive of underlying scleroderma, mixed connective tissue disease, SLE, and antisynthetase syndrome.[11]

Ophthalmologic symptoms may direct the clinician toward particular clinical entities. Inquiries regarding dry eyes or the use of eye drops may uncover sicca syndrome, as seen in Sjögren syndrome and overlap connective tissue diseases. Patients with a history of uveitis may have underlying SLE or sarcoidosis. Neurologic symptoms may suggest vasculitis or sarcoidosis.

A detailed review of systems may uncover sequelae of longstanding ILD. Increasing edema, syncopal events, or exertional chest discomfort may indicate severe pulmonary hypertension and *cor pulmonale* in the patient with advanced fibrotic lung disease and hypoxemia. Alternatively, in a patient with systemic sclerosis, these findings might indicate a second primary problem such as pulmonary arterial hypertension. The presence of palpitations or syncope in a patient with sarcoidosis can lead to a diagnosis of cardiac sarcoidosis.

The review of systems will sometimes also lead to a related secondary diagnosis. For example, more typical causes of exertional chest discomfort, such as cardiac ischemia, may be truly present and may be exacerbated by exertional desaturation. This is particularly important to remember, as patients with underlying immune-related diseases appear to be at increased risk for coronary artery disease.[12]

In addition, pleuritic chest pain, leg swelling, and increasing dyspnea should prompt consideration of acute pulmonary embolism, as patients with ILD are at increased risk for this complication.[13,14]

PAST MEDICAL HISTORY

As mentioned, a prior diagnosis of connective tissue disease (systemic sclerosis, rheumatoid arthritis, SLE) is extremely pertinent for patients with ILD. In the case of HIV disease, specific forms of lung disease such as lymphocytic interstitial pneumonia (LIP) are more commonly observed. A prior history of acute or chronic kidney disease might suggest underlying vasculitis, pulmonary–renal syndromes, or connective tissue disease. A history of liver disease could suggest sarcoidosis, primary biliary cirrhosis, or underlying genetic abnormalities resulting in short telomere length.[15–17] A history of facial nerve paralysis (Bell's palsy) might represent unrecognized sarcoidosis.[18]

OCCUPATIONAL HISTORY

The occupational history should be thorough, including a review of all jobs held in the past. In particular, attention should be paid to any occupation in which a history of exposure to organic or inorganic products was present (Table 54-2). Specific inquiries may be made regarding a history of construction work, including demolition, plumbing, and electrical work. The patient should be questioned about employment in factories and manufacturing plants, the electronics industry, metal working, stone cutting, and mining. The clinician should specifically inquire about exposure to asbestos, silica, hard metals, and beryllium, as workers often know when these have been present in their work environment.[19,20] Inquiries may additionally be made regarding the jobs held by the household contacts of patients. For example, spouses may have been subjected to significant levels of dust inhalation via clothing worn by the worker.[21] In cases where a relevant exposure has occurred, details should be obtained regarding the worker's specific duties, the typical proximity to the exposure of interest and any use of respiratory protection. In some cases, related respiratory illnesses in coworkers can raise suspicion. There may be a long latency period between the exposure and the onset of symptoms and radiographic changes, so the occupational history must explore jobs held many years in the past. A history of farm work or other agricultural employment should raise suspicion for an environmental cause of ILD. Exposure to moldy hay, bird feathers and droppings, and a variety of organic products can lead to chronic hypersensitivity pneumonitis.

TABLE 54-2 Occupational Interstitial Lung Disease

Occupation	Type of ILD	Exposure
Electrician Plumber Pipe fitter Construction worker Ship builder Insulation installer	Asbestosis	Asbestos
Stone cutter Miner Sand blaster	Silicosis	Crystalline silica dust
Metal grinder	Giant cell interstitial pneumonia Hard metal lung disease	Hard metals Cobalt Tungsten carbide
Metal worker Factory workers Nuclear weapons Aircrafts Electronics Ceramics Golf clubs Bicycle frames	Berylliosis	Beryllium
Coal worker	Coal worker's pneumoconiosis	Coal dust
Paint sprayer Plastic worker	Chemical worker's lung	Isocyanates
Bird breeder	Bird breeder's lung	Bird droppings Bird feathers
Farm worker Haying Mushroom compost	Farmer's lung Mushroom worker's lung	Thermophilic bacteria
Office worker	Humidifier lung Ventilation pneumonitis	Fungi/Molds
Lifeguard	"Hot tub" hypersensitivity pneumonitis	*Mycobacteria*

ENVIRONMENTAL HISTORY

Organic exposures are also frequently encountered in household and office settings. For example, humidification systems may be contaminated with mold.[22] Hot tubs and other aerosolized water sources have led to lung disease related to the growth of *Mycobacterium avium*.[23] The exposure history should include a thorough inquiry regarding the home heating and humidification system, a history of water damage, or visible evidence of significant mold growth on walls. An assessment of the timing of any water damage relative to the onset of the lung disease can be helpful. Domestic birds are a common source of feathers and dropping antigen. Bird owners often have multiple birds and have owned birds for many years. Frequently, these pets are considered to be cherished members of the family, residing in bedrooms and main living spaces. A history of hobbies and materials used should also be obtained.

Cigarette smoke is one of the most common environmental exposures and is strongly linked with several forms of ILD, including desquamative interstitial pneumonitis (DIP), respiratory bronchiolitis-ILD, and LCH. Cigarette smoking has been identified as a risk factor for IPF.

MEDICATION HISTORY

Numerous drugs have been implicated in the development of ILD, ranging from acute pneumonitis to chronic fibrotic lung disease (Table 54-3). The use of several commonly prescribed drugs should be sought. Nitrofurantoin, used for suppression of recurrent urinary tract infections, may lead to severe ILD.[24] Amiodarone, used for management of atrial and ventricular arrhythmias, is known to lead to lung toxicity.[25] Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used and may lead to eosinophilic and other inflammatory lung disease.[26] While less frequently used in the general population, a history of recent chemotherapy should trigger suspicion for drug-related lung disease.[27] Similarly, a history of immunemodulating drug use, such as in the treatment of rheumatoid arthritis or Crohn's disease is suspicious.[24,25,28] So many drugs have been reported in association with ILD that it is recommended to review the patient's entire medication history thoroughly with this in mind. A helpful online source of information is: http://www.pneumotox.com. This independent resource is compiled and regularly updated by members of the University Hospital in Dijon, France, and the GEPPI (Groupe d'Etudes de la Pathologie Pulmonaire Iatrogène). It lists all reports of suspected drug-induced lung disease, categorizes the radiographic patterns observed, and gives an assessment of the quality of the compiled information.

TABLE 54-3 Drugs Implicated in Interstitial Lung Disease

Antibiotics	**Chemotherapeutic**
Nitrofurantoin	All-trans retinoic acid (ATRA)
Minocycline	Alpha-interferon
Cephalosporins	Antithymocyte globulin
Antiarrhythmic	Bleomycin
Amiodarone	Busulfan
Tocainide	Carmustine (BCNU)
Anti-inflammatory	Chlorambucil
Azathioprine	Colony-stimulating factors (GM-CSF)
Etanercept	Cyclophosphamide
Gold salts	Cytosine arabinoside
Infliximab	Docetaxel
Methotrexate	Geftinib
NSAIDs	Gemcitabine
Penicillamine	Interleukin-2
Sulfasalazine	Irinotecan
Neurologic/Psychiatric	Melphalan
Carbamazepine	Mitomycin C
Phenytoin	Paclitaxel
Drugs of Abuse	Procarbazine
Cocaine	Vinorelbine
Heroin	**Other**
Talc	Bacille Calmette-Guérin (BCG)
	Mineral oil
	Radiation

FAMILY HISTORY

Most forms of ILD are not heritable, though several do have a genetic component. When heritable disease is suspected, it is important to consider both systemic disorders as well as those that primarily affect the lung. In particular, by considering a patient's concomitant medical history or the history of family members, specific diagnoses may be uncovered. Several inborn errors of metabolism (Gaucher disease and Niemann-Pick, for example) are inherited in an autosomal recessive fashion. Other rare diseases such as Hermansky–Pudlak syndrome, Burt–Hogg–Dubé syndrome, and neurofibromatosis type I are autosomal dominant disorders.[29] The cystic lung disease, LAM may be associated with mutations in the tuberous sclerosis complex (TSC) genes, in which systemic hamartomas are present, including a high incidence of renal angiomyolipomas.[29]

The telomere shortening syndromes that lead to dyskeratosis congenita may lead to a phenomenon known as genetic anticipation, in which telomere lengths are progressively shortened in subsequent generations. This leads to the earlier onset of more severe disease in each subsequent generation. In the case of IPF, mutations in the telomerase genes have been demonstrated among 8% to 15% of familial cases and among 1% to 3% of patients with sporadic disease.[17] Several other genes have been linked with the onset of IPF, including those involved in the regulation of surfactant protein C and MUC5B.[30,31] There may be familial predisposition to sarcoidosis, but inheritance is more complex, involving an interaction of genetic and environmental factors.[32]

PHYSICAL EXAMINATION

Most patients with pulmonary fibrosis have lung findings characterized by fine, inspiratory, basilar "Velcro" crackles and many will have digital clubbing. In contrast, patients with nonfibrotic lung disease may have clear lung fields on auscultation. The location of the abnormal breath sounds may be suggestive of the underlying diagnosis, such as the upper lobe findings in silicosis and sarcoidosis in contrast to the lower lobe abnormalities in IPF. Additional breath sounds such as wheezing and inspiratory squeaks can indicate airway disease, which may focus the examiner's differential diagnosis on airway-centered diseases such as bronchiolitis, sarcoidosis, and hypersensitivity pneumonitis. These additional sounds should not be present in a patient with IPF.

Other cardiopulmonary manifestations of disease should also be sought. Signs of pulmonary hypertension and right heart failure include an increased P2 component, a right ventricular heave, elevated jugular venous pressure, and lower extremity edema.

Dermatologic and musculoskeletal signs of connective tissue disease, including skin rashes, sclerodactyly, skin thickening, digital ulceration, "mechanic's hands," synovitis, joint deformities, Raynaud's phenomenon, and telangiectasias, may be extremely helpful in narrowing the differential diagnosis. Less common findings such as cutaneous neurofibromas or café-au-lait spots in neurofibromatosis, albinism in Hermansky–Pudlak syndrome, and facial angiofibromas, periungual fibromas, and Shagreen patch in TSC may all be key features only recognized through a careful and focused search.

CHEST IMAGING

Findings on chest radiography and high-resoluaion computed tomography are discussed below.

CHEST RADIOGRAPH

An abnormal chest radiograph is often the first indication of underlying ILD. The pattern and distribution of abnormalities often help in formulating a differential diagnosis (Table 54-4). For example, sarcoidosis, silicosis, and LCH are among the diseases with an upper lobe predominance, while IPF, connective tissue disease–associated ILD, and asbestosis are all lower lobe predominant. Peripheral alveolar opacities are typical findings in organizing pneumonia and chronic eosinophilic pneumonia. The chest radiograph is also helpful for assessing lung volumes. In particular, fibrotic lung disease such as IPF leads to small lung fields whereas lung volumes are maintained and may even demonstrate hyperinflation in diseases such as LAM and LCH. In many cases, the presence of lymphadenopathy, with hilar fullness observed on chest radiograph, is the feature that leads to an accurate diagnosis, such as in sarcoidosis.

HIGH-RESOLUTION CHEST COMPUTED TOMOGRAPHY

High-resolution computed tomography (HRCT) of the chest is significantly more sensitive than chest radiograph for abnormalities in ILD. Characteristic patterns observed on HRCT can be quite specific in some cases. For example, the characteristic radiographic features of IPF are collectively known as the "UIP pattern," since these features have been demonstrated to confidently predict the presence of pathologic UIP when surgical biopsy is obtained (Table 54-5).[33,34] This pattern consists of peripheral, subpleural, basilar-predominant reticular opacities in combination with basilar honeycombing and without features, such as ground-glass opacities, cysts or nodules, to suggest another form of ILD.[35] When these features are accurately recognized, patients can be spared a surgical biopsy for diagnosis (Fig. 54-2).

Several radiographic patterns have been identified that help to focus the differential diagnosis (Table 54-4). In particular, a peripheral reticular pattern, that is basilar predominant may be seen in IPF, NSIP, and connective tissue disease–associated ILD (Fig. 54-3). Nodular infiltrates may suggest sarcoidosis, hypersensitivity pneumonitis, and LCH, though the nature of the nodules

TABLE 54-4

Distribution of ILD	
Upper lung zone	**Lower lung zone**
Sarcoidosis	Usual interstitial pneumonia (UIP/IPF)
Silicosis	Nonspecific interstitial pneumonia (NSIP)
Coal worker's pneumoconiosis	Connective tissue disease–associated ILD
Hypersensitivity pneumonitis	Asbestosis

and their location may make one or another diagnosis more likely (Fig. 54-4). The finding of diffuse cystic abnormalities leads to a specific differential diagnosis, including LAM, LCH, and LIP. The term "ground glass" refers to areas of lung tissues with increased attenuation, but not enough to obscure or distort lung architecture, blood vessels, and lymphatics. Alveolar opacities are a related finding and reflect more dense attenuation of lung tissue, sometimes containing air bronchograms. Many forms of ILD are characterized by ground-glass and alveolar opacities. When observed in characteristic distributions, such as the peripheral, patchy alveolar opacities in cryptogenic organizing pneumonia (COP) and chronic eosinophilic pneumonia, they are quite suggestive of an underlying pathologic pattern (Fig. 54-5).[36] However, the radiographic appearance in such cases is nonspecific and other testing, including lung biopsy, may be required for diagnosis.

TABLE 54-5 Radiographic Characteristics of the UIP Pattern

"Definite UIP"
Peripheral, subpleural distribution
Basilar predominance
Reticular markings and traction bronchiectasis
Honeycombing
Absence of inconsistent features
Atypical for a "Definite UIP"
Upper or mid lung predominance
Peribronchovascular distribution
Ground-glass abnormality (out of proportion to reticulation)
Profuse micronodules
Multiple, bilateral, discrete cysts
Diffuse, bilateral, mosaic attenuation or air trapping
Consolidation

LABORATORY TESTING

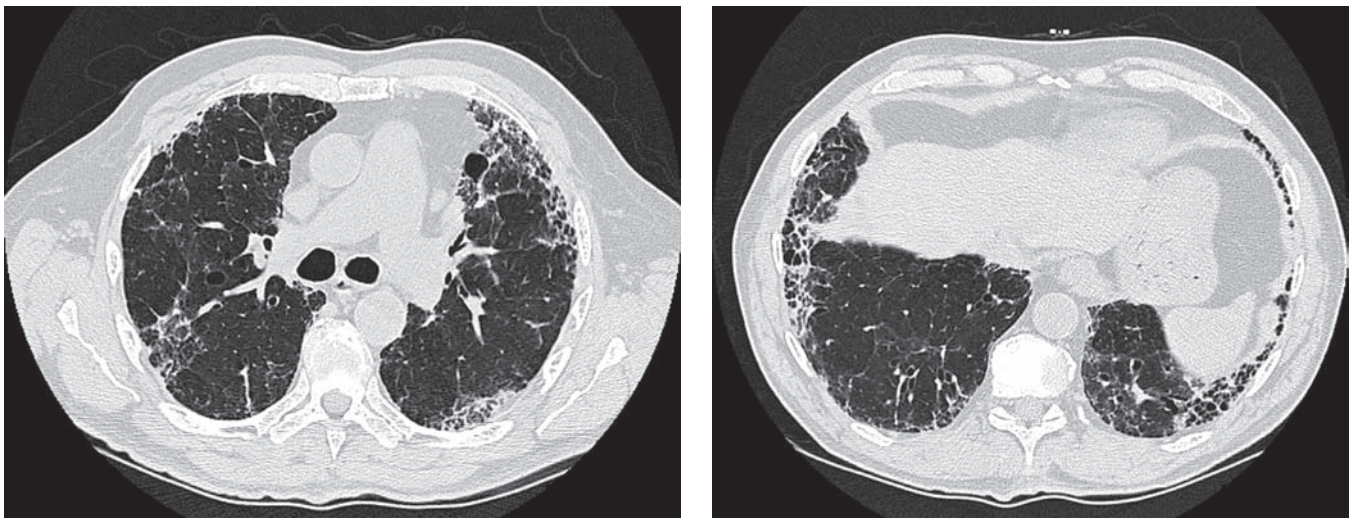
Routine laboratory testing, while often normal, may lead to the diagnosis of a previously unrecognized systemic disease, or may be suggestive of the underlying lung disease. Its importance may also lie in the discovery of associated conditions, such as elevated liver enzymes or hypercalcemia in sarcoidosis, or renal insufficiency in pulmonary renal syndromes and other connective tissue disease with renal involvement. Other examples include the presence of peripheral eosinophilia in chronic eosinophilic pneumonia, Churg–Strauss syndrome, drug reaction, and other forms of vasculitis. Anemia may worsen symptoms of dyspnea in the setting of ILD and may reflect an underlying hemolytic condition, or chronic gastrointestinal blood loss in inflammatory bowel disease. In addition to eliciting causes for the ILD, recognition of underlying chronic organ dysfunction will also help determine the ability of the patient to tolerate treatment.

More advanced testing is often necessary, including serologic testing for underlying connective tissue disease (Table 54-6). Many of the tests listed here are employed by ILD centers in the evaluation of patients newly presenting with diffuse lung disease, though no clear standard exists. Importantly, ILD can be the sole manifestation or the presenting feature of a connective tissue disease, making a careful evaluation for previously unrecognized autoimmune disease essential.[37]

PULMONARY FUNCTION TESTS

Pulmonary function tests (PFTs) are a mainstay in the pulmonologist's armamentarium in the evaluation and management of ILD. Importantly, they assist in assessing the severity of disease and help determine prognosis in many forms of disease.[38,39] They are a relatively noninvasive method to gauge disease progression and measure response to therapy.[40] The testing typically include spirometry, measurement of lung volumes, and diffusing capacity. Exercise testing, such as the 6-minute walk test, is particularly important for patients with ILD.

Typically, spirometry in most forms of ILD demonstrates a restrictive ventilatory defect due to decreased compliance and increased recoil of the lung parenchyma.[41] The presence of obstruction suggests either concomitant obstructive lung disease, often from prior smoking exposure, or the presence of an airway-centered lung ILD such as LCH, LAM, or sarcoidosis. Decreased static lung volumes confirm the presence of restriction. In the case of airway-centered



A B

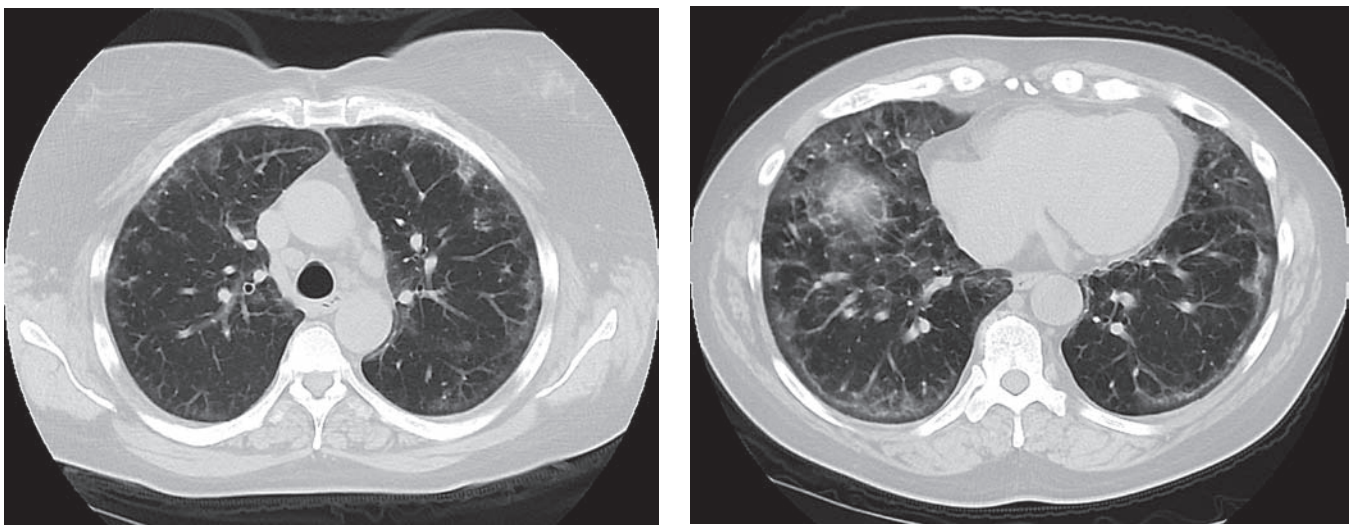
Figure 54-2 An 82-year-old man with progressive dyspnea and a usual interstitial pneumonia (UIP) radiographic pattern. High-resolution (1.25-mm thick sections) CT images at the level of the midthorax (**A**) and lower thorax (**B**) show peripheral reticular markings with architectural distortion and small subpleural cysts/honeycombing. Ground-glass opacities and other features atypical for IPF are absent. The patient had no exposures and no clinical evidence of connective tissue disease. The final diagnosis was idiopathic pulmonary fibrosis (IPF). No lung biopsy was performed, as a diagnosis was made based upon CT criteria alone.

diseases, the lung volume measurements may indicate unrecognized air trapping and hyperinflation.

Diffusion impairment, demonstrated by a decrement in the diffusing capacity (D_{LCO}), is frequently observed in ILD and is often the earliest physiologic abnormality.[42] The decreased D_{LCO} reflects the presence of either fibrotic tissue or inflammatory cells (or both) in the interstitium of the lung, leading to a defect at the level of the alveolar–capillary membrane. The diffusion impairment is typically lower than predicted by alveolar volume.[41] With activity, exertional desaturation is a frequent occurrence among patients with ILD, and which may predict prognosis in certain forms of ILD.[43–45] Formal 6-minute walk testing is quite useful, additionally offering an assessment of exercise capacity in terms of distance walked, heart rate response, and causes for exercise discontinuation (including leg discomfort or chest pain). However, if this is not available, measurement of pulse oximetry with ambulation in the hallway or with stair climbing can offer important information, including an understanding of reasons for the patient's dyspnea as well as a marker of disease severity.

BRONCHOSCOPY

Bronchoscopy is a generally well-tolerated procedure that can be quite useful in the diagnosis of DPLD. It allows inspection of the upper and lower airways, bronchoalveolar lavage (BAL), and the performance of transbronchial lung biopsy. All may be completed as an outpatient procedure, with relatively minimal sedation.



A B

Figure 54-3 A 55-year-old woman with progressive dyspnea on exertion. She had finger swelling and Raynaud phenomenon, with an antinuclear antibody titer of 1:2560 (nucleolar). Axial CT image through the midthorax (**A**) and lower thorax (**B**) show ground-glass opacities in a peripheral distribution, reticular markings, and mild architectural distortion. Subpleural sparing is evident. These findings are all compatible with a nonspecific interstitial pneumonia (NSIP) pattern. The final diagnosis was scleroderma lung disease.

Figure 54-4 A 47-year-old man who enjoyed soaking in the hot tub after exercising at the gym developed dyspnea and hypoxemia. He improved clinically with removal from the presumed source of exposure. High-resolution CT images at the level of the midthorax demonstrate diffuse centrilobular ground-glass nodules as well as areas of lobular lucency, consistent with air trapping. These findings are consistent with subacute hypersensitivity pneumonitis.

BAL allows the sampling of the protein and cellular components of the lung fluid. Tests typically performed on this fluid include cell count and differential, cytology, and a variety of viral assays and microbiologic cultures, depending on the clinical scenario. In some cases, the BAL fluid appearance itself may be diagnostic, for example with the finding of progressively bloody lavage specimens in diffuse alveolar hemorrhage.[46] Similarly, the presence of milky white or tan BAL fluid–containing debris that settles out suggests pulmonary alveolar proteinosis. Periodic acid–Schiff (PAS) staining confirms the diagnosis.

Specific testing on BAL fluid, including cell count and differential, can be diagnostic in the correct clinical context. BAL eosinophilia (>25%) indicates an eosinophilic process, and in combination with the clinical scenario of acute respiratory failure with bilateral alveolar opacities on chest radiograph suggests acute eosinophilic pneumonia. Significant BAL lymphocytosis suggests the presence of a granulomatous ILD, suggestive of hypersensitivity pneumonitis, drug reaction, or cellular NSIP when greater than 50%.[46] A high ratio of CD4+/CD8+ T lymphocytes may be specific, not sensitive for sarcoidosis, though this is not considered a diagnostic test.[46,47] BAL neutrophilia has not been shown to be helpful in distinguishing among the idiopathic ILDs.[48] Notably, increasing patient age may shift the cellular composition of BAL fluid toward lymphocytes and neutrophils so results should be interpreted cautiously.[49]

Specialty testing on BAL fluid may also be important to consider. BAL can accurately confirm a work exposure, for example a positive

TABLE 54-6

Serologic Testing in ILD

Test	Disease
ANA	Scleroderma, SLE, MCTD
SSA	Sjögren syndrome, Polymyositis
SSB	Sjögren syndrome
CK Aldolase Jo-1 Myositis-associated antibodies	Polymyositis, dermatomyositis
Jo-1 Myositis-associated antibodies	Antisynthetase syndrome
Scl-70 Anticentromere antibody	Scleroderma
RF CCP	Rheumatoid arthritis
RNP Antihistone antibody	Mixed connective tissue disease
p-ANCA, c-ANCA	ANCA-associated vasculitis

ANA, antinuclear antibody; CK, creatine kinase; ESR, erythrocyte sedimentation rate; SSA, anti-Ro antibody; SSB, anti-La antibody; RF, rheumatoid actor; CCP, cyclic citrullinated peptide; RNP, ribonucleoprotein; CRP, C-reactive protein; ANCA, antineutrophil cytoplasmic antibody.

Figure 54-5 A 58-year-old woman with organizing pneumonia (OP) secondary to radiation for breast cancer. Frontal chest radiograph (**A**) demonstrates ground-glass and alveolar opacities. High-resolution CT images at the level of the midthorax (**B**) demonstrate both ground-glass opacities and areas of consolidation. She had complete response to corticosteroid therapy.

lymphocyte proliferation assay in chronic beryllium disease or the presence of asbestos bodies in asbestosis.[50] The demonstration of CD1a positive cells on flow cytometry may lead to a diagnosis of LCH, and clonal cell populations may be demonstrated in the BAL fluid of patients with pulmonary lymphoid malignancies.[46,51] Much research has focused on identifying molecular and cellular profiles to predict prognosis and response to therapy, however BAL is not widely used for this purpose outside the research setting.[52]

One of the major reasons to obtain BAL fluid in the diagnosis and treatment of ILD is to rule out infection, either as a primary cause of the diffuse lung disease, or as a secondary complication of immunosuppressive therapy. In the immunocompromised host, BAL fluid is highly sensitive for the diagnosis of bacterial, viral, fungal, and mycobacterial diseases.[53] Specialized staining may identify *Pneumocystis jiroveci* infection, endemic fungi, and mycobacterial disease. Immunofluorescent antibody and polymerase chain reaction (PCR) assays are now commonly utilized, and significantly increase yield.[46,54,55]

Transbronchial biopsy is safe, with risk for pneumothorax of approximately 1% and significant bleeding less than 2%.[56,57] Biopsy forceps are introduced via the flexible bronchoscope and tissue samples are obtained with fluoroscopic guidance. Multiple passes are made, with yield improving when more than four specimens are obtained.[58] Despite the relatively small size of these specimens as compared with surgical lung biopsy, diagnostic information in certain forms of ILD are particularly amenable to diagnosis by bronchoscopy, especially granulomatous diseases such as sarcoidosis, hypersensitivity pneumonitis, and drug toxicity.[59]

SURGICAL LUNG BIOPSY

Despite a high yield in certain forms of lung disease, the utility of transbronchial biopsy for most of the idiopathic interstitial pneumonias (such as IPF, NSIP, and LIP) is low and surgical biopsy is often required for accurate diagnosis.[60] The usual technique is video-assisted thoracoscopic surgery (VATS) that has a low morbidity and mortality in selected populations.[61] VATS biopsy should be performed by surgeons familiar with the techniques needed for ILD diagnosis. Wedge biopsies are taken from three separate lobes, and include areas of normal appearing lung; when only the most affected areas are sampled, specimens demonstrate end-stage honeycomb lung and the procedure may be nondiagnostic. Risks of VATS include prolonged air leak, bleeding, infection, and incisional site pain.[62] Generally, the length of hospital stay after a VATS procedure is 2 to 3 days, though a few centers perform VATS biopsy as an outpatient procedure in selected patients.[63] For most patients, there is no significant loss of lung function; however, cases of acute exacerbation of IPF following biopsy have been reported.[62,64] Patients must be able to tolerate general anesthesia with single lung ventilation.[62] Risk factors for complications and mortality include advanced respiratory failure as indicated by high P_{CO_2} and/or severe hypoxemia, significant pulmonary hypertension, problems with clotting, and immunosuppression.[65,66] Patients older than 65 years of age have morbidity and mortality rates no different than younger patients, though those over 75 may have higher rates of air leak.[67,68] Preoperative cardiac evaluation should be considered since many patients undergoing biopsy for ILD are older, or have a significant smoking history.[69]

A comprehensive approach including the clinical history, laboratory testing, and radiographic appearance can help assess if pathologic information is needed for accurate diagnosis. If a specific cause for the ILD can be identified, such as underlying connective tissue disease or a temporally correlated drug or environmental exposure, pathologic tissue may not change management and may not be worth the operative risk. When no etiology of the lung disease can be found, the radiographic appearance is crucial to help determine if surgical biopsy is needed. The most important question to be answered with biopsy is whether the patient has IPF or some other form of idiopathic interstitial pneumonia.[70] Specific features on HRCT are highly predictive of the histopathologic finding of UIP, the histologic correlate of IPF (Table 54-5).[33,34] An assessment of the HRCT as "definite UIP" by an experienced observer can spare some patients a surgical biopsy in the correct clinical setting.[35] When most features are present, but honeycombing is not, the pattern is called "possible UIP" and it is this group in which surgical biopsy is the most helpful. The differential diagnosis in these cases includes NSIP, UIP, and chronic hypersensitivity pneumonitis and radiographic appearance alone cannot be used to make an accurate diagnosis.[71,72] Each case should be assessed individually before a decision to pursue biopsy is made. In some, it may not be necessary and in others, though potentially helpful, the risk of the procedure outweighs the benefit of the information gained.

PATHOLOGY AND MULTIDISCIPLINARY REVIEW

Several major pathologic patterns are described in the idiopathic interstitial pneumonias, including granulomatous ILD, UIP, NSIP, and organizing pneumonia. However, these same patterns may be observed in patients with systemic diseases and other causes for ILD and therefore the pathology must be interpreted within the context of the clinical scenario and radiographic studies. It has been demonstrated that the final diagnosis will often change after a group discussion involving clinicians, radiologists, and pathologists.[73] The diagnosis also frequently differs between academic and community-based physicians, with academic physicians being less likely to arrive at a diagnosis of IPF.[74]

The UIP pattern is the histologic correlate of IPF and has specific features, including a heterogeneous appearance in which areas of fibrosis and honeycombing are interspersed with areas of normal lung. The changes are most pronounced in the periphery of the lung and should not predominantly involve the airways. Fibroblastic foci should be present and atypical features should be absent. The most recent guidelines offer categories in which the pathologist may interpret the pattern as "UIP," "Probable UIP," "Possible UIP," "Unclassifiable fibrosis," and "Not UIP."[75] These, in combination with the HRCT and clinical features, will lead to a definite, probable, possible IPF diagnosis, or one of "Not IPF." However, the clinical context must always be considered as a UIP pattern is not completely specific for IPF. For example, a patient with a history of bird exposure, whose HRCT demonstrates upper lobe predominance with lobular areas of air trapping, may have UIP on biopsy, but the final diagnosis will be chronic hypersensitivity pneumonitis. A patient with morning stiffness, deforming arthritis, positive serology for anti-CCP antibodies and UIP will be given a diagnosis of rheumatoid arthritis–associated ILD.

Granulomatous histology may be observed in idiopathic disease such as sarcoidosis, but may be present in many other forms of ILD, including drug toxicity and hypersensitivity pneumonitis. In addition to ILD, the possibility of diffuse infections, including mycobacterial disease, must always be kept in mind. The morphology and location of the granulomas, as well as the appearance of the surrounding tissue, must be considered in combination with the clinical features.[76] For example, a history of beryllium exposure in combination with sarcoidal granulomas on pathology will change the diagnosis to chronic beryllium disease. A patient with diffuse centrilobular ground-glass nodules, a history of humidifier use, and loosely formed granulomas on histology most likely carries a diagnosis of subacute hypersensitivity pneumonitis.

Nonspecific interstitial pneumonia is characterized by interstitial inflammation and fibrosis in a homogeneous pattern, as opposed to the heterogeneity of UIP. It may range from predominantly cellular to fibrotic in nature, with interstitial thickening but without significant honeycomb change (Fig. 54-6).[77] While this pattern may be idiopathic, it is much more commonly associated with connective

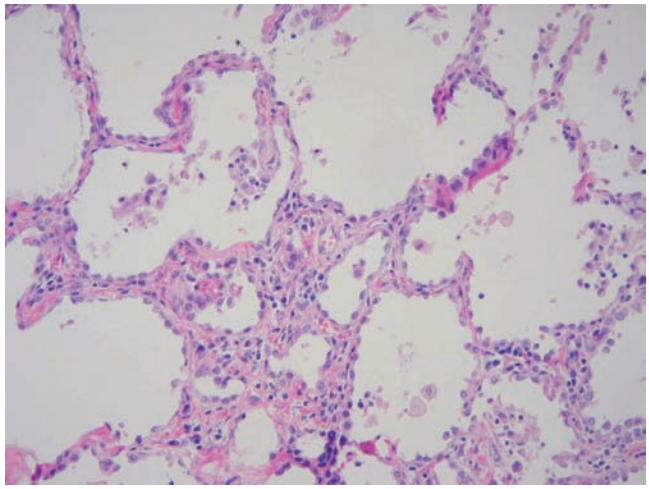

Figure 54-6 Nonspecific interstitial pneumonia (NSIP). There is diffuse, homogeneous septal fibrosis with a mild mononuclear infiltrate, as well as mild diffuse type II cell hypertrophy. No organizing pneumonitis, fibroblast foci, granulomas, or eosinophilic infiltrate are seen. Honeycombing is absent. There is a very mild accumulation of alveolar macrophages in the alveoli. 20× objective. *(Used with permission of Robert Homer, MD, PhD, Yale School of Medicine.)*

tissue disease. For example, a patient with a history of Raynaud's syndrome, skin thickening, diffuse ground-glass opacities on HRCT, and pathologic NSIP is likely to have underlying systemic sclerosis.

Organizing pneumonia is characterized histopathologically by intra-alveolar granulation tissue containing myofibroblasts and connective tissue (Fig. 54-7). The finding of organizing pneumonia on histopathology should prompt an exhaustive search for a cause before being called COP, which is idiopathic. For example, a patient with peripheral alveolar opacities on chest imaging and features of OP on biopsy who is found to have taken chronic nitrofurantoin as suppressive therapy for urinary infections may be suffering from drug toxicity. Likewise, a patient with OP who has muscle weakness, papular lesions on the hands, and heliotrope rash likely carries a diagnosis of dermatomyositis.

TREATMENT

Approach to treatment includes general and specific measures, as discussed below.

■ REMOVAL FROM EXPOSURES

The treatment of ILD varies with the specific diagnosis. Importantly, if any causative exposure can be identified, this should be eliminated. For example, if a drug reaction is suspected, that drug should be discontinued. For environmental exposures, the situation may require more extensive remediation. For example, in addition to removal of birds from the home, extensive cleaning of upholstery, window coverings, and ventilation systems may be required. The cleaning should not be performed by the patient. Even these measures may not remove all residual antigen, and removal of the patient from the location may be necessary.[78] In the case of extensive water damage and mold growth, significant demolition and reconstruction may be necessary. In the case of occupational exposures, some situations may be addressed by altering the particular job being done by the patient, changing the substances used, or using protective respiratory equipment, but others may require complete removal from the suspected exposure.[79] In many cases, patients' livelihoods may be at stake, involving severe financial consequences, disability, and workers' compensation. Identification of a workplace hazard for a patient may lead to the discovery of a public health issue or one that affects the health of coworkers.[80] Referral to and coordination with an Occupational Medicine specialist may be necessary to appropriately assess and remediate home and workplace exposures.

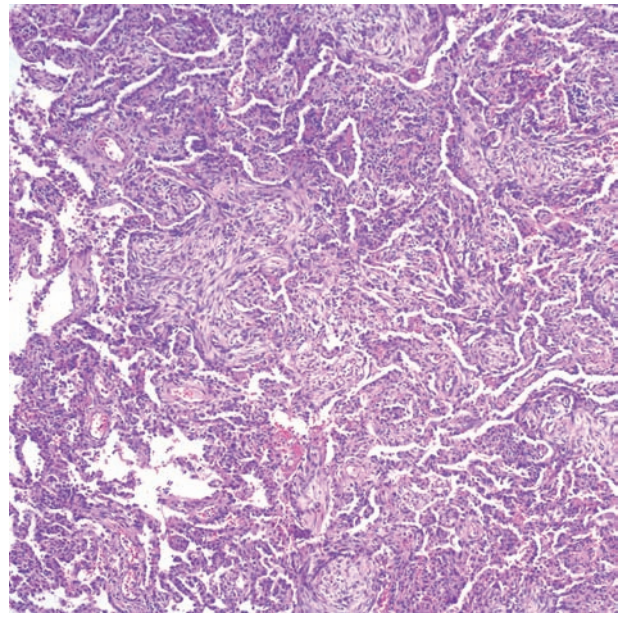

Figure 54-7 Organizing pneumonia (OP). There is fibromyxoid granulation tissue within alveolar ducts accompanied by a lymphoplasmacytic infiltrate. Notable is the absence of hyaline membranes, necrosis, neutrophilic or eosinophilic infiltrate, granulomas, and established fibrosis. 10× objective. *(Used with permission of Robert Homer, MD, PhD, Yale School of Medicine.)*

■ IMMUNOSUPPRESSIVE THERAPY

Some forms of ILD, including COP, connective tissue disease–associated ILD, and sarcoidosis, may demonstrate a favorable response to corticosteroids and other immunosuppressive agents.[81] However, in diseases such as IPF, what was once thought to be standard of care (prednisone plus azathioprine) has been demonstrated to carry harm without potential for benefit.[82] When considering the use of these drugs, an assessment should be made regarding the likelihood of response as well as the relative risks and benefits of the therapy.

The many side effects of corticosteroids include glucose intolerance, bone loss, cataract development, and mood instability.[83] Increased risk for infection may be substantial.[84] Some inflammatory diseases such as COP, CEP, and sarcoidosis can be quite sensitive to corticosteroids and relatively quick weaning to low dosages may be feasible and effective. In disorders such as connective tissue disease–associated ILD, when a more prolonged course of therapy is anticipated, the early addition of steroid sparing medications, such as azathioprine or mycophenolate mofetil, can permit lower doses of corticosteroids to be used. Certain forms of ILD, including scleroderma lung disease, vasculitis with alveolar hemorrhage, and severe cases of connective tissue disease–associated ILD may require drugs such as cyclophosphamide, which carry increased risk for severe side effects. Such medications should only be prescribed by practitioners familiar with the use and toxicities of these agents.

When actively treating ILD, objective measures of improvement, including PFTs, exercise oximetry, and chest radiography should be employed to avoid the unnecessary continuation of therapy. In particular, when corticosteroids are used, there is often an initial boost in mood and energy level that may not correspond to actual improvements in lung function. If no clinical improvement is seen after 3 to 6 months of therapy, discontinuation of immunosuppressive therapy should be strongly considered.

ANTIFIBROTIC DRUGS

For progressive fibrotic lung diseases, particularly IPF, the lack of adequate treatment options has led to a search for new therapies. In particular, pirfenidone, a small-molecule drug which appears to have antifibrotic properties, may stabilize lung function and is approved for use in Japan, Europe, and Canada and is currently being evaluated for approval in the United States. Multiple phase II and III studies of novel agents for IPF and for scleroderma-ILD are ongoing.

SUPPORTIVE THERAPY

Supportive therapy directed at improving quality of life and decreasing respiratory symptoms should be a part of the approach to care of all patients with ILD. Formal exercise testing in the PFT laboratory offers a standardized approach to the assessment of oxygen needs. However, a check of oximetry with simple ambulation in the hallway or with stair climbing can uncover the need for oxygen supplementation. The use of oxygen for patients with ILD is encouraged to maintain saturations >90% both at rest and with exercise.[85] No data exist regarding the impact of nocturnal oxygen use on mortality in ILD, but this is often utilized based upon data suggesting that nocturnal hypoxemia has a significant negative impact on quality of life.[86] Home and portable systems should be used to encourage ease of use and mobility. Collaboration among physicians, patients, and oxygen providers can help identify the ideal system for each patient.

The role of pulmonary rehabilitation has been studied in chronic obstructive lung disease and leads to increased muscle strength and improved endurance.[87] Similar improvements may be evident in the fibrotic lung diseases.[88,89] In addition to the potential benefits of improved muscle strength and stamina, patients with ILD may also benefit from the ongoing education regarding oxygen use, breathing and pacing techniques, and social support.[90] As patients with chronic lung disease frequently suffer from anxiety and depression, pulmonary rehabilitation may benefit patients by identifying these issues, leading to appropriate specialist referrals.[91]

TREATMENT OF COMORBIDITIES

Several common comorbidities should be sought among patients with ILD. In particular, an assessment for underlying coronary artery disease should be undertaken when dyspnea on exertion is present, as the risk for ischemic heart disease is increased among patients with IPF.[92,93] Due in part to prior tobacco exposure, patients with IPF have an increased risk of developing lung cancer.[85] Nodules should be individually assessed based on size, appearance, and growth. No specific screening recommendations for this patient population exist. The prevalence of obstructive sleep apnea appears to be quite high among patients with ILD, even in the absence of excessive sleepiness or large body habitus, although these features are important to assess.[94–96] There is a high prevalence of gastroesophageal reflux (GERD) among patients with IPF, though only a minority have symptoms.[97,98] Studies have suggested that GERD may be intimately involved in the pathogenesis of IPF and be linked with progression of disease.[99] The evaluation and treatment of GERD in patients with ILD is an evolving field. Based on existing data, it is not clear how aggressive therapy should be. If symptoms exist, therapy is typically utilized. However, whether to seek evidence of asymptomatic GERD through more invasive testing and whether to treat such patients is not clear.[85]

In addition to native comorbidities, side effects from therapy should be assessed. In particular, the use of corticosteroids can lead to weight gain, fluid retention, diabetes, and osteoporosis. Glucocorticoid-induced osteoporosis may be prevented by the use of calcium and vitamin D supplementation early in the course of steroid use.[100] Fracture risk assessment can identify patients in whom bisphosphonate therapy is indicated.[100]

Pulmonary hypertension develops in a significant number of patients with ILD and may be due to the effects of chronic hypoxia and the focal destruction of capillaries in fibrotic lung tissue.[101] Pulmonary hypertension contributes to progressive diffusion impairment and may contribute to progressive respiratory failure. It is important to ensure that no other cause for the pulmonary hypertension can be identified. For example, a concomitant pulmonary arterial vasculopathy, such as seen in scleroderma or MCTD should be sought, as specific therapy for the pulmonary arterial hypertension may be indicated in those circumstances.[102] In addition, common causes of pulmonary hypertension, such as left-sided systolic or diastolic cardiac dysfunction may be present.[103] Right heart catheterization can distinguish between the various etiologies of pulmonary hypertension and is often required, as echocardiogram has limited sensitivity and specificity in this population.[101] Whether to utilize pulmonary vasodilator therapy in patients with PH secondary to ILD is uncertain at this time. There is concern that use of these medications may worsen ventilation–perfusion matching, however some patients may have symptomatic and functional improvement.[104]

PALLIATIVE CARE

Symptom control is particularly important for patients with all stages of ILD. Pulmonary rehabilitation is encouraged to improve dyspnea in all symptomatic patients. The breathlessness due to advanced ILD may be treated with oxygen supplementation, low-dose opiates and anxiolytics.[105] Cough can be quite problematic and difficult to control; low-dose opiates may be of some benefit and low dose corticosteroids are occasionally used, understanding their long-term risk.[85] Evaluation for acid and nonacid reflux should be considered whenever intractable cough persists.

Palliative care services and hospice referral are appropriate for advanced ILD to maintain a focus on the physical, psychological and spiritual needs of patients and their families.[106] Prognosis in ILD may be uncertain, depending upon the specific diagnosis, the severity of disease, and progressiveness already demonstrated.[107] Particularly in IPF, the likelihood of either progressive respiratory failure or acute decline due to exacerbation should be discussed. End-of-life discussions and advanced directives regarding mechanical ventilation should be broached.[106]

LUNG TRANSPLANTATION

Although lung transplantation has significant associated morbidity and mortality, it is an important and potentially life-extending alternative for patients with progressive fibrotic lung disease. Most patients with ILD referred for lung transplantation have IPF, and for those with advanced disease, survival after lung transplantation is superior to the natural history of their disease.[108] Patients must have a strong social support system as well as the emotional and physical ability to tolerate a complex medical regimen of immunosuppressive therapy.[109]

The timing of listing is complicated in ILD, since the rate of progression is difficult to predict, and abrupt exacerbation of disease may occur.[110] Historically, patients with IPF had high mortality while on lung transplant waiting lists. With newer systems of prioritization, patients with severe IPF are often transplanted quickly, making the correct timing of listing important.[111] In general, a severely impaired D_{LCO} (<39%) as well as advanced fibrosis on HRCT predict poor survival and are considered to be triggers for active listing.[112] Regardless of ILD diagnosis, severe and progressive impairments in pulmonary function predict earlier mortality.[113] Early referral to a lung transplant center is useful as it allows full evaluation and education earlier in the disease course.

CONCLUSION

The approach to ILD includes a careful history and physical examination, with a focus on identifying an etiology for the ILD. Important considerations include a complete investigation of environmental, occupational, and drug exposures as well as a thorough search for underlying connective tissue disease. Laboratory tests, pulmonary physiologic studies, radiography, and biopsy of lung tissue may be necessary. Multidisciplinary review is an essential part of the diagnostic evaluation. Decisions regarding diagnostic and therapeutic approach must be individualized.

CHAPTER 55

Systemic Sarcoidosis

David R. Moller
Edward S. Chen

Sarcoidosis is a multisystem disorder characterized by noncaseating granulomatous inflammation at sites of disease.[1] Although any organ can be involved, the disease most commonly affects the lungs and intrathoracic lymph nodes. A diagnosis of sarcoidosis is most securely established from compatible clinical and radiologic findings, confirmed by a biopsy showing noncaseating epithelioid granulomas in more than one organ and the exclusion of granulomatous disorders of known cause. Clinical, epidemiologic, and family studies support the hypothesis that sarcoidosis is triggered by exposure to microbial agents in individuals with a genetic susceptibility to the disease. The clinical course is highly variable, with a mortality rate of <1% to 5%. Corticosteroids remain the mainstay of treatment for patients with threatened organ failure or progressive disease.

HISTORICAL PERSPECTIVE

Jonathan Hutchinson was the first to describe a case of sarcoidosis in 1887; he called it Mortimer's malady, after one of his patients who presented with face and limb skin lesions. In 1889, Besnier of Paris described a 34-year-old man with violaceous skin lesions of the nose, ear lobules, and central face; he proposed that the lesions were a variant of lupus erythematosus leading to its designation as "lupus pernio." In 1899, Caesar Boeck first described the characteristic noncaseating granulomas in a patient with peripheral lymphadenopathy and skin nodules. He proposed the term *multiple benign sarcoids of the skin* because he thought the granulomatous changes resembled sarcomatous tissue. Subsequently, descriptions of sarcoid-type lesions in the eyes, bones, lungs, and salivary glands were made, but the systemic and unifying nature of sarcoidosis was not recognized for almost 20 years.

The view that sarcoidosis is a systemic disorder is largely based on the work of Jorgen Schaumann, a Swedish dermatologist, who in 1914 presented the view that Besnier lupus pernio and Boeck's multiple sarcoids were manifestations of the same disease termed "lymphogranulomatose benigne," thought to represent a variant of tuberculosis. In 1935, Williams and Nickerson reported that intradermal inoculation of a suspension of sarcoidosis tissue resulted in firm papules in patients with suspected sarcoidosis. Ansgar Kveim demonstrated that these papules contained sarcoidosis-like granulomas on biopsy. Louis Siltzbach and others would demonstrate in worldwide studies that this "Kveim" reaction was positive (showed granulomas) in up to 80% of sarcoidosis and was highly specific for the disease. Sven Löfgren of Sweden in the 1940s noted that sarcoidosis frequently begins with asymptomatic bilateral hilar adenopathy or with acute erythema nodosum. In the 1950s, corticosteroids were reported to be successful in treating sarcoidosis. More recently, the tools of cell and molecular biology have advanced our understanding of the immunologic, genetic, and etiologic basis of sarcoidosis, but have not yet led to breakthroughs in the development of safe, effective therapies or cure.

EPIDEMIOLOGY

Sarcoidosis is found worldwide, although the frequency of the disease varies among different geographic regions. Accurate measurements of disease prevalence are unknown, because many people with sarcoidosis are asymptomatic and there is neither sensitive nor specific diagnostic tests. Estimated prevalence rates between 10 and 40 cases per 100,000 population are reported in North America, southern Europe, and Japan.[2] Higher prevalence rates are noted in Sweden, Denmark, and US Blacks. More than 80% of cases occur in persons between 20 and 50 years of age, with a second peak in women more than 50 years of age.[1] Sarcoidosis is rare in the preadolescent period.[3] The lifetime risk for developing sarcoidosis has been estimated as 1.4% and 1.0% in women and men of Scandinavian countries, respectively, whereas one US study calculated a lifetime risk "in women and men of 2.7% and 2.1% in Blacks and 1.0% and 0.7% in Whites, respectively" in a midwestern city.[4] Based on autopsy studies, the prevalence of sarcoidosis is likely underestimated.[5] Whether the incidence of sarcoidosis is changing remains unknown given a lack of studies over the past decade.[6]

The frequency of different clinical manifestations of sarcoidosis also varies among geographic regions and ethnic groups, and is influenced by gender. Erythema nodosum is common in Scandinavian countries and Ireland, but found in less than 5% of Black or Japanese patients. In contrast, lupus pernio appears more frequently among Black populations. In Japan, over 50% of patients may have cardiac sarcoidosis.[7] Several studies suggest that race is an important determinant of disease severity with Black populations more likely to have persistent disease and greater mortality than White populations.[4,8] In the United States, 40% to 80% of mortality from sarcoidosis is from advanced pulmonary disease, with higher rates observed in Blacks and women.[9,10] In Sweden and Japan, cardiac involvement is the leading cause of death from sarcoidosis. Overall, mortality rates directly related to sarcoidosis approximate <1% to 5% depending on the study setting.[11,12]

ETIOLOGY

The cause of sarcoidosis remains uncertain. Since sarcoidosis was first described, investigators have postulated an infectious cause of the disease based on the clinical similarities to tuberculosis. Environmental exposures are linked to sarcoidosis due to seasonal clustering of the disease with a predilection for winter and early spring months in both northern and southern hemispheres.[13] Geographic variation and time–space clustering also support a role for environmental factors in sarcoidosis.[14] Occupational associations have been described for healthcare professionals, firefighters, military personnel, and workers involved in the lumber industry. Chronic beryllium disease causes a granulomatous pneumonitis histologically identical to pulmonary sarcoidosis in less than 5% of exposed workers following immunologic sensitization to beryllium.[15] However, there is no evidence that beryllium is a cause of systemic sarcoidosis.[16] An increased risk of a "sarcoidosis-like" pulmonary disease was documented in first-response rescue workers exposed to the heavy dust burden from the World Trade Center disaster; a minority of these workers had multisystem disease confirming a likely diagnosis of multisystem sarcoidosis.[17,18]

The US-based multicenter study of sarcoidosis etiology called ACCESS (A Case Control Etiologic Study of Sarcoidosis) compared 706 newly diagnosed, biopsy-proven sarcoidosis cases to age-, sex-, and race-matched controls.[19,20] Results from the study showed an absence of environmental or occupational associations positively linked to sarcoidosis risk that carried an odds ratio (OR) greater than 2.0 and an exposure prevalence of greater than 5% (prestudy goal). Weak positive associations (OR ~1.5) were found for insecticide use at work, mold/mildew exposures at work, and musty odors, suggesting possible links to microbial-rich environments. Sarcoidosis was not associated with exposure to heavy metals including beryllium, wood dusts, or rural residence as previously hypothesized. The ACCESS study found a robust negative association of smoking and sarcoidosis risk, confirming earlier studies. The

lack of a single, dominant exposure associated with sarcoidosis risk is consistent with the concept that gene–environment interactions are important in causing disease.

Many studies have directly examined a role for infectious agents in sarcoidosis given the clinical similarities to mycobacterial disease. A meta-analysis of studies published between 1980 to 2006 identified a 10- to 20-fold greater likelihood of detecting mycobacterial nucleic acids (DNA, RNA) in sarcoidosis tissues than control tissues.[21] The authors and their colleagues used a limited proteomic approach to identify potential pathogenic antigens in sarcoidosis tissues based solely on the biochemical properties of the Kveim reaction, a delayed granulomatous skin reaction to sarcoidosis tissue extracts.[22] Using homogenized sarcoidosis tissue extracts, mass spectrometry, and protein immunoblotting, we identified the mycobacterial catalase-peroxidase protein (mKatG) as a candidate pathogenic antigen.[23] This unbiased approach was not predicated on any *a priori* hypothesis regarding specific pathogenic microbes or autoantigens, supporting a mycobacterial link to sarcoidosis etiology. Several groups have demonstrated that as many as 70% of sarcoidosis patients have lung and blood T-cell responses to mycobacterial antigens including mKatG, *Mycobacterium tuberculosis* ESAT-6, Ag85, superoxide dismutase.[24–26] Several studies report extensive overlap in peripheral blood gene expression between individuals with sarcoidosis and tuberculosis infection, further supporting a mycobacterial etiology of sarcoidosis.[27–29]

Japanese investigators find *Propionibacterium acnes* DNA in 80% to 98% of sarcoidosis tissues from Japan and Europe but also in 0% to 60% of control tissues.[30] An animal model of granulomatous lung inflammation induced by *P. acnes* has been reported.[31,32] However, a role for *Propionibacteria* in sarcoidosis remains unclear because of the frequent detection and recovery of these organisms from tissues and evidence of immune responses to these commensal organisms in nonsarcoidosis control individuals. Other microbial agents, such as *Borrelia burgdorferi*, *Chlamydia pneumonia,* or *Rickettsia helvetica* have been implicated in sarcoidosis from tissue or serologic studies, but these latter studies all lack wider confirmation. High titers of antibodies against lymphotropic DNA viruses (Epstein–Barr virus, cytomegalovirus, and human herpesvirus type 6) and HTLV1 have been described in patients with sarcoidosis but may reflect generalized B-cell activation in sarcoidosis, since a viral origin has not been substantiated by viral cultures or tissue analysis.

Despite the evidence for linking some microbes to sarcoidosis etiology, there is no histopathologic or microbiologic evidence that viable mycobacterial organisms or other pathogenic organisms are present in sarcoidosis tissues. Cell-wall deficient microbes have been suggested to cause sarcoidosis, but none are supported by independent, reproducible studies.[33] Although direct demonstration of an infectious etiology remains unproven, many investigators favor the hypothesis that certain classes of microbial organisms trigger sarcoidosis in those with genetic susceptibility.

Some investigators hypothesize an etiologic association with autoimmunity, perhaps triggered by an infectious agent through molecular mimicry. In support of this concept, sarcoidosis is associated with features of autoimmunity, such as antinuclear antibodies, rheumatoid factor, hypergammaglobulinemia, and immune complexes. Sarcoidosis patients often express low titer autoantibodies of unclear significance, although no disease-specific autoantibody profile has been identified. One recent study identified several potential autoantigens such as vimentin, ATP synthase, and lysyl-tRNA whose derived peptides stimulated Th1 lymphocytes in the blood or lung of sarcoidosis patients, suggesting these responses may help sustain chronic inflammation.[34]

GENETICS

Family and case control association studies provide strong evidence for a genetic influence on the risk of developing sarcoidosis and in determining clinical expression of the disease. Familial clustering of sarcoidosis occurs in 3% to 14% of patients, with a greater frequency among Black compared with White populations. The US ACCESS study found siblings of sarcoidosis cases have a higher relative risk (RR) (OR ~5.8) than parents (OR ~3.8).[35] The significantly higher adjusted familial RR estimates reported for Whites in both the US ACCESS study (RR ~18) and in a UK study with mostly Whites (RR ~36–73) and Blacks (RR ~2.8), suggest that genetic factors have a greater influence in susceptibility to sarcoidosis in Whites than Blacks.

Early studies examined the role of HLA class I alleles using serologic techniques. The HLA-B8 allele has most consistently been associated with disease susceptibility, increasing sarcoidosis risk in Whites from the United States and Europe but not in Blacks or Japanese.[36–38]

The role of HLA class II alleles has been intensively studied in sarcoidosis. HLA-DR3 has been associated with sarcoidosis susceptibility, while HLA-DR1 and -DR4 alleles have been associated with disease protection in Scandinavian and European populations. Using molecular genotyping, the ACCESS study found a significant association between HLA-DRB1*1101 in both Blacks and Whites, while HLA-DRB1*1501 was associated with sarcoidosis risk only in Whites.[39] Other studies find the class II HLA-DR17 (DR3) haplotype and specifically HLA DRB1*0301 or the closely linked DQB1*0201 alleles to be associated with favorable outcomes (Löfgren syndrome, acute arthritis, stage I chest radiograph, or remission within 2 years) in European and Japanese populations.[40,41] The DRB1*1501 or the closely linked DQB1*0602 alleles were associated with more severe or chronic disease in a Danish cohort. HLA-DPB1 and DQB1 alleles have been associated with disease susceptibility in some studies, although linkage disequilibrium makes it difficult to separate from effects of HLA-DR alleles.[42] One study identified four DR and nine DQ gene polymorphisms associated with increased risk of developing sarcoidosis.[43] Since the pockets within the HLA class II sequence determine specific antigenic peptide binding, these results are consistent with the existence of etiologically important antigens in sarcoidosis. Family linkage studies employing genome-wide microsatellite analysis confirm the importance of genes from the MHC locus in determining susceptibility to sarcoidosis.[44] These data support a consensus view that MHC class II alleles are the major contributor to disease susceptibility across different ethnic populations in sarcoidosis, likely through binding specific pathogenic antigens.

Non-HLA genes have been the subject of multiple case control studies but most candidate genes linked to sarcoidosis lack replication. A meta-analysis concluded that polymorphisms of the tumor necrosis factor (TNF) gene located within the MHC locus is associated with a 1.5-fold increase risk of developing sarcoidosis.[45] There appears to be no increased risk associated with polymorphisms in genes encoding angiotensin-converting enzyme (ACE) or vitamin D receptor.

Genome-wide association studies of both familial and sporadic sarcoidosis incident cases have identified multiple chromosomal regions that may contribute to sarcoidosis susceptibility, suggesting multiple small genetic effects may influence risk. German and US investigators reported that the butyrophilin-like 2 (*BTNL2*) gene is associated with sarcoidosis risk in White and to a lesser extent, Black populations.[46,47] In addition to increased risk for disease susceptibility, recent studies suggest that BTNL2 polymorphisms may associate with chronic active disease.[48,49] Since *BTNL2* is a member of the B7 receptor family that functions in T-cell costimulation, a plausible hypothesis links the *BTNL2* gene with T-cell immunity and sarcoidosis susceptibility.

German investigators reported novel genetic loci at chromosome 6p12.1, and 11q13.1 to be associated with sarcoidosis susceptibility.[50,51] This group also identified risk associations with annexin A11, which has been also associated with Crohn disease.[52] Other studies have

identified additional loci including 10p12.2 to have associations with both sarcoidosis and inflammatory bowel disease.[53,54]

PATHOLOGY

The pathologic hallmark of sarcoidosis is the presence of discrete, noncaseating, epithelioid cell granulomas (Fig. 55-1). The dominant cell in the central core is the epithelioid cell, thought to be a differentiated form of a mononuclear phagocyte. CD4 lymphocytes and mature macrophages are typically interspersed throughout the epithelioid core, whereas both CD4+ and CD8+ T cells and B lymphocytes may be seen in the periphery of the granuloma. Occasionally, focal fibrinoid but not caseating necrosis may be seen. Giant cells, often containing cytoplasmic inclusions such as calcium and iron-laden Schaumann bodies and Hamazaki–Wesenberg bodies are scattered throughout the inflammatory locus. These features are not specific for sarcoidosis, as similar histopathologic findings can be seen in infections, berylliosis, Crohn disease, and local "sarcoid reactions" that occur near neoplastic, foreign body, or chronic inflammatory areas.

In the lung, granulomas tend to form along perivascular, peribronchial, and septal regions, areas rich in lymphatic vessels. In the lung, a mononuclear cell infiltration composed predominantly of lymphocytes is often present in the adjacent interstitium. Granulomas in sarcoidosis may resolve or undergo fibrosis, leaving a stellate scar or hyalinized ghost of a former granuloma.

PATHOPHYSIOLOGY

Important considerations in the pathophysiology of sarcoidosis are discussed below.

■ IMMUNOPATHOLOGY

Experimental models indicate that the first step in granuloma formation involves the tissue deposition of poorly soluble antigenic material. An initial innate immune response involves the recruitment and activation of antigen-presenting cells such as macrophages or dendritic cells expressing pattern recognition receptors and Toll-like receptors (TLRs). This results in the phagocytosis and degradation of antigenic proteins, generating peptide: MHC complexes that are displayed on the cell surface for analysis by CD4+ T cells. The resulting adaptive immune response is characterized by the expression of effector cytokines dominated by either a type 1 T helper cell (Th1; IFNγ), Th2 (IL4/IL13), or Th17 (IL17/IL21/IL22) response, depending on the nature of the antigen and host genetic/epigenetic factors.[55] Granuloma formation is orchestrated by the subsequent release of cytokines, chemokines, and other mediators by activated innate and adaptive immune cells. Granulomatous inflammation is downregulated with clearance of antigen along with release of anti-inflammatory mediators such as transforming growth factor-b (TGFβ) and IL10 by local immune cells.[56,57]

The immunopathology of sarcoidosis can be modeled in this experimental context (Table 55-1). Sites of granulomatous

TABLE 55-1 Hallmarks of the Pathobiology of Sarcoidosis

Pathology of noncaseating epithelioid granulomas
Genetic susceptibility determined primarily by HLA genes of MHC locus
Oligoclonal expansion of αβ+T cells consistent with antigen-driven inflammation
Polarized Th1 immunity with upregulated Th1 cytokines and chemokines at sites of disease
Potential contribution of Th17 immune responses
Reduced regulatory T-cell function
Microbial triggers with mycobacterial or propionibacterial organisms most commonly implicated
Serum amyloid A dysaggregation within granulomas provides a mechanism for chronic disease

inflammation such as the lung contain activated T cells and mononuclear phagocytes that express the same proinflammatory cytokines and chemokines that have been shown experimentally to be critical in granuloma formation.[58] Lung T cells are predominantly of the CD4 T helper, CD45R0 "memory" phenotype, express the activation markers, VLA-1 (very late activation antigen-1, CD49a) and HLA-DR molecules. Sarcoidosis alveolar macrophages (AMs) spontaneously produce TNF, interleukin-6 (IL6), IL1α, IL15, osteopontin, and the Th1 regulatory cytokines, IL12 and IL18 as well as increased amounts of lysozyme, ACE, and reactive oxygen species. Sarcoidosis AMs express increased density of the costimulatory molecules, CD80, CD86, and CD40, consistent with their enhanced antigen-presenting capability. Dendritic cells likely play a critical role in regulating local immune responses in sarcoidosis but have been the focus of few studies.[59–61] TNF is considered to be a major effector cytokine of granuloma formation in sarcoidosis (and therapeutic target) as enhanced release of TNF by BAL cells is associated with persistent disease.[62] Other proinflammatory cytokines such as IL1, macrophage migration inhibitory factor, IL6, and osteopontin are upregulated in sarcoidosis. Consistent with upregulated proinflammatory cytokine expression, there is increased activation of the transcription factor NF-κB in the lung of sarcoidosis patients,[63] and downregulation of the inflammation-suppressive transcription factor, peroxisome proliferator–activated receptor-γ.[64]

Studies of T-cell receptor (TCR) gene expression provide direct evidence that sarcoidosis is an antigen-driven disorder. Oligoclonal expansions of T cells expressing specific Vβ- or Vα-specific TCR gene segments have been found in the lung (BAL T cells), skin (Kveim biopsy sites), and blood.[65,66] The best studied example involves the remarkable expansion of Vα2.3 (AV2S3)+ BAL T cells from HLA-DRB1*0301-positive Scandinavian patients with sarcoidosis.[67] The specific antigens driving these clonally expanded T-cell populations remain uncertain but may include autoantigens such as vimentin and microbial antigens such as mKatG.[34] These studies provide evidence that oligoclonal T-cell expansions in sarcoidosis are driven by conventional antigens.

TH1 AND TH17 IMMUNITY

There are compelling data that sarcoidosis is characterized by dominant Th1 cytokine production compartmentalized to sites of inflammation.[68,69] Multiple studies confirm that pulmonary sarcoidosis is associated with enhanced expression of Th1 associated IFNγ, IL12, and IL18 in the lung but low or undetectable levels of IL4 or IL5. Characteristic of a Th1 response, the Th1-differentiation transcription factors, T-bet (T-box, expressed in T cells), and STAT-1 and its phosphorylated form are upregulated in sarcoidosis.[70,71] Consistent with Th1 polarization, most sarcoidosis BAL T cells express a functional, high-affinity IL12 receptor and the chemokine receptors CXCR3 and CCR5. This dominant Th1 polarization is characteristic of sarcoidosis at time of diagnosis and after years of known disease.

The role of Th17 responses in sarcoidosis is uncertain. Several studies show upregulated Th17 responses in sarcoidosis blood and tissues,[72,73] with release of IL17 and IL22,[74] but others show decreased or no upregulated Th17 responses in sarcoidosis compared to control subjects.[75–77] Despite an established role for Th17 effector T cells in granulomatosis with polyangiitis (GPA), (formerly known as Wegener granulomatosis) and tuberculosis,[78,79] whether Th17 responses play a critical role in disease outcome or can substitute for the polarized Th1 responses documented in sarcoidosis needs further study.

IMMUNOREGULATORY CELLS

Regulatory T cells (Tregs) maintain immune homeostasis by suppressing the function of antigen-presenting cells and effector T cells. Several groups have reported that FoxP3-positive natural Tregs (nTreg) accumulate at sites of granulomatous inflammation in sarcoidosis but may have reduced function in suppressing proinflammatory cytokine expression and granuloma formation.[80–82] Diminished numbers of immunoregulatory natural killer T (NKT) cells have also been reported and may contribute to chronic active sarcoidosis.[83] Whether the functional impairment of nTreg or NKT cells in sarcoidosis are primary defects or secondary to the hyperimmune Th1 responses in sarcoidosis remains uncertain.

One group studied the effects of nebulized vasoactive intestinal peptide (VIP) in sarcoidosis and found it significantly reduced TNF production by BAL cells.[84] This effect was associated with an increased frequency of lung CD4+CD127-CD25+ Tregs. Since VIP converted naïve CD4+CD25-T cells into CD4+CD25+FoxP3+ Tregs in vitro, the authors suggested inhaled VIP as a potential treatment of immune-mediated lung diseases including sarcoidosis.

MECHANISMS OF PULMONARY FIBROSIS

The mechanisms that promote pulmonary fibrosis in sarcoidosis remain uncertain. IFNγ has direct antifibrotic effects,[85] but this pleotropic cytokine may mediate fibrosis by enhancing lung injury.[86] There is evidence that sarcoidosis AMs transition to an alternative profibrotic M2-like phenotype in fibrotic pulmonary sarcoidosis with upregulated expression of chemokines such as CCL18.[87] The lack of evidence for IL4 upregulation in sarcoidosis suggests that IL10 or IL13 may foster this profibrotic macrophage phenotype.[88]

Increased expression of TGFβ, fibronectin, insulin-like growth factor-1 (IGF-1), laminin, and matrix metalloproteases by sarcoidosis AMs may promote a fibrosis-permissive environment in chronic active sarcoidosis through the recruitment and activation of fibroblasts.[69,89] While increased TGFβ is associated with the presence of structural lung disease among sarcoidosis patients,[90,91] the exact role of TGFβ in sarcoidosis remains unclear since it not only has profibrotic but immunoregulatory effects.

SERUM AMYLOID A DYSAGGREGATION HYPOTHESIS

The major challenge of sarcoidosis is to understand what drives chronic granulomatous inflammation given the lack of evidence for an active mycobacterial or other viable microbial infection in sarcoidosis tissues at any point in the disease. The lack of evidence of viable pathologic organisms in sarcoidosis tissues occurs in the context of often long-term treatment with corticosteroid, immunosuppressive or anti-TNF therapy in these patients. This observation, together with evidence of nonviable remnants of mycobacterial or other microbial DNA in sarcoidosis tissues, and relevant immune responses to these

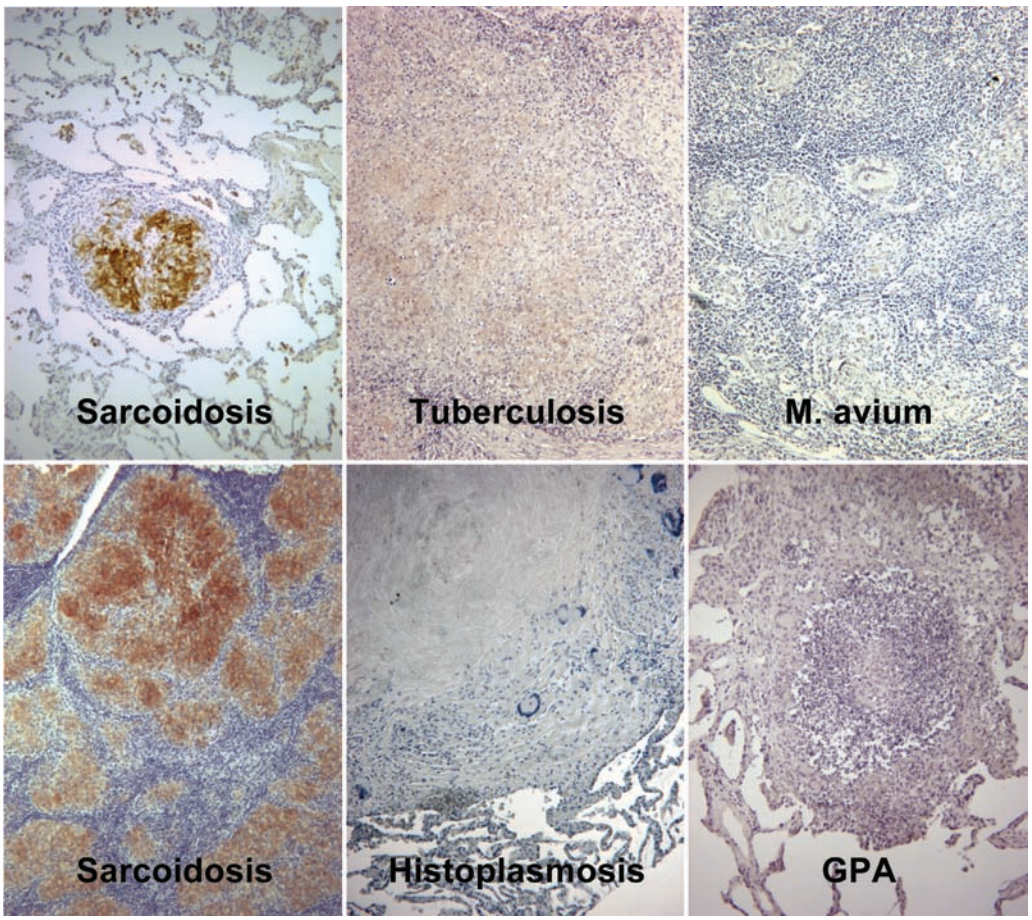

Figure 55-2 Immunohistochemistry showing focal deposition of serum amyloid A *(brownish stain)* in tissues from patients with sarcoidosis but little or no staining for SAA in tuberculosis, *Mycobacterium avium* infection, histoplasmosis, or granulomatosis with polyangiitis (GPA).

organisms, suggests that specific microbes may trigger sarcoidosis, but that a local hyperpolarized Th1 response results in permanent immune control of the triggering infectious agent.

The authors and their colleagues recently reported on a potential mechanism for chronic granulomatous inflammation in sarcoidosis involving the host protein serum amyloid A (SAA).[92,93] Our investigation of SAA was based on our recognition that the granuloma-inducing component in Kveim reagent had physicochemical properties that closely resemble amyloid or prion proteins.[94] SAA is an amyloid precursor protein and acute phase reactant[95] that was previously reported to be upregulated in the blood of sarcoidosis patients as an inflammatory biomarker.[96–98] We reported that SAA was highly concentrated within sarcoidosis granulomas unlike all other granulomatous disorders examined (Fig. 55-2). Our studies showed SAA could promote experimental granulomatous lung inflammation and stimulated the expression of TNF, Th1-related cytokines, and immunoregulatory IL10 by lung BAL cells from sarcoidosis patients, effects mediated in part through TLR-2. We hypothesized that the pathobiology of sarcoidosis is caused by the induction, misfolding, and progressive aggregation of insoluble SAA within granulomas in an amyloid-like process (Fig. 55-3). Tissue SAA and its released peptides then promote the subsequent feed-forward amplification of local Th1 responses to pathogenic antigens at sites of granulomatous inflammation to promote slowly progressive chronic inflammation centered around insoluble SAA as a nidus for granuloma formation.

CLINICAL FEATURES

The clinical features of sarcoidosis are discussed in detail below.

■ CLASSIFICATION

The clinical manifestations and course of sarcoidosis vary greatly (Table 55-2). Although any organ of the body can be affected, the lungs or intrathoracic lymph nodes are involved in more than 90% of patients with sarcoidosis. Patients may manifest with no symptoms or develop acute, subacute, or indolent manifestations. Systemic constitutional symptoms such as fever, fatigue, malaise, and weight loss are seen in over 50% of patients and may be disabling. One classification scheme with prognostic information categorizes patients based on their initial manifestations as follows: asymptomatic, acute sarcoidosis with or without erythema nodosum, sarcoidosis with symptoms or signs of pulmonary disease for less than 2 years, chronic pulmonary sarcoidosis of more than 2 years, and dominant extrapulmonary sarcoidosis. Two years represent an arbitrary but useful reference point for distinguishing patients who usually, but not always, have long-term disease.

Rare manifestations of sarcoidosis include unusual patterns of organ involvement, the result of granulomatous inflammation developing in unusual locations for sarcoidosis, or when sarcoidosis is associated with a second disorder (Table 55-2). In general, rarer manifestations reflect the known pathophysiology and clinical behavior of more common organ involvement.

■ ASYMPTOMATIC SARCOIDOSIS

Up to two-thirds of patients are asymptomatic but have sarcoidosis diagnosed after an incidental radiographic finding of bilateral hilar adenopathy. Occasionally, interstitial infiltrates are seen in association with intrathoracic adenopathy in asymptomatic patients, most commonly in Whites.

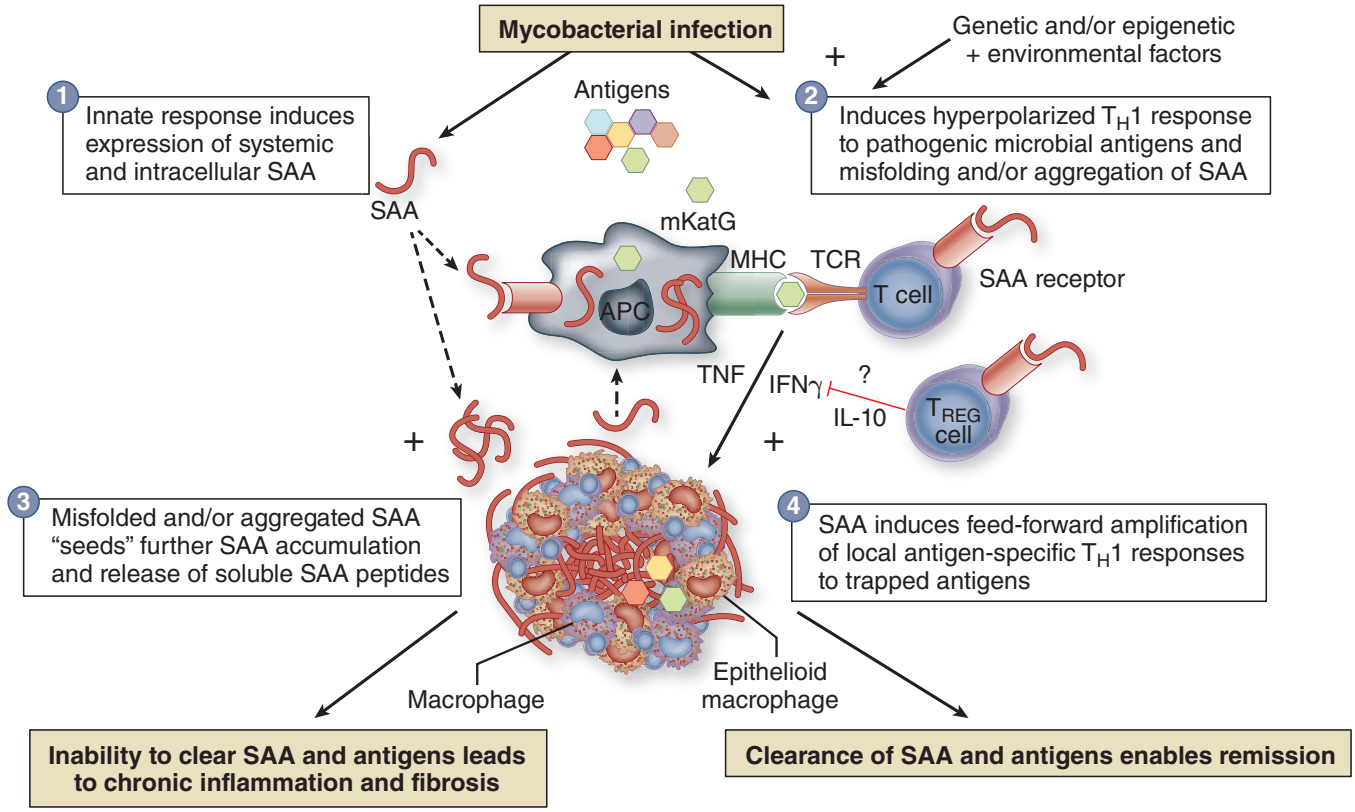

Figure 55-3 Serum Amyloid A dysaggregation as a disease-defining pathway for chronic sarcoidosis. In this scenario, misfolded amyloid-like SAA aggregates serve as "seed" that provides a poorly soluble nidus and a template for further SAA aggregation within sarcoidosis granulomas. SAA and SAA peptides released from the granulomas stoke a feed-forward stimulation of macrophages and T cells that amplifies polarized Th1 responses to local pathogenic antigens with production of TNF, Th1 promoting cytokines and IL10 (which partially dampens the inflammatory response). These effects are mediated in part through TLR2. Persistent tissue antigens may derive from degradation-resistant pathogenic microbial antigens such as mKatG, new antigens trapped by the granuloma matrix and cells or from induction of autoimmune responses. This pathobiologic course continues unabated unless there is clearance of SAA and local pathogenic antigens with downregulation of Th1 responses. Although the model depicts mycobacterial organisms as inciting agents, nonmycobacterial microbes or environmental agents could trigger a similar pathobiologic outcome. *(Reproduced with permission from Chen ES, Moller DR. Sarcoidosis–scientific progress and clinical challenges. Nat Rev Rheumatol. 2011;7(8):457–467.)*

■ ACUTE SARCOIDOSIS WITH OR WITHOUT ERYTHEMA NODOSUM

Sarcoidosis may manifest with the acute onset of erythema nodosum associated with bilateral hilar adenopathy, fevers, polyarthritis, and often uveitis, known as Löfgren syndrome. Erythema nodosum is characterized by tender reddish nodules several centimeters in diameter, usually located on the lower extremities; histologic examination shows panniculitis, not granulomas. The polyarthritis is often severe and incapacitating, typically involving the ankles, feet, knees, and occasionally, wrists, and elbows. Approximately 10% of patients with this syndrome have a normal chest radiograph. Löfgren syndrome is more common in European and White populations, but found in less than 5% of Blacks with sarcoidosis. Some patients manifest acute arthritis, bilateral hilar lymphadenopathy, and constitutional symptoms without erythema nodosum. In either case, the prognosis is excellent for remission in 70% to 80% of patients, typically within several months.

■ PULMONARY SARCOIDOSIS

Respiratory symptoms occur in 40% to 60% of patients.[99] The most common symptoms are cough and shortness of breath, usually of a progressive, insidious nature. The cough is usually nonproductive and may be severe. Dyspnea is typically worse with exertion. Sputum production and hemoptysis are frequent in patients with fibrocystic sarcoidosis that is often associated with bronchiectasis. Ill-defined chest pain is a frequent complaint, possibly caused by nerve irritation from inflammation, scarring, or lymph node enlargement in the chest. Chest tightness and wheezing are common with endobronchial disease or fibrocystic changes. These symptoms are usually poorly responsive to bronchodilators, except in those with reversible airway hyperreactivity. Physical findings are infrequent, with lung crackles heard in less than 20% of patients; clubbing is rare.

Chest Imaging

The chest radiograph is abnormal in more than 90% of known cases and carries prognostic information. Chest radiographs are categorized by international convention: stage 0 (<15%) denotes a normal chest X-ray; stage I (30% to 50%) shows symmetric bilateral hilar adenopathy often with right paratracheal adenopathy; stage II (40% to 60%) and stage III (10% to 20%) indicate the presence of pulmonary infiltrates with (stage II) or without (stage III) bilateral hilar adenopathy; stage IV (<15%) shows obvious scarring with fibrocystic changes with cephalad hilar retraction (Fig. 55-4). The hilar adenopathy often has a symmetric "potato node" appearance and calcifications are uncommon. Infiltrates most commonly appear as linear or reticulonodular markings in the middle and upper lung fields, but occasionally can present with patchy, focal alveolar consolidations mimicking infectious pneumonia, granulomatosis with polyangiitis (GPA), eosinophilic pneumonia, or malignancy. Less frequently, a miliary pattern is observed but would warrant exclusion

TABLE 55-2 Clinical Manifestations of Sarcoidosis

Organ System (Percent Clinical Disease)	Major/Uncommon Manifestations
Pulmonary (>90%)	Restrictive, obstructive impairment, reduced diffusing capacity, fibrocystic disease, bronchiectasis/pulmonary vasculitis, mycetomas, cavitating nodules, lobar atelectasis, tracheal or bronchial stenosis, superior vena cavae syndrome, pleural disease, pneumothorax
Constitutional symptoms (>50%)	Fevers, night sweats, malaise, excessive fatigue, unintentional weight loss
Upper respiratory tract and oral cavity (5–10%)	Hoarseness, laryngeal or tracheal obstruction, nasal congestion, sinusitis/saddle nose deformity, respiratory failure from upper airway obstruction, sleep apnea
Ocular (20–30%)	Anterior and posterior uveitis, chorioretinitis, conjunctivitis, optic neuritis/granulomatous orbital inflammation
Skin (20–30%)	Erythema nodosum, chronic nodules and plaques, lupus pernio, alopecia/subcutaneous sarcoidosis, ichthyosis, alopecia, scar granulomas
Hepatic/Abdominal (10–20%)	Hepatosplenomegaly, jaundice, cirrhosis, abdominal/retroperitoneal lymphadenopathy/massive hepatomegaly, jaundice with pruritus, cirrhosis with portal hypertension, massive splenomegaly, pancreatic mass, gastric involvement, small or large intestine involvement, appendicitis
Cardiac (5–20%)	Arrhythmias, heart block, cardiomyopathy, sudden death/valvular disease, pericardial disease, ventricular or atrial mass
Neurologic (5–10%)	Facial and other cranial neuropathies (e.g., Bell palsy) aseptic meningitis brain mass, seizures, obstructing hydrocephalus, hypothalamic hypopituitarism, myelopathy, polyneuropathy, peripheral neuropathies, small fiber neuropathy/optic chiasmal involvement, cerebritis (white matter involvement), cerebral vascular occlusion, encephalitis, corpus callosum involvement, hydrocephalus, Horner syndrome, Argyll Robertson or Adie pupil, cerebellar involvement, pseudotumor cerebrei, brain stem involvement, transverse myelitis, intraspinal mass, cauda equina or spinal root involvement, mononeuritis multiplex
Exocrine gland (10–20%)	Salivary, lacrimal, and parotid gland enlargement, sicca syndrome/Heerfordt syndrome, hypopituitarism, diabetes insipidus, thyroid mass, thyroiditis, parotid mass, dacryoadenitis, sicca syndrome
Hematologic (20–30%)	Peripheral or retroperitoneal lymphadenopathy, splenomegaly, hypersplenism, anemia, lymphopenia/hypogammaglobulinemia, lymphedema, idiopathic thrombocytopenic purpura (ITP)
Joints and musculoskeletal (10–20%)	Polyarthritis, Achilles tendinitis, heel pain, polydactylitis, bone cysts, myopathy/polymyositis, bone cysts—long bones, skull, vertebrae
Endocrine (10–30%)	Hypercalciuria, hypercalcemia, hypopituitarism, diabetes insipidus
Renal (<5–10%)	Renal calculi, nephrocalcinosis, renal failure
Genitourinary (<5%)	Ovarian or uterine mass, dysmenorrhea, testicular mass, epididymitis/uterine mass, ovarian involvement, menometrorrhagia, testicular mass, epididymitis, intermittent azoospermia
Psychosocial manifestations (30–60%)	Depression, pain, fatigue

of tuberculosis, hypersensitivity pneumonitis, chronic beryllium disease, or lymphangitic carcinomatosis. While stage IV sarcoidosis is associated with a poor prognosis, the recent ACCESS study affirms the weak correlation between stages I, II, or III chest radiographs and clinical status.[12,100] Unusual radiographic signs of sarcoidosis include pneumothorax, mycetoma, isolated nodule or mass, lobar atelectasis, or pleural effusions.

Chest computed tomography (CT) typically demonstrates that infiltrates tend to be central, following bronchovascular structures. Ground-glass infiltrates or honeycombing can also be seen. The adenopathy of sarcoidosis typically appears as multiple discrete enlarged lymph nodes rather than amorphous, mass-like growths more suggestive of malignancy. CT of the chest is often useful in the evaluation of patients with suspected sarcoidosis and to help plan bronchoscopic biopsy of enlarged lymph nodes, define unusual radiographic features, fibrocystic disease, or bronchiectasis.

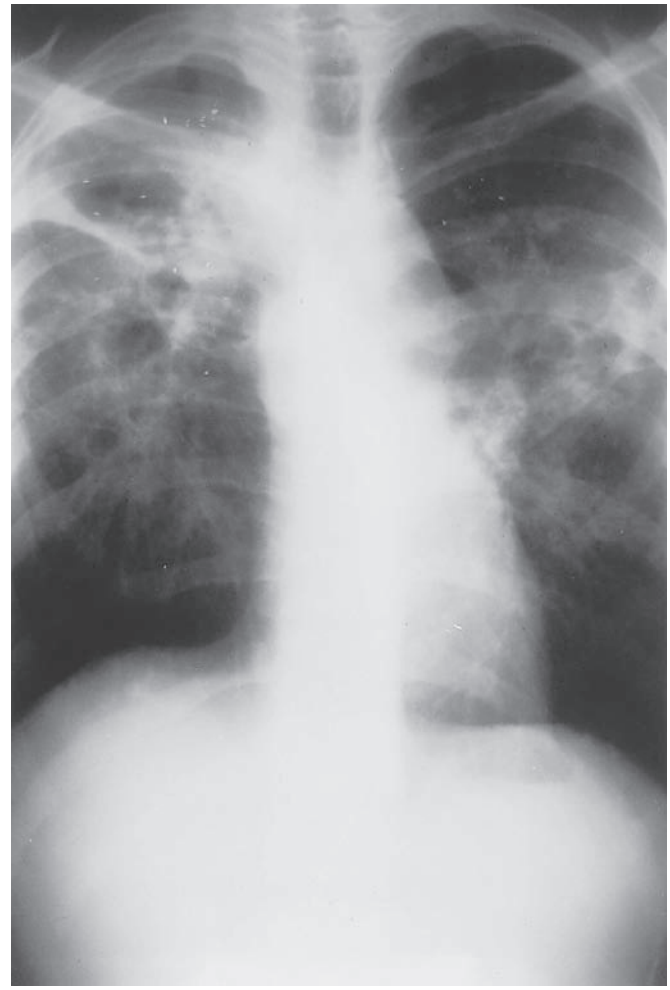
Pulmonary Function Tests

Pulmonary function may be normal even when the chest radiograph demonstrates pulmonary infiltrates. However, restrictive impairment with reduction in lung volumes, forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1), is common, particularly when pulmonary infiltrates are present on chest radiograph. Reduction in diffusing capacity can be seen in association with restrictive impairment or as an isolated deficit. Obstructive impairment is as common as restrictive impairment, particularly in advanced fibrocystic disease or endobronchial disease. A subgroup of patients have bronchial hyperresponsiveness and airway obstruction that may respond to bronchodilators. Resting hypoxemia and exercise O_2 desaturation are typical when there is severe obstructive or restrictive impairment. CO_2 retention is unusual except in advanced pulmonary disease.

Pulmonary Hypertension

Pulmonary hypertension represents an important complicating factor of pulmonary sarcoidosis because it is associated with increased mortality. In patients with end-stage pulmonary sarcoidosis awaiting lung transplantation, pulmonary hypertension is associated with a fivefold increased rate of mortality.[101,102] Overall, ~6% of patients with sarcoidosis have pulmonary hypertension, but is seen in over 70% of patients with advanced lung disease. In patients with dyspnea disproportionate to pulmonary function impairment, pulmonary hypertension may be seen in 50% of cases.[103] The causes of pulmonary hypertension include extensive interstitial lung disease with loss of pulmonary capillary bed, granulomatous pulmonary vasculitis, pulmonary arterial impingement by lymphadenopathy or traction lung scarring of bronchovascular bundles, left heart dysfunction, or rarely, pulmonary venous occlusion.[104] Patients typically present with progressive dyspnea. Echocardiography is a useful screening technique, but right heart catheterization is needed to confirm clinically significant pulmonary hypertension.

A



B

Figure 55-4 Chest radiographs of pulmonary sarcoidosis. **A.** Stage II sarcoidosis pattern with prominent, discrete "stand-away" hilar nodes, right paratracheal adenopathy, and fine reticulonodular infiltrates. **B.** Fibrocystic sarcoidosis with extensive scarring, bullous and cystic changes, hilar retraction, and parenchymal infiltrates.

Necrotizing Sarcoid Granulomatosis

This disorder is characterized by large, confluent, noncaseating granulomas involving both pulmonary arteries and veins but without systemic vasculitis, and is often considered a variant of pulmonary sarcoidosis.[105] Patients may be asymptomatic or have cough, dyspnea, fever, chest pain, or constitutional symptoms. Chest radiographs typically demonstrate multiple, usually noncavitating, nodules. Pleural disease with pleurisy or pleural effusions occurs in the majority of patients and may be a clue to the diagnosis. Most patients have spontaneous improvement or a rapid response to corticosteroid therapy.

■ EXTRAPULMONARY SARCOIDOSIS

Many patients have manifestations of granulomatous inflammation in one or more organ systems either in addition to pulmonary involvement or without evidence of pulmonary disease (Table 55-1). The presence of these characteristic extrapulmonary manifestations may help distinguish sarcoidosis from other systemic diseases. Defining clinically significant organ involvement remains a challenge despite improved imaging techniques.

Sarcoidosis of the Upper Respiratory Tract and Oral Cavity

Sarcoidosis of the upper respiratory tract (SURT) occurs in 5% to 10% of patients, usually involving the nasal sinuses or laryngeal structures. Symptoms of nasal congestion, sinusitis, and intermittent epistaxis are often chronic and unresponsive to decongestants or topical corticosteroids. Chronic disease or surgical intervention may result in destruction of the nasal septum and a "saddle nose" deformity. Laryngeal sarcoidosis may manifest with severe hoarseness, stridor, or acute respiratory failure secondary to upper airway obstruction. Frequently, laryngeal sarcoidosis is associated with chronic skin lesions, lupus pernio, or sinus disease. Oral and pharyngeal sarcoidosis is rare, but may manifest with macroglossia, tongue mass, or palatal mass with cartilaginous or bone destruction.

Ocular Sarcoidosis

Ocular involvement is detected in approximately 20% to 30% of patients, more frequently in Black populations.[1] Uveitis is the most common manifestation and is often associated with bilateral hilar adenopathy. The uveitis is more commonly anterior, and may be unilateral or bilateral, with either granulomatous or nongranulomatous features. Granulomatous conjunctivitis is less common. Optic neuritis, or severe chorioretinitis, may present dramatically with blindness. The International Workshop on Ocular Sarcoidosis (2006) has proposed seven clinical signs of ocular inflammation consistent with sarcoidosis including mutton-fat keratic precipitates, nodules in the iris, stroma, or trabecular meshwork, optic disk, and periphlebitis.[106]

Cardiac Sarcoidosis

Although myocardial sarcoidosis is clinically apparent in less than 10% of cases in the United States at initial diagnosis, autopsy studies

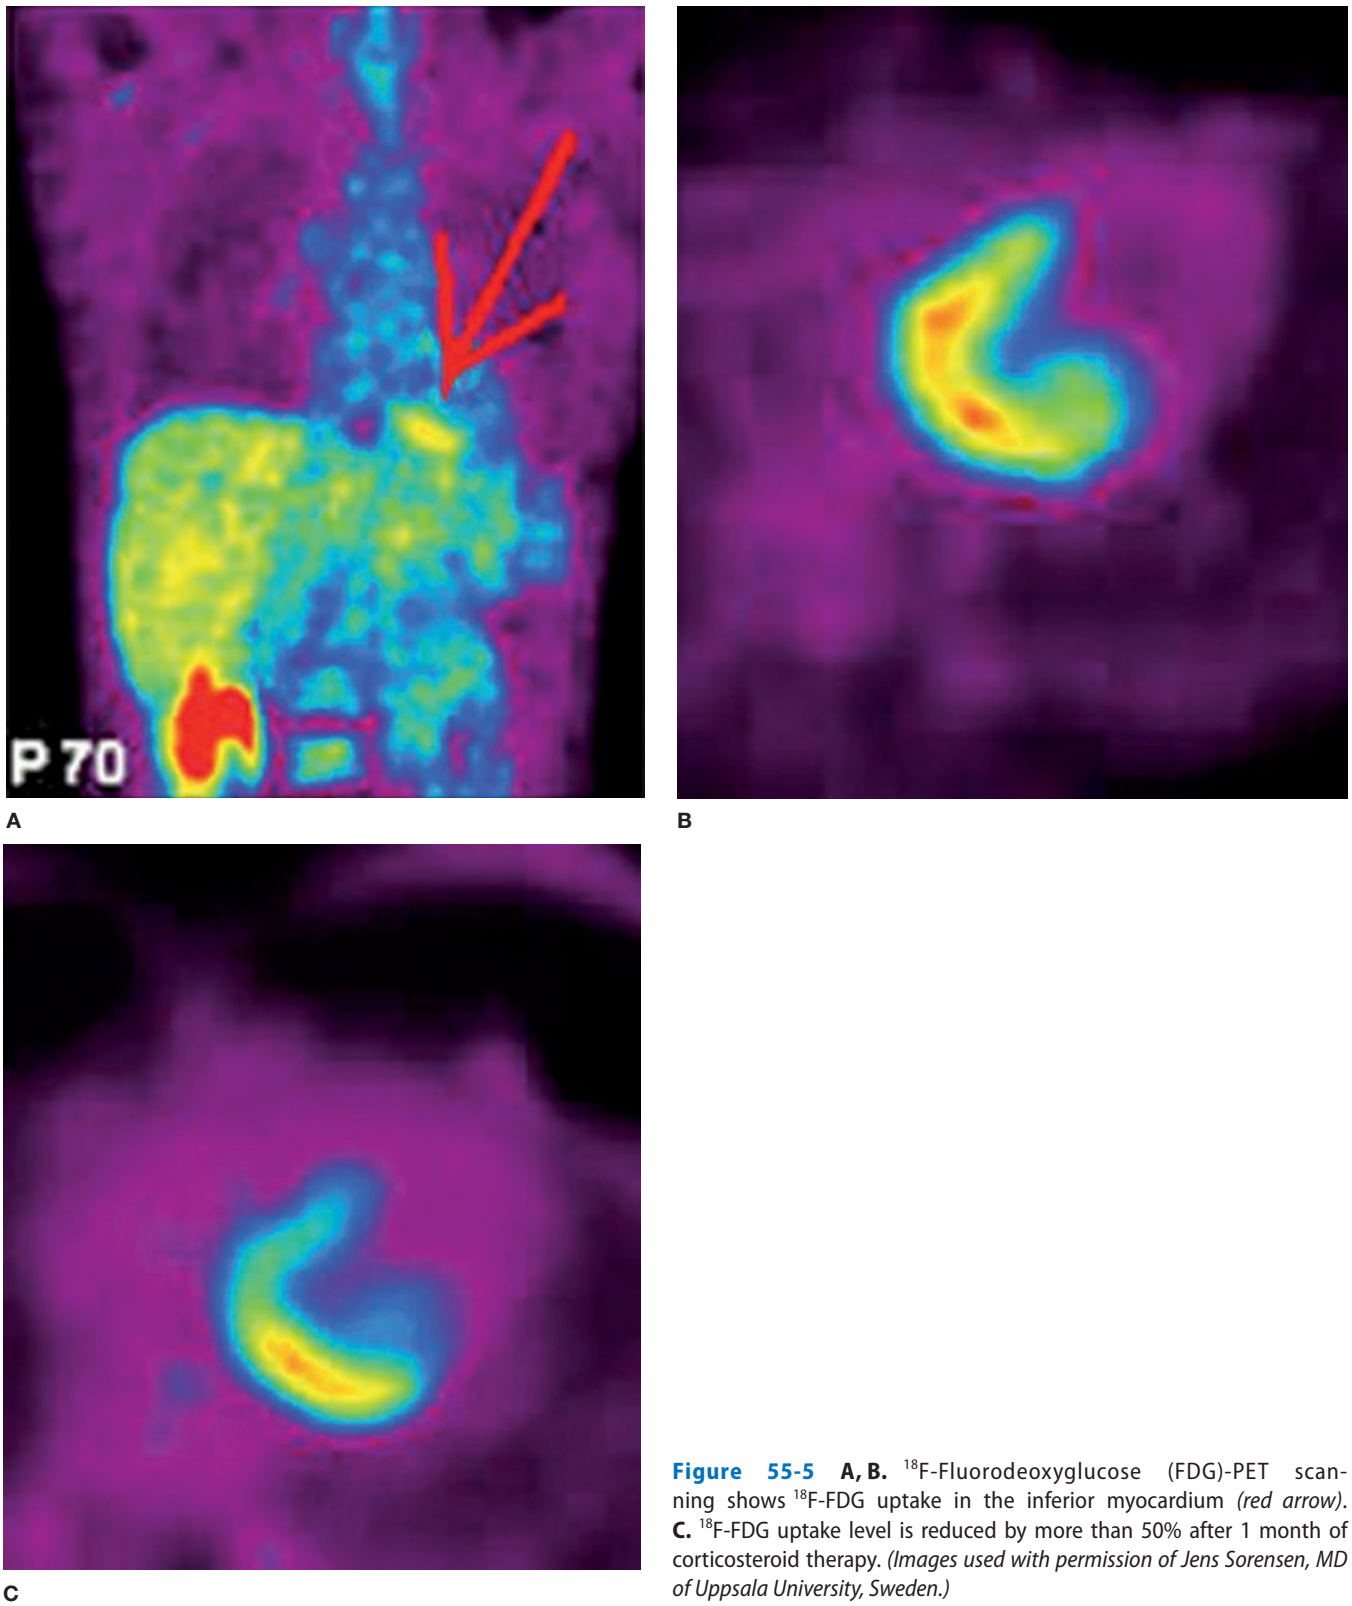


Figure 55-5 **A, B.** ^{18}F-Fluorodeoxyglucose (FDG)-PET scanning shows ^{18}F-FDG uptake in the inferior myocardium *(red arrow)*. **C.** ^{18}F-FDG uptake level is reduced by more than 50% after 1 month of corticosteroid therapy. *(Images used with permission of Jens Sorensen, MD of Uppsala University, Sweden.)*

suggest the prevalence may be greater than 20% in the United States and greater than 50% in Japan.[107,108] Arrhythmias, heart block, or sudden death may be the initial manifestation due to involvement of the conduction system. Myocardial inflammation can lead to dilated cardiomyopathy and congestive heart failure, local akinesia, or aneurysms. Myocardial mass, valvular dysfunction from papillary muscle dysfunction, pericarditis, and myocardial ischemia are rarer manifestations.[109] Radiographic scanning using thallium or technetium sestamibi myocardial scanning, cardiac MRI or cardiac PET reveal myocardial inflammation in a distribution not defined by normal coronary vascular anatomy (Fig. 55-5). The severity of pulmonary involvement does not appear to predict the presence or severity of cardiac sarcoidosis.

Neurosarcoidosis

Neurologic manifestations of sarcoidosis are varied and are estimated to occur in 10% to 20% of patients with sarcoidosis.[110] Cranial neuropathies, with unilateral or bilateral seventh nerve (Bell) palsy being the

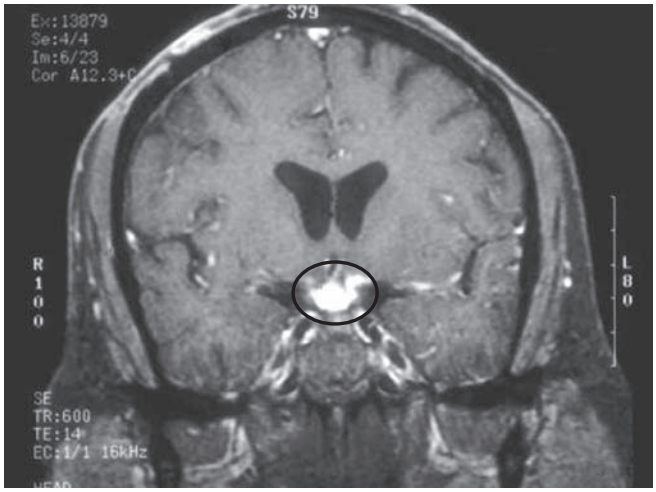

Figure 55-6 Sarcoidosis involving the optic chiasm *(circle)* resulting in blindness.

most common, often resolve spontaneously or with corticosteroids but may recur years later. Optic neuropathy may result in sudden blindness (Fig. 55-6). Impingement of the recurrent laryngeal nerve may cause vocal cord dysfunction. The more typical presentations of sarcoidosis in the brain include a basilar meningitis or aseptic encephalitis, sometimes associated with hypothalamic pituitary dysfunction leading to diabetes insipidus, hypogonadism, or hyperprolactinemia. Meningeal granulomatous masses may mimic meningioma. Spinal cord involvement is rare and can present as a transverse myelitis or mass-like lesion resulting in paraparesis, hemiparesis, back and leg pains mimicking radiculopathy. Peripheral neuropathies account for about 20% of cases of neurosarcoidosis, typically presenting as mononeuritis multiplex or a predominant sensory deficit. The presence of a small fiber neuropathy has been demonstrated in a subset of patients with sarcoidosis and can contribute to chronic pain, excessive fatigue, and autonomic dysfunction.[111]

Cutaneous Sarcoidosis

Chronic skin sarcoidosis is seen in approximately 25% of patients, usually manifesting as plaques or subcutaneous nodules and is more common and severe in Blacks. Typically, the plaques are located around the hairline, eyelids, ears, nose, and extensor surfaces of the arms and legs. Lupus pernio is a disfiguring form of cutaneous sarcoidosis of the face, with violaceous plaques and nodules covering the nose, nasal alae, malar areas, and areas around the eyes. Erythema nodosum is a nongranulomatous panniculitis seen in acute sarcoidosis.

Hepatic Sarcoidosis

Liver biopsies show granulomatous inflammation in over 50% of patients, but clinical manifestations are much less frequent. Active hepatic inflammation may be associated with fever, tender hepatomegaly, or pruritus that may mimic primary biliary cirrhosis except that autoimmune serologies are negative. Characteristically, the serum alkaline phosphatase and γ-glutamyltransferase are elevated proportionately higher than the transaminases or bilirubin, although the latter may be observed with advancing liver dysfunction. Progressive cirrhosis occurs in a subset of patients if not treated.

Gastrointestinal Sarcoidosis

Sarcoidosis involvement of the gastrointestinal tract is rare. Occasionally, direct esophageal involvement may cause dysphagia, but more commonly this symptom may be caused by extensive mediastinal lymphadenopathy that impinges esophageal motility. Gastric sarcoidosis may manifest as dyspepsia, abdominal pain, or gastric nodule. Although autopsy studies show scattered granulomas in the gut, clinically symptomatic intestinal sarcoidosis is rare.

Abdominal Sarcoidosis

A variant of sarcoidosis, often called abdominal sarcoidosis, manifests with liver, spleen, and often bone marrow involvement with hypercalcemia or abdominal lymphadenopathy. Constitutional symptoms are frequent with fevers and fatigue. This "triad" pattern may be seen with or without pulmonary involvement; in the latter instance, intra-abdominal malignancy must be excluded.

Hematologic Sarcoidosis

Persistent, bulky, painful, or disfiguring adenopathy is seen in <10% of patients, most commonly involving the cervical, supraclavicular, axillary, or epitrochlear lymph nodes. Splenomegaly occurs in <10% of patients, and may be massive and associated with hypersplenism. Because many of the clinical features of sarcoidosis and lymphoma are similar, clinicians should employ heightened awareness to exclude malignancy in patients with a known diagnosis of sarcoidosis who experience new onset of adenopathy and splenomegaly.[112]

Peripheral blood lymphopenia is common in sarcoidosis.[113] Granulomas in the bone marrow are found in about 20% of patients who come to autopsy but usually do not cause symptoms. A known feature of sarcoidosis is the impaired cutaneous response to common antigens that elicit delayed-type hypersensitivity reactions, seen in >30% of patients. The mechanism is unknown but may be related to alterations in regulatory T-cell function.

Joint and Musculoskeletal Sarcoidosis

Arthralgias are a frequent complaint in sarcoidosis. A short-lived polyarthritis is typical of acute sarcoidosis, usually associated with erythema nodosum. Chronic joint disease is found in less than 5% of patients. Joint cartilaginous erosion is rare, but "punched out" bony lesions with cystic changes and loss of bony trabeculae may be seen in subchondral locations. Cystic lesions of the long bones, pelvis, sternum, skull, and vertebrae are uncommon. Symptomatic myopathy with marked elevation of serum creatinine phosphokinase, aldolase, aspartate aminotransferase, weakness and tenderness is uncommon. Typically, the myositis from sarcoidosis is responsive to systemic immunosuppression, and recalcitrant cases prompt consideration of alternative diagnosis such as inclusion body myositis.[114]

Exocrine Gland Sarcoidosis

Granulomatous inflammation of salivary, parotid, and lacrimal glands results in enlarged, tender glands, and/or sicca syndrome with dry mouth and dry eyes in less than 5% of patients with sarcoidosis. The association of fever, parotid enlargement, facial palsy, and uveitis is known as uveoparotid fever, or Heerfordt syndrome, and is usually accompanied by bilateral hilar adenopathy.

Endocrine Sarcoidosis

Abnormal calcium metabolism is found in sarcoidosis; hypercalciuria is more frequent than hypercalcemia. These abnormalities are due primarily to increased conversion of 25(OH) vitamin D metabolites to active $1,25(OH)_2$ vitamin D by tissue macrophages and epithelioid cells at sites of granulomatous inflammation.[115] Hypothalamic/pituitary insufficiency may be a manifestation of neurosarcoidosis.

Renal Sarcoidosis

Kidney stones are the most frequent manifestation of renal sarcoidosis, usually related to abnormal calcium metabolism. Renal failure due to nephrocalcinosis may result from chronic, often asymptomatic hypercalcemia or hypercalciuria. Granulomatous involvement of the kidneys occurs but is rarely the cause of significant renal dysfunction.

Genitourinary Sarcoidosis

Sarcoidosis of the reproductive system has been estimated to occur in less than 1% of clinically diagnosed cases and in 5% of autopsy cases. Genitourinary manifestations of sarcoidosis in men include testicular masses and acute epididymitis-orchiditis. In women, sarcoidosis may manifest with uterine or ovarian involvement that may cause dysmenorrhea or mimic malignancy or fibroids.

Psychosocial Manifestations

A Dutch study found the prevalence of depression was 4% in asymptomatic patients and 30% in symptomatic patients with sarcoidosis while the prevalence of depression was found to be 60% in a US study of both White and Black patients with sarcoidosis.[116,117] In this latter study, depression was associated with the female sex, lower socioeconomic status, poor access to care, and increased disease severity, but not race.

Fatigue is commonly reported and may be disabling for a subset of patients.[118] The prevalence of pain in sarcoidosis is unclear, but clinical experience suggests it is common with frequent reports of arthralgias, myalgias, headache, and chest pain. The cause of pain is often multifactorial with causes ranging from direct granulomatous inflammation of bones, joints, muscles, or peripheral nerves to small fiber neuropathy. A subset of patients meets diagnostic criteria for fibromyalgia. In addition to its association with pain, small fiber neuropathy may cause autonomic dysfunction with gastrointestinal dysmotility, incontinence or retention, sicca syndrome, flushing, sweats, orthostatic hypotension, and sexual dysfunction.[119]

■ ASSOCIATED CONDITIONS

Important selected conditions associated with sarcoidosis are discussed briefly below.

Sarcoidosis and Pregnancy

There is usually little long-term effect on the course of sarcoidosis from pregnancy. In contrast to diseases such as asthma and systemic lupus that may progress during pregnancy, spontaneous improvement in chronic sarcoidosis has been reported in some patients during pregnancy, although exacerbations often follow several months after delivery. The reasons for the temporary clinical improvement are not known but might be related to suppressed Th1 immunity during pregnancy associated with enhanced Treg function.

Altered Th1 Immunity

Sarcoidosis is associated with several clinically disparate situations associated with altered, enhanced Th1 immunity. The clearest example involves the administration of Th1-promoting therapeutics such as IFNα, IFNγ, IL2, and IFNβ that may be associated with initiation or recrudescence of sarcoidosis.

Common Variable Immunodeficiency Granulomatous inflammation has been identified in several immunodeficiency states, particularly in patients with hypogammaglobulinemia secondary to common variable immunodeficiency (CVID). Within subsets of patients with CVID, case series reports suggest that a diagnosis of concurrent sarcoidosis can be inferred by a compatible history of systemic illness and confirmed by biopsy.[120] In other CVID patients who present with dominant pulmonary manifestations, a recently described CVID-associated granulomatous-lymphocytic interstitial lung disease may be present and is often resistant to treatment.[121] Since CVID occurs at any age, a high index of suspicion must be maintained, particularly in sarcoidosis patients who have recurrent infections or in any child with sarcoidosis given the low frequency of sarcoidosis in this age group.

Human Immunodeficiency Virus Sarcoidosis may develop in HIV-infected patients with immune reconstitution following initiation of highly active antiretroviral therapy, perhaps from reconstituted Th1 immunity.[122] Granulomatous inflammation of the lungs or skin is most often reported.

Autoimmune Disorders Sarcoidosis is associated with a variety of disorders of the immune system, such as Crohn's disease, ulcerative colitis, primary biliary cirrhosis, scleroderma, Sjögren syndrome, autoimmune hemolytic anemia, and autoimmune endocrinopathies.[123] Given the rarity of some of these disorders, it is reasonable to postulate that these associations are the result of a common immune disturbance, with altered Th1 immunity that may predispose to both disorders.

Recently, a syndrome of immune-mediated disorders in patients with elevated serum IgG4 levels has been described, commonly presenting as adenopathy, constitutional symptoms, and mass-like tumors.[124] Granulomatous inflammation is observed in a subset of such patients and can mimic sarcoidosis.[125,126]

Cancer Noncaseating granulomas may be seen in or nearby 3% to 10% of tumors and in approximately 4% of regional draining lymph nodes. Less commonly, multi-system granulomas consistent with systemic sarcoidosis develop in patients with a recent or past diagnosis of cancer or following chemotherapy treatment. Often the diagnosis is established by biopsy of enlarged lymph nodes or lung where the presurgical diagnosis is recurrent malignancy. There is usually little functional lung impairment from pulmonary sarcoidosis in these instances, and treatment is often unnecessary with eventual remission. A possible link involves dysregulated Th1/Th2 immunity, a premise supported by several cases of sarcoidosis developing in patients with changes that result in deletion of several Th2 genes (IL4, IL13, CSF2).[127]

Pediatric Sarcoidosis

Sarcoidosis is rare in the preteen ages. In the teenage years, clinical manifestations and prognosis in children is similar to that of adults.[128] Early onset disease in children under 5 years of age typically involves skin, eye, and joint involvement that can mimic juvenile rheumatoid arthritis or Blau syndrome, an autosomal dominant granulomatous disease caused by a NOD2 mutation.[129] This form of sarcoidosis carries a much worse prognosis than disease presenting in older children.[130,131] Pediatric sarcoidosis may also be associated with CVID.

Sarcoidosis in the Elderly

There is a second peak incidence of sarcoidosis between 50 and 65 years. In the ACCESS study, one-third of patients were over the age of 50.[132] Recurrent sarcoidosis after many years, even decades of apparent remission, is also seen, often manifesting with new onset neurologic involvement, or recurrent manifestations of original organ involvement.

DIAGNOSTIC APPROACH

There is no reliable, noninvasive screening test to help confirm a diagnosis of sarcoidosis. A diagnosis of sarcoidosis is based on compatible clinical and radiologic manifestations together with a tissue biopsy demonstrating noncaseating granulomatous inflammation and exclusion of other granulomatous disorders. Exceptions to this approach include patients who manifest with Löfgren syndrome in areas with a low prevalence of histoplasmosis, which may mimic Löfgren syndrome, in which case most experts believe a biopsy is not necessary.[133] Many experts suggest that patients with asymptomatic bilateral hilar adenopathy with presumptive stage I sarcoidosis do not need biopsy unless atypical features are present, given a low pretest probability for alternative diagnoses and the risks for potential complications of a diagnostic biopsy.[134,135] Clinical involvement of more than one organ system helps exclude local granulomatous reactions to foreign bodies, infection, or malignancy.

In general, the easiest accessible biopsy site can be approached to confirm a diagnosis of sarcoidosis. Biopsy of a skin or conjunctival

nodule, enlarged superficial lymph node, or lacrimal gland may help to establish a diagnosis. Noncaseating granulomas on a liver or bone marrow biopsy are nonspecific and support a diagnosis only when competing diagnoses such as infection, drug reaction, or malignancy are excluded.[136]

When a more easily accessible site is not available, biopsy by fiberoptic bronchoscopy remains the most common approach because of its high yield and relative safety. The diagnostic yield of transbronchial biopsy (TBB) is estimated to be >40% even in patients with a stage I chest radiograph and approaches 80% in the presence of lung infiltrates.[137] Transbronchial lung biopsy in advanced fibrocystic sarcoidosis has a low yield, owing to extensive fibrotic changes. Sampling by endobronchial mucosal biopsy (EMB) and transbronchial needle aspiration (TBNA) of thoracic lymph nodes provides additional sensitivity when combined with TBB.[137] The sensitivity of endoscopic bronchial ultrasound (EBUS)-guided TNBA has been found to be superior to standard TBNA in diagnosis of sarcoidosis, but in cases of suspected lymphoma, mediastinoscopy may be needed for histologic diagnosis.[138]

Bronchoalveolar lavage obtained as part of a diagnostic bronchoscopy remains an important method for excluding infectious causes of granulomatous inflammation. Some studies suggest a CD4:CD8 ratio >3.5 of BAL T cells supports a diagnosis of sarcoidosis, but may not differentiate some infectious or noninfectious inflammatory lung diseases.

A diagnosis of cardiac sarcoidosis is usually established by a noncardiac biopsy confirming systemic sarcoidosis along with consistent myocardial imaging studies or rhythm disturbances (Fig. 55-5). Endomyocardial biopsy is positive in <20% of cardiac sarcoidosis owing to sampling inefficiencies and the infrequency of right ventricular involvement; thus a negative biopsy never excludes cardiac sarcoidosis.[139]

A diagnosis of neurosarcoidosis is usually confirmed by biopsy of a non-CNS site. Rarely, brain biopsy is needed to exclude infectious or malignant disease.

For organs that are rarely involved in sarcoidosis, directed biopsy of the involved tissue is often recommended to exclude alternative causes, even when there is documentation of a prior biopsy that confirmed an original diagnosis of sarcoidosis. For organs that are difficult to biopsy, ^{18}F-fluorodeoxyglucose-positron emission tomography (FDG-PET) scanning, or contrast enhanced MRI scanning have replaced gallium[67] scans in helping define sites of clinically occult inflammation that could provide an alternative biopsy approach.[140]

Laboratory tests are generally not helpful in confirming a diagnosis of sarcoidosis but may assist in establishing an alternative diagnosis, such as autoimmune disease. A diagnostic biomarker has not been identified for sarcoidosis. Serum ACE (SACE) levels are elevated in 30% to 80% of patients with clinically active disease from activated epithelioid cells and macrophages at sites of inflammation, but can be also seen in infectious granulomatous diseases, lymphoma, primary biliary cirrhosis, and thyroid disease and lack specificity for use as a diagnostic tool.[141]

CLINICAL ASSESSMENT

Once a diagnosis is established or suspected, an initial evaluation should consist of tests to evaluate the presence and extent of pulmonary involvement and assess the presence and severity of extrathoracic disease (Table 55-3).

Specialized testing is indicated when symptoms or signs suggest extrapulmonary sarcoidosis. Guidelines for when and how to screen for potential cardiac involvement remain uncertain.[142] Given the risk for sudden death, screening for cardiac sarcoidosis is recommended whenever symptoms such palpitations, near-syncope, or syncope are present.[143] A second-level screening may include a Holter monitor, signal-averaged ECG, and echocardiogram to detect conduction abnormalities, heart rate variability, or myocardial dysfunction. Advanced cardiac imaging with cardiac MRI with gadolinium enhancement or cardiac PET scanning is recommended for those patients with continued uncertainty of possible cardiac sarcoidosis.[144] Unexplained dyspnea or chest pain may also be suggestive for sarcoidosis but may also prompt investigations for other etiologies such as pulmonary hypertension. Thallium or technicium sestamibi myocardial scanning is useful to exclude coronary artery disease and may detect patchy fixed or reverse ischemia–perfusion defects consistent with myocardial inflammation or fibrosis.[145] Electrophysiologic testing may be indicated to exclude arrhythmias not detected by routine studies and assess indications for prophylactic cardiac pacemaker or implantable defibrillator to reduce the risk of sudden death. There is no consensus on risk stratification of patients with known cardiac sarcoidosis for placement of an implantable defibrillator, but is typically recommended for patients with moderate or severe cardiomyopathy or serious ventricular arrhythmias.[109,146]

Evaluation for possible CNS and spinal sarcoidosis should include MRI with gadolinium enhancement, now considered the optimal test to detect characteristic inflammatory lesions[147]. The distribution of inflammatory loci has a propensity for periventricular and leptomeningeal areas, although the images are nonspecific, and can be produced by infectious, malignant, or occasionally demyelinating disease. A normal scan does not exclude neurosarcoidosis, particularly for cranial neuropathies or in the presence of corticosteroid therapy. Examination of the cerebrospinal fluid is less often performed today, but may be useful by demonstrating characteristic lymphocytic pleocytosis and/or elevated protein levels. In suspected cases of peripheral neuropathy or myopathy, EMG or nerve conduction studies or rarely, tissue biopsy, may help to establish a link to sarcoidosis. Specialized evaluation including skin biopsy analysis of intraepidermal nerve fiber density may be considered to confirm cases of small fiber neuropathy.[148]

TABLE 55-3 Recommended Tests in the Clinical Evaluation of Systemic Sarcoidosis

All Patients	Organ-Specific Testing for Suspected Involvement
Chest radiograph or chest CT	Cardiac: Echocardiogram, Holter monitoring, thallium or sestamibi myocardial scan, cardiac MR, cardiac PET
Pulmonary function tests: Spirometry, diffusion capacity, lung volumes	Neurologic: Brain or spine MRI with gadolinium enhancement, cerebrospinal fluid examination, nerve conduction studies, small fiber nerve analysis
Ophthalmologic examination	Upper respiratory tract: Flow–volume loop, ENT evaluation
Complete metabolic panel	Endocrine: Pituitary function tests; thyroid function tests
Complete blood count with differential count	
Electrocardiogram	
Purified protein derivative (PPD) skin test	

CLINICAL COURSE AND PROGNOSIS

A clinical framework can be constructed to assist in decisions regarding monitoring and planning treatment strategies. First, organ involvement usually defines itself early in the disease. For example, only 23% of patients in the ACCESS study were found to have one or more new

organ systems involved with sarcoidosis during a 2-year follow-up evaluation; the presence of extrapulmonary involvement at presentation was a risk factor for new organ development.[100] Second, patients who undergo remission usually do so within the first 2 to 3 years. Clinical experience suggests sarcoidosis rarely recurs after a prolonged period of remission, with exceptions most often involving neurologic or ocular manifestations. Third, patients with chronic sarcoidosis generally have progressive, unremitting organ impairment. High rates of relapse are observed in patients (>50%) requiring systemic immunosuppressive medications compared with those who experience spontaneous disease remission (<10%).[149–151] In these patients, the rate of progression varies from individual to individual, as does their response to treatment. A waxing–waning clinical course is uncommon except for a subset of patients with neurologic or ocular manifestations or occasionally recurrent erythema nodosum. Fourth, prognosis in sarcoidosis is strongly influenced by the initial manifestations of disease. Patients with Löfgren syndrome have remission rates of 70% to 80%. An initial stage I chest radiograph is associated with a 60% to 90% remission rate. Patients manifesting with type II chest radiographs have a poorer outcome, with spontaneous remission occurring 40% to 70% of the time. A stage III chest radiograph is associated with remission in only 10% to 20% of patients. Patients with extensive pulmonary fibrosis (stage IV) rarely undergo remission.

Currently, a consensus recommendation is that treatment decisions are best based on repeated clinical examinations and direct measurement of organ function and not on laboratory markers of disease "activity."[152] SACE levels tend to correlate with the extent of granulomatous inflammation throughout the body particularly when interpreted in the context of known polymorphisms of ACE alleles and usually decrease in response to corticosteroids or with disease remission, but the test is highly variable, correlates poorly with functional assessments of disease activity and has no prognostic value.[153] Similarly, BAL parameters such as the proportion of CD4 lymphocytosis or the CD4:CD8 ratio of BAL T cells have been inconsistent in predicting outcomes. Many inflammatory molecules have been proposed as helpful biomarkers for disease activity including sIL2R, TNF, and neopterin but are not reliable prognostic indicators. More recently, studies suggest transcriptomic signatures may be useful for prognosis, but there are no currently validated markers useful for clinical purposes.[154] Monitoring for at least 3 years following presumed "disease remission" is recommended; longer periods of observation are indicated for patients with serious pulmonary or extrapulmonary manifestations.

TREATMENT

A variety of approaches have been utilized in the treatment of sarcoidosis and are outlined in this section.

INDICATIONS

There have been attempts to provide evidence-based recommendations for treatment of sarcoidosis, but the lack of placebo-controlled clinical trials in this highly heterogeneous disease have made firm conclusions problematic. Most physicians agree that corticosteroid or other systemic therapy is indicated for the manifestations listed in Table 55-4.

Indications for treatment must take into account the overall excellent prognosis for most patients with sarcoidosis, particularly for patients with stage I disease, for whom systemic therapy is usually not required. Symptomatic or local therapy is recommended whenever possible. Löfgren syndrome is usually managed with bed rest and nonsteroidal anti-inflammatory drugs; corticosteroids are recommended when symptoms, particularly arthritis, are disabling and persistent. The following consensus recommendations from the British Thoracic Society and the Thoracic Societies of Australia, New Zealand, and Ireland are shown in Table 55-5.[155]

TABLE 55-4 Indications for Treatment of Sarcoidosis

Threatened organ failure—severe ocular, cardiac, or neurologic disease
Progressive or persistent pulmonary disease
Uveitis unresponsive to topical corticosteroids
Persistent hypercalcemia, renal or hepatic dysfunction
Palpable splenomegaly or hypersplenism
Severe myopathy
Disfiguring skin disease
Painful lymphadenopathy
Severe fatigue and weight loss

SYSTEMIC TREATMENT

There are no FDA-approved systemic therapies for sarcoidosis.

CORTICOSTEROID THERAPY

Corticosteroids remain the cornerstone of therapy for sarcoidosis. Although controversy exists regarding the overall effectiveness of corticosteroids in altering the long-term course of the disease, there is no disagreement that corticosteroids provide prompt symptomatic relief and reverse organ dysfunction in most patients with the degree of reversibility dependent on the extent of pre-existing fibrosis. Case series and several but not all clinical trials support the view that corticosteroids favorably affect disease outcome in chronic pulmonary sarcoidosis. One large study by the British Thoracic Society

TABLE 55-5 Consensus Approach to Treatment of Sarcoidosis

1. Treatment is not indicated for asymptomatic patient with only intrathoracic lymphadenopathy
2. Treatment is not indicated in asymptomatic patient with pulmonary infiltrates and mildly abnormal lung function and stable disease
3. Oral corticosteroids are the first line of therapy in patients with progressive disease determined by radiology or lung function, significant symptoms or extrapulmonary disease requiring treatment
4. Treatment with prednisone (or equivalent) 20–40 mg/d initially for 4 wk, then reduced to a maintenance dose that will control symptoms and disease progression for a period of 6–24 mo
5. Bisphosphonates are recommended to minimize steroid-induced osteoporosis
6. Inhaled corticosteroids are not of significant benefit as initial treatment or for maintenance therapy. Inhaled corticosteroids may be considered for symptom control (cough) or bronchial hyperreactivity in a subgroup of patients
7. Steroid-sparing immunosuppressive or anti-inflammatory treatments only have an undefined role in sarcoidosis, but should be considered in patients when corticosteroids are not controlling the disease or side effects are intolerable. At present, methotrexate is the treatment of choice if there are no relative contraindications for its use. Azathioprine is often used when methotrexate is contraindicated or not tolerated
8. Lung (and heart) transplantation should be considered in end-stage pulmonary and cardiac sarcoidosis

Source: Data from Bradley B, Branley HM, Egan JJ, et al. Interstitial lung disease guideline: the British Thoracic Society in collaboration with the Thoracic Society of Australia and New Zealand and the Irish Thoracic Society. Thorax. 2008;63(Suppl 5):v1–v58.

found long-term improved lung function in patients with stage II or III pulmonary disease treated with daily corticosteroid therapy compared with a group treated intermittently with corticosteroids based on symptoms.[149]

Optimal dosing of corticosteroid therapy has not been established by clinical trials. Most authorities suggest that initial treatment of pulmonary sarcoidosis usually does not require more than 20 to 40 mg per day of prednisone followed by a slow taper to a maintenance dose of 5 to 15 mg per day of prednisone. A qod regimen of prednisone in patients may be effective in some but not all patients. Treatment is usually continued for a minimum of 6 to 24 months, since premature attempts to taper off steroids are likely to result in relapse of disease. Inhaled steroids appear to have limited effectiveness in chronic pulmonary sarcoidosis and are not recommended as sole therapy. Overall, recurrent progressive pulmonary disease occurs in more than 20% of patients as oral corticosteroids are tapered or discontinued.

■ ALTERNATIVE AGENTS

Several classes of drugs have been reported to be beneficial in subgroups of patients with sarcoidosis but none of these drugs has been proved effective by rigorous clinical trials.

Nonimmunosuppressive Drugs

Case series suggest hydroxychloroquine is effective in many patients with mucocutaneous sarcoidosis, hypercalcemia and occasionally, as a steroid-sparing agent in systemic sarcoidosis. Ocular toxicity is rare, and its overall safety profile provides a rationale for an early trial of this drug. Chloroquine may be efficacious in treating lupus pernio, SURT, or sinus disease, which is often recalcitrant to other therapies, although ocular toxicity has limited its use.

The tetracyclines, minocycline, and doxycycline, may be effective in a subgroup of patients with mild cutaneous sarcoidosis but rarely as a steroid-sparing drug in systemic disease. These antibiotics have mild anti-inflammatory effects, which probably account for their mechanism of action given that other antibiotics with similar antimicrobial activity have not been found effective in sarcoidosis.

Pentoxifylline is a phosphodiesterase inhibitor with anti-inflammatory effects that was found to be effective in early pulmonary sarcoidosis in one study.[156] Other experiences have not been as favorable with responses in less than 10% of patients, generally those with mild pulmonary or systemic sarcoidosis.

Melatonin was found to be beneficial in a small case series of patients with generally mild disease but wider experience has not confirmed its efficacy.

Thalidomide was found in one study to be beneficial in over 80% of patients with severe skin sarcoidosis (lupus pernio unresponsive to other therapies), but was not effective in pulmonary sarcoidosis.[157] Given the drug's well-known teratogenicity and potential to cause peripheral neuropathy and sedation, the drug is recommended only in patients refractory to other treatments.

Immunosuppressive Drugs

Clinical experience in sarcoidosis suggests that all immunosuppressive therapies share the following characteristics: beneficial responses are seen in no more than 50% to 70% of patients; responses may take 3 to 6 months or longer; low-dose corticosteroid therapy is often needed for synergistic effect to obtain adequate suppression of granulomatous inflammation. Dosing and monitoring for these therapies should follow the recommendations of the American College of Rheumatology.[158]

Methotrexate is often the first immunosuppressive therapy used as an alternative therapy for refractory pulmonary or systemic sarcoidosis when corticosteroid and antimalarial therapies are ineffective or poorly tolerated. Hepatic, pulmonary, and renal toxicities limit the use of the drug. Azathioprine has shown benefit in small clinical trials and is used by some authorities as an initial potent steroid-sparing therapy. Clear advantages of methotrexate or azathioprine over low-dose corticosteroids in the routine management of sarcoidosis have not been established. Other immunosuppressive agents, such as mycophenylate mofetil, leflunomide, or cyclophosphamide, have been found beneficial in a small series of patients with manifestations of sarcoidosis refractory to corticosteroids.

Small studies have shown that cyclosporine and FK506, drugs known to inhibit T-cell activation, are not effective in pulmonary or ocular sarcoidosis or in suppressing recurrent sarcoidosis in transplants. Given their toxicities, consensus is to avoid these medications until new studies demonstrate potential benefits.

Anti-TNF Therapies

The scientific basis for the use of TNF inhibitors in sarcoidosis is firmly established based on the role of TNF in experimental models of granuloma formation. One multicenter study found infliximab to be effective in one of several primary end points (improved FVC after 24 weeks of therapy), although the effect was modest.[159] Etanercept was not shown to be effective in a smaller clinical trial of pulmonary sarcoidosis.[160] Anecdotal cases suggest adalimumab may be effective in some patients with sarcoidosis, although larger studies are lacking. Given the risk profiles of current immunosuppressive drugs, additional clinical trials of these agents are warranted but most authorities reserve these therapies after failure of one or more immunosuppressive drugs.

■ SPECIAL CIRCUMSTANCES

Several special considerations in the management of systemic sarcoidosis warrant particular mention.

Fibrocystic Sarcoidosis

Advanced pulmonary sarcoidosis may be complicated by mycetomas, usually from *Aspergillus fumigatus* that colonize pre-existing cystic spaces. The fungi rarely cause invasive disease. Spontaneous resolution may be seen. The benefit of antifungal agents has not been established but may be used for serious hemoptysis. Massive hemoptysis associated with mycetomas or bronchiectasis may be life-threatening, requiring therapeutic embolization of the appropriate bronchial or collateral artery for control. Surgery is usually not feasible because of the severe restrictive lung disease.

Pulmonary Hypertension

Moderate or severe pulmonary hypertension is an independent predictor of reduced survival in patients with advanced lung disease awaiting lung transplantation. Studies suggest drugs used to treat primary pulmonary hypertension may improve dyspnea and pulmonary hypertension but no study has yet demonstrated survival benefit.[161–163] Further studies are underway to determine the role of these therapies in sarcoidosis.

Cardiac Sarcoidosis

Several large case series find prognosis in cardiac sarcoidosis, and response to treatment is related to the degree of cardiac dysfunction. Treatment of cardiac sarcoidosis consists of antiarrhythmic therapy, diuretics, and afterload-reducing agents for specific cardiac abnormalities. Although randomized trials are lacking, studies from Asia, Europe, and the United States consistently report that corticosteroids in moderate doses are associated with improved cardiac function and outcomes.[164,165] Maintenance doses often range between prednisone 10 to 25 mg a day, although higher doses may be needed for intractable arrhythmias. Immunosuppressive drugs are frequently used as steroid-sparing agents since treatment often must be maintained for years. Automatic implantable

cardioverter-defibrillators (ICDs) may prevent sudden death in patients with serious arrhythmias; guidelines for prophylactic placement of ICDs or pacemakers have not yet been established.

Neurosarcoidosis and Ocular Sarcoidosis

High doses of oral corticosteroids or high-dose pulse intravenous therapy are often indicated for serious ocular or CNS disease, such as optic neuritis or encephalitis followed by maintenance corticosteroid or immunosuppressive therapy. Anterior uveitis can usually be treated with topical ophthalmologic steroid drops. Systemic immunosuppression may be necessary in cases of severe or recurrent disease, but aggressive treatment of neurosarcoidosis is generally associated with favorable outcomes.[166] Small fiber neuropathy typically does not reliably respond to corticosteroid therapy, prompting trials of neuropathic drugs, TNF-inhibitors or other novel agents.[167,168]

Pregnancy

Corticosteroids are the only drugs recommended for use during pregnancy because of the potential of other steroid-sparing drugs to cause fetal toxicity or teratogenicity. Sometimes, spontaneous abatement of chronic sarcoidosis occurs in pregnant patients, allowing a temporary reduction in steroid dosage. After pregnancy, however, an exacerbation often occurs, requiring a return to the original maintenance dose.

Quality of Life

There is increasing recognition of the need to treat depression and pain to improve quality of life in patients with these manifestations. The utility of nonpharmacologic treatments, such as exercise training or rehabilitation, merits investigation because of the impact of these problems in sarcoidosis patients.

Lung and Heart Transplantation

Successful lung, heart–lung, and heart transplantations have been performed in patients with advanced pulmonary sarcoidosis or cardiomyopathy. Although noncaseating granulomas have been found in some transplanted lungs or hearts, these findings do not appear to significantly affect outcome. Outcomes for lung transplant in sarcoidosis are similar to other interstitial lung diseases.[169–171]

CHAPTER 56

Idiopathic Pulmonary Fibrosis

Robert M. Tighe
Eric B. Meltzer
Paul W. Noble

OVERVIEW

In simplest terms, pulmonary fibrosis equates with the growth of "scar" in the lung. Scarred lung can assume any one of a variety of patterns; these patterns define unique pathologic phenotypes. When scar assumes a patchy distribution and appears to emanate from the pleural surface, it is recognized as the "usual" type—otherwise known as usual interstitial pneumonia (UIP). The disease in which UIP manifests without cause or trigger is called idiopathic pulmonary fibrosis (IPF). IPF is, therefore, a type of pulmonary fibrosis (also known as interstitial lung disease [ILD]). IPF is recognized by a unique compilation of clinical, radiographic, and pathologic features. IPF causes breathlessness, disability due to respiratory insufficiency and, in most instances, eventually leads to death.

While there are many causes of ILD, IPF is the most common form of ILD and certainly the most serious. IPF is characterized by an inexorable progression of interstitial pulmonary fibrosis that results in restrictive lung disease and worsening gas exchange. Death from respiratory failure is reported to ensue within 5 years of diagnosis in the majority of patients.

By definition, IPF is UIP in the absence of cause or explanation. It is equally important to remember what IPF is not. IPF is not pulmonary fibrosis from chronic aspiration, drug toxicities, environmental exposures (such as chronic hypersensitivity pneumonitis), and collagen vascular diseases, even if the pattern of fibrosis resembles UIP. Therefore, the diagnosis of IPF can only be made by excluding other possibilities. One of the major challenges in diagnosing IPF is the reasonable exclusion of other potential causes of pulmonary fibrosis. This requires a careful clinical and diagnostic evaluation; and often verges on areas of clinical uncertainty.

IPF typically comes to medical attention later in life, beginning in the sixth decade. IPF is rarely the cause of ILD in patients under the age of 40. The predominant presenting symptoms of IPF are exertional breathlessness and a dry, harassing cough. These are nonspecific complaints shared by a variety of pulmonary and cardiac diseases. In particular, exertional breathlessness is often attributed to advancing age by patients in their sixties and seventies, leading to delays in seeking medical evaluation. In addition, many patients are poorly conditioned and overweight and attribute their symptoms of breathlessness to these circumstances. In addition to nonspecific clinical symptoms, initial nonspecific radiographic findings also fail to trigger prompt medical evaluation. Fine peripheral linear radiographic opacities on plain chest radiographs, predominantly in the lower lung zones, may be interpreted as chronic and nonspecific pulmonary fibrosis, which often does not elicit an alarming response. Delay in diagnosis is therefore the norm. However, in recent years important scientific advances have improved the understanding of IPF pathogenesis; new therapeutic trials are under way and this has increased the enthusiasm for an early diagnosis of IPF.

HISTORICAL PERSPECTIVE

A brief review of the evolution in our understanding of IPF illustrates the contributions made by earlier investigators and account for much of the confusion that many clinicians have regarding IPF. One of the challenges in defining IPF has been the variety of antiquated terms formerly used to describe pulmonary fibrosis. While there are many causes of ILD in general, and pulmonary fibrosis in particular, it is important to note that IPF is a unique disease, although it had not been formally codified until recently when a group of expert pulmonologists, radiologists, and pathologists collaborated on a classification of ILD. Reviewing the history of IPF will both clarify the present terminology and distinguish contemporary nomenclature from the outmoded terms encountered in earlier literature.

Fibrosis of the lung was long recognized in association with infection or dust inhalation. In the 19th century, pulmonary fibrosis was known as "cirrhosis" of the lung. Yet little attention was paid to this form of respiratory illness.[1] Interest in pulmonary fibrosis was ignited in 1944 when Drs. Louis Hamman and Arnold Rich published a seminal paper describing "acute diffuse interstitial fibrosis of the lungs."[2] Hamman and Rich reported a series of unusual cases that shared a unique clinical presentation featuring idiopathic subacute respiratory failure followed by death. Their report was complete with pathologic findings from autopsy. They described thickening of the alveolar interstitium and areas of dense fibrotic scar tissue within the lung. This was the first pathologic depiction of pulmonary fibrosis and, to this day, is considered an accurate portrayal. In retrospect, the cases of Hamman and Rich best fit a diagnosis of the fibrosing interstitial pneumonia now known as acute interstitial pneumonitis (AIP).[3] Yet in the 1940s, the "Hamman–Rich syndrome" became synonymous with IPF. So it remained for the next three decades.

Over the years, clinical reports of pulmonary fibrosis suggested a number of alternate presentations that were referred to as "variants" of the Hamman–Rich syndrome.[4] This included cases that exhibited a rather protracted duration of illness compared to the "classic" Hamman and Rich cases. It was also noted that pulmonary fibrosis occurred in patients who suffered from the "rheumatoid group of collagen diseases." An assortment of abnormal patterns was noted under the microscope. Eventually, the breadth of the Hamman–Rich syndrome encompassed a heterogeneous mixture of clinical manifestations and a variety of histologic forms of pulmonary fibrosis with no distinction made between systemic and limited illness nor any concession to the prognostic implications of an acute versus chronic presentation.

In the 1960s authors began to regularly substitute the term "IPF" for "acute diffuse interstitial fibrosis."[5,6] A debate began concerning the chronicity of this disease, with some authors suggesting a slow course punctuated by "terminal complications,"[5] while others reported an average illness of no more than 2 years.[6]

The term "fibrosing alveolitis" was introduced in England in 1964.[7] Cryptogenic fibrosing alveolitis (CFA) became the preferred term for pulmonary fibrosis in the European literature and it is essentially synonymous with IPF. This term was originally meant to improve upon its predecessor by capturing pathologic features in a manner that was more precise and descriptive. CFA refers to the interalveolar location of the inflammation in pulmonary fibrosing as compared with the intra-alveolar inflammation of infectious pneumonia. This interalveolar septal inflammation was dubbed "alveolitis." It was maintained that alveolitis was responsible for the subsequent development of fibrosis and it was first suggested that corticosteroids be used to treat alveolitis and therefore pulmonary fibrosis.

The most important advance came in 1964 with the publication of an improved and safe technique for performing open lung biopsy.[8] With this procedure, it became possible to carry out a widespread analysis of lung tissue from patients with suspected

pulmonary fibrosis. Before long there were new insights into the pathology associated with fibrotic lung disease.

In 1969 Liebow and Carrington[9] heralded the modern era of ILD histopathology with the notion that idiopathic interstitial pneumonia (IIP) could be split into separate pathologic subtypes. They described distinct patterns of IIP that were identified by examination of lung biopsy specimens with light microscopy. Moreover, these subtypes were found to predict prognosis and response to treatment. Based on their research findings, Liebow and Carrington produced the first detailed histopathologic classification of IIP. They created five categories that were termed UIP, desquamative interstitial pneumonia (DIP), bronchiolitis obliterans interstitial pneumonia (BIP), lymphocytic interstitial pneumonitis (LIP), and giant cell interstitial pneumonia (GIP). More recent observations have led to a modification of this classification of IIP subtypes.[10,11] New categories have been added, such as respiratory bronchiolitis–associated interstitial lung disease (RB-ILD) and nonspecific interstitial pneumonia (NSIP).[10,11]

Simultaneously, a revolution in thinking about the pathogenesis of IPF affected the way in which experts talked about the disease. Researchers at the National Heart, Lung, and Blood Institute (NHLBI) were major proponents of an "inflammatory theory" of pathogenesis as originally proposed by European investigators. This theory was based on studies at the NHLBI throughout the 1970s during which excessive amounts of inflammatory cells were identified in bronchoalveolar lavage (BAL) fluid obtained from IPF patients.[12] The NHLBI agreed with European researchers who had coined the term "alveolitis" and the NHLBI also endorsed corticosteroid treatments. The inflammatory theory has since fallen from favor, mostly as a consequence of corticosteroid inefficacy, and the term "alveolitis" has also fallen out of vogue.

A new hypothesis has replaced the "inflammatory theory" of IPF. This new concept proposes that IPF is the result of alveolar epithelial injury, which is then followed by aberrant repair mechanisms. This theory emerged from landmark ultrastructural studies performed in the mid-1980s.[13,14] Using electron microscopy, it was discovered that the alveolar epithelial cells were injured in IPF. In addition, foci of subepithelial fibrosis were first described. This concept of injury and repair was modified and expand on by subsequent investigators.[15]

In 1997 a modified version of Liebow's pathologic classifications were proposed.[16] The new classification scheme reinforced acceptance of certain categories within the context of an updated understanding of ILD pathogenesis. For instance DIP and UIP categories were retained in the new classification scheme. Some original categories were discarded and two modern categories were added. RB-ILD was recognized in the spectrum of smoking-related lung diseases and a provisional category, NSIP, was also added.[16,17] This modern pathologic classification became the basis for a consensus statement that finally standardized the nomenclature of ILD and IPF for the very first time.

In 2002 a panel of experts convened sponsored jointly by the American Thoracic Society and the European Respiratory Society.[18] This panel released an official statement for the purpose of providing a new and comprehensive classification of IIP that considered all clinical, radiographic, and pathologic features. The diseases recognized by the 2002 ATS/ERS classification of IIP are IPF, NSIP, cryptogenic organizing pneumonia (COP), acute interstitial pneumonia, RB-ILD, DIP, LIP. Further classification of IPF has been undertaken by joint consensus statements of the American Thoracic Society, and European Respiratory Society, in 2000 and 2010.[19,20] These statements attempt to offer strict definitions for each subtype of IIP with practical guidelines for diagnostic purposes. The benefit of attempting to utilize precise definitions is to provide a uniformity of diagnostic decisions in both clinical practice and in research.

Despite the utility of rigorously defining IIP (and IPF), there are several potential pitfalls. For instance, the current classification system relies upon an assumption that each specific IIP is a discrete clinical entity. There has never been validation of this assumption by careful phenotyping and prospective trials. In addition, these definitions are heavily reliant on surgical pathology, suggesting that pathology be considered the "gold standard"; however, evidence shows even expert pathologists can have difficulty agreeing on pathologic classification.[21] This continues to create confusion and difficulty in the diagnosis of IIPs and IPF. Hopefully continued refinement of consensus guidelines, greater expertise of clinicians and greater identification and use of genetic signatures/biomarkers will lead to more confident separation of the IIPs and a clear definition of IPF.

EPIDEMIOLOGY

Below are considered the incidence and prevalence of IPF, along with risk factors and associated familial and genetic factors.

INCIDENCE, PREVALENCE, AND VITAL STATISTICS

The epidemiology of IPF is difficult to determine and the available data are of limited value. It has been principally assessed by large population studies using death certificates and/or medical coding as the principle component for determination of disease. The main criticism of these studies is that surgical lung biopsy (SLB) was rarely performed or incorporated into the criteria used for analysis, although SLB remains the gold standard of diagnosis. In addition, many of these studies have not incorporated the up-to-date definition of the disease and use disparate methodologies to develop their assessments of the epidemiology of IPF.[22,23] The most recent update of the diagnostic criteria for IPF may help to clarify these difficulties but will also make it difficult to compare data over time. Early studies from Great Britain and from the United States suggest that IPF is widely underreported.[24,25] Though this is probably still the case heightened clinical awareness of the disease and the greater availability of high-resolution computed tomography (HRCT) appear to be changing the landscape; and this may explain recent studies that suggest an increasing incidence of the disease.[22]

The precise incidence and prevalence of IPF remains difficult to determine. However, there are several studies worth considering. Coultas et al.[26] utilized a population-based registry in which cases were determined using a combination of medical records, pathology reports, and death certificates. With this data, the prevalence/annual incidence was estimated at 20.2/10.7 cases per 100,000 males and 13.2/7.4 per 100,000 females.

Recent studies by two different groups have attempted to update and further define these estimations.[27,28] Both studies employed sensitivity analyses to examine the impact of diagnostic reliability; they examined the epidemiology of IPF using both narrow- and broad case definitions. Fernandez et al.[27] reported a prevalence of 27.9 per 100,000 people, using a narrow case definition, and 63.0 per 100,000 people using a broad case definition; similarly, annual incidence was estimated at 8.8/100,000 and 17.43/100,000 using the narrow and broad definitions respectively. Raghu et al.[28] relied on yet another North American database and reported a prevalence of 14.0 per 100,000 persons with their narrow definition and 42.7 per 100,000 persons with their broad case definition; annual incidence was reported as 6.8 and 16.3 per 100,000 persons for narrow and broad definitions respectively. It is important to point out that Fernandez et al. and Raghu et al. used different definitions of IPF in their separate studies, which likely accounts for some of the difference in the incidence and prevalence between the two studies. In European epidemiologic studies, there is even wider variation in case definition and reported incidence and prevalence; though some authors have claimed that IPF is more common in the United States than in Europe.[23]

Mortality data is equally difficult to determine, as data is scant and varies by country and race. Retrospective longitudinal studies have suggested that median survival is 2 to 3 years from time of diagnosis.[29–33] However, new information is coming from the placebo arms

of recent clinical trials. This data suggests that survival time may be greater than previously expected.[34–36] As a result of this emerging data, the actual mortality of IPF therefore remains without clear definition.

RISK FACTORS

IPF remains a disease without known pathogenesis, which makes the definition of risk factors problematic. Despite this shortcoming, a few case-control observational studies have identified potential risk factors that include age, gender, smoking status, environmental exposures, gastroesophageal reflux, and viral infections. The identification of these risk factors remains just associations as research identifying causality is either ongoing or inconclusive. Despite the lack of clear causality these risk factors can help to identify patients who have higher risk of developing IPF.

Age/Gender

The incidence of IPF undoubtedly increases with age and appears to have a higher predilection for men. Patients with IPF are usually between 40 and 70 years old. Two-thirds of IPF cases present in patients over the age of 60 years, with a mean age of 66 years at the time of diagnosis.[19] IPF occurs infrequently amongst those younger than 40 years and rarely affects children, if at all. Several studies stratified the incidence and prevalence of IPF by age.[26–28,37,38] Amongst adults aged 35 to 44 years the prevalence was 2.7 cases per 100,000 persons. In contrast, the prevalence for individuals older than 75 years was greater than 175 cases per 100,000.[26] Other studies in both USA and Europe have demonstrated similar findings.[23] In addition, there appears to be a higher incidence and prevalence of IPF in males than in females with the notable exception of a study in Norway, which identified a higher incidence and prevalence in females.[37]

Smoking

Another risk factor that emerges from case-control studies is a history of cigarette smoking. The prevalence of tobacco use in patients with IPF is high, ranging from 41% to 83%.[19,39] A meta-analysis of five case-control studies demonstrated that IPF patients were significantly more likely to report a history of smoking than controls with an odds ratio of 1.58 (95% CI 1.27–1.97).[40] There may even be a dose–response relationship. Baumgartner et al.[41] reported that IPF patients with a greater than 21-pack-year smoking history had an odds ratio of 2.26 (95% CI = 1.3–2.8) compared to individuals with less than a 20-pack-year history. This finding was corroborated in a subsequent study.[42] Despite the association, a mechanistic link between smoking and IPF remains undefined.[43]

Environmental Exposures

A number of papers have implicated environmental exposures to such particulate materials as metal and wood dusts.[20] In a related finding, an increased incidence of IPF was noted in industrial centers of the southeastern United States and central regions of the United Kingdom.[44] There is also an association between farming and risk of IPF.[40] A specific association exists between exposure to livestock and the risk of developing IPF though this seems to be strongest at exposures greater than 5 years.[45] At this point these types of risk factors are only associations as the causative link to environmental exposures remains undefined.

Viral Infections

Several articles have implicated a variety of viruses such as the Epstein–Barr virus, influenza virus, cytomegalovirus, and hepatitis C.[46–48] All are found with higher incidence amongst patients with IPF. The best studies are of herpes viruses (including EBV, CMV, human herpes virus 7 and 8). Tang et al.[49] identified DNA from herpes virus in 33 patients with IPF. Herpes virus antigens have also been detected by immunohistochemistry in type II alveolar epithelial cells from IPF patients but were not seen in cells from patients with normal lungs.[49–51] The significance of these findings remains unclear because there is still no evidence to support a pathogenic mechanism for IPF involving viruses. Interestingly, new animal models have shown a role for viral infection in the development of experimental fibrosis.[52,53] Despite the suggestive evidence of virus in human IPF cells and potential mechanistic links from animal modeling, direct causal links to human disease remain undefined.

FAMILIAL AND GENETIC FACTORS

Familial cases of IPF have been described in dozens of reports. The clinical features of familial IPF are indistinguishable from those of the nonfamilial form, except that the familial form may have an earlier age of onset.[54] Familial IPF or familial interstitial pneumonia (FIP) is defined by at least two members of a primary biologic family (parent, child, siblings) presenting with a characteristic appearance of IPF that is confirmed by biopsy. Familial IPF seems to account for 0.5% to 2% of all cases of IPF.[55]

In 2000, a report was published describing 25 families and comprising 67 cases of familial IPF.[55] In this report the mean age at time of diagnosis was 56 years. Only half of the patients were smokers. The male-to-female ratio was 2:1 in contrast to earlier reviews of FIP, which suggested an inverted male-to-female ratio. This was followed by a larger study of FIP published in 2005.[56] This impressive report described a much larger cohort of 111 families with 309 affected family members. Most of these subjects were identified as having probable or definite IPF by the American Thoracic Society/European Respiratory Society diagnostic criteria. Interestingly, correlation with biopsy specimens suggested that FIP could present with a variety of pathologic patterns (other than UIP), even within the same family. This study revealed a mean age at diagnosis of 68.3 years, with a slight male predominance (55%) and an increased association with cigarette smoking (even after controlling for age and gender differences). Analysis of pedigrees confirmed vertical transmission and provided strong evidence for an autosomal dominant inheritance pattern of disease with variable penetrance.

These accounts of FIP provide compelling evidence for genetic factors that predispose to the development of IPF. One such factor is a mutation in the gene that encodes surfactant protein C (SPC) gene.[57] Other studies have implicated mutations in the gene for surfactant protein A; and mutations in the genes that encode telomerase reverse transcriptase and the telomerase RNA template.[58,59] By leveraging genomic linkage, investigators have recently described a common polymorphism in the promoter of MUC5B, which is associated with both FIP and sporadic IPF.[60] This was followed by a large genome-wide association study of patients with IIPs, which identified additional genetic loci suggesting potential genetic markers of disease.[61] This data is opening up insights into potential genetic pathways of this disease and confirms a generally understood concept that there is a combination of genetic factors and environmental exposures, which account for the significant disease heterogeneity observed in individual patients. While these studies provide useful insights they do not define a direct causal link at present. Several candidate genes have been selected, because of their bearing on proposed mechanisms of the disease, and these genes are currently under investigation.

CLINICAL PRESENTATION

In this section, we discuss important aspects of the clinical presentation of IPF.

DIAGNOSIS

Differential

In the setting of exertional breathlessness, the hallmark of IPF is a predominance of radiographically visualized lower lung zone reticular opacities that spread out over time to involve an ever

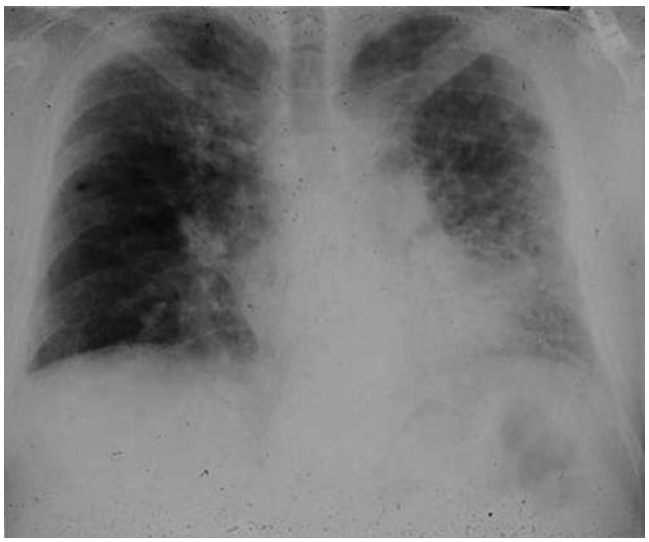

Figure 56-1 Posteroanterior chest radiograph of a 67-year-old man with progressive dyspnea revealing bilateral reticular infiltrates with lower lobe predominance.

enlarging area of lung parenchyma (Fig. 56-1). The differential diagnosis of IPF includes the other IIP, connective tissue diseases (principally scleroderma and rheumatoid arthritis), chronic hypersensitivity pneumonitis, environmental exposures, occupational exposures, chronic aspiration, and heritable conditions such as the Hermansky–Pudlak syndrome. The aforementioned disorders all present with exertional dyspnea coupled with radiographic abnormalities indicative of an interstitial pulmonary disorder.

HRCT has emerged as the single most important diagnostic modality in ILD. A number of diseases share a radiographic pattern that is similar to IPF, in other words, reticular abnormalities are demonstrated by HRCT with a tendency to involve the lower lobes. Examples include asbestosis, chronic aspiration, radiation pneumonitis, chronic hypersensitivity pneumonitis, end-stage sarcoidosis, and congenital disorders such as Gaucher disease, Niemann–Pick disease, and tuberous sclerosis–lymphangioleiomyomatosis. The presence of extensive ground-glass opacities on HRCT should prompt the consideration of an alternative diagnosis such as DIP, cellular NSIP, or acute hypersensitivity pneumonitis. Other IIP that are included in the differential diagnosis of IPF are fibrotic NSIP and COP.

History

Patients with IPF typically present with exertional dyspnea and a nonproductive cough. The dyspnea begins insidiously and is usually progressive. Dyspnea is the most prominent symptom in IPF. Associated systemic symptoms can occur but are not common. Systemic symptoms may include weight loss, low-grade fevers, fatigue, arthralgias, or myalgias.

Patients will often have symptoms for longer than 6 months before seeking medical attention. It is not unusual for symptoms to be present for up to 2 years before an initial consultation is arranged with a pulmonary specialist. Patients are frequently evaluated and treated for other ailments, such as asthma or heart failure, before IPF is identified as the final diagnosis. Because most patients present over the age of 60 where coronary artery disease is highly prevalent, many patients are referred for a cardiac evaluation before pursuing a pulmonary evaluation.

The patient's age is an essential clue to the recognition of IPF. While IPF mostly occurs in older patients (>50 years), the other ILDs are more common among the young or middle-aged (examples include sarcoidosis, lymphangioleiomyomatosis, and pulmonary Langerhans cell histiocytosis).

A history of cigarette smoking is a vital piece of information. While IPF, DIP, and PLCH are diseases found in former and current smokers, other diseases such as hypersensitivity pneumonitis are rare among the smoking population.

It is critical to obtain a detailed occupational history with particular attention to exposures such as asbestos, silica, or any other respiratory toxins. This history is necessary to exclude the presence of pneumoconiosis. It is equally important to inquire about exposure to molds and/or pets in the home environment as this information may suggest a diagnosis of hypersensitivity pneumonitis.

A general health history, including an accounting of all medications, can be revealing. A review of systems may uncover photosensitivity, Raynaud phenomenon, dry eyes, or dry mouth that implies a connective tissue disorder. Certain drugs have been associated with pulmonary fibrosis, most notably nitrofurantoin, bleomycin, and amiodarone.

Physical Examination

In most patients the physical examination reveals fine, bibasilar inspiratory crackles, known as "Velcro rales." As the disease progresses, rales can extend toward the upper lung zones. Clubbing is found in up to 50% of patients with IPF. Resting arterial oxygen saturation may be normal but desaturation is expected with exercise. Extrapulmonary involvement does not occur in IPF. Thus the physical examination is otherwise unremarkable in the early stages of the disease.

Later in the course of disease weight loss, cyanosis, and signs of pulmonary hypertension with cor pulmonale may become apparent. Findings at this stage include an accentuated pulmonic second heart sound, presence of a third heart sound, a right ventricular heave, and edema of the lower extremities.

Routine Laboratories

A routine laboratory evaluation is not helpful except for its role in ruling out other causes of diffuse parenchymal lung disease. Polycythemia is a rare finding despite the frequency of chronic hypoxemia. Elevation of systemic inflammatory markers (i.e., erythrocyte sedimentation rate or C-reactive protein level) or the presence of hypergammaglobulinemia is found in IPF yet such findings are nondiagnostic. The lactate dehydrogenase activity is often elevated but is also nonspecific. Up to 30% of patients with IPF may have positive tests for antinuclear antibodies or rheumatoid factor. These titers are not generally high. The presence of a high titer of autoantibodies suggests connective tissue disease while an elevated angiotensin-converting enzyme level or antineutrophil cytoplasmic antibodies indicates alternative diagnoses.

■ PULMONARY FUNCTION AND PHYSIOLOGY

Pulmonary function tests in IPF normally identify a restrictive ventilatory defect with reductions of total lung capacity (TLC), functional residual capacity (FRC), and the residual volume (RV). These changes are the result of diminished lung compliance. Pressure–volume studies will yield a curve that is shifted downward and to the right, indicative of lost lung compliance. As the disease progresses, compliance decreases further. Forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) will also be decreased.

Unless a complicating airways disease is present (e.g., chronic obstructive pulmonary disease [COPD]), isovolume flow rates are preserved. While functional alterations associated with small airways disease have been reported in IPF, this description is exclusive to smokers and likely represents a concurrent smoking-related airways disorder.[62]

Impaired gas exchange is demonstrated by the measurement of a lowered diffusing capacity. The decline of diffusion capacity may even precede the development of abnormal lung volumes. Resting arterial blood gases are usually normal in IPF or else they will reveal mild hypoxemia with a respiratory alkalosis. Patients with

IPF have tachypnea and often develop a pattern of rapid-shallow breathing. The work of breathing is increased in IPF. While no chemical changes can explain the observed hyperventilation, it is felt that rapid respiratory rates are secondary to altered mechanical reflexes resulting from an increase in elastic recoil and elastic load. The major cause of hypoxemia is ventilation and perfusion (V/Q) mismatching, not anatomic shunting or reduced oxygen diffusion as was previously suspected.[62]

During exercise, patients with IPF and may exhibit evidence of pulmonary hypertension, even in early cases that have preserved lung function at rest. Pulmonary hypertension can also be present at rest, and is an expected finding, once the vital capacity drops below 50% of predicted or the diffusing capacity falls below 45% of predicted. The presence of pulmonary hypertension may be a predictor of poor outcome yet may not correlate with lung function.[63]

RADIOLOGY

Conventional Chest Radiograph

The chest radiograph is abnormal in nearly all patients with IPF (Fig. 56-1). Yet, in up to 10% of patients with histologically proven IPF, the chest film might be normal. In most of these cases, the use of HRCT will uncover evidence of the disease.[20]

The most common abnormalities seen on a conventional chest film are reticular opacities. In other words there is an appearance of net-like linear and curvilinear densities. Reticular markings may be found bilaterally, in an asymmetrical distribution with a predilection for the lower lobes. A course reticular pattern on the plain radiograph, taking the form of translucent "honeycombing," will emerge late in the course of disease and portends a poor prognosis. The chest radiograph lacks specificity for the diagnosis of IPF. The correct diagnosis is made on the conventional radiograph in less than 50% of cases. In addition, the interpretation of conventional radiographs with an interstitial pattern shows poor interobserver agreement. Studies have examined this particular characteristic and report that concordance between radiologists is only 70%.[64,65]

Figure 56-2 Computed tomography scan illustrates the "classic" features of idiopathic pulmonary fibrosis (IPF). Bilateral, peripheral, and subpleural reticular infiltrates are evident. The presence of advanced fibrosis is indicated by honeycomb changes *(arrowheads)* and traction bronchiectasis *(arrow)*. These features permit experienced clinicians to make a confident radiographic diagnosis of IPF.

High-Resolution Computed Tomography

Development of the high-resolution CT scanner has revolutionized the diagnostic evaluation of the ILDs. HRCT allows a detailed examination of the lung parenchyma by creating 1- to 2-mm thin slices of the chest. HRCT uses a computerized reconstruction algorithm to maximize spatial resolution. This generates much improved image clarity such that the specificity of interpretations is increased, interobserver variability is reduced, and the overall accuracy of diagnosis is enhanced. HRCT scanning allows for the earlier diagnosis of IPF and permits the identification of alternate patterns of disease. The primary role of HRCT in the diagnostic evaluation of ILD is the discrimination of typical IPF from the other ILDs. Given the utility and availability of scanners, HRCT has become the primary diagnostic tool for identifying IPF.

The HRCT appearance of IPF is characterized by patchy, predominantly peripheral, predominantly subpleural, and bibasilar reticular opacities (Fig. 56-2). Ground-glass opacities can be found, but should occupy no more than a limited amount of territory. Areas that are severely involved with reticular markings may also demonstrate traction bronchiectasis. The presence of subpleural honeycombing (small, round translucencies with a density equal to that of air), traction bronchiectasis, and thickened interlobular septae will increase the specificity of the CT scan for diagnosing IPF. Several studies have examined the diagnostic accuracy of HRCT scans in IPF.[64–68] Studies were conducted in which observers were asked to determine a radiographic diagnosis that was then compared with the histopathology of UIP as the "gold standard." In the hands of experienced observers, radiographic diagnosis of IPF has a reported specificity and positive predictive value for IPF histology that exceeds 90%.[66–68] However, the "confident" HRCT is not a sensitive tool for the diagnosis of IPF.[66] The full spectrum of a "confident" radiographic pattern will only be seen in two-thirds of biopsy-proven IPF. One-third of IPF cases will not show a definitive CT pattern and would be missed if the HRCT was relied upon exclusively (Fig. 56-3). In such cases, and in the right clinical context, an SLB should be considered to clarify the diagnosis. Nonetheless it has become apparent that, in the right clinical setting, an experienced radiologist can diagnose IPF by the HRCT with considerable accuracy, obviating the need for biopsy.

Given the evolving importance of HRCT in the diagnosis of IPF, CT scan criteria were defined during the most recent expert consensus statement on the diagnosis of IPF.[20] HRCT patterns were

Figure 56-3 Computed tomography scan of an 81-year-old man with biopsy-proven idiopathic pulmonary fibrosis. A peripheral distribution of reticular opacities is demonstrated. Honeycombing and traction bronchiectasis are notably absent. In the absence of specific findings, a surgical lung biopsy was needed to make a diagnosis.

separated into three groups: A UIP pattern; a possible UIP pattern; and a pattern labeled "inconsistent with UIP." The UIP pattern has four features: (1) Subpleural, basal predominance of disease; (2) reticular abnormality; (3) honeycombing with or without traction bronchiectasis; and (4) absence of any inconsistent features. The inconsistent features include (1) upper or midlung predominance; (2) peribronchovascular predominance; (3) extensive ground-glass abnormalities that are greater than the amount of reticulation; (4) profuse micronodules; (5) multiple discrete cysts that are located away from areas of honeycombing; (6) diffuse mosaic attenuation/air trapping; and (7) consolidation in bronchopulmonary segments.[20] Features defined as consistent with a "possible UIP pattern" were those of the UIP pattern except without evidence of honeycombing.

BRONCHOALVEOLAR LAVAGE

An enormous amount of scientific information has been obtained by analyzing the content of BAL fluid from patients with IPF. Notable increases of immune cells (neutrophils, eosinophils, and activated alveolar macrophages) are present in BAL fluid from IPF. In addition, BAL has aided in the identification of cytokines, growth factors, and other cellular products that are now implicated in the pathogenesis of IPF. As a research tool, BAL has been immensely valuable. However, the role of BAL in the clinical diagnosis of IPF remains limited. Though much effort has been invested in evaluating the clinical utility of this modality, study results have been contradictory and generally disappointing.[69] Most samples of BAL from IPF patients demonstrate simultaneous increases of several effector cell types including neutrophils (70%–90% of patients); eosinophils (40%–60% of patients); and lymphocytes (10%–20% of patients).[20] Despite this finding, studies have failed to demonstrate a clear distinction amongst pulmonary diseases based upon the predominant type of cell in the BAL fluid.[62] As a consequence of this, in standard practice, BAL is no longer generally recommended for the routine evaluation of IPF.

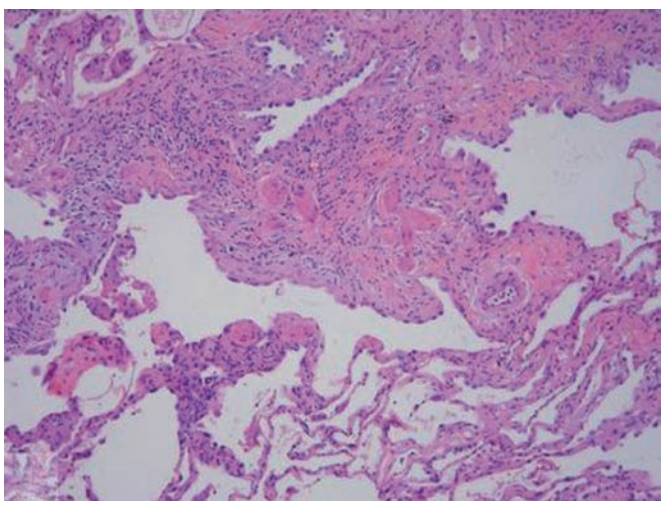
PATHOLOGY

Previously, SLB was recommended to confirm all cases of suspected IPF. With the advent and availability of HRCT this is no longer the case, as the positive predictive value of HRCT is comparable and in some studies better than that of biopsy.[70] Despite this fact, SLB remains critical to the diagnosis of IPF in the context of HRCT scans that are equivocal (e.g., without the full complement of radiographic features that are expected in IPF). Biopsy may be achieved by either open thoracotomy or by video-assisted thoracoscopy (VATS). VATS is preferred as it has been associated with less morbidity and shorter hospital stays compared to open biopsy. An SLB provides the best sample from which to distinguish UIP from other forms of IIP. The recommendation is that the SLB be taken from at least two lobes, preferably the upper and lower lobes. The basis of this recommendation is from studies that identified that different pathologies could exist in different sections of the lung. Despite the coexisting patterns, if one of these had UIP pathology then the patient's clinical course followed that of the UIP pathology.[71] Transbronchial biopsies are less helpful in identifying IPF lesions because the small size of the sample prohibits the pathologist from identifying all the necessary features for a confident pathologic diagnosis of IPF.

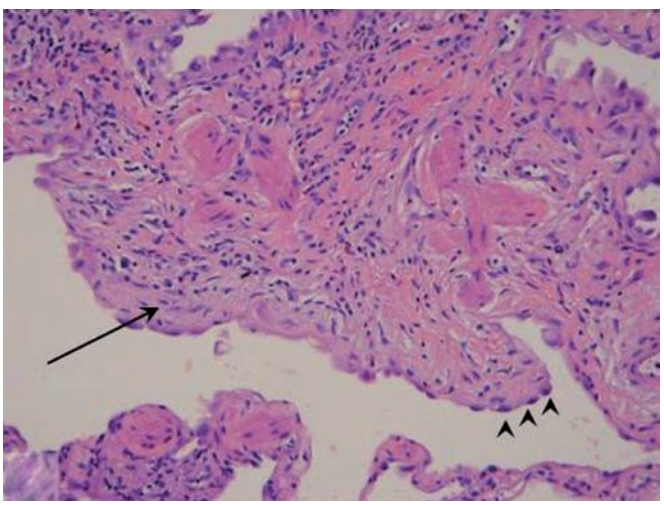
The gross appearance of an IPF sample may be normal but often has a distinctive nodular pleural surface that has been likened to cirrhosis. The histopathologic lesion associated with IPF is UIP. This lesion is defined by a variegated structure. Normal lung alternates with patchy collagen fibrosis (Figs. 56-4 and 56-5). The fibrosis takes the form of alveolar septal thickening with a predominantly subpleural distribution. Whirls of fibroblasts embedded in a loose extracellular matrix embody the fibroblastic foci that are found in numerous quantities at the leading edge of dense scar (Figs. 56-4 and 56-5). Interstitial inflammation is present but remains scant and confined to areas of fibrosis. This limited inflammation consists of lymphocytes and plasma cells. Associated hyperplasia of the type 2 pneumocytes is found within areas of active inflammation. Areas that contain dense collagen may develop cystic structures, which may be filled with mucin or lined by bronchiolar epithelium. These cysts are referred to as microscopic honeycomb change. Hyaline membranes and organized alveolar exudates are absent. Occasionally alveolar macrophages are present.

The UIP pathologic pattern exhibits a wide range of severity with regards to the extent of honeycomb change and the extent of involved lung. A history of smoking may alter the histopathologic appearance of UIP. Emphysematous change can be superimposed upon UIP. Pigmented alveolar macrophages, the hallmark feature of RB-ILD and DIP pathologic patterns, may be present in small number in UIP lesions from former or current smokers.

The UIP pattern can be found in other diseases besides IPF. The presence of granulomas in a UIP lesion favors a diagnosis of fibronodular sarcoidosis or chronic hypersensitivity pneumonitis. Asbestos bodies found within a UIP pattern suggest the diagnosis of asbestosis.



A



B

Figure 56-4 **A.** Low-magnification photomicrograph of usual interstitial pneumonia (UIP) showing the characteristic heterogeneous involvement of the parenchyma. Zones of interstitial fibrosis are seen alternating with areas of normal lung. **B.** Higher magnification demonstrates enlarged cystic air spaces lined with hyperplastic alveolar epithelium *(arrowheads)*. Beneath the mucosal layer is an advancing region of young fibrosis containing loose extracellular matrix *(pale pink staining)* and fibroblasts *(arrow)*.

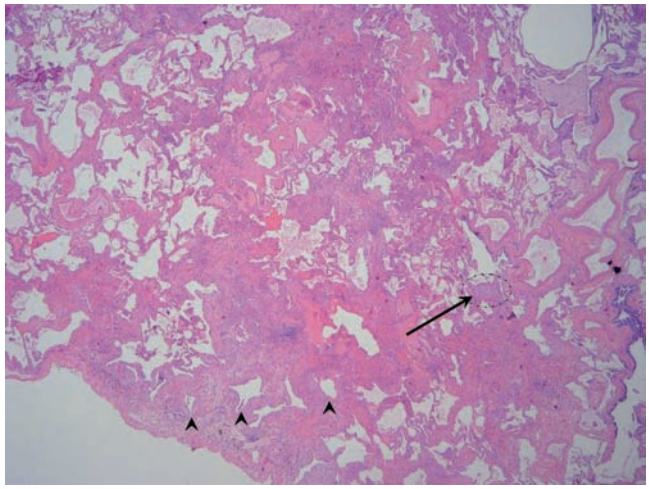


Figure 56-5 Scanning view of usual interstitial pneumonia (UIP) demonstrates the characteristic variegated appearance of UIP. Note the honeycomb change *(arrowheads)* present in the region of dense fibrosis adjacent to the pleural surface. A fibroblast focus *(arrow)* is seen at the leading edge of advancing fibrosis.

The histopathologic pattern of UIP can also be found in several conditions other than IPF. UIP can be found in association with connective tissue diseases, asbestosis, chronic hypersensitivity pneumonitis, the Hermansky–Pudlak syndrome, neurofibromatosis, or in the setting of a toxic drug reaction (typically after administration of either bleomycin, methotrexate, nitrofurantoin, or amiodarone; [this is a partial list]). The identification of these conditions is largely a matter of correlation with the clinical history. It is important to note that the presence of honeycombing on biopsy is a nonspecific finding with a broad differential. Honeycombing is a common endpoint for a myriad of pathologic processes. Although honeycombing carries the connotation of end-stage fibrosis it can also occur in a focal distribution after any lung injury. Seen alone, honeycombing is not indicative of IPF.

To standardize the pathologic definition of UIP, a set of consensus criteria were established to represent expert opinion.[20] The consensus definition allows for four pathologic categories: The UIP pattern; a probable UIP pattern; a possible UIP pattern; and a pattern referred to as "not UIP." The UIP pattern requires (1) evidence of marked fibrosis/architectural distortion generally with honeycombing in a predominant subpleural distribution; (2) patchy involvement of the fibrosis in the lung parenchyma; (3) presence of fibroblastic foci; and (4) absence of features such as hyaline membranes, organizing pneumonia, granulomas, predominant airway-centered pathology, inflammatory cell infiltrate away from honeycombing or pathologic features suggestive of another disorder. The "probable" UIP pattern requires (1) evidence of marked fibrosis/architectural distortion with or without honeycombing; (2) absence of either patchy involvement or fibroblastic foci but not both; plus (3) an absence of features such as hyaline membranes, organizing pneumonia, granulomas, etc. In the right clinical context, "probable" UIP can be considered when honeycomb changes alone are present in the SLB. The "possible" UIP pattern incorporates (1) patchy or diffuse fibrosis within the pulmonary parenchyma; (2) in the absence of other criteria for a UIP pattern; and (3) in the absence of the features such as hyaline membranes, etc.

DIAGNOSTIC ALGORITHM

The objective is to secure an accurate diagnosis of IPF. The task is critical, to provide patients with accurate prognostic information; and, also to define cohorts for clinical/therapeutic trials. As previously discussed, the central issue is that the diagnosis of IPF is a diagnosis of exclusion. However, complete exclusion of other diagnostic possibilities is a daunting challenge. For one, there are multiple studies demonstrating significant interobserver disagreement between pulmonologists, radiologists, and pathologists especially when their decisions are made in isolation from each other's expertise.[21,72,73] By corollary, a multidisciplinary approach to diagnosis has been shown to improve diagnostic accuracy. The multidisciplinary approach requires real-time collaboration between the diagnosing physicians: The pulmonologists, radiologists, and pathologists involved with the case. If these groups are not available, then referral of patients to a center where this expertise is available is recommended.[20]

Given the complexity of making an accurate diagnosis, and the lack of definitive molecular biomarkers to aid such a diagnosis, practical diagnostic algorithms have relied on the practices and opinions of a consensus of experts. It must be noted that such diagnostic criteria (adopted from expert opinion) have never been validated. The most recent expert diagnostic guideline was endorsed by the American Thoracic Society, European Respiratory Society, Japanese Respiratory Society, and the Latin American Thoracic Association (ATS/ERS/JRS/ALAT).[20] In the revised 2011 guidelines, SLB is no longer considered an absolute necessity for a definitive diagnosis. Rather, HRCT may qualify as a surrogate in appropriate circumstances. As per the ATS/ERS/JRS/ALAT statement, the diagnosis of IPF requires (1) exclusion of other known causes of ILD; and (2) either (a) UIP pattern from SLB, supported by a UIP pattern of fibrosis on HRCT; or (b) UIP pattern by HRCT alone (in patients not subjected to an SLB).[20] In clinical practice, the most critical (yet most challenging) factor is to exclude other known causes of ILD. This requires a careful history, physical examination, and evaluation with a focus on environmental/work place exposures; medication use; family history; clinical evidence connective tissue disease (oftentimes, the evidence is subtle); and other comorbidities.

A diagnostic algorithm follows: Patients with suspected IPF in whom there are no identifiable causes of ILD will undergo HRCT scans of the chest; if there is definitive evidence of a UIP pattern on the HRCT, then the diagnosis is complete. If the HRCT pattern is equivocal, SLB can be considered to clarify the diagnosis. Prior to SLB, the safety of such an invasive procedure must be weighed against the utility of a definitive diagnosis (in other words, a careful risk–benefit analysis is indicated). Expert consultation with a multidisciplinary group of ILD experts is recommended in this setting. A UIP or probable UIP pattern on biopsy was felt to confirm the diagnosis of IPF in the setting of a HRCT pattern, which is defined as a possible UIP pattern. An HRCT possible UIP pattern in the setting of a not UIP pathology pattern was defined as not IPF. In this algorithm, if the HRCT scan was inconsistent with UIP, and the pathology was a UIP pattern then this was determined to be possible IPF. Per the algorithm, these types of cases require a multidisciplinary discussion to resolve any potential inconsistencies and come to a consensus diagnosis.

Although this algorithm provides a clear path toward the diagnosis of IPF several caveats must be considered. This algorithm is based on experience and expert opinion; it has never been validated in prospective studies. It also requires a high level of expertise (to define the radiographic, clinical, and pathologic evidence) that may not be available in all clinical settings. Such diagnostic algorithms and diagnostic criteria are best suited to defining populations for clinical research. A much more elegant and streamlined approach is needed for standard clinical practice. As of yet, this state of art is lacking.

NATURAL HISTORY AND PROGNOSIS

The natural history of IPF has never been fully defined. IPF is felt to be a progressive disorder of subjective and objective decline in pulmonary function ultimately resulting in death. The exact length of time from diagnosis to mortality has been difficult to clearly define. Studies utilizing the modern definition of IPF first reported median survival between 2 and 5 years from the time of diagnosis.[29] Recent data from the placebo arms of clinical trials suggest longer survival.[34,36] There

are few, if any, reports of long-term survival with biopsy-proven IPF/UIP.

Several factors have combined to create barriers preventing the further, more rigorous description of the natural history of IPF. First, the diagnosis of IPF can be challenging and, not infrequently, the presence of "early" disease gets overlooked. Patients develop IPF in the later decades of life and often attribute their symptoms to old age. When their disease eventually comes to medical attention, there may be further delay in diagnosis because the symptoms are nonspecific. Most patients with IPF are evaluated for other diseases before a diagnosis of pulmonary fibrosis is considered. Moreover, the interstitial markings found on a chest radiograph are subtle and tend to go unnoticed or else simply get disregarded as clinically unimportant. Experts in IPF agree that patients usually have symptoms for 2 or more years before receiving a definitive diagnosis. It is therefore apparent as to why many older cohorts are enriched with advanced, late-stage IPF. The epidemiology is shifting with the advent and more commonplace use of HRCT, which may detect interstitial markings and pick up the diagnosis of IPF at an earlier stage.

The other major issue is that there is clear heterogeneity in the clinical course of individual patients. This heterogeneity has led to the consideration that there are several possible natural histories of IPF.[20] This determination is the result of observations that have occurred over clinical trials especially in circumstances that placebo groups have had different clinical trajectories despite similar clinical definition of disease. The majority of patients appear to follow a slowly progressive clinical course, though others appear to have a more rapid course. Selman et al.[74] described different clinical groups based on the length of symptoms prior to diagnosis. The patients who had symptoms <6 months (rapid progression) prior to diagnosis had higher mortality than those who had symptoms for more than 24 months (slow progression). In the "rapid progression" patients there were associated alterations to their gene expression profile, as well as increased BAL active matrix metalloproteinase-9 and fibroblast migration. What influences these different clinical courses is not well known or understood.

■ ACUTE EXACERBATION OF IPF

Japanese investigators made the initial observation that patients with IPF can experience episodes of sudden decline, which they characterized as acute exacerbations.[75] Recent observations from the placebo arm of two randomized clinical trials have suggested that acute exacerbations may be more common that previously appreciated.[33,76,77] The acute exacerbation of IPF (AE-IPF) is characterized by a sudden worsening of symptoms and has been associated with hypoxemia and new radiographic infiltrates. It is important in making the diagnosis of AE-IPF to rule out infection, congestive heart failure, and pulmonary embolism. AE-IPF typically occurs in patients with established IPF however it has been recognized that AE-IPF can form the initial presentation of IPF as well, mimicking AIP. Patients with established IPF satisfy the criteria for an acute exacerbation if they have (1) previous or concurrent diagnosis of IPF; (2) unexplained development or worsening of dyspnea in the past 30 days; (3) HRCT with evidence of new ground-glass opacities superimposed on the background of a radiographic pattern of UIP; (4) no evidence of pulmonary infection; and (5) exclusion of alternative causes.[76] Histopathologic examination of AE-IPF commonly reveals a UIP pattern with superimposed diffuse alveolar damage (DAD) characterized by diffuse alveolar septal thickening within a pale matrix that includes hyaline membranes and fibrin. UIP with superimposed organizing pneumonia has also been reported in AE-IPF. The prognosis of AE-IPF is poor. Series of patients with AE-IPF reported in-hospital mortality rates between 78% and 96%.[77–80] Mortality is strongly associated with the need for mechanical ventilation. The etiology of AE-IPF is poorly understood and remains an area of active research.

■ PROGNOSIS

While accurate predictions of the prognosis of IPF are essential for clinical decision making, such predictions remain challenging for a variety of reasons. Still, rudimentary predictions can be based on pathologic, physiologic, and radiographic information. In addition, various composite scores have been developed for prognostic purposes.

■ PATHOLOGIC PREDICTORS

One of the most important features of the spectrum of illness encompassed by IIP is the fact that pathologic patterns predict survival. In the late 1990s it was recognized that the UIP pathologic pattern had a precise correlation with clinical parameters and with outcome.[17] Survival is significantly worse amongst patients whose biopsy contains a UIP pattern as compared to either NSIP or other patterns of fibrosis.[29] Within biopsy specimens, specific traits have also been correlated with survival.[33] The degree of cellularity does not seem to affect survival nor does the degree of fibrosis. However, the number of fibroblastic foci has been shown to predict survival. Fibroblastic foci have been linked to high mortality and large declines in physiologic measures such as the FVC and diffusion capacity.[81]

■ PHYSIOLOGIC PREDICTORS

Baseline pulmonary function as a determinant of prognosis has not been reproducible,[82–90] though more recent studies utilizing standardized definitions and involving patients with earlier disease suggest that it may have better prognostic value than initially appreciated.[91–93] Changes in pulmonary function over time have been more clearly correlated with measures of long-term survival. For instance, a 10% decline in FVC over 6 months, or a 15% decline in D_{LCO} over 6 months, predicts shortened survival.[91,94] For this reason, clinical trials in IPF have utilized changes in FVC as a clinical outcome measure to assess drug efficacy,[95] though some disagreement exists on this issue.[96] In clinical practice, at the present time, the use of decrements in pulmonary function remains an important objective means of assessing clinical disease progression.

An issue that affects the predictive value of physiologic variables in IPF is the confounding influence of coexistent emphysema. This problem is addressed by the composite physiologic index (CPI), which corrects for emphysema by combining several physiologic measures into a single-weighted score.[97] The formula for the CPI includes diffusion capacity, FVC, and FEV_1 in its calculations. The CPI was validated by comparison with HRCT. In addition, it was shown that the CPI is a more accurate prognostic determinant than any individual test of pulmonary function.

■ RADIOGRAPHIC PREDICTORS

The utility of HRCT in predicting the outcome of IPF is supported by a study, which compares HRCT patterns to biopsy.[98] Patients who had both an HRCT and a biopsy were analyzed and it was found that an HRCT pattern consistent with UIP correlated pathologically with the UIP pattern. However, an indeterminate HRCT pattern could be a manifestation of either UIP or NSIP. Patients with combined pathologic UIP and radiographic "confident UIP" had a worse outcome compared to patients with pathologic UIP and an indeterminate HRCT.

■ COMPOSITE SCORES

Some authors have proposed that a composite scoring system for IPF would have better predictive value than measuring individual disease-related factors. The first clinical, radiologic, and physiologic (CRP) scoring system was developed in 1986 and employed seven variables that accounted for parameters such as dyspnea, specific radiographic findings, and physiologic function.[99] This CRP score was validated through comparison to histopathology in a group of

26 patients. No single component of the CRP score had a better correlation than the composite score.

Over time further scoring systems have been developed. In 2001, a CRP score was derived to predict death rather than just histopathology.[82] A large cohort of patients was followed prospectively to devise the revised CRP score, utilizing multivariate statistical models to identify significant disease-related parameters. The revised CRP score incorporates age, smoking status, the presence of clubbing, TLC, arterial oxygen during maximal exercise, radiographic infiltrates, and radiographic findings consistent with pulmonary hypertension. The revised CRP score ranges from 0 to 100, with higher scores indicating more severe disease. Five-year survival can be predicted in individual patients by calculating a CRP score employing the published formulas and then referencing published survival curves. This system was felt to be cumbersome and therefore Collard et al. developed a simplified staging system from retrospective data of three large cohorts in California, Minnesota, and Italy (Ley B Annals of Internal Medicine 2012).[100] Utilizing gender; age; physiology, which included FVC and D_{LCO}(GAP) patients with IPF could be grouped into stages I, II, or III and that had defined 1-, 2-, and 3-year predicted mortality rates. This simple system using readily available clinical and physiologic data could provide important prognostic data for patients at the time of initial evaluation and assist with immediate management decisions.

PATHOGENESIS

IPF is a complex disorder and many pathogenic events have been observed. Despite significant research effort, no definitive, unifying hypothesis has yet emerged. Multiple pathways have been implicated in both experimental models of pulmonary fibrosis and patients with IPF. Despite this information, drug targets to modify these pathways have thus far been largely ineffectual. It remains distinctly possible that there is no single common pathway that results in the IPF phenotype; but rather, a combination of multiple factors that lead to aberrant wound healing, progressive fibrosis, and diffuse scar formation. Although more questions than answers currently exist, great strides are being made to elucidate new mechanisms in IPF pathogenesis.[101,102]

A primary change in our understanding of the pathogenesis of IPF has been a movement away from inflammation as the driver of the fibrotic response in the IPF lung. "Inflammation" dominated the field in the 1970s and 1980s and was based largely on the observation that BAL fluid from patients with IPF had increased numbers of inflammatory cells (mostly neutrophils and eosinophils) relative to normal individuals.[103–108] The concept that permeated the literature in that era was that IPF resulted from an unremitting inflammatory response to an exogenous insult, culminating in progressive fibrosis. By targeting the inflammatory response, the belief was that fibrosis could be limited or prevented. Unfortunately, it now appears that the data are more likely explained by structural abnormalities in lung architecture (traction bronchiectasis) that result in airway inflammation but do not appear to be causative of the fibrosis inflammation.[17,109] This is further supported by the pathologic observation that there is a lack of inflammation at the leading edge of the fibrosis and the fact that patients with IPF do not respond to systemic immunosuppression with corticosteroids. As a consequence of this understanding the overall research into mechanisms of IPF has made a clear transition from the belief of a primary "inflammatory-driven" process to one that focuses on dysfunctional repair of alveolar epithelial cells with generation of profibrotic mediators, activation of fibroblasts, and resultant scarring.[101]

BASEMENT MEMBRANE INJURY

A unique feature of the UIP pathologic pattern is a loss of integrity of the subepithelial basement membrane. This has been definitively demonstrated through the use of electron microscopy.[14] Basement membranes in IPF are denuded of the usual type I pneumocytes. It is theorized that loss of this protective epithelial barrier results in further oxidative injury that degrades basement membranes. At the same time it appears that hyperplastic type II pneumocytes are abundantly present. This likely represents an attempt at epithelial cell regeneration. While the exposed basement membrane may provide the signal for epithelial growth, new epithelial cells cannot attach to a damaged membrane. The result is a "frustrated" epithelial cell response with failure to signal a termination of epithelial cell proliferation. Further examination of tissue from patients with IPF has confirmed an irregular pattern of alveolar epithelial cell proliferation, concurrent with dysregulation of the proteins that control the cell cycle.[110,111]

An accumulation of growth factors in IPF may originate from the persistent proliferative response of epithelial cells. A downstream consequence of "frustrated" epithelial cell regeneration would be recruitment of fibroblasts and myofibroblasts through the release of such growth factors. In essence, the signal to recruit and maintain a pool of mesenchymal cells (fibroblasts) might originate from an inability to successfully re-epithelialize the alveolar lining surface.

ALVEOLAR EPITHELIUM

Multiple lines of investigation suggest that the alveolar epithelium is critically involved in the pathogenesis of IPF.[53,109,112] The prevailing hypothesis is that repetitive low-level injury to a vulnerable or susceptible alveolar epithelium drives the pathologic features of IPF.[102] Why IPF alveolar epithelium is more vulnerable appears to be from a combination of age-related and genetic factors that are not clearly defined but being actively investigated.

Epithelial Apoptosis/Injury

An emerging body of literature supports alveolar epithelial cell injury and apoptosis as important features of IPF and in the development of experimental pulmonary fibrosis. Electron microscopic studies of human IPF tissue demonstrate injury and apoptosis of alveolar epithelial cells.[14] BAL from patients with IPF has established the presence of proapoptotic proteins.[113] In the bleomycin model of lung injury and fibrosis in animals, fibrosis can be abrogated by various approaches to inhibit epithelial cell apoptosis.[114–116] These include a reduction in experimental fibrosis by inhibiting the Fas–Fas ligand pathway, angiotensin production, or caspase activation.

In addition direct inhibition of apoptotic pathways, factors that cause epithelial cell apoptosis are critical to the development of fibrosis. Evidence suggests that fibroblasts produce angiotensin peptides that lead to epithelial apoptosis. Other researchers have demonstrated that transforming growth factor-β (TGF-β) is involved with promoting epithelial cell apoptosis.[117] Oxidant injury may also promote epithelial cell death and several studies of IPF patients have confirmed excessive oxidant production as well as glutathione deficiency.[118–120] Tumor necrosis factor-α (TNF-α) has been shown to promote alveolar epithelial cell apoptosis in vitro.[121] In a mouse model, knockout of the TNF-α receptor confers resistance to bleomycin-induced lung fibrosis, while overexpression of TNF-α in the mouse has been associated with an increase in experimental fibrosis.[122] Patients with IPF are known to exhibit an exaggerated expression of TNF-α, which may contribute to epithelial injury.[123]

Evidence of direct injury to the alveolar epithelium suggests that this may be an important model of pulmonary fibrosis. Utilizing a transgenic mouse directing expression of human diphtheria toxin receptor in SPC-expressing cells, it was shown that targeted injury of type II epithelial cells resulted in the development of experimental lung fibrosis.[124] The development of fibrosis in this targeted epithelial cell injury is dependent on plasminogen activating factor 1 and the recruitment of monocytes and macrophages into the lung.[125,126]

Endoplasmic Reticulum Stress

Mutations of surfactant proteins A2 and C have been associated with familial types of pulmonary fibrosis and suggest a potential genetic mechanism for alveolar epithelial injury.[57,58,127–130] In alveolar epithelium, during both homeostatic and inflammatory conditions, surfactant proteins are regularly produced. This production requires appropriate and coordinated folding and packaging of the proteins in the endoplasmic reticulum (ER) prior to their release.[131] When this folding does not occur correctly, the cell experiences ER stress, which results in activation of the unfolded protein response (UPR) a cellular pathway designed to limit the deleterious consequences of misfolded proteins.[132] The fact that mutations in these proteins were associated with pulmonary fibrosis suggested that misfolding of these proteins could result in cellular stress and thereby enhance the vulnerability of the epithelium.[51] Using a mouse model that expressed a mutant form of SPC, Lawson et al.[133] demonstrated that misfolded SPC caused ER stress and thereby activating the UPR. Despite this activation the mice did not spontaneously develop pulmonary fibrosis but rather required a secondary challenge with bleomycin or viral infection.[133,134] With secondary challenge, the mice exhibiting enhanced ER stress were more susceptible to fibrosis. A growing body of literature suggests that the UPR response is defective with advancing age, which may provide a direct link to IPF as it is a disease of advanced age. ER stress and secondary insults provide an attractive model for IPF as this model system has the potential to link both genetic- and age-related disease factors to microinjuries and a vulnerable epithelium.

■ THE FIBROBLAST

The hallmark of pulmonary fibrosis is the development and expansion of scar tissue in the lung. In this context, patients develop progressive respiratory failure associated with unrelenting accumulation of extracellular matrix in the gas-exchanging regions. The generally accepted predominant sources of this matrix are fibroblasts. In IPF, fibroblasts accumulate in areas of advancing fibrosis and are associated with regions of alveolar epithelial hyperplasia, a.k.a. the fibroblast foci. Though not completely unique to IPF[101] (they can be found in small numbers in NSIP), fibroblastic foci are pathognomonic for IPF.[135] Supporting their importance two groups have observed that a large number of fibroblast foci within lung biopsies correlate with a worse prognosis in IPF.[33,81]

Myofibroblast

One of the hallmarks of IPF pathology is the development of a subset of cells called myofibroblasts.[136] Much attention has been focused recently on the role of the myofibroblast in the pathogenesis of IPF. The defining characteristics of myofibroblasts are positive staining for α-smooth muscle actin (α-SMA) and production of new collagen. Myofibroblasts have contractile properties critical to normal wound healing, though they only appear transiently in this circumstance.[137] In IPF lung biopsies, myofibroblasts have been described in abundance especially in the fibroblastic foci.[138] Myofibroblasts have also been shown to accumulate in bleomycin-induced lung fibrosis.[139] Immunohistochemical studies have suggested that they are important in the production of newly synthesized collagen.[139] The source of these myofibroblasts and the reasons for their persistence in IPF lung are just starting to be clarified.[140]

Origin of Fibroblasts and Myofibroblasts

The source of fibroblasts has been a subject of intense research and debate. Several possibilities include resident lung fibroblasts, bone marrow progenitors called fibrocytes, and epithelial cell transition in a process called epithelial to mesenchymal transition (EMT).

Evidence has accumulated over the past several years that suggests that bone marrow–derived cells may contribute to the pool of lung fibroblasts in IPF. In an animal model of experimental lung fibrosis it was shown that fluorescently tagged bone marrow–derived cells trafficked to the lung where they became a source of collagen expression.[141] Interestingly these bone marrow–derived cells did not express α-SMA, nor did they express α-SMA when stimulated in vitro with TGF-β, suggesting that they are not capable of acquiring the myofibroblast phenotype. Another group of researchers observed that a newly defined cell type migrated into the lungs of animals following bleomycin injury called fibrocytes.[142] Fibrocytes are a recently recognized cell type of hematopoietic origin that circulate in the peripheral blood and have been suggested to play a role in wound repair.[143] They also have been implicated in the pathogenesis of hypertrophic scars, scleroderma, and asthma-related airway fibrosis.[144] Fibrocytes are present in the blood of patients with IPF and appear to be a marker of disease progression.[145] Still, the exact role of these cells (and their relationship to the fibroblast) remains unclear due to the lack of specificity in lineage-tracing markers.

Another possibility is that the fibroblasts in IPF are derived from the alveolar epithelium. A transformation of cell type from epithelium to mesenchyme is a well-documented phenomenon that takes place during embryogenesis. In culture, it has been shown that isolated type II alveolar epithelial cells (AEC2) exhibit a loss of AEC2 markers and express fibroblast markers when stimulated with TGF-β, a critical fibrogenic factor. Whether this occurs in IPF remains a point of controversy with some studies demonstrating colocalization of AEC2 and fibroblast markers[146] and others that do not observe evidence of this phenomenon.[147] To address this question in vivo, lineage-tracing experiments were performed. Initial studies utilized a fragment of the human SPC promoter to drive the expression of a lineage label to track AEC2 cells.[148,149] Tracking AEC2 cells after TGF-β or bleomycin exposure suggested that these cells were a significant source of mesenchymal cells in experimental lung fibrosis. In contrast to these observations, alternative in vivo lineage tracing using a knock-in allele of the SPC gene directing inducible expression of a fluorescent lineage tag in mature AEC2 cells did not demonstrate evidence of EMT after bleomycin.[150] This work suggested a complex and heterogeneous proliferation of mesenchymal cells in experimental lung fibrosis. None of the cells that they explored appeared to be the origin of myofibroblasts.[150] Determining the origin of these cells remains an area of active investigation.

Fibroblast Phenotypes and Functions in IPF

Various growth factors that influence fibroblast function have been shown to be produced in the lung tissue of patients with IPF and also shown to mediate the pathogenesis of experimental fibrosis.[151,152] Examples include keratinocyte growth factor, TGF-β, insulin-like growth factor-1 (IGF-1), platelet-derived growth factors (PDGF-A and PDGF-B), fibroblast growth factor-2, and hepatocyte growth factor. Many of these growth factors activate tyrosine kinase signaling pathways that promote fibroblast proliferation and matrix production.

TGF-β is a critical mediator of lung fibrosis in animal models.[153] Several studies have shown that antagonizing TGF-β prevents the development of lung fibrosis.[154] Alternatively, targeted overexpression of TGF-β has been shown to produce progressive pulmonary fibrosis.[155] Evidence suggests that TGF-β has the capacity to promote epithelial cell transformation into a mesenchymal phenotype.[146] Studies have suggested that fibrosis is attenuated in the setting of targeted loss of TGF-β signaling in epithelial cells[156,157] and that epithelial expression of the integrin αvβ6 responsible for the activation of latent TGF-β is also critical to the development of fibrosis.[158] TGF-β also induces the differentiation of fibroblasts to myofibroblasts.[159,160] This effect appears to be dependent on NADPH oxidase 4.[161]

Secreted factors that influence fibroblast migration may also be important to fibrogenesis. The production of CXCL10 by innate immune cells may be critical to fibroblast migration and fibrogenesis.[162–164] Recent work highlighted lysophosphatidic acid (LPA) as an additional chemotactic factor for fibroblasts.[165] LPA interacting with

its cognate receptor LPAR1 is critical for recruitment of fibroblasts. LPA was increased in the BALF from IPF patients and inhibition of LPAR1 markedly attenuated the migration of fibroblasts to IPF BALF.

It appears that IPF fibroblasts have an enhanced proliferative capacity as compared to non-IPF fibroblasts.[166,167] The mechanism of enhanced proliferation is not fully elucidated but data suggest that several pathways may be involved. These include defective fibroblast/extracellular matrix interactions, aberrant activation of PI3 K/Akt/S6K1 signaling pathways, and genome-wide derangements in translation control.[168–171] The derangements in transcriptional control have the potential to allow IPF fibroblasts to circumvent normal negative feedback signals that would inhibit fibroblast proliferation and therefore limit fibrogenesis.

It has also been suggested that IPF fibroblasts have the capacity to invade through tissue. Such an invasive capacity might lead to the destruction of the basement membrane and collapse of alveolar tissue, both hallmarks of IPF pathology. It was recently shown that IPF fibroblasts may spontaneously invade an artificial matrix in an in vitro model.[172] It was also shown that targeted overexpression of hyaluronan, an extracellular matrix component, in myofibroblasts resulted in enhanced invasive capacity.[173] The invasive capacity of human IPF fibroblasts could be abrogated by either blockade of CD44 (the receptor for hyaluronan) or inhibition of hyaluronan synthase 2 (the enzyme responsible for HA production).[173] The importance of fibroblast capacity to invade matrix was also demonstrated in mice where there was deletion in regulators of G-protein–coupled receptor functioning called β-arrestins. β-Arrestin null mice were protected from experimental fibrosis and both mouse and IPF fibroblasts had suppression of fibroblast invasion when β-arrestins were inhibited.[174]

TREATMENT

Treatment for IPF is discussed below. Both pharmacologic and nonpharmacologic approaches are considered.

PHARMACOTHERAPY

The management of patients presents several challenges, namely (1) whom to treat; (2) when to treat; and (3) how to select treatment. In IPF, selection of treatment has been a contentious issue due to lack of drugs conferring a survival benefit, physiologic improvement, or quality of life (QOL) benefit. Recently, this landscape has changed due to a combination of promising novel treatment pathways and two recent clinical trials demonstrating positive outcomes in the treatment of IPF.

Historically, treatment strategies have been directed at suppressing the inflammatory processes of IPF. This strategy was employed despite histologic evidence demonstrating that inflammation is but a meager component of this disease. Alternative therapeutic agents were then developed to inhibit cytokines, proteases, oxidants, and mesenchymal growth factors. Several clinical trials have been undertaken over recent years to study these pathways. More recently potential targets for treatment have shifted to targeted therapies directed at the specific pathways that appear to mediate fibrogenesis. The goal continues to remain to prevent the onset and progression of fibrosis as there remains little evidence to support the notion that mature fibrosis can ever be reversed.

Corticosteroids and Immunosuppressants

Corticosteroids have never been studied head-to-head against placebo to determine their benefit in treating IPF. Retrospective studies have failed to demonstrate benefit from steroid monotherapy.[175] The most recent consensus guidelines on IPF recommend against the use of steroid monotherapy for the treatment of IPF.[20] Combination immunosuppressant therapy (steroid plus azathioprine, for instance) is also lacking for evidence of efficacy. Current guidelines recommend against the use of combination immunosuppressant therapy as the limited evidence in support of its benefit does not outweigh concerns for associated morbidity and mortality with such treatment. This opinion relies heavily on new data from a trial that compared the use of prednisone and azathioprine to placebo (the PANTHER trial).[176] The study was halted early due to an excess of mortality in the arm of the trial receiving combination prednisone and azathioprine.

N-acetylcysteine

Previous studies have demonstrated both an increased oxidant burden in the epithelial-lining fluid from patients with IPF as well as diminished antioxidant capacity.[118,119] These studies formed the basis for a controlled study comparing prednisone and azathioprine to prednisone, azathioprine, and N-acetylcysteine (NAC).[177] The results of this study showed that NAC slowed the deterioration of FVC and diffusion capacity after 1 year to a statistically significant extent. There was a high dropout rate in both arms and there was no difference in mortality. In order to address these concerns, an arm of the PANTHER trial was designed to compare NAC to placebo. The results of this study failed to demonstrate a change in either the primary or secondary endpoints. These results suggest that NAC does not have a benefit in IPF patients who had evidence of mild-to-moderate impairment in pulmonary function (FVC >50% predicted and D_{LCO} >30% predicted). The effect on later stage disease and other interstitial lung diseases is not known.

Pirfenidone

Pirfenidone is an orally administered agent with anti-inflammatory, antioxidant, and antifibrotic properties. There is evidence to suggest that pirfenidone has efficacy in slowing the progression of IPF. The first study of pirfenidone evaluated 105 Japanese patients with IPF using a 2:1 randomization and a physiologic endpoint incorporating gas exchange with exertion.[178] The study was discontinued prematurely due to concern over excess morbidity in the placebo group though it failed to demonstrate efficacy as measured by the primary endpoint. However, there were differences in FVC at the end of the study that stimulated interest in further clinical trials. As a result of this observation, two large international efficacy trials were completed.[179] In one of these studies a statistically significant reduction in the decline of FVC was observed in the active arm (patients who took 2403 mg/d of pirfenidone daily). However, the other trial, with a nearly identical protocol, failed to demonstrate efficacy. Based on this data and the data from the Japanese trial, pirfenidone was approved for use in Japan and in the European Union. Similar approval did not occur in the United States. A new phase III trial was undertaken at the request of the United States Food and Drug Administration (FDA) to clarify the concern over the results of the CAPACITY trials. In the ASCEND trial, 555 patients with idiopathic pulmonary fibrosis were randomized to receive 2403 mg of oral pirfenidone or placebo and then followed for 52 weeks. The enrolled patients had: (1) mild to moderate functional impairment, defined by an FVC range from 50–90% perdicted; (2) D_{LCO} range from 30–90% predicted; (3) FEV_1/FVC >0.80; and (4) 6-minute walk distance >150 meters. In recently published data from the ASCEND trial, pirfenidone was associated with a significant reduction in the proportion of patients who had a decline of 10% or greater in their predicted FVC. Additionally, there was a significant increase in the numbers of patients who demonstrated no decline in FVC. In a combined analysis of the ASCEND and CAPACITY trials, pirfenidone was associated with a decrease in both all-cause and IPF-related mortality. On the basis of these results, pirfenidone is in the process of being re-evaluated by the FDA for approval as a therapy for IPF in the United States.

Thalidomide

Thalidomide is a drug with a variety of properties including anti-inflammatory, immunomodulatory, and antiangiogenic effects.[180–182] In animal models thalidomide has attenuated pulmonary fibrosis after bleomycin challenge.[183] When a small open label trial was performed, hoping to assess the safety and efficacy of this drug as a disease-modifying agent, a reduction of cough was serendipitously

observed. This led to a follow-up randomized crossover design study in which thalidomide was shown to significantly reduce cough and improve QOL in patients with IPF.[184] Since cough is a particularly debilitating aspect of IPF this could represent a potential future therapy to impact QOL in this disease.

Tyrosine Kinase Inhibitor BIBF 1120 (Nintedanib)

BIBF 1120 is a triple tyrosine kinase inhibitor with efficacy on fibroblast growth factor (FGF), vascular endothelial growth factor (VEGF), and on platelet-derived growth factor (PDGF).[185] The activation of these pathways has been implicated in the pathogenesis of experimental fibrosis. In a 12-month phase II trial (the TOMORROW trial) patients who received 150 mg of BIBF 1120 twice daily had a trend toward reduction in the decline of FVC.[186] In addition, there was an improved QOL and a reduction in acute exacerbations of IPF. These results led to a phase III trial. This was designed as two identical phase III studies called INPULSIS-1 and INPULSIS-2. The INPULSIS trials tested the effect on IPF disease progression over 52 weeks using 150 mg of twice daily nintedanib (formerly BIBF 1200) versus placebo. The inclusion criteria included patients diagnosed with idiopathic pulmonary fibrosis based on established criteria.[20] In addition, the participants' HRCT scans and biopsies, if available, were reviewed by a central radiologist or pathologist to confirm the diagnosis. Enrolled subjects had a FVC which was >50% of the predicted value and a D_{LCO} from 30–79% of predicted values. Published data from the two trials indicated that patients who received nintedanib demonstrated a statistically significant reduction in the rate of decline in lung function compared with the placebo group. In the INPULSIS-2 trial, there was a significant reduction in the time to first acute exacerbation of IPF. This was not replicated in the INPULSIS-1 trial data. The most common side effect for the medication was diarrhea. On the basis of this study, nintedanib is pending evaluation for approval for use in the United States.

Gastroesophageal Reflux Therapy

It has been observed that IPF patients have a high prevalence of gastroesophageal reflux disease (GERD). A retrospective cohort study identified that GERD treatment in IPF patients was associated with an increased length of survival and reduced radiographic evidence of fibrosis.[187] The contribution of this observation to the pathogenesis of the disease is unknown as no rigorous prospective studies have been performed. Nevertheless, pursuing the diagnosis of GERD in IPF patients appears warranted and, when identified, treatment according to established practice guidelines is appropriate.

■ NONPHARMACOLOGIC THERAPY

The roles of lung transplantation and additional nonpharmacologic measures are presented briefly below.

Lung Transplantation

Lung transplant remains the only therapeutic intervention of proven benefit in IPF. Transplant has been reserved for patients at the advanced stages of IPF and the 5-year survival data approach 50%. However, complications of lung transplant remain common and severe. Among the most important complications and the major cause of long-term mortality following lung transplant is bronchiolitis obliterans syndrome (BOS). BOS is an enigmatic process characterized by progressive fibrosis of terminal and respiratory bronchioles leading to an inexorable decline in transplant function. New therapeutic approaches are sought to control BOS. Therapy for BOS is limited at this time.

Supplemental Oxygen

Patients with hypoxemia (Pa_{O_2} <55 mm Hg or Sp_{O_2} <88%) at rest or during exercise can be managed with supplemental oxygen. There is evidence in patients with COPD, which suggests that supplemental oxygen relieves exercise-induced hypoxemia and improves exercise performance. Studies examining QOL in patients with IPF emphasize the importance of maintaining a patient's independence and participation in physical activities. In one study that examined QOL in IPF patients, no difference was found between patients receiving supplemental oxygen compared to those who were not receiving oxygen. Thus, any concern can be put to rest that supplemental oxygen would have a deleterious effect on QOL domains such as "self-esteem," "dependence on therapy," and "body image."[188]

Pulmonary Rehabilitation

Patients with IPF should be encouraged to enroll in pulmonary rehabilitation programs. Although pulmonary rehabilitation has not yet been shown to be effective in the IPF population, recent evidence suggests the possibility of benefit from a tailored exercise program. Exercise capacity in the IPF population has been correlated with quadriceps strength, which implies that training of the lower extremities would increase exercise capacity in IPF much the same as it does in COPD.[189] Furthermore, it has been shown that overall QOL is impaired in IPF, with specific defects in areas of physical health and perceived social independence. Therefore it has been suggested that pulmonary rehabilitation programs for IPF be designed to include education and psychosocial support elements with the goal of improving coping skills affecting a better QOL.[188]

CHAPTER 57

Idiopathic Interstitial Pneumonias Other Than Idiopathic Pulmonary Fibrosis

Erica L. Herzog
Ami N. Rubinowitz
Mridu Gulati

INTRODUCTION

The idiopathic interstitial pneumonias (IIPs) encompass a subcategory of interstitial lung diseases (ILDs) that pose significant diagnostic and management challenges. The general diagnostic approach to these disorders is discussed elsewhere in this textbook (Chapter 54), as is the diagnosis and management of idiopathic pulmonary fibrosis (IPF), (Chapter 56). This chapter details the classification, diagnosis, and management of non-IPF forms of IIPs including nonspecific interstitial pneumonia (NSIP), organizing pneumonia (OP), desquamative interstitial pneumonia (DIP), and respiratory bronchiolitis-associated interstitial lung disease (RB-ILD), acute interstitial pneumonia (AIP), and lymphocytic interstitial pneumonia (LIP). Historical perspectives, current definitions, and epidemiologic information will be provided along with clinical aspects, imaging, and pathologic findings. Each section ends with a discussion of current therapeutic options. This information is summarized in Table 57-1.

NONSPECIFIC INTERSTITIAL PNEUMONIA

The important entity of nonspecific interstitial pneumonia is discussed below.

DEFINITION AND HISTORICAL PERSPECTIVES

In 1994, the term "nonspecific interstitial pneumonia" (NSIP) was developed by Katzenstein and Fiorelli[1] to describe a histologic pattern that demonstrates a temporally uniform appearance of interstitial inflammation and fibrosis This definition was further refined in 1998, when Katzenstein went on to formally designate NSIP as a distinct category within the IIPs.[2] While most sources are in agreement about the presence of NSIP as a distinct *histologic* entity, the existence of NSIP as a distinct *clinical* entity remains controversial.[3–5] For example, the American Thoracic Society (ATS) reports that in one review of 193 cases of NSIP, only 67 cases (or approximately one-third) were truly idiopathic while the rest were associated with a discrete diagnosis. As a result, when a radiographic or pathologic diagnosis of NSIP is made, clinicians should search for one of the underlying conditions with which this pattern is known to be associated.

UNDERLYING DISEASE ASSOCIATIONS

Nonidiopathic NSIP is associated with a number of underlying causes.[5,6] NSIP is the most prevalent form of ILD to complicate connective tissue diseases (CTD) and as such is frequently the histologic pattern seen when ILD complicates polymyositis and dermatomyositis,[7] Sjögren syndrome,[8] and systemic sclerosis (SSc).[9] NSIP is seen in rheumatoid arthritis though far less commonly than is usual interstitial pneumonia (UIP).[10] NSIP is also encountered in the setting of hypersensitivity pneumonitis,[11] drug reactions,[12] and in some forms of familial ILD.[13] Some cases of apparently idiopathic NSIP may later develop CTD, indicating that NSIP is a forme fruste of CTD.[14]

CLINICAL PRESENTATION

NSIP most commonly affects nonsmoking middle-aged adults between 40 and 60 years of age and has a female predilection.[1,4,15] Like most other IIPs, NSIP tends to present with the subacute onset of dyspnea and cough. Lung examination frequently reveals bilateral crackles though in some settings lungs will be clear. Extrapulmonary examination may provide clues to an underlying CTD (Chapter 60). For example, the presence of a heliotrope rash, shawl-like rash, and digital edema/desquamation (the so-called "mechanic's hands") suggests underlying dermatomyositis. The presence of telangiectasis, calcinosis, and sclerodactyly suggests a diagnosis of scleroderma. The presence of joint effusions and radial deviation of the MCP joints suggests an underlying diagnosis of rheumatoid arthritis. Clubbing is seen only rarely.

Patients sometimes present without an established diagnosis. In this case, a complete history regarding occupational, environmental, and medication exposures must be obtained. In addition, because idiopathic NSIP is frequently associated with CTD, an exhaustive rheumatologic history should be obtained. This includes questions regarding the presence of arthralgias, swallowing difficulties, myopathic symptoms, rash and mechanic's hands commonly encountered in antisynthetase syndrome, ocular and/or salivary gland dryness associated with Sjögren syndrome, and Raynaud phenomenon and swallowing difficulties that are characteristic of SSc. While most sources recommend serologic testing in the diagnosis of NSIP, there exist no standardized practice guidelines in this area. At minimum, ANA and rheumatoid factor should be ordered, along with extractable nuclear antigens (which include Jo-1 and Scl-70) and anticyclic citrullinated peptide (anti-CCP). Serum creatine phosphokinase (CPK) and aldolase are useful in the diagnosis of myositis. Because hypersensitivity pneumonitis may also present with NSIP, antigen testing for mold or birds is sometimes performed though the clinical relevance of a positive (or negative) test is unclear and as such these tests are insufficient for diagnostic purposes.

PULMONARY FUNCTION TESTING

Pulmonary function testing demonstrates a restrictive ventilatory defect characterized by a preserved FEV_1/FVC ratio and a depressed FVC, TLC, and D_{LCO}. The presence of obstructive physiology should raise suspicion of an alternate or superimposed diagnosis.

CHEST IMAGING

The imaging appearance of NSIP may vary, depending on if it is cellular, fibrotic, or mixed. Chest radiograph may be normal in patients with early disease or show nonspecific interstitial markings and ground-glass opacities mostly in the lower lobes with more advanced disease. Distribution of disease at CT is typically peripheral and lower lobe predominant, but may also involve the upper lobes without an obvious apicobasal gradient and can be patchy or peribronchovascular in distribution as well.[16–19] The most common CT findings include ground-glass density and reticular markings with or without traction bronchiectasis (Figs. 57-1 and 57-2). Honeycombing is sometimes seen in fibrotic NSIP but is usually not the dominant feature.[18,19]

PATHOLOGY

When a tissue biopsy is required for diagnosis of NSIP, video-assisted thoracoscopic surgery (VATS) is the procedure of choice because this approach yields sufficient tissue to accurately diagnose the IIPs. The original description of NSIP categorizes its temporally uniform appearance of fibrosis and inflammation into three groups:

TABLE 57-1 Key Features of Idiopathic Interstitial Pneumonias

Features	IPF/UIP	NSIP	COP	AIP	DIP/RB-ILD	LIP
Mean age of onset	60s	50s	50s	50s	40s	50s
Duration of illness	Chronic	Subacute to chronic	Subacute	Acute	Subacute to chronic	Chronic
Frequency of diagnosis	47–64%	14–36%	4–12%	Rare	10–17%	Rare
Smoking	Up to 2/3	Uncommon	Up to 1/2	Unknown	Most	Unknown
HRCT	Peripheral, subpleural; basilar predominant; reticular opacities; traction bronchiectasis architectural distortion and honeycombing	Peripheral, subpleural; basal, symmetric; ground-glass opacities, reticular markings, traction bronchiectasis	Patchy, bilateral, subpleural and peribronchovascular consolidation	Diffuse consolidation and ground-glass opacities often with lobular sparing	DIP: peripheral or diffuse ground-glass opacities, reticular markings, +/− small cysts RB-ILD: bronchial wall thickening; centrilobular nodules; patchy ground-glass opacity	Diffuse; centrilobular nodules; ground-glass opacities; septal thickening; thin-walled cysts
Key pathologic features	Variegated temporal appearance; scant inflammation; patchy fibrosis; fibroblastic foci; honeycomb change	Uniform temporal appearance; prominent inflammation; variable, diffuse fibrosis; rare honeycomb	Uniform temporal appearance; moderate inflammation; intra-alveolar (Masson bodies) fibroblast proliferation; foamy macrophages	Structural cell death responses; acute inflammation; hyaline membranes may be present	Uniform temporal appearance DIP: diffuse variable moderate fibrosis with diffuse intra-alveolar macrophage accumulation RB-ILD: peribronchilar intra-alveolar macrophage accumulation with only focal, mild fibrosis	Diffuse interstitial infiltration, infiltrates comprises T and/or B cell lymphocytes, plasma cells, macrophages, lymphoid hyperplasia
Prognosis	50–70% mortality in 5 y	<10% mortality in 5 y	Rare deaths	50–60% mortality at 1 mo	5% mortality in 5 y	Not well defined
Response to steroids	Poor response	Responsive (particularly cellular)	Responsive	Unknown	Responsive	Not well defined

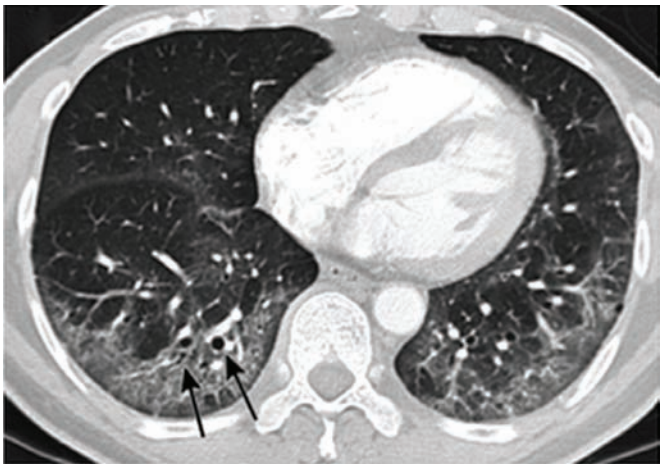
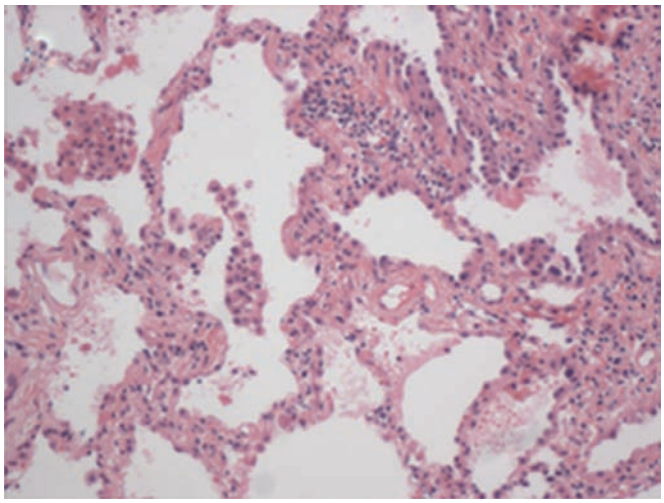
A



B



C

Figure 57-1 A 60-year-old male with antisynthetase syndrome and cellular nonspecific interstitial pneumonia (NSIP). High-resolution CT images through the upper (**A**) and lower (**B**) thorax demonstrate peripheral and lower lobe predominant ground-glass opacities with mild reticular markings and minimal traction bronchiectasis *(arrows)*. **C.** Open lung biopsy revealed temporally uniform septal thickening and inflammation consistent with a cellular NSIP. *(Pathology images used with permission of Robert J. Homer, MD, PhD, Yale School of Medicine.)*

those dominated by active inflammation (later called, "cellular" NSIP [Fig. 57-1]), those dominated by established fibrosis (later called, "fibrotic" NSIP [Fig. 57-2]), and those demonstrating a combination of inflammation and fibrosis (later called, "mixed" NSIP.[1])

■ CLINICAL COURSE, OUTCOME, AND TREATMENT

Patients with NSIP demonstrate a good to fair prognosis as shown by several studies. Those individuals with cellular NSIP can expect 74% survival at 5 years[20] and this specific pathologic pattern is associated with reduced event-free survival compared to the fibrotic forms.[21] Similarly, radiographic changes that would be expected to accompany fibrotic NSIP such as honeycombing have been associated with reduced survival, as have progressive dyspnea and desaturation during 6-minute walk test.[20]

■ PHARMACOLOGIC THERAPY

Immunosuppression is commonly employed in the management of NSIP but the lack of prospective, randomized controlled trials in this area means that evidence for a therapeutic effect of these agents is lacking. For cases of exposure-related NSIP related to drugs or inhalations, cessation of the offending agent is the initial treatment strategy. In very mild situations this intervention may be sufficient but oftentimes patients with significant disease burden radiographically or physiologically require treatment with systemically administered immunosuppressive agents. Patients with arterial hypoxemia at rest or during exercise require the administration of supplemental oxygen. Patients with exercise impairment may benefit from pulmonary rehabilitation. Finally, due to the rapid deterioration that is sometimes encountered in patients with NSIP, referral for orthotopic lung transplantation (OLT) should be considered for any eligible patient.

The use of immunosuppression is based on the rationale that the inflammation seen on pathology at least partially contributes to disease. Most of the immunosuppressive agents used to treat NSIP have not been formally evaluated in prospective, randomized clinical trials and all of them have significant toxicities. Thus, the decision to embark upon a course of immunosuppression should be considered in light of the risk–benefit ratio. Similarly, when treating a patient with NSIP in the setting of CTD, the management of these medications is best performed with the patient's rheumatologist because since the pulmonary and systemic involvement may demonstrate independent responses, systemic effects must be monitored as well. Patients should be seen frequently and should have lab monitored monthly in order that serious and potentially fatal side effects can be recognized in a timely fashion.

Corticosteroids

Despite a lack of clinical trials in this area, expert opinion recommends a trial of corticosteroid therapy in patients with NSIP. Patients are typically treated with 1 mg/kg per ideal body weight of oral prednisone for several months and then assessed for evidence of objective response on PFTs or HRCT.[16] The side effects of steroid therapy are well-known and include diabetes, bone complications, cataracts, hypertension, weight gain, and opportunistic infection so patients should be followed closely with serial monitoring blood chemistry and CBC. Due to these

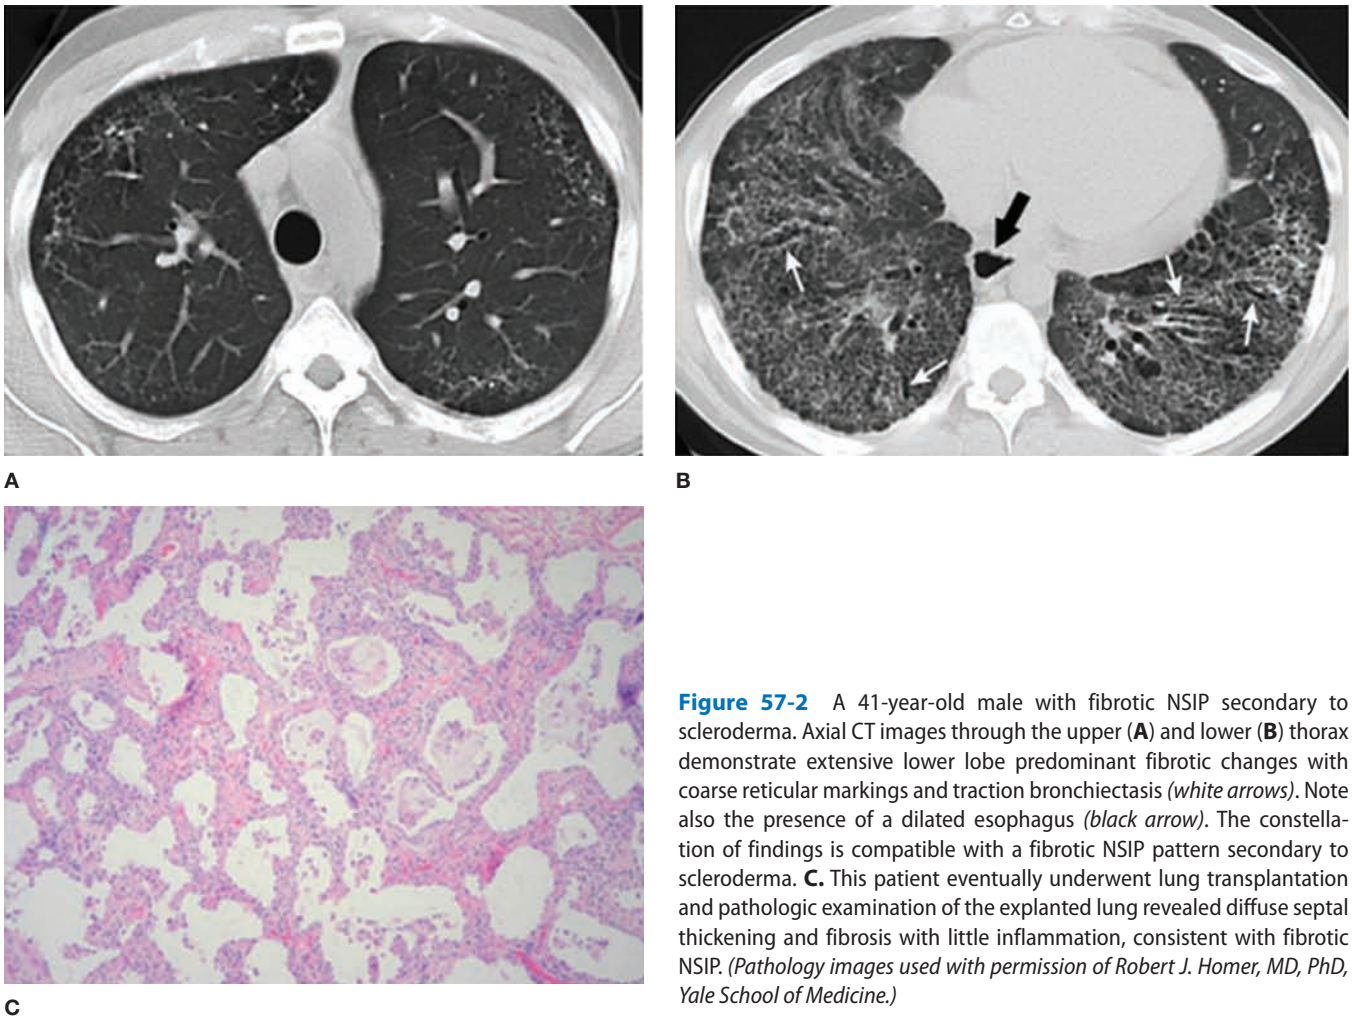


Figure 57-2 A 41-year-old male with fibrotic NSIP secondary to scleroderma. Axial CT images through the upper (**A**) and lower (**B**) thorax demonstrate extensive lower lobe predominant fibrotic changes with coarse reticular markings and traction bronchiectasis *(white arrows)*. Note also the presence of a dilated esophagus *(black arrow)*. The constellation of findings is compatible with a fibrotic NSIP pattern secondary to scleroderma. **C.** This patient eventually underwent lung transplantation and pathologic examination of the explanted lung revealed diffuse septal thickening and fibrosis with little inflammation, consistent with fibrotic NSIP. *(Pathology images used with permission of Robert J. Homer, MD, PhD, Yale School of Medicine.)*

toxicities, every attempt to transition the patient to a steroid-sparing agent is made once the patient has responded to therapy.

Azathioprine

Azathioprine is a commonly used alternate therapy used in patients with NSIP. The evidence for this approach derives from an early study of subjects with IIPs in which a small subset comprised in part of patients with NSIP were found to improve. There have since then been no large-scale clinical trials in this area though one small case series found that patients with fibrotic NSIP experienced improved outcomes when treated with combination therapy of prednisone and azathioprine.[20] Because azathioprine carries several risks including bone-marrow suppression and hepatotoxicity most centers perform genotyping for thiopurine methyltransferase prior to initiation of therapy and when a mutation is uncovered reduce dosage accordingly though evidence for this approach is currently lacking.

Cyclophosphamide

Cyclophosphamide (Cytoxan™) is used in patients with significant or rapidly progressive lung involvement. In a prospective study comparing patients with confirmed fibrotic NSIP versus those with UIP/IPF receiving pulse therapy with methylprednisolone followed by low-dose prednisone and cyclophosphamide, 33% of subjects with NSIP improved with steroids alone and 66% improved with combined therapy. In contrast, only 15% of the subjects with UIP/IPF demonstrated clinical improvement at either timepoint.[22] Further suggestion of efficacy was provided by a small retrospective study in which patients with known or suspected NSIP showed stabilization of lung function following 6 months of therapy. Perhaps the best evidence for a therapeutic benefit of Cytoxan™ was seen in patients with SSc-ILD (most of whom have NSIP) randomized to placebo or Cytoxan™. A small but significant improvement in lung function was noted in those subjects assigned to the treatment arm[23] though subsequent analysis found this effect to dissipate after 2 years.[24] Because cyclophosphamide is associated with many side effects including bone-marrow suppression, hemorrhagic cystitis, and the long-term risk of bladder cancer and hematologic malignancies, its use is reserved for severe and progressive cases of NSIP and it is recommended that it only be used by experienced practitioners with appropriate monitoring.

Other Immunosuppressive Agents

Several case series indicate that mycophenolate mofetil (MMF) may be efficacious in delaying lung function decline in patients with SSc-ILD.[25,26] Because most of these patients have NSIP, these studies are viewed as providing direct evidence of a potential role for MMF in the management of this form of ILD. A large-scale randomized controlled trial of MMF versus cyclophosphamide is currently underway in for the treatment of SSc-ILD. MMF is started at 500 mg b.i.d. and titrated up to a maximum dosage of 2000 mg b.i.d. This agent is pregnancy category D due to its teratogenic potential. A role for tacrolimus in the treatment of NSIP is supported by one retrospective series[27] of patients with polymyositis- and dermatomyositis-related ILD. However, because no large-scale studies have been performed, consideration of this agent for the treatment of NSIP should be considered on a case-by-case basis and patients should be managed with physicians who are experienced in the interpretation

of serum levels. The most feared side effect is renal toxicity, which can in some cases be permanent and lead to kidney failure.

CRYPTOGENIC ORGANIZING PNEUMONIA

The entity of cryptogenic organizing pneumonia was described over 30 years ago. Important clinical aspects and associations are described below.

DEFINITION AND HISTORICAL PERSPECTIVES

First described by Davison[28] and Epler[29] in the early 1980s, cryptogenic organizing pneumonia (COP) was categorized as an IIP in a 2002 working group sponsored by the ATS and the European Respiratory Society (ERS).[16] The pathologic hallmark of COP consists of whorls of myofibroblasts and inflammatory cells in a connective tissue matrix within the distal airspaces. This nonspecific pathologic pattern is termed "organizing pneumonia" and is found in a variety of settings such as in the context of infection, drug toxicity, posttransplant, radiation exposure, or rheumatologic conditions. Therefore, it is only in the absence of an associated condition or inciting factor that clinicians may establish a diagnosis of COP. Thus, the diagnosis of COP rests on an integrated assessment of clinical symptoms, radiographic patterns, compatible histopathologic features, when available, and the exclusion of other associated causes and conditions.

The pathology was initially called "bronchiolitis obliterans organizing pneumonia" (BOOP) and this term initially dominated the North American literature and was included in the seminal paper by Katzenstein and Myers in 1998.[30] Given clinical confusion between the term BOOP and the distinct airway-centered disease of bronchiolitis obliterans syndrome ("BOS"), the terminology was changed in 2002. However, because many cases of COP are associated with an underlying etiology, the inclusion of COP as an "idiopathic" interstitial pneumonia has also been confusing for some. Perhaps most perplexing to clinicians is the fact that the disease in COP dominates the airspaces and not the interstitium. However, the working group justified the inclusion of COP within the IIPs because in clinical practice COP is part of the differential diagnosis of other IIPs, and because interstitial inflammation and fibrosis may be present in COP.

CLINICAL PRESENTATION

Similar to other IIPs, the epidemiology of COP is not well characterized though it seems to affect both genders equally with a mean age of onset of 58 years. Nonsmokers or former smokers may be affected more frequently than current smokers.[31] The classic presentation of COP includes an initial prodromal flu-like illness and symptoms of fever, cough, and dyspnea. Complaints such as hemoptysis, chest pain, arthralgias, or myalgias are uncommon. Chest auscultation may be clear or may reveal crackles. Patients are frequently treated with multiple courses of antibiotics before being diagnosed. The presence of systemic symptoms and/or findings consistent with CTD should lead to careful investigation for an associated underlying disease.[32]

UNDERLYING ASSOCIATIONS

A diagnosis of *COP* requires exclusion of associated causes. It has been suggested that gastroesophageal reflux with silent aspiration may play a role in the development of OP; however, this association has not been firmly established.[33] Many viral, bacterial, fungal, and parasitic infections have been implicated[31,34] as has influenza A H1N1 flu.[35] OP is a frequently encountered manifestation of drug-induced lung disease caused by antibiotics such as nitrofurantoin, medications such as phenytoin, amiodarone, sulfasalazine,[36] and illicit drugs such as cocaine.[37] Occupational exposures are also associated with an OP pattern of lung injury including but not limited to the aerosolized textile dye Acramin FWN, titanium nanoparticles in paint, and certain chemicals used in spice processing.[38–40] OP has been reported in patients with dermatomyositis-polymyositis[41–46] as well as other conditions such as rheumatoid arthritis,[47–49] scleroderma,[50–52] and systemic lupus erythematosus.[53–55] Rheumatologic serologies can be helpful in identifying the presence of disease because this form of lung injury may present as the initial manifestation of systemic disease. OP may be present in other inflammatory diseases such as in patients with Crohn's disease and ulcerative colitis.[56] Radiotherapy treatment is also associated with the development of OP particularly after treatment for breast cancer 3 to 6 months following therapy. Compared to radiation pneumonitis which is fairly well circumscribed and characterized by retracted lung and traction bronchiectasis, postradiotherapy OP occurs diffusely, is migratory, and is highly steroid responsive.[57] OP can also occur following transplantation of lung or bone marrow. While BOS is the most commonly reported lung injury pattern in patients experiencing lung transplant rejection, OP patterns have also been described.[58,59] Similarly, bone-marrow transplant recipients may develop OP as a manifestation of transplant rejection, graft-versus-host disease, or idiopathic pneumonia syndrome.[60–62] OP can also complicate malignant or hematologic conditions such as various forms of acute and chronic leukemias and lymphomas.[63]

PULMONARY FUNCTION TESTING

Similar to other IIPs, a restrictive ventilatory defect, characterized by a reduction in total lung capacity is generally present. In a subset of patients, an obstructive ventilatory defect can be found. Hypoxemia is typically mild although in a subgroup of patients with infiltrative opacities severe hypoxemia may be seen.[64,65]

CHEST IMAGING

OP displays a variable imaging appearance. The CXR usually shows nonspecific patchy areas of consolidation. Sometimes the imaging appearance mimics infectious pneumonia with lobar consolidation that is unresponsive to antibiotics. Peripheral, patchy, and peribronchovascular areas of ground-glass opacity and consolidation are the most classic CT appearance (Fig. 57-3).[16,17,66] Nodular areas of ground glass and consolidation as well as fleeting or migratory areas of consolidation can also be seen with OP.[16,17,66] Findings suggestive of fibrosis such as reticulation, architectural distortion, traction bronchiectasis, and honeycombing are not typically present with this entity. An area of ground-glass opacity surrounded by a rim of increased density, also known as the atoll (or reverse-halo) sign, when present, is strongly suggestive of OP[66] but can also be present with other entities such as vasculitis, certain infections, or pulmonary infarction.

PATHOLOGY

When the clinical presentation and chest imaging is insufficient for a confident diagnosis of COP, bronchoscopy with transbronchial biopsy or surgical lung biopsy can be employed. Bronchoalveolar lavage (BAL) typically reveals significant accumulation of lymphocytes, neutrophils, and eosinophils. Transbronchial biopsies may be performed to make a diagnosis; however, the quantity of lung tissue obtained during these procedures is quite small and may be insufficient to fully evaluate the spectrum of pathology that may exist within the lung parenchyma.[67–69] Thus, larger lung tissue specimens obtained by VATS are frequently used to provide the opportunity for more thorough analyses.

The pathology of OP is characterized by intraluminal plugs of inflammatory debris within the alveolar ducts and surrounding alveoli. The plugs consist of buds of granulation tissue, whorls of fibroblasts and myofibroblasts in a connective tissue matrix referred to as Masson bodies (Fig. 57-3). OP patterns can be seen concomitantly in patients with NSIP or UIP and may in certain patients represent an exacerbation of underlying ILD. In this setting, interpretation of the pathology in the context of the radiographic and clinical features can greatly aid in accurate diagnosis.

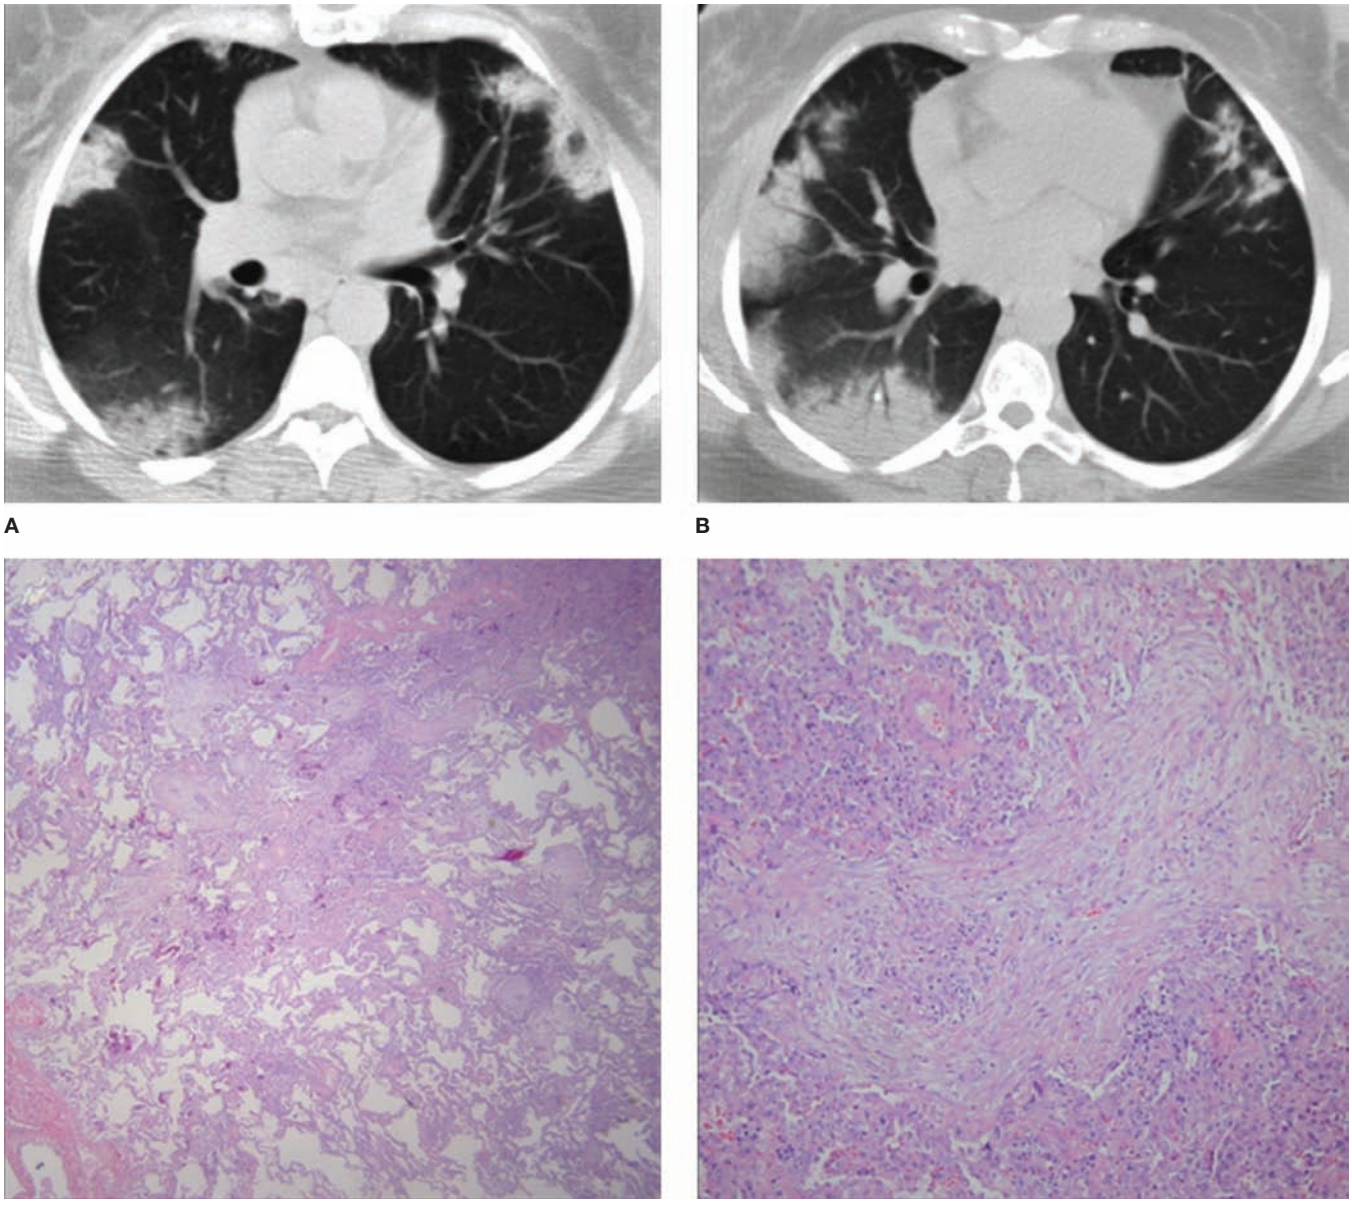

Figure 57-3 A 50-year-old female with cough and dyspnea secondary to organizing pneumonia (OP). Axial CT images through the mid (**A**) and mid to lower (**B**) thorax demonstrate multifocal, peripheral areas of consolidation with a distribution compatible with OP. Low (**C**) and high (**D**) power views of lung tissue from this patient reveal a patchy organizing pneumonia pattern of exudates, fibroblasts, and inflammatory cells. *(Pathology images used with permission of Robert J. Homer, MD, PhD, Yale School of Medicine.)*

■ CLINICAL COURSE, OUTCOME, AND TREATMENT

Patients with mild or asymptomatic disease may not require treatment.[70] When compared to other fibrotic lung diseases such as IPF, COP is impressively steroid responsive though a significant proportion of patients, ranging from 13% to 58%, experience relapse. Fortunately, relapses are not associated with poorer long-term outcomes and death is very infrequent.

■ PHARMACOLOGIC THERAPY

Historically, a 6-month course of treatment has been advised. More recently, shorter 3-month durations of corticosteroids have been recommended to avoid unnecessarily prolonged courses of steroids in patients who do not relapse.[32] Macrolide antibiotics[71] and steroid-sparing agents[72,73] have been used as alternative immunosuppressants for individuals with COP or secondary OP. However, the clinical utility of these approaches has not been completely validated. It is not known whether individuals with secondary causes of OP experience different long-term outcomes from individuals with COP.

While the majority of COP patients have favorable prognosis, a subset of patients present with a rapidly progressive and fatal form of OP. Some investigators have suggested that such cases represent an overlap group with acute interstitial pneumonia or acute respiratory distress syndrome (ARDS). In another series, AFOP, an acute fibrinous organizing pneumonia pattern was reported. In AFOP, organizing pneumonia and intra-alveolar fibrin balls are present.[74] Nonetheless, the literature does suggest that a small subgroup of COP patients suffer a progressive fibrotic course. Alternative forms of immunosuppression such as cyclophosphamide have been used in such rapidly deteriorating patients though experience with this approach is at best limited and the clinical utility is not entirely clear.[72]

RESPIRATORY BRONCHIOLITIS-ASSOCIATED INTERSTITIAL LUNG DISEASE AND DESQUAMATIVE INTERSTITIAL PNEUMONIA

The entities of respiratory bronchiolitis-associated interstitial lung disease and desquamative interstitial pneumonia are part of a spectrum of disorders affecting smokers. Important clinical and pathologic considerations in these two entities are described below.

DEFINITION AND HISTORICAL PERSPECTIVES

While regarded clinically as two discrete forms of IIPs, RB-ILD and DIP are generally thought of as representing ends of a continuous spectrum of disease primarily affecting tobacco smokers. The diagnostic distinction persists due to evidence indicating that RB-ILD and DIP have divergent natural histories and prognoses. The pathologic hallmark of both diseases features cytoplasmic accumulation of golden-brown pigment in macrophages. RB-ILD pathology appears to reflect inhalational exposure as findings center around the bronchioles with peribronchiolar inflammation and fibrosis. In contrast, DIP involves the airways but also extends into the alveolar space and may even include mild to moderate associated interstitial fibrosis. Because RB-ILD and DIP reactions are frequent and often incidental findings in the lung tissue of smokers, formal clinical diagnosis of RB-ILD or DIP hinges upon the presence of symptomatic, radiographic, and functional impairment. Taken together, DIP and RB-ILD account for up to 15% to 20% of patients with biopsied IIPs.[75–78]

CLINICAL PRESENTATION

Patients diagnosed with RB-ILD and DIP are typically males in the fourth or fifth decade of life with an average 30 pack-year smoking history. Affected patients report nonspecific complaints of progressive dyspnea and nonproductive cough. Physical examination may be normal but might reveal dry inspiratory crackles and clubbing as seen in other forms of ILDs. Extrapulmonary findings are usually absent.

UNDERLYING ASSOCIATIONS

Tobacco smoke exposure accounts for the most cases of RB-ILD and DIP, despite their categorization as "IIPs." In fact, it has been reported that up to 90% of RB-ILD and DIP cases are causatively linked to tobacco smoke.[75] However, in one review of 49 cases, it was noted that only 60% of DIP patients versus 93% of RB-ILD patients had a prior smoking history.[79] Although the lower prevalence of smoking in this study compared to prior studies may reflect referral bias, investigators should remain cognizant that such pathologies can occur independently of smoking. When viewed in this light, it is relevant that a number of exposures have been reported in association with DIP such as marijuana smoking, diesel fume, beryllium, copper, fire extinguisher powder, asbestos, and certain chemicals used to process textiles.[79–82] DIP has also been reported as a complication of autoimmune disorders including rheumatoid arthritis and scleroderma[50,52,80,83] and has occurred in association with infections such as hepatitis C, cytomegalovirus, and aspergillus.[84–86] Finally, idiopathic DIP has also been reported.[79] Genetic factors seem unlikely to play a dominant role; however, a few studies particularly among children and sibling studies have implicated genetic abnormalities of surfactant function, such as mutations in SP-B, SP-C, and ABCA-3 genes[87–89] though the applicability of these studies to the adult IIPs described herein remain uncertain. The difficulty in determining the contribution of other exposures may occur because when evaluating individuals with a smoking history, clinical providers dismiss the possible contribution of alternate etiologies. Furthermore, since many individuals with conditions such as rheumatologic disease do not proceed to lung biopsy, the specific underlying pathology of the associated IIP may remain unconfirmed and individuals may be assumed to have NSIP.

PULMONARY FUNCTION TESTING

Patients with RB-ILD often manifest a restrictive physiologic pattern with concomitant reduction in $D_{L_{CO}}$. However, given the bronchiolocentric nature of the pathology, a mixed pattern with some elements of obstruction may also be seen. DIP patients generally demonstrate restrictive ventilatory defects along with reductions in diffusion capacity. Hypoxemia may be seen in more severely affected patients. On occasion spirometry and lung volume impairments seem less severe compared to the patient's clinical status. This phenomenon may be due to the mixed or obstructive patterns seen due to the airway-centered nature of RB-ILD or concomitant smoking-related lung pathologies such as chronic obstructive pulmonary disease (COPD).

CHEST IMAGING

The imaging findings of RB-ILD are usually subtle and not visualized on CXR. CT findings include subtle, mild diffuse or upper lobe predominant, centrilobular ground-glass nodules, and patchy ground-glass densities (Fig. 57-4).[16,17,90,91] Ancillary findings associated with cigarette smoking may also be present such as bronchial wall thickening from chronic bronchitis and tissue rarefaction and bullae reflecting emphysema. The main alternative diagnosis in a patient with centrilobular ground-glass nodules on CT is subacute hypersensitivity pneumonitis. However, the ground-glass nodules with hypersensitivity pneumonitis are usually not as subtle as those seen with RB-ILD. Similar to the CXR findings in RB-ILD, the CXR in DIP are usually quite faint and although sometimes hazy, nonspecific, ground-glass opacities may be present. Ground-glass opacities that are usually peripherally located (Fig. 57-5), but which can also be diffuse, are the most common finding seen on CT.[26,62,86,87] Other CT findings include reticular markings and small cysts, which may indicate a component of fibrosis[26,62,86,87] can be seen but more extensive fibrotic changes such as traction bronchiectasis and honeycombing are rare. In addition, bronchial wall thickening and emphysema may be seen here as well.[87] When peripheral ground-glass opacities exist in this disease, the differential diagnosis includes NSIP, OP, and chronic eosinophilic pneumonia.

PATHOLOGY

The diagnosis of RB-ILD and DIP hinges upon a comprehensive clinical assessment integrating history, physical examination, PFTs, and HRCT. Because the histopathology of DIP and RB-ILD may exist in the lung tissue of asymptomatic smokers, pathology alone does is not diagnostic. Bronchoscopy may have a role in ruling out other processes resembling RB-ILD or DIP. BAL reveals characteristic pigmented macrophages. A pronounced eosinophilia has also been reported in the BAL specimens of some DIP patients. Investigators have suggested that in the appropriate clinical setting and BAL profile, transbronchial biopsy showing RB may be sufficient to support the diagnosis of RB-ILD. Nonetheless, for both RB-ILD and DIP surgical lung biopsy may be necessary to formally establish the diagnosis as well as exclude alternative causes.

The pathologic hallmark of RB-ILD and DIP centers around the accumulation of pigmented macrophages, commonly referred to as smoker's macrophages. These macrophages contain iron and display glassy eosinophilic cytoplasm with a finely granular, yellowish-brown pigment that likely contains components of tobacco smoke. In heavy smokers, the pigmentation may become coarser making the distinction from hemosiderin deposition seen in chronic alveolar hemorrhage more challenging.[79,92] Clinicians must also differentiate the common pathologic finding of respiratory bronchiolitis (RB), first described by Niewoehner in 1974, from the specific disease entity referred to as RB-ILD.[93] In the 1980s, Myers described the phenomena of RB-ILD characterized by the intensified RB response.[94] Lung tissue from RB-ILD may demonstrate a chronic inflammatory

A

C

Figure 57-4 A 42-year-old male with smoking history and chronic cough secondary to respiratory bronchiolitis-interstitial lung disease (RB-ILD). High-resolution CT images through the upper (**A**) and mid (**B**) thorax show diffuse, centrilobular ground-glass nodules *(arrows)*. These findings are compatible with the pathologic pattern of RB-ILD, which features the peribronchial accumulation of pigmented macrophages. Note the relative sparing of the alveolar space (**C**). *(Pathology images used with permission of Robert J. Homer, MD, PhD, Yale School of Medicine.)*

cell infiltrate as well as a peribronchiolar fibrotic pattern more pronounced as compared to uncomplicated RB (Figs. 57-4 and 57-5). Churg has proposed that an RB-ILD diagnosis should be differentiated from RB in smokers when individuals demonstrate evidence of significant functional and physiologic impairment along radiographic abnormalities.[95]

First described by Liebow in 1965,[96] DIP was highlighted as a diagnostic entity in a 1978 study by Carrington.[97] Comparison of DIP and RB-ILD reveals that in DIP the macrophages extend more diffusely into the lobule in contrast to the more limited peribronchiolar involvement found in RB-ILD and that interstitial fibrosis, giant cells, and eosinophils are more commonly found in DIP (Fig. 57-5). Pathologists must exclude the presence of alternative ILDs on biopsy. A clinical diagnosis of RB-ILD or DIP necessitates overall assessment of the patient incorporating pathologic and radiographic findings, functional impairment and exclusion of other diagnostic considerations pathologically and radiographically.

■ CLINICAL COURSE, OUTCOMES, AND TREATMENT

Patients with RB-ILD or DIP are generally characterized by less fibrosis and experience a more favorable prognosis compared to IPF, perhaps in part due to the finding that smoking cessation and corticosteroids are often effective therapies in RB-ILD and DIP patients.[77,78,98] Progressive disease is uncommon in RB-ILD and is more often seen in patients with DIP as one study found that 33% of DIP patients versus 64% of RB-ILD patients experienced objective radiographic or physiologic improvement.[75] Similarly, another study found that 26% of patients with DIP died compared to no patients in the RB-ILD, a finding that confirmed prior work by Carrington and Yousem.[92,97,99]

Smoking Cessation

The cornerstone of treatment for these diseases includes tobacco smoking cessation. In patients with mild to moderate symptoms and impairment a period of observation after smoking cessation is reasonable. Many patients stabilize and improve; however, concomitant corticosteroid therapy often confounds interpretation of the efficacy of smoking cessation alone[77] and earlier studies by Carrington and Yousem failed to comprehensively characterize the effect of smoking cessation. Additional confounders that complicate assessment of improvement include the presence of other smoking-related lung pathologies such as emphysema whose contribution to impairment will not generally respond to any intervention.

Corticosteroids

When symptoms and impairment are severe, treatment with systemic corticosteroids may be of benefit. A 6- to 9-month course of therapy starting at a level of 40 to 60 mg/d for 6 weeks is reasonable.

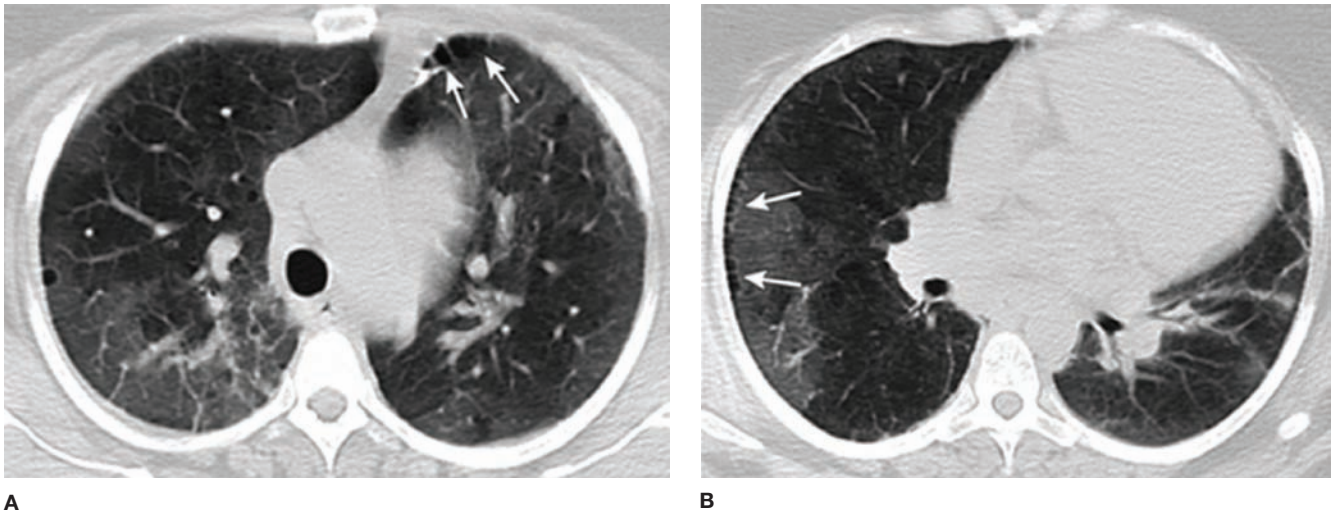

Figure 57-5 A 36-year-old female with significant cigarette smoking history, cough, and dyspnea. Axial CT images through the upper (**A**) and lower (**B**) thorax demonstrate bilateral, patchy, and peripheral ground-glass opacities. Small bullae along the pleural surfaces compatible with paraseptal emphysema are also present *(arrows)*. The ground-glass opacities did not resolve on follow-up imaging so the patient underwent video-assisted thoracoscopic surgery (VATS) and pathology revealed desquamative interstitial pneumonia (DIP) shown in (**C**), demonstrating the peribronchial and intra-alveolar accumulation of pigmented macrophages. *(Pathology image used with permission of Robert J. Homer, MD, PhD, Yale School of Medicine.)*

The role of alternative immunosuppressants that are used in other ILDs have been less well defined in RB-ILD and DIP although macrolide antibiotic therapy has been reported to be an effective steroid-sparing treatment in DIP.[100] Lung transplantation may be necessary for patients with severe progressive disease. Recurrence of disease after transplant has been reported.[99]

ACUTE INTERSTITIAL PNEUMONIA

The original description of acute interstitial pneumonia dates back over 75 years. Clinical hallmarks of this entity are described below.

■ DEFINITION AND HISTORICAL PERSPECTIVE

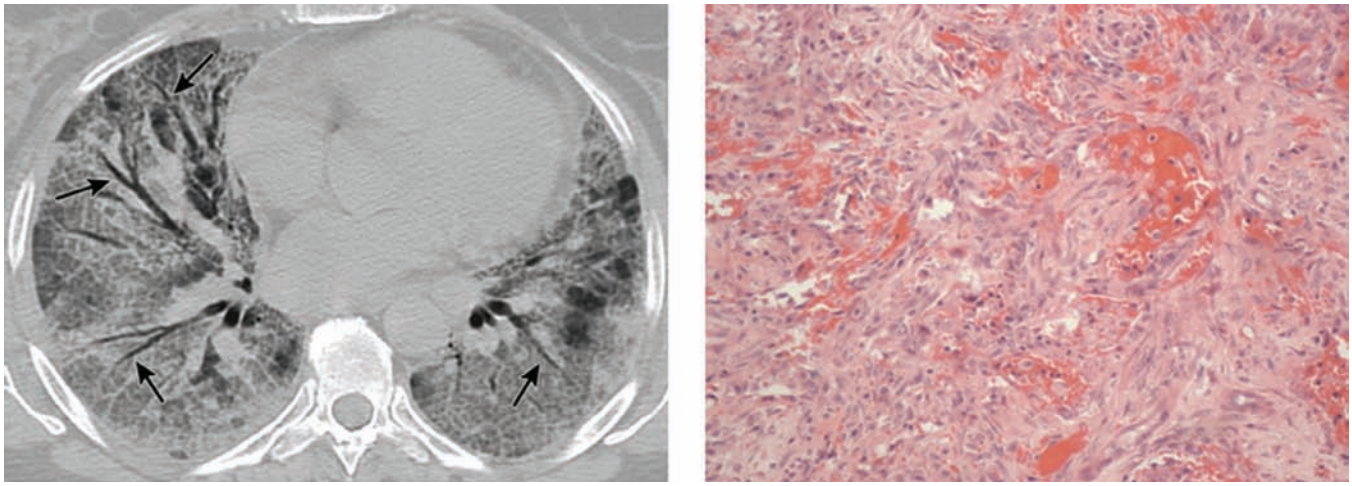
Acute interstitial pneumonia, also called "AIP" or "Hamman–Rich syndrome," was first described by Hamman and Rich in 1935 and is a rare and fulminant IIP.[101] Current ATS/ERS diagnostic criteria for AIP include the following[16]: (1) rapidly progressive clinical course (≤2 months) leading to respiratory failure; (2) exclusion of infectious, toxic, autoimmune, or any other known cause of ARDS; (3) diffuse alveolar damage (DAD) on biopsy specimens (see below); (4) radiologic findings consistent with ILD; and (5) absence of chronic lung disease.

■ CLINICAL PRESENTATION

AIP is quite rare and most frequently presents in previously healthy individuals with no prior lung disease. The disease has no gender predominance and most commonly affects patients over 40 years old with a mean age of 50 to 55 years.[102–104] Unlike most other IIPs,[102] AIP typically presents as the acute onset of fever (75%), cough (70%), and rapidly progressive dyspnea (90%)[105] with many patients reporting the sensation of an infectious prodrome. Most patients are hypoxemic upon presentation and rapidly progress to respiratory failure requiring mechanical ventilation. Physical examination frequently reveals tachypnea and bilateral crackles in all lung fields. Signs of chronic lung disease such as clubbing are uncommon and argue against a diagnosis of AIP while the presence of skin or joint abnormalities might suggest an underlying autoimmune process. While initial management focuses on stabilizing the patient's respiratory status, diagnostic evaluation should be undertaken. Once cardiogenic pulmonary edema has been ruled out by EKG, cardiac enzymes, and echocardiogram, causes of noncardiogenic pulmonary edema and ARDS should be evaluated. Given the broad array of diseases and exposures associated with the development of ARDS, this assessment should include careful exposure history including medications and occupational hazards, as well as a complete rheumatologic history. The serologic and muscle enzyme testing described earlier for NSIP may also be valuable in this setting.

■ UNDERLYING ASSOCIATIONS

The differential diagnosis of AIP is broad and includes left heart failure, diffuse alveolar hemorrhage, OP, hypersensitivity pneumonitis, UIP/IPF, and DIP. AIP can generally be distinguished from these entities based on careful history, examination of chest films, and ancillary tests described earlier. Once the AIP diagnosis has been established, it is imperative to further seek underlying causes



A B

Figure 57-6 A 45-year-old female with acute shortness of breath. High-resolution CT image through the thorax (**A**) demonstrates diffuse ground-glass opacities involving every lobe. Within areas of ground-glass opacity are reticular markings and traction bronchiectasis *(arrows)* suggestive of organization and underlying fibrosis. Lung tissue obtained at autopsy revealed findings of diffuse alveolar damage which was including obliteration of the alveolar space with structural cell death responses, acute inflammation, and hyaline membrane formation (**B**). *(Pathology image used with permission of Robert J. Homer, MD, PhD, Yale School of Medicine.)*

such as collagen vascular disease such as antisynthetase syndrome[106] or lupus[107]; therapeutic exposures such as certain chemotherapies, biologic therapies, radiation, hyperoxia[108,109]; illicit drugs such as heroin or cocaine[110]; toxic exposures such as smoke inhalation and other gases[108]; massive transfusion,[111] fat embolism, aspiration,[112] and infections such as atypical pneumonias (mycoplasma[113] or legionella[114]) and viral infections (influenza).[115] AIP should also be differentiated from acute exacerbations of underlying IIPs or other pre-existing forms of underlying lung disease.

■ PULMONARY FUNCTION TESTING

Most patients are too ill to undergo pulmonary function testing but a restrictive ventilatory defect and impaired diffusion capacity would be expected.

■ CHEST IMAGING

AIP is radiographically and pathologically indistinguishable from ARDS. Imaging findings depend upon whether the early, exudative phase or chronic, fibrotic phase is present. Diffuse consolidation and ground-glass opacities are typically seen in the early, exudative phase, with the dependent areas of lung being more affected.[16,17,116] The early, exudative phase is difficult to distinguish radiographically from other entities such as cardiogenic or noncardiogenic edema, diffuse infection or diffuse hemorrhage. In patients who survive the acute phase (sometime after the first week), in addition to the lung consolidation, findings of underlying fibrosis such as architectural distortion, traction bronchiectasis, with or without honeycombing, become apparent at imaging and are usually more severe in the nondependent portions of the lung (Fig. 57-6).[16,17,116]

■ PATHOLOGY

If microbiologic testing yields negative sputum culture and viral studies, bronchoscopy with BAL is next performed to rule out undiagnosed infection or alternate diagnosis. There is generally no role for transbronchial biopsy in the diagnosis of AIP as when a tissue diagnosis is required, surgical lung biopsy is the preferred approach. A pathologic diagnosis of DAD demonstrates diffuse and extensive cell death accompanied hyaline membranes, which are histologically apparent layers of fibrin mixed with necrotic epithelium. This material lines the alveolus and reflects the severity and acuity of the injury (Fig. 57-6). As the injury progresses, it evolves into its organizing phase, which can either resolve into relatively normal lung or result in lung fibrosis.

■ CLINICAL COURSE, OUTCOMES, AND TREATMENT

The fulminant and often untreatable nature of AIP endows this disease with a particularly high mortality. More than 50% of patients die during hospitalization and most patients die within 6 months of diagnosis. Those who survive are at risk for disease recurrence or the development of other forms of ILD. However, a small fraction of survivors may experience complete recovery of lung function.[103,105] Treatment is detailed below and is aimed at supporting the patient and attempting to limit the acute injury and inflammation.

Nonpharmacologic Therapy

The mainstay of therapy for AIP is supportive care.[103,105] This includes supplemental oxygen or mechanical ventilation, adequate sedation, nutritional support, and prevention of ICU-related complications such as stress-induced ulcers, venous thromboembolism, catheter-related bloodstream infections, and ventilator-associated pneumonias.

Pharmacologic Therapy

High/pulse-dose glucocorticoid therapy is frequently administered to patients suffering from AIP though, due to the rarity and often grave nature of AIP, there have been no clinical trials assessing efficacy of this treatment.[105] Therefore, the evidence supporting this approach is anecdotal and is, in fact, based on case reports that showed a conflicting survival benefit.[102,105,117] For example, in the largest case series published in 1990, of 29 patients treated with glucocorticoids, survival was 45% in the treated group versus 33% in the untreated group.[102] Similarly, in smaller series of only eight patients treated with pulse-dose steroids, seven patients survived.[117] Conversely, a different study of nine patients treated with 8 mg/kg of methylprednisolone found a mortality of 100% with this regimen.[105] Despite this lack of clear benefit, expert opinion recommends continuation of high-dose steroids for several days followed by a maintenance dose of the equivalent of prednisone 60 mg/d that can be tapered over the ensuing weeks if the patient survives.[103,105]

The side effects of high-dose steroids cannot be understated. In addition to the long-term side effects described earlier, short-term risks in the ICU include hyperglycemia, immunosuppression, neuromuscular complications, and delirium. Thus, in some settings when steroids are contraindicated or a steroid-sparing agent is required, practitioners might employ a trial of nonsteroid-based therapy. Use of other agents such as azathioprine, cyclosporine,[118] Cytoxan™, and vincristine have been reported in AIP though these agents are not recommended for routine use.[112] OLT has been successful in several patients with respiratory failure attributed to AIP. However because these patients are frequently too unstable for transfer to a transplant center, the utility of OLT in AIP is at best limited.

LYMPHOID INTERSTITIAL PNEUMONIA

The final entity discussed within this group of idiopathic interstitial pneumonias is lymphoid interstitial pneumonia.

DEFINITION AND HISTORICAL PERSPECTIVES

In 1969, Liebow and Carrington developed the term "lymphoid interstitial pneumonia" (LIP) to describe a benign polyclonal infiltration of the alveolar space and interstitium with mature B or T cells. LIP exists within a spectrum of lymphoproliferative disorders affecting the lung and as such its classification as an IIP has been debated. Furthermore, the malignant potential of LIP is not well defined[119,120] but all sources agree that identification of monoclonal features effectively rules out LIP and points to a malignant etiology.[121,122] However, because the clinical and radiographic features overlap with the other IIPs in terms of differential diagnosis[123] and treatment approach, the most recent ATS and ERS statement on IIPs retained LIP within this classification.[16] LIP is also sometimes seen in children; however, because this chapter addresses the adult IIPs, pediatric LIP will not be discussed.

CLINICAL PRESENTATION

Given its rarity, the demographics of LIP are difficult to define but the available data indicate that this diagnosis is more commonly seen in women and that the mean age of onset is during the fifth decade of life.[16,124] LIP typically presents as slowly progressive cough and dyspnea over several years.[124] Systemic symptoms are rare though fever, weight loss, chest pain, and joint aches have been reported.[16,124] Chest auscultation may be normal or may reveal crackles as the disease progresses.[25,42] Extrapulmonary findings may include lymphadenopathy or joint findings consistent with an underlying diagnosis of Sjögren syndrome or rheumatoid arthritis. Findings consistent with severe lung disease such as clubbing, are rarely detected.[16] Laboratory examination may reveal mild anemia. Quantification of serum immunoglobulins reveals either a polyclonal gammaglobulinemia or a monoclonal increase in either IgG or IgM up to 75% of patients.[122,125] Immune complexes are sometimes seen but only infrequently.[126]

UNDERLYING DISEASE ASSOCIATIONS

Most cases of LIP are associated with an underlying cause such as Sjögren syndrome[127] or immunodeficiency such as severe combined immunodeficiency and HIV.[42,43] LIP has also been reported in association with rheumatoid arthritis,[128] Hashimoto disease,[129] pernicious anemia,[130] chronic active hepatitis,[131] systemic lupus erythematosus,[132] autoimmune hemolytic anemia,[125] primary biliary cirrhosis,[122] and hypogammaglobulinemia.[130,133] LIP is also seen in association with certain viral infections including Epstein–Barr[134,135] and human T cell lymphotropic virus type I (HTLV-I).[136,137] Truly idiopathic LIP accounts for less than 20% of cases.[124] Thus, as with NISP, a diagnosis of LIP should prompt a dedicated search for an underlying cause.

PULMONARY FUNCTION TESTING

When present, PFT abnormalities include a restrictive defect characterized by reduced FVC and TLC, an impaired D_{LCO}, and, potentially, hypoxemia.[138]

CHEST IMAGING

The imaging findings of LIP are variable and depend upon the underlying disease process. The CXR reveals nonspecific findings such as bilateral reticular markings and hazy, ground-glass opacities. As with the other IIPs, LIP is much better characterized by HRCT. Diffuse, patchy, or lower lobe predominant ground-glass opacities with reticular markings and small cysts is the pattern most commonly seen on CT in patients with AIDS, and can be difficult to distinguish from viral or opportunistic infections such as pneumocystis or CMV pneumonia.[17,139] Thickened bronchovascular bundles, septal thickening, and centrilobular nodules are less commonly present. LIP in patients with Sjögren syndrome typically manifests as bilateral, thin-walled cysts of varying sizes (but usually larger than the cysts seen in AIDS-associated LIP) scattered throughout the lungs with intervening normal lung parenchyma (Fig. 57-7).[16] Often times a vessel appears to be associated with (or adjacent to) the wall of a cyst, thus the term "perivascular cyst." Ground-glass opacities may exist as well.[16,123,140] The main differential diagnosis for this appearance would include other causes of cystic lung disease, such as lymphangioleiomyomatosis (in a female patient), Langerhans cell histiocytosis (in a cigarette smoker), and pneumocystis pneumonia (in immunocompromised patient) though the latter two entities usually manifest with upper lobe predominant cysts.

PATHOLOGIC FINDINGS

LIP pathology demonstrates a dense interstitial lymphoid infiltrate containing lymphocytes, plasma cells, and histiocytes, in combination with Type II cell hyperplasia (Fig. 57-7). The alveolar septa are extensively infiltrated. Lymphoid follicles with germinal centers are often seen.[16,122] Honeycombing and nonnecrotizing granulomas are sometimes detected[122] along with intra-alveolar organization and macrophage but when these latter aspects are the dominant pathologic feature, the diagnosis of LIP should be reconsidered.[16]

NATURAL HISTORY, CLINICAL COURSE, AND TREATMENT

Little is known about the clinical course and prognosis of LIP. The results of several case series suggest that approximately 50% of patients improve, 10% remain stable, and 40% will die of disease within 2 years even when treated with immunosuppression.[122,124,141] Those patients surviving are subject to a small but significant chance of progression to pulmonary lymphoma[122] as well as increased risk of serious and potentially fatal infections related either to the underlying cause of LIP (inherited or acquired immunodeficiency) or to the immunosuppressive therapies used to treat this disease.

Idiopathic LIP

Treatment for LIP in part depends upon the patient's symptoms and the underlying cause. Asymptomatic patients with mild, idiopathic disease are typically subject to careful longitudinal follow-up with serial PFTs and chest imaging because a small percentage of these patients will spontaneously improve.[16] Patients who deteriorate over time, or those who are highly symptomatic or significantly impaired upon initial diagnosis, are offered treatment with immunosuppression. While there exist no data regarding the safety or efficacy of glucocorticoids in patients with idiopathic LIP,[16] extrapolation of case series of patients with CTD-associated LIP (in which approximately 50% of patients show some evidence of response) suggests potential benefit.[141] Patients are typically started on the equivalent of 1 mg/kg (ideal body weight) oral prednisone for 8 to 12 weeks after

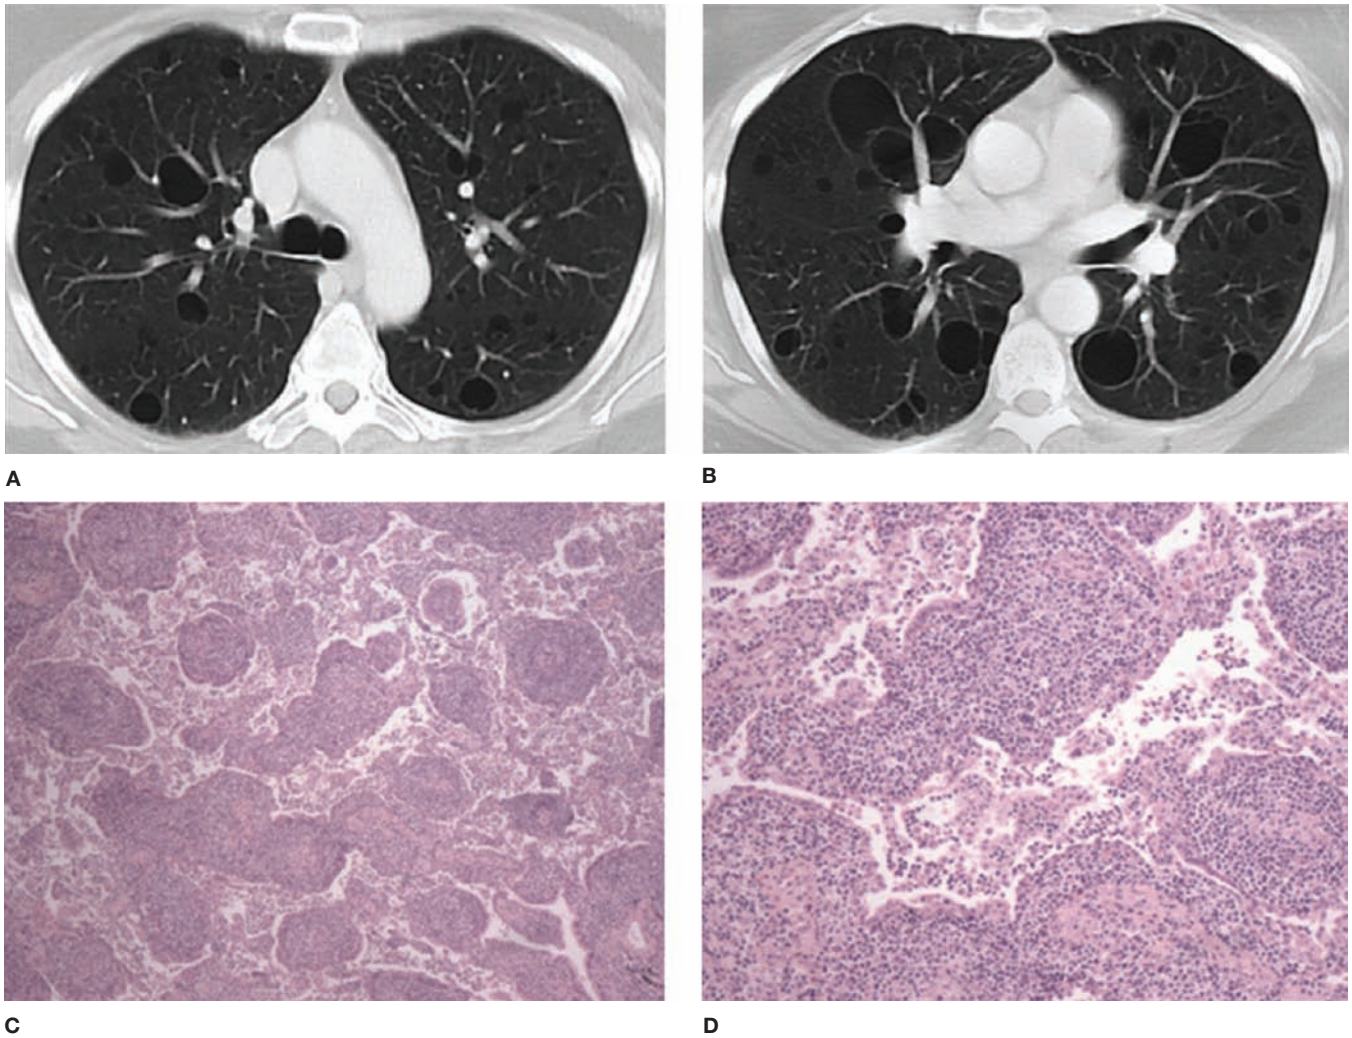


Figure 57-7 A 51-year-old female with Sjögren syndrome and lymphocytic interstitial pneumonia (LIP). Axial CT images through the upper (**A**) and mid (**B**) thorax show multiple thin-walled cysts of varying sizes bilaterally involving the upper and lower lobes. Note the presence of normal lung parenchyma between the cysts. Low (**C**) and high (**D**) power views of LIP lung tissue reveal a dense interstitial infiltrate containing lymphocytes, plasma cells, and histiocytes, combined with Type II cell hyperplasia and increased alveolar macrophages. *(Pathology images used with permission of Robert J. Homer, MD, PhD, Yale School of Medicine.)*

which chest imaging and PFTs are repeated. Those patients who demonstrate an objective response may continue their prednisone at a tapered dose for several months longer; those patients who do not respond generally have therapy discontinued or are offered an alternate disease modifying agent such as cyclosporine or azathioprine. Again, it should be noted that the evidence for this approach is scarce and the risk of side effects, and possible lack of efficacy, should be weighed against the potential benefit inherent in this class of drugs. In addition, patients on long-term steroid therapy should be offered prophylaxis against pneumocystis pneumonia and should be monitored for bone health.

Nonidiopathic LIP

Management of LIP in the setting of CTD is similar to that of idiopathic LIP and in fact the use of immunosuppression in this population is based on stronger evidence.[124,141] Treatment of LIP in the setting of HIV usually involves institution of HAART as in many patients this intervention will reduce symptoms and improve both radiographic disease burden and lung physiology.[142–144] For those patients whose disease persists despite use of HAART, glucocorticoids are commonly used though evidence for this regimen precedes the HAART era.[138,145] As with idiopathic and CTD-related LIP, pneumocystis prophylaxis should be strongly considered for patients with HIV-related LIP that are treated with immunosuppression.

CONCLUSION

The non-IPF IIPs are characterized by diverse presentations, underlying associations, natural history, and response to therapy. Given the complexity of diagnosis and management, these diseases are best managed by highly experienced practitioners using a multidisciplinary approach.

CHAPTER 58

Hypersensitivity Pneumonitis

Alex H. Gifford
Richard I. Enelow

EPIDEMIOLOGY AND ETIOLOGIES

Hypersensitivity pneumonitis (HP), or extrinsic allergic alveolitis, is a spectrum of interstitial, alveolar, and bronchiolar lung diseases resulting from immunologically induced inflammation in response to inhalation of a wide variety of different materials that are usually organic or low–molecular-weight chemical antigens (or haptens), which may lead to irreversible lung damage. Despite the terms *hypersensitivity* and *allergic,* HP is not an atopic disease and is not associated with increased IgE or eosinophils. The prevalence of HP is quite variable in different populations, presumably because of differing intensity, frequency, and duration of inhalation exposure, and also probably due to host factors that have yet to be identified. Once thought to be a relatively rare disease, it is becoming more frequently recognized as awareness is of the limitations of classical diagnostic criteria has increased. Among pigeon breeders, 8% to 30% of members of pigeon-breeding clubs who participated in surveys exhibited evidence of HP, so-called pigeon breeder's disease (Fig. 58-1). Among farmers, 0.5% to 5% have symptoms compatible with HP, so-called farmer's lung disease. The prevalence of symptoms is lower in farms that use hay-drying methods that decrease exposure to the responsible antigens and increased after a wet summer season.

The population at risk and the season of exposure vary with the type of HP. For example, most cases of farmer's lung disease occur in cold, damp climates in late winter and early spring, when farmers (usually male) use stored hay to feed their livestock. Pigeon breeder's disease occurs chiefly in men in Europe and the United States but predominantly in women in Mexico, owing to differing patterns of exposure, but without a seasonal preference in either population. Bird fancier's disease in Europe and the United States occurs in subjects who keep domestic birds and does not exhibit a predilection to either sex. Japanese summer-type HP occurs mostly in women without an occupation outside the home in June to September in warm, moist parts of the country. The disease has been reported in children as well, though rarely.

In contrast to other pulmonary diseases, there is a curious predominance (80%–95%) of nonsmokers in all examples of HP, which is substantially higher than the proportion of nonsmokers in similarly exposed individuals without HP.[1] The mechanisms of this phenomenon are unknown, but could include anti-inflammatory effects of nicotine. This clinical finding suggests that the presence of

The patient had kept pigeons for 5 years and presented with fever, dyspnea, and myalgias approximately 8 hours after cleaning the pigeon coop. He had serum antibody to pigeon dropping extract. Note bilateral lower lobe 2- to 3-mm nodules. **B.** Chest radiograph of the same patient 2 weeks later without specific treatment. Note clearing of the lower-lobe nodules and the staples in the left chest from the open lung biopsy.

active smoking may be evidence against the diagnosis of HP, although this has not been consistently observed.[2]

An important feature of HP is the great variability of susceptibility among exposed populations and the apparent resistance to illness of most exposed persons. Possible reasons include differences in exposure, or differences in the host response to exposure, which may be inborn and/or acquired. There are no differences in the prevalence of atopy or HLA-A, B, or C haplotypes in exposed subjects with and without HP,[1] although there may be an alteration in the prevalence of several HLA-DR and -DQ alleles.[3]

Several case-control studies have identified single nucleotide polymorphisms (SNPs) that are disproportionately represented in patients with HP and have accordingly garnered interest as potential pathogenetic determinants. Compared with healthy controls of the same ethnic heritage, a Mexican cohort with HP was found to have SNPs in MHC class II genes encoding a family of transporters associated with antigen processing (TAP).[4] Mexican HP patients also more frequently possess the KQ genotype of the PSMB8 gene, which codes for a constituent of the low–molecular-weight proteosome required for peptide processing and eventual presentation in the context of class I MHC.[5] SNPs in the interleukin-6 (IL-6) gene have been correlated with higher levels of epithelial neutrophil-activating protein (CXCL-5) in the BAL fluid of HP patients,[6] but the clinical implications of cytokine gene variation in this disease are undefined. An increased prevalence of a particular polymorphism in the tumor necrosis factor-α (TNF-α) promoter has been reported in patients with pigeon breeder's disease compared with exposed subjects without pigeon breeder's disease,[7] as well as protective variants in the tissue inhibitor of metalloproteinase-3 (TIMP3) promoter in exposed subjects without pigeon breeder's disease,[8] the possible significance of which is discussed below (see Immunopathogenesis).

A large number of agents are associated with HP, shown in Table 58-1. Some types of HP have apparently disappeared from their originally described clinical settings (e.g., bagassosis in Louisiana) but presumably exist in areas with similar agricultural or industrial settings. In addition, other forms of HP are being newly recognized (e.g., potato riddler's lung and machine operator's lung). Both the disappearance of previously described examples of HP and the appearance of new examples are due to changing agricultural or industrial practices that result in changes of exposure of subjects to antigenic material that can cause HP. At the present time farmer's lung disease, bird fancier's disease, ventilator lung, and Japanese summer-type HP are the most commonly recognized forms of HP.

Recognition of new examples of HP usually requires a cluster of new cases with a unifying exposure history, underscoring the importance of obtaining at least a basic occupational and avocational history whenever possible. Such diligence revealed that a group of musicians developed HP from instruments contaminated with *Mycobacteria* in the case of trombonists[9] and by molds in the case of a saxophonist.[10] Use of a new metalworking fluid (MWF) led to recognition of machine operator's lung in an auto parts–manufacturing facility due to clustering of cases and a common unusual exposure (*Pseudomonas* in cooling fluid). Highly sensitive genomic testing applied to MWF used in the automotive and nonautomotive industries suggests that HP risk may be associated with microbial colonization patterns,[11] particularly the presence of *Mycobacterium immunogenum*.

CLINICAL FEATURES

The manifestations of the disease may be acute, subacute, or chronic. The stereotypical acute clinical presentation includes transient fever, hypoxemia, myalgias, arthralgias, dyspnea, and cough that occur 2 to 9 hours after exposure and resolve in 12 to 72 hours without specific treatment (sometimes longer after a particularly intense exposure). Patients exhibit tachypnea, bibasilar rales, and occasionally cyanosis. There is usually peripheral blood leukocytosis with neutrophilia and lymphopenia (without eosinophilia), and BAL neutrophilia. Subacute or intermittent disease may result from repeated exposures, and manifest as productive cough, dyspnea, fatigue, and weight loss. There may be BAL lymphocytosis, frequently (though not always) with a predominance of $CD8^+$ T lymphocytes.

The chronic form is clinically more insidious, and patients may lack a history of acute episodes, but present with a gradual onset of cough, dyspnea, fatigue, and weight loss. Symptoms are usually present for months to years. There is typically no fever, but tachypnea and bibasilar dry rales are usually present. This form of the disease may be difficult to distinguish from idiopathic pulmonary fibrosis (IPF). Symptoms and signs of cor pulmonale are not uncommon at presentation.

The reasons for the different clinical presentations (i.e., acute, subacute, and chronic) of HP are not clear, but could include differences of intensity and duration of exposure (low-intensity long-duration exposure tending to cause chronic HP; high-intensity short-duration exposure tending to cause acute HP). This is most clearly demonstrated in HP due to bird exposure. Long-term exposure to low amounts of bird antigens is associated with chronic HP. Pigeon breeder's disease has different presentations in different geographic areas, manifesting as an acute HP in some and chronic HP in others. Intermittent exposure of pigeon breeders to large amounts of pigeon antigens in the United States and Europe is associated with acute disease and a good prognosis, whereas chronic exposure to a few household pigeons in Mexico is associated with chronic disease and a much poorer prognosis. In the United States and Europe, pigeon breeders keep their animals in an enclosure separate from their living areas, which they visit periodically so that exposure is intermittent. In Mexico, birds are often kept in living quarters so that exposure is constant. It is of interest that bird antigens can persist in a room for substantial lengths of time (>18 months) after removal of the birds,[12] so that Mexicans with pigeon breeder's disease might be exposed to pigeon antigens for prolonged periods even after removal of the pigeons. Therefore, pigeon breeder's disease in Mexico resembles bird fancier's disease in the United States and Europe in type of exposure, clinical presentation, and prognosis. It differs greatly from the acute HP that characterizes the pigeon breeder's disease in the United States and Europe. Since the relevant antigens are similar in these two examples of bird-associated HP, it is likely that the type of exposure, and not the antigen characteristics, determines clinical presentation and prognosis. The recognition of a new example of HP is usually associated with the acute form, which is likely related to the relative ease in making the association of acute disease and an acute exposure.

The previous discussion indicates that HP, and particularly chronic HP, may be more prevalent than is readily apparent and may often be confused with other diseases, such as chronic bronchitis or IPF. The latter may be particularly important because detailed histories are not always obtained from patients with IPF, the serum antibody levels to the agents responsible for HP tend to wane after cessation of exposure, and chest high-resolution computed tomography (CT) scans of chronic HP can resemble those of IPF.

RADIOGRAPHIC FEATURES

The chest radiographs of patients with acute and chronic HP differ significantly. In acute HP, chest radiographs demonstrate diffuse poorly defined nodular radiodensities, often with areas of ground-glass radiodensities or occasionally even consolidation. These radiodensities tend to occur in the lower lobes and spare the apices. Linear radiodensities (presumably representing

TABLE 58-1 Etiologies of Hypersensitivity Pneumonitis

Disease	Antigen Source	Probable Antigen
Farmer's lung disease	Moldy hay	*Thermophilic actinomycetes, M. faeni (S. rectivirgula), Thymus Vulgaris, Aspergillus* spp.
Bagassosis	Moldy pressed sugarcane (bagasse)	*Thermophilic actinomycetes, Thermoactinomyces Sacchari, T. vulgaris*
Mushroom worker's disease	Moldy compost and mushrooms	Thermophilic actinomycetes, *M. faeni, T. vulgaris, Aspergillus* spp., Mushroom spores
Suberosis	Moldy cork	*Penicillium* spp.
Malt worker's lung	Contaminated barley	*Aspergillus clavatus*
Maple bark disease	Contaminated maple logs	*Cryptostroma corticale*
Sequoisis	Contaminated	*Graphium* spp., redwood dust, *Pullularia* spp.
Soybean lung	Soybeans in animal feed	Soybean hull antigens
Wood pulp worker's disease	Contaminated wood pulp	*Alternaria* spp.
Wood dust HP	Contaminated wood dust	*Bacillus subtilis, Alternaria*
Compost lung	Compost	*Aspergillus* spp., *T. vulgaris*
Cheeseworker's disease	Cheese or cheese casings	*Penicillium* spp.
Wood trimmer's disease	Contaminated wood trimmings, at times in sawmills	*Rhizopus* spp., *Mucor* spp.
Thatched roof disease	Dried grasses and leaves	*Saccharomonospora viridis*
Greenhouse lung	Greenhouse soil	*Aspergillus* spp., *Penicillium* spp., *Cryptostroma corticale*
Coffee worker's lung	Green coffee dust	Unknown
Potato riddler's lung	Moldy hay around potatoes	*Thermophilic actinomycetes, M. faeni, T. vulgaris, Aspergillus* spp.
Tobacco worker's disease	Mold on tobacco	*Aspergillus* spp.
Wine grower's lung	Mold on grapes	*Botrytis cinerea*
Woodman's disease	Mold on bark and fuel chips	*Penicillium* spp.
Soy sauce brewer's lung	Fermentation starter for soy sauce	*Aspergillus oryzae*
Domestic allergic alveolitis	Decayed wood	*Serpula lacrymans, Leucogyrophana pinastr, Paecilomyces variotii, Aspergillus fumigatus*
Riding school lung	Hay in horse stall	*Thermophilic actinomycetes, M. faeni (S. rectivirgula), T. vulgaris*
Stipatosis	Esparto grass (Stipa tenacissima), used to make plaster	Esparto grass antigens
Pigeon breeder's disease	Avian droppings, feathers, serum	Altered serum/feather proteins
Turkey handler's disease	Turkey products	Turkey proteins
Chicken breeder's lung	Chicken feathers	Chicken feather proteins
Bird fancier's lung	Domestic and wild bird products	Bird proteins
Duvet lung	Duvet and pillow	Goose proteins
Laboratory worker's HP	Rat fur	Rat urine protein
Pituitary snuff taker's disease	Pituitary powder	Vasopressin
Shell lung	Oyster or mollusk shell	Shell proteins
Miller's lung	Grain weevils in wheat flour	*Sitophilus granarius* proteins
Sericulturist's lung	Silkworm larvae	Silkworm larvae proteins
TDI HP	Toluene di-isocyanate	Altered proteins (albumin + others)
MDI HP	Diphenylmethane diisocyanate	
HDI HP	Hexamethylene diisocyanate	
TMA HP	Trimetallic anhydride	Altered proteins
Ventilator lung	Contaminated humidifiers, dehumidifiers, air conditioners, heating systems	*Thermophilic actinomycetes, T. candidus, T. vulgaris, Penicillium* spp., *Cephalosporium* spp., *Amoebae, Klebsiella* spp., *Candida* spp.
Basement lung	Contaminated basement (sewage or mold)	*Cephalosporium spp., Penicillium* spp.
Sauna taker's disease	Sauna water	*Aureobasidium* spp.
Detergent worker's disease	Detergent enzymes	*Bacillus subtilis*
Japanese summer house HP	House dust, bird droppings	*Trichosporon cutaneum*
Hot-tub lung	Mold on ceiling	*Cladosporium* spp.
Tractor lung	Contaminated tractor, cab air conditioner	*Rhizopus* spp.
Machine operator's lung	Contaminated metal working fluid	*Pseudomonas* spp.
Fertilizer lung	Contaminated fertilizer	*Streptomyces albus*
Sax lung	Saxophone mouthpiece	*Candida albicans*

Figure 58-2 Chest radiograph of a patient with bird fancier's disease who presented with progressive dyspnea and weight loss. She had kept two to three parakeets in her home for 15 years and did not notice episodic fever or acute dyspnea. She had positive serum precipitins to parakeet serum, severe restrictive disease, and resting hypoxemia. Note the diffuse radiodensities, loss of volume of the upper lobes, and pulmonary hypertension.

areas of fibrosis from previous episodes of acute HP) may also be present. The nodular and ground-glass densities tend to disappear after cessation of exposure, so the chest radiograph may be normal after resolution of an acute episode of HP (Fig. 58-2). High-resolution CT scans often demonstrate ground-glass densities better than chest radiographs and at times reveal diffusely increased pulmonary radiodensities. They may also become normal after resolution of an acute episode. Pleural effusions or thickening, calcification, cavitation, atelectasis, localized radiodensities (coin lesions or masses), and intrathoracic lymphadenopathy are rare.

In chronic HP, chest radiographs are notable for diffuse linear and nodular radiodensities, with sparing of the bases and upper-lobe predominance, and volume loss (Fig. 58-3). Pleural effusions and thickening are very unusual, although subcutaneous emphysema (presumably as a consequence of pleural rupture due to bronchiolitis and lobular overinflation) has been reported.

High-resolution CT scans of patients with chronic HP demonstrate several patterns. Most commonly there are multiple centrilobular nodules 2 to 4 mm in diameter throughout the lung fields, with some areas of ground-glass radiodensities, especially in the lower lobes (Fig. 58-4). Unlike sarcoidosis, the nodules are seldom attached to the pleura or bronchovascular bundles, and the border between the nodules and the surrounding lung is well demarcated. There are also well-delineated areas of increased radiolucency, which are presumably overinflated pulmonary lobules subserved by partly occluded bronchioles. The ground-glass densities and micronodules tend to resolve after cessation of exposure. Although these findings are suggestive of HP, they are found in only a subset (50%–75%) of patients with HP, and high-resolution CT scans of the lungs of patients with HP can resemble those of patients with IPF. In cases of chronic avian-related HP, honeycombing and airspace consolidation on high-resolution CT scans are independently associated with increased mortality risk, even after controlling for spirometric and demographic

Figure 58-3 High-resolution CT scan of a nonsmoking patient with exposure to both birds and shells who presented with progressive dyspnea and weight loss and had hypoxemia and a restrictive ventilatory defect. Note the diffuse nodular radiodensities in the lower lobes, with areas of ground-glass densities posteriorly.

variables.[13] Emphysematous abnormalities are also commonly detected by high-resolution CT scans in nonsmoking patients with farmer's lung disease.

■ LABORATORY FINDINGS

Patients with acute HP often have a peripheral blood leukocytosis with neutrophilia and without eosinophilia. Prominent cellular abnormalities may also be seen in their BAL fluid, which may be useful in supporting the diagnosis of HP. At time points greater than 5 days after the last exposure, a two- to fourfold increase in BAL fluid leukocytes and lymphocytosis (typically 30%–70% of total cells) are frequently noted. In most instances of HP, the BAL fluid lymphocytes are virtually all $CD3^+$ (T lymphocytes), with a relative increase of $CD8^+$ cells, so that the CD4:CD8 ratio is usually less than 1 (normally 2–2.5, as in peripheral blood).[14] This profile varies considerably with the stage of disease. Indeed, only 33 of 98 HP patients (34%) in one case series displayed a lymphocytic $CD8^+$ alveolitis.[15] Findings of a higher $CD4^+$:$CD8^+$ ratio, fewer $\gamma\delta$ T cells,

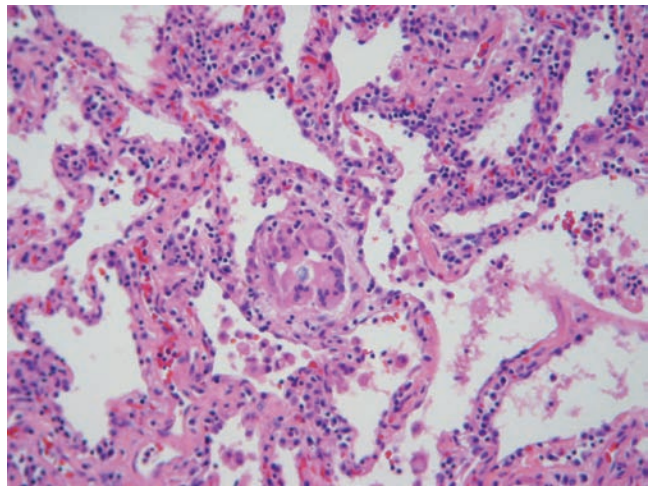

Figure 58-4 Low power view (20×) of H&E-stained section of surgical lung biopsy from a patient with bird fancier's disease. There are nonspecific interstitial mononuclear inflammation and loosely formed granulomatous lesions.

and more terminally differentiated memory $CD4^+$ and $CD8^+$T cell subsets in BAL fluid from patients with chronic HP compared to that from patients with subacute HP suggest that fibrosis may be related to a shift toward Th2 immunity in the lung.[16] Furthermore, BAL lymphocytosis may persist for years following clinical improvement and apparent removal from antigen exposure. Conversely, exposed asymptomatic individuals may exhibit BAL lymphocytosis, further limiting its utility in diagnostic evaluation. After recent (<48 h) exposure, as well as in advanced disease, the lavage is frequently characterized by BAL fluid neutrophilia.[17] The concentrations of IgG, IgM, IgG, and albumin are increased in BAL fluid, presumably a nonspecific manifestation of pulmonary inflammation.

Many patients with HP have easily demonstrable antibodies (typically IgG, IgM, and IgA) to the offending material in the serum, detectable by a variety of methods. Since antigen preparations are not standardized, it is difficult to be confident of the meaning of a negative result; therefore negative "HP panel" does not exclude the diagnosis of HP. Furthermore, since serum antibody is also present in many exposed, but not ill, subjects in virtually the same amounts as in patients with HP, the presence of antibody should be considered supporting data in the proper clinical context.

In asymptomatic pigeon breeders, the prevalence of antibody to pigeon antigens is 30% to 60%. In farmers, the prevalence of anti-*Micropolyspora faeni* serum antibody is 2% to 27%. The occurrence of serum antibody is not consistently related to apparent exposure (i.e., hours of exposure or intensity of exposure) in most instances of HP. This may be related to a threshold effect, so that most exposures are above the minimum required to induce antibody and increases above that threshold are not associated with increases of the prevalence of antibody. In addition, serum antibody tends to wane after cessation of exposure, so patients with chronic HP who have not been exposed for some time may not have demonstrable antibody. In farmer's lung disease, approximately 50% of patients with initially positive serum antibody to *M. faeni (Saccharopolyspora rectivirgula)* lose demonstrable antibody 6 years after cessation of exposure. Farmers who continue to farm also lose detectable antibody (35%–50% in 5 years),[18] and some asymptomatic farmers who were initially negative later develop antibody without farmer's lung disease. In pigeon breeder's disease and bird fancier's disease, approximately 50% of patients with initially positive serum antibody to avian antigens lose demonstrable antibody 2 to 3 years after cessation of exposure. Therefore, it is possible that patients with HP will have no detectable serum antibody owing to either use of an inappropriate antigen in the assay or the waning of antibody in time since the last exposure.

Nonspecific markers of inflammation, such as increased sedimentation rate and C-reactive protein, are often elevated during an acute episode of HP, though are quite nonspecific. In contrast to sarcoidosis, the serum angiotensin-converting enzyme levels are usually not elevated. Skin tests (either immediate or delayed type) to detect sensitization to the suspected antigens are not useful, since extracts of agents that cause HP produce nonspecific reactions that do not indicate sensitization and do not discriminate between sensitized and nonsensitized subjects.

Pulmonary function tests may be restrictive, obstructive, or mixed. There is an increased lung elastic recoil, and usually decreased diffusing capacity. Arterial hypoxemia with hypocapnia reflecting an increased alveolar-arterial oxygen gradient either at rest or after exercise is common. However, 39 of 177 patients (22%) with $D_{L_{CO}}$ data available to the HP Study Group displayed normal diffusion capacity, defined as a $D_{L_{CO}} \geq 80\%$ predicted at the time of diagnosis.[19] Many patients with HP (20%–40%) exhibit increased nonspecific airway reactivity, and 5% to 10% also develop clinical asthma.[20] The increased airway reactivity and asthma tend to diminish after cessation of exposure.

DIAGNOSIS

The symptoms, signs, and laboratory findings of acute HP can resemble those of many other lung diseases, including pulmonary edema, organic dust toxic syndrome (ODTS), inhalation fever, chronic bronchitis, and some pneumoconioses. Acute HP is also often confused with infectious pneumonia (viral, mycoplasma, or chlamydia in subjects exposed to birds). Subacute HP is characterized by a more gradual onset of cough, fatigue, dyspnea, and weight loss, and such symptoms may also develop with intermittent acute attacks. There is considerable overlap in the presentations of acute and subacute HP, in contrast to chronic progressive HP (discussed below).

Chronic bronchitis in nonsmoking farmers and bird breeders is more common than HP, and may share overlapping immunopathogenic mechanisms with HP. The finding of serum precipitins is more frequent in farm workers with chronic bronchitis than those who are asymptomatic. ODTS has been seen in some of the same populations exposed to materials that cause HP, although its cause is likely mycotoxins from bioaerosols contaminated with toxin-producing fungi. ODTS can occur in a larger proportion of the exposed population than HP and is characterized by transient fever, dyspnea, nonproductive cough, peripheral blood leukocytosis, and BAL fluid neutrophilia. The manifestations commonly include diffuse opacities on chest radiograph, restrictive ventilatory defects, reduced $D_{L_{CO}}$, and bronchiolitis obliterans without granulomas on lung biopsy. Diffuse alveolar damage may occur in severe cases. In contrast to HP, prior sensitization is not required (as indicated by the absence of serum antibodies). Patients presenting with ODTS tend to have more intense exposure of shorter duration than those who present with farmer's lung disease. Another disease caused by exposure to the some of the same agents associated with HP is inhalation fever. This is manifested as fevers, chills, malaise, headaches, and myalgias without prominent pulmonary findings, although mild dyspnea and cough may occur. The onset usually occurs 4 to 12 hours after exposure. Usually there are normal lung volumes and diffusing capacity. The clinical syndrome remits after 12 to 24 hours without specific therapy. Symptoms and signs are exaggerated following an exposure that occurs after a period of nonexposure (such as vacations or weekends), but then become blunted despite continued exposure ("Monday illness"). All signs and symptoms of inhalation fever remit after cessation of exposure, and there are no permanent physiologic or radiographic changes.

In contrast to acute and subacute HP, the classic or typical clinical findings are usually not present in chronic HP. The chronic form of HP often resembles IPF, and these entities may be extremely difficult to distinguish. The differential diagnoses also includes other causes of pulmonary fibrosis (e.g., drug reactions, rheumatologic disease, asbestosis, radiation). Further complicating matter is the frequent lack of clear history of acute episodes. In addition, removal from the presumptive offending agent may result in little or no clinical improvement at this stage.

A thorough and complete occupational and avocational history is essential to the diagnosis of all forms of HP. The history should seek to establish a link between a particular exposure (at work, at home, or elsewhere) and previous episodes of "pneumonia." Knowledge of other exposed persons with similar symptoms should be sought. Evidence of repetitive appropriate symptoms and laboratory and radiologic abnormalities associated with exposure to a particular environment is also highly suggestive of HP. In questionable instances, a "natural exposure" (i.e., documentation of appropriate symptoms and laboratory abnormalities after exposure to a suspect environment) can be used to diagnose HP. A "natural exposure" challenge should not be considered positive unless there is objective

evidence of a change in temperature, total peripheral white blood cell count, chest radiograph (or high-resolution CT scan), or a decrease in diffusing capacity (or arterial P_{O_2}). If the history suggests a relationship between exposure and pulmonary symptoms, evidence of sensitization and the nature of the pulmonary inflammatory response should be determined. Sensitization is indicated by the presence of serum antibody to an agent known to cause HP. A large proportion of lymphocytes in BAL fluid (usually over 40%) is highly suggestive of, though not specific for, HP.

A variety of tools exist that have utility in the diagnosis of HP, all of which have advantages and disadvantages. One of the difficulties in assessing the value of diagnostic methods in HP is the vagueness of the "gold standard."[21] Though most would agree that the presence of poorly formed, airway-centered nonnecrotizing granuloma on lung biopsy in a patient with exposure to a known offending agent is supportive enough to be "diagnostic," these features are commonly absent, and a number of histologic variants have been described (see below).[22,23] Since the utility of lung biopsy, absent classic features, is largely supportive, several prediction rules have been devised to determine the probability of a diagnosis of HP based upon clinical features. One such model, developed by the Hypersentitivity Pneumonitis Study Group,[24] examined a cohort of 400 patients with suspected HP and found six significant predictors retrospectively (116 were ultimately diagnosed with HP). These were then validated prospectively in 261 patients (83 of whom were eventually given the diagnosis). It should be noted that the ultimate determination, or gold standard, was the consensus of experts, in many cases without tissue. Although not ideal, at the current level of understanding of the nature of HP, this may be the best method available.[21] The criteria used in this study were (1) exposure to a known offending antigen, (2) positive precipitating antibodies to the offending agent, (3) recurrent episodes of symptoms, (4) inspiratory crackles on physical examination, (5) symptoms occurring 4 to 8 hours after exposure, and (6) weight loss. The probability of having HP was determined based upon the presence or absence of these predictors. The probability of HP ranged from 0% in those patients with none of the predictors to 98% in patients with all six of these features. Exposure to a known offending antigen was the strongest clinical predictor with an odds ratio of 38.8. In cases lacking a compatible exposure history, the diagnosis of HP was made only after further investigation, including supportive findings on lung biopsy (discussed below). It should be emphasized that these clinical prediction rules are of little value in chronic HP, which is usually a more difficult diagnostic problem (often even when histopathology is available). Of course, in the evaluation of individual patients, the threshold for further investigation clearly depends upon the clinical setting and the consequences of the diagnosis.

HISTOPATHOLOGY

A lung biopsy specimen is generally required when there is significant doubt about the diagnosis. Transbronchial lung biopsies often do not provide sufficient material to fully establish the presence and interrelationships of granulomas, bronchiolitis, and interstitial inflammation, so either open or thoroscopically obtained lung biopsies may be necessary. These often reveal chronic interstitial and alveolar inflammation with infiltration of plasma cells, mast cells, macrophages, and lymphocytes, usually with poorly formed nonnecrotizing granulomas (Figs. 58-4 and 58-5). The inflammation usually extends from the terminal bronchioles into the parenchyma. Foamy macrophages are usually evident in the alveoli. There is often bronchiolitis as well as bronchiolitis obliterans. Organizing pneumonia is also present in up to 50% of patients with HP (Fig. 58-6). Conversely, patients with recognized bronchiolitis obliterans with organizing pneumonia (BOOP) may have underlying HP, whether or not other histologic manifestations are evident.

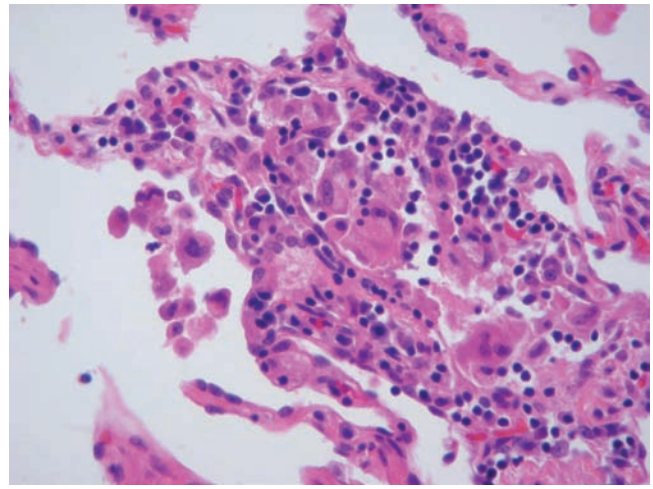

Figure 58-5 Higher power view (40×) of the section shown in Figure 58-4.

Varying degrees of interstitial fibrosis are also often present. The granulomatous interstitial inflammatory responses of HP and sarcoidosis can be difficult to differentiate, though in HP these are usually smaller, poorly differentiated, loosely arranged and contain more lymphocytes and fewer multinucleated giant cells. In contrast to sarcoidosis, the interstitial inflammatory cell infiltrate in HP occurs distal as well as proximal to the granulomas. The granulomas of HP also tend not to occur in groups and tend not to occur near bronchi or in subpleural locations. Instead, they are usually adjacent to bronchioles and are often single. In the absence of granulomas, the pattern may resemble that of nonspecific interstitial pneumonitis, though the bronchiolocentric nature of the lesions and the presence of giant cells or organizing pneumonia may be clues suggesting underlying HP.

The predominant pattern of inflammation and fibrosis in a patient's lung biopsy stands to inform his or her prognosis. In a study of 110 patients with pigeon breeder's lung, the survival rate was highest for those with biopsy specimens displaying a nonspecific interstitial pneumonia (NSIP) pattern and lowest for those with changes of UIP.[24] Interestingly, the survival prediction for patients with typical HP biopsy findings fell between the Kaplan–Meier curves for patients with NSIP and UIP in this investigation. Another

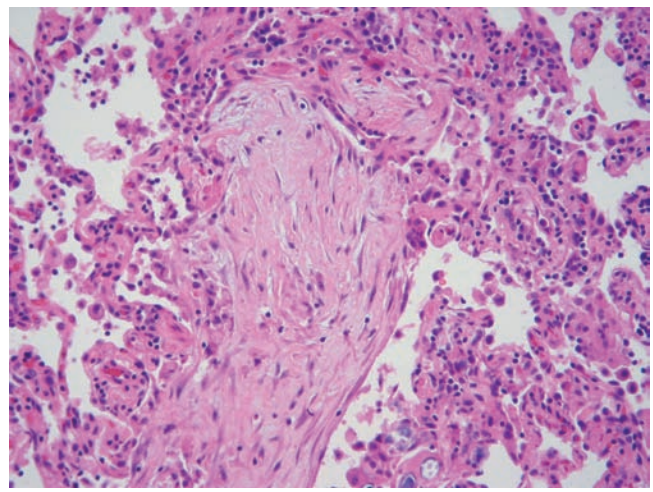

Figure 58-6 Organizing pneumonitis in a patient with bird fancier's disease.

study that considered more diverse causes of HP demonstrated that survival is considerably shorter for patients with UIP-like and fibrotic NSIP-like histology compared to those with isolated peribronchiolar fibrosis.[25] Therefore, lung biopsy results may play an important role in counseling patients about the anticipated natural history of their disease.

The specific histologic changes of HP, when present, are quite helpful in making the diagnosis. However, the granulomas and respiratory bronchiolitis may not be present years after cessation of exposure, so only interstitial inflammation and fibrosis remain in many subacute and most chronic cases.[26] Although these findings might be useful in supporting the clinical diagnosis of HP, they would be insufficient to confirm it.

IMMUNOPATHOGENESIS

Considerable evidence obtained over the past 25 years suggests a primary role for T cell–mediated events in the pathogenesis of HP. A contribution of humoral immunity, especially in acute HP, has not been excluded however. The presence of serum antibody in patients with HP and the timing of symptoms after exposure (2–9 hours) led to the hypothesis that HP represents an example of immune complex–mediated lung disease. Therefore, it is possible that immune complexes initiate the injury upon antigen exposure, which is then perpetuated and amplified by T cell activities. By the time the disease is clinically evident, lung tissue gene expression profiles indicate T cell–driven inflammation (in contrast to the profiles of IPF and NSIP).[27] The T cell responses evident in HP are notable for the predominance of $CD8^+$ cells and the expression of interferon-gamma (IFN-γ), the prototypic cytokine of type 1 inflammatory processes. Expression of IFN-γ–dependent chemokines, such as CXCL9 and CXCL10, is also observed in HP lungs, which undoubtedly serves to amplify the type 1 inflammation. Not unexpectedly, $CD8^+$ T cells in BAL of HP patients strongly express CXCR3, the receptor for both of these chemokine.[28]

Although the Th1 response has canonically defined HP, recent evidence suggests that dysfunctional regulatory T cells (Tregs) are involved with a loss of tolerance to inhaled antigens. Broadly speaking, these $CD4^+Foxp3^+$ lymphocytes suppress the activity of Th1 and Th2 effector cells, which is important for antigen self-recognition and the prevention of autoimmune diseases.[29] Compared to Tregs from BAL and blood of healthy controls, those obtained from HP patients cannot suppress T-lymphocyte activation in vitro, perhaps because of IL-17 production, given that significantly higher IL-17 levels are found in sera and BAL samples from the latter population.[30] The importance of Th17 polarized $CD4^+$ T cells in generating fibroinflammatory lung injury has been described in mice using *S. rectivirgula*.[31] This murine model has also been used to demonstrate that Tregs concurrently reduce IFN-γ production and pulmonary infiltration by $CD4^+$ and $CD8^+$ lymphocytes.[32] Whether Tregs and/or Th17 immunity explain the clinical heterogeneity of HP has yet to be determined.

In animal models of HP, macrophage-derived cytokines such as IL-1, IL-6, IL-12, and TNF-α (as well as a variety of chemokines) play a central role in models that entail intrapulmonary administration of various antigenic substances.[33] TNF-α, produced by activated macrophages as well as $CD8^+$ T cells, likely participates both in the amplification of the inflammation and the activation/degranulation of neutrophils recruited to the alveolar space.[34,35] Interestingly, polymorphisms in the TNF-α promoter have been reported in a group of patients with farmer's lung disease, which correlated with higher serum levels of TNF-α after challenge with hay dust, compared with a group of sensitized asymptomatic controls.[7] Two small genetic susceptibility studies in Mexican[8] and Dutch[36] patients with bird fancier's disease found protective polymorphisms in the tissue inhibitor of metalloproteinase-3 (TIMP-3) gene, which is involved in the inhibition of metalloproteinases associated with extracellular matrix turnover. TIMP-3 has also been identified recently as the primary inhibitor of TNF-α–converting enzyme (TACE/ADAM-17), and this enzyme is responsible for processing TNF-α to its soluble form, which is intensely proinflammatory.[37] The TIMP-3 polymorphism was not found in patients with IPF or NSIP.[8] It is therefore reasonable to speculate that the expression and/or proteolytic processing of TNF-α is important in the pathogenesis of HP, though clearly this leaves much to be explained concerning the varying clinical pictures of the disease.

PROGNOSIS AND TREATMENT

Prognosis varies considerably with the type of HP and even the geographic location. For example, farmer's lung disease has a good prognosis in Quebec, even in farmers who continue to farm. However, farmer's lung disease in Finland often results in significant physiologic impairment and even death. Pigeon breeder's disease has a good prognosis in the United States and Europe, whereas the same disease in Mexico has a 30% 5-year mortality.[38] The reasons for these differences are not clear but may include differences in the nature of the antigen and the exposure.

Identification of the offending antigen is critical to effective avoidance, which is the primary intervention in all forms of HP. This is not always practical when the exposure is occupational, such as in farmer's lung disease. In addition most farmers who continue to be exposed may fare no worse than those who leave their farms.[39] Nevertheless, removal from exposure to the offending antigen(s) is usually sufficient to resolve symptoms and physiologic abnormalities. Measures to reduce antigenic burden may include protective equipment and reducing microbial contamination of the home or work environment. Elimination of excess moisture, reduction in humidity, repair of water damaged materials, regular cleaning of humidifiers, ventilation, and air conditioning equipment all contribute to reduction in mold and other microbial colonization, which may predispose to sensitization. Removal of birds from the home of patients with bird fancier's disease is a critical aspect of treatment, but antigens may persist for extended periods despite thorough cleaning of the home environment.[12]

Systemic glucocorticosteroids are usually required to treat severely symptomatic patients, although there is no formal evidence that such treatment is associated with long-term abatement of symptoms or radiologic or pulmonary function test abnormalities.[30,40] The usual treatment is prednisone or prednisolone, 40 to 60 mg a day for 2 weeks, followed by a gradual decrease over 2 to 4 weeks. Patients with farmer's lung disease treated with prednisolone, compared with those not treated with prednisone, demonstrated slightly more rapid resolution of some radiologic (ground-glass opacities) and some physiologic abnormalities than untreated patients (slight improvement of diffusing capacity, no difference in lung volumes or arterial P_{O_2}). However, there were no differences between the groups 6 months after the diagnosis of HP. The evidence mentioned earlier suggests that systemic steroids may slightly increase the rate of resolution of acute pulmonary inflammation but have little or no effect on chronic residue of HP.

If patients are removed from exposure before there are permanent radiologic or physiologic abnormalities, the prognosis is excellent, with little evidence of long-term ill effects. If removal from exposure is impossible, the use of efficient masks during exposure can result in prevention of acute HP and an excellent prognosis. The prognosis varies considerably with different types of HP. In general, bird fancier's disease carries a worse prognosis than other forms of HP, though even this varies considerably depending on the specific nature of the exposure. It appears that long-term low-level exposure is associated

with a poorer prognosis, whereas short-term intermittent exposure is associated with a more favorable one. Unfortunately, many patients with chronic HP present with pulmonary fibrosis and physiologic abnormalities that are only partly reversible after cessation of exposure. The specific nature of histopathologic findings on biopsy in these patients at the time of diagnosis may help predict subsequent clinical course of the disease.[41] Not surprisingly, patients with organizing pneumonia/BOOP or cellular NSIP have a better prognosis than those with fibrotic NSIP or other patterns of fibrosing pneumonitis.

SUMMARY

In conclusion, HP is an immunologically mediated lung disease likely mediated primarily by T cell responses to inhaled antigens. The diagnosis requires careful history, appropriate laboratory tests, and lung biopsy in selected cases. Avoidance of exposure is usually associated with a good prognosis, and corticosteroids are indicated in severely symptomatic patients. Because of constantly changing environmental exposures, new examples of HP are continually being described, and represent an ongoing challenge in patients presenting with undefined interstitial lung disease.

CHAPTER 59
Radiation Pneumonitis

Kenneth B. Roberts
Roy Decker
Sara Rockwell

INTRODUCTION

The discovery of X-rays by Roentgen in 1895 and of radium by the Curies in 1898 revolutionized medicine at the turn of the 20th century. Roentgen's first paper on X-rays illustrated the power of diagnostic imaging with a remarkably detailed radiographic image of Frau Roentgen's hand. As researchers around the world built vacuum tubes and acquired radioactive sources for their studies, it rapidly became apparent that these invisible radiations could produce dangerous, and even lethal, injuries.[1–3] Erythema, chronic dermatitis, ulceration, loss of hair, and eye injuries were soon reported in patients who received large doses of radiation during prolonged fluoroscopy procedures. Even greater injuries were reported among the physicians, technicians, and scientists who performed diagnostic procedures or laboratory studies using unshielded X-ray-generating equipment and highly radioactive sources. The development of these radiation injuries suggested that radiation might be useful in the treatment of cancer; indeed, patients with cancer were treated with radiation therapy as early as 1896.[1–3]

Radiation was found to inhibit the growth of tumors, but this benefit came with the cost of injury to normal tissues within the irradiated areas. Because of the very low energies of the early X-ray and gamma-ray sources, radiotherapy in its early days was limited to using poorly penetrating radiations, which delivered much higher doses of radiation to skin than to even very superficial tumors. As a result, severe early radiation reactions in the skin limited the doses of radiation that could be delivered to tumors. Studies of these skin reactions led to the development of the concept of normal tissue tolerance and an appreciation of the benefits of "fractionated" radiotherapy, using multiple treatments with small doses of radiation.[2] The relative sensitivity of the lung to injury from radiation became apparent early in the development of radiation oncology. The clinical syndromes of dyspnea, cough, fever, and radiographic infiltrates occurring weeks to months after irradiation of the thorax were dramatic enough to be described as early as 1922.[4]

The field of radiation oncology has matured immeasurably over the last century and has incorporated significant advances from fields as diverse as theoretical and applied physics, radiation biology, pathology, cell biology, and immunology.[1,2,5–7] The importance of advances in physics and engineering to the maturation of radiation oncology is especially notable.[2,7] These advances have led to the development of modern linear accelerators capable of delivering very high-energy, deeply penetrating radiations, which can be used to deliver high radiation doses with great precision to tumors deep within the body. Precise systems for radiation dose measurement, or *dosimetry,* rapid computers, and precise algorithms for the rapid computerized three-dimensional planning of individualized radiotherapy treatments based on computed tomography (CT) scans and magnetic resonance imaging (MRI) studies have been developed. These advances have changed the dose-limiting toxicities of radiation therapy from painful early reactions in the skin to life-threatening late reactions in the normal tissues invaded by and surrounding the tumors, including the lung.

For clinicians interested in pulmonary medicine, understanding radiation pneumonitis is important. An understanding of radiation injury to the lung can be useful in understanding other lung diseases. Because the chemical mediators of radiation effects, both beneficial and harmful, are free radicals, the pathway leading to radiation injury in the lung overlaps with those leading to many other lung injuries.[8,9] In addition, understanding radiation pneumonitis has practical value to physicians in many areas of medicine. Approximately one in three people in the United States will be diagnosed with cancer at some point in their lifetimes. Over half of these patients will be permanently cured of their malignancies. Approximately 65% of all patients with cancer receive radiotherapy at some point in the treatment of their malignancies, and radiotherapy seems destined to remain an important component of cancer treatment for the foreseeable future. Because of this, every physician can expect to care for many patients who are receiving radiotherapy or have received radiotherapy at some point in the past.

In addition to the association of radiation therapy with acute or subacute pulmonary disease, recent studies of plutonium workers have shown an excess incidence of pulmonary fibrosis.[10] These

findings, which are supported by data from a large number of studies in experimental animals, show that lung injury may be produced by inhalation of insoluble particulate radionuclides that are deposited in lung tissue and produce long-term irradiation of the tissue.

Respiratory diseases are also known to be a cause of increased late morbidity and mortality in the survivors of the atomic bombs in Hiroshima and Nagasaki.[11] Therefore, radiation injury to lung is possible in cases in which people are exposed to high levels of inhaled radionuclides or external irradiation through their occupations, accidents, or acts of war or terrorism.[9] A working knowledge of the basics of radiobiology and radiation oncology is important to every physician and healthcare provider. An understanding of the potential toxicities of radiotherapy and other exposures to radiation, including radiation pneumonitis, can be critical to patient care.

Many neoplasms involving the thorax are treated with regimens that include the use of radiotherapy to produce either cure or palliation. Radiotherapy is principally a localized, anatomically based modality. The success of radiotherapy hinges on delivering radiation selectively to the sites of malignant disease, while sparing to the maximal extent possible the uninvolved normal tissues.[1,2,5] To plan radiotherapy treatments effectively, the radiation oncologist must have a sophisticated appreciation of the malignancy being treated and understand its biologic behavior, patterns of local and metastatic spread, radiosensitivity, and factors that influence the responses of individual patients to therapy. The radiation oncologist must also consider the effects of radiation on normal tissues within the treatment volumes.

Many factors, including radiation dose, fractionation pattern, volume of the tumor and involved margins, prior or planned use of other therapies such as surgery or systemic chemotherapy, and presence of other diseases influence both the probability of controlling the neoplasm and of producing toxic reactions. For cancers of the lung, esophagus, pleura, breast, and chest wall, as well as for lymphomas involving the thorax, optimal treatment frequently involves use of multiple overlapping X-ray beams and possibly electron beams, planned to encompass all of the cancer-containing tissues. Although treatments are carefully planned to include the smallest possible amount of healthy normal tissue, some normal tissue will necessarily be included in the radiation fields. The radiation sensitivity of the specific tissues in the irradiated fields and the acceptable level of risk for complications combine to limit the dose of radiation that can be administered. The planning of radiotherapy always involves a balance of benefit and risk, because the probabilities of controlling the malignancy increase with increasing radiation dose, but the probabilities and severities of the potential complications increase with dose as well.

To illustrate the mechanisms involved in planning radiotherapy treatments, a treatment plan is depicted in Figure 59-1A. The first panel shows the isodose distribution for treatment of a stage IIIB non–small-cell lung cancer, using a color-wash display in which the highest radiation dose is shown in red and lower doses in shades of yellow, green, and blue. This represents the sum of multiple radiation portals using intensity-modulated radiation therapy (IMRT), in which computer-based planning is used to deliver high dose to the tumor target with specific dose limits to normal tissue structures, such as the spinal cord, esophagus, heart, and lungs. The volume of normal lung receiving significant radiation can be readily appreciated.

The radiation dose delivered to the lung tissue is shown in a cumulative dose–volume histogram, in Figure 59-1B, which integrates the percentage of the volume of the organ at risk (on the vertical axis) receiving the specified cumulative radiation dose (on the horizontal axis). While this is a simplified representation of a complex dose/volume relationship, this formalism has become important in analyzing radiation dose delivery and correlating dosimetry with treatment outcome. In the illustration, the volume of lung receiving greater than or equal to 20 Gy is referred to as the V_{20}. In this case, the V_{20} is 35%, which predicts at least a 25% risk of grade 2 or greater pneumonitis (see discussion below, Clinical Syndromes). In Figure 59-2, the patient's pretreatment CT scan (panel A) is shown in comparison to a 3-month postradiation scan (panel B). The latter demonstrates radiation-induced inflammatory changes corresponding to the high-dose region of the radiotherapy. In this case, these changes were associated with increasing dyspnea, cough, and a decrease in diffusion capacity. Panel C shows slowly resolving changes, with persistent pulmonary fibrotic changes, on a CT scan obtained 1 year post treatment.

In the case presented, if the malignancy is cured, or the patient experiences the desired improvement in symptoms with minimal or manageable toxicity from the radiotherapy, the treatment is a success even if accompanied by radiographic changes or by other subclinical damage to the lung or other organs. Overt pulmonary toxicity is, however, a potential consequence of thoracic radiotherapy that sometimes overshadows the benefits of treatment.

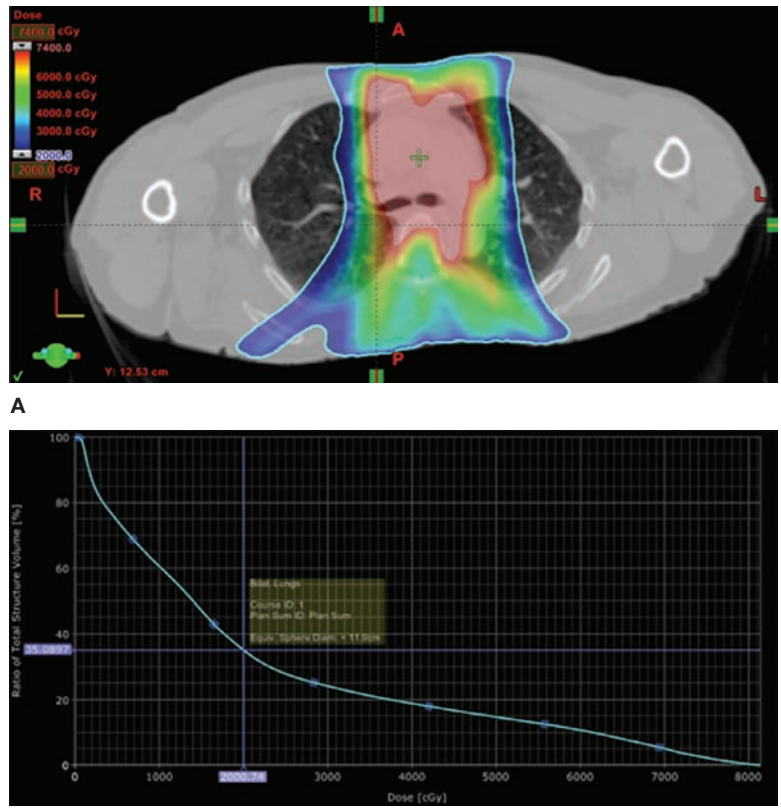

Figure 59-1 A 60-year-old man with stage IIIB non–small-cell lung cancer was treated with radiotherapy and concurrent cisplatin-based chemotherapy. The plans for his radiation treatments are summarized. **A.** The isodose distribution from a complex multifield radiation plan is overlaid on a treatment-planning CT scan. Using a color-wash format, radiation dose is demonstrated from 20 Gy *(green)* to 70 Gy *(red)*. **B.** Cumulative dose–volume histogram of the entire treatment course for bilateral lung tissue. The volume of normal lung receiving 20 Gy or more (V_{20}) is 35%.

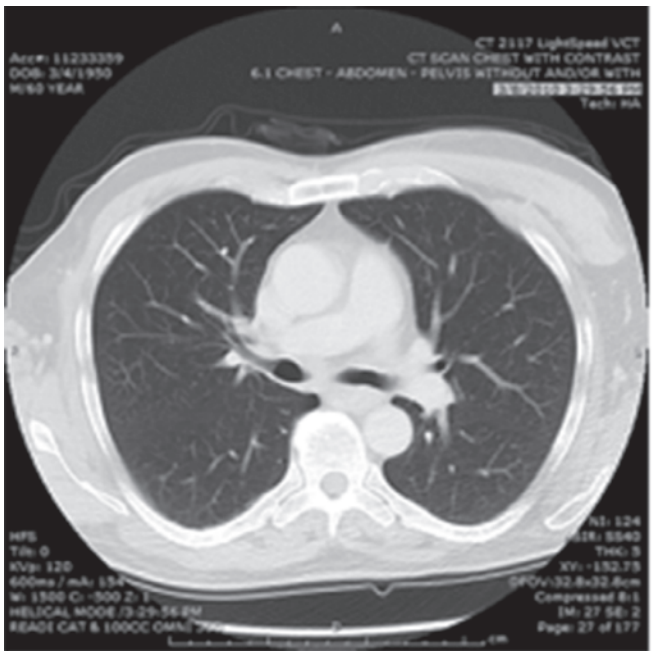
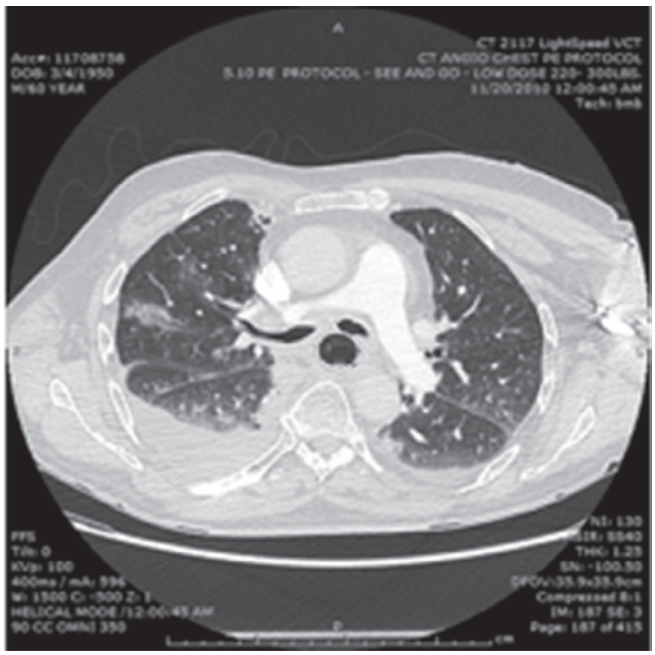
BRIEF OVERVIEW OF RADIOLOGIC PHYSICS

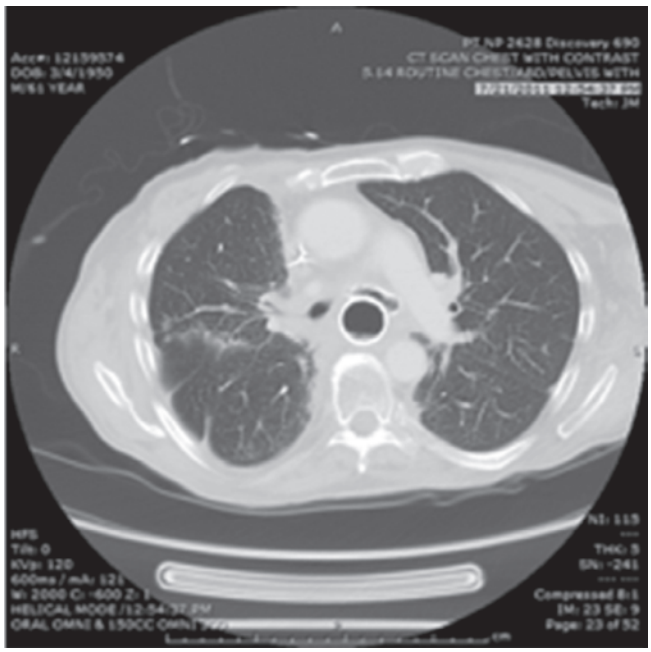
External beam radiotherapy is generally delivered using X-rays or gamma rays. Both of these radiations are high-energy electromagnetic waves or photons that are able to cause ionizations when



A



B



C

Figure 59-2 The same patient as in Figure 59-1, developed a progressive dyspnea and nonproductive cough. A comparison of chest CT imaging from before treatment (Panel A) and 3 months after treatment (**Panel B**) demonstrated interstitial infiltrates and ground-glass changes in a distribution consistent with the prior radiation, as well as the development of new pleural effusions. This is consistent with radiation pneumonitis, and the patient was treated with corticosteroids. He symptomatically improved over several months. A chest CT scan at 1 year (**Panel C**) shows residual fibrotic changes in the paramediastinal region. **Panels** (**B**) and (**C**) also show bronchial and esophageal stents placed for palliation of a tracheoesophageal fistula.

interacting with matter.[7] The only difference between them lies in the manner in which they are produced: Gamma-ray photons are emitted from atomic nuclei during the decay of radioactive atoms, and X-rays are produced when high-energy electrons strike a target material and interact with the electron shells of atoms in that target, causing them to emit X-ray photons (the *bremsstrahlung effect*). After its emission, an individual X-ray photon is indistinguishable from a gamma-ray photon. Thus, although the discussion below uses X-rays as examples, the principles are equally applicable to radiotherapy using high-energy gamma rays (e.g., from cobalt-60 teletherapy units or brachytherapy using implanted radioactive sources).

The X-rays used for diagnostic imaging are in a relatively low-energy range, in which the dominant interaction of photons with matter is through the "*photoelectric effect*." In this process, absorption of a photon causes an electron to be ejected from the inner shell of an atom. The probability of photoelectric interactions increases as a function of the cube of the atomic number, that is, as Z^3. Consequently, large, heavy atoms absorb low-energy diagnostic X-rays much more efficiently than smaller, lighter atoms.

Diagnostic radiology capitalizes on the large differences between the absorption of low-energy X-rays in materials with different compositions, for example, air, soft tissue (which is 70% water and, therefore, composed primarily of the small atoms hydrogen and oxygen), bone (with its high calcium content), and administered contrast agents containing barium, iodine, or other heavy atoms. The differences in absorption are used to image anatomical structures. In contrast, high-energy X-rays used in radiotherapy interact with matter primarily by a phenomenon called the "*Compton effect,*" in which X-rays cause ionization of atoms via interactions with their outer electron shells. The Compton effect is not dependent on the atomic number, but is, instead, a function of the electron density. Because the electron densities of most biologic tissues are relatively uniform,

for the purposes of most radiotherapy dosimetry, it is reasonable to assume that a patient is of uniform density, equivalent to water.

An important caveat to radiation dosimetry involves the standard specification of doses in tissues that include a large proportion of air, such as the lung. As a single X-ray beam penetrates through water or tissue, the dose received by the tissue falls progressively, generally as an exponential function of distance. Because of its markedly lower density, air absorbs less radiation energy and, therefore, attenuates the X-rays less than does tissue or water. With the quantitative knowledge of lung density that can now be derived from CT scanning, algorithms have been devised to estimate the inhomogeneity in the absorbed dose resulting from differences in the density of lung and other soft tissues.[7,12] These heterogeneity corrections show that routine dosimetric calculations, which assume uniform density, underestimate the radiation doses to lung and tissues beyond the lung by 5% to 25%.

Although the effect of tissue heterogeneity is a very important consideration when quantifying the radiation dose delivered to the lungs, one must remember that doses delivered to the thorax and the lungs historically have been reported in the medical literature *without* heterogeneity corrections. Moreover, because the preponderance of clinical data concerning lung tolerance have been determined and reported using older dosimetric algorithms, which assume that lung has water-equivalent density, the impetus to change dose reporting is tempered by the desire to avoid confusion between the newer and older literature. The reader should assume, unless explicitly stated otherwise, that the historic radiation doses given in this chapter, or for that matter any publication, are not necessarily corrected for lung density. Most modern radiotherapy planning systems now include the ability to account for tissue heterogeneity. Without such corrections, actual dose delivery to the chest region is modestly higher than the nominal doses reported. However, the variability of the actual dose delivery is highly individual and only recently has been accounted on a routine basis with improvements in computerized treatment planning.

Radiation dose is currently reported using the unit of the Système International (SI), the gray (Gy). The Gy is a measure of the energy absorbed by 1 kg of tissue; 1 Gy = 1 J/kg. The former unit of absorbed dose, called the "rad" (an acronym for "radiation absorbed dose") was measured with the CGS system; by definition, 1 rad = 100 ergs per gram. To compare old and recent literature, one must remember that 1 Gy = 100 rad. Despite the fact that it is not an approved SI unit, some radiotherapy literature avoids this conversion by giving the dose in centigray (cGy), where 1 cGy = 0.01 and Gy = 1 rad. Other measures of radiation dose seen in the literature include the roentgen, the Sievert, and the rem.

The roentgen measures radiation *exposure,* rather than energy *absorption,* and refers specifically to the amount of ionization produced in air under standard conditions (1 R = 1 electrostatic unit/cc = 2.58×10^{-4} coulombs/kg of "standard air" at a density of 1.29×10^{-4} g/cm^3 at 0°C and 760 torr). This unit is frequently encountered in the radiation dosimetry literature, not only because it was historically used as a measure of dose, but also because many widely used radiation monitors (e.g., ionization chambers) directly measure radiation exposure at the surface of the body. The dose absorbed by tissue is then calculated from this exposure.

The radiation protection literature uses the unit of "equivalent dose," the Sievert (Sv), which is calculated as the absorbed dose (in Gy) multiplied by a "weighting factor" that considers the differing biologic effects of different radiations. Although the weighting factors for some radiations, such as neutrons and alpha particles, can be as high as 20, the weighting factors for X-rays, gamma rays, and electrons are all defined as 1. For most purposes in diagnostic and therapeutic radiology, therefore, 1 Sv = 1 Gy. The Sv replaces the older unit of equivalent dose, the rem (1 Sv = 100 rem). Unfortunately, the literature on radiation-induced lung injury includes papers using all of these different units, creating great confusion for readers. For simplicity, all doses in this chapter have been converted to Gy.

RADIOBIOLOGY OF RADIOTHERAPY

When X-rays pass through tissue, a complex series of physical and chemical reactions occurs.[1,13,14] As the X-rays interact with atoms along their path, energy is absorbed, and energetic fast electrons are ejected. These fast electrons travel through tissue, producing secondary ionizations, which lead within milliseconds to the generation of a variety of highly reactive free radical species. Because biologic materials are about 70% water, ions and free radicals derived from water (e.g., H, OH, H_2O^+, H_3O^+) are the main reactive species produced. These ions and radicals react with each other and with other nearby molecules, creating a wide variety of chemically reactive species and producing many kinds of damage in biologic macromolecules. Because DNA contains information that is critical to the cell, while most other molecules can be replaced readily, damage to DNA is the most important biologic effect of irradiation. Radiation produces a wide variety of lesions in DNA, including single- and double-strand breaks, damaged bases and loss of bases, as well as chromosomal breaks and rearrangements. If these lesions are not repaired, the result can be permanent mutations or changes in chromosomal structure that lead to the death of the cell or changes in its behavior.

The cytotoxic effects of radiation are the basis for both the antineoplastic effects and the toxicities of radiotherapy. A theoretical concern is that radiotherapy may produce a mutation in a previously normal cell that leads to the development of a new malignancy. Although radiation-induced malignancies do occur and are a primary concern in considerations of environmental and occupational exposures,[1,11,13] malignant transformation is, fortunately, a rare enough event at the doses used in radiotherapy that the risk of inducing a second cancer in an individual patient is very small relative to the great benefit of curing the existing malignancy.[5] The greater risk to the patient lies in the fact that radiation is not selectively toxic to the tumor cells, but instead, kills both normal and malignant cells within the treatment field.

Although the radiochemical reactions that lead to cytotoxic damage are complete within milliseconds after the end of irradiation, cells dying from radiation injury do not die immediately. In fact, soon after irradiation, radiation-sterilized cells are indistinguishable from cells that ultimately survive irradiation in their appearance, metabolic activities, and even rates and patterns of proliferation. Most radiation-sterilized cells ultimately die during mitosis, but they may first undergo one or even several divisions, producing an abortive clone of sterile cells, all of which ultimately die and disintegrate through apoptosis, necrosis, mitotic catastrophe, senescence, autophagy, or other pathways of cell death.[15,16] This delayed cytotoxicity underlies many of the effects seen in radiotherapy. Rapidly growing tumors, for example, generally begin shrinking sooner than slowly growing tumors, and many tumors continue to shrink progressively for months after radiotherapy.[13,17] Analogously, radiation reactions in normal tissues reflect the normal patterns of cell turnover in the tissue.

After irradiation, nonproliferating, terminally differentiated cells continue to perform their differentiated functions throughout their normal life spans. Other cells that are not proliferating at the time of irradiation likewise continue to function normally until they are recruited into proliferation, perhaps months or even years after irradiation; when they begin to proliferate, their progeny die. Rapidly proliferating cells, such as mucosal or intestinal epithelium or nucleated blood and bone marrow cells, die within a few days of irradiation, leading to the familiar early radiation reactions of epilation, desquamation, mucositis, and hematologic depression.[3,5] Some cell types, especially hematopoietic cells, may be induced by radiation-induced damage to enter a pathway of

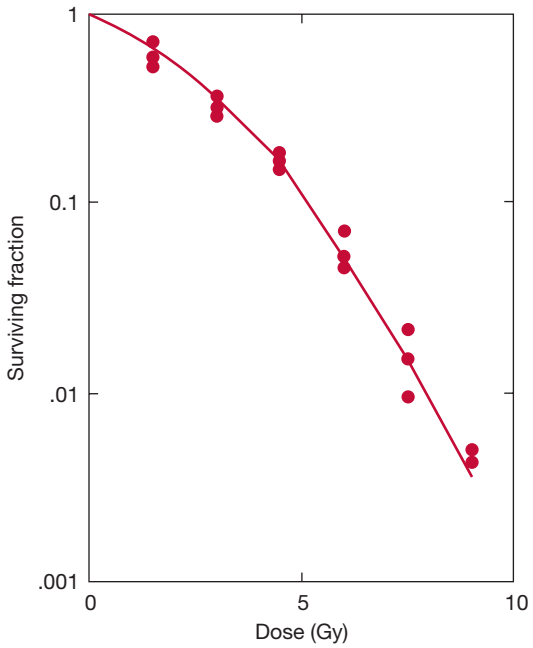


Figure 59-3 Survival of lung cells treated with different doses of radiation. Cells were explanted from mouse lungs, irradiated in vitro, and assayed for viability using a colony formation assay. *(Reproduced with permission from Guichard M, Deschavanne PJ, Malaise EP. Radiosensitivity of mouse lung cells measured using an in vitro colony method. Int J Radiat Oncol Biol Phys. 1980;6(4):441–447.)*

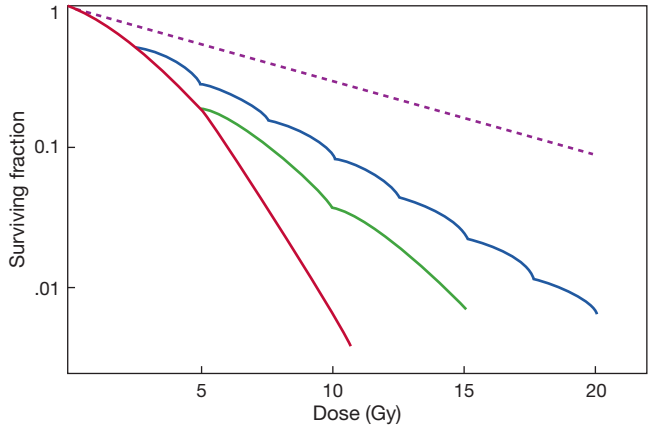

Figure 59-4 Effect of fractionated irradiation and low-dose rate irradiation on cell survival. The survival curve for lung cells treated with a single dose of radiation is redrawn from Fig. 59-3. The calculated effect of dividing the radiation dose into several daily treatments with 5 Gy/fraction or 2.5 Gy/fraction is illustrated. The *dashed line* illustrates the survival curve that would be expected for irradiation delivered continuously at a low-dose rate over several hours, allowing repair and proliferation to occur during treatment. Changes in the cytotoxicity of radiation with fractionation and at low-dose rates lead to decreased injury in lungs irradiated with analogous regimens.

programmed cell death that leads to apoptosis; the role of early and delayed apoptosis in determining the response of tumors and normal tissues to radiotherapy is the subject of intensive investigation.

A typical survival curve for mammalian cells, obtained using mouse lung cells, is shown in Figure 59-3. As a first approximation, cell survival falls exponentially as the radiation dose increases. Statistically, this implies that each incremental dose of radiation has the same cytotoxic effect; that is, each incremental dose kills the same proportion of the viable cells that were present in the population at the beginning of that irradiation. Very low doses of radiation have somewhat lesser effects; the shoulder on the cell survival curve reflects the ability of the cells to accumulate and tolerate or repair some of the damage produced by radiation.

The effect of the repair of radiation damage can be seen when the radiation dose is divided into two or more treatments separated by hours or days, rather than being delivered in a large single dose. Dividing, or "fractionating," the radiation dose allows cells to repair damage to their DNA and to proliferate between treatments.[1,5] As a result, there is less cytotoxicity from a fractionated treatment regimen than from the same total radiation dose delivered as a large single fraction (Fig. 59-4). Smaller fractions produce less cytotoxicity than larger fractions. Similarly, the cytotoxic effects of radiation are diminished when the radiation is delivered continuously at a low-dose rate, over hours or days, allowing repair and proliferation to occur during irradiation (Fig. 59-4).

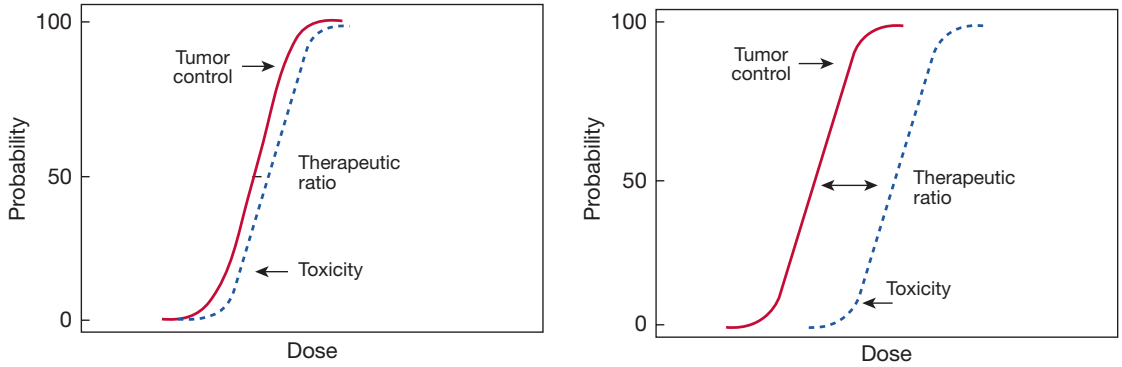
Fractionating therapeutic irradiations or delivering the radiation at low-dose rates generally appears to increase the therapeutic ratio by protecting normal tissues against radiation injury, while producing a smaller increase in the relative radioresistance of the tumor; treatment outcomes are thereby improved. This increase in the therapeutic ratio is thought to reflect qualitative and quantitative differences between normal and malignant cell populations, including differences in the intrinsic radiosensitivity of the critical cells and in the patterns of cell proliferation and cell loss, as well as differences in the ability of the normal and malignant cells to repair radiation damage. Empiric observations of patients treated with radiotherapy, laboratory experiments with tumors and normal tissues in rodents, and studies with cells in culture have all been used to guide the development of the clinical fractionation schedules now in use. This optimization process is ongoing and will undoubtedly continue, incorporating new information about the repair of radiation damage in normal and malignant cells and about the physiologic factors that modulate development of late radiation injuries in specific normal tissues. In addition, efforts will continue in the development of new technologies for targeting and delivering radiation.

In this process, as in any change in cancer therapy, the critical parameter is the therapeutic ratio (Fig. 59-5). A new treatment regimen is superior *only* when it produces an increased effect on the tumor without an equivalent increase in toxicity to critical normal tissues, reflected in an increase in the therapeutic ratio and therapeutic gain. The art of radiotherapy lies in the design of treatment fields that minimize radiation doses to normal tissues and in the development of treatment regimens that use all available information on the biology of the tumor and of the critical normal tissues.

PATHOPHYSIOLOGY OF RADIATION PNEUMONITIS

Much of our current understanding of the pathophysiology of radiation injury to the lungs is derived from animal experimentation. Translation of animal data to human conditions is always problematic, because differences in the biology and physiology of different species may preclude direct and definitive extrapolation from animals to humans.[9,13,18] Instead, studies with experimental animals must be designed to identify physiologic factors and biologic mechanisms that can be used to interpret clinical data and suggest avenues for clinical investigations.

Data on radiation pneumopathy in humans is fragmentary and complicated by the variability in the patients treated with thoracic irradiation. Most studies of radiation pneumonitis include patients with a variety of malignancies who have been treated with different irradiation regimens, often in combination with chemotherapy and surgery. Moreover, patients vary widely in age and the presence of



Increasing the therapeutic ratio, either by selectively increasing the effect on tumor or by selectively protecting normal tissues from injury, produces therapeutic gain.

Figure 59-5 The therapeutic ratio is the critical factor determining the success of cancer therapy.

other diseases and risk factors. Therefore, our current understanding of radiation injury to the lung remains incomplete. What is known suggests a complex, multifactorial mechanism of injury and disease progression that reflects cytotoxic effects on both epithelial and endothelial tissues. Inflammatory responses involved in this injury cascade include transient increases in reactive oxygen and nitrogen species, macrophage infiltration and activation, oxidative stress, induction of interstitial fibrosis with regional tissue hypoxia, and disordered cytokine and cellular signaling—including profibrogenic transforming growth factor-beta (TGF-β), proangiogenic hypoxia-inducible factor-1 alpha (HIF-1α), and vascular endothelial growth factor (VEGF).[8,9,14,19–25] Similarities to lung injuries resulting from cancer chemotherapy, other drugs, inhaled chemicals, oxygen toxicity, immune reactions, and idiopathic pulmonary fibrosis are intriguing, especially when one considers that many of these diseases include pathologic responses to free radical chemical species and are likely to reflect similar underlying initial lesions.

Partial-lung resection and localized irradiation have certain similarities: Their effects are largely localized to the treated areas and, consequently, depend on the number of pulmonary lobules or alveolar–capillary units functionally destroyed. Thus, the volume of lung irradiated is an important determinant of toxicity. Consequently, the radiation oncologist plans treatment to minimize the volume of lung receiving high radiation doses, just as the thoracic surgeon plans lung resection with due consideration to anticipated residual lung function. Of course, this simple analogy has its limitations. For example, inactivation of enough lobules by radiation increases the ventilatory dead space and could lead to shunting and ventilation–perfusion mismatching. However, in clinical practice, extensive shunting generally is not observed.[26] In fact, postradiation radionuclide ventilation–perfusion scans tend to show both underperfusion and underventilation that is dose dependent in irradiated areas of partially irradiated lungs.[27] In most cases, radiation injury in lung conforms to the radiation treatment fields, but in some, effects outside the treated areas are observed, with localized radiation inducing a more generalized or diffuse hypersensitivity pneumonitis.[28]

The effects of radiotherapy on the lung reflect the proliferation patterns of the different cellular components of the terminal capillary–alveolar units.[29] Type I pneumocytes are the dominant epithelial cells of the lung, covering about 83% of the alveolar surface. Type I pneumocytes are normally nonproliferating and do not proliferate in response to injury. Consequently, they are thought to be relatively resistant to the cytotoxic effects of radiation.

Type II pneumocytes, which comprise about 16% of the cells in the human lung, are the principal source of surfactant that modifies alveolar surface tension to prevent atelectasis. Type II pneumocytes have turnover times of about 1 month. In response to certain injuries, these granular pneumocytes can be induced both to undergo rapid mitosis and differentiate into type I pneumocytes.

Endothelial cells comprise about 30% of the cells in human lungs and form a continuous layer between the blood and the lung tissue. Although endothelial cells are classified in most tissues as stromal cells, endothelial cells in lung are actually parenchyma, because they are critical to the function of this organ. Capillary endothelial cells are a constantly renewing population, with an estimated turnover time on the order of 2 months. Endothelial cells can be induced into rapid compensatory proliferation after injury; therefore, radiation may result in depletion of both type II pneumocytes and endothelial cells.

Several lines of evidence suggest that radiation injury is related primarily to cytotoxic damage, especially to the surfactant-producing type II pneumocytes and vascular endothelial cells. Although clinical signs of pneumonitis require weeks to develop, laboratory studies reveal evidence of lung injury within hours after large single doses of radiation.[6,22,30–32] Shortly after irradiation, electron microscopy may detect abnormalities in surfactant-containing lamellar bodies. There is an increase in surfactant in bronchoalveolar lavage specimens within hours of irradiation that persists for several weeks. Ultrastructural evidence of endothelial cell damage is also seen soon after lung irradiation, and a rapid increase in capillary permeability occurs, reflecting loss of integrity of cell junctions, intracellular vacuolization, cellular pleomorphism, and sloughing of the basement membrane. Capillary occlusion by cellular debris and microthrombi may occur at high doses.

The clinical course of lung injury occurs later and includes a pneumonitic phase, developing weeks to months after radiation, followed by a fibrotic phase, developing months to years later. To explain the two clinical phases, Rubin and Casarett's original model of radiation lung toxicity suggested that the pneumocytes and endothelium represented two separate and distinct cellular targets, and that damage to pneumocytes led to pneumonitis, while vascular damage led to fibrosis. This older model is now thought to be incorrect; current data[19,20,22,29,33–38] suggest that the pneumonitic and fibrotic processes both are manifestations of a common pathway of injury and response.

Histologically, one can recognize a typical sequence of events developing in the lung after large doses of radiation.[6,21,30] Within days to weeks, vascular congestion and intra-alveolar edema and exudation occur, followed by infiltration of inflammatory cells and epithelial desquamation. Weeks later, collagen fibrils are deposited within areas of injury and interstitial edema, leading to a thickening of alveolar septa similar to that in hyaline membrane disease. The probability and severity of these changes are quite variable and depend on such factors as the radiation dose and treatment volume. The severity of the damage and volume of tissue affected determine whether a pneumonitic picture becomes clinically evident. Resolution of inflammatory infiltrates and alveolar exudates, which

can be improved by anti-inflammatory agents such as glucocorticoids, correlates with symptomatic improvement and resolution of radiographic opacities in the affected lung.

Inflammatory cells, particularly alveolar macrophages, migrate into areas of radiation injury. This induces an ensuing cytokine cascade and mediates the host response,[9,20,22,25] similar to that which occurs in other inflammatory conditions, which can lead to pulmonary fibrosis.

Rubin et al. have detected a biphasic increase in mRNA expression for the proinflammatory cytokines IL-1α, IL-1β, and TNF-α at 2 and 8 weeks after radiation.[22] Preliminary clinical trials also suggest that elevated serum levels of IL-6 before and during radiotherapy predict an elevated risk of radiation pneumonitis. Beginning 24 hours following radiation, TGF-β, a cytokine that mediates fibrotic responses, increases.[21] Elevated levels of VEGF may be detected 2 weeks later. Tissue hypoxia accompanies the inflammatory response. Clinical data implicating TGF-β as a predictive marker for pneumonitis, however, have been mixed. Collagen gene expression is also appreciably increased corresponding to the fibrotic changes seen histologically. These studies suggest that early and persistent elevations of cytokine production and alterations of intercellular signaling are critical to the development of radiation reactions in the lung. There is increasing evidence from studies with inbred mice that genetic differences, age, and past health and treatment history modulate the development and severity of fibrosis and hyaline membrane formation, thus determining the nature of the late toxic lesion and the time of development of radiation pneumotoxicity.[9,33,34]

The processes described earlier lead to pathologic changes that conform spatially to the areas to which localized radiation was administered. Interestingly, it has been discovered that radiation can also induce an allergic alveolitis. This is observed infrequently as a diffuse pneumonitis, or occasionally as a patchy, transient bronchiolitis obliterans organizing pneumonia (BOOP; see Chapter 57) occurring outside the treated fields. In its most severe form, the result is the acute respiratory distress syndrome (ARDS; see Chapter 141). Morgan and Breit[28] have suggested that this form of radiation-induced pneumonitis be termed "sporadic". The occurrence of the syndrome actually may be more common than appreciated. One series showed a 2.3% incidence of BOOP in women undergoing whole breast radiotherapy, occurring outside the radiotherapy fields four or more months after exposure.[39] Bronchoalveolar lavage in humans and in experimental animals frequently shows a significant increase in activated T-helper ($CD4^+$) lymphocytes, temporally related to irradiation and occurring equally in the irradiated lung and the contralateral, nonirradiated lung. Gallium scanning may also show bilateral uptake not corresponding to the treated regions. Frequent reports of autoantibodies, including antibodies to collagen, in the sera of patients with cancer even before treatment suggest the possibility that malignancy-associated autoimmune reactions may be involved in the syndrome.

CONFOUNDING EFFECTS OF CHEMOTHERAPY

Many cytotoxic drugs employed as antineoplastic agents can produce pulmonary toxicity (see Chapter 65).[40–42] Bleomycin, which has been extensively studied, kills cells by generating reactive free radical species similar to radiotherapy and may give rise to both pneumonitis and fibrosis.[42] Doxorubicin, mitomycin C, irinotecan, and gefitinib have been associated with lung toxicity, as have the antimetabolites (methotrexate, cytosine arabinoside, gemcitabine, fludarabine, and the nitrosamines) and the podophyllotoxins (etoposides, paclitaxel, and docetaxel). Interestingly, lung injury has also been reported after treatment with immune modulators, including interferons, IL-2, and TNF-α.

As high-dose alkylating agent chemotherapy is used more frequently in the setting of bone marrow or peripheral stem cell transplantation, agents such as cyclophosphamide, BCNU, and busulfan have been associated increasingly with clinically significant pneumonitis. The direct toxicity of many widely used anticancer drugs to the lungs sounds a note of caution for those considering development of treatment protocols combining systemic chemotherapy with lung irradiation. Moreover, the concurrent administration of antineoplastic agents and radiotherapy may make it difficult to discern to what degree pulmonary injury in an individual patient is related to radiotherapy alone.

Animal studies addressing changes in respiratory rates and/or death resulting from lung injury show that the severity of the lung injury can be increased when doxorubicin, bleomycin, cyclophosphamide, mitomycin C, dactinomycin, or vincristine are administered along with radiation.[43,44] No enhancement has been documented in studies with 5-fluorouracil, cisplatinum, carboplatinum, hydroxyurea, vinblastine, or methotrexate, despite reports of lung toxicity from methotrexate alone.

As a wide variety of cytokines and molecularly targeted agents are now available for pharmacologic administration, modulation of radiation injury by these biologic agents needs increased study. Interferons have been shown both to increase and decrease radiation lung toxicity, whereas interleukins 1 and 2 may have protective effects. Some radiation-drug interactions in the lung have been shown to be schedule dependent, with the effect of the combination varying with the sequence and the time between treatments with the two agents.[43,44] Additive, subadditive, and even supra-additive toxicities may be observed in rodents when single treatments with the same dose of radiation and drug are given over a 24-hour period, but in different sequences and different times between treatments. Such findings highlight the complexities of combined-modality therapy and the difficulty of using animal data to plan clinical treatment regimens.

Data from several specific clinical situations show that regimens combining radiation with particular chemotherapy agents can produce significant risks of pneumonitis. As summarized in reviews of chemotherapy and radiation-induced pneumonitis, docetaxel, mitomycin C, gemcitabine, and irinotecan given concurrently with radiotherapy seem to elevate the risk of pneumonitis or lung toxicity.[45,46] On the other hand, drugs that are commonly used in lung cancer concurrent with radiotherapy, such as cisplatin, carboplatin, paclitaxel, and etoposide, do not consistently elevate the risk of pneumonitis; alternatively, the clinical data regarding pneumonitis risk so commonly include these chemotherapy agents that the risk may already be incorporated into consideration.[47–51] Older clinical data from pediatric trials strongly suggest that administration of concurrent doxorubicin or actinomycin D with thoracic radiotherapy generally should be avoided or, alternatively, that the radiation doses should be reduced significantly where these drugs are used.

Sequential treatment with doxorubicin or actinomycin D and radiation is less likely to produce lung injury. However, a phenomenon termed "radiation recall" has been well described, in which either of these two drugs given even several months after radiotherapy will produce an inflammatory reaction in the region corresponding to the radiation treatment fields.[52] Although this reaction is best known in skin, it also has been well documented in the lungs in several case reports and has been produced in experimental animals. Radiation recall probably reflects the fact that the irradiated areas of the lung still retain residual, subclinical injury, which is exacerbated into clinical pneumonitis as a result of the additional injury from the drug. Therefore, the biologic basis of the recall phenomenon is analogous to that of the residual radiation injury, which decreases the ability of heavily irradiated lung tissue to tolerate a second course of radiotherapy delivered months or years later.[5,6,37]

CLINICAL SYNDROMES

Radiation oncologists conventionally divide clinical toxicities into acute and late effects,[5,6] with both radiation pneumonitis and fibrosis considered late toxicities. Several grading systems for pneumonitis

TABLE 59-1 Toxicity Criteria for Pneumonitis

Scoring System	Grade 1	2	3	4	5
CTCAE	Asymptomatic; radiographic findings only	Symptomatic; not interfering with ADL	Symptomatic; interfering with ADL; O_2 indicated	Life-threatening ventilatory support indicated	Death
RTOG/EORTIC (LENT-SOMA)	Asymptomatic or mild symptoms (dry cough), with radiographic findings	Moderately symptomatic (severe cough fever)	Severely symptomatic	Severe respiratory insufficiency; continuous oxygen/assisted ventilation	Death
SWOG (33)	Asymptomatic or symptoms not requiring steroids with radiographic findings	Initiation of or increase in steroids required	O_2 required	Assisted ventilation necessary	Death

CTCAE, common terminology criteria for adverse events; ADL, activities of daily living; RTOG, Radiation Therapy Oncology Group; EORTC, European Organization for the Research and Treatment of Cancer; LENT-SOMA, late effects on normal tissue-subjective, objective, management and analytic scales; SWOG, Southwest Oncology Group. Source: Reproduced with permission from Mehta V. Radiation pneumonitis and pulmonary fibrosis in non-small-cell lung cancer: pulmonary function, prediction, and prevention. Int J Radiat Oncol Biol Phys. 2005;63(1):5–24.

have been developed for scoring lung injury during clinical trials (Table 59-1).

■ ACUTE MANIFESTATIONS

It is relatively uncommon to observe acute pulmonary toxicity during the administration of fractionated radiotherapy. However, at relatively high therapeutic doses (50–60 Gy), acute radiation changes in the tracheobronchial tree can be expected. Bronchoscopic examination is likely to reveal erythematous mucosa, with thickened secretions that can accumulate in and obstruct the airways. Although a majority of patients remain asymptomatic, occasional patients experience an irritative, dry cough. Antitussive agents, such as codeine, adequate hydration, and reassurance are usually all that are required to manage this problem. Once radiotherapy has been completed, the bronchial epithelium regenerates and heals over several weeks, accompanied by resolution of symptoms.

■ LATE MANIFESTATIONS

The clinical course of late radiation injury to the lungs is biphasic, with both inflammatory and fibrotic components.[19,30,32]

Radiation Pneumonitis

A pneumonitic process frequently becomes evident 6 weeks to 6 months following radiotherapy. At this time, radiographs show alveolar opacities that generally conform to the treatment portals. The severity of radiation pneumonitis varies dramatically from patient to patient, even in those receiving identical therapeutic regimens. In most cases, the pneumonitis is asymptomatic, even though radiologic abnormalities are quite common, as noted in some prospective studies, in which as many as 50% of patients who have completed a course of thoracic radiotherapy were asymptomatic.

When symptomatic, this syndrome is often characterized by the abrupt onset of fever, cough, and dyspnea. The severity of symptoms depends on the extent of radiotherapy, increasing with the treated volume and with the radiation dose. Symptoms in patients irradiated to limited lung volumes or to relatively low doses may consist of low-grade fever, cough, congestion, and chest fullness or discomfort. Any hemoptysis tends to be minimal. In more severe situations, dyspnea, high fever, and cough occur. When large volumes of normal lung receive high radiation dose, acute radiation pneumonitis is more likely and can be extremely severe, producing respiratory distress. The radiation oncologist is probably most likely to see clinically significant radiation pneumonitis that can be life-threatening when it occurs as a rare and unanticipated consequence of standard treatment, despite appropriate treatment planning designed to minimize the volume of lung treated with high doses of radiation. Fortunately, with well-planned radiotherapy, severe radiation pneumonitis is a rare event. Milder pneumonitis is not uncommon, but is readily manageable.

It is important to distinguish radiation pneumonitis from infection, recurrent tumor (particularly with lymphangitic spread), drug reactions, congestive heart failure, and other respiratory disorders. These distinctions may not be easy; one series from Duke suggested that up to 28% of patients with radiation-associated lung toxicity have complex comorbidities that make it difficult to assign a definitive diagnosis.[53] Bacterial, fungal, viral, and pneumocystis pneumonias can be quite difficult to differentiate from pneumopathy induced by chemotherapy or radiation.

Aids in the differential diagnosis include the clinical course and temporal relationship between the irradiation and respiratory illness. Definition of the radiographic pattern of the infiltrate is also very useful, because radiation pneumonitis often conforms to the outline of the sharply demarcated radiation portal (Figs. 59-2 and 59-6). Bronchoscopy and lung biopsy can also be helpful diagnostic tools to direct therapeutic decisions. Ruling out infection is particularly important, because treatment of symptomatic radiation pneumonitis relies on supportive care in conjunction with corticosteroids.

Doses of glucocorticoids generally can be tailored to the severity of the symptoms. Asymptomatic pneumonitis may be managed with close observation. Severe cases generally warrant treatment with prednisone (or its equivalent) at a dose of 0.5 to 1 mg/kg per day in divided doses. Response rates between 20% and 100% have been reported, and dramatic clinical and radiographic responses are not infrequently seen. Steroids should be tapered slowly after the patient is stabilized, because it is common to see a recrudescence of symptomatology when steroids are discontinued too rapidly. Failure to respond to steroid therapy is an adverse prognostic factor that suggests the prospect of rapid disease progression.

Most studies show at least a transient decline in pulmonary function in patients who receive radiation to a significant lung volume (i.e., patients with lung cancer receiving a potentially curative course of fractionated radiotherapy). There may be a transient reduction in FEV_1 and FVC 3 to 6 months post radiation. Carbon monoxide diffusing capacity (D_{LCO}) may be reduced over a similar time course, but typically to a greater degree relative to baseline.[54] Absent the development of radiation fibrosis, these parameters tend to recover toward the patient's baseline, reaching maximal recovery at approximately 12 months.

Radiation Fibrosis

A more indolent fibrotic process may follow either subclinical or symptomatic radiation pneumonitis.[19,30,32] This begins several

months after radiotherapy and peaks in radiographic severity several years later. Fibrosis tends to occur in, or adjacent to, areas of prior pneumonitis,[33] but it can also occur in the absence of clinically overt radiation pneumonitis. Fibrotic changes and the retraction of the lung parenchyma from scarring occur in the irradiated regions (Fig 59-2). When the volume of lung irradiated is relatively small and the remaining lung parenchyma contains sufficient respiratory surface area, the changes tend to be asymptomatic.

With increasing relative volumes of pulmonary fibrosis, a spectrum of symptomatology is possible, ranging from mild dyspnea on exertion to severe fibrosis with respiratory compromise, chronic cor pulmonale, cyanosis, and finger clubbing. At the severe end of the spectrum, the syndrome can be life-threatening. In general, in the absence of other underlying lung disease, symptoms are mild when less than 25% to 30% of total lung parenchyma is involved.

Radiation-induced Pleural Reactions

Pleuritis may also be seen 2 to 6 months following radiation. It can be associated with pleuritic chest pain, a pleural friction rub, and an exudative pleural effusion. Large effusions are, however, distinctly unusual in the absence of other pathology. Like radiation pneumonitis, radiation-induced pleuritis may heal without significant residue, or it may proceed through a fibrotic phase that generates pleural thickening.

Radiation-induced Bronchial Stenosis

With improvements in the technical delivery of radiotherapy, recent clinical trials for lung cancer have emphasized escalation of the administered radiation dose. Stereotactic body radiotherapy (SBRT) utilizes —three to five large fractions (i.e., >10 Gy per fraction), delivering significantly higher biologically effective doses than are feasible with conventional fractionated radiotherapy.[55] As a result, there is an increasing appreciation that, particularly for perihilar tumors, radiation-induced fibrosis may result in bronchial stenosis or necrosis, causing postobstructive atelectasis, volume loss, and functional impairment.[56–58] Clinically, this complication needs to be differentiated from recurrent tumor; bronchoscopy or positron emission tomography (PET) imaging may be of help. One retrospective series in which radiation doses ranged from 60 Gy to as high as 86 Gy demonstrated that radiation-induced bronchial stenosis may occur in up to 25% of patients; the incidence directly correlates with radiation dose.[59] However, severe bronchial injury is rare with fractionated chest radiotherapy using conventional doses.

DEFINING THE RADIATION TOLERANCE OF THE LUNGS

While we customarily refer to radiation doses that can be delivered safely either to the whole body or to a particular organ, radiation *tolerance* is usually defined as the dose that yields a 5% risk of severe late radiation injury.[60] When discussing the tolerance of the lungs, one must consider several different therapeutic situations. The tolerance of the lung varies with the volume of lung tissue irradiated.[5,35,60,61] In addition, single-dose irradiations, fractionated irradiations, and irradiations given at low-dose rates each pose different risks of injury, and therefore, they must be considered separately.[5,38,62] Additional injury from surgery or chemotherapy or from a prior course of radiotherapy also must be considered, as must the confounding effects of injury to lung tissue from coexisting cardiopulmonary disease and from the underlying malignancy.

Infections and immunologic reactions are also important. The clinical endpoints used to define a case of radiation pneumonitis vary as well, because the severity of the lung injury spans a wide spectrum of diagnostic signs and clinical symptoms. Moreover, with improvements in imaging and three-dimensional dose-calculation algorithms, there is a concerted effort within the radiation oncology community to better define dose–volume determinants for a variety of organ radiation-related toxicities. Known as QUANTEC (quantitative analysis of normal tissue effects in the clinic), this broad compilation of data shows that there are strong correlations of pneumonitis risk with radiation dose, fractionation, and tissue volume.[63] Given the heterogeneity of clinical circumstances and biologic data in general, it is not surprising that the medical literature that defines the risks for radiation pneumonitis and fibrosis is extremely complex and often difficult to interpret.

■ WHOLE-LUNG IRRADIATION

A good starting point for considering lung tolerance is analysis of the effects of irradiating the entire lung. This construct has direct clinical relevance because there are several circumstances in which the entire lung is irradiated. These include total-body irradiation (TBI) for bone marrow or hematologic stem cell transplantation, hemibody irradiation for palliation of widespread metastatic disease, and whole-lung irradiation given electively or therapeutically for relatively radiosensitive tumors, such as Wilms tumor, Ewing sarcoma, or Hodgkin lymphoma. These are often circumstances in which chemotherapy is administered as well.

Published experience from the Princess Margaret Hospital in Toronto[12,64–67] provides some of the best data regarding whole-lung tolerance. Investigators from that institution have an extensive experience with delivering upper hemibody irradiation to different doses and varying fractionation patterns. They reported in 1978 on a cohort of 245 patients, most with metastatic solid tumors, who received single-fraction, upper hemibody irradiation at dose rates of 0.3 to 0.8 Gy/min to doses of up to 10 Gy.[64] The actuarial incidence of acute radiation pneumonitis, defined as the sudden onset of cough, dyspnea, and opacities visible on chest radiographs at about 16 weeks following treatment, was strikingly dose dependent

TABLE 59-2 Actuarial Incidence of Radiation Pneumonitis after Single-fraction Whole-lung Irradiation

Uncorrected Dose	Patients	Pneumonitis (%)
<6 Gy	49	2.7
6 Gy	24	17.5
8 Gy	149	35.6
10 Gy	23	83.9

Note: Doses are not corrected for heterogeneity in tissue density.

(Table 59-2). The doses shown in Table 59-2 were not corrected for heterogeneity in density.[12] When doses are corrected, resulting in an upward estimation of the doses actually received by the lungs, analysis yielded the sigmoid-shaped curve shown in Figure 59-7.

Using heterogeneity-corrected data, the incidence of pneumonitis is estimated to be negligible for single doses less than about 7.5 Gy. Other published data regarding upper hemibody single-fraction irradiation are in general agreement with these findings.

Careful analysis suggests that the single-fraction data might predict an unacceptable risk for pneumonitis when single-fraction TBI is utilized in the setting of bone marrow transplantation (BMT). The most important treatment factor making single-fraction TBI in the range of 8 to 10 Gy (uncorrected for heterogeneity) tolerable is that treatments generally are given at a low-dose rate (less than or equal to 0.1 Gy/min) over 1 to 2 hours.[38,68] In Seattle, where hundreds of patients with leukemia have undergone BMT after TBI, using single fractions of 10 Gy (uncorrected) delivered at dose rates on the order of 0.08 Gy/min, the incidence of pneumonitis is roughly 25%. Review of transplant-related single-fraction TBI with variable dose rates shows incidences of clinical lung injury varying from 25% to 70%.[65,69–71]

Studies in mice show that the toxicities of TBI can be improved further by fractionating the irradiation, as well as by delivering radiation at a low-dose rate. This concept is supported by a randomized clinical trial comparing low-dose rate, single-fraction TBI (10 Gy)

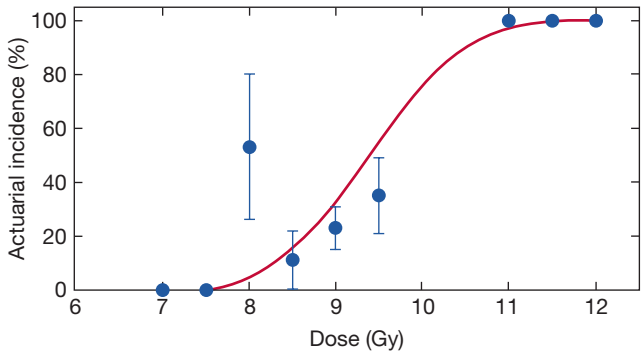

Figure 59-7 Incidence of radiation pneumonitis in patients receiving single-dose, whole-lung irradiation at dose rates of 0.3 to 0.8 Gy/min. Unlike most doses given in the text, doses on this figure *are* corrected for heterogeneity in density. The effect of this correction can be seen by comparing these data with those in Table 59-1, which were derived from an earlier analysis by the same group and are presented using uncorrected doses. *(Reproduced with permission from Van Dyk J, Keane TJ, Kan S, et al. Radiation pneumonitis following large single dose irradiation: a re-evaluation based on absolute dose to lung. Int J Radiat Oncol Biol Phys. 1981;7(4):461–467.)*

with low-dose rate, fractionated TBI (12 Gy in six fractions over three days) for patients with acute myelogenous leukemia in first remission. A significant improvement in event-free survival was noted with fractionation, mainly because of an improvement in early mortality.[68] Interstitial pneumonitis was decreased from 26% to 15% with fractionation. Other studies have corroborated a reduced incidence of pneumonitis to less than 20% without increasing the rate of tumor recurrence using fractionated TBI.[72–74] Within a range of 1.5 to 2 Gy per fraction given once or twice daily, there is no significant increase in pneumonitis risk using doses up to 15 Gy.[72,75,76] Nevertheless, total dose delivered to the lung is a key determinant of pneumonitis risk.[65,77] In addition, at many transplant centers it has become common practice to utilize lung transmission blocks to attenuate the lung dose and thereby reduce the risk of pneumonitis, in part by compensating for the heterogeneity in tissue density due to the air within the lungs.[71]

Another radiobiologic approach to reduce the incidence of interstitial pneumonitis has been to lower the dose rate at which the radiation is delivered—in essence, a kind of continuous fractionation. While efficacious,[78,79] treatment times of 2 to 3 hours are impractical and poorly tolerated by patients. Within the context of fractionated TBI schemes, instantaneous dose rates of 0.05 to 0.18 Gy/min generally have been employed due to practical considerations. Whether or not higher instantaneous dose rates are detrimental in the context of fractionated TBI remains unclear. One small study comparing dose rates of 0.075 versus 0.15 Gy/min for TBI prescribed to 12 Gy in six fractions reported pneumonitis risks of 13% and 43%, respectively, for these dose rates, although there were many confounding covariates.[80]

Pneumonitis in the BMT setting has a multifactorial etiology, reflecting not only the effects of radiation, but also the effects of chemotherapy, graft-versus-host disease (GVH), lung injury from tumor, opportunistic infections, and other risk factors.[69,71,81] Cyclophosphamide is almost universally given with TBI. The addition of other drugs is based on institutional treatment policies; many of these anticancer drugs are known to injure the lung.[41,42] BMT conditioning regimens that do not use TBI (which often use high-dose busulfan in place of radiation) in fact have rates of interstitial pneumonitis comparable to regimens that include TBI. The presence of GVH is also important, not only because GVH causes lung injury directly, but also because the drugs used to control GVH injure the lung. Perhaps, for this reason, T-cell-depleted transplants, which produce less GVH, tend to have lower risk for pneumonitis.[82]

Whole-lung irradiation has been used in the treatment of widespread lung metastases. In two published series, a combined total of 70 patients with osteosarcoma who received elective whole-lung irradiation to prevent pulmonary metastases (which is not currently a standard practice pattern) received 15 to 17.5 Gy in 10 fractions. None of these patients developed pneumonitis.[19] Similarly, in a series of 40 patients who received 20 to 25 Gy of thoracic irradiation in 1.5-Gy fractions to treat pulmonary metastasis, no cases of pneumonitis were reported.[19] This and other clinical experience with fractionated whole-lung irradiation in the nontransplant setting and in the absence of chemotherapy indicate that the following dose schemes should have a relatively low risk (<5%) for radiation pneumonitis: 25 Gy given in 20 fractions over 4 weeks or 20 Gy given in 10 fractions over 2 weeks. (All doses noted are without heterogeneity corrections.)

Historically, radiotherapy for Hodgkin disease has used whole-lung treatment in situations in which there is massive mediastinal adenopathy, hilar adenopathy, or overt pulmonary disease treated with chemotherapy. Risks of symptomatic pneumonitis ranging from 7% to 35% have been reported, with the risk highly dependent on the total radiation dose and the fractionation pattern.[19,83] When the whole lung is to be irradiated, available data suggest that the lungs should be treated through transmission blocks, rather than using open fields. This reduces both the total dose and the dose per fraction to the lungs,

thereby reducing the risk of symptomatic pneumonitis to 4% to 7% over a broad range of total lung doses of 10 to 20 Gy.

There is a suggestion that the addition of mediastinal irradiation to fractionated whole-lung radiotherapy increases the risk of pneumonitis. To many oncologists, the risk of radiation pneumonitis from such a treatment seems too great. As a result, such patients are often treated primarily with chemotherapy (often with adjuvant low-dose radiotherapy), even though these regimens also produce significant risks for lung toxicity. In the setting of pulmonary metastases, the addition of low-dose radiotherapy to the whole lung after chemotherapy is controversial. There are few clinical data to quantify risks and benefits, but doses of 10 to 16 Gy, given in 0.7- to 1.5-Gy fractions, are associated with only modest risk.[19,83]

Lung radiotherapy using 12 to 14 Gy for pulmonary metastases in pediatric patients with Wilms tumor (who also receive sequential doxorubicin and actinomycin D) is associated with a 10% incidence of pneumonitis.[84] Long-term follow-up in such children also shows restrictive lung disease, with total lung and vital capacities approximately 70% of the predicted values. In children receiving thoracic irradiation, inhibition of normal growth and development of the lung parenchyma and bones as a result of radiotherapy also produces significant morbidity. The effects of radiation on growth and development and the radiosensitivity of growing tissues raise special concerns in the treatment of pediatric patients.[5]

■ PARTIAL-LUNG IRRADIATION

The role of partial-lung irradiation in the treatment of various malignancies and assessment of its risks are considered below.

Assessment of Risk

Estimating the risks of radiation pneumopathy for individual patients receiving fractionated external beam radiotherapy is a daunting task, because so many confounding factors must be considered. With lung cancer, the tumor size and location influence the volume of adjacent normal lung that must be irradiated. The volume irradiated should determine the number of capillary–alveolar units destroyed and, therefore, should influence the risk of symptomatic radiation pneumonitis and fibrosis.[29] This qualitative prediction is borne out by clinical experience, but quantifying the risks is not straightforward. The lung region irradiated is also important, because the upper lung regions contribute less to gas exchange than do the lower regions. Treatment-related factors such as total dose, dose per fraction, and overall treatment time are also important, as are the other confounding factors described in the preceding sections.[32]

Patients begin radiotherapy with a wide range of pulmonary function, reflecting age, smoking history, and the presence or absence of underlying cardiopulmonary disease. Because regional pulmonary fibrosis may be partially compensated by functional lung parenchyma, pretreatment lung status influences the severity of symptoms. The clinical endpoints used to measure lung injury are quite varied and include symptom and quality-of-life scores; radiographic changes, such as changes in CT-assessed lung density, pneumonitis, and fibrosis; and other objective measures.[32]

Pulmonary function tests are global measure of organ function that correlate imperfectly with symptomatology after partial-lung irradiation. A large tumor mass may cause localized obstructive or restrictive changes in lung function or phrenic nerve dysfunction, any of which may improve or worsen as the tumor shrinks with treatment. These factors add to the variability produced by patient-to-patient differences in the treatment volume, dose, fractionation, etc. Thus, radiotherapy-induced changes in global lung function with regard to gas exchange, physiologic dead space, shunting, ventilation–perfusion mismatch, and respiratory surface area, as measured by arterial blood gases, spirometry, and $D_{LCO,}$ are complex and highly individualized.

Several clinical studies have attempted to predict radiotherapy-induced changes in FEV_1 by superimposing radiation treatment portals on quantitative ventilation and perfusion scans.[85–88] Unfortunately, the simple notion that the proportion of lung irradiated should match the drop in FEV_1, akin to the highly useful preoperative assessment of predicted postresection lung function, has not been verified. In fact, a report from the Massachusetts General Hospital[88] examining global and regional pulmonary function in patients with lung cancer showed improvement in pulmonary function in 52% of patients and a mild decline in 37%; the decline was predicted from changes in radionuclide scans in only 11%. Similar observations have been made in nonoperative lung cancer patients.[86] Whereas the mean pretreatment FEV_1 of 1.71 ± 0.67 L declined to an average of 1.15 ± 0.43 L after treatment, the change was not consistent: Posttreatment FEV_1 was improved in 19% of the patients, unchanged in 53%, mildly decreased in 22%, and decreased below predicted levels in 5%. The technique of superimposing radiation treatment portals over quantitative lung perfusion scans is, therefore, of limited utility in predicting pneumonitis in individual patients. In fact, it has been suggested that the diffusing capacity is a more sensitive indicator of tolerance to radiotherapy.[85]

Unfortunately, there are no firm tests or data to guide the development of tolerable regimens of radiotherapy for patients with borderline lung function, except that we know the treatment volumes should be minimized. If the initial FEV_1 is below 1.0 L or D_{LCO} is less than 50% of predicted, large-volume radiotherapy (e.g., elective nodal irradiation for lung cancer) may well be too hazardous. Despite its limitations, quantitative perfusion scanning in selected patients may give a worst-case scenario and help the radiation oncologist decide on dose and treatment volume.

The quantitative relationship between the volume of lung irradiated and toxicity has only recently been studied in any systematic fashion. An interesting set of mouse data published by investigators at MD Anderson showed a clear shift in dose–response curves for changes in respiratory rate and pulmonary death as a function of the volume of lung irradiated.[35] As expected, the region of the lung irradiated was important: Effects were more pronounced when the well-perfused base of the lung was irradiated, rather than the less well-perfused apex. The response to lung irradiation was quite heterogeneous, even within mice of the same age and sex, from a single highly inbred mouse strain, maintained in microbiologic isolation under rigorously controlled environmental conditions. The morbidity and symptomatology observed in the individual mice was not always reflected in the histology findings found after necropsy.

In patients, radiation dose–volume histogram analyses derived from detailed three-dimensional treatment evaluations and applied to an empirical normal tissue complication model show only a fair correlation between volume and risk of complications.[61,89] Nevertheless, it is common practice to evaluate dosimetric parameters, such as V_{dose} or mean lung dose (MLD), in an effort to predict the risk of pneumonitis prospectively. The V_{dose} (i.e., $V_{20\ Gy}$ or $V_{30\ Gy}$) parameter is defined as the percentage of total volume receiving greater than the threshold dose (i.e., 20 Gy or 30 Gy, respectively). The MLD is defined as the average dose delivered to the whole lungs. These simple metrics predict pulmonary risk based on a single-radiation dose point, used as a mean or threshold.

More complex dosimetric models have also been derived that fit observed normal tissue complication probabilities (NTCPs) to functions that include more comprehensive evaluations of low- and high-dose partial-volume organ exposures using standard radiobiologic models. These approaches may have broader applicability across various radiation treatment techniques, but they are infrequently used because of their complexity. Recently, a multidisciplinary effort, the QUANTEC (see above), was undertaken to summarize the published three-dimensional dose–volume/toxicity

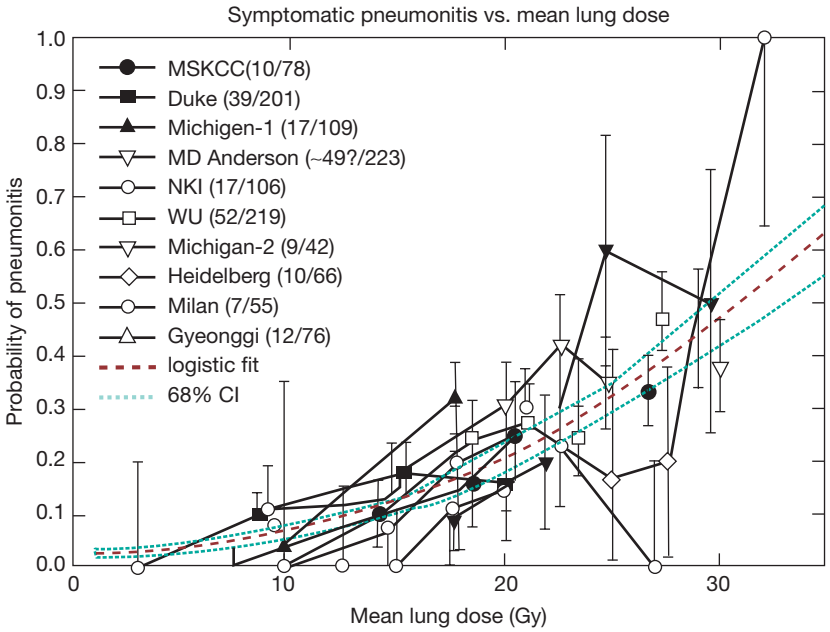

Figure 59-8 Probability of symptomatic pneumonitis versus mean lung dose; data from 10 clinical studies with *dashed line in red* fit by logistic Lyman–Kutcher–Burman dose–volume histogram model with one standard deviation shown in *light blue curves*. *(Reproduced with permission from Marks LB, Bentzen SM, Deasy JO, et al. Radiation dose-volume effects in the lung. Int J Radiat Oncol Biol Phys. 1;76(3 Suppl):S70–S76.)*

data in the literature, review NTCP modeling, and provide practical guidance for radiotherapy treatment planning.[63] From collected data in the QUANTEC effort, the risk of radiation pneumonitis is less than 20% when the MLD is less than approximately 20 Gy, when V_{20} <30 to 35 Gy, or when V_5 <60%. These predicted risks apply to patients receiving conventional fractionation of 1.8 to 2 Gy per day and are less relevant when the dose per day is greater than 2 Gy.

For hypofractionated treatments, such as SBRT, where doses in excess of 10 Gy per day are given in one to five fractions, the incidence of radiation pneumonitis is significantly lower.[90] This is primarily because the target volume for this type of treatment is quite small. While the risk of symptomatic pneumonitis does seem to follow a radiation dose-volume relationship similar to that seen in conventionally fractionated treatment, specific dose threshold guidelines have not yet been definitively elucidated. In one large series, the risk of grade 2 or greater pneumonitis was 17% when the MLD was >4 Gy, compared with 4% for lower values, and this risk was 16% when the V_{20} was >4% compared with 4% when V_{20} was <4%.[90] The American Association of Physicists in Medicine (AAPM) Task Group 101 report included a first approximation of tissue tolerance doses for SBRT.[91] For lung, they recommended 12.4 Gy to no more than 10 cc, and 11.6 Gy to no more than 15 cc of lung for three-fraction SBRT, and no more than 13.5 and 12.5 Gy to 10 and 15 cc for five-fraction SBRT.

In patients undergoing pneumonectomy for mesothelioma who will then require radiotherapy, dosimetric parameters to avoid pneumonitis of the remaining lung are even more stringent: V_{20} should be below 4% to 10% and MLD should be below 8 Gy.[92] QUANTEC has reviewed over 70 reports on dose–volume parameters and the risk of pneumonitis, selecting the largest series for use in performing a meta-analysis of complication probability models.[61] Such clinical data is challenging to interpret, owing to a host of confounding covariates. However, there are clear trends showing increasing pneumonitis risk with increasing radiation dose. Figure 59-8 shows the risk of symptomatic pulmonary complications as a function of MLD from 10 studies.

Investigators at Duke[93] and the Netherlands Cancer Institute[94,95] have attempted to refine the correlation of dose–volume histograms with toxicity by factoring out nonfunctioning lung using lung perfusion scans. In patients with lung cancer, particularly those with chronic obstructive pulmonary disease (COPD), areas of hypoperfusion separate from tumor are seen frequently; irradiation of such irreversibly hypoperfused lung may not contribute additional toxicity. Such a "functional" dose–volume histogram analysis has not been proven to be of clinical value, but it does provide an interesting analytical framework. The existing data show a direct correlation between regional changes in ventilation, perfusion, or CT density with increasing radiation dose to that region (Fig. 59-9).[96]

Perhaps the most accurate and clinically relevant approach to estimating risks for symptomatic radiation pneumopathy is to study a large group of patients who receive a relatively standard dose and fractionation scheme for a specific disease. As discussed earlier, the variability of the treatment volumes for individual patients with diseases such as lung cancer, as well as the frequent coexistence of other lung diseases, especially COPD from tobacco use, makes this a difficult task.

More complex prediction models that factor in baseline $D_{L_{CO}}$, serum cytokine levels, or tumor locations in upper versus low lobes have yielded variable improvements in prognostication. Similar data regarding the incidence of radiation fibrosis are quite difficult to obtain, largely because of the wide spectrum of severity in symptomatology. Clinical experience suggests that radiographic fibrosis is rare below 20 Gy and common above 40 to 50 Gy, with symptoms of respiratory insufficiency dependent on the volume of injured lung and the presence of coexisting lung disease.

Lung Cancer: Local Tumor Boosting

In the treatment of lung (and, perhaps, esophageal) cancer, it is quite standard to boost the primary tumor and a small volume of the lung to total cumulative doses above 50 Gy, commonly to 60 to 70 Gy. Clinical data, notably the dose-escalation lung cancer trials of the

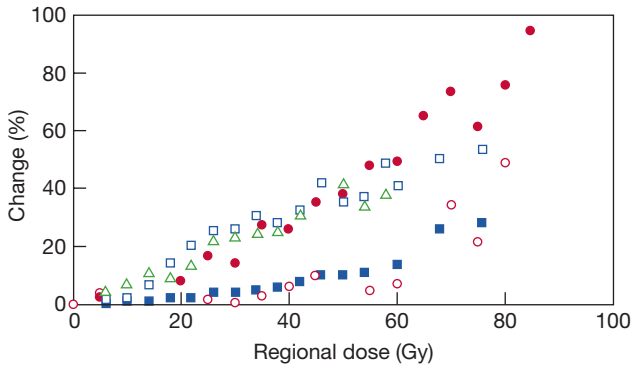

Figure 59-9 Regional changes in ventilation, perfusion, and computed tomography (CT) density from partial lung radiotherapy as a function of regional radiation dose: data from Duke University (Duke) and Netherlands Cancer Institute (NKI). Symbols in graph represent: (●) reduction in perfusion-Duke; (¡) increase in CT density-Duke; (■) change in air-filled fraction-NK; (□) reduction in perfusion-NKI; and (Δ) reduction in ventilation-NKI. *(Reproduced with permission from Marks LB, Yu X, Vujaskovic Z, et al. Radiation-induced lung injury. Semin Radiat Oncol. 2003;13(3):333–345.)*

Radiation Therapy Oncology Group, suggest that increasing doses to small volumes from approximately 50 to approximately 65 Gy is not associated with a significant increase in lung toxicity,[97] probably because the number of nonfunctional alveoli is not increased by this increase in dose. In most series of patients receiving radical thoracic radiotherapy, the risk of symptomatic radiation pneumonitis is usually about 10% to 20%, and some degree of radiographic fibrosis is almost universal.

Breast Cancer

Breast cancer radiotherapy, whether after lumpectomy or after mastectomy, typically uses opposed tangential beams, as depicted in Figure 59-6, which irradiate a volume of lung anterolateral to a plane demarcating the midchest to the lateral axillary line to doses of 45 to 50 Gy in 23 to 25 fractions. The volume of the ipsilateral lung irradiated can be estimated for individual patients from the simulator films and is typically about 20% of the lung volume. If the supraclavicular and axillary nodes are irradiated as well, the anterior treatment portals are matched to the tangential chest wall fields. As a result, the apex of the lung (roughly another 10%–15% of ipsilateral lung volume) is also irradiated. The incidence of symptomatic pneumonitis from tangential fields alone is roughly 0.5%, with some series documenting an increased risk with increasing lung volume.[98,99] It is desirable to keep the irradiated volume below approximately 25%, if possible. Nodal irradiation increases the risk for pneumonitis to 0.5% to 1.5%. Risk further increases to as high as 9% when chemotherapy is given concurrently. The risk of pneumonitis is much lower when chemotherapy and radiation are given sequentially.[98]

Early-stage Hodgkin Disease

Radiotherapy for early-stage Hodgkin lymphoma, using moderate doses (40–45 Gy in 1.5–2 Gy fractions) and large volumes to treat lymph node-bearing regions, has represented a remarkable success story in oncology.[5,100] Because it now has produced very high cure rates in a young patient population, allowing for extended follow-up over several decades, this experience also has produced considerable data regarding late radiation toxicities.

With the protocols employed, the chest is irradiated with treatment portals, generically called "mantle fields," as depicted in Figure 59-10. With modern radiation techniques that use sequential shrinking fields, the incidence of symptomatic radiation pneumonitis is 3% to 4%. The risk of pneumonitis increases to roughly 10% when full doses of both chemotherapy and radiation to a mantle field are given sequentially, even when bleomycin is not part of the regimen.

Studies on pulmonary function in patients with Hodgkin disease suggest that a transient reduction in FEV_1 and vital capacity, on the order of 5% to 20%, occurs 3 to 9 months after radiotherapy, corresponding to the period of pneumonitis. There tends to be some recovery by about 1 year. Late follow-up of pulmonary function in patients with Hodgkin disease[100] further suggests that mantle field radiotherapy is associated with small, and, for the most part, clinically insignificant, reductions in vital capacity and D_{LCO}. These decreases in pulmonary function tests were associated with minor, if any, symptomatology, even for treatment regimens that included sequential chemotherapy with doxorubicin or bleomycin.

Primary radiotherapy for Hodgkin disease is now rarely practiced. Decades of follow-up in patients cured of their lymphomas show a steady increase in secondary cancers as well as cardiac complications. As a consequence, clinical trials have shown improved disease-free survival over 5 to 10 years with primary chemotherapy. In this setting in which lower-dose (20–30 Gy) involved-field radiotherapy is often delivered after chemotherapy, the incidence of clinical pneumonitis is quite low, although small changes in spirometry and diffusion capacity may be detected in up to 50% of the patients. Longer-term follow-up of toxicities from combined-modality therapy in Hodgkin disease is in progress.

PROGNOSTIC ASSAYS AND FUTURE TRENDS

Our understandings of the molecular and cellular mechanisms of radiation injury in general, and radiation pneumonitis in particular, are still evolving and improving. We hope that increased understanding of these processes will lead to new approaches for avoiding radiation injury to the lung, for modulating the development of injury or ameliorating its symptomatology, and for identifying patients at unusually high risk of injury. Several different lines of investigation leading to these ends are being pursued.

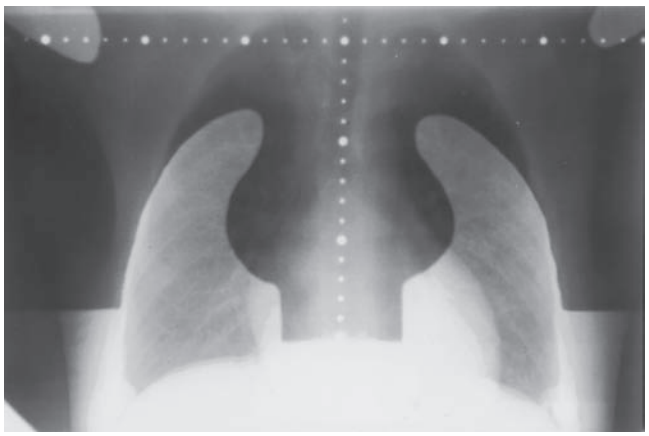
Innovations in radiation therapy techniques are under active investigation. These include modifications in the dose rates, fractionation patterns, and radiation dose distributions used in radiation therapy regimens for specific diseases. Improvements in diagnostic imaging that allow better identification of tumor-involved regions, computerized treatment planning and dosimetry systems, improved patient immobilization systems, the use of multiple "noncoplanar, noncoaxial" radiation portals (three-dimensional conformal radiotherapy), and the use of multiple radiation fields that have variable rather than uniform spatial intensities (intensity-modulated radiotherapy) are now standard techniques in the radiotherapy clinic.

Proton radiotherapy takes advantage of the "Bragg peak," in which the radiation dose is deposited at a well-defined maximum depth that depends on the proton energy to produce very precise, highly localized dose distributions. This type of charged-particle radiation technique is being explored in the hope that the approach will enable the radiotherapist to increase the dose to the tumor while decreasing the volume of surrounding normal tissue irradiated to high doses.

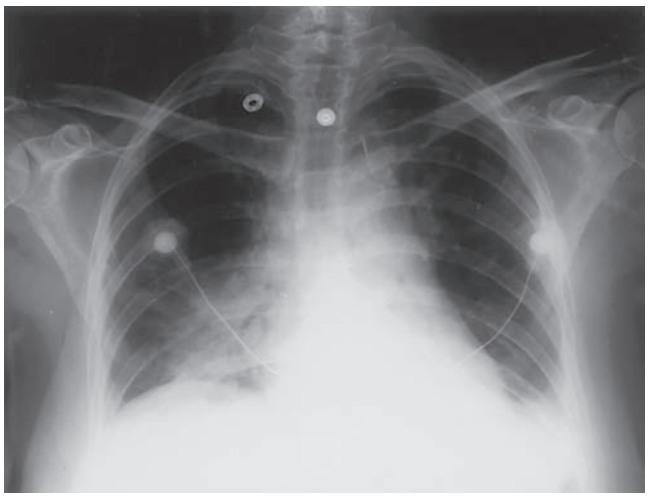
Four-dimensional treatment planning to take into account respiratory motion, along with deep inspiration breath-hold methods, are also being examined in an effort to better limit the volume of normal tissue exposed to radiotherapy. In addition, refinements in combined-modality therapy may also lead to the development of regimens that increase the therapeutic ratio for the treatment of thoracic tumors and, therefore, decrease the risk and severity of radiation pneumonitis after effective antineoplastic therapy.

The risk of developing radiation pneumonitis varies dramatically in different patients. To a certain extent, increased risk can be predicted from identifiable risk factors, such as prior treatment with thoracic radiotherapy, treatment with pneumotoxic drugs, or the existence of lung disease from other causes. However, even when the known risk factors are considered, the risk of symptomatic injury after radiotherapy varies dramatically from patient to patient. Studies with mice indicate that genetic factors contribute to individual variability in the development of late radiation injury in the lung.[34] This raises the possibility that pretreatment measurements of genetic or proteomic polymorphisms or of enzyme or cytokine levels in the lung, analyses of changes in cytokine levels during treatment or of tissue response to cytokines, or some other relevant measure may be useful in predicting patients at high risk for the development for pneumotoxicity.[36]

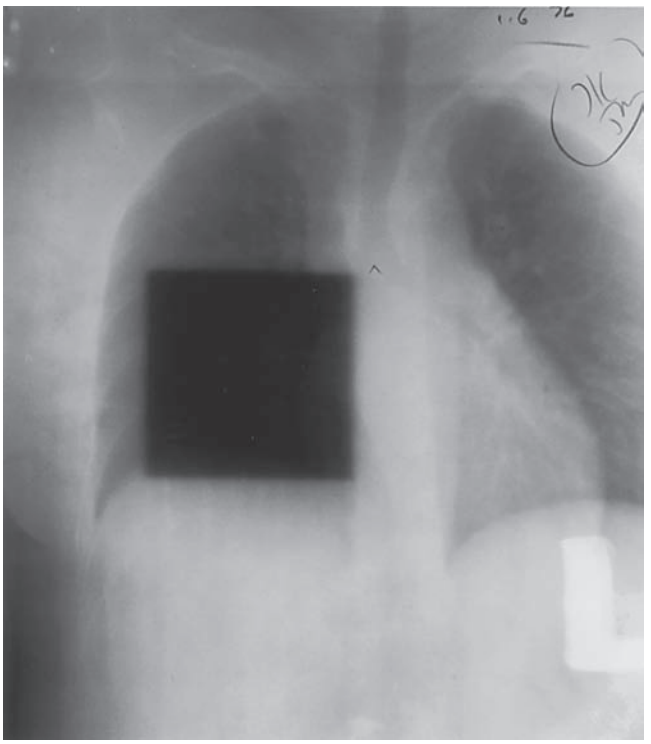
Assays of surfactant levels shortly after irradiation predict radiation pneumonitis in some rodent studies but have not predicted radiation pneumonitis in individual patients in the clinical trials performed to date. TGF-β1, a cytokine that mediates fibrosis, is currently the subject of intense investigation. Serum levels of TGF-β1 have been reported to predict pulmonary toxicity after high-dose chemotherapy for breast cancer[101] and may also predict for breast fibrosis from radiotherapy,[102] but its application to predicting toxicities after radiotherapy for lung cancer has been tenuous and controversial due to the fact that TGF-β1 correlates with adverse dosimetric parameters, thus eliminating any independent prognostic importance as a biomarker.[32,103–106] Nevertheless, there is laboratory evidence that antagonists of TGF-β1 receptors may someday be useful in the clinic.[107]



A



C



B

Figure 59-10 **A.** Shows the port film for a "mantle field" used for treatment of a patient with Hodgkin lymphoma. Note the effect of the lung blocks in reducing the dose to large volumes of the lung. (In this example, the whole heart/pericardium is not being treated.) A 30-year-old female underwent mantle field and subdiaphragmatic radiotherapy (not shown) for early-stage Hodgkin lymphoma. Ten years later, a recurrence in the right lower lobe and mediastinum was treated with MOPP-type chemotherapy and low-dose involved-field radiotherapy. The treatment field to the right lung, shown in (**B**), was irradiated to 15 Gy in 10 fractions, in addition to the 40 Gy given to the mantle field 10 years previous. Radiation pneumonitis occurred 6 months later, as seen in (**C**). This responded to prednisone. Twenty years later, the patient remains well and free of recurrence.

Assays of other cytokines such as interleukins, IL-6 and IL-1α are being explored clinically in studies that suggest high positive predictive values for pneumonitis.[108] Similarly, analyses of the intrinsic radiosensitivity in vitro of fibroblasts from patient biopsies have been suggested as a possible approach to measuring the general risks of individual patients for radiation injury. Such assays have proved useful in planning treatments for patients with the genetic disease ataxia telangiectasia (AT), which leads to unusual radiosensitivity. One intriguing study of AT polymorphisms in a cohort of lung cancer patients treated with chemoradiation does suggest increased susceptibility to radiation pneumonitis with certain genotypes.[109] Prognostic assays predicting high or low risks for radiation pneumopathy could be used to guide clinical decision making and plan optimal therapy for individual patients.

Insights into the physiology underlying the development of radiation pneumopathy may also lead to the development of regimens that prevent the development of this disease or ameliorate its symptomology.

The "radioprotector," amifostine (Ethyol, WR2721) has been examined extensively because of its widespread distribution into most normal tissues, limited distribution into tumors, and its activity as a free radical scavenger, which results in a decrease in radiation cytotoxicity. Amifostine has been of variable benefit in reducing mucositis or xerostomia in patients with head and neck cancer undergoing radiotherapy (without apparent effect on tumor control). This has led to analogous clinical investigations of amifostine to prevent pneumonitis.

Several small phase III trials in lung cancer suggested a benefit to amifostine during thoracic radiotherapy, with a decrease not only in pneumonitis, but also in radiation esophagitis as well.[110] A large multi-institutional trial sponsored by the Radiation Therapy Oncology Group involving 242 patients, however, failed to document a difference in pneumonitis rates with amifostine.[111] The trial has been criticized for its twice a day fractionation scheme, in which amifostine was administered with only one fraction each day, the unusually high patient dropout rate of 19% due to toxicity, and the fact that 52% of patients did not receive their intended dose of amifostine.

The development of radiation pneumopathy has not been appreciably altered by the use of prophylactic steroids, antibiotics, or anticoagulants. The use of gamma interferon in conjunction with radiation actually worsened pneumonitis in recent clinical trials.[112] Beta interferon is under clinical investigation. Nutritional factors and neutraceuticals merit further consideration, as subclinical vitamin

A deficiency has been shown to increase radiation injury in the rat lung[113] and genistein decreases effects in irradiated mouse lungs.[114]

Numerous other approaches are being investigated in laboratory studies, including the use of captopril, superoxide dismutase analogs, lovastatin, pentoxifylline, IL-11, and inhibitors of TGF-β.[9,115] Captopril, which is an angiotensin-converting enzyme (ACE) inhibitor used clinically for the treatment of hypertension and heart failure, is especially promising in laboratory studies. As a thiol compound, captopril can act as a free radical scavenger. It can also form copper complexes, which have superoxide dismutase-like activity. Moreover, in animal studies, captopril has vascular effects and can inhibit platelet aggregation, perhaps mediated by IL-2 release, which ameliorate radiation injury to pulmonary endothelium and decrease pulmonary fibrosis.[116,117]

One retrospective clinical review failed to demonstrate a benefit for ACE inhibitors in general, but it did not specifically evaluate captopril and may have been further confounded by including older radiation techniques.[118] Two clinical series of lung cancer patients treated with chemoradiation have shown a significant decrease in pneumonitis associated with the incidental use of ACE inhibitors.[119,120] Experiments in a mouse model suggest that captopril administration subsequent to radiation exposure may mitigate radiation lung injury.[121] In another mouse study, another experimental agent having superoxide dismutase activity, EUK-207, mitigated lung injury following thoracic irradiation.[122]

Lovastatin, a cholesterol-lowering drug that inhibits 3HMG coenzyme A reductase and also has potent anti-inflammatory effects, improved survival and reduced pulmonary infiltration by macrophages and lymphocytes in a murine model of whole-lung irradiation.[123] This approach has not yet been investigated in the clinic.

Pentoxifylline, with or without vitamin E, has been shown to reduce radiation-induced breast or soft tissue fibrosis[124–126] and has been proposed as a potential agent for mitigating pulmonary fibrosis. A number of promising compounds, some in clinical use for other indications, have been proposed for clinical testing as agents for mitigating radiation-induced lung injuries.

All attempts to modulate the development of radiation pneumonitis must be pursued cautiously, however, because these therapeutic strategies are based on biologic epiphenomena and rely on an incomplete understanding of the mechanisms by which radiation pneumopathies are produced. In testing such interventions, as with any alteration of cancer therapy, it will be critical to consider the effects of the intervention on the response of the malignancy, as well as its effects on normal tissue injury; the intervention will be of value only if it increases the therapeutic ratio.

CHAPTER 60

Pulmonary Manifestations of the Collagen Vascular Diseases

Gregory P. Cosgrove
Marvin I. Schwarz

Pleuropulmonary involvement associated with the collagen vascular diseases occurs frequently. All the structures within the respiratory tract may be affected, either separately or in combination. This includes the respiratory muscles, the pleura, the conducting airways, and the lung parenchyma—the small airways, the interstitium, or the pulmonary vessels. Moreover, these patients experience an increased incidence of community-acquired pneumonia as well as pneumonia associated with the immunosuppressive drugs employed for treatment. Anti–tumor necrosis factor-α (anti–TNF-α) agents increase the risk for infections, particularly mycobacterial pathogens, both tuberculous and nontuberculous. Cytotoxic drugs, particularly methotrexate and gold, can also induce various noninfectious interstitial reactions, which are often difficult to distinguish from a primary interstitial complication of a collagen vascular disease.[1]

Although most pulmonary complications appear in an established case of a collagen vascular disease, lung disease may precede the more typical systemic manifestations.[2] For example, in both rheumatoid arthritis and polymyositis–dermatomyositis, the interstitial lung disease may precede the joint and muscle disease for several months to several years. This is also the case, but to a lesser extent, for scleroderma. In one study, 19% of patients initially diagnosed with idiopathic pulmonary fibrosis developed a collagen vascular disease over a period of 1 to 11 years, primarily rheumatoid arthritis or polymyositis–dermatomyositis. These individuals were younger and more likely to be women. Pleuritis with or without effusion sometimes heralds the onset of rheumatoid arthritis or systemic lupus erythematosus (SLE). An acute immunologic pneumonitis or diffuse alveolar hemorrhage has been reported to be the signal event in SLE, polymyositis–dermatomyositis, and mixed connective-tissue disease.

The incidence of the pleuropulmonary complications (Table 60-1) is variable. Interstitial lung disease is reported to be as high as 60% in premortem and 100% in postmortem studies in scleroderma. In contrast, interstitial lung disease in ankylosing spondylitis is an uncommon event. In general, the incidence of interstitial lung disease is increasing for most of the collagen vascular diseases, primarily due to increased recognition and more sensitive screening techniques such as high-resolution computed tomography and bronchoalveolar lavage, which will detect abnormalities in both asymptomatic as well as symptomatic patients with normal chest radiographs. Prior studies assessing the incidence of disease relied on physiologic testing, which included spirometry, lung volumes, and diffusing capacity but did not measure rest and exercise gas exchange, which is the most sensitive physiologic marker of interstitial lung disease and pulmonary vascular disease.

PULMONARY PARENCHYMAL, VASCULAR, AND AIRWAY PATHOLOGY IN THE COLLAGEN VASCULAR DISEASES

The spectrum of pathologic changes in the lung parenchyma, pulmonary vasculature, and airways are considered below, prior to a discussion of clinical findings in individual collagen vascular diseases.

INTERSTITIAL LUNG DISEASE

Interstitial involvement is a common manifestation of the collagen vascular disorders, presenting with a number of different

TABLE 60-1 Pulmonary Complications of the Collagen Vascular Diseases

	Relative Frequency (0–4)						
Manifestation	SLE	RA	SS	PM-DM	MCTD	AS	Sjögren's
Respiratory muscle dysfunction	2	1	0	2	1	0	0

SLE, systemic lupus erythematosus; RA, rheumatoid arthritis; SS, systemic sclerosis (scleroderma); PM-DM, polymyositis-dermatomyositis; MCTD, mixed connective-tissue disease; AS, ankylosing spondylitis; Sjögren's, Sjögren syndrome; DAH, diffuse alveolar hemorrhage.

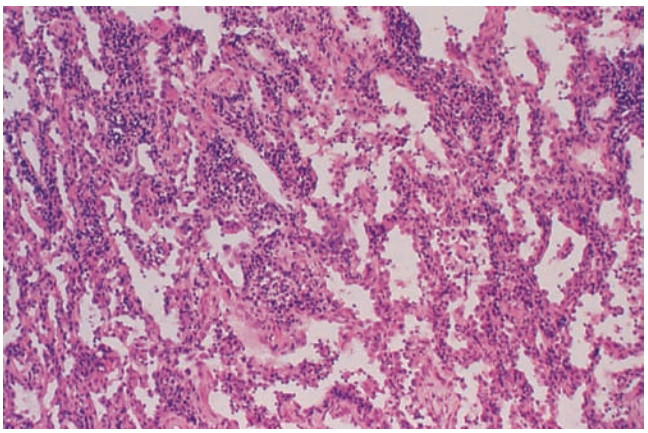

Figure 60-1 Nonspecific interstitial pneumonitis (NSIP) in rheumatoid arthritis. There is a lymphoplasmacytic infiltration of the interstitial compartment with minimal collagen deposition.

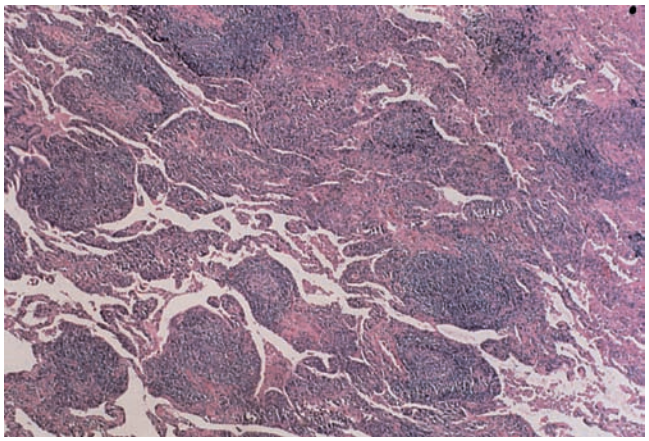

Figure 60-2 Lymphocytic interstitial pneumonitis in a patient with primary Sjögren syndrome. There is a dense lymphocytic infiltrate, broadening the interstitium and lymphoid follicles.

inflammatory responses within the lung. Each response may represent a different form of lung injury or response to injury. Defining which response is underlying a patient's interstitial lung disease has important prognostic and therapeutic significance.

Diffuse alveolar damage (DAD) is the underlying histologic lesion that is also seen in the acute respiratory distress syndrome, idiopathic acute interstitial pneumonitis (Hamman–Rich syndrome), severe viral pneumonias, and cytotoxicity from some drugs. This damage consists of a mixed interstitial inflammatory infiltrate, interstitial edema and fibrin deposition, and characteristic intra-alveolar hyaline membrane formation. Intra-alveolar red blood cells (diffuse alveolar hemorrhage) may be present in severe cases. With progression, there is intra-alveolar organization, intra-alveolar and interstitial fibrosis, alveolar collapse, and the development of an end-stage fibrotic or "honeycomb" lung. An acute immunologic pneumonia, seen in SLE (acute lupus pneumonitis) and in polymyositis–dermatomyositis, may also demonstrate this underlying histologic appearance.

Nonspecific interstitial pneumonitis (NSIP) refers to a spectrum of histologic features with varying degrees of lymphoplasmacytic infiltration of the interstitium and collagen deposition (Fig. 60-1). In the cellular form, lymphoplasmacytic interstitial inflammation exists with associated type II alveolar epithelial cell hyperplasia. In the fibrosing form, the inflammation is accompanied by a temporally and spatially homogeneous deposition of collagen (fibrosis). Architectural distortion or honeycombing may occur in advanced cases and the presence of fibrosis dramatically changes the clinical course and prognosis to one resembling that seen in usual interstitial pneumonitis (UIP) (see below). NSIP is most frequently seen in patients with rheumatoid arthritis, polymyositis–dermatomyositis, mixed connective-tissue disease, and scleroderma.

Lymphocytic interstitial pneumonitis refers to a monotonous infiltration of the interstitium by mature lymphocytes (Fig. 60-2). These lymphocytes tend to form germinal centers within the interstitium as well as displaying an angiocentric distribution. Other features of lymphocytic interstitial pneumonia include macrophagic giant cells, granuloma formation, and amyloid deposition. Lymphocytic interstitial pneumonitis can progress to UIP and end-stage honeycomb lung. Among the collagen vascular diseases, this pneumonitis most commonly accompanies the primary form of Sjögren syndrome and, to a lesser extent, the secondary form of Sjögren syndrome appearing with other collagen vascular diseases, particularly rheumatoid arthritis.

UIP is the underlying lesion of idiopathic pulmonary fibrosis and can also appear in all the collagen vascular diseases. It consists of varying degrees of mononuclear cell infiltration and fibroblastic proliferation leading to collagen deposition within the alveolar interstitium (Fig. 60-3). With progression, this fibrotic reaction results in marked distortion of the lung architecture and what remains are 2- to 3-mm cystic spaces lined by metaplastic epithelium, the so-called honeycomb lung (Fig. 60-4). Other features of UIP include type II epithelial cell hyperplasia producing a "hob-nailed" appearance on the alveolar surface, collections of intra-alveolar macrophages, and smooth-muscle proliferation within the interstitium. Additional abnormalities seen in collagen vascular disease-associated UIP but not in patients with idiopathic pulmonary fibrosis may include: focal chronic pleuritis, lymphoid follicles with germinal center formation, perivascular collagen deposition, and an increase in CD4+ T lymphocytes, especially in rheumatoid arthritis.

Organizing pneumonia, previously termed bronchiolitis obliterans organizing pneumonia, is a distinctive histologic lesion that follows a variety of insults to the alveolar structures including drugs, infection, radiation, and an idiopathic variety. Organizing pneumonia can also complicate the collagen vascular diseases, particularly rheumatoid arthritis and polymyositis–dermatomyositis. Three features comprise the histologic picture: (1) intra-alveolar space and intra-alveolar ductal fibroblastic proliferation with early collagen deposition (Masson bodies), (2) inflammatory polyps consisting of fibroblasts and mononuclear cells protruding into the lumens of respiratory and terminal

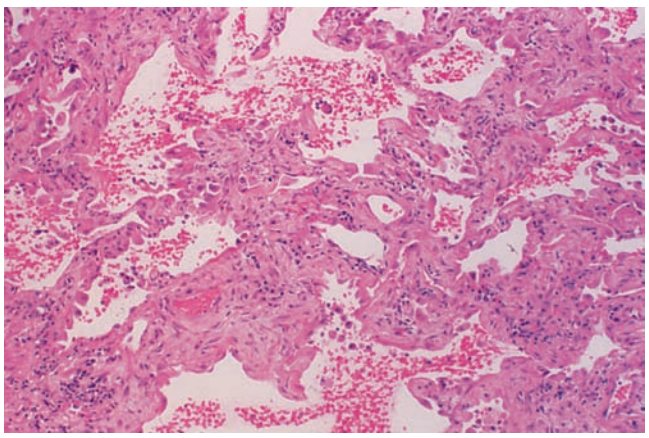

Figure 60-3 Usual interstitial pneumonia (UIP) in a patient with rheumatoid arthritis. There is broadening of the interstitium by varying degrees of mononuclear cell infiltration and collagen deposition.

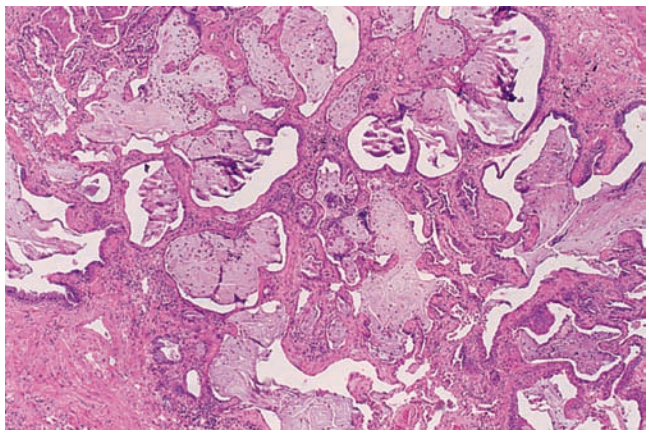

Figure 60-4 Advanced UIP in a patient with scleroderma (honeycomb lung). Normal alveolar tissue is replaced with broad bands of fibrous tissue lined by metaplastic epithelium and filled with inspissated mucus producing a cyst-like network. *(Used with permission of the Armed Forces Institute of Pathology [AFIP].)*

bronchioles, and (3) alveolar septal lymphoplasmacytic infiltrate with type II pneumocyte hyperplasia within affected areas (Fig. 60-5). Bronchiolitis obliterans organizing pneumonia has the potential for being a completely reversible lesion; however, with continuing injury it may progress to end-stage fibrosis and honeycomb lung.

PULMONARY VASCULAR DISEASE

A form of pulmonary artery hypertension, which most commonly appears in patients with scleroderma and is now being increasingly recognized in SLE, rheumatoid arthritis, and mixed connective-tissue disease, is histologically identical to the syndrome of idiopathic pulmonary artery hypertension (IPAH) seen in young women without collagen vascular disease, formerly known as primary pulmonary hypertension. This is a proliferative disorder (plexogenic arteriopathy) affecting the arterioles and small muscular pulmonary arteries. This form of pulmonary hypertension must be differentiated from secondary forms as a result of hypoxic vasoconstriction induced by interstitial lung disease or severe emphysema. In the plexogenic variety, there is endothelial cell intimal proliferation and smooth muscle cell proliferation causing medial thickening with a resultant "onion ring" configuration and luminal obliteration. In the secondary forms

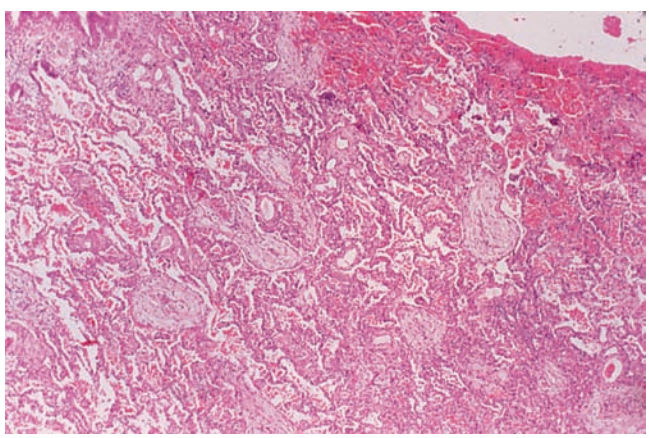

Figure 60-5 Bronchiolitis obliterans organizing pneumonia in a patient with rheumatoid arthritis. There is a mononuclear cellular infiltration of the interstitium without collagen deposition as well as alveolar duct and intra-alveolar fibroblastic proliferation and early collagen production.

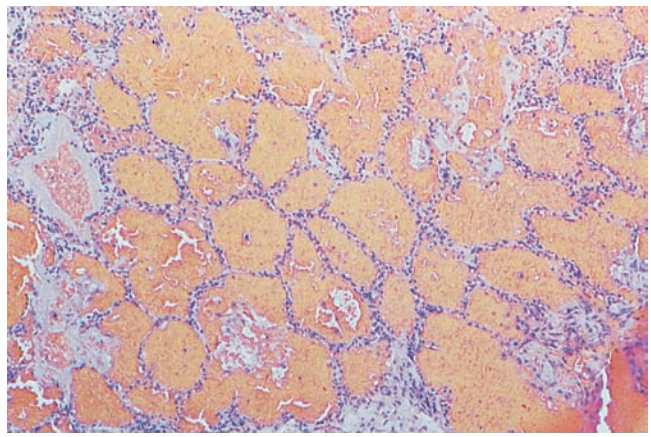

Figure 60-6 Bland diffuse alveolar hemorrhage in SLE. There is little if any interstitial reaction except for type II pneumocyte epithelial cell hyperplasia. The alveolar spaces are filled with red blood cells.

of pulmonary hypertension due to hypoxia, medial hypertrophy is the primary finding. In patients with SLE and the antiphospholipid syndrome, pulmonary artery hypertension may develop as a result of recurrent pulmonary emboli and mimic the clinical picture of IPAH.

Vasculitis refers to an acute inflammatory angiodestructive process resulting in fibrinoid necrosis of the vascular wall. In the collagen vascular diseases, this is most often a small-vessel vasculitis involving arterioles and small muscular pulmonary arteries. Although uncommon, this is seen with greatest regularity in SLE and less frequently in rheumatoid arthritis, polymyositis–dermatomyositis, and mixed connective-tissue disease. Often accompanying the arteriolitis is the lesion of pulmonary capillaritis (see below).

DIFFUSE ALVEOLAR HEMORRHAGE

Diffuse alveolar hemorrhage is recognized by the accumulation of red blood cells within the alveolar spaces, and with recurrent episodes, intra-alveolar and interstitial hemosiderin is deposited and fibrosis may result. There are two different histologic subtypes seen in diffuse alveolar hemorrhage. One is devoid of inflammation and is referred to as *bland hemorrhage* (Fig. 60-6). It is therefore similar in histologic appearance to idiopathic pulmonary hemosiderosis. The other, pulmonary capillaritis is a unique neutrophilic infiltration of the alveolar interstitium, which results in necrosis and loss of integrity

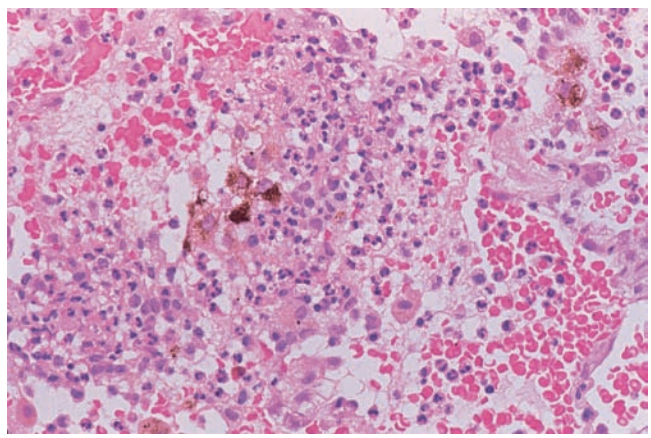

Figure 60-7 Low-power view of pulmonary capillaritis in a patient with SLE. There is marked thickening of the interstitial compartment and infiltration by acute and chronic inflammatory cells. The alveolar spaces are filled with red blood cells and neutrophils.

of the alveolar–capillary basement membrane, capillary destruction and thrombosis, and a leakage of red blood cells into the alveolar space (Fig. 60-7). A unique feature in pulmonary capillaritis is that many of the infiltrating neutrophils are undergoing fragmentation (leukocytoclasis), and others appear as densely staining apoptotic cells. Nuclear debris ("dust") subsequently accumulates within the necrotic, edematous interstitium, and intra-alveolar compartments while red blood cells freely leak into the interstitial matrix due to capillary destruction. Capillary and arteriolar thrombosis, organizing pneumonia, and type II epithelial cell hyperplasia may also be seen.

Capillaritis is most commonly seen in the systemic vasculitides, particularly granulomatosis with polyangiitis (GPA/Wegener granulomatosis) and microscopic polyangiitis (MPA), the small-vessel variant of polyarteritis nodosa. Of the collagen vascular diseases, both bland pulmonary hemorrhage and diffuse alveolar hemorrhage secondary to pulmonary capillaritis appear most commonly in SLE. Cases of pulmonary capillaritis have also been reported to occur in rheumatoid arthritis, Sjögren syndrome, polymyositis–dermatomyositis, and mixed connective-tissue disease.

■ BRONCHIOLITIS

Bronchiolitis refers to an inflammatory-fibrotic process involving the terminal and respiratory bronchioles and possibly the surrounding alveolar structures. Respiratory bronchiolitis is primarily seen in smokers with or without an associated collagen vascular disease. There is also a primary form of cellular bronchiolitis that complicates the collagen vascular diseases, most often appearing in rheumatoid arthritis and Sjögren syndrome. Histologically, there is a mononuclear cell infiltration of the wall of the bronchiole without impingement of the bronchiolar lumen. In contrast, in bronchiolitis obliterans, or obliterative bronchiolitis, there is a concentric fibrous obliteration of the bronchiolar lumen leading to a severe obstructive lung disease (Fig. 60-8). Bronchiolitis obliterans is most often reported as a complication of rheumatoid arthritis.

■ PARENCHYMAL NODULES

Noninfectious inflammatory parenchymal nodules occur in both rheumatoid arthritis and Sjögren syndrome. In rheumatoid arthritis the nodules are referred to as the *necrobiotic* or *rheumatoid nodules*. These lesions are found both in the pleura and lung parenchyma and are identical in appearance to a subcutaneous rheumatoid nodule. In the lung parenchyma, these nodules are located in the interlobular septa and in the subpleural parenchyma. The necrobiotic nodule is comprised of palisading histiocytes, giant cells, and other mononuclear cells surrounding an area of fibrinoid debris (Fig. 60-9). In Sjögren syndrome, a rounded lesion known as pseudolymphoma can occasionally be detected on the chest radiograph. Pseudolymphoma is considered to be a localized form of lymphocytic interstitial pneumonia and is made up of a dense infiltrate of lymphocytes and histiocytes with occasional granuloma formation. There is a potential risk for malignant transformation in pseudolymphoma as well as in the other forms of lymphocytic interstitial pneumonia.

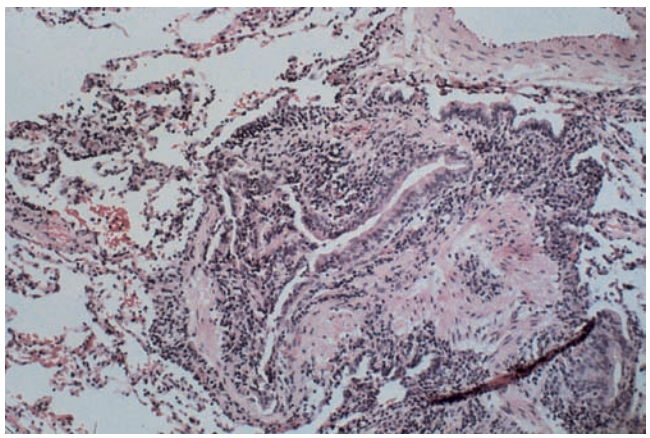

Figure 60-8 Obliterative bronchiolitis in rheumatoid arthritis. There is a marked reduction of the luminal diameter due to concentric fibrous obliteration and dense chronic inflammation. *(Reproduced with permission from Schwarz MI, Lynch DA, Tuder R. SYSTEMIC LUPUS ERYTHEMATOSUS: CLINICAL FEATURES

SLE is characterized by the production of antibodies against various cellular antigens derived from the nucleus, cytoplasm, or cell membrane. Tissue injury appears to be associated with the development of immune complexes, the presence of low serum complement levels, and the production of antibodies to native DNA. Pleuropulmonary involvement in SLE occurs in the vast majority of patients (97.8%), with pleuritis (77%), bacterial infections (58%), and diffuse alveolar hemorrhage (26%) being the most common.[3,4] Lung injury is thought to be the result of an immune complex-mediated injury and appears to increase in incidence depending on the age of the patient, duration of illness, pleuritis, and the presence of specific autoantibodies. Pulmonary vascular and shrinking lung syndrome appear to be associated with the development of the anti-RNP autoantibody.[5] A number of syndromes (Table 60-2) are associated with acute respiratory-type illness in SLE. Patients with SLE who present with a febrile illness, cough with or without productive sputum, and new pulmonary infiltrates must be considered

TABLE 60-2 Acute Lung Syndromes in Systemic Lupus Erythematosus

Diffuse alveolar hemorrhage

to have an infectious pneumonia, although acute lupus pneumonitis and diffuse alveolar hemorrhage may have a similar presentation.[6] Infection can be community-acquired or a complication of immunosuppressive therapy. Infectious pneumonia represents the most common cause of pulmonary disease in SLE, and infections in general represent the most common reason for death (33%–77%).[7] Bronchoalveolar lavage is often helpful in excluding an infectious pneumonia in the immunocompromised SLE patient.

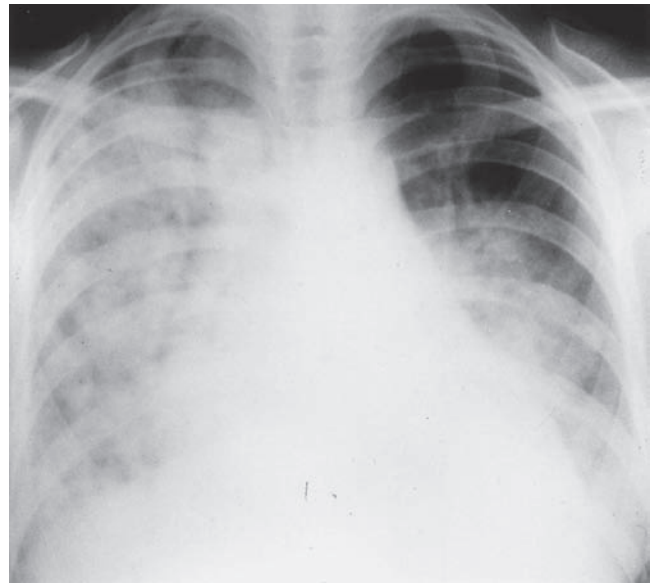
Another important consideration in an acutely dyspneic SLE patient is pulmonary embolism, a complication reportedly occurring in up to 25% of patients and a significant cause of mortality.[8] The occurrence of thromboembolic disease correlates with the presence in the serum of acquired antiphospholipid antibodies (lupus anticoagulant or anticardiolipin).[9] The most common epitope(s) to which antibodies exist in these patients is β_2-glycoprotein I. A more appropriate term may therefore be anti-β_2–glycoprotein syndrome. Up to a third of patients with SLE have the antiphospholipid syndrome. Thrombocytopenia, recurrent venous or arterial thrombosis, hemolytic anemia, leg ulcers, and recurrent fetal loss are also manifestations of antiphospholipid syndrome.

Other causes for acute respiratory failure in patients with SLE include a volume overload state, due either to renal failure or to congestive heart failure secondary to myocarditis. Uremic pneumonitis with underlying DAD is also a possible cause of an acutely dyspneic SLE patient with renal failure. A syndrome, *acute reversible hypoxemia*, occurring in acutely ill SLE patients who are experiencing systemic exacerbations has been described.[10] These patients have hypoxemia and a widened alveolar–arterial oxygen gradient, but both the chest radiograph and ventilation–perfusion lung scans are normal. It is postulated that there is complement-activated neutrophil aggregation in the pulmonary vasculature. The hypoxemia improves with immunosuppressive therapy. Given the high incidence of antiphospholipid syndrome in SLE, acute reversible hypoxemia should be considered only after excluding thromboembolic disease.

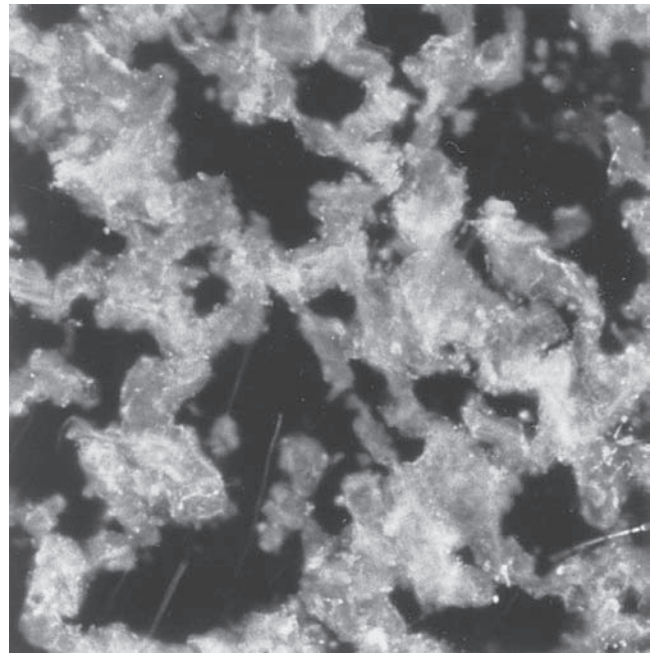
■ ACUTE LUPUS PNEUMONITIS

Acute lupus pneumonitis is a clinical syndrome with an underlying histology of DAD, bronchiolitis obliterans organizing pneumonia, NSIP, or a combination of these.[11] Acute lupus pneumonitis mimics an acute infectious pneumonia and may be the presenting manifestation of SLE in up to 50% of patients. In those with an established diagnosis, it also appears during a flare-up of the other systemic manifestations of SLE, particularly pleuritis, pericarditis, arthritis, and nephritis. Acute lupus pneumonitis is reportedly more common in the postpartum period. It frequently recurs and cases have been documented that have progressed to a more chronic interstitial lung disease (UIP). Fortunately, acute lupus pneumonitis is a relatively uncommon complication, occurring in less than 5% of patients.

Bilateral alveolar infiltrates, which can be patchy or densely consolidated and often accompanied by pleural effusions and cardiomegaly due to underlying pericardial effusion or myocarditis (Fig. 60-10A), are present on chest radiographs at presentation. White blood cell counts and sedimentation rates are elevated and serum complement is often low. Immunopathologic studies reveal the presence of complement as well as antibodies to IgG and DNA in some patients, supporting the concept of an immune complex pathogenesis (Fig. 60-10B). Because of the difficulty in distinguishing acute lupus pneumonitis from an infectious pneumonia, a bronchoalveolar lavage and sometimes an open (thoracoscopic) lung biopsy are indicated prior to instituting anti-inflammatory and immunosuppressive therapy. Acute respiratory failure in acute lupus pneumonitis often requires assisted mechanical ventilation. The mortality rate has been reported to be as high as 50%, with the causes of death in patients with acute lupus pneumonitis being due to respiratory failure, another complication of SLE (nephritis, cerebritis), or a superimposed infection.



A



B

Figure 60-10 Acute lupus pneumonitis. **A.** The chest radiograph demonstrates diffuse alveolar filling with cardiomegaly (pericardial effusion vs. myocarditis). There is also a left pleural effusion. **B.** The immunofluorescent study demonstrates granular immune complex deposition in the alveolar interstitium.

■ DIFFUSE ALVEOLAR HEMORRHAGE

Diffuse alveolar hemorrhage, although rare, may be a presenting manifestation of SLE. In several cases, recurrent diffuse alveolar hemorrhage was present for years prior to the diagnosis of SLE.[12] The majority of cases, in contrast to acute lupus pneumonitis, first appear in a well-documented case of SLE. Diffuse alveolar hemorrhage accounts for 1% to 4% of SLE-related hospitalizations.

Diffuse alveolar hemorrhage can also present with symptoms reminiscent of an infectious pneumonia or acute lupus pneumonitis, and the additional symptom of hemoptysis raises the possibility of this diagnosis. Hemoptysis is present in 30% to 50% of patients during their initial presentation, but up to 90% will have hemoptysis

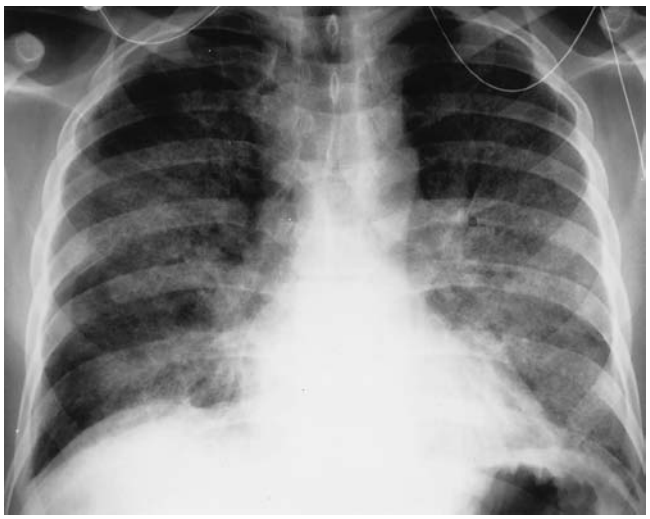


Figure 60-11 Diffuse alveolar hemorrhage in SLE. There are diffuse alveolar infiltrates without cardiomegaly or pleural effusions.

during their subsequent course. Routine laboratory work demonstrates a falling hematocrit, and in 60% to 90% of patients an active glomerulonephritis is invariably present. A progressive serosanguineous bronchoalveolar lavage may be the first clue to this diagnosis. Diffuse alveolar infiltrates are present on chest radiography (Fig. 60-11), but in contrast to acute lupus pneumonitis, pleuritis and pericarditis are not prominent features. Pathologic changes that are reminiscent of both acute lupus pneumonitis (DAD and NSIP) and diffuse alveolar hemorrhage with or without pulmonary capillaritis are not unusual in a single biopsy specimen.[13] The mortality rate is approximately 50% and is independent of the underlying histopathology (bland hemorrhage vs. pulmonary capillaritis). Recurrent DAH is common and should be expected in the absence of therapeutic intervention.

There are no controlled clinical trials for the treatment of either acute lupus pneumonitis or diffuse alveolar hemorrhage. Once infection has been excluded, corticosteroids are the mainstay of therapy. Intravenous methylprednisolone, 1 to 2 g daily in divided doses for 3 to 4 days before tapering, should be considered. Concomitant oral or parenteral cyclophosphamide or azathioprine is commonly administered, given the associated incidence of lupus nephritis. Plasmapheresis, immunoglobulin therapy, and rituximab have been used successfully, consistent with the proposed immune complex pathogenesis.[14–17]

LUPUS PLEURITIS

Pleurisy and pleural effusion are the most common primary pulmonary complications of SLE, occurring in 50% to 80% of patients. Pleurisy and/or a pleural effusion may also be the presenting and sole manifestation of the disease. They are usually recurrent and may accompany more severe complications such as acute lupus pneumonitis or nephritis. Patients complain of pleuritic pain, fever, and dyspnea. The chest radiograph may be normal (dry pleurisy) or demonstrate small to moderate pleural effusions (massive effusions are rare), which are bilateral in 50% of patients. When unilateral, there is no predilection for either side.

Effusions are serous or serosanguineous and exudative in nature. The white cell counts range from 5 to 10,000 cells/mm.^{3} Early on, neutrophils predominate, but with time mononuclear cells appear. These characteristics are nonspecific and are often seen with infectious parapneumonic effusions. In contrast to rheumatoid arthritis, the pleural fluid glucose concentration in lupus pleuritis is not reduced. Rheumatoid factor may be positive in lupus pleuritis. Pleural fluid complement levels are abnormally decreased in lupus, with both total complement activity and C3 and C4 reduced. A positive double-stranded pleural fluid DNA titer is nonspecific as opposed to the serum test, since it has been found in pleural effusions due to malignancy and tuberculosis. The most helpful measurement is the pleural fluid antinuclear antibody titer. Levels greater than 1:160 are very suggestive of lupus pleuritis. Examination of the pleural tissue reveals infiltration with plasma cells and lymphocytes, and, with repeated episodes, pleural fibrosis supervenes. Occasionally, a vasculitis of the pleural vessels is detected, and immune complex deposition has been reported. Corticosteroid treatment is effective for relief of pleural pain, but time to resolution of the pleural effusion is quite variable and probably unaffected by this treatment. In the unusual case, recurrent lupus pleuritis may result in massive pleural fibrosis and lung entrapment, necessitating a pleural stripping procedure.

While pleural effusions and pleurisy are common in patients with SLE, a broad differential diagnosis should be considered. The increased incidence of infectious complications, thromboembolic disease, and pulmonary hypertension in SLE predisposes patients to parapneumonic effusions and empyema, congestive heart failure, and effusions secondary to thromboembolic disease.

INTERSTITIAL LUNG DISEASE

Clinically significant interstitial lung disease is an uncommon pulmonary manifestation in SLE but UIP, lymphocytic interstitial pneumonitis, NSIP, and organizing pneumonia have all been reported. UIP is known to appear following acute lupus pneumonitis and in some cases has been documented to appear as an independent insidious disease. Using high-resolution computed tomography, 38% of patients with SLE patients with normal chest radiographs demonstrate pulmonary abnormalities consistent with some form of interstitial lung disease. In those who develop interstitial lung disease, a prior episode of acute lupus pneumonitis and an insidious onset of dyspnea are often noted. The prevalence of interstitial lung disease is increased in the subset of SLE patients with features suggestive of a mixed connective-tissue disease.

In patients who develop the insidious form of interstitial lung disease, the diagnosis of SLE is present for several years, and no other pattern of organ involvement predicts its appearance. These patients have progressive dyspnea and cough with interstitial infiltration on the chest radiograph. High-resolution computed tomography indicates combinations of ground-glass attenuation, inter- and intralobular septal thickening, and honeycomb change. Pulmonary function tests reveal a restrictive pattern with reduction in the diffusing capacity and hypoxemia accentuated by exercise. Response to therapy, either corticosteroids alone or in combination with cyclophosphamide or azathioprine, depends upon the underlying histology. Those cases with underlying NSIP or organizing pneumonia are more likely to respond to treatment than those who demonstrate excess collagen deposition and cystic honeycomb formation.

PULMONARY VASCULAR DISEASE

Idiopathic pulmonary hypertension due to plexogenic arteriopathy was previously thought to be an uncommon complication of SLE. It is now estimated to occur in 1% to 9% of patients.[18,19] This form of pulmonary hypertension is associated with Raynaud phenomenon, digital vasculitis, serositis, antibodies to ribonucleoprotein, rheumatoid factor, antiphospholipid antibodies, and most recently antiendothelial cell antibodies. Patients complain of dyspnea and fatigue but have normal chest radiographs. In advanced cases, pulmonary arterial enlargement appears. Spirometry and lung volumes are normal, but there is often an isolated reduction of the diffusing capacity for carbon monoxide as well as gas exchange abnormalities. Ventilation–perfusion lung scanning and, occasionally, pulmonary

arteriography are indicated, particularly in those patients with the antiphospholipid syndrome who have a potential for recurrent small pulmonary emboli. Therapeutic options include vasodilator therapy, anticoagulation, immunosuppression with cyclophosphamide, and transplantation.

Vasculitis in SLE is more likely to be discovered in lung biopsy specimens, demonstrating either diffuse alveolar hemorrhage or acute lupus pneumonitis as opposed to being an isolated finding. Autopsy series indicate small-vessel vasculitis in 20% of cases.

BRONCHIOLITIS

Five percent of SLE patients are reported also to have obstructive physiology. Obliterative bronchiolitis has been documented in SLE, but is rare in contrast to rheumatoid arthritis. Organizing pneumonia, with inflammatory polyps protruding into bronchiolar lumens, is one of the interstitial patterns that occurs in acute lupus pneumonitis and in chronic interstitial lung disease in SLE, but this entity causes restriction rather than obstructive lung disease. Bronchiectasis may occur in up 20% of patients but is often asymptomatic. Large airway involvement including tracheal and subglottic stenosis, vocal fold paralysis, epiglottitis, and necrotizing tracheitis have all been reported, but are rare.

RESPIRATORY MUSCLE DYSFUNCTION

It is estimated that weakness of the diaphragm and other respiratory muscles is found in 25% of patients with SLE. This accounts for the previously unexplained findings of dyspnea without evidence of interstitial or pulmonary vascular disease. These patients have subsegmental atelectasis, an elevated diaphragm on chest radiograph (Fig. 60-12), and restrictive physiology. This has been referred to as *unexplained dyspnea and shrinking lungs syndrome.* Although there is a reduction in static lung volumes, the diffusing capacity, when corrected for alveolar volume, remains normal, thereby distinguishing respiratory muscle dysfunction from interstitial lung disease. The likely explanation for this is a reduction in the transdiaphragmatic pressure generated during maximal inspiration, which in turn reduces static lung compliance, producing the linear atelectasis seen on the chest radiograph. Moreover, in the patients with respiratory muscle weakness, no evidence for a generalized neuromuscular disease can be found. The pathogenesis of respiratory muscle dysfunction remains unexplained, although phrenic nerve conduction abnormalities have been excluded.[20] Abnormal diaphragmatic activation, due in part to voluntary inhibition due to pleuritic pain, may contribute to diaphragmatic dysfunction in this disorder. Clinical variables associated with the development of shrinking lung syndrome include: pleuritis, double-stranded DNA antibody and RNP antibody seropositivity, serositis, and a prolonged course of SLE.[5] Corticosteroids are not a frequently effective treatment modality. Rituximab has been used successfully in the treatment of shrinking lung syndrome, albeit anecdotally in nature.[21] Progression is uncommon and most patients stabilize. Positive-pressure ventilation, particularly at night, may improve these patients' daytime symptoms, although there is limited evidence available. Rituximab has been used successfully in patients with respiratory muscle dysfunction with significant physiologic improvement.[21]

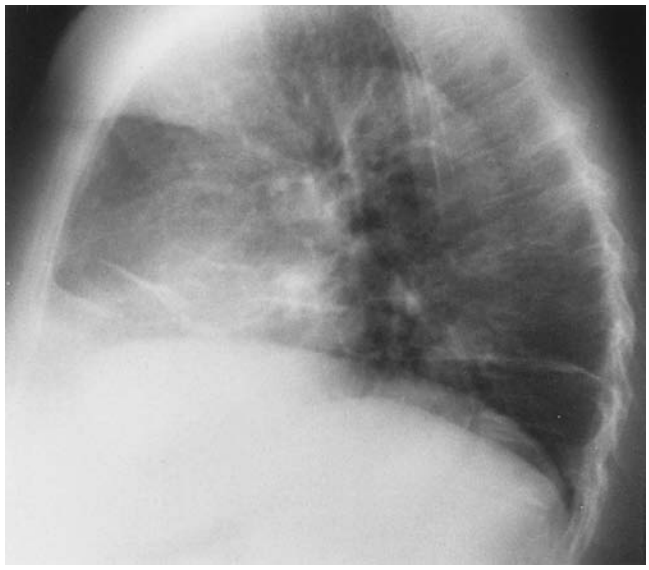

Figure 60-12 Diaphragmatic dysfunction in SLE. There is diaphragmatic elevation resulting in plate-like atelectasis.

RHEUMATOID ARTHRITIS: CLINICAL FEATURES

Rheumatoid arthritis classically affects the articular surfaces, but pleuropulmonary complications are responsible for significantly increased morbidity and mortality.[22] Most often cited is a 50% incidence for these complications, but it is likely that this underestimates their frequency.[23] Rheumatoid arthritis–associated interstitial lung disease abnormalities may be present in over 60% of patients with RA and are clinically asymptomatic during the initial assessment.[24] In those that manifest symptoms, the presence of RA-ILD, which approximates 10%, is associated with increased mortality.[25–27] Pleuropulmonary complications are more apt to occur in patients with more severe chronic articular disease, with high titers of rheumatoid factor, and in patients who have subcutaneous nodules, as well as other systemic complications such as cutaneous vasculitis, myocarditis, pericarditis, ocular inflammation, and Felty syndrome. An association between smoking and an increased risk for the development of pleuropulmonary disease, radiographic progression, and nodule formation in rheumatoid factor–seropositive patients has been reported. More recent observations series suggest that in those patients with anticitrullinated protein antibodies (anti-CCPs) there is an increase in parenchymal lung abnormalities, independent of current or prior tobacco exposure, supportive of the hypothesis that anti-CCPs are important in the pathogenesis of lung disease in RA.[28,29] Pleuropulmonary disease may occur in seronegative patients and both cytolytic and biologic therapies, commonly employed for treatment, can induce an interstitial lung disease, which is often difficult to distinguish from the primary forms complicating rheumatoid arthritis.[30] Moreover, interstitial lung disease, pleuritis, and occasionally obliterative bronchiolitis may be the first and only manifestation of the rheumatoid state in up to 20% of patients, preceding the articular manifestations by months to years.

PLEURISY AND PLEURAL EFFUSION

Pleural disease in a postmortem series was found in 40% of patients with rheumatoid arthritis. The incidence of clinically apparent pleural disease is closer to 5%, and the majority of patients experience mild symptoms. In approximately 20% of the patients who develop pleural complications, they do so prior to the onset of articular disease. In patients with rheumatoid arthritis, pleural complications are more common in men and occur most frequently during episodes of active articular disease and in patients with subcutaneous rheumatoid nodules.

Pleural disease is often first discovered on routine chest radiograph, and both pleural fibrosis and effusions have been reported to occur in asymptomatic patients. In more recent series using multidetector CT imaging, pleural thickening was noted in 49% of patients and did not correlate to the presence of symptoms.[31] Pleural effusions can be unilateral or bilateral and coexist with interstitial lung disease or necrobiotic nodules. Symptomatic patients present with pleuritic pain, dyspnea, and occasionally fever. The effusion

is an exudate by protein and lactic dehydrogenase criteria, and, if chronic, cholesterol concentrations are increased. Other characteristics include a low pleural fluid pH (<7.2), thought to be due to impaired carbon dioxide exit from the pleural space. The leukocyte counts can be as high as 15,000 cells/mm^3 and consist of a mixture of neutrophils and mononuclear leukocytes. As in SLE, the total and individual complement components are low, and the rheumatoid factor level is increased. The presence of rheumatoid factor in pleural fluid has also been reported with tuberculosis, malignancy, and other infectious diseases. A low pleural fluid glucose concentration, thought to be due to a defect in glucose transport, is characteristic of rheumatoid effusions. Up to 40% of patients have pleural fluid glucose levels less than 10 mg/dL, and 75% have levels under 50 mg/dL. It has been stated that cytologic examination of the pleural fluid, which demonstrates a background of necrotic debris, spindle-shaped macrophages, and multinucleated histiocytes, is characteristic of a rheumatoid effusion. Necrobiotic nodules are thought to be involved in the pathogenesis of the pleural effusions, but transthoracic pleural biopsy only occasionally will demonstrate this finding.

Treatment is not indicated for asymptomatic cases; however corticosteroids, when used for active articular disease, are also effective in hastening the resolution of the pleural effusion. Rarely, is any other form of intervention such as intrapleural corticosteroids necessary for these patients. In the unusual case, pleural fibrosis with resultant lung entrapment occurs, requiring surgical intervention. Spontaneous pneumothorax due to rupture of a necrobiotic nodule, another uncommon complication, necessitates tube thoracostomy, and with persistence of the bronchopleural fistula, surgical intervention is indicated.

■ PULMONARY VASCULAR DISEASE

In general, pulmonary vascular disease is the least common pleuropulmonary complication in rheumatoid arthritis. The fibroproliferative plexogenic arteriopathy typical of scleroderma and SLE is an infrequent complication. When it does occur, Raynaud phenomenon is commonly present. The chest radiograph reveals normal lung fields and enlarged pulmonary arteries, and there is an isolated reduction of the diffusing capacity for carbon monoxide as well as hypoxemia.

Small-vessel vasculitis in rheumatoid arthritis occurs in the setting of diffuse alveolar hemorrhage due to pulmonary capillaritis and is a very rare event in rheumatoid arthritis. Several cases have been well documented and, in one, antineutrophilic cytoplasmic antibody to myeloperoxidase (p-ANCA) was present in the serum. Treatment with intravenous methylprednisolone, followed by oral corticosteroid preparations in addition to cyclophosphamide, is indicated for this complication.

■ NECROBIOTIC (RHEUMATOID) NODULE

Radiographically visible parenchymal rheumatoid nodules are infrequently seen in a rheumatoid population (1%). If present, necrobiotic nodules are more common in men, particularly those who smoke, with active articular disease and high rheumatoid factors, and in those who have subcutaneous nodules. The nodules are primarily a radiographic finding, subpleural in distribution, and asymptomatic in most. Cavitation and rupture may occur rarely and are associated with pneumothorax, pleural effusions, and hemoptysis. Radiographically, the nodules can be single or multiple with upper- and midzone predilection, and approximately 50% will undergo cavitation due to the large amounts of proteolytic enzymes in these lesions. The size is variable, and nodules up to 7 cm have been reported. Spontaneous resolution and recurrence are to be expected. Continuous growth, although possible, should prompt a more aggressive diagnostic approach. In most cases, no treatment is required. The major problem is differentiating the necrobiotic nodule from either malignant or infectious granulomatous disease, particularly given the increased risk of lung cancer in patients with RA.[32]

Figure 60-13 Caplan syndrome in a patient with rheumatoid arthritis and silicosis (hard-rock miner). There are multiple small nodules in the middle and upper lung representing the silicosis. In addition, multiple upper-zone rheumatoid nodules are present.

Caplan syndrome refers to a radiographic picture that developed in Welsh coal miners with rheumatoid arthritis and a pneumoconiosis.[33] It consists of the sudden appearance of discrete nodules primarily in the upper lobes that are histologically identical to the necrobiotic nodule (Fig. 60-13). The incidence of necrobiotic nodules is higher in rheumatoid patients with underlying pneumoconiosis, including coal workers' pneumoconiosis, silicosis, and asbestosis, than it is in a general rheumatoid population.

■ AIRWAY DISEASE

Upper airway involvement by the rheumatoid process most commonly involves the cricoarytenoid joint, causing difficulty with inspiration and occasionally resulting in stridor. A sore throat, hoarseness, and globus sensation are other common complaints. The prevalence of this complication, although asymptomatic in the majority of cases, approaches 50% when computed tomography screening is employed. Clinically significant disease can be detected by performing flow–volume loops, which indicate a variable extrathoracic obstruction of the inspiratory loop. Cricoarytenoid arthritis may further complicate endotracheal intubation and should be considered in all patients with rheumatoid arthritis requiring general anesthesia.

Bronchiolitis obliterans or obliterative bronchiolitis is a well-recognized cause of progressive and often severe obstructive lung disease in patients with rheumatoid arthritis.[34] The majority of patients develop bronchiolitis subsequent to the diagnosis of RA. Of note, bronchiolitis obliterans may be the initial manifestation of RA in a small group of patients.[35] This complication was first thought to be a consequence of either penicillamine or gold therapy, but many cases have appeared in the absence of either treatment. The onset of obliterative bronchiolitis is insidious, with patients complaining of progressive dyspnea and cough while having a normal or hyperinflated chest radiograph (Fig. 60-14A). It was thought that this complication was limited to women, but this is not the case. Physical examination reveals a generalized reduction of breath sounds and

occasionally an inspiratory squeak. Physiologic testing reveals varying degrees of airflow limitation and hyperinflation, and the diffusing capacity may be normal or reduced. High-resolution computed tomography demonstrates adjacent areas of decreased and increased attenuation (geographic pattern), suggesting air trapping, which may be further identified by expiratory imaging (Fig. 60-14B). The response to therapy is poor. Some patients have responded to treatment with a combination of corticosteroids and cyclophosphamide, but the majority of cases progress to hypercapnic respiratory failure.

Another form of bronchiolitis seen in rheumatoid arthritis is a respiratory or follicular bronchiolitis, consisting of a dense infiltration of lymphocytes and plasma cells surrounding the terminal and respiratory bronchioles. Cough and dyspnea are common symptoms. Chest radiographs may be normal or demonstrate a fine nodular pattern more predominant in the middle and lower lung zones. High-resolution computed tomography reveals a pattern of follicular bronchiolitis in up to 33% of patients with RA, demonstrating centrilobular nodules and bronchiectasis (Fig. 60-15).[31] There is usually no physiologic evidence for airflow limitation or reduced lung volumes, but rather gas exchange abnormalities dominate the physiologic picture. Treatment with corticosteroids yields variable results.

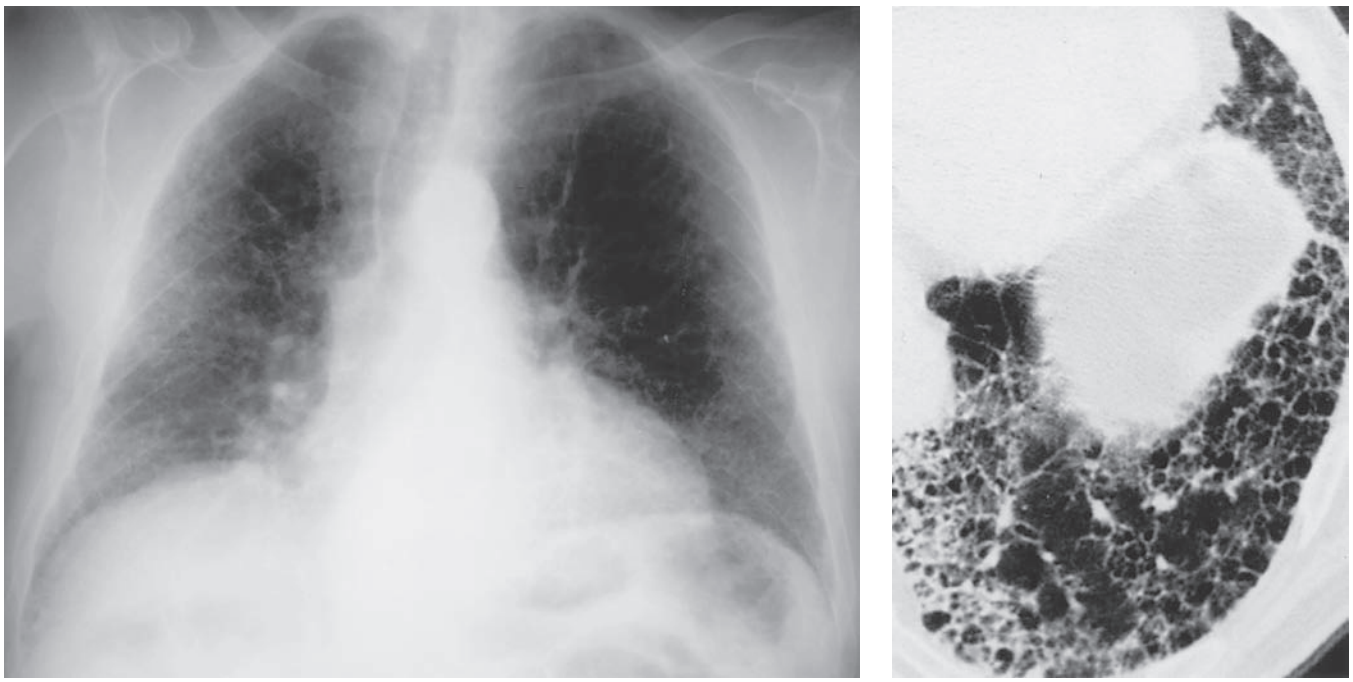
Diffuse panbronchiolitis has been reported in Japanese patients with rheumatoid arthritis. In both diffuse panbronchiolitis and rheumatoid arthritis, an association with HLADR4 and B54 haplotypes has been reported, suggesting a common genetic predisposition.[36,37]

INTERSTITIAL LUNG DISEASE

Interstitial lung disease is a relatively common complication in patients with rheumatoid arthritis. In contrast to most connective-tissue diseases, interstitial lung disease is more common in males than females (3:1), individuals who have late-onset disease, high-titer rheumatoid factors, and in those who smoke. It is not unusual for interstitial lung disease to precede the articular manifestations for a period of months to years. The incidence of this complication in a rheumatoid population is difficult to determine, being reported in 5% to 40% of patients depending upon the methods of detection. The use of bronchoalveolar lavage indicating alveolar inflammation and high-resolution computed tomographic scans indicating various interstitial changes, often in the face of a negative chest radiograph, are difficult to interpret. This is because follow-up studies determining whether these patients developed clinically apparent interstitial lung disease are lacking. Furthermore, some parenchymal changes described on computed tomography such as bronchiectasis have very little, if any, clinical significance. It is likely that clinically important interstitial lung disease occurs in 5% to 10% of patients with rheumatoid arthritis, the most common forms being UIP and NSIP. These patients are dyspneic and complain of cough. Physical examination reveals bibasilar crackles, clubbing of the digits, and evidence of cor pulmonale when pulmonary hypertension appears secondary to hypoxic vasoconstriction. The chest



A B

Figure 60-16 UIP in rheumatoid arthritis. **A.** Chest radiograph demonstrating lower zone and peripheral reticulonodular infiltrates. **B.** High-resolution computed tomography demonstrating a cystic network (honeycomb lung) at the lung base in a patient with advanced disease.

radiograph and computed tomographic scan demonstrate varying degrees of interstitial infiltrates with predilection for the lung bases and lung periphery (Fig. 60-16A). Other features include ground-glass attenuation on computed tomography with mixed alveolar–interstitial infiltrates on chest radiograph indicating a component of NSIP. Both imaging studies in advanced disease reveal the presence of honeycomb lung (Fig. 60-16B).

Several other interstitial reactions, which produce subacute or chronic symptoms, complicate rheumatoid arthritis. The first is organizing pneumonia, which can present with identical symptoms to UIP and preempt the onset of the articular disease as well. The chest radiograph (Fig. 60-17) and computed tomography scan differ from that seen in UIP because the infiltrates are primarily alveolar and localized, patchy, or diffuse. The second interstitial reaction is lymphocytic interstitial pneumonia, which occurs when rheumatoid arthritis is complicated by Sjögren syndrome. In addition to dyspnea and cough, these patients complain of dry mouth and eyes (xerophthalmia and xerostomia). The chest radiograph indicates patchy alveolar infiltrates primarily seen at the lung bases. In contrast to patients with primary Sjögren syndrome in which large cystic structure may develop within the lung, parenchymal cysts are uncommon in patients with RA-ILD. Eosinophilic pneumonia has been reported as a pleuroparenchymal complication of rheumatoid arthritis and may be the primary presentation of the disease. Acute interstitial pneumonitis is a rare, acute form of interstitial lung disease in rheumatoid arthritis. While it may occur as a result of an immunologic injury to the lung, medication-related pulmonary toxicity and opportunistic infections should be considered. Finally, fibrobullous disease, similar to that seen in ankylosing spondylitis, has been reported in rheumatoid arthritis and may precede the articular manifestations of the disease.

It is important to establish the underlying histology, since response to therapy and prognosis differs. Unless the imaging studies indicate end-stage honeycomb lung, which can also result from unresponsive or recurrent organizing pneumonia, lymphocytic interstitial pneumonia, or UIP, further evaluation is indicated. Bronchoalveolar lavage will not necessarily help differentiate between these three histologic pictures, but the finding of increased lymphocytic percentages as opposed to neutrophils and eosinophils indicates the potential for therapeutic responsiveness. Alveolar infiltrates and increased lymphocyte percentages are seen in lymphocytic interstitial pneumonitis. Organizing pneumonia is associated with increases in neutrophil, eosinophil, and lymphocyte percentages as well as radiographic alveolar infiltrates. The finding of increased

Figure 60-17 Bronchiolitis obliterans organizing pneumonia in rheumatoid arthritis. Chest radiograph demonstrating lower-zone mixed alveolar-interstitial infiltrates.

neutrophil and eosinophil percentages in suspected underlying UIP is an indicator of poor prognosis. Therefore, patients with lymphocytic interstitial pneumonitis and organizing pneumonia are more treatment-responsive when compared to those with UIP. If imaging studies and bronchoalveolar lavage cellular analysis are not definitive, thoracoscopic open lung biopsy should be considered. Treatment consists of a corticosteroid preparation and often the addition of cytotoxic drugs in the nonresponsive cases. As opposed to the idiopathic variety of organizing pneumonia, in which 66% of cases have favorable responses to corticosteroid medications, those associated with collagen vascular diseases are less responsive to treatment, often recur with tapering of the treatment regimen, and can progress to honeycomb lung. While the histopathology may be similar between rheumatoid arthritis and idiopathic pulmonary fibrosis, improved survival exists for those with rheumatoid arthritis–associated UIP but the long-term prognosis remains poor.[25,26,38]

Gold-induced pneumonitis must be differentiated from the primary forms of interstitial lung disease in patients with rheumatoid arthritis, particularly since the underlying histology can be similar, indicating varying degrees of NSIP and organizing pneumonia.[39] Dyspnea and cough usually begin 4 to 6 weeks following initiation of therapy, and peripheral eosinophilia occurs in a minority of cases. Occasionally, the chest radiograph will demonstrate upper- as opposed to lower-zone mixed alveolar interstitial infiltration. Bronchoalveolar lavage indicates a predominance of lymphocytes, and differentiation from rheumatoid interstitial lung disease can only be made after withdrawal of the drug results in remission. In severe cases with marked gas exchange abnormalities, corticosteroid therapy will occasion prompt reversal.

Methotrexate given in relatively low weekly doses (10–20 mg) is associated with the development of an interstitial disease in rheumatoid patients. No correlation with age, sex, duration of disease, or weekly or cumulative dose could be found. Conflicting data suggest that rheumatoid patients with underlying primary rheumatoid lung disease are predisposed to develop methotrexate pneumonitis. In rheumatoid patients treated with methotrexate, the incidence of methotrexate pneumonitis is 1% to 11%. The clinical onset is relatively acute with cough, fever, dyspnea, and new mixed alveolar and interstitial pulmonary infiltrates on chest radiograph. Increased white blood cell counts with mild eosinophilia, elevated sedimentation rates, and increased serum lactic dehydrogenase are nonspecific findings. Bronchoalveolar lavage indicates lymphocytosis and should be performed to rule out an infectious etiology. Lung tissue reveals an NSIP, organizing pneumonia, and granuloma formation reminiscent of a hypersensitivity pneumonitis. In patients who develop this clinical syndrome while on methotrexate, the drug should be discontinued since progression to end-stage fibrosis may occur. With life-threatening respiratory failure, corticosteroids given intravenously are an effective therapy.

The advent of TNF-α antagonists has revolutionized therapy for patients with rheumatoid arthritis. Their efficacy in the treatment of pleuroparenchymal complications remains unknown, with conflicting data having been reported. Of concern in those patients being treated with these agents should be the increased risk of infections, particularly both typical and atypical mycobacteria and fungi, as well as common bacterial pathogens. Several series suggest a temporal association between the use of biologic therapies and the development of ILD. It remains unclear if the association is temporal or causative.[30,40–43]

SCLERODERMA: CLINICAL FEATURES

Scleroderma or systemic sclerosis is an inflammatory-fibrotic disease that results in deposition of excessive extracellular matrix in the skin and several visceral organs including the lungs, heart, kidneys, and gastrointestinal tract. Two subtypes of systemic sclerosis exist: diffuse and limited. In diffuse systemic sclerosis, extensive skin involvement of the extremities, face, and torso exists with accompanying marked visceral involvement that is progressive in nature. The limited form, or CREST variant (*c*alcinosis, *R*aynaud phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasias), has a more protracted course in most patients and usually affects an older subset of patients. Pulmonary disease contributes significantly to both the morbidity and mortality of patients. The pathogenesis, although not well understood, involves a complex interaction among immune cells, endothelial cells, and fibroblasts. In addition to the excessive extracellular matrix, which in the lung results in interstitial fibrosis, endothelial cell damage with intimal thickening of pulmonary and systemic arteries occurs, leading to luminal obliteration. This may result in a form of idiopathic pulmonary hypertension.

The lung is involved in the great majority of cases of scleroderma, with postmortem series indicating a 70% to 100% incidence.[44] Most patients with scleroderma develop dyspnea during the course of their illness due either to interstitial lung disease or pulmonary hypertension. Both bronchoalveolar lavage and high-resolution computed tomographic scans, in the face of normal chest radiographs, have indicated interstitial lung disease in both symptomatic and asymptomatic patients (Fig. 60-18). Although unusual, interstitial lung disease and pulmonary hypertension have preceded the dermatologic manifestations, defined as systemic sclerosis sine scleroderma.[45] Despite the lack of skin involvement, the course in systemic sclerosis sine scleroderma does not significantly differ from the more common forms, with exception of a greater tendency toward the development of pulmonary hypertension.

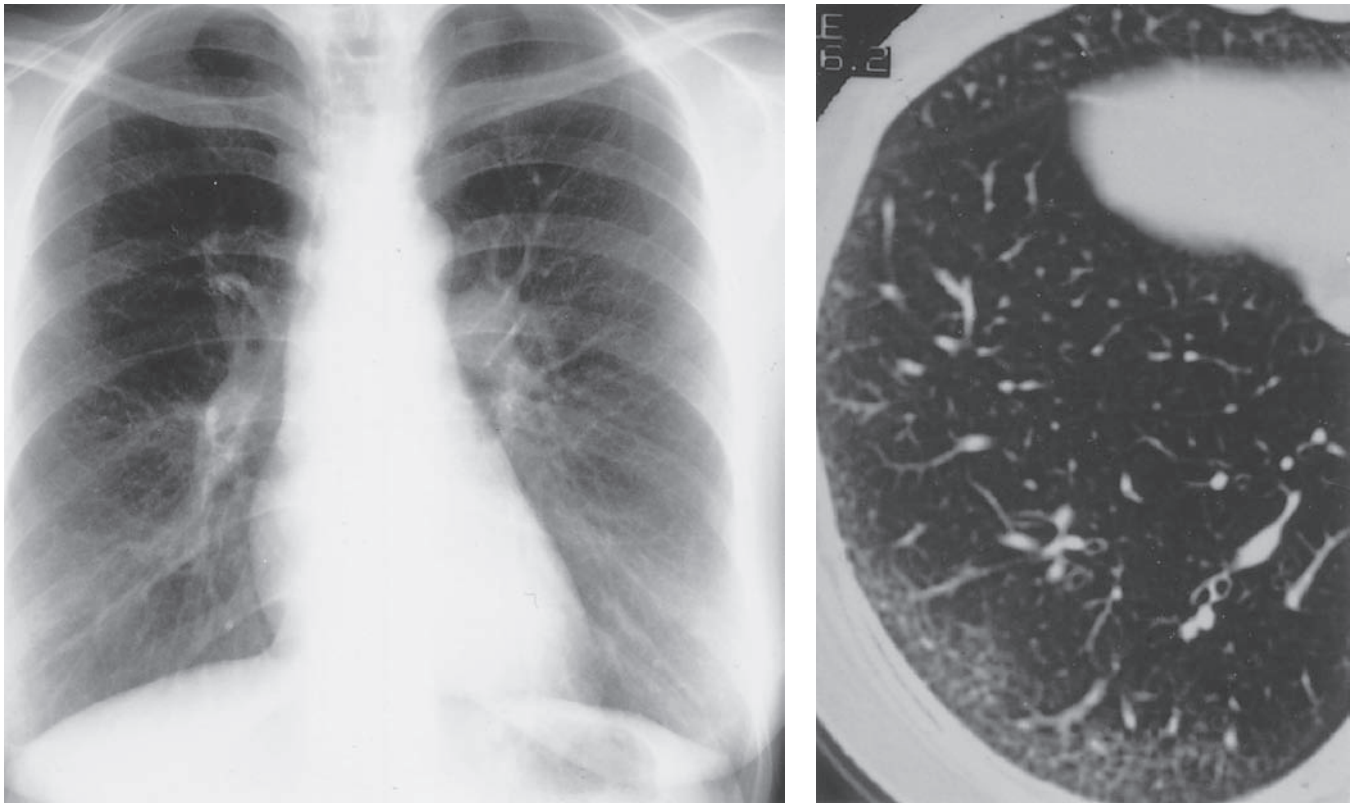
PLEURAL DISEASE

Although pleural fibrosis and adhesions are reported to be present in 40% of patients with scleroderma in postmortem studies, clinically apparent pleural thickening or pleural effusions on chest radiographs are considerably less frequent. The exception to this is pleural effusions secondary to congestive heart failure due to a scleroderma-associated cardiomyopathy.

INTERSTITIAL LUNG DISEASE

Interstitial lung disease, progressing to honeycomb lung, is the most common pulmonary complication of scleroderma, occurring in 30% to 100% of cases. A high-resolution computed tomographic study indicated a greater than 90% incidence of this abnormality with up to two-thirds of patients having normal chest radiographs. As many as 60% of patients who undergo bronchoalveolar lavage will demonstrate an abnormal inflammatory cell distribution. Chest radiographic and physiologic screenings indicate somewhat lower prevalence. The significance of the bronchoalveolar lavage and computed tomographic findings remain unclear, since no longitudinal follow-up is available. Following the histologic reclassification of idiopathic interstitial pneumonias, the most common underlying histology in systemic sclerosis is NSIP with honeycomb lung. UIP, unclassifiable fibrosing interstitial lung disease, and rarely, organizing pneumonia and granulomatous lung disease resembling sarcoidosis have also been reported.[46] It was previously thought that interstitial lung disease in scleroderma was primarily a fibrotic disorder. However, recent information derived from high-resolution computed tomography demonstrating ground-glass attenuation, which indicates more cellular disease, bronchoalveolar lavage revealing increased inflammatory cell populations, and biopsy material demonstrating cellular infiltration of the interstitium indicates the presence of a cellular inflammatory response.[47] This predates the development of fibrosis, consistent with the cellular subtype of NSIP. It is likely that the inflammatory phase in most cases is clinically silent.

Interstitial lung disease is more likely to occur in diffuse systemic sclerosis, although it may also complicate limited systemic sclerosis, formerly referred to as the CREST syndrome. Dyspnea on exertion



A B

Figure 60-18 **A.** Normal chest radiograph in a dyspneic patient with scleroderma. **B.** High-resolution computed tomography of the same patient demonstrating reticular interstitial infiltrates.

progressing to dyspnea at rest and cough are the predominant symptoms. Bibasilar crackles are heard, but clubbing is unusual due to the capillary destruction in the nail beds. Physical findings of cor pulmonale eventually appear. Bibasilar interstitial infiltrates followed by more diffuse changes, loss of lung volume, honeycomb cysts, and pulmonary hypertension are the typical radiographic features. Scleroderma was the first interstitial lung disease in which scar carcinoma (adenocarcinoma or alveolar cell carcinoma) was reported. Several reports suggest an increased incidence of lung neoplasms in patients with scleroderma.[48,49] Physiologic testing eventually reveals restrictive lung disease, preserved flow rates, and a reduced diffusing capacity. Early on, the aforementioned measurements may be normal, and hypoxemia and a widened alveolar–arterial oxygen gradient at rest and heightened by exercise may be the only physiologic abnormality. A disproportionally greater reduction[50] of the diffusing capacity, when compared to lung volumes, most likely indicates the presence of idiopathic pulmonary hypertension due to plexogenic arteriopathy, particularly in the limited form of systemic sclerosis.

Other forms of interstitial lung disease seen in scleroderma include lymphocytic interstitial pneumonitis in those cases associated with Sjögren syndrome; rare cases of diffuse alveolar hemorrhage, and DAD in association with exacerbations of fibrotic lung disease in scleroderma have been reported.

Immunosuppression is the mainstay of treatment, with corticosteroids and cyclophosphamide being the agents of choice. The NHLBI-sponsored Scleroderma Lung Health Study confirmed prior retrospective studies suggesting improved lung function in those patients treated with cyclophosphamide. Although the improvement in lung function is of questionable clinical significance, a therapeutic effect is expected in those with ground-glass attenuation on HRCT imaging, a lymphocytic or eosinophilic predominant bronchoalveolar lavage, and a cellular interstitial pneumonia on lung biopsy.[51,52] Unfortunately, the durability of response to cyclophosphamide was limited as the majority of physiologic benefit waned after 12 months of discontinuation of treatment.[53] Mycophenolate mofetil and rituximab have been reported to benefits patients with progressive disease in scleroderma.[54–57] The efficacy of mycophenolate is currently the focus of an ongoing study sponsored by the National Institutes of Health.

PULMONARY VASCULAR DISEASE

Pulmonary hypertension, due to a plexogenic arteriopathy involving the pulmonary arteries, occurs in approximately 10% of cases of scleroderma and is primarily seen in the limited form (CREST syndrome). In this form of scleroderma, pulmonary hypertension may coexist with interstitial lung disease. Patients present with a gradual onset of dyspnea and increasing fatigue. Physical examination and chest radiograph may initially be normal, and, with disease progression, physical and radiographic signs of pulmonary hypertension appear. Lung volumes and airflow parameters are maintained, unless there is concomitant interstitial lung disease. Typically there is an isolated reduction in the diffusing capacity as well as progressive hypoxemia. Prior to the use of vasodilator therapy, the mean survival following a diagnosis of pulmonary hypertension was approximately 2 years. Treatment with continuous intravenous prostacyclin, phosphodiesterase type 5 inhibitors, and endothelin antagonists have improved the quality of life and exercise performance. Improved survival has been suggested with the use of these agents, specifically in those patients with isolated pulmonary arterial hypertension, in contrast to those with ILD-associated pulmonary hypertension.[58]

ASPIRATION PNEUMONIA

There is a high incidence of esophageal dilatation and decreased peristalsis (dysmotility) in patients with scleroderma, particularly in

Figure 60-19 Mild peripheral, linear, ground-glass opacities in both lungs with marked thickening of the esophageal wall and severe dilatation of esophageal lumen with extensive debris filling the lumen in a patient with limited systemic sclerosis.

the limited variety (Fig. 60-19). This leads to dysphagia, heartburn, gastroesophageal reflux, and possibly aspiration with subsequent pneumonia.[59] It has long been held that reflux and aspiration contribute to the development of interstitial lung disease, albeit with a paucity of direct evidence.[60] In scleroderma, several different abnormalities contribute to the risk of reflux and aspiration: altered peristalsis, reduced lower esophageal pressure, presence of a hiatal hernia, gastroparesis, and autonomic nerve dysfunction.[61] Aggressive treatment to reduce the risk of reflux and aspiration is recommended despite inconclusive evidence to suggest an association. Behavioral modification and pharmacologic acid suppression are the initial interventions. In refractory situations, fundoplication may be considered in the appropriate patient, particularly in those with advanced lung fibrosis awaiting transplantation in an attempt to decrease the incidence posttransplantation bronchiolitis obliterans and chronic rejection.[62–64]

POLYMYOSITIS-DERMATOMYOSITIS: CLINICAL FEATURES

Polymyositis is a systemic autoimmune disorder characterized by an inflammatory myopathy. Dermatomyositis differs from polymyositis in that prominent skin involvement, characterized by a heliotropic rash and/or erythematosus scaling over the proximal interphalangeal joints, termed *Gottron papules* or *rash*, occurs with less severe myositis. In polymyositis–dermatomyositis, pulmonary complications are common and important causes of morbidity and mortality and as seen in other connective-tissue diseases, often predate or overshadow the muscle or skin manifestations. Pulmonary involvement has been reported in up to 40% of cases.[65] In contrast to the other collagen vascular diseases, in polymyositis–dermatomyositis primary involvement of the airways and pleura do not routinely occur. Pulmonary hypertension secondary to plexogenic arteriopathy has been reported on several occasions, most often in cases in which a crossover with scleroderma was suspected.

■ ASPIRATION PNEUMONIA

Aspiration pneumonia is a common pulmonary complication, occurring in 10% to 20% of patients with polymyositis–dermatomyositis; almost half of the patients complain of dysphagia as well. This complication results from an inflammatory myositis affecting the striated muscle of the hypopharynx and upper third of the esophagus. As a result, there is loss of normal swallowing function and failure to protect the airway. Aspiration is more likely in those patients with extensive skin or muscle involvement given the associated myositis.

■ RESPIRATORY MUSCLE DYSFUNCTION

Hypercapnic respiratory failure requiring assisted ventilation, due to extensive myositis involving the respiratory muscles and diaphragm, is an uncommon event (5% prevalence). In those patients presenting with unexplained hypercapnic respiratory failure, polymyositis–dermatomyositis as well as demyelinating neuromuscular disorders should be considered. With less extensive involvement of these muscles, however, there is a reduction in cough generation and the potential for the development of hypostatic pneumonia and atelectasis due to mucus plugging. Weakness can also cause a restricted physiologic defect with resulting tachypnea and dyspnea in the face of a normal diffusing capacity, normoxia, and hyperventilation. Respiratory muscle dysfunction as the cause of restrictive lung disease can best be demonstrated by measurement of the maximal pressure generated during both phases of the respiratory cycle. Sequential measurements are useful for monitoring the disease course and response to treatment.

■ INTERSTITIAL LUNG DISEASE

The prevalence of interstitial lung disease in polymyositis–dermatomyositis ranges from 5% to 30%.[66,67] The incidence is significantly higher in certain populations. In Japan, it approached 40% to 80% in one series. As in the other collagen vascular diseases, the use of bronchoalveolar lavage and high-resolution computed tomography for screening increases the documented incidence. In those screened with high-resolution CT imaging, the incidence approaches 78% within 3 years of diagnosis.[68]

Although UIP was previously reported to be the predominant histologic type of interstitial lung disease seen in polymyositis–dermatomyositis, NSIP now appears to be most common, based on the revised classification system for idiopathic interstitial pneumonias. DAD, organizing pneumonia, and diffuse alveolar hemorrhage secondary to pulmonary capillaritis may also occur.[69] All forms of interstitial lung disease may precede, appear simultaneously with, or follow the muscle or skin manifestations. There is no relationship between interstitial lung disease and the extent of muscle or skin disease, the level of creatinine phosphokinase elevation, or the presence of serum rheumatoid factor or antinuclear antibodies. There is, however, a relationship between interstitial lung disease and a serum antibody directed against the cellular enzymes tRNA-synthetases, the most common of which being known as anti–Jo-1.[70] This antibody appears in 25% of patients with polymyositis–dermatomyositis in total, but in 50% of patients with interstitial lung disease and in 13% of patients without lung disease. Depending on which tRNA-synthetase antibody is present, different clinical phenotypes may occur with varying degrees of myositis and lung involvement.[71,72]

All forms of interstitial lung disease in polymyositis–dermatomyositis are more common in women. Several clinical syndromes occur and are associated with the underlying interstitial lung disease. The most common presentation is chronic cough and progressive dyspnea due to NSIP with varying degrees of fibrosis.[73] Digital clubbing is rarely, if ever, seen. Chest radiographs demonstrate reticulonodular infiltrates, and with disease progression there is a reduction of the lung volume and the development of radiographic honeycomb lung and pulmonary hypertension. Physiologic testing indicates a restrictive pattern with a low diffusing capacity. Response to treatment depends upon the underlying histology, the more cellular disease being more responsive. In

Figure 60-20 Bronchiolitis obliterans organizing pneumonia in a patient with polymyositis-dermatomyositis and acute symptoms. Chest radiograph demonstrating diffuse patchy alveolar infiltrates.

corticosteroid-resistant patients, cyclophosphamide, cyclosporine, tacrolimus, mycophenolate mofetil, intravenous immunoglobulins, and rituximab have been used with efficacy.[74]

In polymyositis–dermatomyositis, an acute pulmonary presentation with a clinical and radiographic picture reminiscent of a diffuse infectious pneumonia may occur and is associated with a poorer prognosis. The underlying lesion is DAD. Severe respiratory failure occurs, and recovery is unusual in spite of aggressive anti-inflammatory and immunosuppressive therapy. Organizing pneumonia may have either an acute or subacute presentation (Fig. 60-20). The differentiation from DAD becomes important because of the marked disparity in treatment outcome and survival. In organizing pneumonia, corticosteroid responsiveness with or without an additional agent is the rule rather than the exception. Diffuse alveolar hemorrhage due to pulmonary capillaritis may also occur.[75] This complication appears simultaneously with the onset of the muscle disease. Hemoptysis may or may not be present. As with other forms of pulmonary capillaritis, immunosuppression with corticosteroids and cyclophosphamide is utilized and been efficacious.

MIXED CONNECTIVE-TISSUE DISEASE: CLINICAL FEATURES

Patients with mixed connective-tissue disease have features of SLE, polymyositis–dermatomyositis, and scleroderma. Mixed connective-tissue disease is characterized by elevated titers of a specific antinuclear antibody directed against nuclear ribonucleoprotein (anti-RNP). Because of the similarity of mixed connective-tissue disease to the aforementioned collagen vascular diseases, pleuropulmonary complications are frequent, occurring in 20% to 80% of cases.[76,77]

PLEURAL DISEASE

Although pleurisy has been reported to occur in 40% of cases, pleural effusions are uncommon, appearing in approximately 5% of cases.[78] Effusions have been characterized as exudative in nature, but limited information is available in the literature.

PULMONARY VASCULAR DISEASE

Pulmonary hypertension may be caused by recurrent pulmonary emboli, hypoxic vasoconstriction secondary to interstitial lung disease, or plexogenic arteriopathy, as occurs in SLE and scleroderma. This is a significant problem for these patients; however, the incidence is unknown but may be less common than previously believed.[79] These patients, primarily women, present with dyspnea and fatigue. They have normal chest radiographs except for pulmonary arterial enlargement and an isolated reduction in the diffusing capacity for carbon monoxide. The prognosis in pulmonary hypertension secondary to mixed connective-tissue disease is similar to that noted in pulmonary hypertension seen in scleroderma and SLE. In contrast to patients without pulmonary arterial hypertension, 5-year survival is decreased from 96% to 73%.[80,81]

Medium-sized pulmonary artery vasculitis has been reported in mixed connective-tissue disease, with evidence suggesting immunologic-mediated injury with deposition (IgG, C_3) in the vascular walls. Circulating lupus anticoagulant (antiphospholipid syndrome) may also complicate the course of patients with mixed connective-tissue disease, predisposing them to thromboembolic disease.[82] It is in these patients that recurrent small pulmonary emboli may mimic the clinical picture of idiopathic pulmonary hypertension.

ASPIRATION PNEUMONIA

Patients with mixed connective-tissue disease, presenting with predominant features of scleroderma or polymyositis–dermatomyositis, are predisposed to esophageal dysmotility and dilatation, which can be a significant problem leading to reflux esophagitis and recurrent aspiration pneumonia. The presence of radiographic evidence of ILD closely associates with esophageal dilation and motor dysfunction, suggesting a common pathobiology.[83]

RESPIRATORY MUSCLE DYSFUNCTION

In those patients with features of polymyositis–dermatomyositis, an inflammatory myositis with respiratory muscle involvement may lead to hypercapnic respiratory failure or a restrictive lung disease with the development of hypostatic pneumonia.

INTERSTITIAL LUNG DISEASE

The incidence of interstitial lung disease in mixed connective-tissue disease is increased in comparison to other collagen vascular diseases, with greater than 50% of patients having abnormal high-resolution CT imaging abnormalities.[84] The histologic pattern of NSIP and/or UIP are noted, both of which may progress to honeycomb lung, particularly in those patients with the features of scleroderma. As with the other connective-tissue diseases, this interstitial lung disease manifests as progressive dyspnea, bibasilar reticulonodular infiltrates on chest radiograph, and physiologic parameters with low lung volumes and a reduction in the diffusing capacity for carbon monoxide.

Diffuse alveolar hemorrhage has been reported in a few cases of mixed connective-tissue disease and is similar in presentation to that in SLE. It is assumed that the histology is one of either bland pulmonary hemorrhage or pulmonary capillaritis but remains unknown.[85]

SJÖGREN SYNDROME

Sjögren syndrome refers to a triad of xerophthalmia, xerostomia, and polyarthritis. This autoimmune exocrinopathy is characterized by lymphocytic infiltration of the lacrimal and salivary glands.[86] A primary form, occurring in the absence of another collagen vascular disease, and a secondary form, associated with one of the other collagen vascular diseases, most frequently rheumatoid arthritis, exist.[87] A strong female predominance exists in Sjögren syndrome (90%). A positive rheumatoid factor (95%) and antinuclear antibodies in a speckled pattern (80%) are to be expected, as well as positive tests for antibodies to extractable nuclear antigens (anti-SSA, anti-SSB), which are specific for the primary form of the syndrome.

AIRWAY DISEASE

Lymphocytic infiltration and destruction of airway mucus glands result in desiccation of the tracheobronchial tree in Sjögren syndrome.[88] Patients may develop hoarseness, cough, inspissation of secretions resulting in luminal obstruction and atelectasis, recurrent pneumonias, and bronchiectasis. There is a high incidence of obstructive ventilatory dysfunction in these patients, secondary to follicular bronchiolitis. Obliterative bronchiolitis, constrictive bronchiolitis, and bronchiolectasis have also been reported.

INTERSTITIAL LUNG DISEASE

In primary Sjögren syndrome, patients present with a nonproductive cough, dyspnea on exertion, or asymptomatic radiographic abnormalities. As occurs in the lacrimal and salivary glands, interstitial lung disease in these patients is the result of lymphocytic infiltration of the lung parenchyma. This occurs in two forms, lymphocytic interstitial pneumonitis and, less commonly, pseudolymphoma. Both of these lesions have the potential for lymphomatous conversion. Lymphocytic interstitial pneumonitis is an interstitial lung disease in which cough, dyspnea, and restrictive physiology manifest. Because lymphocytes may also infiltrate the alveolar spaces as well as the interstitium, the radiologic studies indicate mixed alveolar and interstitial infiltrates. In a subset of patients, variably sized cystic lesions with associated ground glass may be the only radiographic abnormality (Fig. 60-21). The development of pleural effusions or the appearance of hilar or mediastinal adenopathy should be investigated further as it may suggest a malignant transformation to a lymphoma. Lymphocytic interstitial pneumonia is responsive to anti-inflammatory agents such as corticosteroids. Occasionally, cytolytic therapy, such as azathioprine or cyclophosphamide, is required but remains of unproven benefit. Cyclosporine has also been recommended as an additional agent in corticosteroid-resistant cases. Rituximab, an anti-CD20 monoclonal antibody, may be beneficial in selected patients but further controlled studies are required to better assess its efficacy in primary Sjögren syndrome. While the majority of patients will respond to immunosuppressive therapy, a subset of patients progress to fibrotic lung disease with honeycomb change.

Pseudolymphoma is a tumor-like proliferation appearing as single or multiple masses on the chest radiograph. It is often difficult to distinguish from a malignant lymphoma and it has been suggested that pseudolymphoma, which is considered to be a localized form of lymphocytic interstitial pneumonitis, is a premalignant lesion.[89] When associated with a monoclonal gammopathy, malignant transformation to lymphoma is suggested.[90]

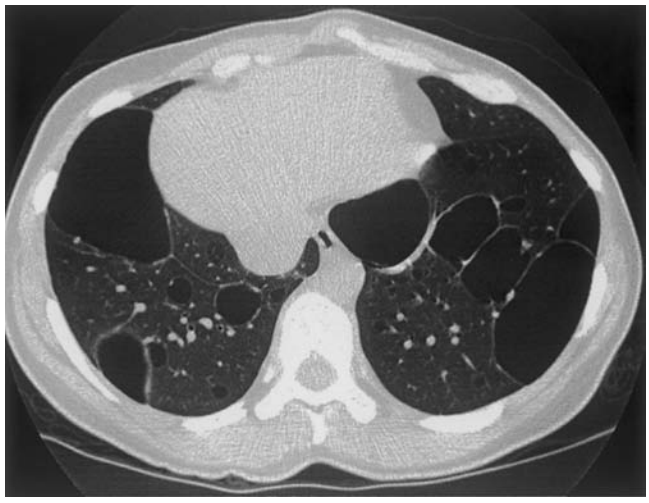


Figure 60-21 Multiple cysts of varying sizes scattered throughout both lungs in a patient with Sjögren syndrome and lymphocytic interstitial pneumonia.

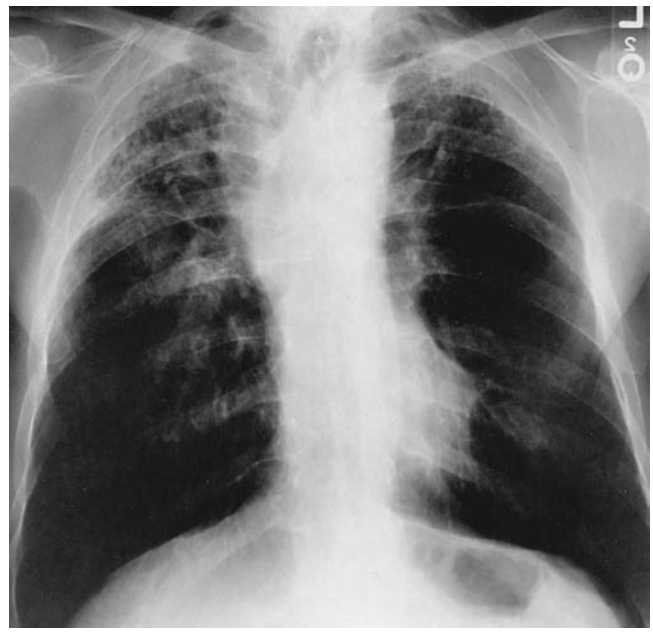

Figure 60-22 Ankylosing spondylitis. Chest radiograph demonstrating bilateral upper-zone fibronodular infiltrates.

Interstitial lung disease occurs more commonly in the secondary forms of Sjögren syndrome and most likely represents a complication of the associated collagen vascular disease.[2] The histologic pattern in secondary Sjögren syndrome mimics that seen in rheumatoid arthritis, with NSIP, UIP, and organizing pneumonia reported. UIP is uncommon in the primary form of Sjögren syndrome.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis is one of the seronegative spondyloarthropathies that may eventually result in fixation of the chest wall and a mild to moderate restrictive lung disease. Muscular involvement, in contrast to polymyositis–dermatomyositis, does not occur and diaphragmatic function is preserved, limiting ventilatory failure given the preserved respiratory muscle function.

The incidence of interstitial lung disease complication is reportedly less than 2%.[91] In contrast to the other collagen vascular diseases that primarily affect the basilar portion of the lung, ankylosing spondylitis has a predilection for the upper lung zones, only appears late in the course of the chronic spondylitis, and never precedes it.[92] Interstitial lung disease often appears as fibrocystic disease on the chest radiograph (Fig. 60-22) and is difficult to distinguish from apical lung infections such as tuberculosis. Histologically, it is a fibrosing process with cystic formation. Progressive dyspnea and cough are the predominant symptoms, and treatment with corticosteroids is ineffective and therefore not suggested. Etanercept may afford patient a short-term benefit with improvements in spinal mobility and pulmonary physiology.[93] The most serious complication of this apical fibrocystic disease is infection with invasive aspergilla species as well as atypical mycobacteria. Further, saprophytic colonization of the cysts by aspergilla species (aspergilloma) may induce life-threatening hemoptysis.

CHAPTER 61

Pulmonary Langerhans' Cell Histiocytosis

Sergio Harari
Olga Torre
Talmadge E. King Jr.
Joel Moss

INTRODUCTION

Pulmonary Langerhans' cell histiocytosis is part of a large spectrum of disorders characterized by abnormal organ infiltration by Langerhans' cells, which are highly differentiated cells in the monocyte-macrophage line that are also found in the dermis of the skin, reticuloendothelial system, pleura, and lung. Clinically, these disorders vary greatly, ranging from mild, single-organ disease to acute, disseminated life-threatening presentations. Depending on the sites involved and severity, the entity now referred to as Langerhans' cell histiocytosis has been previously defined as eosinophilic granuloma, Hand–Schüller–Christian disease, and Letterer–Siwe disease. A more recent and simplified system of classification includes Langerhans' cell histiocytosis with single-organ involvement or with multisystem involvement.[1]

Pulmonary Langerhans' cell histiocytosis is an uncommon, smoking-related, interstitial lung disease that primarily affects young adults. Usually, lung involvement occurs in isolation; less frequently, involvement of other systems, for example, bone, skin, pituitary gland, is seen. Although there is some similarity to other diffuse interstitial lung diseases, pulmonary Langerhans' cell histiocytosis, as a specific disease entity, is distinct in its clinical, radiologic, and pathologic manifestations.

EPIDEMIOLOGY

The true incidence and prevalence of pulmonary Langerhans' cell histiocytosis are unknown. Studies in which diagnoses were confirmed by lung biopsy showed that pulmonary Langerhans' cell histiocytosis is an uncommon, if not rare, disease.[2,3] A Japanese study of discharge diagnoses in hospitals with 200 beds estimated the disease prevalence at 0.27 and 0.07 per 100,000 population in males and females, respectively.[4] These reports may underestimate the true incidence of the disease, as lung biopsy is not performed in all cases of pulmonary Langerhans' cell histiocytosis, and some patients exhibit no symptoms or experience spontaneous remission. Occupational or geographical predisposition has not been reported.

Of note, nearly all affected persons report a current or prior smoking history. Thus, tobacco smoke is thought to play a key role in the pathogenesis of pulmonary Langerhans' cell histiocytosis of adulthood. Other diffuse parenchymal lung diseases associated with cigarette smoking are respiratory bronchiolitis-associated interstitial lung disease and desquamative interstitial pneumonitis.[5]

Most patients with pulmonary Langerhans' cell histiocytosis present to medical attention in young adulthood (20–40 years of age). Pulmonary Langerhans' cell histiocytosis, however, may present in any age group. Older literature suggested a male preponderance; however, recent literature suggests an equal sex distribution, with increasing presentations in middle age. In general, women tend to present at an older age than men. These differences in prevalence may reflect the changing smoking habits of women in our society. For unknown reasons, whites are affected much more commonly than blacks or Asians, in whom this disease is very rare.

Pulmonary Langerhans' cell histiocytosis has reportedly been associated with a number of malignancies and may be a premalignant condition. Lymphoma, both Hodgkin's and non-Hodgkin's, and other hematologic and solid cancers have been reported in association with pulmonary Langerhans' cell histiocytosis.[6] However, the evidence regarding this association is inconclusive. Malignancies may precede, follow, or occur concomitantly with the diagnosis of the interstitial lung disease. The carcinogenic effects of cigarette smoke are probably responsible for some of these tumors; thus, other components of tobacco may be responsible for pulmonary Langerhans' cell histiocytosis. Given the complexity of factors involved in the pathogenesis of cancer and pulmonary Langerhans' cell histiocytosis, it has been difficult to define the effects of tobacco on the pathogenesis of malignancies in patients with pulmonary Langerhans' cell histiocytosis. Possibly, shared genetic predisposition factors may also have a role in the development of malignancies in patients with the disorder.[7]

NATURAL HISTORY AND CLINICAL PRESENTATION

Patients with pulmonary Langerhans' cell histiocytosis come to medical attention in a variety of ways: as an incidental diagnosis that is suggested by a screening chest radiograph, after pneumothorax, or with respiratory or constitutional symptoms. Symptomatic patients most often have a nonproductive cough (56%–70%), dyspnea (40%), chest pain (10%–21%), fatigue (~30%), weight loss (20%–30%), and fever (15%). Pleuritic pain and acute dyspnea with a spontaneous pneumothorax can be a recurrent problem in as many as 25% of patients. Pleural thickening or effusion is rarely seen in the absence of a history of pneumothorax. Hemoptysis (13%) is occasionally reported, and it should prompt consideration of superimposed infection (e.g., *Aspergillus*) or tumor.[8]

Cystic bone lesions are present in 4% to 20% of patients with pulmonary Langerhans' cell histiocytosis and may produce localized pain or a pathologic bone fracture. The precise number of patients with bone lesions is not known because complete bone surveys are not routinely performed. Skeletal involvement may be either the sole symptomatic manifestation of pulmonary Langerhans' cell histiocytosis or may precede the more typical pulmonary manifestations. The radiographic pattern is not diagnostic. In most instances, the lesions are solitary and affect the flat bones. Central nervous system involvement with diabetes insipidus (approximately 15% of patients) is also seen and is believed to portend a poor prognosis. Skin involvement may also be present in adults with pulmonary Langerhans' cell histiocytosis.

Skin lesions are usually erythematous, maculopapular, or nodular. In these patients, the scalp is often involved by characteristic seborrheic and crusted lesions.[9]

The physical examination is usually unremarkable. On chest examination, crackles are uncommon. Digital clubbing is also uncommon. Secondary pulmonary hypertension (PH) may occur and is probably underrecognized. Manifestations of cor pulmonale are seen in advanced stages. Routine laboratory studies are usually unrevealing; the peripheral eosinophil count is normal.[1]

PATHOGENESIS

The pathogenesis of adult pulmonary Langerhans' cell histiocytosis is still poorly understood. However, the nearly universal association with cigarette smoking strongly implies causation. Smoke may activate alveolar macrophages through bombesin-like peptides. Bombesin is a neuropeptide produced by neuroendocrine cells, which are increased in the lungs of smokers.[10] Bombesin-like peptides are chemotactic for monocytes, are mitogenic for epithelial cells and fibroblasts, and stimulate cytokine secretion. Several antigens in cigarette smoke, including tobacco glycoprotein, may stimulate macrophage and epithelial cell production of cytokines, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), dendritic cell chemokines, for example, chemokine (C-C motif) ligand 20 (CCL20), osteopontin, and tumor necrosis factor-α (TNF-α) that promote recruitment and activation of Langerhans' cells.[11] In fact, GM-CSF and TNF-α have been found in the lesions of patients with Langerhans' cell histiocytosis and have been shown to facilitate the in vitro generation of Langerhans' cells from CD34+ hematopoietic stem cells.[12] TNF-α and other cytokines, for example, tumor necrosis factor-β (TNF-β), may also stimulate fibroblasts leading to fibrosis.[13] Moreover, tobacco glycoprotein may also cause an abnormal differentiation of T lymphocytes and a reduction in interleukin (IL)-2 release by lymphocytes, thereby enhancing survival or proliferation of Langerhans' cells (Fig. 61-1).[14]

Abnormalities in immune function, with a nonspecific increase in immunoglobulin G (IgG) in bronchoalveolar fluid, circulating and tissue-bound immune complexes, and abnormalities in T-cell function, have been observed in association with pulmonary Langerhans' cell histiocytosis and may be important in the pathophysiology of this disorder.[15] It is possible, however, that these findings represent nonspecific consequences of a generalized activation of immune effector cells.

Recent studies report high serum levels of IL-17A during active Langerhans' cell histiocytosis, IL-17A synthesis by dendritic cells of patients with multisystem Langerhans' cell histiocytosis, and an IL-17–dependent pathway for dendritic cells fusion, showing that IL-17 may play a role in pathogenesis, although its significance in pulmonary Langerhans' cell histiocytosis is not known.[16] Some studies suggest that the pathogenesis of pulmonary Langerhans' cell histiocytosis entails alterations of the expression of the adhesion molecules that regulate interactions between white blood cells and endothelial cells.[17,18] One important adhesion molecule for neutrophils that is expressed by endothelial cells is intercellular adhesion molecule-1 (ICAM-1). ICAM-1 expression by Langerhans' cells has been demonstrated in biopsy specimens of subjects with Langerhans' cell histiocytosis. Expression of other leukocyte adhesion molecules, such as the β_1 and β_2 integrins, has also been noted.[19] The significance of these findings and their relevance to pulmonary Langerhans' cell histiocytosis remain to be elucidated.

Alternatively, a viral infection has been suggested as the underlying cause of generalized Langerhans' cell histiocytosis. However, there are no convincing data to suggest a role for viral infection as a cause of pulmonary Langerhans' cell histiocytosis.[20] Although clonality of histiocytes has been shown in children and adults with multisystem Langerhans' cell histiocytosis or unifocal bone disease, pulmonary Langerhans' cell histiocytosis appears to be primarily a reactive process to cigarette smoke in which nonmalignant clonal evolution of LCH cells may occur in the setting of abnormal Langerhans' cell hyperplasia in the airways.[21,22]

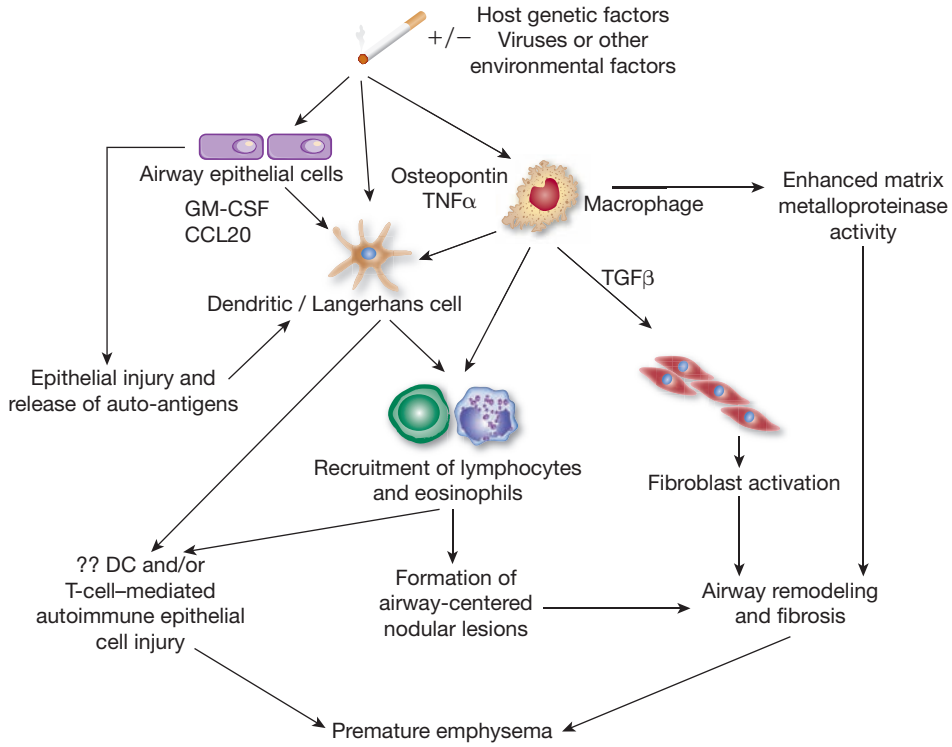

Figure 61-1 The primary event in the pathogenesis of pulmonary Langerhans' cell histiocytosis probably involves cigarette-smoke–induced recruitment to the lung and activation of Langerhans' cells, a process that may result from a variety of potential mechanisms. Antigens in cigarette smoke, including tobacco glycoprotein (TGP), may stimulate alveolar macrophages and epithelial cells to produce cytokines or other factors that enhance recruitment and activation of Langerhans' cells. Cigarette smoke may also directly activate Langerhans' cells to secrete cytokines (such as TNF or GM-CSF) that mediate local accumulation of inflammatory cells, with resultant formation of nodules. Uptake of cigarette-smoke antigens by alveolar macrophages or Langerhans' cells may also promote local expansion of T lymphocytes and further inflammation. Through the action of tobacco glycoprotein, reduced interleukin-2 secretion by lymphocytes may occur, thereby enhancing local survival and proliferation of Langerhans' cells. T lymphocytes may further stimulate B-lymphocyte activation, promoting secretion of antibodies and immune-complex formation. Fibroblast activation and fibrosis may result from the local synthesis of tumor growth factor-β (TGF-β) and by alveolar macrophages. *(Reproduced with permission from Suri HS, Yi ES, Nowakowski GS, Vassallo R. Pulmonary langerhans cell histiocytosis. Orphanet J Rare Dis. 2012;7:16.)*

HISTOPATHOLOGY

The pathologic cell type of pulmonary Langerhans' cell histiocytosis is the Langerhans' cell, a differentiated cell of the monocyte-macrophage line (Fig. 61-2). Langerhans' cells are distinguished by a pale-staining cytoplasm and large convoluted nucleus. Electron microscopy may demonstrate the classic pentalaminar cytoplasmic inclusion known as a Birbeck granule (Fig 61-3). Langerhans' cells are also characterized by the presence of the CD1a antigen on the cell surface, a feature not found in other cells of histiocytic origin. Langerhans' cells also react with anti-S-100 antibody, but this reactivity can also be observed in other cell types. More recently, langerin, a type II mannose lectin that is constitutively associated with Birbeck granules, has been identified as a specific marker of Langerhans' cells.[23] Although this cell can be found in association

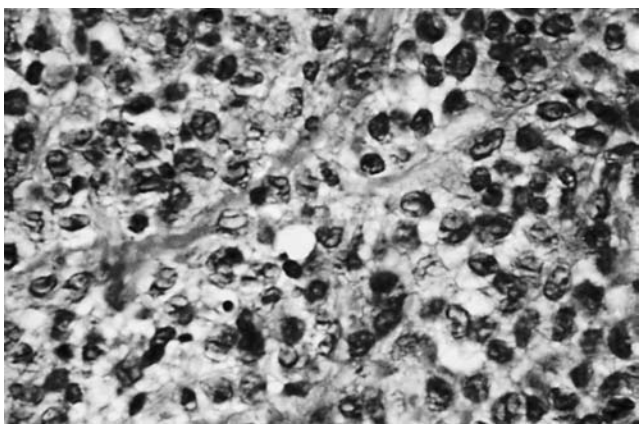

Figure 61-2 Lung tissue in pulmonary Langerhans' cell histiocytosis. The Langerhans' cells are typical. A characteristic longitudinal groove is seen along the center of some cells (×96.)

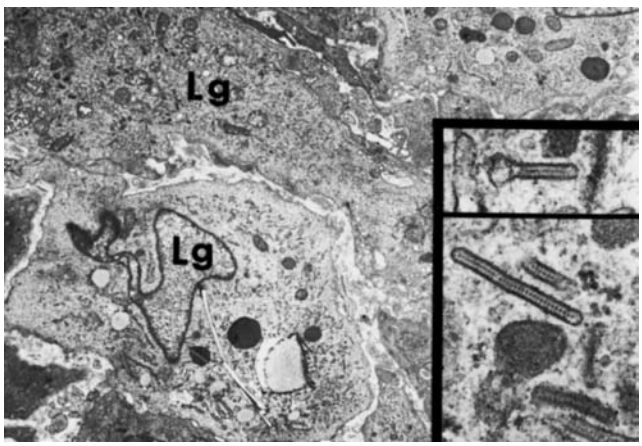

Figure 61-3 Electron micrograph of Langerhans' cell (Lg) of the lung. Typical X bodies (Birbeck granules) are seen in the two insets.

with cigarette smoking in otherwise healthy persons and with other pulmonary pathologies (e.g., idiopathic pulmonary fibrosis) or in normal lung, its presence is characteristic of pulmonary Langerhans' cell histiocytosis. In pulmonary Langerhans' cell histiocytosis, the Langerhans' cells are characteristically found in clusters and significantly outnumber those seen in other lung diseases. Absolute quantitative guidelines for diagnosis of pulmonary Langerhans' cell histiocytosis have not been established.

Early inflammatory lesions center around the smaller bronchioles and usually contain a mixture of Langerhans' cells, eosinophils, lymphocytes, and neutrophils. The cells appear to invade the bronchiole, destroying the bronchiolar wall in an eccentric fashion. The lesions often affect pulmonary arterioles and venules, so that the disorder can be described as having a bronchovascular distribution.

Pseudodesquamative interstitial pneumonia (characterized by the accumulation of alveolar macrophages in the alveolar parenchyma between pulmonary Langerhans' cell lesions) and respiratory (smoker's) bronchiolitis (with pigmented macrophages filling the lumen of bronchioles and the surrounding alveolar spaces) have also often been found on lung biopsy.[3,8] In addition, intraluminal fibrosis was often present (86% of specimens). The fibrosis was characterized by mural incorporation, alveolar obliteration, and intraluminal buds. It was mild in extent in 59% of specimens, moderate in 20%, and marked in 9%. These findings support the hypothesis that intraluminal fibrosis serves as a mechanism for alveolar collapse, with progression to interstitial fibrosis and lung remodeling.[8]

Interstitial fibrosis and small cyst formation with a middle- to upper-zone predominance occur in advancing disease. This middle- to upper-zone predominance differs from that of idiopathic pulmonary fibrosis, which generally has a lower-zone predominance. More advanced lesions extend widely into the lung parenchyma that surrounds the bronchovascular structures and produce the so-called stellate lesions that are characteristic of this disorder.[3] Kambouchner et al.[24] used three-dimensional reconstructions of serial histologic sections to demonstrate that pulmonary Langerhans' cell histiocytosis lesions are elongated, sheath-like structures of variable diameter that extend proximally and distally along bronchioles and do not necessarily have a spherical morphology (Fig. 61-4).

Older lesions are relatively acellular, lacking Langerhans' cells entirely and producing a diffuse interstitial pathology that can be difficult to distinguish from other forms of end-stage pulmonary fibrosis, with extensive areas of fibrosis and honeycombing accompanying the cystic lesions. The mechanism for cyst formation is unknown. It may be a consequence of central necrosis of older stellate lesions. Alternatively, the cysts may occur as a result of secondary inflammatory foci in relatively avascular areas distal to more advanced bronchovascular lesions. Finally, these cysts may form, in part, because of obstruction of the more proximal airway by the stellate lesions (traction emphysema).

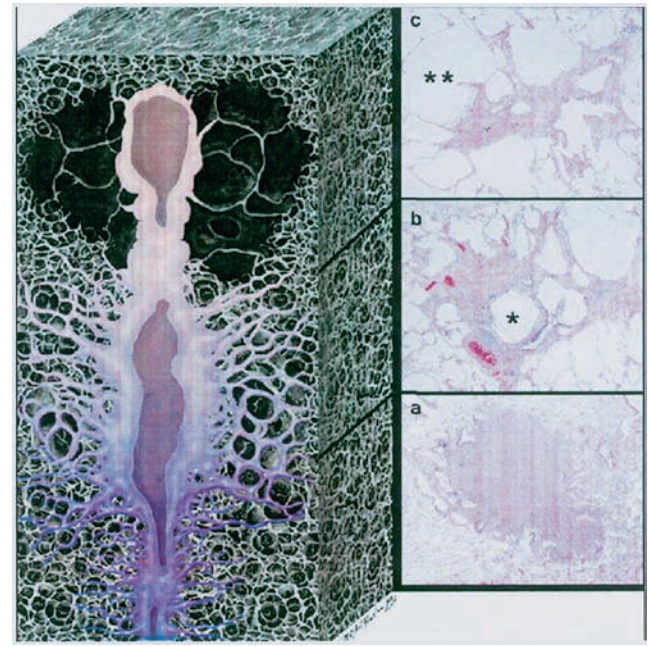

Figure 61-4 Three-dimensional appearance of a pulmonary Langerhans' cell histiocytosis (PLCH) lesion. Artist's rendering, based on the reconstructions by Kambouchner et al.,[24] illustrates the elongated morphology and variable cellular and fibrotic composition of PLCH with correlative histologic sections. As a PLCH lesion evolves, the nodule of densely packed cells (*bottom*, A) is centripetally replaced by fibrous tissue and ultimately becomes a stellate scar (*top*, C). This continuum of change may be evident within a single lesion. PLCH lesions are bronchiolocentric and propagate both proximally and distally along the small airways. The involved bronchiolar lumen may become either dilated or obliterated. The histologic sections correspond to the early, middle, and late phases of PLCH. In the early phase (*a*), there is a densely cellular nodule with delicate stellate extensions along the adjacent alveolar walls (original magnification, ×12; H&E stain). As the disease progresses (*b*), cellularity diminishes as fibroblasts replace the lesion (original magnification, ×19.2; H&E stain). Note that the stellate extensions have become more prominent, the central bronchiole (*) is dilated, and adjacent alveolar spaces have coalesced because of focal destruction of alveolar walls (paracicatricial airspace enlargement). In the final phase (*c*), the characteristic Langerhans' cell histiocytosis is absent and only a fibrous, stellate scar remains (original magnification, ×24; H&E stain). This phase is often accompanied by paracicatricial airspace enlargement (**). *(Used with permission of the Armed Forces Institute of Pathology (AFIP).)*

RADIOLOGY

The appearance of Langerhans' cell histiocytosis on routine chest x-ray, computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) are described below.

CHEST RADIOGRAPH

The radiographic appearance of pulmonary Langerhans' cell histiocytosis may be very characteristic. The combination of ill-defined or stellate nodules (2–10 mm in size), reticular opacities, upper-zone cysts or honeycombing, preservation of lung volume, and costophrenic angle sparing are believed to be highly specific for this disorder.[25] Typically, in keeping with the pathology, the reticular or nodular opacities are seen in the middle to upper zone (Fig. 61-5). The total lung volume is most often normal, although both hyperinflation and reduced volume have been described. In addition to pulmonary Langerhans' cell histiocytosis, other interstitial diseases that may present with an increased lung volume are lymphangioleiomyomatosis, chronic hypersensitivity pneumonitis, stage III sarcoidosis, constrictive bronchiolitis, and any interstitial lung disease in an individual with emphysema.

Small cysts and nodules are the radiographic hallmark of pulmonary Langerhans' cell histiocytosis (Fig. 61-6A); occasionally miliary disease is seen. Hilar or mediastinal adenopathy in pulmonary Langerhans' cell histiocytosis is rare and should prompt consideration of malignancy as a secondary diagnosis. Pleural thickening is most often due to treated pneumothorax, since pleural involvement by the primary disease process is uncommon. Bone lesions can occur in any bone, including the ribs. On rare occasions, patients come to medical attention with a solitary pulmonary nodule that, on biopsy, proves to be pulmonary Langerhans' cell histiocytosis.[26]

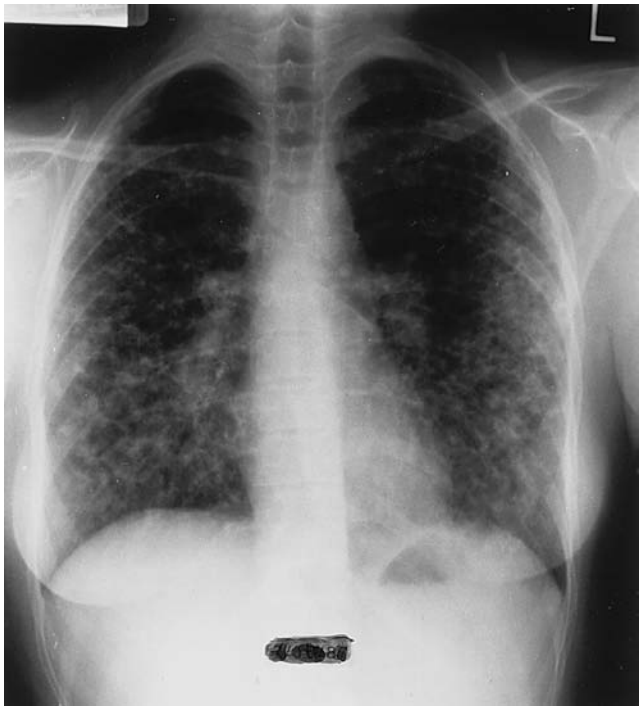

Figure 61-5 Pulmonary Langerhans' cell histiocytosis in a 22-year-old woman. Chest radiograph demonstrates the classic features of profuse ill-defined nodules, reticulonodular opacities, cysts, costophrenic angle sparing, and preservation of lung volumes.

■ COMPUTED TOMOGRAPHY

The combination of multiple cysts and nodules with a middle- to upper-zone predominance with interstitial thickening in a young smoker is so characteristic as to be diagnostic of pulmonary Langerhans' cell histiocytosis (Fig. 61-6B). The nodules can be well or poorly defined. Occasionally, they can be large and bizarrely shaped (Fig. 61-6C). Cysts may vary in shape, size, and wall thickness from a few to several millimeters. Honeycombing can be seen in advanced disease.[27,28] Serial chest CT scanning often suggests a sequence of progression from nodular to cavitating to cystic lesions over time.[29] Moreover, the CT pattern seems to reflect the histopathologic evolution of lung lesions, with cystic changes prominent in the advanced, fibrotic stages of the disease.[30]

The degree of cyst formation is often underappreciated with routine chest radiography. Thus, this progression may explain a number of "spontaneous remissions" in the literature reported before the routine use of thin-section CT scanning.[31] Although the extent of the cystic lesions present on HRCT at one point in time has been correlated with impaired lung function, the utility of serial CT scanning in managing these patients has yet to be determined.[32,33]

■ MAGNETIC RESONANCE IMAGING

The role of MRI in pulmonary Langerhans' cell histiocytosis is limited to evaluation of bone and central nervous system lesions.

■ POSITRON EMISSION TOMOGRAPHY

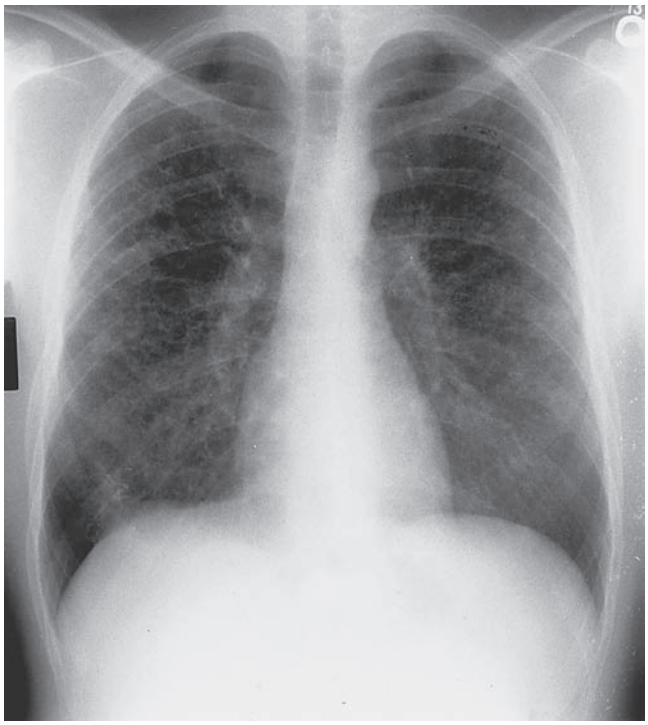
Fluorodeoxyglucose (FDG)-PET scan imaging has shown to be useful in quantifying disease activity, with positive scan results seen in patients with nodular, inflammatory lung disease. Moreover, FDG-PET scan may provide valuable information regarding extrapulmonary involvement in patients with a known diagnosis of pulmonary Langerhans cell histiocytosis. Nevertheless, the mean maximum standardized uptake value (SUV) of the PET scan-positive lesions may vary significantly, suggesting that PET scan imaging cannot reliably distinguish between the benign, inflammatory nodular lesions of Langerhans' cell histiocytosis and malignant lesions.[34]

PHYSIOLOGIC TESTING

Basic physiologic assessment in Langerhan's cell histiocytosis includes pulmonary function and exercise testing.

■ PULMONARY FUNCTION TESTING

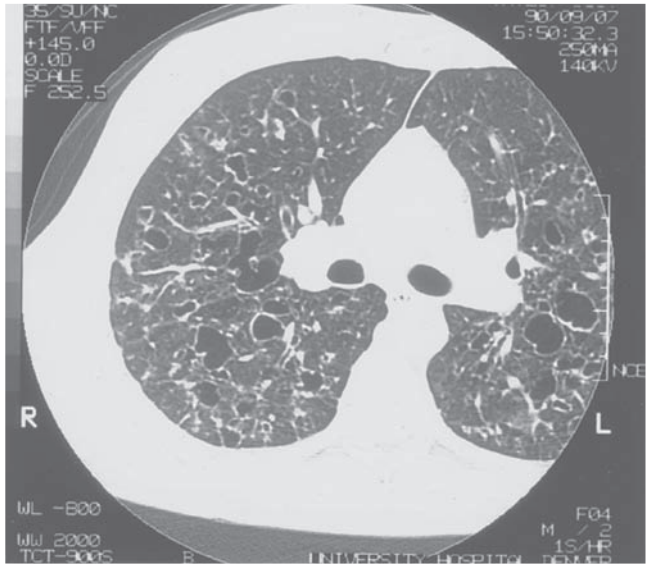
Pulmonary function testing of subjects with pulmonary Langerhans' cell histiocytosis may demonstrate all possible patterns of function abnormality—normal, obstructive, restrictive, or mixed. In general, total lung capacity (TLC) is well preserved, with nearly normal airflow. Most often, the diffusing capacity (D_{LCO}) is disproportionately reduced.[7,22,24] This pattern of pulmonary function abnormality suggests pulmonary vascular involvement by the disease process.



A

B

Figure 61-6 Pulmonary Langerhans' cell histiocytosis in a 33-year-old man. **A.** Chest radiograph reveals reticulonodular opacities in midlung zones, cysts, costophrenic angle sparing, and preservation of lung volumes. **B.** Conventional CT scan helps confirm the presence of bilateral reticulonodular opacities and cysts. *(continued)*



C

Figure 61-6 *(Continued)* **C.** High-resolution CT with thin section shows more clearly that the reticulonodular or emphysematous changes on chest radiography are actually cysts. In this instance, few nodules are present. The cysts vary markedly in size and may be larger than 10 mm. The cysts are bizarre in shape, and many are closely related to pulmonary arteries, often mimicking bronchiectasis.

In the experience at San Giuseppe Hospital in Milan, among 35 patients with pulmonary Langerhans' cell histiocytosis, an obstructive functional pattern was present in 43% of subjects. 10.5% of patients had a restrictive pattern and 3.5% a mixed pattern; 43% of patients showed normal airflow and volumes. A reduction in D_{LCO} was evident in 78% of patients.

Airflow limitation is sometimes associated with reactive airways; significant improvement may occur after administration of a bronchodilator. When present, reactive airways disease may reflect coexisting chronic obstructive pulmonary disease (COPD).

The mean alveolar–arterial difference in P_{O_2} (AaP_{O_2}) may be normal at rest, but the subset with more severe disease had a markedly elevated AaP_{O_2} and required supplemental oxygen. Resting pH and Pa_{CO_2} were most often normal. Thus, the resting arterial blood gas was a very insensitive indicator of disease.[35]

■ EXERCISE TESTING

Clinically, we have observed that patients with established pulmonary Langerhans' cell histiocytosis generally demonstrate a limitation in physical activity and intolerance for exercise that is out of proportion to their pulmonary function abnormalities.

In our cross-sectional study of 23 subjects with pulmonary Langerhans' cell histiocytosis, a marked decrease in exercise capacity, as measured by either work achieved (mean + SEM, 54 ± 4% of predicted) or oxygen utilization ($\dot{V}_{O_2}$, 44% ± 3) at maximal exercise, was found.[35] The oxygen pulse at maximal exercise was reduced to 56 ± 3%. The anaerobic threshold was decreased to 33% ± percent of expected $\dot{V}_{O_{2max}}$ (it was ≤40% in all subjects). The maximal ventilatory response ($\dot{V}_{E_{max}}$, 83 ± 5%) was excessive for the maximal level of work. The maximal ventilatory response was not limiting, and the $\dot{V}_{E_{max}}$ was well below predicted ventilatory ceilings. Gas exchange abnormalities were reflected in increasing AaP_{O_2} differences as the level of exercise increased. In addition, alveolar dead space to tidal volume ratio (V_D/V_T), a parameter believed to reflect pulmonary vascular function, was either abnormally elevated or failed to decrease

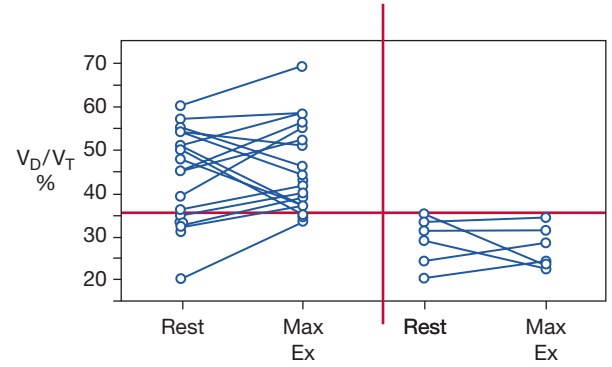


Figure 61-7 Dead space to tidal volume ratio (expressed as percentage, V_D/V_T%) at rest and maximal exercise (max ex) in patients with pulmonary Langerhans' cell histiocytosis (n = 23). Seventeen patients demonstrated either an abnormal V_D/V_T at rest or response to exercise *(left panel)*. Six patients had a normal V_D/V_T at rest and normal response to exercise *(right panel)*. *(Data from Crausman RS, Jennings CA, Tuder R, et al. Pulmonary histiocytosis X: Pulmonary function and exercise pathophysiology. Am J Respir Crit Care Med. 1996;153:426–435.)*

in most patients (Fig. 61-7). This abnormality suggested either pathologic or functional involvement of the pulmonary vasculature.

Two linear regression models derived from pulmonary function indices predicted 73% (r^2 = 0.73) and 75% (r^2 = 0.75) of the variability in the maximal achieved workload and predicted oxygen consumption at maximal exercise, respectively. The following equation was derived for the maximal achieved workload:

$$\text{Maximal achieved workload} = 0.884 - (0.0088 \times V_D/V_T \text{ baseline}) - (0.002 \times RV) + (0.0044 \times D_{LCO}) \quad (1)$$

Here the partial r^2 was V_D/V_T baseline (r^2 = 0.40, p = 0.0007), RV (0.19, 0.001), and D_{LCO} (0.15, 0.004). Figure 61-8 shows the regression model for the predicted oxygen consumption at maximal exercise.

Analysis of the composite results suggests that exercise intolerance in subjects with pulmonary Langerhans' cell histiocytosis is

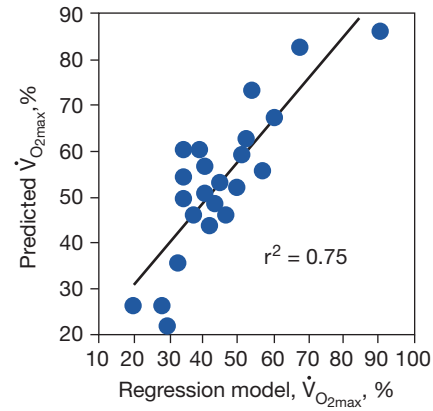

Figure 61-8 Correlation between predicted oxygen consumption at maximal exercise ($\dot{V}_{O_{2max}}$ and predicted $\dot{V}_{O_{2max}}$ from the linear regression model): $\dot{V}_{O_{2max}}$ = 0.062 − (0.0074 * baseline V_D/V_T) − (0.0014 * RV) + (0.0017 * baseline $P(Aa)_{O_2}$) + (0.0011 * D_{LCO}); r^2 = 0.75. *(Data from Crausman RS, Jennings CA, Tuder R, et al. Pulmonary histiocytosis X: Pulmonary function and exercise pathophysiology. Am J Respir Crit Care Med. 1996;153:426–435.)*

due to a combination of mechanical factors and pulmonary vascular involvement by pulmonary Langerhans' cell histiocytosis.[35]

Precapillary PH is a complication of advanced pulmonary Langerhans' cell histiocytosis and is associated with increased mortality.[36] Severe PH has been reported in a high percentage of patients referred for lung transplantation.[37,38]

In patients with respiratory insufficiency, chronic hypoxemia is a relevant factor, but the pathophysiology of PH in pulmonary Langerhans' cell histiocytosis is likely to be multifactorial, with other contributors including abnormal pulmonary mechanics and vascular remodeling. Histopathologic analysis of patients with end-stage disease shows proliferative vasculopathy involving muscular arteries and frequent venular involvement, with aspects of veno-occlusive disease.[37] The degree of PH appears not to be related to variables of pulmonary function; in a subgroup of patients, vasculopathy worsened, although parenchymal and bronchiolar lesions were unchanged, consistent with intrinsic pulmonary vascular disease.[37]

DIAGNOSTIC EVALUATION

The history and physical examination are the first steps in the diagnostic evaluation of a patient suspected of having pulmonary Langerhans' cell histiocytosis. Unfortunately, the signs and symptoms of pulmonary Langerhans' cell histiocytosis are generally nonspecific and often point to other, more common pulmonary diagnoses.[7,22] For example, wheezing, cough, and dyspnea in a 50-year-old patient with a prominent smoking history are much more commonly due to COPD than to pulmonary Langerhans' cell histiocytosis. However, when present, a history of recurrent pneumothorax, diabetes insipidus, or bone pain can be helpful. A smoking history is a consistent but not an essential component of the history, since pulmonary Langerhans' cell histiocytosis may occur without an antecedent smoking history especially in a young adult.

Most evaluations for pulmonary Langerhans' cell histiocytosis are prompted by an abnormal chest radiograph. As previously noted, the chest CT, if classic, may be diagnostic, and should, therefore, be obtained in all who are suspected of having this disease. We recommend high-resolution chest CT as a prebiopsy step in the evaluation of any patient with diffuse interstitial lung disease suspected of having pulmonary Langerhans' cell histiocytosis. A sufficiently characteristic chest CT, in association with the appropriate history, is believed by many to obviate the need for tissue confirmation. It should be noted that most often chest CT scans in pulmonary Langerhans' cell histiocytosis are not diagnostic and may be confused with chest CT scans of lymphangioleiomyomatosis, hypersensitivity pneumonitis, sarcoidosis, or idiopathic pulmonary fibrosis. In these instances, further diagnostic evaluation is warranted.

Bronchoalveolar lavage (BAL) fluid may be of diagnostic value in cases of suspected pulmonary Langerhans' cell histiocytosis.[39] The total number of cells recovered is usually increased (as expected in smokers), and a modest increase in the concentration of neutrophils and eosinophils is common. In active disease, the total number of lymphocytes recovered may also be increased, and the CD4:CD8 ratio may be decreased. Langerhans' cells in BAL fluid may be recognized by their characteristic reactivity with anti-S-100 protein antibodies or peanut agglutination antigen. These cells are also OKT-6 (CD1) positive, are identified by a specific monoclonal antibody (MT-1), and contain characteristic Birbeck or pentilaminar bodies on electron microscopic evaluation (Fig. 61-3).

Quantitative criteria for the definitive diagnosis of Langerhans' cell histiocytosis based on BAL fluid Langerhans' cell numbers have not been conclusively established. A BAL cell differential with more than 5% Langerhans' cells strongly suggests the diagnosis. Lower proportions of Langerhans' cells may be seen in current smokers, in patients with other interstitial lung disorders, in bronchoalveolar carcinoma, or even in normal subjects. Thus, the mere presence of Langerhans' cells is of little diagnostic value, and the effective sensitivity of this tool seems to be lower than previously believed.[40] BAL is also useful to exclude other inflammatory or infectious lung diseases.

When tissue confirmation is sought, transbronchial biopsy may be performed, but the patchy nature of the disease, with a focal distribution of the lesions, the potential for sampling error, and the inability to obtain sufficient tissue may account for the substantial number of false-negative or nondiagnostic biopsies.[41] Open, video-guided thoracoscopic lung biopsy, is generally definitive and may be done with a minimal operative risk. Tissue reactivity with the monoclonal antibody CD1 (OKT-6) distinguishes Langerhans' cells from other histiocytes and can be a useful diagnostic adjunct. It may be performed on routinely fixed tissue and is less expensive than electron microscopy.

In patients with progressive disease and extensive fibrosis, the number of Langerhans' cells in either tissue specimens or BAL fluid decreases dramatically. Diagnosis at this stage may be difficult, regardless of the laboratory methods used. In most cases, the combination of transbronchial lung biopsy and BAL, supplemented with the identification of CD1-positive cells in tissue and BAL fluid, is highly likely to result in the correct diagnosis.

TREATMENT AND PROGNOSIS

The natural history of pulmonary Langerhans' cell histiocytosis is extraordinarily variable, with some patients experiencing spontaneous remission of symptoms and others progressing to end-stage fibrotic lung disease and severe respiratory failure. A poor outcome in pulmonary Langerhans' cell histiocytosis has been associated with older age at the time of diagnosis, severe airway obstruction, reduced carbon monoxide diffusing capacity, and the need for corticosteroid therapy during follow-up.[42] Most subjects who continue to smoke demonstrate gradual progression; regression of disease is noted following smoking cessation.[43] Therefore, it is important to stress smoking cessation (Fig. 61-9). Patients with radiographic sparing of

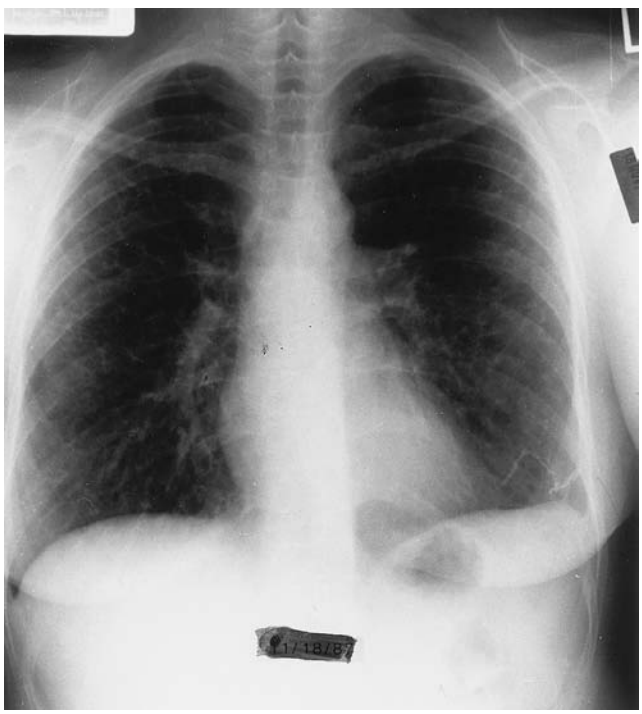

Figure 61-9 Follow-up chest radiograph in a 22-year-old woman obtained 4 months after the initial film shown in Figure 61-6. After an open lung biopsy performed on the left, she was told to stop smoking and treated with prednisone. The chest radiograph shows marked clearing of the ill-defined nodules and preservation of lung volumes.

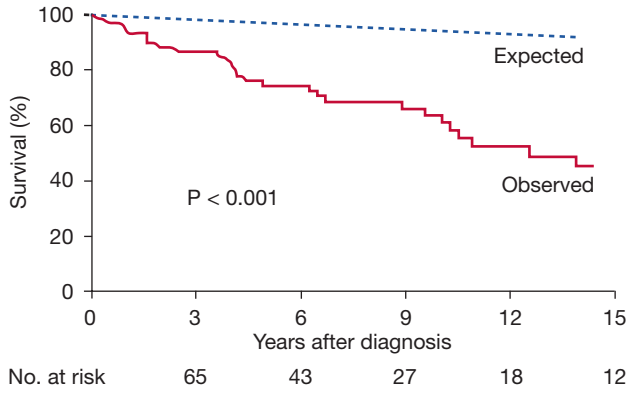

Figure 61-10 Kaplan–Meier analysis of expected and observed survival among 102 adults (40 men and 62 women) with pulmonary Langerhans' cell histiocytosis. The expected survival was defined as that for age- and sex-matched members of the general US population. The median follow-up period after the diagnosis of pulmonary Langerhans' cell histiocytosis was 4 years (range, 0–23). There were 33 deaths, 15 of which were attributable to respiratory failure. Survival was significantly shorter than that expected for healthy persons of the same sex and calendar year of birth ($p < 0.001$). *(Reproduced with permission from Vassallo R, Ryu JH, Schroeder DR, et al. Clinical outcomes of pulmonary Langerhans'-cell histiocytosis in adults. N Engl J Med. 2002;346(7):484–490.)*

the costophrenic angle are more likely to remain stable or to improve than are patients with involvement of the costophrenic angle.

Although corticosteroids have historically been employed in patients with progressive disease, their efficacy in the treatment of pulmonary Langerhans' cell histiocytosis has not been proved. Cytotoxic therapy, which may be of value in the treatment of disseminated disease, has not shown to be effective in pulmonary Langerhans' cell histiocytosis.

Recently, cladribine (2-chlorodeoxyadenosine), an agent cytotoxic for lymphocytes and monocytes, has been reported to have some efficacy in patients with progressive pulmonary Langerhans' cell histiocytosis.[44,45] Cladribine has been used successfully alone or in combination with an alkylating cytostatic agent and corticosteroids in a small number of adult patients with a multisystem or aggressive multifocal form of Langerhans' cell histiocytosis.[46] A randomized controlled trial is needed to assess the effectiveness and tolerance of cladribine in a larger population of patients. Successful use of therapy for PH has been reported in patients with Langerhans' cell histiocytosis.[47,48]

Radiotherapy for symptomatic bone lesions may be palliative. Radiation is not useful in the treatment of the pulmonary manifestations. Lung transplantation has been successfully accomplished in a number of centers. It is a viable option for selected patients with end-stage disease or severe PH. Recurrence of pulmonary Langerhans' cell histiocytosis after lung transplantation has been reported, especially in patients who resumed smoking after the transplant.[49]

The rate of recurrence of pneumothoraces is high in the absence of interventions to prevent additional episodes. Pleurodesis may be needed in patients with recurrences.[50]

Figure 61-10 shows a Kaplan–Meier analysis of expected and observed survival among adults with pulmonary Langerhans' cell histiocytosis.

CHAPTER 62

Pulmonary Lymphangioleiomyomatosis

Angelo M. Taveira-DaSilva
Talmadge E. King Jr.
Joel Moss

Lymphangioleiomyomatosis (LAM) is a multisystem disorder, predominantly affecting women, which is characterized by cystic lung lesions, abdominal angiomyolipomas (AML) and lymphatic abnormalities, for example, lymphatic tumors, chylous effusions.[1–5] These pathologic features are caused by the proliferation of a neoplastic smooth muscle–like LAM cell that also has characteristics of melanocytes.[6] Inherited and sporadic forms of LAM have been described. Sporadic LAM is caused by somatic mutations in an unknown susceptible cell of the tuberous sclerosis complex (TSC) 2 (*TSC2*) gene.[7,8] LAM also occurs in TSC, an autosomal dominant disorder resulting from germline mutations in the *TSC1* or *TSC2* genes that is characterized by widespread hamartomas in several organs including the brain, heart, skin, kidney, eyes, lung, and liver, and occurs in 1 of 6000 live births.[9]

EPIDEMIOLOGY

Until the establishment of LAM registries,[1] LAM was considered to be a fatal disease of women of child-bearing age for which oophorectomy, antiestrogen therapy, and lung transplantation were the only therapeutic options.[10–13] LAM is now best defined as a chronic disease of post- and premenopausal women with a life expectancy spanning decades.[14] Sporadic LAM is an uncommon disease occurring in approximately 4.9/1,000,000 women.[15] Although the association of TSC and cystic lung disease has long been recognized,[11–13] little is known about the prevalence and the natural history of LAM in TSC (TSC-LAM). The prevalence of cystic lung disease in women with TSC was reported to range from 30% to 40%; in male patients, it has been estimated to be 13%.[16] Males with TSC tend to have milder, subclinical lung involvement.

CLINICAL PRESENTATION

Patients with LAM often present with a history of progressive dyspnea. Pneumothorax, another common presentation of LAM, is often recurrent, occurring in about 50% to 60% of patients.[1–4] The size of the lung cysts, as seen on high-resolution computed tomography (HRCT) scans (Fig. 62-1A), appears to parallel the incidence of pneumothorax; higher incidence of pneumothorax is seen in patients with larger cysts.[17] Other modes of presentation include chylothorax, abdominal lymphangioleiomyomas, chylous ascites, hemoptysis, chyluria, chyloptysis, and hemorrhage caused by renal AML (Table 62-1).[1,5,18] Lymphatic involvement in LAM occurs in the posterior mediastinum, retroperitoneal and pelvic areas and includes lymphadenopathy, chylous effusions, and lymphangioleiomyomas.[5,18] AML are benign tumors, usually localized in the kidneys and found in approximately 90% of patients with TSC-LAM and 30% of those with sporadic LAM (Table 62-1).[1,5,18] The physical examination of LAM patients may disclose wheezing, pleural effusions, ascites, or intra-abdominal masses. In patients with TSC, typical skin lesions or signs of brain involvement may be evident.[9]

PATHOLOGY

Gross examination of lung sections shows cysts ranging in size from 0.2 to 2 cm.[6,19] Microscopically, cysts characterize lung lesions and proliferation of LAM cells in the walls of cysts and along blood vessels, lymphatics, and bronchioles (Fig. 62-1B1,B2), causing airways narrowing, vascular wall thickening, lymphatic disruption, and venous occlusion are observed.[6,19] Focal hemosiderosis may be present. Often LAM cells grow in a haphazard, disorderly fashion.[6,19] Two types of LAM cells have been described. Small, spindle-shaped cells predominate in the center of the lung nodules; epithelioid cells with large cytoplasm predominate at the periphery.[6,19] Both cell types react with antibodies against smooth muscle–cell antigens (e.g., smooth muscle α-actin, vimentin, desmin). The epithelioid cells also react with human melanin black antibody (HMB-45), a monoclonal antibody that recognizes gp100, a premelanosomal protein encoded by the *Pmel17* gene (Fig. 62-1B2, inset).[6,19] Spindle-shaped LAM cells react with proliferating cell nuclear antigen, indicating that these cells are more proliferative.[6] Receptors for estrogen, progesterone, insulin-like growth factors, angiotensin II, hyaluronic acid (CD44), chemokines, and erythropoietin have been identified in LAM cells.[20–27]

AML are highly vascular tumors comprising smooth muscle–like cells, immature, poorly differentiated blood vessels, and fatty tissue (Fig. 62-1D).[6,19] Tumors vary in size from 1 mm to more than 15 cm in diameter.[18,19] Smooth muscle–like cells found in AML have the same immunocytochemical properties as lung LAM cells (Fig. 62-1D).[6,19] All the major cell types in AML (vascular, fat, smooth muscle) may have mutations in the TSC genes.[7,8] The blood supply of AML originates from the renal arteries or aberrant vessels and may completely disrupt normal kidney architecture.[18,19] Hilar, mediastinal, and retroperitoneal lymphadenopathy may be seen.[18,19] The thoracic duct may be thickened and dilated.[19] Lymphangioleiomyomas consist of encapsulated lymphatic masses of varying sizes comprising chyle-filled cysts, with infiltration of LAM cells, displaying the immunoreactivity profile of LAM lung cells, arranged in fascicular, trabecular or papillary patterns and associated with slit-like vascular channels (Fig. 62-1F).[6,19]

PATHOGENESIS

Sporadic LAM is caused by proliferation of neoplastic LAM cells that have mutations or deletions in the *TSC2* (16p13) gene.[7,8] Consistent with Knudson's "two-hit" hypothesis of tumor development,[28] loss of heterozygosity of *TSC2* has been reported in LAM cells isolated from lung, blood, chyle, urine, and AML from both sporadic LAM and TSC-LAM patients.[8,29–31] LAM cells having identical mutations were identified in AML and lungs of the same patient.[8,31] LAM cells from patients receiving lung transplantation have been detected in the donor lung, suggesting migration from other sites, such as the kidney or lymphatic system, to the lungs.[32,33] The metastatic properties of LAM cells were also demonstrated by the presence of LAM cells in blood, urine, expectorated chyle and pleural, or abdominal chylous fluid of LAM patients.[29,30] LAM cell clusters, consisting of LAM cell aggregates covered by lymphatic endothelial cells, which have been proposed to originate from lung LAM lesions, have also been identified in chylous fluid.[34] Potential sources of lung LAM cells include AML, the lymphatic system, and the uterus,[35] in which case they may originate from abnormal leiomyoma.

A role of estrogens in the pathogenesis of LAM has been suggested by its predominance in premenopausal women, worsening of lung disease during pregnancy or following the administration of estrogens[36,37] and the presence of estrogen and progesterone receptors in lung and angiomyolipoma LAM cells.[20–22] Estrogens promote the proliferation of TSC-null rat ELT3 leiomyoma–derived cells

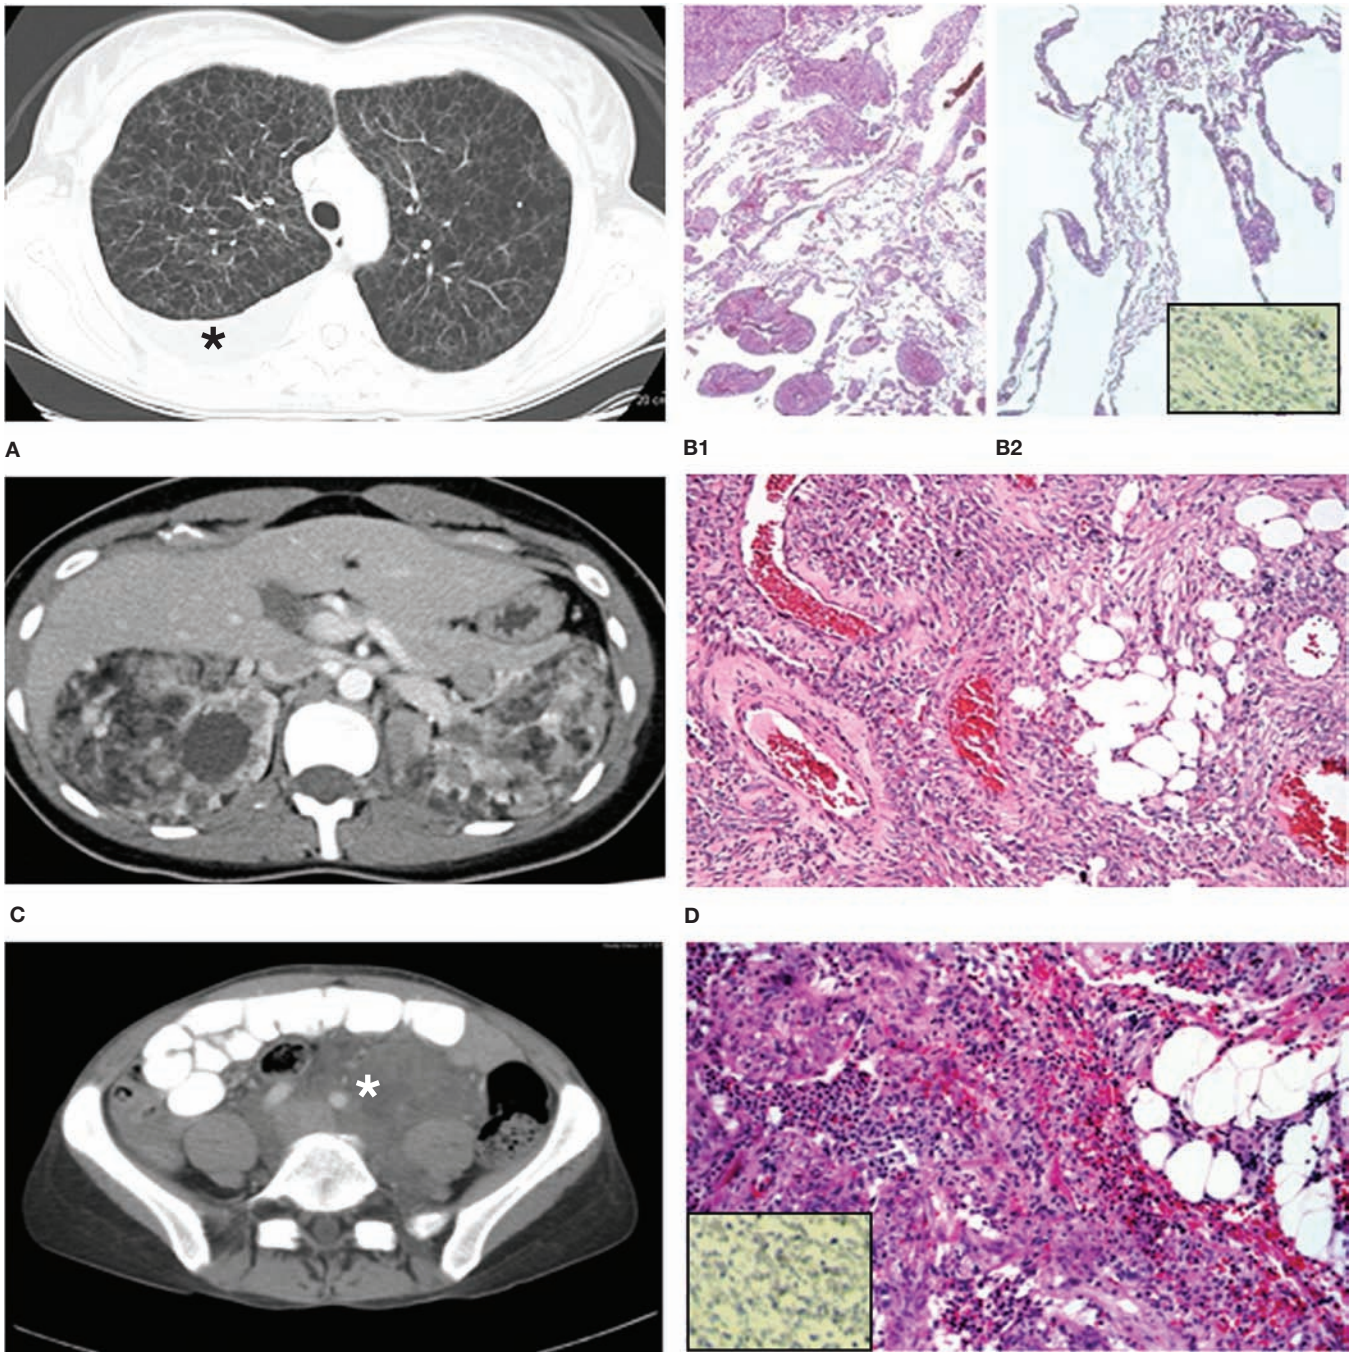

Figure 62-1 Computed tomography scans showing pulmonary and extrapulmonary images of patients with LAM, and the corresponding histopathologic findings. **A.** Multiple thin-walled cysts scattered throughout the lungs that have completely replaced the normal lung parenchyma. The *black asterisk* indicates the presence of a right pleural effusion. **B1 and B2.** Histopathology of the lung showing characteristic nodular smooth muscle cell–like infiltrates and cystic lesions. Inset image on **B2** shows immunocytochemistry of lung tissue showing reactivity with monoclonal antibody HMB45. **C.** Bilateral angiomyolipomas in a patient with TSC-LAM. The fatty, low-density component is clearly visualized. **D.** Histopathology of AML showing smooth muscle cell–like infiltrates, fatty tissue, and poorly differentiated vascular structures. **E.** Large, fluid-filled lymphangioleiomyoma (*white asterisk*) surrounding vascular structures. **F.** Histologic appearance of a lymphangioleiomyoma showing smooth muscle–like cells arranged in fascicular, trabecular or papillary patterns. Inset image on **F** shows immunocytochemistry of lymphangioleiomyoma tissue showing reactivity with monoclonal antibody HMB45.

in vitro, and the growth of subcutaneous tumors in a nude mouse xenograph system.[38] Estrogens stimulate the growth of human angiomyolipoma $TSC2^{-/-}$ cells, increase the survival and metastatic properties of $TSC2^{-/-}$ ELT3 cells in mice, and enhance matrix metalloproteinase (MMP)-2 activity of LAM lung-derived cells, thereby promoting cell invasiveness.[39–41]

The mechanism by which interstitial LAM cell proliferation causes lung cyst formation is unknown.[42] It has been proposed that compression of the airways by LAM cells leads to distention of the terminal airspaces and cyst formation.[6,19] It has also been proposed that degradation of lung elastic fibers is a major cause of the cystic lesions.[42] Matrix metalloproteinases, which play a role in

TABLE 62-1 Clinical and Physiologic Features of Patients with Sporadic LAM and TSC-LAM

Demographics	TSC-LAM	Sporadic LAM
Number of patients	34	196
Age of LAM diagnosis	39.0 ± 1.6	41.4 ± 0.7
Signs and symptoms		
Dyspnea	70.6%	73.5%
Pneumothorax	47.1%	56.9%
Wheezing	58.8%	44.4%
Cough	26.5%	31.6%
Hemoptysis	20.6%	32.1%
Pleural effusions	5.9%	23.5%
Lung function		
Airflow obstruction	37.5%	60.8%
Low diffusion capacity	38.2%	60.3%
Normal spirometry	53.1%	30.7%
Extra-pulmonary LAM		
Number of patients	67	256
Renal angiomyolipoma	32%	93%
Hepatic angiomyolipomas	2%	33%
Lymphangioleiomyomas	6%	29%
Ascites	6%	10%

TSC-LAM, Lymphangioleiomyomatosis associated with Tuberous Sclerosis Complex.

lung remodeling and lymphangiogenesis, are associated with LAM lesions.[43] LAM nodules contain MMP2, MMP9, MMP1, and MMP activators (MT1-MMP), and their inhibitors (TIMPs).[44,45] Levels of TIMP-3, which inhibits some MMP, were reportedly reduced in LAM lesions.[45,46] Compared with normal subjects, serum levels of MMP-9 were higher in patients with LAM,[47] suggesting that an imbalance between MMP and their inhibitors may contribute to lung destruction.[48] Growth of TSC2-null lesions was associated with an increase in MMP activity and vascular endothelium growth factor D (VEGF-D).[48] Elastic fibers were demonstrated in alveoli of mice with TSC2-null lesions[48] and human lung LAM nodules show disrupted elastic fibers. The presence of lymphatic spaces in the LAM nodules and strong immunoreactivity towards vascular endothelium growth factor C (VEGF-C), VEGF-D, vascular endothelium growth factor receptor (VEGFR) 3, and podoplanin, markers of lymphatic endothelial cells, led to the hypothesis that disorganized lymphangiogenesis enhances metalloproteinase expression and lung remodeling.[48] Some combination of these mechanisms may be the best explanation for the pathogenesis of cystic lung destruction.

PULMONARY PHYSIOLOGY

Airflow obstruction was seen in approximately 61% of patients with sporadic LAM[1,49]; normal spirometry was present in about 31%. The remaining patients had restrictive disease. By comparison, normal lung function was observed in 53% of patients with TSC-LAM (Table 62-1).[1] Increased gas trapping may be also present. The cause of airflow limitation in LAM has been attributed to alveolar destruction,[50] but a study of pulmonary mechanics showed that lung elastic recoil was not significantly reduced.[51] Instead, upstream airway resistance was increased, suggesting increased airways resistance as the major cause of airflow obstruction.[51,52] Reduced diffusing capacity (D_{LCO}) occurred in approximately 60% of sporadic LAM patients.[1] Most patients have both decreased FEV_1 and D_{LCO}, but some patients have only a reduced D_{LCO}.[49] Gas exchange, especially during exercise, is often abnormal (Table 62-2).[52,53] An abnormal ventilatory response with excessive minute ventilation and reduced breathing reserve are seen during exercise. Baseline and exercise dead space to tidal volume ratio and alveolar–arterial oxygen difference (A-a/O_2) are increased both at rest and during exercise.[52] The primary determinants of exercise limitation in LAM are airflow limitation, decreased breathing reserve, dynamic hyperinflation,[52–54] and limitation of oxygen transfer due to loss of alveolar capillary surface area. The latter exerts a significant effect upon exercise performance, because the increase in physiologic dead space produces excessive ventilation. The interdependence between airflow obstruction, which produces a decrease in the ventilatory reserve, and cystic lung destruction, which affects gas exchange during exercise, leads to severe impairment in exercise performance.[52,53] Pulmonary hypertension may also contribute to reduce oxygen transfer during exercise.[55]

RADIOLOGY

Chest radiographic findings in LAM range from being normal, to showing a reticular or nodular irregular shadowing or, in advanced stages, severe cystic changes. Computed tomography (CT) demonstrates diffuse, well-defined, round thin-walled cysts scattered throughout the lungs. Cysts vary in size from a few millimeters to up to 2 cm (Fig. 62-1A).[56,57] Additional findings are pleural effusions and lung opacities caused by chyle (Fig. 62-1A). Correlation between the extent of the cystic parenchymal replacement, as measured by high-resolution chest CT (HRCT), and the severity of the disease, as determined by spirometry, D_{LCO} or exercise performance, has been reported.[53,57–61] Computer analysis of HRCT can quantify the extent of cystic changes and detect abnormalities in areas adjacent to the cysts that may appear to be radiographically normal[60,61]; these emphysematous changes were also seen by histopathology.[61]

Abdominal CT and ultrasonography studies may show renal AML, abdominal lymphadenopathy, lymphangioleiomyoma, ascites, and dilatation of the thoracic duct.[18] AML occur predominantly in the kidney and liver and are recognized by their characteristic appearance consisting of areas of fatty density, intermixed with more dense

areas and normal-appearing renal parenchyma (see Fig. 62-1C).[18] Atypical AML lacking adipose tissue have a predominance of epithelioid LAM cells and radiologically may mimic renal cell carcinoma. Lymphangioleiomyomas appear as well-circumscribed masses of variable dimensions, comprising a wall and a central fluid-rich region (Fig. 62-1E).[18] Diurnal variation in size of lymphangioleiomyomas has been demonstrated by CT and ultrasound, which may help differentiating them from malignant tumors and explain worsening of symptoms during day time.[62,63]

DIAGNOSIS

The characteristic CT scan appearance and its histologic features on open or thoracoscopic lung biopsy can diagnose LAM. Transbronchial lung biopsy may yield adequate sample size for pathologic diagnosis.[64,65] The diagnosis of LAM should be strongly suspected in any woman who presents with progressive dyspnea, recurrent pneumothorax, or a chylous pleural effusion.[1–5] The differential diagnosis includes pulmonary emphysema, asthma, chronic extrinsic allergic alveolitis, Langerhans cell histiocytosis, sarcoidosis, Birt–Hogg–Dubé syndrome, and follicular bronchiolitis. Definite LAM may be diagnosed in the presence of a characteristic HRCT and a lung biopsy showing the pathologic features of LAM or a characteristic lung HRCT and (1) angiomyolipoma, (2) chylous effusion, (3) lymphangioleiomyoma or lymphadenopathy, and (4) TSC.[66] A diagnosis of probable LAM may be established in the presence of a characteristic HRCT and a compatible clinical history or a characteristic HRCT and angiomyolipoma or chylous effusions. Possible LAM may be diagnosed in the presence of a characteristic or compatible HRCT.[66]

Serum VEGF-D, a lymphangiogenic factor, is increased in the serum of patients with LAM compared to normal individuals and is a measure of lymphatic involvement in LAM.[67–70] In the appropriate clinical and radiologic setting, a VEGF-D serum level equal or greater than 800 pg/mL is unlikely to be found in other cystic lung diseases and appears to be diagnostic of LAM.[69,70]

PROGNOSIS

The clinical course of LAM is highly variable. The estimated median transplant-free survival time for LAM patients in the United States is 29 years from symptom onset and 23 years from diagnosis.[71] The estimated 10-year transplant-free survival is 86%. Age appears also to affect survival, as rapid decline in lung function is more common in younger premenopausal patients.[49,72] Patients whose lung tissue shows predominance of cystic lesions tend to have worse lung function and prognosis than those with more LAM cell infiltrates.[73]

The severity of lung involvement in LAM may be assessed in patients who had a lung biopsy using the LAM Histology Score (LHS), which grades the extent of replacement of normal lung tissue by cystic lesions and LAM cell infiltrates.[74] The amount of tissue involvement is graded semiquantitatively based on percent of lung tissue involved: LHS-1, <25%; LHS-2, 25% to 50%; and LHS-3, >50% lung tissue. LHS-2 and LHS-3 scores and the presence of hemosiderin-laden macrophages are associated with decreased survival.[74] Patients with more cystic disease are likely to have lower FEV_1 and D_{LCO}, lower peak oxygen uptake ($\dot{V}_{O_{2max}}$), and more exercise-induced hypoxemia.[53,75]

The severity of lung disease in LAM can be also graded by HRCT. HRCT findings correlate with lung function tests, gas exchange, and exercise performance.[53,56–59] HRCT computer analysis can quantify the percentage of lung volume affected by cysts and evaluate the texture of areas not involved with cysts.[60,61] Using these methods, percentage of lung volume occupied by cysts was found to correlate with FEV_1, residual volume, and D_{LCO}.[60,61]

The simplest method of assessing the severity of lung disease in LAM is pulmonary function testing.[1,49] Most patients have airflow obstruction and impaired gas exchange. Early in the disease, a significant number of patients may have normal spirometry or only mild airflow obstruction, along with a marked decrease in diffusion capacity. In these patients, the severity of disease is best graded by tests of gas exchange such as D_{LCO}, arterial blood gases, A-a/O_2 gradient, cardiopulmonary exercise testing, and 6-minute walk test.[52,53,59] Exercise-induced hypoxemia may occur in the presence of near-normal D_{LCO} and FEV_1.[53] Correlation between $\dot{V}_{O_{2max}}$ and LHS scores, and between CT severity grade and A-a/O_2 gradient, dead space/tidal volume ratio, and $\dot{V}_{O_{2max}}$ have been demonstrated.[53,58–61] Rates of functional decline over time may help in defining the course of disease, that is, whether it is rapidly or slowly progressive. Sequential lung function testing every 3 to 6 months is warranted to assess the progression of disease.[49,72] A positive response to bronchodilators occurs in 25% to 30% of LAM patients.[75,76] Patients who respond to bronchodilators tend to have a predominantly cellular pattern of LAM lung lesions and greater rates of decline in FEV_1.[75] A low initial D_{LCO} was also reported to be a predictor of accelerated loss of FEV_1.[77]

OTHER PROGNOSTIC INDICATORS

There is some evidence that older age and/or menopause are associated with slower disease progression.[49,72] Patients who present with exertional dyspnea and hemoptysis tend to have more severe disease, greater rates of progression of disease, and lower survival than those with a history of pneumothorax.[78] This may be due to either a delay in diagnosis or an insidious course in those who present with dyspnea. Lymphatic involvement, for example, chylous effusions, lymphadenopathy, lymphangioleiomyomas, may be associated with a more severe form of disease.[68,79,80] Correlation between LHS and the expression of VEGF-C has been reported.[80] Serum levels of VEGF-D are especially elevated in patients with lymphatic abnormalities and show a correlation with D_{LCO} and HRCT scan grading of severity of lung disease.[68,79,80] Measurement of serum VEGF-D may be of value in establishing a diagnosis and grading the severity of disease and response to therapy.

TREATMENT

Treatment includes general principles of management and specific therapeutic interventions.

GENERAL PRINCIPLES OF MANAGEMENT

LAM patients should be told about the chronic nature of LAM and be advised to lead, as much as possible, a normal life. If there is an excess body mass, they should be encouraged to lose weight, engage in physical activities, and exercise regularly. The limits of exercise should be dictated only by the severity of their lung disease. Sports involving physical contact and martial arts should be avoided because of potentially causing bleeding from AML. Patients should be advised to continue with normal activities, and be allowed to travel by land or air except to high altitude locations, depending on disease severity. The risk of life-threatening pneumothorax associated with air travel is minor. However, if patients should experience sudden onset of breathlessness or chest pain, pneumothorax should be excluded prior to travelling. An arterial blood gas may help to determine whether a patient may travel by air without supplemental oxygen. A 6-minute walk test or a cardiopulmonary exercise test to uncover exercise-induced hypoxemia and determine the need for supplemental oxygen is recommended. Patients who desaturate during exercise should be given supplemental oxygen at flow rates adjusted to sustain oxygen saturation above 88% to 90%. Patients should be advised against using estrogen-containing contraceptives and avoid phytoestrogen-rich food.

SPECIFIC THERAPIES

Specific therapies include antiestrogen therapy, mTOR inhibitors, matrix metalloproteinase inhibitors, statins, and inhibitors of autophagy.

Antiestrogen Therapy

Oophorectomy, progesterone, and gonadotrophin-releasing hormone (GnRH) analogs have been employed in the treatment of LAM. Case reports and uncontrolled studies claimed a beneficial effect of antiestrogen therapies.[81] Taylor et al.[13] however, found no benefit from oophorectomy and improvement in dyspnea only in 2 of 19 patients treated with progesterone. A reduced rate of decline in FEV_1 and D_{LCO} was reported in premenopausal patients treated with progesterone.[72] However, when patients with short-term follow-up were excluded from the analysis, the effect of progesterone was not significant.[72] In a retrospective study, no difference was observed in disease progression between patients treated with or not treated with progesterone.[49] Data from studies that assessed the effect of GnRH analogs have also been inconclusive.[82,83] Experimental data however, appear to provide a rational for hormonal manipulations in the treatment of LAM.[38–41] Further studies aimed at suppressing estrogen secretion with aromatase inhibitors (i.e., letrozole) are undergoing a clinical trial (clinicaltrials.gov) in postmenopausal women in whom the main source of estrogens are the adrenal glands (Frank X. McCormack P.I. ClinicalTrials.gov Identifier:NCT01353209).

Mammalian Target of Rapamycin (mTOR) Inhibitors

Since the discovery that TSC genes *TSC1* and *TSC2* were involved in the pathogenesis of LAM, major advances were made in treatment of LAM. *TSC1* and *TSC2* are tumor suppressor genes that encode respectively, hamartin and tuberin (Fig. 62-2).[84–87] These proteins form a cytosolic complex that regulates the intracellular serine/threonine kinase mTOR, which integrates growth factor, energy, and stress signaling, thereby regulating cell growth, proliferation, and survival.[84,85] Two different complexes involving mTOR, mTORC1, and mTORC2, have been identified.[85–87] Tuberin, which exists in a complex with hamartin, is a GTPase-activating protein for the guanine nucleotide–binding protein Rheb (Ras homolog enriched in brain), promoting the formation of inactive Rheb-GDP from active Rheb-GTP.[85] Inhibition or absence of tuberin, as occurs with *TSC2* gene mutations, results in accumulation of active Rheb-GTP, leading to stimulation of mTORC1, which results in phosphorylation of S6 kinase and eukaryotic initiation factor 4E-binding protein, and increased translation and cell growth.[85]

Sirolimus is an immunosuppressant drug that forms a complex with FK506-binding protein-12 and inhibits mTORC1.[85,88] Sirolimus provides only partial inhibition of mTORC1 and has some inhibitory effect on mTORC2 signaling (Fig. 62-2B).[87,89,90] In experimental models, sirolimus was shown to decrease tumor size in animals with a germline mutation of *TSC2*.[91] Treatment with a sirolimus analog decreased the severity of renal cystadenomas and liver hemangiomas in $TSC2^{+/-}$ mice, and decreased tumor growth and improved survival of nude mice with $TSC2^{+/-}$ tumors.[92] In human subjects with TSC or LAM who had AML, treatment with sirolimus decreased tumor size by half after 1 year of therapy.[93] Following withdrawal of sirolimus, the angiolipomas partially regained their size. Subsequent studies have confirmed these findings.[94–96] The most recent study found that 42% of 79 patients with AML, treated with everolimus, responded with a 50% reduction in tumor size after 24 weeks of therapy.[96] Sirolimus also appears to be effective in reducing the size of giant-cell astrocytomas in patients with TSC.[97,98]

The effect of sirolimus on pulmonary function was examined in 89 patients with LAM (MILES trial). Forty-six patients were treated with sirolimus and 43 with placebo for 12 months and followed for an additional year after discontinuation of therapy.[99] Compared to the placebo group, the sirolimus group had improvements

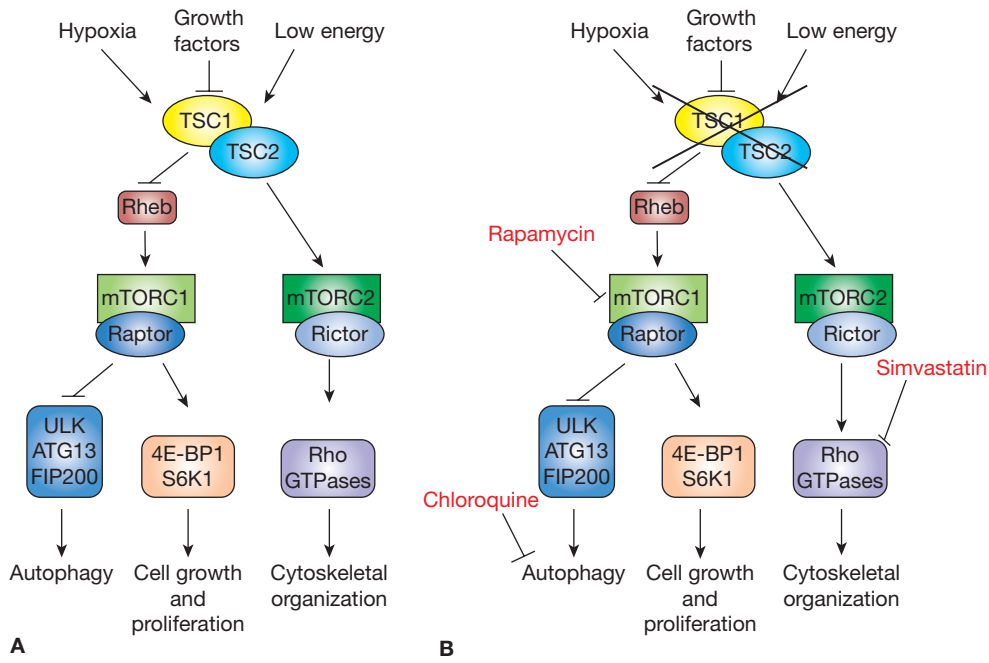

Figure 62-2 Simplified scheme of the mTOR signaling pathways. **A.** TSC1/2 integrates multiple signals, such as growth factors, energy state and hypoxia, to control cell growth and proliferation. Growth factors stimulate several signaling pathways leading to phosphorylation of TSC2 and its inactivation. TSC1/2 negatively regulates mTORC1 through its actions on Rheb, while it positively regulates mTORC2. Activation of mTORC1 leads to cell growth and proliferation and inhibition of autophagy. mTORC2 regulates the actin cytoskeleton through Rho GTPases, which affects cell migration and morphogenesis. **B.** mTORC1 is acutely inhibited by sirolimus (rapamycin) treatment. mTORC2 is sensitive to prolonged rapamycin treatment, which may affect mTORC2 assembly and function. Simvastatin inhibits Rho GTPases, whereas chloroquine inhibits autophagy by blocking fusion of autophagosomes with lysosomes. mTOR, mammalian target of rapamycin; Rheb GAP, Ras homolog enriched in brain GTPase-activating protein; S6K1, S6 kinase 1; 4E-BP1, factor 4E binding protein 1; raptor, regulatory associated protein of mTOR; rictor, rapamycin-insensitive companion of mTOR; ULK 1, UNC-51–like kinase 1; ATG13, autophagy-related protein 13; FIP200, focal adhesion kinase family interacting protein of 200 kDa.

from baseline of FVC, FEV_1, quality of life, and functional performance. After discontinuation of sirolimus, decline of lung function resumed and paralleled that of the placebo group.[99] In another study, 19 patients with either rapidly progressive lung disease or lymphangioleiomyomas and chylous effusions were treated with sirolimus for approximately 2.5 years. Instead of the expected decrease in lung function, an increase in FEV_1 and D_{LCO} was observed.[100] Nine patients experienced complete resolution of their chylous effusions and abdominal lymphangioleiomyomas.[100]

Based on the findings in the MILES trial we recommend that sirolimus be given to patients in whom lung function is declining rapidly. We also recommend sirolimus therapy for LAM patients with symptomatic lymphangioleiomyomas and chylous pleural effusions or ascites.[100,101] The role of sirolimus in patients with normal or stable lung function or very slow rates of decline is unclear. Currently the starting dose of sirolimus is 2 mg/d. Sirolimus serum levels must be monitored and dosage adjusted to attain serum trough levels between 5 and 15 ng/mm, a range thought to be therapeutic for patients with renal transplants.[99] Adverse events associated with sirolimus therapy include oral mucosa ulcers, hypertension, hyperlipidemia, proteinuria, increased serum creatinine, infections, acne, amenorrhea, and sirolimus-related interstitial pneumonitis. Close patient monitoring is recommended. Given the limited experience with sirolimus in the treatment of LAM, it is not known whether treatment must be continued for life or whether resistance to sirolimus may eventually develop.

Matrix Metalloproteinase Inhibitors

Doxycycline is a MMP inhibitor that affects MMP production in TSC-null ELT3 cells,[102] and inhibits MMP2 secretion by TSC-null mouse embryonic and human LAM cells.[103] A potential role of doxycycline in the treatment of LAM was suggested by a report of one patient with LAM in whom treatment with doxycycline decreased urinary MMP levels and improved lung function.[104] A decrease in serum and urine levels of MMP-9 and MMP-2 in 34 patients treated with doxycycline has been reported.[105] A controlled study showed that it is unlikely that doxycycline has a useful effect in LAM.[105A]

Statins

There is evidence that both mTORC1 and mTORC2 are necessary for tuberin-dependent cell proliferation and survival.[106] In the absence of tuberin, RhoA activity is increased, resulting in increased cell survival.[106] Since sirolimus primarily suppresses mTORC1 signaling, there is a rational for new therapies targeting mTORC2 signaling. Statins inhibit both sirolimus-sensitive and sirolimus-insensitive mechanisms of TSC-null cell growth by inhibiting RhoA GTPase activity.[107] In one study, atorvastatin was shown to inhibit the growth of *TSC2*$^{-/-}$ ELT-3 cells and mouse embryonic fibroblasts while decreasing Rheb-GTPase activity and function.[107] A synergistic effect of simvastatin and sirolimus in inhibiting proliferation of TSC2-null cells and TSC-null tumor growth has been described.[106] This effect appears to be specific for simvastatin; in a mouse model of TSC, atorvastatin failed to reduce the size of liver and renal tumors.[108] In a mouse model of LAM, simvastatin prevented alveolar space enlargement and, combined with sirolimus, blocked MMP upregulation, reducing TSC2-null lesions and alveolar destruction.[48] However, in a retrospective study, it was found that the rate of decline in lung diffusion for patients treated for hypercholesterolemia with statins was greater than that of their matched off-statin therapy controls.[109]

Inhibitors of Autophagy

Autophagy is a mechanism by which cells maintain energy homeostasis and recycle proteins and organelles.[110] Autophagosomes are formed that encapsulate damaged organelles or cellular debris and fuse with lysosomes to degrade their contents.[111] Autophagy is controlled by signaling from mTOR, and the human homolog of ATG1 (ULK1) kinase complex, comprising ULK1, Atg13, and Atg17; mTORC1 is a major regulator of autophagy.[111–113] Under conditions of cellular stress, mTORC1 is downregulated, triggering autophagy. mTOR inhibitors such as sirolimus stimulate autophagy by causing phosphorylation of Atg13, which interacts with ULK1 and inhibits the formation of autophagosomes which increases autophagy and, within limits, increases cell survival.[110–113] Since LAM cells have been shown to have low levels of autophagy, blockade of mTOR signaling with sirolimus may result in increased survival of LAM cells.[114,115] Hydroxychloroquine and its analogs inhibit the growth of cancer cells and induce cell death by blocking autophagy.[113–115] The combination of mTORC1 inhibition with sirolimus and inhibition of autophagy with hydroxychloroquine was found to be more effective than either treatment alone in inhibiting the survival of TSC2-null cells and the growth of TSC2-null xenograph tumors, as well as the spontaneous development of renal tumors in *TSC2*$^{+/-}$ mice.[115] Inhibition of autophagy with hydroxychloroquine could potentially complement the effect of sirolimus in the treatment of LAM. These observations provide a rational for testing the effect of chloroquine and sirolimus in LAM patients. A current study (SAIL trial) testing the effects of sirolimus and hydroxychloroquine is ongoing (Elizabeth Henske P.I.; ClinicalTrials.gov Identifier:NCT01687179).

TREATMENT OF COMPLICATIONS

Treatment of well recognized complications of LAM and special considerations are discussed below.

■ PNEUMOTHORAX

Small pneumothoraces may be treated conservatively by chest tube drainage. Because of the high rate of pneumothorax recurrence if air leak persists or the pneumothorax recurs, chemical or surgical pleurodesis by video-assisted thoracoscopy should be considered.[3,116] Chemical sclerosis, pleurectomy, mechanical abrasion, and talc poudrage are most effective.[116] Talc pleurodesis may result in fibrothorax that can complicate removal of the lung at the time of transplantation.[3,116] The risk of developing a pneumothorax during air travel appears to be small.[117]

■ CHYLOUS EFFUSIONS AND LYMPHANGIOLEIOMYOMAS

Chylous effusions and lymphangioleiomyomas may compromise respiratory function and cause abdominal pain, urinary frequency, obstipation, tenesmus, and peripheral edema. Abdominal symptoms may suggest malignancy.[63,118–120] Frequent drainage of chylous effusions may result in protein loss, lymphopenia, and weight loss.[100,121] Several treatments such as low fat diet, pleuro-peritoneal or peritoneal-venous shunts, have been employed but there is little experience with these therapeutic modalities in LAM.[122,123] The same is true of treatment with somatostatin and octreotide.[124,125] The finding that sirolimus is effective in decreasing the size of chylous effusions and lymphangioleiomyomas strongly suggests that instead of undertaking invasive procedures such as pleurodesis, symptomatic patients should be treated with sirolimus.[100,126]

■ ANGIOMYOLIPOMAS

AML occur primarily in the kidney, although other organs, for example, liver, may be involved.[127] Small AML, for example, less than 4 cm in diameter, are well tolerated and are associated with well-preserved renal function.[127] The principal complication of larger AML is bleeding. Embolization, rather than resection, is recommended to preserve kidney function.[128–130] Severe pain may be also an indication for selective embolization of the tumor. Prophylactic embolization may be undertaken in patients with large AML and no known episodes of bleeding but evidence favoring this approach is lacking. Indeed, embolization appears to be of little value in the long-term management of AML.[130] Since treatment with sirolimus reduces tumor size in about 44% to 50% of the patients, it may also prevent bleeding and

Figure 62-3 Skin manifestations of TSC in an adult women. **A.** Large hypomelanotic macule on the back. **B.** Multiple facial angiofibromas involving the nose and adjacent cheek. **C.** Shagreen patch on the lower back. **D.** Periungual fibroma near the fingernail.

the need for embolization or surgical intervention.[99–102] Accordingly, treatment with mTOR inhibitors is currently the initial approach for the treatment of large AML. Arterial embolization, which has a response rate similar to mTOR inhibitors, should be reserved for patients with acute bleeding or those who do not respond or do not tolerate sirolimus therapy.[93–95,130] Discontinuation of sirolimus therapy may result in return of the AML to its original a size.

■ PREGNANCY

Of 353 pregnancies recorded in the LAM registry, 66.9% resulted in live birth, 16.7% had spontaneous abortion and 15% had therapeutic abortion.[1] Twenty-two percent of those who had been pregnant experienced worsening of respiratory symptoms during pregnancy.[1] Patients who were diagnosed with LAM during pregnancy had more premature births, higher frequency of dyspnea, pneumothorax, and chylothorax than those diagnosed either before or after pregnancy.[131] These data, along with anecdotal reports of worsening symptoms during pregnancy,[132] raise the question whether LAM patients should be advised not to become pregnant. In patients with moderate to severe disease or those in whom lung function is declining rapidly, pregnancy should be discouraged. Instead, these patients should be treated with sirolimus. Patients with mild disease who wish to become pregnant should be told about the potential risks (e.g., pneumothorax, decline in lung function) and advised that with close medical and obstetrics monitoring they have a chance of having a normal pregnancy and delivering a normal child.

■ LUNG TRANSPLANTATION

Except in advance stages, dyspnea at rest is not a major feature of LAM. Exercise limitation and hypoxemia requiring supplemental oxygen are major factors affecting the ability of the patient to conduct activities of daily living. Consequently, patients with an FEV_1 less than 1 L and a D_{LCO} less than 30% predicted receiving supplemental oxygen might be comfortable at rest. In the series of Pechet et al.[133] preoperative FEV_1 and D_{LCO} were respectively, 20 ± 8 and 23 ± 9% predicted and there was resting hypoxemia prior to transplantation. The average 6-minute walk test distance was 250 m. The 5-year survival was 69%.[133–135] The European experience is similar to that of the USA.[136] Before transplantation is considered, lung function needs to be severely compromised because LAM patients with very low FEV_1 and D_{LCO} on supplemental oxygen may live for many years. We suggest that lung transplantation be considered when FEV_1

and D_{LCO} are less than 30% predicted, and the patient is on continuous supplemental oxygen and unable to carry out activities of daily living. Importantly, the patient should rate her quality of life as being poor and be certain that she wishes to undergo lung transplantation.

TUBEROUS SCLEROSIS COMPLEX

TSC is a multisystem autosomal-dominant disorder that affects men and women equally. Its frequency is 1 in 12,000 to 14,000 children under the age of 10, or 1 in 6000 births.[9] It is characterized by mental retardation, seizures, facial angiofibroma, periungual fibromas, Shagreen patches, cortical tubers, giant-cell astrocytomas, and cardiac rhabdomyomas (Fig. 62-3).[9] The association of TSC and cystic lung disease has long been reported in the literature,[137] but little is known about the natural history of LAM in the presence of TSC (TSC-LAM). Initially the prevalence of clinically significant LAM in TSC was thought to be relatively low, ranging from 0.6% to 2.3% of TSC patients.[137–140] However, subsequent studies showed that the prevalence of lung cysts in women with LAM ranges from 26% to 38%.[141–143] Lung cysts were demonstrated in only 13% of men with TSC.[16] If it is accepted that visualization of four or more cysts in the lungs of a TSC patient equates the presence of LAM, then the prevalence of LAM in males may be as high as 38% but the lung disease is mild.[144] The NHLBI LAM registry reported data from 34 TSC patients who were known to have LAM or were later confirmed to have LAM.[1] In a study comparing CT features of 67 patients with TSC-LAM and 256 patients with sporadic LAM,[145] severe disease was present in 25% of TSC-LAM patients versus 40% of sporadic LAM patients (Table 62-1). Renal AML occurred in 93% of TSC-LAM patients and in only 32% of sporadic LAM subjects. Lymphangioleiomyomas and chylous effusions were more common in sporadic LAM. Sclerotic bone lesions were very common in patients with TSC-LAM.[146]

Lung disease in TSC tends to be milder than in sporadic LAM, often comprising only a few cysts scattered throughout the lungs. These patients have subclinical disease and usually are diagnosed with LAM only because they have TSC. TSC patients who initially present with characteristic symptoms of pulmonary LAM may have more severe lung disease and a clinical course similar to patients with sporadic LAM.

CHAPTER 63

Benign Metastasizing Leiomyoma

Gustavo Pacheco-Rodriguez
Angelo M. Taveira-DaSilva
Joel Moss

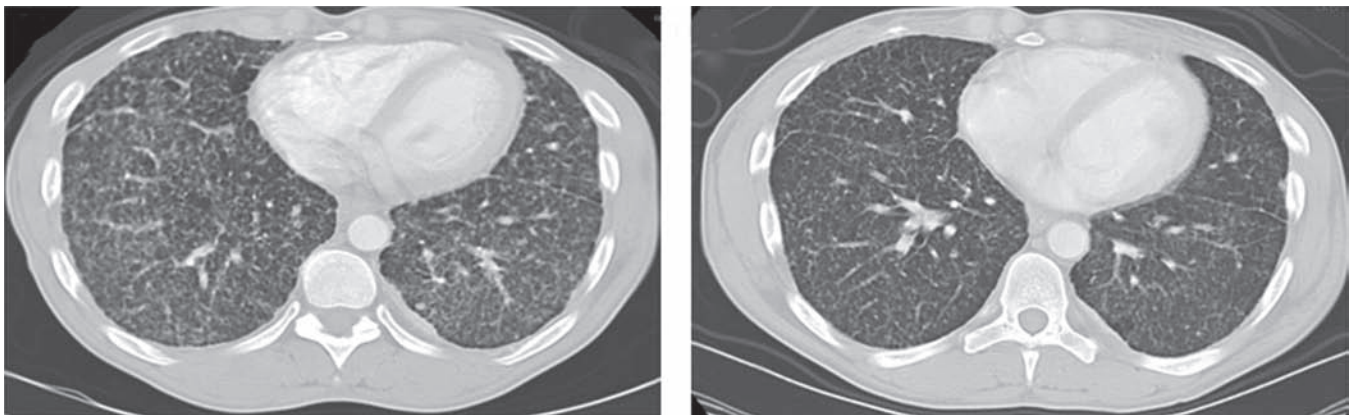
Benign metastasizing leiomyoma (BML) is a rare disease of women, which is characterized by noninvasive, well-circumscribed tumors composed of differentiated smooth muscle cells, localized to sites other than the uterus.[1–5] Lungs and lymph nodes[6] are the most common sites involved, but BMLs have also been identified in the mediastinum,[7,8] retroperitoneum,[9] vascular channels,[10] bone,[11] heart,[12] skeletal muscle,[13] and soft tissues.[14] Pulmonary BML has been associated primarily with uterine leiomyomas and has been mainly diagnosed in patients who have undergone uterine myomectomy or hysterectomy.[1,4]

The first report of BML, in 1939, described a 36-year-old woman who presented with dyspnea and wheezing. Chest X-rays showed multiple lung nodules. At autopsy, lymph nodes, uterus, and lungs showed nodules of smooth muscle cells with identical morphology[15] and the term "metastasizing fibroleiomyoma of the uterus" was adopted. This term was later abandoned and the name BML was proposed because of the metastatic behavior of this disease.

Pathologically, BML lung nodules resemble hamartomas (the most common benign lung tumor), low-grade leiomyosarcomas, and nodules of proliferating smooth muscle cells.[16] Pulmonary BML is usually asymptomatic and presents with either single or multiple lung nodules of varying sizes.[17] The tumors do not appear to invade adjacent tissues.[18] BML, however, represents a diagnostic and therapeutic challenge because of its pathogenesis and metastatic potential.

EPIDEMIOLOGY

The occurrence and prevalence of pulmonary BML is unknown. There are over 100 cases of BML reported in the literature but only a few studies reported more than one case. BML is a rare disease, found primarily in premenopausal women who have undergone surgical procedures for treatment of uterine leiomyomas.[1,4,18] However, cases of lung BML have also been reported in women with no history of these surgical procedures.[19] Leiomyomas, including BML of the lung, may be found in women and, to a lesser extent, in men and children.[20] There is no ethnic or racial preference for BML and this differs from uterine leiomyoma, which is more frequent in African-American women.[21] Cases of BML have been reported from countries all over the world[4,22] including, but not limited to, the United States,[19] Portugal,[23] Brazil,[24] China,[25] India,[14] South Korea,[13] Japan,[26] and Turkey.[6]



A B

Figure 63-1 Nodular structures in BML. High-resolution computed tomography (HRCT) shows multiple diffuse small bilateral nodules before (**A**) and after treatment (**B**). *(Reproduced with permission from Taveira-DaSilva AM, Alford CE, Levens ED, Kotz HL, Moss J. Favorable response to antigonadal therapy for a benign metastasizing leiomyoma. Obstet Gynecol. 2012;119(2 Pt 2):438–442.)*

CLINICAL PRESENTATION

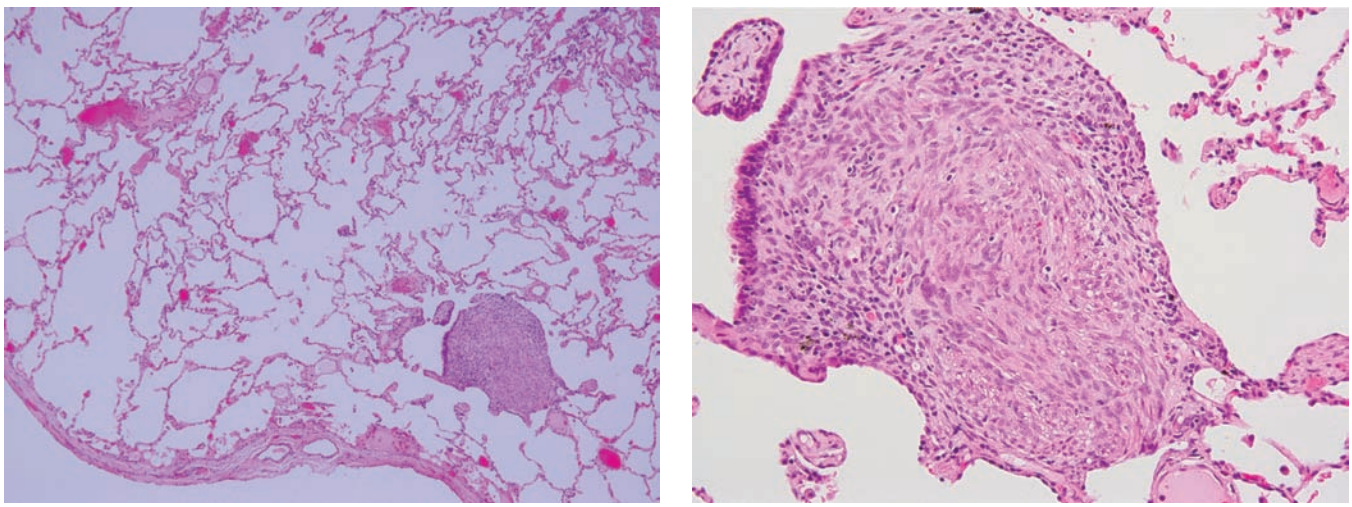
Most cases of lung BML have been identified as an incidental finding on imaging procedures performed for other purposes (Fig. 63-1).[1] BML nodules may present in premenopausal women as unilateral or bilateral tumors with no specific lobar distribution.[17,27] A number of different types of uterine tumors (e.g., leiomyoma, smooth muscle tumors of uncertain malignant potential, leiomyosarcomas, other smooth muscle tumors, endometrial stromal tumors) are associated with the diagnosis of BML. BML may present with respiratory symptoms including cough, wheezing, dyspnea, and chest pain.[15,17,19,28,29] BML lung nodules have been detected in women in a few months to over 30 years after they have undergone uterine myomectomy or hysterectomy.[30]

PATHOLOGY

BML lung lesions consist of well-circumscribed nodules ranging in size from few millimeters to several centimeters in diameter.[1,4] The lung tumors are composed of well-differentiated proliferative smooth muscle cells that form intersecting fascicles and show positive immunoreactivity toward actin, desmin, and caldesmon (Fig. 63-2).[4,31] Most of these cells also react with antibodies against receptors for estrogen and progesterone.[1,3,22]

Benign lung nodular or mass lesions may be either of epithelial or mesenchymal origin.[32] BML lesions consist of well-differentiated smooth muscle cells, which form lung nodules with low cellularity, exhibiting low mitotic index and no nuclear atypism. The lung nodules do not invade the surrounding tissue and lack evidence of necrosis. Since most of the BML cases are discovered after hysterectomy or myomectomy, it would be important to identify the type of uterine cell causing the tumor. BML cells without a clearly distinct smooth muscle phenotype may exhibit unusual growth patterns.[33] In general, BMLs have been classified as benign tumors of mesenchymal origin.

BML lesions contain vascular structures as determined by anti-CD34 antibody reactivity within nodules adjacent to vessels. BML lesions express variable levels of p53, but the role of this tumor suppressor in BML cells has not been reported.[31] BML lung lesions also show reactivity with antibodies against proliferating cell nuclear



A B

Figure 63-2 Histologic section of proliferative areas of lung BML. Tissue section shows proliferative smooth muscle cells forming fascicles characteristic of leiomyomas and BML. **A, B.** Show low- and high- resolution pictures of lung proliferative nodules. *(Reproduced with permission from Taveira-DaSilva AM, Alford CE, Levens ED, Kotz HL, Moss J. Favorable response to antigonadal therapy for a benign metastasizing leiomyoma. Obstet Gynecol. 2012;119(2 Pt 2): 438–442.)*

antigen (PCNA). In contrast to what is seen in leiomyomatous hamartoma, most of the histopathologic sections of lung BML are not reactive with the monoclonal antibody Human Melanoma Black-45 (HMB-45), which recognizes Pmel17,[31] a melanosomal protein expressed in cells from lung hamartomas, PEComas (perivascular epithelioid cells), and lymphangioleiomyomatosis (LAM).[34] BML nodules are in most of the cases not reactive to antibodies against EMA, CD10, CD117, TTF-1, BCL-2 GPAP, calretinin, and cytokeratin chromogranin. S-100 is expressed at very low levels in BMLs. PEComas of the uterus with pulmonary metastases have a similar presentation to BML but the proliferating smooth muscle cells are mostly nonreactive to HMB-45.[19,35,36] Thus, BML lung nodules appear to have distinct pathologic characteristics.

It has been proposed that leiomyomas should be classified as benign or malignant based on the number of mitotic figures. If 10 mitotic figures per 10 high power field (HPF) are present, the tumor is classified as a neoplasm and if there are more than 5 mitotic figures per 10 HPF it should be considered a leiomyosarcoma. Benign lesions should have less than 5 mitotic figures per HPF.[37] The fact that BML lesions contain less than 5 mitotic figures per HPF, identifies them as a benign tumor.

It is possible to identify cancer cells based on their molecular phenotype,[38,39] however, the molecular characteristics of BML cells remain unknown. Expression of the micro-RNA 221 (miR-221), which has been correlated with different malignancies,[40] appears to differentiate leiomyosarcoma from BML.[41] Molecular assays of X-chromosome inactivation have shown that it is very likely that the lung and uterine cells have a similar origin.[42] BMLs proliferate without telomeric changes, suggesting that their proliferative behavior is independent of telomeric attrition as is the case in other malignant diseases.[43,44] Cytogenetic studies of BML lung tumors have shown that the cells have abnormalities in several chromosomes. BML tumors from five cases showed 19q and 22q terminal deletions.[45] Interestingly, a single case showed multiple chromosomal deletions from cells isolated from different metastatic sites.[46] Rearrangement of the 6p21 region was correlated with changes in the high mobility group A1 gene (*HMGA1*). Chromosomal translocation and mutations have been associated with HMGIC in leiomyomas but they have not been identified in the leiomyomas present in BML patients. It has been possible to correlate the proliferative behavior of BML cells with chromosomal translocations present in other noninvasive tumors.[45–47]

Some of the factors potentially involved in the development of uterine leiomyoma are basic fibroblast growth factor (bFGF), transforming growth factor-beta (TGF-β) and granulocyte macrophage colony–stimulating factor (GM-CSF),[48] although a role for these factors in the pathogenesis of BMLs has not been defined. Analysis of BML tumor cells from different sites suggests a clonal origin.[42] The balanced karyotype of BMLs is consistent with the findings seen with leiomyomas.[49] The clonality of these tumors should be interpreted with caution due to the fact that the founding mutation has not been identified in any case.

PATHOGENESIS

BMLs are considered mesenchymal tumors not mixed tumors of the uterus. Although there are different types of leiomyomas (e.g., mitotically active, cellular, hemorrhagic cellular, atypical, epitheliod, myxoid, vascular, lipoleiomyomas), the type of leiomyoma associated with BML has not been determined. Hamartomas, the most common tumor of the lung, are seen in both genders. PEComas of the uterus with pulmonary metastases may have a similar presentation to BML but these tumors express Pmel7, and are recognized by the monoclonal antibody HMB-45.

The source of the cells that form the lung nodules remains unknown, but due to the strong association with uterine leiomyomas, it is believed that the main source of the cells is the uterus. It has been proposed that those cells responsible for the formation of pulmonary BML are derived from (a) low-grade tumors; (b) cells dislodged from uterus at the time of myomectomy and hysterectomy; (c) metastasis from uterus or an unknown site; (d) proliferation of lung smooth muscle cells; and/or (e) simultaneous-independent development of multiple leiomyomas.

LOW-GRADE TUMORS

Although other tumors may occur in patients with BML including leiomyosarcoma, adenocarcinoma,[50] breast carcinoma, and skeletal muscle tumors, their association with BML is not clear. Leiomyomas of the esophagus, lung, and uterus are found in association with multiple endocrine neoplasia type I (MEN1) but loss of heterozygosity for MEN1 has not been investigated in BML, as is the case in many MEN cases.[51] Tumors characterized as low-grade leiomyosarcomas and high-grade leiomyosarcomas do not appear to metastasize to the lung; these tumors occur mainly in the abdominal cavity.[52] It has also been proposed that BML could be an intermediate tumor stage leading to a malignant leiomyosarcoma[7] but high-grade leiomyosarcomas involving the lung reappear in a short period of time following surgery.[52] Low-grade leiomyosarcomas do not express progesterone and estrogen receptors as is the case in BML. Thus, it is very unlikely that BMLs arise from low-grade malignancies.

CELLS DISLODGED FROM UTERUS AT THE TIME OF MYOMECTOMY AND HYSTERECTOMY

Since pulmonary BML has been associated with hysterectomy and myomectomies, it has been postulated that some of the uterine cells move into the blood circulation at the time of surgery and migrate to the lung where they remain and grow at a slow rate.[18] Lung BML has been associated with tumors in the retroperitoneal cavity,[9] pelvis, and the para-aortic lymph nodes arguing against the passive passage of cells from uterus to lung.[18] The presence of BML tumors in the pelvic region is not in agreement with the concept that uterine cells became dislodged and seeded the lung. Although most cases of BML report multiple pulmonary tumors after hysterectomy, few cases describe the occurrence of nodules before hysterectomy.[53] BML has been correlated with endometriosis as BMLs and endometriosis have a similar course and may develop after hysterectomy or myomectomy.[3,4] Estrogen and progesterone receptors are found in lung BML cells and uterine leiomyomas, which are the most likely source of the cells. However, it is not clear if lymphatics or blood vessels are involved in the metastatic process leading to pulmonary BML.

METASTASIS FROM UTERUS OR UNKNOWN SITE

Due to the fact that BMLs are present in multiple sites, it is possible that either uterine smooth muscle cells or cells from other non-uterine sites metastasize to the lung. Forty percent of leiomyomas or myomas possess specific chromosomal abnormalities.[49] Uterine leiomyomas comprise smooth muscle cells with the extracellular matrix containing a high collagen content. Lung BML nodules however, do not have a high content of extracellular matrix. Leiomyomas contain high concentrations of estrogen[54] and progesterone[55] receptors, which drive the proliferation of cells in response to their ligands. In addition, leiomyomas contain large amounts of aromatase,[56] an enzyme involved in estrogen synthesis.[57] The presence of leiomyomas in lung, lymph nodes, muscular tissue, heart, vascular structures, retroperitoneal cavity, and parietal pleura[58] suggest a metastatic process.[9,12] Leiomyomatosis of the uterus does not tend to metastasize to the lung[59] but BML can present with uterine vascular invasion,[25] supporting a metastatic model. Similar patterns of X-chromosome (human androgen receptor) inactivation suggest that there is a single BML cell source, which is the uterus.

PROLIFERATION OF LUNG SMOOTH MUSCLE CELLS

BML nodules could originate from proliferative lung smooth muscle cells as is the case in primary leiomyoma.[60] However, pathologic sections of a primary pulmonary leiomyoma lacked immunoreactivity for estrogen and progesterone receptors as is found in BML.[61]

SIMULTANEOUS INDEPENDENT DEVELOPMENT OF LEIOMYOMAS AT MULTIPLE SITES

Multiple BML tumors have been identified in some cases and it is possible that they occur independently or via a metastatic process.[13] Since initial mutations have not been identified, it is possible that the mutations occur independently in the different sites. Experimental models to study BML are not available. Interestingly, N-nitroso compounds promoted formation of tumors in lung, reproductive and mammary organs.[62] In fact, chronic treatment of mice with N6-(Methylnitroso) adenosine (m6(NO)Ado) caused tumors in lungs and reproductive tract.[62] These findings support the idea that BML could be promoted by carcinogenic processes.

Metastatic dissemination of BML cells appears to be the most accepted mechanism for localization of BML to the lungs. BML cells could metastasize via the lymphatics, hematologic spread, coelomic metaplasia, and intraperitoneal seeding.[3] Galactins have been identified in pathologic sections of BML lesions, suggesting that these proteins could play a role in cell transformation, regulation of apoptosis and cell growth, cell adhesion during metastasis, and regulation of tumor invasiveness.[63] Molecular studies support the notion that BML metastasis to the lung is promoted by the inherent properties of BML cells and is not a mere by-product of the surgical procedures.

PULMONARY PHYSIOLOGY

Few studies have evaluated lung function in patients with BML.[19,29,52,64] In one study, a patient was followed for more than 10 years and serial pulmonary function tests were obtained.[19] Initially, the patient presented with diminished vital capacity and total lung capacity (TLC) without any evidence of airflow obstruction or impairment in diffusion capacity (Fig. 63-3). As the disease progressed, the patient experienced a decline in diffusion capacity that could be accounted by the decline in lung volumes. In response to antiestrogen therapy, an increase in vital capacity and TLC were observed. In this case, the pathophysiologic profile was consistent with that of an interstitial lung disease.

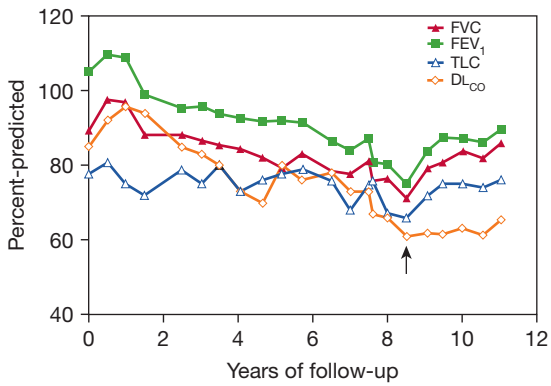


Figure 63-3 Changes in lung function before and after leuprolide acetate therapy. The patient was followed for 8.5 years before therapy and for over 2 years after therapy. Respiratory parameters, for example, forced vital capacity (FVC), force expiratory volume in the first second (FEV_1), total lung capacity (TLC), diffusion capacity for carbon monoxide (D_{LCO}), declined prior to therapy but improved following treatment with leuprolide. *(Reproduced with permission from Taveira-DaSilva AM, Alford CE, Levens ED, Kotz HL, Moss J. Favorable response to antigonadal therapy for a benign metastasizing leiomyoma. Obstet Gynecol. 2012;119(2 Pt 2):438–442.)*

RADIOLOGY

BML nodules may be identified by chest X-rays, computed tomography (CT), positron emission tomography (PET), and magnetic resonance imaging (MRI). The nodular structures observed in BML are well circumscribed. Bilateral pulmonary BML nodules are more common than unilateral nodules. Lung BML may occasionally present with cystic lung destruction.[19] Fluorodeoxyglucose-positron emission is negative in BML and may be used to differentiate BML from other tumors. BMLs and tumors such as adenomas, bronchoalveolar carcinomas, carcinoid tumors, and low-grade lymphomas also have low glycolytic activity.[65] ^{18}F-FDP-PET however, can distinguish a BML from leiomyosarcoma, which is a more glycolytically active tumor and may be found in association with BML.[6] CT and magnetic resonance has also been used to identify BML lesions in the retroperitoneal space and pelvic cavity.[66] Leiomyomas can be easily recognized on pelvic examination. The dimensions and locations of the fibroids may be identified by ultrasound.[67] Since, in most instances the lung nodules are detected by incidental X-rays, a chest X-ray may be warranted after a woman is diagnosed with uterine leiomyomas.

DIAGNOSIS

The differential diagnosis of BML nodular lesions include infectious or neoplastic metastatic lesions.[68] BMLs are usually asymptomatic but may result in lung-related symptoms.[69] Diagnosis requires a compatible medical history and pathologic analysis of biopsies and/or surgically removed tumor. CT-guided, transbronchial or open lung biopsy may be used to establish the diagnosis.[37] Although most cases of pulmonary BML are asymptomatic, some patients present with dyspnea, cough, wheezing, chest pain, chylothoraces, and pneumothoraces. The respiratory symptoms of BML are more prevalent in younger patients. The manifestations of BML in other sites such as uterus, heart, and lymph nodes, for the most part, may be nonspecific. The symptoms of uterine fibroids include abnormal uterine bleeding, pelvic pressure/pain, and reproductive dysfunction. Some of these symptoms have been reported in patients diagnosed with BML prior to myomectomy or hysterectomy.[3,19] BML patients do not present with dysregulated levels of tumor biomarkers, for example, carcinoembryonic antigen (CEA), carbohydrate antigen 19-9, also called cancer antigen 19-9 or sialylated Lewis (a) antigen (CA19-9), carcinoma antigen 15-3 (CA 15-3), cancer antigen-125 (CA-125), cytokeratin 19 fragment (CyFRA21-1), neuron-specific enolase (NSE), alpha-fetoprotein (AFP), hyperglycosylated hCG (HCG-β), beta-2-microglobulin *(β2-MG)*.

Differential diagnosis of BML includes primary pulmonary leiomyoma, primary pulmonary leiomyosarcoma, metastatic leiomyomatosis of an extrauterine source, pulmonary hamartomas, and lymphangioleiomyomatosis (LAM).[1] BML, depending on location, has been classified as intravenous leiomyomatosis and disseminated BML.[9] BML lung nodules have been associated primarily with leiomyomas. Lung hamartomas are associated with other cancers and express the melanogenic protein Pmel17.[70] High-grade leiomyosarcomas may involve the lung. In leiomyosarcomas, the mean time to recurrence is 19 months and metastasis to the lung is seen in 16% of patients for low-grade and 70% for high-grade leiomyosarcomas. Low-grade leiomyosarcomas do not express progesterone and estrogen receptors, which distinguish them from BML. Leiomyomatosis peritonealis disseminata could be one of the confounding diagnoses to consider when a BML patient presents with peritoneal lesions.[9] The slow growth of BMLs could be mistaken by other potential causes of lung nodules for example, infectious processes (fungal, parasitic and tuberculosis), metastatic cancers, benign neoplasms (e.g., chondrohamartomas, hamartomas, BML),

amyloidosis, mucoid impaction syndromes, multiple arteriovenous malformation, paraffinoma, plasma cell granuloma, rheumatoid nodules, sarcoidosis, silicosis.[68]

PROGNOSIS

The prognosis of patients with BML is favorable. Although most cases of BML present with multiple pulmonary tumors after myomectomy and hysterectomy, few cases reported the presence of these nodules before hysterectomy.[53] There are only scattered reports where BML was described as a cause of death. Other cancers detected in association with BML could influence prognosis.

TREATMENT

There is no standard treatment for BML. Treatment involves tumor resection and manipulation of hormonal status. Lung tumors may regress at menopause and during/after pregnancy, supporting a role for estrogen in BML.[71] Treatments have been adapted from those used for uterine leiomyoma, and include hysterectomy, myomectomy, dilation of the cervix, uterine artery embolization and endometrial ablation, and scrapping of the uterus (curettage).

Oophorectomy has been reported to improve lung function and cause regression of the lung tumors.[29,64,72–76] Another line of treatment has involved antiestrogenic therapy. Gonadotropin-releasing hormone (GnRH) analogs (e.g., Lupron) have been used to reduce estrogen levels.[10,19,77] Other drugs include the selective estrogen receptor modulators (SERMs), e.g. raloxifene.[24,64,78] Aromatase inhibitors such as anastrozole[64] have been shown to be effective treatments. Progesterone therapy has also proven to be effective.[79–81] However, there have been some cases of BML refractory to progesterone and aromatase inhibitors.[82] Treatments of uterine leiomyoma have also included combination of GnRH analogs and aromatase inhibitors.[64,83] Patients with BML have been treated with a single drug or combination of drugs,[22,83] e.g. leuprolide acetate, letrazole, leuprolide acetate and aromatase inhibitors, and antiprogestin (CDB-2914)[22,83] e.g., In some cases total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH/BSO) has been combined with drugs. Although bilateral oophorectomy has been the most commonly used treatment, unilateral oophorectomy has been effective in treating some BML tumors.[74] It is important to consider loss of bone mineral density due to antiestrogenic therapies. The slow-growing behavior of BML suggests that these tumors can be left untreated unless the patient becomes symptomatic.

CHAPTER 64

Depositional Diseases of the Lungs

Robert J. Homer

INTRODUCTION

Deposits of endogenous body constituents or exogenous materials in amounts sufficient to deform structure and impair function can occur virtually anywhere in the body. Deposits of endogenous materials in the lungs or airways cause a variety of diseases (Table 64-1). These may have different clinical manifestations, depending on localization (i.e., pulmonary parenchyma or conducting airways). This chapter deals with a few of these manifestations: amyloidosis; diffuse pulmonary calcification; alveolar microlithiasis; diffuse alveolar hemorrhage (DAH) syndromes; and idiopathic pulmonary hemosiderosis. Others are discussed elsewhere in this text.

AMYLOIDOSIS

Characteristics of amyloid and the various forms of pulmonary amyloid are considered below.

NATURE OF AMYLOID

Amyloidosis refers to the extracellular deposition of amyloid, a fibrillar, proteinaceous, insoluble material that has characteristic light, ultrastructural, and histochemical features (Fig. 64-1). Electron microscopic examination of amyloid reveals a dominant (95%) fibrillar component with distinctive periodicity, associated with a lesser (5%) pentagonal doughnut-shaped glycoprotein component, physically and chemically identical in all forms of amyloid, which is derived from a soluble plasma protein, soluble amyloid P protein (SAP). Amyloid also includes various glycosaminoglycans and certain apolipoproteins (E and J). Radiographic diffraction studies of amyloid show the fibrils to be arrayed in a β-pleated sheet configuration.

TABLE 64-1 Depositional Diseases of the Lungs

Biologic Material	Disease
Interstitial Deposition	
Amyloid	Amyloidosis
Water	Interstitial edema
Calcium	Metastatic calcification
Alveolar Deposition	
Surfactant	Alveolar proteinosis

Figure 64-1 Amyloid deposition. **A.** Amyloidoma. Cut surface of lung with *white arrows* indicating a dense, wax-like lesion that is characteristic of nodular amyloid. Incidental finding at autopsy. *(Used with permission of Leslie A. Litzky, MD, Department of Pathology and Laboratory Medicine, Hospital of the University of Pennsylvania, Philadelphia.)* **B.** The typical amorphous appearance of amyloid is seen deposited within the wall of a pulmonary venule. *Green* birefringence on polarized light examination after staining with *Congo red* will confirm the amyloid nature of the deposit (H&E ×700). **C.** Amorphous amyloid in the alveolar interstitial space. *Arrow* indicates a thickened alveolar septum (H&E ×420).

This accounts for the ordered binding of the histochemical stain Congo red such that Congo red–stained amyloid appears apple-green under polarized light.[1,2] When amyloid is deposited in tissues it may produce atrophy of parenchymal cells (e.g., glomeruli), interference with mechanical function (e.g., heart and lungs), or impaired vasoconstriction of blood vessels, leading to hemorrhage (e.g., lungs and gastrointestinal tract). Other mechanisms of tissue injury are also hypothesized including direct tissue toxicity.[3]

While the main fibrillar component of amyloid can be derived from any one of 27 precursor proteins,[2] only a few are common in systemic disease, including immunoglobulin light-chain, serum amyloid–associated (SAA) protein (a family of acute phase reactants), transthyretin (TTR, a prealbumin molecule that binds and transports thyroxine and retinol), and β_2-microglobulin.[1,4–6] The established amyloid fibril nomenclature is based on the chemical nature of the fibril protein, where an A, for amyloid, is followed by a suffix that is an abbreviated form of the parent or precursor protein. These forms of amyloidosis are therefore known as AL, AA, ATTR, and Aβ_2M, respectively. An entity related to amyloidosis is light-chain deposition disease (LCDD) in which tissue deposits are also

derived from immunoglobulin light chains and are similar to amyloid by light microscopy, but show granular deposition by electron microscopy and do not stain with Congo red.[7] It seems likely that the biochemical properties of the light chain determine the nature of the deposit produced.

AL amyloidosis usually occurs in association with a neoplastic clonal proliferation of B cells or plasma cells which produce a monoclonal immunoglobulin or immunoglobulin fragment (monoclonal gammopathy). The neoplastic clone may clinically manifest as multiple myeloma or lymphoma (generally lymphoplasmacytic lymphoma) or may be subclinical (formerly known as primary amyloidosis), causing bone-marrow plasmacytosis. Most often the protein source is a λ-light chain, either intact or the amino terminal fragment. Amyloid-associated (AA) amyloidosis (previously referred to as secondary amyloidosis) is associated with a chronic increase in serum acute-phase reactants. It was formerly seen predominantly in patients with chronic infections (e.g., tuberculosis, leprosy, and chronic osteomyelitis) but is now seen more commonly with noninfectious chronic inflammatory diseases (e.g., rheumatoid arthritis, familial Mediterranean fever, Crohn disease, and heroin abuse with "skin popping").[1,6] TTR is deposited in familial amyloid polyneuropathies and senile systemic amyloidosis (ATTR amyloidosis).[5] β_2-microglobulin deposition ($A\beta_2M$ amyloidosis) is seen in patients with chronic renal failure on dialysis.

■ PULMONARY INVOLVEMENT IN AMYLOIDOSIS

It is important to distinguish secondary involvement of the respiratory tract in patients with systemic disease from localized pulmonary involvement with the latter being much less common than the former.[4,8,9] Tracheobronchial amyloid deposition and nodular parenchymal amyloid deposition (amyloidoma) (Fig. 64-1A) most often occur as isolated phenomena, whereas diffuse interstitial deposition is more often seen in systemic amyloidosis. In addition to pulmonary involvement per se, amyloidosis may also cause symptoms in any portion of the respiratory tract or there may be secondary effects from deposition in other organs. For example, deposits in the tongue may be extensive enough to cause obstructive sleep apnea. Persistent pleural effusions may be due to both pleural and cardiac disease.[10] Diaphragmatic deposition may lead to respiratory failure. Pulmonary hypertension is a rare complication.[11] The vast majority of cases of pulmonary amyloidosis can be categorized as tracheobronchial amyloidosis, nodular parenchymal amyloidosis, and diffuse septal amyloidosis.

Nodular Parenchymal Amyloidosis

Solitary amyloid nodules (amyloidomas) are commonly incidental radiographic findings in asymptomatic individuals (Fig. 64-1).[4,8] When multiple, such nodules may be associated with cough, dyspnea, or hemoptysis. These nodules have no distinctive features, although occasionally, they may show radiographic evidence of calcification or cavitation. Usually the diagnosis of an amyloid nodule is made after surgical resection. Occasionally, the diagnosis has been made by transbronchial biopsy or percutaneous fine-needle aspiration. However, surgical excision of one or more nodules may be prudent, since, on rare occasion, amyloid deposition occurs within a pulmonary neoplasm (e.g., a primary neoplasm such as atypical carcinoid or a metastatic neoplasm such as medullary carcinoma from the thyroid). It is possible that advances in biochemical analysis of the amyloid (see below) may influence this decision, but this is not yet commonly discussed in the literature.

Nodular parenchymal amyloidosis most often represents AL. Histologically, the amyloid deposit is often associated with an intense inflammatory reaction consisting of plasma cells, macrophages, and multinucleated giant cells. Interestingly, when the accompanying plasma cells have been analyzed for clonality, they are more often polyclonal than monoclonal. In such cases, the inflammatory cells may therefore be a local reaction to the presence of amyloid, rather than the source of the amyloid precursor light chains. In a few instances, nodular amyloidosis has been associated with a histologically apparent low-grade pulmonary lymphoma. Rare cases of AA amyloidosis have also been reported. Clinical follow-up of nodular parenchymal amyloidosis unassociated with systemic or, frankly, neoplastic disease is generally benign.[8]

Tracheobronchial Amyloidosis

Amyloid deposition in the tracheobronchial tree can produce either plaques or tumoral masses.[4,9] The more common presentation as plaques is diffuse and multifocal, and represents submucosal deposition of amyloid. Diffuse or proximal involvement of the airways is apt to be symptomatic, producing cough, stridor, or hemoptysis. Less commonly, deposition of amyloid in the tracheobronchial tree produces a solitary mass, which mimics an endobronchial neoplasm with signs of bronchial obstruction or hemorrhage. Tracheobronchial amyloid deposition, like parenchymal nodule amyloid, is most often of light-chain derivation and a localized phenomenon. Again, like nodular amyloidosis, this form is rarely associated with systemic disease. Both types of airways lesions can be readily identified by bronchoscopic examination. However, as is the case with amyloid deposition at all sites, with biopsy there is a risk of hemorrhage. Although localized tumoral masses may be treated by excision or observation, more diffuse involvement may be treated by laser ablation, stents, or radiation. Involvement of proximal airway leads to significant mortality while involvement of distal or mid airway has generally good prognosis.

Diffuse Interstitial Amyloidosis

Widespread, *diffuse interstitial amyloidosis* of the pulmonary parenchyma may produce either a reticulonodular or miliary pattern on the chest radiograph.[4,8,12] The deposition of amyloid may involve the alveolar septal interstitium, the walls of small blood vessels, or both (Fig. 64-1B,C). Such pulmonary involvement occurs most often in patients with systemic amyloidosis, derived from either immunoglobulin light-chain or AA protein. Pulmonary interstitial amyloid deposition in secondary involvement is rarely sufficiently severe to produce clinical manifestations but, uncommonly, it may produce progressive dyspnea, hemoptysis, or restrictive pulmonary function tests. It is thought that the morbidity and mortality of diffuse septal amyloidosis in patients with systemic disease is related to concurrent cardiac amyloidosis with which tissue burden closely correlates, possibly explaining why septal amyloidosis by itself in this setting is not of more significance.[4] On the other hand, primary diffuse interstitial pulmonary amyloidosis has been considered to have a relatively poor prognosis.[4,12]

■ DIAGNOSIS AND TREATMENT OF AMYLOIDOSIS

Diagnosis of amyloidosis requires tissue examination and Congo-red staining and/or electron microscopy. The biochemical nature of the amyloid fibril in patients with systemic amyloidosis cannot be predicted from clinical manifestations alone.[13–18] Even in patients with a known plasma cell dyscrasia, if amyloid is detected, it should not be assumed that this represents AL amyloid since a significant number of patients with familial or senile type amyloid also have plasma cell dyscrasias. Historically, a variety of immunohistochemical and immunofluorescence tests were used, combined with genetic testing; but these commonly required frozen tissue, which were technically challenging and did not always provide an answer. More recently, improved immunohistochemistry and biochemical techniques have become available and are applicable in formalin fixed paraffin embedded tissue.[13–17,19–21] Published data show these approaches are highly robust and generalizable to multiple clinical scenarios although they have not yet been reported in patients with isolated pulmonary disease.

While it is beyond the scope of this chapter to discuss therapy in depth, it is important to note that therapy for systemic disease is

entirely dependent on the specific peptide responsible. In cases of systemic AL amyloidosis, there has been considerable progress in treatment with introduction of myeloma type therapy with high-dose prednisone and mephalan therapy combined with use of hematopoietic stem-cell transplantation. Newer agents also appear promising such as thalidomide and related compounds and especially bortezomib which targets plasma cells.[3] In contrast, treatment for AA amyloidosis focuses on the underlying inflammatory disease but may also include small molecule inhibitors.[6] Systemic senile amyloidosis due to deposition of transthyretin (ATTR) has also been approached with small molecule inhibitors.[5] In some cases of hereditary disease, either small molecule inhibitors or organ (liver, heart) transplantation has been explored.[5] The significance of these therapies for lung-limited disease is unclear since localized disease is typically treated with ablative therapy such as stents, radiation, laser treatment, resection, and other localized methods. The more recent systemic therapies have not yet been reported in patients with lung-limited disease.

DIFFUSE PULMONARY CALCIFICATION

Calcification of the pulmonary parenchyma can occur by a variety of mechanisms.[22] Dystrophic calcification refers to the deposition of calcium salts, most often crystalline hydroxyapatite, in dead tissue such as within the healing granulomas of tuberculosis or sarcoidosis. It can also be seen in various other conditions such as in pulmonary hypertension, other post infectious conditions or pneumoconiosis. This type of calcification is usually localized; its distinctive radiographic features are sometimes diagnostically helpful. It is rarely of any clinical significance beyond that of the underlying condition.

Metastatic calcification refers to the deposition of calcium salts, usually amorphous, in normal tissues (Fig. 64-2). This latter type of calcification occurs in association with some derangement of calcium metabolism, such as primary hyperparathyroidism, secondary hyperparathyroidism of chronic renal failure, hypervitaminosis D, the milk-alkali syndrome, sarcoidosis, or increased bone turnover due to multiple myeloma or metastatic carcinoma.

Although metastatic calcification can occur in almost any tissue of the body, it occurs most often in the lungs, kidneys, and the stomach (tissues with more alkaline pH), and the walls of blood vessels. Metastatic calcification in the lungs usually affects the interstitium of the alveolar septa and the walls of bronchioles and pulmonary vessels, sometimes localizing on elastic fibers.

Clinical manifestations of diffuse pulmonary calcification are unusual, occurring most often in patients who are in chronic renal failure, particularly in those on chronic hemodialysis. Radiographically, metastatic calcification usually takes the form of a diffuse interstitial infiltrate, sometimes with fine nodularity. Less often, confluent patchy consolidation mimicking pneumonia may be seen. Although the calcific nature of the infiltrate is often apparent on routine chest radiograph, computed tomography (CT) scan is more sensitive both in detecting the interstitial deposits and in revealing their calcific nature. Moreover, CT scan may also demonstrate calcification of chest wall blood vessels, circumstantially implicating calcification as the cause of pulmonary parenchymal abnormalities. Recognition of the calcific nature of the infiltrate is furthered by scanning with ^{99m}technetium.

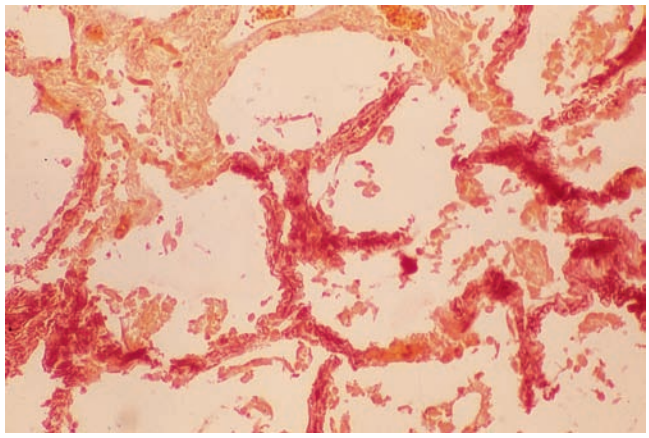

Figure 64-2 Metastatic calcification of alveolar septa in a renal dialysis patient. Photomicrograph shows calcium forming a *dark red* precipitate within the alveolar septa (Alizarin red ×280).

Only rarely do the patients manifest dyspnea or arterial hypoxemia, and pulmonary function tests tend to not show signs of restrictive pulmonary disease. Unexplained dyspnea in a patient with chronic renal failure or hypercalcemia in the presence of a normal chest radiograph should lead to consideration of high-resolution computed tomography (HRCT) or technetium scanning. Rarely, respiratory failure may develop although death from metastatic calcification is typically due to cardiac disease.

The mechanism responsible for diffuse pulmonary calcification is unknown. Although high levels of parathyroid hormone or a marked increase in the calcium-phosphate solubility product occur in some patients, diffuse calcification can occur in the absence of either. Ultrastructural observations of minimal, presumably early, lesions show selective deposition of calcium on elastic fibers, suggesting that they may serve as the initial nidus. In contrast to their apparent role in alveolar microlithiasis, extracellular matrix vesicles do not appear to be involved.

ALVEOLAR MICROLITHIASIS

Pulmonary alveolar microlithiasis (PAM) is a rare autosomal recessive disorder characterized by intra-alveolar accumulation of spherical calcified concretions (called calciferites, calcospherites, or microliths), in the absence of any known calcium metabolism disorder.[23] This disorder usually presents with an abnormal chest radiograph from an asymptomatic patient (Fig. 64-3). Presentation can occur at any age, although symptoms usually occur in third or fourth decade of life. The chest radiograph and/or HRCT are diagnostic, showing a sand-like micronodulation throughout the lung fields. This is caused by the presence of innumerable minute calcified spherules filling the alveolar spaces. Although not usually required, bronchoalveolar lavage or biopsy can confirm the diagnosis. Biopsy shows calcified spherules filling alveolar spaces (Fig. 64-3).

Although usually asymptomatic at the time of presentation, alveolar microlithiasis typically progresses to end-stage lung disease, but the rate of progression is highly variable. When it does, the findings are those of restrictive pulmonary disease or exercise-induced pulmonary hypertension. No therapy has proven effective but lung transplantation has been performed successfully in a few patients.

The disease is due to a mutation in a type IIb sodium-phosphate cotransporter (SLC34A2) gene. As surfactant phospholipids are metabolized, phosphate is liberated and the transporter is needed to eliminate the excess phosphate from the alveolar space. In the absence of this transporter, increased phosphate levels lead to microlith formation. While this is most dramatic in the lungs, other organs can also be affected. The accumulation of microliths ultimately leads to loss of vital capacity by mass effect as well as by inducing underlying parenchymal fibrosis.

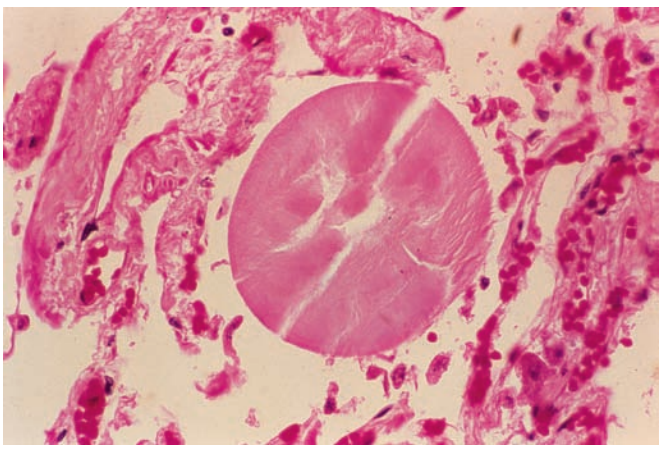
ALVEOLAR HEMORRHAGE SYNDROMES

Pulmonary hemorrhage most commonly arises from endobronchial diseases (tumors, bronchiectasis, bronchitis).[24] However, there is a subset of patients in whom bleeding originates at the level of the alveoli and who are referred to as having DAH.[25] Symptoms range from cough, fever, and dyspnea alone to respiratory failure. While hemoptysis is common, it is not universal, even when DAH is severe. In these

A

B

C



D

Figure 64-3 Alveolar microlithiasis in a 46-year-old man admitted for nonpulmonary problems. History included slight dyspnea on exertion and previous episodes of "pneumonia" in 1947, 1950, and 1952. Clinical examination revealed severe restrictive lung disease, pulmonary hypertension, and cor pulmonale. Diagnosis confirmed by lung biopsy. **A and B.** Posterior–anterior and lateral chest radiographs demonstrate innumerable, tiny calcified nodules throughout both lung fields. Thin, lucent lines on each side represent normal pleura visualized between the calcified pulmonary parenchyma and the chest wall. Emphysematous blebs in the apices displace the calcifications. **C.** Cut surface of explanted lung from a patient undergoing lung transplantation for primary alveolar microlithiasis. Note the fine nodularity which correlated with the chest radiographs. *(Used with permission of Leslie A. Litzky, MD, Department of Pathology and Laboratory Medicine, Hospital of the University of Pennsylvania, Philadelphia.)* **D.** Photomicrograph demonstrating a typical calcospherite in an alveolar space (H&E ×1120).

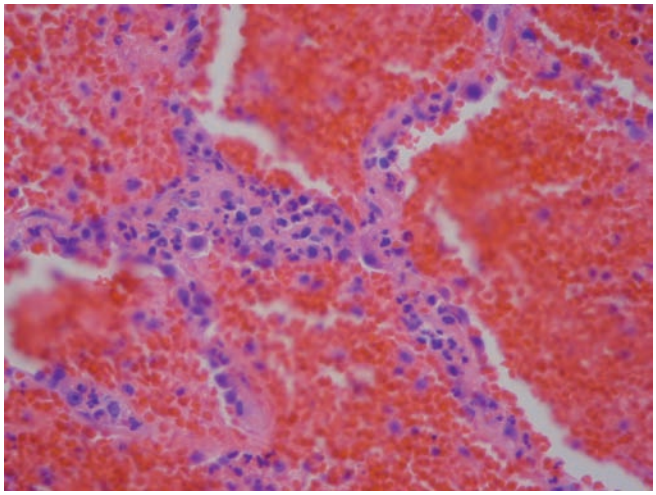


Figure 64-4 Capillaritis as a cause of pulmonary hemorrhage. Note the neutrophils in the alveolar septum (in *center* of image) and the blood and fibrin in the alveolar spaces (H&E ×100).

cases, the diagnosis can be suspected due to a falling hemoglobin level. Evaluation of serial bronchoalveolar lavage aliquots in such patients may show a progressive increase in bloody return, as opposed to endobronchial disease, in which bleeding tends to clear. Bronchoalveolar lavage is also useful to exclude infection in patients with DAH.

The damage to alveolar septa may either be due to immunologic mechanisms (immune complex, antineutrophil cytoplasmic antibody [ANCA], antiglomerular basement antibodies, antiphospholipid antibodies) or to nonimmunologic causes. This distinction is largely, although not perfectly, captured in the presence or absence of the pathologic finding of capillaritis (Fig. 64-4 and Table 64-2).[26]

TABLE 64-2 Causes of Diffuse Alveolar Hemorrhage

Diffuse Alveolar Hemorrhage without Pulmonary Capillaritis
Inhalational toxins (trimetallic anhydride, crack cocaine)
Mitral stenosis
Severe coagulopathy (iatrogenic, renal failure, thrombocytopenia)
Nonspecific inflammation (diffuse alveolar damage, pulmonary gangrene, endocarditis)
Neoplasm/hamartomatous (angiosarcoma, lymphangioleiomyomatosis, tuberous sclerosis)
Pulmonary vascular disease (pulmonary veno-occlusive disease, capillary hemangiomatosis)
Idiopathic pulmonary hemosiderosis
Diffuse Alveolar Hemorrhage with Pulmonary Capillaritis
ANCA-associated vasculitis (granulomatosis with polyangiitis [formerly known as Wegener granulomatosis], microscopic polyangiitis, Churg–Strauss syndrome)
Immune complex—associated with vascular disease (Behçet disease, Henoch–Schönlein purpura, systemic lupus erythematosus, rheumatoid arthritis, mixed connective-tissue disease, polymyositis)
Isolated pauci-immune pulmonary capillaritis
Diffuse Alveolar Hemorrhage with or without Capillaritis
Goodpasture syndrome
Systemic lupus erythematosus
Primary or secondary antiphospholipid syndrome
Drug-induced pulmonary hemorrhage

Capillaritis is characterized by infiltration of alveolar walls by inflammatory cells, usually neutrophils, but sometimes eosinophils or monocytes, with fibrinoid necrosis of the alveolar and vessel wall. However, due to the absence of supporting structures, alveolar necrosis leads to wall breakdown so rapidly that this latter feature may be hard to appreciate. In order to distinguish this process from simple margination of neutrophils, there should be evidence for neutrophils undergoing apoptosis (pyknosis and nuclear fragments). Distinction from infection requires determination that there is minimal accumulation of inflammatory cells within alveoli. The pathologic diagnosis of pulmonary hemorrhage itself requires that there is either hemosiderin-laden macrophages or evidence of hemophagocytosis, since the blood that is commonly seen in lung biopsies may be due to surgery alone. If this evidence is absent, clinical criteria for DAH should be used.

Nonimmunologic mechanisms are quite diverse and include diffuse alveolar damage, inhalation of toxins, coagulopathy, and mitral valve disease, among others listed (Table 64-2).[25] While the presence or absence of capillaritis is a useful way to think about these diseases, the decision about whether to actually perform a biopsy in these cases is challenging as interpretation of these biopsies is difficult, there is potential sampling error, and there is a significant risk of surgery to these patients. These problems limit this procedure's utility while alternative diagnostic schemes usually allow diagnosis in absence of biopsy.

■ GOODPASTURE SYNDROME

This entity was originally described as an association of alveolar hemorrhage with glomerulonephritis.[27,28] It was later determined that pulmonary and renal damage in many such patients was mediated by antibodies that are specifically directed against a component of glomerular and other capillary basement membranes, most often the α_3-chain of type IV (basement membrane) collagen. The anti-basement membrane antibodies cause pulmonary hemorrhage only in genetically predisposed individuals, after some injury such as cigarette smoke, viral respiratory infection, or hydrocarbon vapor inhalation exposes alveolar capillary basement membranes to the immune system.[29] Although there are other causes of concomitant alveolar hemorrhage and glomerulonephritis, Goodpasture syndrome is generally reserved for disease mediated by antiglomerular basement membrane antibodies (anti-GBM antibodies).

Goodpasture syndrome can present with a broad spectrum of clinical findings. The "classic" patient presents with massive hemoptysis, dyspnea, diffuse alveolar infiltrates on chest radiograph (Fig. 64-5) and overt glomerulonephritis, often with acute renal failure.[30] However, some patients present with only hemoptysis and subsequently develop overt renal disease months or even years later. On occasion, patients present with acute glomerulonephritis due to anti-GBM antibodies and either develop pulmonary hemorrhage subsequently or never develop pulmonary hemorrhage. Without pulmonary hemorrhage, the entity should not be called "Goodpasture syndrome."

The histologic findings on lung biopsy in Goodpasture syndrome are not diagnostic. Routine light microscopy reveals intra-alveolar hemorrhage, usually associated with intra-alveolar hemosiderin-laden macrophages (Fig. 64-5).[24,31] There may be no evidence of vasculitis, capillaritis, interstitial or intra-alveolar inflammation, or necrosis. In some cases, subtle capillaritis may be present. In either case, nonspecific reparative proliferation of the alveolar-lining cells may be present.

While the diagnosis of Goodpasture syndrome can be made by detecting anti-GBM antibodies in the patient's serum, the sensitivity and specificity of various methods to detect these antibodies vary considerably. The gold standard remains the detection of the linear pattern of immunofluorescence on a lung or kidney biopsy. However, only occasionally will immunofluorescence microscopy

E

Figure 64-5 Goodpasture syndrome. **A.** Chest radiograph showing bilateral alveolar infiltrates, predominantly in the middle and lower lung fields. **B.** Autopsy specimen showing cut surface of lung with massive alveolar hemorrhage. *(Used with permission of Dr. Richard Garnett, Reid Memorial Hospital, Richmond, IN.)* **C.** Photomicrograph of intact alveoli, containing both red blood cells and hemosiderin-laden macrophages (H&E ×45). **D.** Immunofluorescent demonstration of immunoglobulin-lining alveolar surfaces in a uniform distribution (fluoresceinated anti-IgG ×113). **E.** Smear of bronchoalveolar lavage demonstrating hemosiderin-laden macrophages (*Prussian blue stain*; original magnification ×132). *(Used with permission of Dr. David Lyon, Iankenau Lankenau Hospital, Wynnewood, PA.)*

show diagnostic linear deposits of immunoglobulin and/or complement along alveolar capillary walls (Fig. 64-5D). In contrast, kidney biopsy in Goodpasture syndrome is usually diagnostic. Conventional light microscopy shows nonspecific focal or diffuse glomerulonephritis which may be crescentic and necrotizing.

When pulmonary hemorrhage due to Goodpasture syndrome is life-threatening, plasmapheresis for rapid lowering of circulating levels of anti-GBM antibody and administration of intravenous corticosteroids and cyclophosphamide to suppress antibody synthesis can be life-saving.[25,28,30] If the patient is not in advanced renal failure at the time of diagnosis, chronic immunosuppression with a combination of corticosteroids and cyclophosphamide can prevent progressive renal damage. If irreversible renal failure has already occurred, the patient can eventually be successfully transplanted once anti-GBM antibodies have disappeared from the serum. Elimination of the antibodies usually can be achieved by immunosuppression alone; in some instances, pretransplant nephrectomy may be required.

ANCA-ASSOCIATED PULMONARY VASCULITIS

The ANCA-associated vasculitides, granulomatosis with polyangiitis (GPA, formerly known as Wegener granulomatosis) and microscopic polyangiitis (MPA), represent the most common cause of immunologically mediated DAH.[25,26,30,32] These have been associated with the development of autoantibodies directed against cytoplasmic components of neutrophils (and monocytes), the ANCAs. Detection of ANCAs entails the use of indirect immunofluorescence and heterologous antibodies against human immunoglobulin to detect autoantibodies bound to neutrophils of affected patients. Ethanol fixation of the neutrophils prior to antibody staining produces one of two patterns when autoantibodies are present: (1) a finely granular centrally accentuated cytoplasmic localization (c-ANCA); or (2) a perinuclear localization (p-ANCA). The usual targets of these antibodies have been identified as proteinase 3 for c-ANCA and myeloperoxidase for p-ANCA. Both antigens are found in the primary azurophilic granules of neutrophils. When ethanol is used as the fixative, the cellular granules are disrupted; the positively charged myeloperoxidase molecules then migrate toward the negatively charged nucleus to produce the perinuclear pattern, and the neutral proteinase 3 molecules remain dispersed in the cytoplasm to produce the cytoplasmic pattern. To maximize diagnostic accuracy, dual testing by fluorescence and an antigen-specific solid phase assay is required. Otherwise, a high degree of clinicopathologic correlation is required for correct interpretation of these tests. Some patients with ANCA-associated alveolar hemorrhage also have antibasement membrane antibodies in the serum. These antibodies are directed against basement antigens other than those seen in Goodpasture syndrome and are thought to be a secondary phenomenon, rather than of pathogenic significance.

Overt DAH occurs in approximately 15% of patients with GPA or MPA. Depending on the specific syndrome present, alveolar hemorrhage may be isolated, associated with glomerulonephritis, or associated with widespread systemic vasculitis. In patients with ANCA-associated vasculitis, the occurrence of DAH is a poor prognostic indicator, although among survivors, complete recovery of lung function is common. Therapy does not depend on diagnosis of MPA versus GPA, and is based on immunosuppression with steroids and cyclophosphamide possibly augmented with plasmapheresis. Nevertheless, patients with GPA/c-ANCA/proteinase 3 have worse outcomes with higher mortality and recurrence rate. While Churg–Strauss syndrome (CSS) is classified among the ANCA-associated vasculitides, DAH due to CSS is extraordinarily rare.

Rarely, patients present with isolated pulmonary capillaritis with no serologic or clinical evidence for a systemic disorder.[33] These patients respond to immunosuppression but relapses occur.

ANTIPHOSPHOLIPID ANTIBODY–ASSOCIATED ALVEOLAR HEMORRHAGE

Patients with serum antibodies directed against membrane phospholipid (antiphospholipid syndrome or APS) display hypercoagulability.[25,34] Clinically, this manifests as peripheral arterial and venous thrombosis, fetal wastage in pregnant women, and thrombocytopenia. Pulmonary involvement can include pulmonary thromboembolism, pulmonary hypertension, diffuse alveolar damage, or rarely DAH. The latter produces fever, dyspnea, and diffuse pulmonary infiltrates on chest radiograph. Alveolar hemorrhage in APS has been associated with alveolar capillaritis with or without immune complex deposition and with microvascular thrombosis in the lungs. The combination of both thrombosis and hemorrhage greatly complicates therapy.

Antiphospholipid antibodies were first detected in patients with systemic lupus erythematosus (SLE) and were formerly known as the lupus anticoagulant because they prolong some laboratory tests of clotting. APS can occur in the absence of SLE. How often these antibodies play a role in pulmonary hemorrhage due to SLE is unknown, as there are other possible mechanisms in that syndrome (see below). In patients with isolated APS and alveolar hemorrhage, corticosteroid treatment, sometimes supplemented by cyclophosphamide, can result in a favorable outcome.

COLLAGEN VASCULAR DISEASE AND IMMUNE COMPLEX–ASSOCIATED PULMONARY HEMORRHAGE

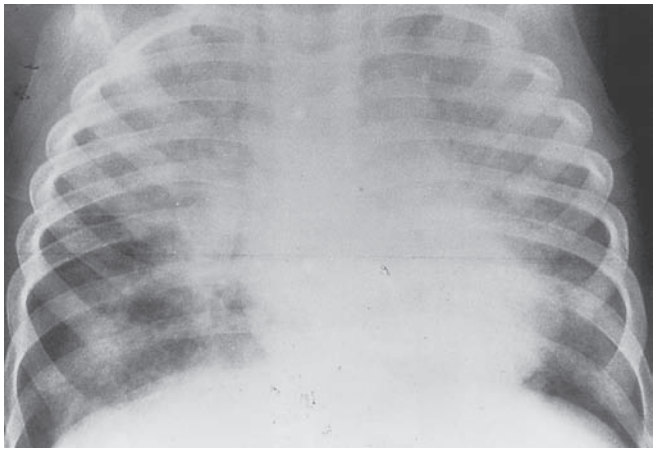
DAH also occurs as a rare complication of certain connective-tissue disease syndromes, most often SLE but also rheumatoid arthritis, progressive systemic sclerosis, and mixed connective-tissue disease.[35] Particularly in SLE, other causes of alveolar hemorrhage must be considered, including infection, uremia, and coagulopathy. When such causes have been eliminated, alveolar hemorrhage is sometimes found to be associated with capillaritis, with interstitial pneumonitis, or with immunofluorescent or ultrastructural evidence of immune complex deposition in alveolar septa. However, none of these disorders are consistently associated with pulmonary hemorrhage in SLE. Early diagnosis and treatment with corticosteroids and cytotoxic drugs are associated with favorable outcomes, although relapse is not uncommon.

DRUG-INDUCED PULMONARY HEMORRHAGE

There is a long list of drugs, both therapeutic and drugs of abuse, associated with vasculitis. The clinical spectrum ranges from isolated mild skin disease to severe multiorgan systemic disease, usually due to a small vessel vasculitis. Some of these drugs can induce an ANCA-associated vasculitis. DAH due to ANCA-associated pulmonary capillaritis is well documented for propylthiouracil, D-penicillamine, allopurinol, diphenylhydantoin, and minocycline. Drug-induced ANCA-associated vasculitis should be treated with cessation of all potential causative agents as well as immunosuppression. Once the offending drug has been eliminated, the possibility of relapse seems low.

NONIMMUNOLOGIC CAUSES OF DIFFUSE ALVEOLAR HEMORRHAGE

There is a wide range of conditions that are associated with DAH with no capillaritis seen on biopsy and which are due to a wide variety of specific conditions, including toxins, neoplasms, nonspecific inflammation, infection, coagulopathy, and pulmonary vascular disease.[25] While all the previously mentioned diseases and syndromes have been excluded as likely possibilities, there still remains a small group of patients who develop recurrent DAH in the absence of extrapulmonary disease and with no evidence of an immune etiology. These patients are considered to have idiopathic pulmonary



A

Figure 64-6 Idiopathic pulmonary hemosiderosis in a 21-month-old child with anemia soon after birth. Iron stain of the sputum showed hemosiderin-laden macrophages. **A.** Chest radiograph showing extensive, bilateral, almost punctate densities throughout both lung fields, most prominent in the perihilar regions where an alveolar filling pattern appears. **B.** Photomicrograph of lung at autopsy, showing intact alveoli containing degenerating red blood cells and hemosiderin-laden macrophages. Immunofluorescence studies for immunoglobulin and complement deposition were negative (H&E ×31). *(Used with permission of Department of Pathology, St. Christopher's Hospital for Children, Philadelphia.)*

hemosiderosis, a diagnosis of exclusion (Fig. 64-6).[30,36] Clinically, the patients form a heterogeneous group with respect to the onset and course of disease, which range from fulminant and fatal to chronic relapse with eventual chronic pulmonary insufficiency due to interstitial fibrosis, to spontaneous remission with little or no residual deficit. The disease usually affects children and young adults. Pathologic examination reveals nonspecific alveolar hemorrhage without evidence of inflammation, vasculitis, or immune complex deposition. Only a few observations on ultrastructure are available. These include focal disruption, smudging, or lamination of alveolar capillary basement membranes.

The pathogenesis of this condition remains unknown, and there are no associated antibodies or other serum markers in the idiopathic cases. However, the clinical and morphologic similarities to some cases of alveolar hemorrhage of known immune pathogenesis, the occasional responsiveness to immunosuppressive therapy, the occasional association with celiac sprue – a presumably immunologic disease of the small intestine – and frequent association with a nonspecific elevation of serum IgA, all point to an as yet unelucidated immune pathogenesis. Rarely, children with hypersensitivity to cow's milk (Heiner syndrome) can present with DAH.

If the diagnosis proves to be idiopathic pulmonary hemosiderosis, high-dose corticosteroid therapy with or without cyclophosphamide and plasmapheresis is useful in controlling acute bleeding, but the long-term effectiveness of these measures in preventing recurrence or progression of this disease is unknown.

CHAPTER 65

Pulmonary Toxicity Related to Chemotherapeutic Agents

Lynn T. Tanoue

Jennifer Possick

INTRODUCTION

Toxicities related to medications comprise a major category of iatrogenic illness. Many agents used for cancer treatment have the potential to cause pulmonary toxicity. As the horizon for treatment options has broadened with our ever-expanding understanding of biological mechanisms fundamental to neoplasia, so has the spectrum of pulmonary complications related to new therapies. Further, with availability of new therapeutic modalities, patients with cancer are living longer, and may, in their long-term survivorship, display delayed toxicities related to treatment. Consequently, for the pulmonologist, drug-induced lung disease is an area of growing complexity.

Chemotherapeutic agents, therapeutic radiation, and biological response modifiers are used in a wide range of regimens, and their use is further complicated by the use of hematopoietic support and bone marrow or stem cell transplantation. Many are, directly or indirectly, associated with pulmonary toxicity. An estimated 5% to 10% of patients undergoing chemotherapy ultimately develop therapy-related pulmonary complications.[1–3] This chapter reviews the evaluation of patients with suspected chemotherapy-induced pulmonary toxicity, as well as the potential toxicities associated with specific classes of drugs.

APPROACH TO THE PATIENT WITH SUSPECTED CHEMOTHERAPY-INDUCED PULMONARY TOXICITY

The differential diagnosis of patients with cancer receiving treatment who develop pulmonary complications is often very challenging, particularly as the diagnosis of drug-induced pulmonary toxicity is typically one of exclusion. Patients most often present with nonspecific constitutional or respiratory complaints. In many cases, symptoms and physical signs may be minimal or even absent. In these situations, the only evidence of an ongoing pulmonary process may be an abnormal chest radiograph (Table 65-1).

The diagnosis of lung disease caused by chemotherapeutic agents poses a particular challenge to the clinician, as there are several complicating features inherent to the oncology patient population.

First, treatment may be given in multidrug regimens or in combination with other modalities such as radiation therapy, bone marrow transplantation, or stem cell transplantation. Assigning pulmonary toxicity to a single drug or modality within such a regimen is often impossible. Moreover, the combined toxicity of two or more drugs or a single drug with radiation therapy may exceed the individual toxicities of those drugs.

Second, patients undergoing chemotherapy are often immune suppressed, either from the malignancy itself or from myelosuppressive or immunosuppressive effects of their treatment. These patients are therefore susceptible to opportunistic infection, which may be indistinguishable radiographically from drug toxicity. This is particularly challenging, as the lung is the most common site of serious infection in patients with cancer. It has been estimated that a relative minority (5%–30%) of pulmonary complications in immunocompromised patients are actually due to drug toxicity; hence it is important to remember that infection is still the most likely culprit when pulmonary decompensation occurs. Since changing a treatment regimen may affect the chance for cure or prolongation of survival, reasonable certainty of drug-related complications necessarily involves exclusion of infection.

Third, cancers themselves may mimic lung disease. This is particularly true in cases of lymphangitic tumor spread or metastases to the lung parenchyma or pleura.

Fourth, toxicity from some drugs appears to be related to cumulative dosage levels. However, adverse reactions may occur even with a low cumulative dose, when clinical suspicion for toxicity is low.

Finally, pulmonary toxicity due to a single chemotherapeutic agent may present with several different syndromes that vary clinically, radiographically, and temporally. While a severe pulmonary reaction acutely following drug administration usually raises suspicion of drug toxicity, as patients survive for longer periods of time it is becoming increasingly clear that toxicity due to some chemotherapeutic agents may be delayed by months to even years after treatment. In such situations, clinical suspicion of drug toxicity may be low.

Monitoring for potential pulmonary toxicity in the patient undergoing chemotherapy requires ongoing clinical vigilance. Symptoms such as cough, dyspnea, or chest discomfort may be mild or even absent. Radiographic findings may be equally subtle. Even if clinical symptoms and radiographic abnormalities are present and severe, they are usually nonspecific. The possibility of adverse drug effects must be considered within the complex medical context inherent to the patient with cancer undergoing physically challenging or immunosuppressive treatment.

PULMONARY PHYSIOLOGICAL TESTING

Pulmonary physiological testing has been utilized in surveillance of patients receiving drugs with potential for pulmonary toxicity. A multitude of investigations studying the utility of pulmonary function testing (PFT) in monitoring pulmonary effects related to administration of chemotherapy have been reported, but the

TABLE 65-1 Differential Diagnosis of Radiographic Abnormalities in Cancer Patients

Pulmonary toxicity related to chemotherapy or other medication
Infection
Primary malignancy
Lymphangitic tumor, metastatic disease, leukemic infiltration
Radiation lung injury
Acute respiratory distress syndrome
Interstitial lung disease, unrelated to drug toxicity
Pulmonary edema (cardiogenic)
Pulmonary thromboembolism
Pulmonary hemorrhage
Transfusion-related acute lung injury

application of these findings to clinical management has been a subject of debate.

Various physiological abnormalities have been described, the most common of which are decreases in lung volumes and diffusing capacity for carbon monoxide (D_{LCO}). Patients receiving chemotherapy who are monitored serially by PFT frequently demonstrate physiological abnormalities in the absence of clinical signs of toxicity.[4–6] Abnormalities in D_{LCO} in particular have been thought by some to be indicative of early-onset, drug-related pulmonary injury. Most such studies have been performed in patients receiving bleomycin, busulfan, or carmustine. Discontinuation of drug, with or without initiation of treatment, including corticosteroids, typically results in improvement. Whether early intervention based on D_{LCO} abnormalities in the absence of clinical symptoms decreases the likelihood of long-term pulmonary impairment related to toxicity is unclear. Conversely, in situations of clinically evident drug toxicity accompanied by PFT abnormalities, withdrawal of culprit therapy may not be paralleled by improvement in physiological measurements. For example, in a study examining pulmonary function in 116 long-term (5–13 years after treatment) survivors of Hodgkin disease in Norway, nearly 30% of patients had exertional dyspnea with associated pulmonary function abnormalities.[7] Multivariate analysis of these patients identified chemotherapy with a combination of bleomycin and anthracyclines as the sole significant predictor of lung function impairment. In all patients in whom drug toxicity is of concern, consideration must be given to the possibility that discontinuation of a specific treatment might result in substitution of less effective therapy.

A number of factors further complicate the practice and interpretation of PFT in the oncology population. Many physiological parameters are effort dependent. The ability of a patient to consistently perform test maneuvers may be affected by weakness, pain, or the use of analgesic or sedating medications. Reproducibility of results therefore may be a significant concern in patients whose functional status and strength are impaired by their malignancy or its treatment. Many patients have anemia induced by malignancy, medication, or chronic illness. Since D_{LCO} is affected by hemoglobin concentration, it is critical that appropriate corrections for anemia be made. Patients with cancers may also be subject to processes other than drug toxicity that will affect PFT results. Primary pulmonary malignancy, metastatic lung disease, infection, thoracic or abdominal surgical procedures, and a host of other clinical situations may all independently cause variation in physiological measurements. Therefore, identifying pulmonary physiological abnormalities specific to drug effect may prove very difficult.

Ultimately, even though the predictive value of baseline or serial PFT remains unclear, most clinicians will continue to rely on such testing as screening and monitoring tools. Though there are no definitive data that toxicity can be averted by physiological monitoring, we are limited by the absence of other means of identifying toxicity early enough to prevent severe pulmonary disease. Though the presence of subclinical abnormalities does not imply that patients will develop irreversible lung disease, these abnormalities may dictate closer monitoring, or even the withdrawal of drug. Conversely, normal physiology cannot predict abrupt toxicity that may produce profound pulmonary injury. As always, medical decisions based on pulmonary physiological findings must be made in the context of the patient's clinical situation as a whole.

■ DIAGNOSTIC EVALUATION

Given the potential impact of pulmonary drug toxicity on a patient's present and future cancer treatment, it is important to establish this diagnosis as firmly as possible. Thoughtful and judicious use of invasive procedures plays an important role in that evaluation.

The approach to the cancer patient in whom drug toxicity is suspected should parallel the approach to any immunocompromised patient with diffuse or localized lung disease (see Chapter 123). Because clinical features are usually not specific, sampling of respiratory tract secretions and/or lung tissue may be critical to this evaluation. Direct sputum examination or culture may suggest specific pathogens or may be diagnostic of infections such as invasive fungal disease, *Pneumocystis jiroveci* pneumonia, or tuberculosis. In the absence of diagnostic sputum findings, invasive procedures may be necessary. Fine-needle aspiration of the lung may be useful with focal lesions. However, the utility of this procedure in diffuse lung disease is relatively low. This is particularly problematic for patients with drug-induced pulmonary toxicity, which often presents with a diffuse interstitial pattern on chest radiograph. Fiberoptic bronchoscopy with bronchoalveolar lavage (BAL) and transbronchial biopsy has become central to the evaluation of both diffuse and localized lung disease in the immunocompromised host. The procedure is associated with a low rate of major complications. Diagnostic yield varies widely, reflecting the broad range of disease processes that can involve the lung in the immunocompromised patient. Highest diagnostic yields are obtained in patients with infections; lower yields are seen in interstitial inflammatory processes, which may include toxicity from drugs. However, even in situations in which a specific etiology is not identified, exclusion of infection by bronchoscopy often provides clinically useful information.

Open or thoracoscopic lung biopsy is associated with the highest diagnostic yield and can be performed with low complication rates even in critically ill patients. If drug-induced pulmonary injury is suspected, surgical biopsy may be necessary to definitively exclude other causes of lung disease.

The evaluation of a patient in whom chemotherapy-related pulmonary toxicity is a consideration clearly presents significant challenges. Clinicians must be vigilant in the evaluation and management of patients receiving chemotherapeutic regimens. An awareness of potential iatrogenic complications related to drug therapy is, therefore, essential.

CYTOTOXIC ANTIBIOTICS

A variety of cytotoxic antibiotics have been associated with pulmonary toxicity (Table 65-2). Important examples are discussed below.

■ BLEOMYCIN

Bleomycin, a cytotoxic antibiotic produced by *Streptomyces vermiculus*, is used in the treatment of various malignancies, including lymphomas, germ cell tumors, and squamous cell cancers of the head and neck.[8] Unfortunately, it has significant potential for pulmonary toxicity due to relative lack of the inactivating enzyme bleomycin hydrolase in the lungs.[9] The most severe complication is interstitial pneumonitis progressing to fibrosis and respiratory failure, though there are also less severe syndromes, including organizing pneumonia and hypersensitivity pneumonitis.[10]

The pulmonary toxicities of bleomycin have been studied extensively, primarily in animal models. Endothelial injury via oxidative stress is the sentinel event, followed by the influx of inflammatory cells (predominantly macrophages, neutrophils, and lymphocytes), development of perivascular edema, elaboration of inflammatory cytokines, and, ultimately, fibroblast activation and fibrosis (Fig. 65-1).[11] A variety of mediators have been implicated in bleomycin-induced lung injury, including tumor necrosis factor α (TNFα), transforming growth factor-β (TGF-β), interleukin-6 (IL-6), and interleukin-1 (IL-1).[10] Human studies have demonstrated activation of in vitro alveolar macrophages in response to bleomycin,[12] and patients treated with bleomycin for testicular cancer demonstrate a rise in serum TNFα 3 to 24 hours after drug administration.[13] The continued expression of TNFα and IL-1 may predispose to the production of TGF-β and promotion of dysregulated collagen production and fibrosis. Animal studies have shown that bleomycin-induced pulmonary toxicity can

TABLE 65-2 Cytotoxic Antibiotics

Drug	Pulmonary Syndrome	Treatment	Comments
Bleomycin	Chronic pneumonitis; pulmonary fibrosis; rare fulminant variant with acute respiratory failure	Discontinue drug; corticosteroids	Risk factors: Cumulative dose >400 units; supplemental oxygen; therapeutic radiation; renal insufficiency; age >70 y; additional cytotoxic drugs
	Hypersensitivity-type lung disease	Discontinue drug; corticosteroids	Dyspnea, cough, skin rash, and peripheral eosinophilia
	Chest pain syndrome	Discontinue drug	Associated with drug infusion
Mitomycin C	Chronic pneumonitis; pulmonary fibrosis; rare fulminant variant after single dose	Discontinue drug; corticosteroids	Risk factors: Oxygen therapy; therapeutic radiation; additional cytotoxic drugs
			May relapse after withdrawal of corticosteroids
	Acute dyspnea and/or bronchospasm	Discontinue drug; bronchodilators; supportive care; consider corticosteroids	Risk factors: Vinca alkaloid use; may develop noncardiogenic pulmonary edema and/or chronic interstitial disease
			Can recur with rechallenge of vinca alkaloids
	Hemolytic uremic syndrome	Discontinue drug; supportive care; poor response to plasmapheresis or corticosteroids	Microangiopathic hemolytic anemia thrombocytopenia, renal insufficiency, noncardiogenic pulmonary edema; rare hemorrhage
Actinomycin D	"Radiation recall" pneumonitis	Discontinue drug	Effect may be longstanding

be ameliorated or prevented by antibodies to TNFα and TGF-β, or receptor antagonists to IL-1; knockout of the TNFα receptor has also demonstrated protective effects.[14–16] Bleomycin also induces direct free-radical damage after oxidation of the bleomycin-Fe (II) complex; this effect has been mitigated by iron depletion with chelators both in vitro and in vivo.[10]

The incidence of bleomycin-induced pneumonitis varies from 6% to 18%, though this figure may be higher depending on the criteria used for diagnosis and the presence of other chemotherapeutic agents in a multidrug regimen; overall mortality is estimated at 3% or less, depending on risk factor subgroup.[10,17]

Several risk factors for severe bleomycin-induced pneumonitis have been identified: (1) Toxicity appears to correlate with higher cumulative dosages. While fatal injury has been observed after administration of <100 units, there is a significant escalation in toxicity with total doses over 400 units, and severe toxicity develops in 20% of patients receiving >500 units.[18] (2) Exposure to high concentrations of supplemental oxygen, particularly in the setting of general anesthesia, may create a synergistic toxic effect. This is primarily based on animal data, including a study which demonstrated a 75% increase in mortality in hamsters treated with bleomycin and 70% oxygen for 72 hours versus bleomycin alone.[19] As a result, high fractions of supplemental oxygen are generally avoided whenever possible in clinical practice, and the evidence substantiating human risk has been largely anecdotal. There have also been case reports of recrudescence in patients exposed to even modest levels of supplemental oxygen several months after bleomycin exposure, so caution in limiting oxygen exposure for at least 6 months after treatment appears warranted.[20] (3) Thoracic irradiation prior to, concomitant with, or subsequent to, bleomycin administration may be associated with an increase in toxicity. This "radiation recall" may extend outside the original port of irradiation, and may last for years after bleomycin therapy. More recent data suggests that the augmented risk from consolidative radiation therapy may be attenuated if there is an interval of at least 28 days between chemotherapy and radiation.[21] While there is still certainly an increase in pulmonary symptoms during treatment for patients receiving combined therapy, and patients must be closely monitored, long-term sequelae may be less pronounced than originally feared.[22] (4) Since bleomycin is excreted by the kidneys, and is often coadministered with potentially nephrotoxic agents, decreased creatinine clearance below 35 mL/min is associated with increased risk of toxicity.[23] (5) The risk for pulmonary toxicity rises proportionately for every decade after 30 years, and patients over 70 years of age are at particular risk.[24] (6) Concurrent use of

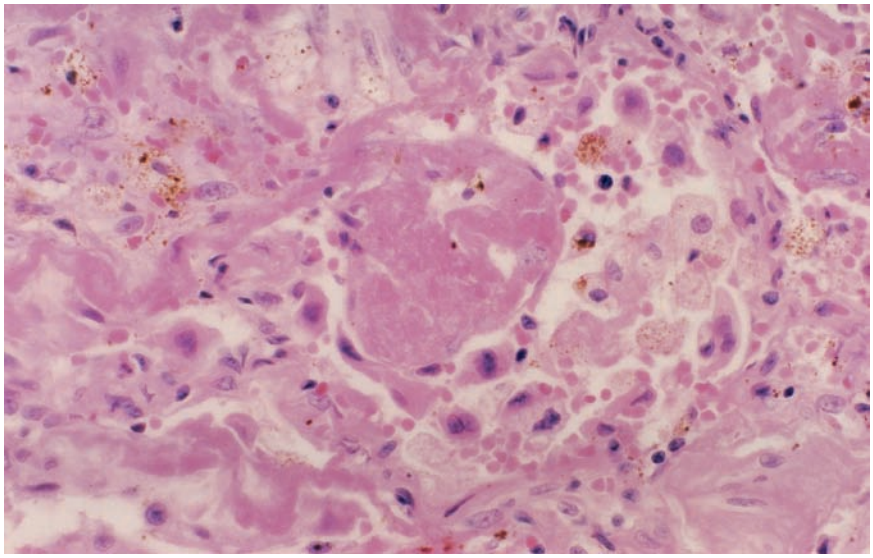

Figure 65-1 Lung biopsy specimen from a patient with clinical and radiographic evidence of bleomycin-induced pulmonary toxicity shows drug effect with acute and chronic changes. The alveolus contains an exudate of fibrin, which is undergoing organization and is surrounded by alveolar macrophages. The large and atypical cells are markedly reactive alveolar type II pneumocytes. The alveolar wall itself is scarred with collagen deposition by the spindle-shaped fibroblasts. *(Used with permission of Dr. Darryl Carter, Professor of Pathology, Yale University School of Medicine.)*

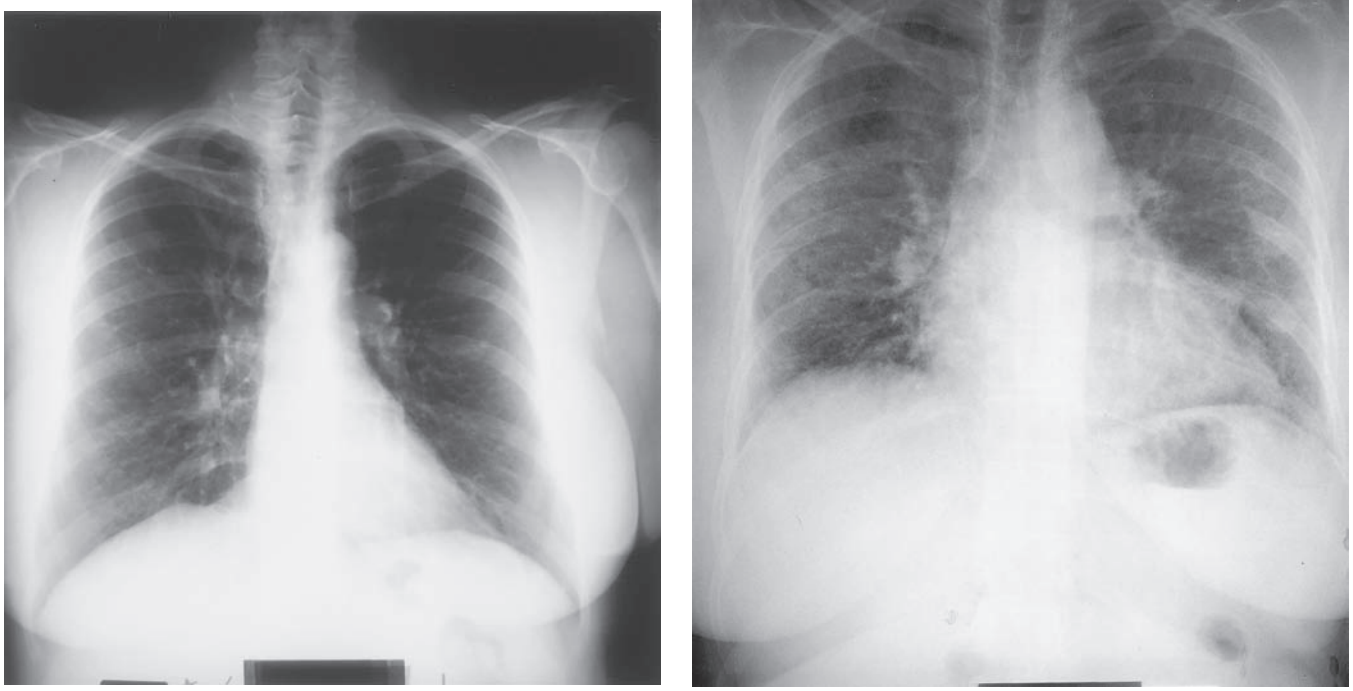
other chemotherapeutic regimens, including gemcitabine, cisplatin, and drugs in the ABVD regimen, may result in synergistic toxicity.[21,22] Though these effects have not been clearly reproducible in all cases, convention has been to reduce bleomycin dosage in drug regimens in which this synergy is a concern. (7) Smoking appeared to confer an increased risk of bleomycin toxicity in one study,[25] however this has not been confirmed in other studies, and may be confounded by the presence of other risk factors. (8) Similarly, though there have been case reports of increased incidence of bleomycin toxicity in patients receiving granulocyte colony–stimulating factor (G-CSF), likely due to increased cytokine induction, larger series have not clearly demonstrated a relationship.[26]

The clinical presentation of bleomycin-induced pneumonitis is usually subacute and insidious, occurring within a few weeks to 6 months after treatment.[10] A more fulminant presentation with acute respiratory failure has been reported but is far less common. Patients generally present with dyspnea, nonproductive cough, and low-grade fever, though some patients may be asymptomatic. Substernal or pleuritic chest pain occurs, but is infrequent. Common physical findings include hypoxemia and fine bibasilar crackles; rhonchi and a pleural rub may also develop.[27] Chest radiograph usually shows bilateral reticular or fine nodular infiltrates with a basilar predominance, often beginning at the costophrenic angles (Fig. 65-2A,B). Loss of lung volume with diaphragmatic elevation is also commonly seen. However, various radiographic patterns including alveolar infiltrates, lobar consolidation, organizing pneumonia, asymmetric lung involvement, pneumothorax, pneumomediastinum, and even lung nodules have been described. Computed tomographic (CT) scanning, particularly high-resolution computed tomography (HRCT) scanning, is more sensitive in the evaluation of radiographic abnormalities and may be useful in patients who have spirometric or clinical evidence of toxicity but negative chest radiographs (Fig. 65-3); CT scanning provides more accurate assessment of anatomic distribution of disease that correlates well with lung function impairment.[28] Most patients receiving bleomycin demonstrate a decrease in $D_{L_{CO}}$ over the course of therapy, though only a small percentage of these patients will go on to manifest clinical signs of pulmonary toxicity, which is typically also associated with restrictive ventilatory defect.[29]

Bleomycin may also cause an acute hypersensitivity syndrome of dyspnea, cough, and rash immediately following administration of drug. Lung biopsy in these cases shows eosinophilic infiltration, and changes consistent with hypersensitivity pneumonitis; peripheral eosinophilia may also be observed. These cases show a particularly favorable response to steroid therapy.[30] An acute chest pain syndrome has also been reported in 1% of patients; it occurs during infusion, resolves with termination of drug, and does not appear to predict other pulmonary toxicity from bleomycin.[31]

Discontinuation of drug is recommended for patients with clinically significant bleomycin-induced toxicity, and may be sufficient treatment for individuals with mild presentations. For more significant disease, corticosteroids are usually given in the range of 60 to 100 mg of prednisone per day for 4 to 8 weeks, with slow taper over the following 4 to 6 months guided by clinical stability of the patient. It should be noted that the steroid responsiveness of bleomycin-induced pulmonary toxicity is highly variable, with more responsive cases likely representing hypersensitivity pneumonitis or organizing pneumonia.[10] Improvement often occurs within weeks of drug cessation, but complete resolution may take up to 2 years; patients may be left with residual radiographic and/or physiological abnormalities, particularly if fibrosis has developed. Though a number of promising agents have been explored in animal models, none have yet been shown to be effective in humans.



A B

Figure 65-2 Posteroanterior chest radiographs of a 56-year-old woman with cervical carcinoma (**A**) before and (**B**) after chemotherapy with a bleomycin-containing regimen. Note the decrease in lung volume and diffusely increased interstitial lung markings in the post-chemotherapy radiograph.

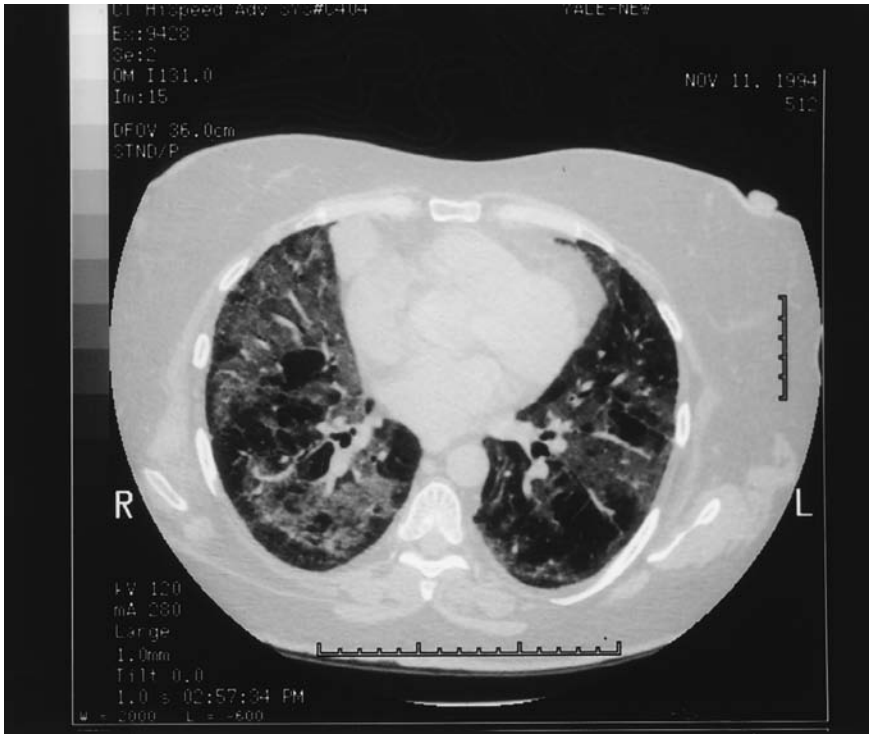


Figure 65-3 Chest computed tomography (CT) scan of same patient as in Figure 65-2, taken at the time of radiograph in Figure 65-2. Note the patchy distribution of bilateral infiltrates, whose extent is clearly delineated by CT.

■ MITOMYCIN C

Mitomycin C is an alkylating agent derived from *Streptomyces caespitosus*. It is used in multidrug regimens for multiple solid organ malignancies including non–small-cell lung, breast, gastric, pancreatic, cervical, prostate, and bladder cancers.[32] The incidence of pulmonary toxicity due to mitomycin is variably reported between 2% and 38% (with clinically relevant toxicity likely <10%), and appears to be potentiated by concurrent administration of other agents, particularly vinca alkaloids.[32] Though typically associated with intravenous therapy, cases of significant pulmonary toxicity have been reported in patients receiving both intravesicular and intraperitoneal mitomycin C.[33,34] Mitomycin C lung injury presents with multiple distinct pulmonary syndromes, including interstitial pneumonitis and fibrosis, bronchospasm, acute lung injury, thrombotic microangiopathy, venoocclusive disease with pulmonary hypertension, and pleural disease.

The most common form of mitomycin-induced lung toxicity is a chronic pneumonitis with pulmonary fibrosis similar to that seen with bleomycin; it similarly appears potentiated by exposure to supplemental oxygen and radiation.[35] Some studies have suggested a dose–response effect, with increased risk of toxicity after cumulative doses ranging from 20 to 39 mg/m^2, though this finding has not been consistently reproducible.[28,29] The exact mechanism of injury is unknown, though several have been proposed, including lipid peroxidant injury, hypersensitivity reactions, or immune complex–mediated disease.[36] Pulmonary toxicity usually occurs after 2 to 12 months of therapy, though a more fulminant form of acute lung injury has been reported after a single dose.[36]

Clinically, patients present with a subacute syndrome of cough and progressive dyspnea, often with fatigue and sometimes with pleuritic chest pain.[37] Fever is less common. Chest radiographs usually show bilateral interstitial infiltrates, occasionally with alveolar or fine nodular patterns. PFTs demonstrate a restrictive pattern with impairment in D_{LCO}, though degree of impairment correlates poorly with prognosis.[6] Histologically, biopsy specimens show mononuclear cell infiltration, alveolar-lining cell hypertrophy, collagen deposition, and alveolar septal thickening; type II pneumocyte enlargement and lymphocytic or eosinophilic infiltration have also been described. This syndrome may respond to discontinuation of drug and institution of corticosteroids at an initial dose of 60 mg/d tapered over a 4- to 6-week period; patients may demonstrate relapse once steroids are discontinued.[37]

The second syndrome of mitomycin-induced pulmonary toxicity is primarily seen in patients who have also received vinca alkaloids. While drugs of this latter category (vinblastine, vinorelbine, and vindesine) confer little in the way of risk of pulmonary toxicity when used alone, they may precipitate a syndrome of acute pulmonary toxicity when given concurrently with or subsequent to administration of mitomycin C.[38] Patients present with rapid onset of dyspnea or bronchospasm hours to weeks after exposure; symptoms generally abate in 12 to 24 hours with cessation of drug, supportive care, and bronchodilators. In some cases, however, bilateral interstitial infiltrates or noncardiogenic pulmonary edema may also develop, and patients may go on to develop chronic interstitial lung disease with permanent physiological impairment.[39] Rechallenge with vinca alkaloids alone, independent of mitomycin C, can also result in recrudescence of symptoms.[38]

The third syndrome of mitomycin C toxicity is a microangiopathy, with a presentation similar to thrombotic thrombocytopenic purpura and hemolytic uremic syndrome (TTP–HUS); in the case of mitomycin C microangiopathy, it is also associated with acute lung injury and respiratory failure in 50% of cases.[40] Pulmonary alveolar hemorrhage in this setting has also been described.[41] The mechanism of toxicity appears related to endothelial injury in the pulmonary vasculature. Unfortunately, prognosis is poor, and patients with chemotherapy-induced TTP–HUS respond poorly to the plasma exchange and corticosteroids that are the mainstay of therapy; there are case reports of successful treatment with rituximab, though it should be noted that these patients did not have respiratory failure.[42,43]

In addition, mitomycin C has been implicated in two cases of fatal pulmonary hypertension caused by pulmonary venoocclusive disease in patients with non–small-cell lung cancer (NSCLC) treated prior to surgical resection.[44] There have also been reports of pleural toxicity, with exudative effusions and pleural fibrosis.[6]

■ ACTINOMYCIN D

Actinomycin D is an older antitumor antibiotic derived from *Streptomyces*, which is still used in the treatment of Ewing sarcoma, rhabdomyosarcoma, Wilms tumor, and gestational choriocarcinomas. While this drug is not often associated with primary lung toxicity, it may potentiate "radiation recall" pneumonitis in patients who have received prior thoracic irradiation.[45]

ALKYLATING AGENTS

Alkylating agents (Table 65-3) have been implicated in chemotherapeutic agent–related lung disease. Important examples are described below.

The chemotherapeutic properties of the alkylating agents result from the formation of covalent linkages (alkylation) of DNA

TABLE 65-3 Alkylating Agents

Drug	Pulmonary Syndrome	Treatment	Comments
Cyclophosphamide	Chronic pneumonitis; pulmonary fibrosis	Discontinue drug; corticosteroids	Risk factors: High cumulative dose; additional cytotoxic drugs; supplemental oxygen; therapeutic radiation Toxicity may occur years after treatment is completed Pleural fibrosis may occur in late-stage disease
Busulfan	Chronic pneumonitis; pulmonary fibrosis	Discontinue drug; consider corticosteroids	Risk factors: Cumulative dose >500 mg Often occurs after cessation of drug; prognosis poor
Oxaliplatin	Eosinophilic pneumonitis; organizing pneumonia; diffuse alveolar damage	Discontinue drug; corticosteroids	Risk factors: Pre-existing interstitial lung disease
Chlorambucil Melphalan Ifosfamide	Chronic pneumonitis; pulmonary fibrosis	Discontinue drug; consider corticosteroids for patients with hypersensitivity features	Clinical pulmonary toxicity is rare with exception of high-dose melphalan (>200 mg/m^2)

components.[46] Nitrogen mustards are the prototypic alkylating agents and were the first drugs to be used as modern cancer chemotherapy, but many other drugs also exert antineoplastic effects by alkylation. Alkylating agents that have been associated with pulmonary toxicity include derivatives of nitrogen mustards (cyclophosphamide, melphalan, chlorambucil, ifosfamide), alkyl sulfonates (busulfan), platinum-based therapies (oxaliplatin), and the nitrosoureas (carmustine/BCNU, lomustine/CCNU). The nitrosoureas are considered in a separate section below.

CYCLOPHOSPHAMIDE

Cyclophosphamide is widely used in the treatment of many malignancies, including lymphomas, breast and ovarian cancers, and a variety of other solid tumors. It may be used as part of myeloablative conditioning regimens prior to bone marrow or peripheral blood stem cell transplantation. It is also used alone or in combination with corticosteroids in the treatment of autoimmune diseases and systemic vasculitides.[3] The overall incidence of cyclophosphamide-induced lung injury is less than 1%, though as with other agents, increased pulmonary toxicity may occur in the setting of radiation therapy, oxygen supplementation, or combination treatment with other cytotoxic agents.[47]

Cyclophosphamide is administered as an inactive prodrug that is metabolized by the liver, and to lesser extent, in the lung, to 4-hydroxycyclophosphamide, phosphoramide mustard (responsible for alkylation and DNA cross-linking), and acrolein (responsible for the hemorrhagic cystitis which can complicate therapy).[48] Though the exact mechanism of cyclophosphamide-induced injury to the lung is unknown, in vitro models suggest contributions from oxidative stress, and upregulation of TGF-β, increase in collagen synthesis and, ultimately, fibrosis.[49] Cyclophosphamide toxicity lacks a clear dose–response relationship in humans, possibly due to genetic variations in drug metabolism.[50] In addition, the pharmacokinetics of both the inactive parent compound and the active alkylating derivative can be affected by variations in the cytochrome P450 superfamily of enzymes, as well as by interactions with other drugs. Therefore, functionally higher exposure to active drug may occur in the setting of substances that induce hepatic enzyme activity, such as rifampin, phenytoin, and alcohol, or with decreased renal clearance.

As with a number of other chemotherapeutic agents, cyclophosphamide-induced pulmonary toxicity may present either early in the course of treatment or in a delayed, progressive fashion that may begin years after treatment is completed. In cases where pulmonary symptoms occur long after exposure, an association with the drug may be difficult to identify. Clinical features are nonspecific, including nonproductive cough, dyspnea, fatigue, and fever. Occasionally, patients are asymptomatic but are discovered to have radiographic abnormalities compatible with drug toxicity. Chest radiographs and CT scans usually show evidence of bilateral interstitial lung disease (either bilateral reticular or nodular markings with ground-glass opacities or, later, fibrosis) but may also show pleural fibrosis in late-stage disease.[51] This latter radiographic finding may be helpful in distinguishing cyclophosphamide-associated interstitial lung disease from the idiopathic interstitial pneumonias.

Histological findings in the lung are not specific. Lung biopsy in these patients is primarily useful for exclusion of other identifiable causes of interstitial lung disease in immunocompromised patients, including infection and malignancy. When used to treat nonneoplastic lung disease, the distinction between underlying lung disease from a systemic syndrome and lung disease exacerbated by drug toxicity is often very difficult to delineate. When cyclophosphamide is used as a chemotherapeutic agent, its identification as the specific etiology of lung injury may also be difficult, as it is rarely used alone, pinpointing specific toxicity to a single agent may be impossible. Like other agents, cyclophosphamide may have synergistic toxicity with therapeutic thoracic radiation, high levels of supplemental oxygen, and other chemotherapeutic drugs with potential for lung injury.[52]

Cyclophosphamide-induced lung injury may cause significant morbidity, and a high clinical suspicion for pulmonary toxicity should result in prompt discontinuation of the drug. Early-onset pneumonitis can occasionally be fatal, but when recognized quickly, prognosis is generally favorable and recovery, though slow, is expected for most individuals. Discontinuation of the drug alone may be sufficient, though most patients also receive glucocorticoid therapy. The optimal regimen and magnitude of benefit in these cases remain unclear.[53] Unfortunately, late-onset toxicity follows an irreversible and progressive course, which appears steroid unresponsive; mortality due to progressive respiratory failure exceeds 60%.[51]

BUSULFAN

Busulfan, previously used as a treatment for chronic myelogenous leukemia (CML) prior to the advent of oral tyrosine kinase inhibitors, is now mainly used as a component of conditioning regimens for bone marrow and stem cell transplantation. Toxicity may develop within weeks of exposure, but is more typically insidious, with the average onset of symptoms more than 3 years after treatment.[3] Estimates of frequency vary widely, with an average of approximately 6%.[54] Because of the indolent nature of CML, patients were often treated for months to years with busulfan. Though it was generally well tolerated in this setting, patients receiving a cumulative dose above 500 mg appeared to be at higher risk for pulmonary complications.[55]

Currently, busulfan is used in combination with other chemotherapeutic agents in conditioning regimens prior to bone marrow and stem cell transplantation. Pulmonary complications in this situation are not uncommon though it is difficult to clearly attribute toxicity to busulfan rather than other causes including infection (notably cytomegalovirus), radiation therapy, and other drugs (particularly etoposide).[56,57] In long-term comparisons of patients receiving busulfan and cyclophosphamide versus total body irradiation prior to allogeneic transplantation, bronchiolitis obliterans was far more frequent in the former group (26% vs. 5%), while rates of pneumonitis were similar; this raises the concern that the main source of pulmonary toxicity in busulfan-based conditioning regimens may be an increase in chronic pulmonary graft versus host disease.[58]

Symptoms of busulfan lung injury usually present insidiously, weeks to years after exposure, with cough, progressive dyspnea, fever, fatigue, and weight loss. Chest radiographs typically show bilateral interstitial infiltrates with a basilar predominance. Pathological findings are consistent with other cytotoxic drug–induced pulmonary injuries, with type II pneumocyte hyperplasia, dysplasia, and desquamation into alveolar spaces. Fibroblast proliferation, collagen deposition, and fibrosis are usually evident. Desquamation and accumulation of alveolar debris can be severe in some cases, yielding a pattern similar to pulmonary alveolar proteinosis; unfortunately, total lung lavage is usually ineffective in such cases.[3,59]

There is no specific treatment for busulfan-induced pulmonary injury, except withdrawal of the drug. However, due to the delayed nature of presentation, patients are often no longer on therapy by the time toxicity is detected; thus, treatment is largely supportive. Though some spontaneous improvement may occur, when there is clinically evident busulfan-induced pulmonary toxicity the prognosis for recovery is generally poor. Corticosteroids have anecdotally been reported to be of benefit but, as with most chemotherapeutic agents, no prospective studies are available.[3] Given the possibility of late-onset pulmonary toxicity, it seems prudent that long-term follow-up of recipients of bone marrow or peripheral blood stem cell transplants with busulfan-based conditioning regimens should include pulmonary evaluation. However, guidelines for identification or treatment of pulmonary toxicity in this situation are lacking.

OTHER ALKYLATING AGENTS

Chlorambucil and melphalan are both slow-acting nitrogen mustards. Chlorambucil has an important role in the treatment of lymphoreticular malignancies including chronic lymphocytic leukemia (CLL) and has also been used in the treatment of nonneoplastic diseases, such as rheumatoid arthritis and sarcoidosis. Though pulmonary toxicity is less common than with other alkylating agents, occurring in less than 1% of patients, mortality from irreversible fibrosis when it occurs exceeds 50%.[60] As with busulfan, chlorambucil may be administered over a prolonged time in the treatment of CLL, but there does not appear to be a clear relationship between toxicity and either cumulative dose or duration of therapy. The number of cases of reported chlorambucil pulmonary toxicity is relatively small, thus no distinct clinical pattern has emerged. In cases of chlorambucil-related interstitial pneumonitis, BAL has demonstrated a CD8+ T cell alveolitis suggestive of hypersensitivity reaction.[61] Given the possibility of hypersensitivity pneumonitis, clinical suspicion should prompt immediate discontinuation of the drug, and administration of corticosteroids can be considered in patients with progressive pulmonary disease.

Melphalan has traditionally been used in the treatment of multiple myeloma, but, like other alkylating agents, it is now used to treat a variety of malignancies. High-dose melphalan (200 mg/m^2 or more) is used in conditioning regimens prior to stem cell transplantation and has been associated with fatal pneumonitis and fibrosis.[62] Since large series of such patients are not available, the incidence of pulmonary toxicity associated with high-dose melphalan given in these situations is not known. As these types of treatments become more widely available, new data should define whether pulmonary toxicity related to melphalan or other alkylating agents is indeed more prevalent than has been historically appreciated.

Ifosfamide is an alkylating agent that is structurally related to cyclophosphamide. It is used in the treatment of lymphoma and acute and chronic leukemias, as well as in solid tumors including sarcomas, ovarian cancer, and breast cancer. Dose limitation is usually related to bladder toxicity. Clinically evident ifosfamide-induced pulmonary toxicity appears to be rare and typically presents as interstitial pneumonitis.[63] It has also been described as a cause of acquired methemoglobinemia; this should be considered in the differential for patients on ifosfamide presenting with dyspnea, cyanosis, or altered mental status.[64]

Oxaliplatin is a platinum-derivative cytotoxic agent primarily used as part of multidrug regimens with 5-fluorouracil and leucovorin (FOLFOX) for treatment of colorectal cancer, as well as for treatment of pancreatic, breast, ovarian, and NSCL cancers. Though pulmonary complications are relatively rare, variable patterns of lung toxicity have been reported with FOLFOX regimens, including eosinophilic pneumonia, organizing pneumonia, and diffuse alveolar damage.[65–68] The timing, severity, progression, and prognosis of individual cases have been heterogeneous, probably owing to the diversity in pathological mechanisms. Some cases have demonstrated complete resolution with withdrawal of drug, with or without administration of corticosteroids, but others have nonetheless progressed rapidly to respiratory failure and death.[66,68] In some cases, patients were successfully rechallenged with 5-fluorouracil and leucovorin, indicating oxaliplatin as the likely culprit in the original drug reaction.[65,67] Mechanism of toxicity is still poorly understood, and likely multifactorial; glutathione depletion has been suggested based on the mechanistic role in oxaliplatin-induced hepatic injury, and an anecdotal case report of an individual who improved when treated with a combination of corticosteroids and N-acetylcysteine.[69,70] Patients with pre-existing interstitial lung disease, even when subclinical, may be at increased risk for oxaliplatin toxicity, progression of underlying interstitial disease, or both.[70] Individuals with baseline physiological and radiographic abnormalities, even in absence of symptoms, should be monitored carefully, and the threshold for withdrawal of drug and trial of corticosteroids should be low. It is unclear whether prophylactic N-acetylcysteine might be of benefit in these cases.

ANTIMETABOLITES

Antimetabolites are associated with lung injury (Table 65-4). Representative examples are discussed below.

METHOTREXATE

Methotrexate is an antimetabolite used to treat malignancies, as well as connective tissue diseases and other inflammatory conditions, including sarcoidosis and psoriasis. When used in high doses for the treatment of cancers, the incidence of pulmonary toxicity is estimated at 1% to 8%. The exact nature of methotrexate causing pulmonary toxicity in the context of cancer treatment is less well defined than in treatment of inflammatory diseases. Methotrexate, as a chemotherapeutic agent, would rarely be used alone, making interpretation of its role in any pulmonary syndrome challenging. In patients with rheumatoid arthritis, polymyositis, and other collagen vascular diseases, the potential for a variety of pulmonary manifestations related to the underlying disease can make the diagnosis of methotrexate-induced pneumonitis challenging.

The diagnostic criteria of Searles and McKendry (Table 65-5) are frequently employed in an effort to determine whether pulmonary involvement is related to methotrexate.[71] Though the criteria have

TABLE 65-4 Antimetabolites

Drug	Pulmonary Syndrome	Treatment	Comments
Methotrexate	Chronic pneumonitis; pulmonary fibrosis	Corticosteroids; discontinue drug	Most common syndrome of methotrexate-induced lung toxicity; risk factors: older age, pre-existing lung disease, diabetes, previous use of disease-modifying drugs, hypoalbuminemia
	Hypersensitivity-type lung disease	Corticosteroids; discontinue drug	May resolve even if drug is continued, but can progress to fibrosis
	Acute chest pain syndrome	Discontinue drug	Often accompanied by pleural effusions
	Noncardiogenic pulmonary edema	Supportive care; discontinue drug	Associated with intrathecal administration
Cytosine arabinoside	Noncardiogenic pulmonary edema	Supportive care; discontinue drug	Onset of symptoms usually occurs within days of initiation of treatment; risk factor: cumulative dose
	Cryptogenic organizing pneumonia	Discontinue drug; corticosteroids	Risk factors: combined therapy with anthracyclines or interferon-α
Fludarabine	Hypersensitivity-type lung disease; interstitial pneumonitis	Discontinue drug	Toxicity is uncommon; treatment associated with increased incidence of delayed opportunistic infections
Gemcitabine	Dyspnea	Occurs within hours of dose	Usually self-limited
	Interstitial lung disease; noncardiogenic pulmonary edema	Discontinue drug; corticosteroids; diuretics	Risk factors: combination treatment with taxanes or bleomycin

not been validated in a prospective cohort, they may be useful in situations where methotrexate pulmonary toxicity is a consideration.

In a multicenter case-control study of methotrexate-induced lung toxicity in patients with rheumatoid arthritis, Alarcon et al.[72] identified risk factors associated with the development of pneumonitis, including age greater than 60 years (associated with a sixfold increase in risk of pneumonitis compared with those <50 years of age), prior history of rheumatoid pleuropulmonary disease, diabetes, previous use of disease-modifying antirheumatic drugs, and hypoalbuminemia. Toxicity does not appear to have dose dependency, but daily versus weekly administration and higher weekly doses of methotrexate have been suggested as associated with increased risk, as well as pre-existing lung disease, prior PFT abnormalities, and the presence of renal insufficiency.[1,73–75] Synergistic toxicity has been reported with combination therapy using cyclophosphamide. Tapering of corticosteroid therapy or adrenalectomy may also increase the risk of methotrexate-induced toxicity.[1,76]

TABLE 65-5 Diagnosis of Methotrexate Pneumonitis

Diagnostic criteria:

- Acute onset of shortness of breath
- Fever (>38.0°C)
- Tachypnea (≥28 breaths/min) with nonproductive cough
- Radiographic evidence of interstitial or alveolar infiltrates
- WBC ≤15,000
- Negative blood or sputum cultures for pathogenic organisms (required)
- Pulmonary function tests demonstrating restrictive disease with low diffusion capacity
- Pa_{O_2} <55 mm Hg on room air (at presentation)
- Biopsy histopathology consistent with bronchiolitis or interstitial pneumonitis with giant cells and without evidence of pathogenic microorganisms

Presence of methotrexate pneumonitis:

- Definite: at least 6 of 9 criteria
- Probable: 5 of 9 criteria
- Possible: 4 of 9 criteria

Source: Data from Searles G, McKendry RJ. Methotrexate pneumonitis in rheumatoid arthritis: potential risk factors. Four case reports and a review of the literature. J Rheumatol. 1987;14(6):1164–1171.

Methotrexate is a folate analog; its therapeutic effect is related to its ability to inhibit cellular proliferation by inducing deficiencies of folate coenzymes, and ultimately to decreased synthesis of DNA and RNA.[77] The mechanism(s) of methotrexate-induced lung injury is unknown. Clinically, toxicity presents with several syndromes. The most common of these is development of a symptom complex characterized by fever, dyspnea, cough, malaise, and myalgias, usually within weeks after initiation of therapy. Chest radiography usually shows diffuse interstitial infiltrates. Chest radiography may demonstrate unilateral or bilateral effusion, a nodular appearance, or hilar and/or mediastinal adenopathy, or may be normal. Rash is present in up to 17% of patients and peripheral blood eosinophilia in up to 40% of patients. BAL in this setting may show a lymphocytic alveolitis, suggestive of a hypersensitivity reaction. However, illness may resolve even with continuation of the drug, and rechallenge does not necessarily result in relapse, suggesting that hypersensitivity may not be the true mechanism of injury. This presentation of methotrexate-induced pulmonary toxicity parallels the hypersensitivity-type syndrome that is sometimes observed with bleomycin. As some patients may go on to develop chronic pneumonitis and pulmonary fibrosis, the drug is generally withdrawn when toxicity occurs.

Pulmonary toxicity from methotrexate may also present as a more insidious subacute syndrome of interstitial lung disease. Symptoms including cough, fever, dyspnea, headache, and malaise typically occur within 4 months after the initiation of treatment. Radiographically and clinically this syndrome more closely resembles the type of chronic pneumonitis seen with other cytotoxic drugs and has been reported with all routes of methotrexate administration (oral, intravenous, intrathecal). In contrast to the lung injury associated with many other chemotherapeutic agents, the pneumonitis caused by methotrexate appears, in general, to be responsive to corticosteroids. Pathological findings in the lung parallel those seen with lung injury due to other cytotoxic drugs, with interstitial and alveolar inflammation and fibrosis.[3] In addition, eosinophilic

infiltration of the interstitium, as well as granulomatous inflammation, may be observed. These latter findings are again suggestive of a potential hypersensitivity-type mechanism of inflammation.

Methotrexate-induced lung injury may also appear as an acute syndrome with pleuritis and pleural effusion. Respiratory distress progressing to noncardiogenic pulmonary edema has been described after intrathecal administration of the drug and may be neurogenic in origin.

The prognosis with methotrexate-associated lung toxicity is generally thought to be favorable. As noted, symptoms and radiographic abnormalities may resolve even with continuation of treatment. The use of corticosteroids is generally recommended, though prospective trials of this intervention are not available.

CYTOSINE ARABINOSIDE

Cytosine arabinoside (Ara-C) is a pyrimidine nucleoside analog that rapidly inhibits DNA synthesis. It is important in the treatment of acute leukemias and non-Hodgkin lymphoma. Pulmonary toxicity parallels intensity of treatment; high-dose regimens are associated with a 5% to 44% incidence of acute or subacute respiratory insufficiency.[1,78,79] Symptoms include fever, cough, dyspnea, and tachypnea; their onset may coincide with chemotherapeutic treatment or may be delayed for up to several weeks after treatment is initiated. Hypoxemia may be present. The chest radiograph generally shows a diffuse interstitial or alveolar pattern.

The pathogenesis of pulmonary toxicity due to Ara-C is unknown, but it appears to result in a syndrome of noncardiogenic pulmonary edema. In an autopsy series of 181 patients who died of acute leukemia, Haupt et al.[80] described a group of 42 patients who had received Ara-C within 30 days of death and who had moderate to severe pulmonary edema. Lung pathology showed protein-rich infiltrates in both alveoli and interstitium. Twenty-eight of these 42 patients had no other identifiable cause of their pulmonary edema. In these cases, Ara-C was thought to be the most likely precipitant. Treatment for Ara-C lung toxicity is standard supportive care for noncardiogenic pulmonary edema. Administration of corticosteroids has been recommended by some authors but is of unclear benefit.

Ara-C has also been associated with cryptogenic organizing pneumonia when administered with anthracyclines or interferon-α.[81,82] The pulmonary manifestations typically occur within a few weeks to 2 months after drug exposure and are characterized by fever, shortness of breath, and radiographic infiltrates that may be either lobar or nodular. All patients reported to date have achieved resolution of their pulmonary disease, either spontaneously or with the use of corticosteroids. Overall mortality associated with Ara-C–induced pulmonary toxicity ranges from 6% to 13%.[1,3,78,80–82]

FLUDARABINE

Fludarabine monophosphate is a purine nucleotide analog used in the treatment of CLL, low-grade non-Hodgkin lymphoma, and a variety of other lymphoproliferative disorders. A major clinical issue related to pulmonary complications with fludarabine therapy is the profound immunosuppression that may persist for months after treatment. The persistent nature of this immunosuppression is unusual when compared to other chemotherapeutic agents. The risk of opportunistic infections, including *P. jiroveci* pneumonia is increased by the use of corticosteroids in this setting. Therefore, symptomatic pulmonary disease in patients treated with fludarabine within this time frame is most likely to be related to infection.

Pulmonary toxicity from fludarabine, including interstitial pneumonitis and acute eosinophilic pneumonitis, is uncommon but has been described.[83–85] Helman et al.[83] reported the largest series to date, which included nine patients with fludarabine-related pulmonary toxicity out of a total of 105 patients (8.6%) treated with fludarabine over an 11-year period at a single institution. Toxicity did not correlate with age, prior treatment regimens, or history of prior lung disease, but occurred more frequently in patients with CLL compared to those with other lymphoproliferative disorders. The onset of symptoms ranged from 3 to 6 days after therapy, with radiographs notable for new interstitial or mixed interstitial and alveolar infiltrates. BAL fluid revealed increased cellularity without a consistently predominant cell type. Multifocal nodular pulmonary infiltrates have also been described.[85]

Biopsy specimens most commonly reveal diffuse, chronic interstitial inflammation and fibrosis, although in some cases granulomas have been observed, suggesting the possibility of a hypersensitivity reaction. In the report by Helman et al., patients with fludarabine-associated pulmonary toxicity generally demonstrated subjective and objective improvement with corticosteroid therapy. Most patients responded within days, although more delayed responses were possible. Recrudescence of noninfectious pulmonary infiltrates has been described with fludarabine retreatment; thus, fludarabine should be avoided in future regimens in patients who have developed drug-related pulmonary toxicity.

GEMCITABINE

Gemcitabine is a pyrimidine analog used in the treatment of cancers of the lung, pancreas, ovary, and uroepithelium. It is structurally similar to cytosine arabinoside. Gemcitabine is generally well tolerated when used as a single agent, which may make it appealing for use in older patients. Myelosuppression is its major toxicity. The most common respiratory complaint is dyspnea, which occurs in less than 1% of patients.[86] Dyspnea may occur within hours to days of treatment and is generally self-limited. More serious pulmonary side effects, including interstitial lung disease, pulmonary fibrosis, and acute respiratory distress syndrome, are reported much more frequently when gemcitabine is used in combination with other chemotherapeutic agents. Gemcitabine appears to have a reasonable safety profile when given with carboplatin, a treatment regimen often used for NSCLC.[5] However, severe pulmonary toxicity appears to be much more common when gemcitabine is given in combination with taxanes or bleomycin.[87–90] Acute respiratory distress has been reported with these regimens, with development of noncardiogenic pulmonary edema characterized radiographically by mixed interstitial and alveolar infiltrates. Though responses to diuretics and corticosteroids have been noted, severe pulmonary complications in this setting can be fatal. Histological evaluation most commonly reveals type II pneumocyte hyperplasia, interstitial inflammation, and hyaline membrane formation, consistent with acute lung injury. Some patients with ultimately fatal outcome have demonstrated early symptomatology, including dyspnea, hypoxemia, and radiographic infiltrates to a milder degree with prior doses of gemcitabine. Such findings should raise consideration for discontinuation of gemcitabine.

NITROSOUREAS

The nitrosoureas (Table 65-6) include carmustine or BCNU (1,3-bis-(2-chloroethyl)-1-nitrosourea), lomustine or CCNU (1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea), semustine or methyl-CCNU, and chlorozotocin. These cytotoxic drugs are active against a variety of neoplasms. BCNU and CCNU are highly lipophilic and can cross the blood–brain barrier, which makes them particularly useful in the treatment of central nervous system malignancies. BCNU is also used in high-dose conditioning regimens prior to bone marrow or stem cell transplantation for a variety of malignancies, including breast cancer, Hodgkin and non-Hodgkin lymphomas, multiple myeloma, and gliomas.

CARMUSTINE (BCNU)

Of the nitrosoureas, BCNU has been most extensively studied. Like bleomycin, this drug has been used in animal models of lung injury.

TABLE 65-6 Nitrosoureas

Drug	Pulmonary Syndrome	Treatment	Comments
Carmustine (BCNU)	Early-onset interstitial lung disease Late-onset pulmonary fibrosis	Discontinue drug; corticosteroids May appear years after treatment	Risk factors: total dose, female sex, underlying lung disease, cigarette smoking, combination treatment with other cytotoxic drugs
Lomustine Semustine Chlorozotocin	Interstitial lung disease	Discontinue drug	By extrapolation, toxicities and risk factors probably parallel BCNU

Intraperitoneal injection of BCNU in rats results in granulomatous inflammation and interstitial fibrosis, which progresses even after withdrawal of drug. Oxidant lung injury may play a role in the pathogenesis of toxicity as BCNU is known to inhibit glutathione reductase in pulmonary macrophages and reduces lung glutathione stores; however, the exact mechanisms by which pulmonary fibrosis occur are not well defined.

Like bleomycin, the toxicity of BCNU appears to be dose related. In a study of 94 patients with Hodgkin lymphoma who received chemotherapeutic regimens including BCNU, doses less than 475 mg/m^2 were associated with a 15% incidence of pulmonary toxicity; doses ranging between 475 and 525 mg/m^2 with a 32% incidence; and doses in excess of 525 mg/m^2 with a 47% incidence of pulmonary toxicity.[91] Treatment of intracranial gliomas may result in substantially higher cumulative BCNU doses. Very high doses (>1200–1500 mg/m^2) result in pulmonary toxicity in as many as 20% to 50% of patients.[91–93] Of note, BCNU may be used in single high doses pre–bone marrow or stem cell transplantation or may be given sequentially over longer periods of time. Whether the pattern of administration of a given total dosage has an impact on the potential for lung injury is unknown. Reported risk factors contributing to the development of pulmonary toxicity with BCNU include underlying lung disease, a history of smoking, previous or simultaneous treatment with other chemotherapy agents (including cyclophosphamide or bleomycin), chest radiotherapy, and female sex; of these, higher dose of drug and female sex are most consistently reported as related to development of pulmonary fibrosis.[92,94–98]

Pulmonary fibrosis related to BCNU falls into two patterns: An early-onset group that typically occurs within days to weeks of treatment or up to 3 years, and a late-onset group that may present years later. Early-onset pulmonary injury appears to be an underappreciated event. In a study of 152 patients treated for breast cancer with a regimen of BCNU (600 mg/m^2), cyclophosphamide, and cisplatin followed by stem cell transplantation, 59% developed a significant decrease in D_{LCO} at a median time after treatment of 45 days.[92] The vast majority of patients had subclinical disease and appeared to have improvement in their pulmonary status with initiation of corticosteroid therapy. Early-onset toxicity can also present as fulminant lung injury with progression in some cases to fatal pulmonary fibrosis.[97–99]

Late-onset pulmonary toxicity, typically presenting as pulmonary fibrosis, may occur years after BCNU treatment. In 1990, O'Driscoll et al.[95] first reported their observations on this phenomenon in survivors of childhood brain tumors. Of 31 original patients, 14 died of their tumors. In their last report in 2004 of a 25-year follow-up of the 17 survivors, 9 (53%) had died of complications related to pulmonary fibrosis.[100,101] Two patients died within the first 3 years after chemotherapy, four died between 6 and 13 years after chemotherapy, and three died between 13 and 25 years after chemotherapy. Furthermore, of the remaining eight patients still surviving, seven had radiographic and physiological evidence of pulmonary fibrosis. Thus, in this population of children treated with high-dose BCNU, late toxicity in the lung was extremely common and of severe clinical consequence.

The clinical presentation of BCNU-induced lung toxicity is variable. As noted, it may present as fulminant acute respiratory failure but more commonly presents insidiously with asymptomatic physiological abnormalities or radiographic evidence of pulmonary fibrosis. Symptoms of this latter subacute course include cough, fatigue, and progressive dyspnea. Chest radiograph is rarely normal in symptomatic patients, usually showing bilateral interstitial infiltrates with a basilar predominance. However, in O'Driscoll's series of patients with childhood brain tumors treated with high-dose BCNU and who developed late-onset pulmonary fibrosis, patients demonstrated an upper lobe predominance to the distribution of fibrotic changes.[95,100,101] Patients with an acute presentation may present with confluent alveolar infiltrates. Pneumothorax has been described in a number of cases and may be bilateral (Fig. 65-4). Pulmonary physiology generally shows a restrictive ventilatory defect, with diffusion abnormalities and eventually hypoxia. As with bleomycin-related lung injury, D_{LCO} may decrease without radiographic or clinical evidence of disease. While it has been suggested that a decrease in D_{LCO} may be the earliest sign of pulmonary toxicity, prospective evaluation of screening pulmonary function studies in the diagnosis of BCNU-induced lung toxicity has not been adequately studied. However, in light of the frequency and severity with which BCNU-associated pulmonary injury appears to occur, PFT may be helpful in identifying patients at risk and in whom administration of corticosteroids might be considered. Since BCNU toxicity is, unfortunately, common, and the likelihood of progression of BCNU-related lung injury to significant pulmonary fibrosis is seemingly high, it could be argued that surveillance with PFT should be considered, particularly if high doses of drug are to be given.

Pathological changes in the lung from BCNU parallel those seen with other cytotoxic agents. Type II pneumocyte hyperplasia and dysplasia, fibroblast proliferation, and deposition of proteinaceous material in alveoli have been described. However, inflammation tends not to be a prominent histological feature, and the cardinal feature of BCNU-induced lung toxicity appears to be interstitial fibrosis. In some cases, angiocentric necrotizing granulomatous inflammation or, more rarely, pulmonary venoocclusive disease may be seen.

The prognosis for patients with BCNU-induced lung injury is poor. For patients with early-onset lung toxicity, treatment with corticosteroids may be effective. One study of patients with breast cancer for whom BCNU was administered as part of treatment with high-dose chemotherapy followed by stem cell transplantation suggested that inhaled corticosteroids might be helpful in preventing pulmonary toxicity.[102] Late-onset pulmonary fibrosis related to BCNU does not appear to respond to corticosteroid therapy. The primary approach to BCNU toxicity should be to administer the lowest possible effective dose and monitor closely for signs of toxicity. Long-term treatment remains supportive. With the known long potential delay in the onset of signs of toxicity, long-term pulmonary follow-up is also warranted.

OTHER NITROSOUREAS

The other nitrosoureas used as chemotherapeutic agents, lomustine (CCNU), semustine (methyl CCNU), and chlorozotocin, have also been described to cause pulmonary toxicity. In general, these drugs have been used less widely than BCNU and in smaller cumulative doses. Their described lower incidence of pulmonary toxicity is likely due to these factors. As with BCNU, toxicity tends to present

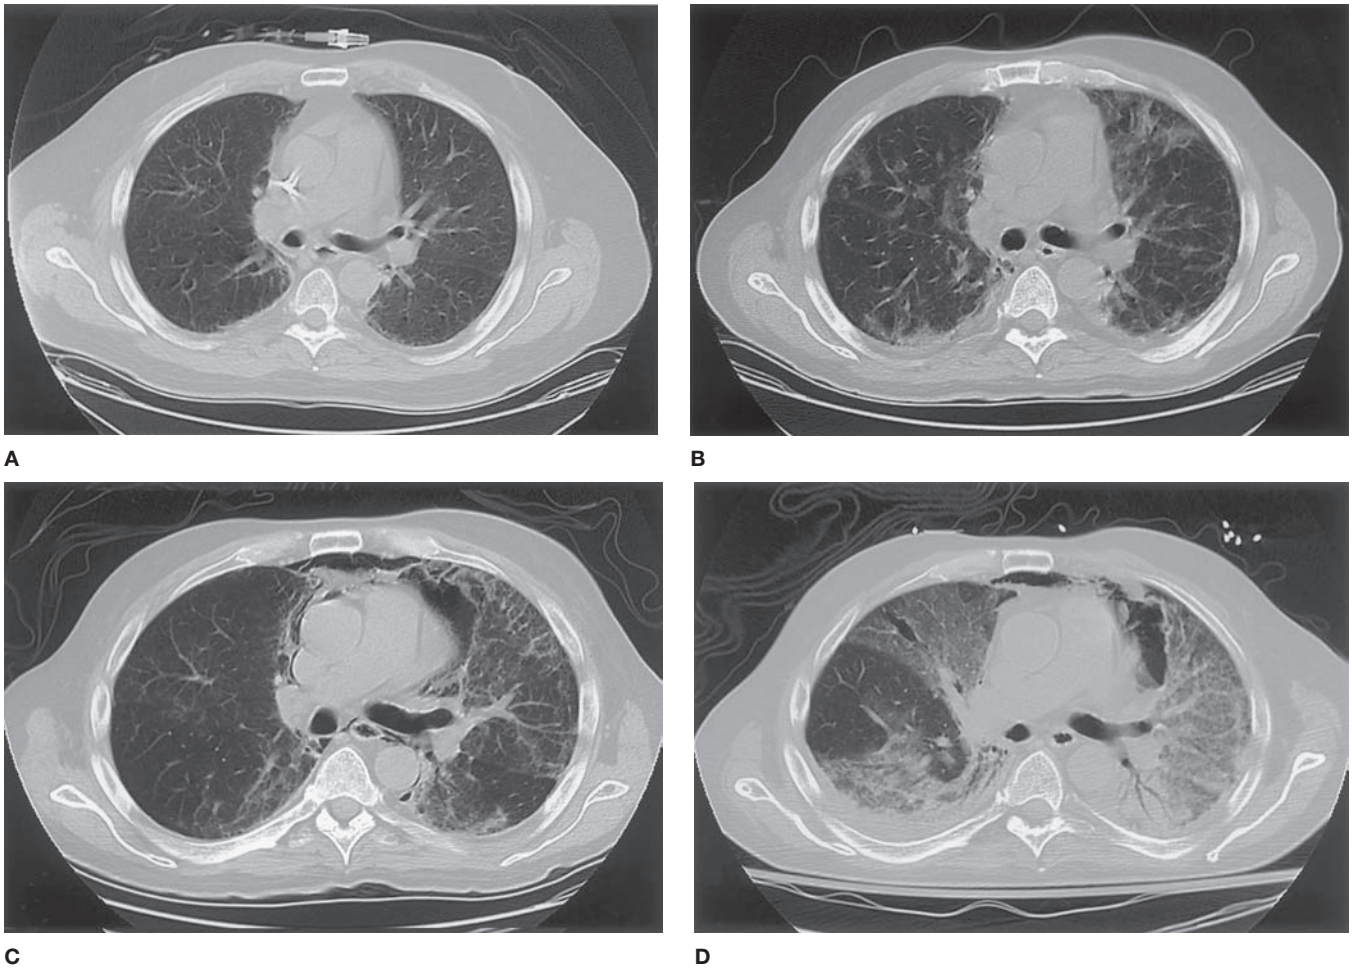

Figure 65-4 Serial chest computed tomography scans of a 54-year-old man with a history of Hodgkin lymphoma, treated with a BCNU-containing regimen. The dates of the examinations span 6 months from (**A**) to (**D**). Note the progression of diffuse interstitial patchy infiltrates, starting with the baseline normal study in (**A**). Pneumomediastinum and left pneumothorax are seen in (**C**) and (**D**). Bronchoscopy was performed between examinations (**B**) and (**C**), and demonstrated no evidence of infection. The patient had progressive dyspnea and respiratory insufficiency and eventually died of respiratory failure.

insidiously with interstitial pneumonitis and pulmonary fibrosis. However, given their close chemical relation, the potential for severe lung toxicity as seen with BCNU must be taken into consideration when using other drugs of this class.

MOLECULARLY TARGETED AGENTS

Examples of molecularly targeted agents (Table 65-7) include epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors (gefitinib and erlotinib), BCR-Abl tyrosine kinase inhibitors (imatinib and dasatinib), and anaplastic lymphoma kinase (ALK) inhibitors (crizotinib).

EGFR TYROSINE KINASE INHIBITORS: GEFITINIB AND ERLOTINIB

Small molecule inhibitors of the EGFR tyrosine kinase were the first successful molecularly targeted agents effective for patients with NSCLC and virtually revolutionized the approach to treatment of this group of patients (Fig. 65-5).

Gefitinib was the first EGFR tyrosine kinase inhibitor available for clinical use. In a prospective study involving over 3000 patients treated with gefitinib for NSCLC in Japan, 4% of patients developed interstitial lung disease by 12 weeks of treatment with gefitinib, compared with 2.1% in patients treated with cytotoxic chemotherapy.[103] Studies done around the world have noted that pulmonary toxicity appears to vary geographically, being seen more commonly in Asian, as opposed to Caucasian or African populations.[104–106] Toxicity typically occurs fairly early in the course of treatment, with median exposure from 24 to 42 days. Withdrawal of drug appears in most cases to be helpful, but inexorable progression to end-stage respiratory failure and death occurs in approximately 31% of patients with gefitinib-induced pulmonary toxicity. Histological evaluation in patients who have succumbed to this illness has revealed diffuse alveolar damage. Risk factors associated with a higher likelihood of developing toxicity include older age, cigarette smoking, pre-existing interstitial lung disease, and poor performance status.[103,106]

The mechanism of gefitinib-induced lung injury remains a subject of investigation. EGFR is known to be upregulated in response to lung injury, and may be important in promoting type II pneumocyte hyperplasia in response to injury. In murine models, gefitinib has been demonstrated to result in more severe lung fibrosis in animals exposed to bleomycin. The increased frequency of this toxicity in patients with pre-existing pulmonary fibrosis lends credence to the hypothesis that gefitinib impairs the regeneration of alveolar epithelial cells in response to injury.

Erlotinib is the EGFR tyrosine kinase inhibitor used most commonly in the United States, as gefitinib is not available for clinical

TABLE 65-7 Molecularly Targeted Agents

Drug	Pulmonary Syndrome	Treatment	Comments
Gefitinib	Interstitial lung disease; pulmonary fibrosis	Discontinue drug	Usually occurs within first 3 mo of treatment; risk factors: older age, cigarette smoking, pre-existing lung disease, Asian ethnicity
Erlotinib	Interstitial lung disease	Discontinue drug	Risk factors: pre-existing lung disease
Imatinib	Pleural effusions	Diuretics	
	Interstitial lung disease	Discontinue drug; corticosteroids	Risk factors: pre-existing interstitial lung disease
Dasatinib	Pleural effusions	Diuretics	
	Pulmonary arterial hypertension	Discontinue drug	
Bevacizumab	Pulmonary hemorrhage	Supportive care; discontinue drug	Risk factors: cavitary tumor, squamous cell histology
Cetuximab	Bronchospasm, stridor	Discontinue drug; supportive care; corticosteroids	May occur during infusion; risk factors: asthma, atopy, history of allergic reactions
Rituximab	Interstitial pneumonitis; cryptogenic organizing pneumonia	Discontinue drug; corticosteroids	
	Bronchospasm, stridor, angioedema	Discontinue drug; supportive care; corticosteroids	May occur during infusion
Trastuzumab	Bronchospasm, hemodynamic instability	Discontinue drug	May occur during infusion
	Interstitial lung disease	Discontinue drug; corticosteroids	

treatment purposes.[93,107,108] While pulmonary toxicity manifesting as interstitial lung disease is also described with erlotinib, the incidence of this complication appears to be lower compared to gefitinib. This may reflect geography, as erlotinib has predominantly been used outside of Asia, but the exact incidence of erlotinib-associated interstitial disease is not clearly defined. In a study comparing treatment of patients with advanced NSCLC with erlotinib combined with carboplatin and paclitaxel followed by maintenance erlotinib versus placebo in combination with the two cytotoxic agents, there were no differences in overall survival.[109] However, five severe cases of interstitial disease occurred in the erlotinib group, compared to one in the placebo group; three cases were fatal, were all in the erlotinib group and were thought to be related to drug toxicity.[110] The time course of lung injury appears to be similar to gefitinib, with appearance of pulmonary injury typically occurring within weeks of initiation of treatment. The presence of underlying interstitial lung disease appears to be a risk factor for the development of drug toxicity.[111]

BCR-Abl TYROSINE KINASE INHIBITORS: IMATINIB AND DASATINIB

Imatinib was the first clinically available and prototypic molecularly targeted therapy. Developed in the 1990s, it is a small molecule tyrosine kinase inhibitor that suppresses proliferation of cells expressing the BCR-Abl fusion protein. The fusion gene created by translocation of the Abl-1 ("Abelson") gene on chromosome 9 to a part of the "breakpoint cluster region" (BCR) gene on chromosome 22 is the "Philadelphia chromosome," a hallmark for CML. Imatinib is used for treatment of patients with CML as well as gastrointestinal stromal tumors.

The most common pulmonary complication related to administration of imatinib is the development of pleural effusions. This reflects the propensity of patients receiving imatinib to retain fluid in various anatomic compartments.[112] Less commonly, imatinib has been associated with the development of interstitial lung disease; underlying fibrotic lung disease may be a predisposing factor.[113,114] In small series, corticosteroids have been reported as potentially beneficial; rechallenge is generally not recommended, but has been reported without recurrent lung disease.[113]

Almost inevitably, tumor resistance to the small molecule tyrosine kinase inhibitors occurs, due to development of new point mutations in the tumor kinase, resulting in resistant clones of cells and relapse of disease. Second generation BCR-Abl tyrosine kinase inhibitors include dasatinib and nilotinib. Like imatinib, these drugs may cause fluid retention and pleural effusions and have generated reports of associated interstitial lung disease.[115,116] Perhaps more concerning, a number of case reports have been published identifying pulmonary hypertension in patients treated with dasatinib.[117,118] Withdrawal of drug does not necessarily result in reversal of the elevation of pulmonary pressures, so rechallenge should not be attempted. Pulmonary hypertension has not been reported as a complication of imatinib.

ALK INHIBITORS: CRIZOTINIB

Crizotinib inhibits the ALK and has been useful in patients with NSCLC demonstrating the EML4-ALK fusion oncogene. Interstitial lung disease has been reported with crizotinib treatment.[119] As this drug is used only in a relatively small population of lung cancer patients with the specific targetable mutation, clinical information relating to potential lung injury is limited.

MONOCLONAL ANTIBODIES

Monoclonal antibodies have been increasingly employed to treat a variety of malignancies. Pulmonary toxicity has been reported with their use.

BEVACIZUMAB

Bevacizumab is a monoclonal antibody directed against vascular endothelial growth factor (VEGF) with activity against breast, colon, renal, and NSCL cancers. Improved response rates for locally advanced and metastatic NSCLC are observed when bevacizumab is added to traditional chemotherapy.[120] In a series including 99 patients

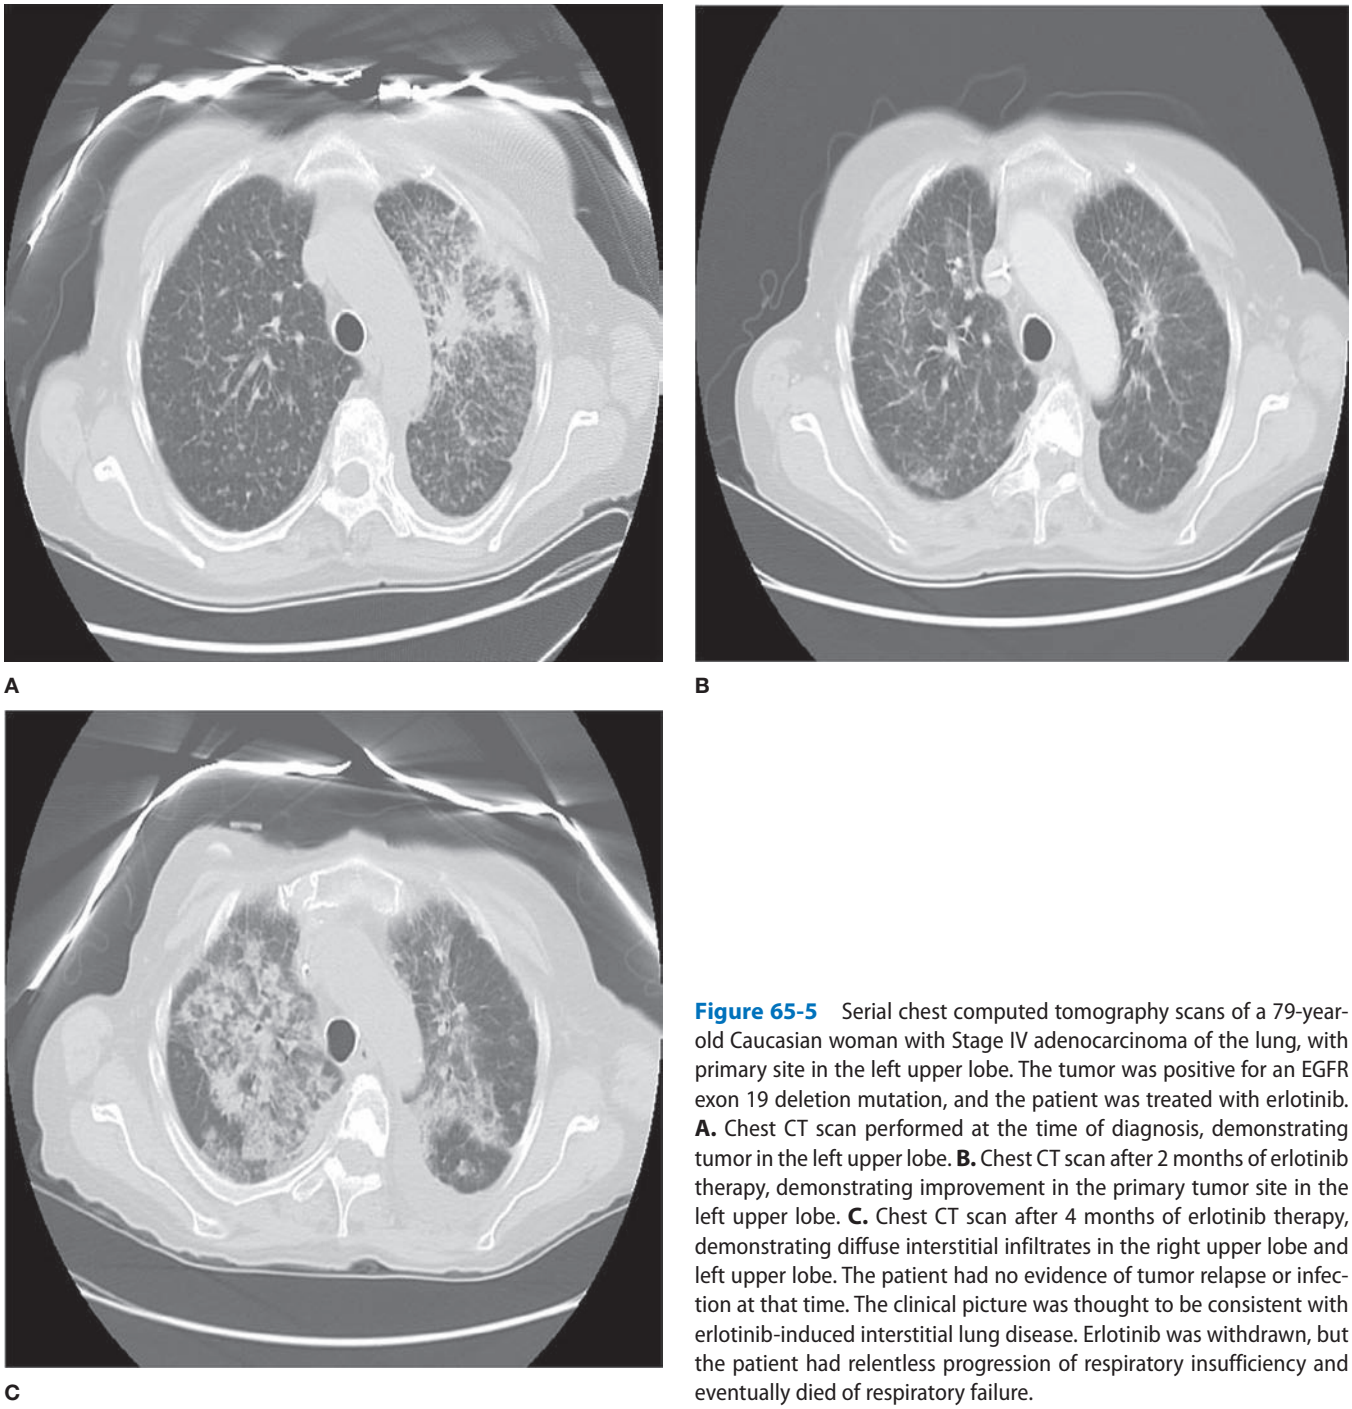

Figure 65-5 Serial chest computed tomography scans of a 79-year-old Caucasian woman with Stage IV adenocarcinoma of the lung, with primary site in the left upper lobe. The tumor was positive for an EGFR exon 19 deletion mutation, and the patient was treated with erlotinib. **A.** Chest CT scan performed at the time of diagnosis, demonstrating tumor in the left upper lobe. **B.** Chest CT scan after 2 months of erlotinib therapy, demonstrating improvement in the primary tumor site in the left upper lobe. **C.** Chest CT scan after 4 months of erlotinib therapy, demonstrating diffuse interstitial infiltrates in the right upper lobe and left upper lobe. The patient had no evidence of tumor relapse or infection at that time. The clinical picture was thought to be consistent with erlotinib-induced interstitial lung disease. Erlotinib was withdrawn, but the patient had relentless progression of respiratory insufficiency and eventually died of respiratory failure.

with newly diagnosed stage IIIB or IV or recurrent NSCLC, six patients developed serious bleeding complications including hemoptysis or hematemesis.[121] Four of the six patients died as a result of the hemorrhage. All six cases of hemorrhage appeared to be tumor related, with four of the six patients having squamous cell histology. Radiographically visible cavitation or necrosis was seen in five of the six cases of hemorrhage. As a result, current clinical investigations of regimens including bevacizumab generally exclude patients with cavitary pulmonary disease or squamous cell histology.

CETUXIMAB

Cetuximab is a chimeric monoclonal antibody directed against EGFR. Infusion of cetuximab may be associated with symptoms suggestive of anaphylaxis, including bronchospasm or stridor. In severe cases, respiratory compromise may be life-threatening. Risk factors for the development of these complications include a history of asthma, atopy, or allergic reactions.[122,123]

RITUXIMAB

Rituximab is a chimeric monoclonal antibody directed against the CD-20 antigen on B lymphocytes; it has demonstrated activity against non-Hodgkin lymphoma. It is increasingly used in inflammatory processes, including connective tissue diseases, autoimmune disorders, and solid organ transplantation. Like cetuximab, rituximab can be associated with infusion reactions, which, in severe form, may include bronchospasm and angioedema. Pulmonary parenchymal toxicity, while rare, is well described.[124–126] In one series of 107 patients with NHL receiving a regimen including

rituximab, 9 of 107 patients developed interstitial pneumonitis associated with fever, dyspnea, and cough.[126] Treatment with glucocorticoids resulted in improvement. Retreatment was attempted in four patients, two of whom developed recurrence of interstitial disease; therefore, rechallenge is usually not recommended.

The clinical syndrome of rituximab-induced pulmonary toxicity typically begins insidiously with cough and dyspnea, which may progress with subsequent reexposure to rituximab. Development of hypoxemia in association with parenchymal ground-glass opacification on CT scan has been noted. Histological examinations have revealed reactions typical of cryptogenic organizing pneumonia/bronchiolitis obliterans organizing pneumonia, as well as interstitial inflammation with T lymphocytes and extensive arterial thrombosis. While fatal outcomes have been reported, generally this entity has responded well to withdrawal of rituximab and administration of corticosteroids.

■ TRASTUZUMAB

Trastuzumab is a humanized monoclonal antibody directed against the HER2 protein expressed by some breast and gastroesophageal tumors. Infusion reactions with trastuzumab are common; in severe cases, symptoms may include bronchospasm and hemodynamic instability. Rarely, patients with breast cancer receiving trastuzumab may develop acute pulmonary toxicity, with interstitial pneumonitis, organizing pneumonia, or acute respiratory distress syndrome; in some cases, glucocorticoids have been used successfully.[127,128]

MISCELLANEOUS AGENTS

A number of other agents used in treating malignant disease have been reported to be associated with pulmonary toxicity (Table 65-8). Representative examples are discussed below.

■ ALL-TRANS RETINOIC ACID

All-*trans* retinoic acid (ATRA) is a vitamin A derivative that has proved beneficial in the treatment of acute promyelocytic leukemia (APL). Activity of ATRA occurs through the induction of maturation of malignant cells into mature neutrophils. A constellation of symptoms and signs called the "differentiation (retinoic acid) syndrome," characterized by fever, weight gain related to volume overload and edema, respiratory distress with interstitial or alveolar infiltrates, pleural or pericardial effusions, hemodynamic instability, and renal insufficiency may occur from 2 to 21 days after drug initiation.[129,130] Pulmonary alveolar hemorrhage has been described as a rare complication.[131] The syndrome is frequently, although not universally, seen coincident with the development of a pronounced leukocytosis.[132]

Differentiation syndrome is not described with treatment on non-APL malignancies with ATRA. Radiographic features of the syndrome include pleural effusions, cardiomegaly, increased pulmonary blood volume, and widened vascular pedicle. Less frequently seen are prominent septal lines, nodules, ground-glass opacities, or parenchymal consolidation with air bronchograms. In the setting of diffuse alveolar hemorrhage, HRCT reveals poorly defined centrilobular nodules and diffuse ground-glass opacification.

Histological examination most commonly reveals infiltration of the lung parenchyma with maturing myeloid cells, with or without pulmonary hemorrhage. Fibrinoid necrosis and pulmonary capillaritis have also been described. The syndrome is thought to result from endothelial damage resulting in edema, hemorrhage, fibrinous exudates, and infiltration of neutrophils. The mechanism of ATRA-mediated pulmonary toxicity is poorly understood, but is thought to reflect systemic release of inflammatory cytokines.[133] Increased expression of cell adhesion molecules on leukemic cells has been demonstrated after ATRA administration, as has increased endothelial expression of intracellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1). In addition, elevated levels of interleukin-1β (IL-1β), IL-6, and TNFα have been observed and may promote leukocyte activation, contributing to tissue injury.

The incidence of the differentiation syndrome varies between 5% and 27% in the published literature.[129,132,134] Mortality rates vary from 5% to 29%. Prompt initiation of corticosteroids may be associated with improved outcome. Continuation of ATRA does not appear to be absolutely contraindicated, as long as corticosteroids are administered in a timely fashion. In cases with severe manifestations, discontinuation of ATRA seems reasonable, although reintroduction of drug on resolution of the syndrome is only infrequently met with recurrence.

■ INTERLEUKIN-2

Interleukin-2 (IL-2) is a glycoprotein secreted by activated lymphocytes. IL-2 therapy alone, or in conjunction with lymphokine-activated

TABLE 65-8 Miscellaneous Agents

Drug	Pulmonary Syndrome	Treatment	Comments
All-*trans* retinoic acid	"Differentiation syndrome"	Discontinue drug; corticosteroids	Treatment regimens for acute promyelocytic leukemia using all-*trans* retinoic acid should include corticosteroids
Interleukin-2	Cardiogenic edema, pleural effusions	Diuretics; supportive care	Vascular leak syndrome; risk factors: cumulative dose; administration of LAK cells
Procarbazine	Hypersensitivity-type pneumonitis	Discontinue drug	
	Interstitial lung disease	Discontinue drug	
Paclitaxel	Dyspnea, bronchospasm	Decrease infusion rate; corticosteroids and/or histamine antagonists	Pretreatment with histamine antagonists and/or corticosteroids reduces incidence
	Interstitial pneumonitis	Discontinue drug	Tends to occur within days to weeks after administration of drug
Docetaxel	Pleural effusions; noncardiogenic pulmonary edema	Discontinue drug; diuretics; supportive care	Pretreatment with corticosteroids may decrease incidence
	Interstitial pneumonitis	Discontinue drug	
Vinca alkaloids	Noncardiogenic pulmonary edema, interstitial pneumonitis, bronchospasm	Discontinue drug; corticosteroids	Risk factor: concurrent treatment with mitomycin C

killer (LAK) cells, has proved beneficial in patients with metastatic renal cell carcinoma or melanoma. Pulmonary complications related to IL-2 largely relate to cardiovascular instability with a vascular leak syndrome. This can result in cardiogenic, as well as noncardiogenic, pulmonary edema and may be associated with hypotension, renal insufficiency, and pleural effusions.

Several mechanisms have been identified that may explain the increase in capillary permeability. IL-2–activated lymphocytes produce a variety of cytokines, including tumor necrosis factor and IL-1. These may alter endothelial permeability and are thought, for example, to contribute to the septic shock syndrome. IL-2 also may promote the adhesion of natural killer cells to the capillary endothelium, thus altering vascular integrity. Furthermore, IL-2 is also associated with toxicity in multiple other organs, including the heart. Therefore, IL-2–induced cardiac dysfunction may contribute to the development of pulmonary interstitial edema.

IL-2 appears to have a cumulative dose-dependent lung toxicity that seems to be compounded by LAK cell administration.[135,136] Lung toxicity does appear to be reversible. In most cases, clinical and radiographic abnormalities resolve within several days after cessation of therapy. IL-2 has also been administered via inhalation to treat pulmonary metastases in patients with renal cell carcinoma and melanoma. The inhalational route of IL-2 appears to abrogate the risk of pulmonary toxicity, while demonstrating efficacy against intrapulmonary metastatic disease.[137]

PROCARBAZINE

Procarbazine is a cytotoxic drug used primarily in the treatment of lymphoma; it is associated with hypersensitivity pneumonitis in a small number of patients. This syndrome typically is seen after the second or third cycle of chemotherapy, although earlier as well as later occurrences have been described. Cough, dyspnea, and fever are typical symptoms, with the development of radiographic interstitial and/or alveolar infiltrates. A variable response to corticosteroids is reported, and rechallenge with procarbazine is associated with recurrence of the syndrome in the majority of patients.

TAXANES

Paclitaxel is a member of the taxane family, which functions through inhibition of microtubule disassembly and disruption of the G2 and M phases of the cell cycle. Paclitaxel has activity against a variety of carcinomas, including breast, ovarian, and NSCL cancers. There is a high incidence (up to 30%) of acute hypersensitivity reactions associated with paclitaxel infusion, with symptoms including dyspnea, bronchospasm, urticaria, and hypotension. Decreasing the infusion rate and/or administration of corticosteroids and histamine antagonists greatly reduces the frequency of this reaction to 1% to 2%. Paclitaxel has also been associated with the development of interstitial pneumonitis occurring days to weeks after paclitaxel administration, and should be suspected in those who develop interstitial infiltrates following paclitaxel therapy.[138–140]

Docetaxel has a much lower incidence of acute hypersensitivity reactions than paclitaxel.[90,141–143] Docetaxel is, however, associated with a syndrome of fluid retention related to capillary leak.[142] This syndrome is characterized by the development of peripheral edema, pleural effusions, or ascites, and is mitigated by pretreatment with corticosteroids. Interstitial pneumonitis has been associated with docetaxel administration, and may progress to respiratory failure and death.[90,141,143] This syndrome may occur as early as 1 to 2 weeks after administration of the drug. Biopsies have been reported to reveal histological changes consistent with drug-induced hypersensitivity pneumonitis or diffuse alveolar damage. As opposed to many cases of drug-induced hypersensitivity, this reaction may have a protracted course prior to recovery.

VINCA ALKALOIDS

The vinca alkaloids given as sole agents are rarely associated with pulmonary toxicity. However, the combination of vinblastine, vindesine, or vinorelbine with mitomycin C has been reported to be associated with noncardiogenic pulmonary edema, interstitial pneumonitis, and bronchospasm, often in conjunction with more diffuse endothelial dysfunction (see earlier section on mitomycin C).[36] Vinorelbine as a sole agent has been associated with dyspnea in less than 5% of cases; it occurs within hours of dosing, and generally responds to bronchodilators and corticosteroids.[144] Respiratory distress with pulmonary edema and interstitial pneumonitis has also been rarely described.

CHAPTER 66

Drug-Induced Pulmonary Disease Due to Nonchemotherapeutic Agents

Hilary C. Cain

INTRODUCTION

Drugs have long been recognized as having the potential to cause pulmonary injury. The precise incidence of drug-induced lung disease is difficult to ascertain, because the signs and symptoms of disease are shared by many other pulmonary conditions and diseases. An analysis of a database of approximately 9 million patients from the United Kingdom describes an incidence density of 0.7 per 100,0000 patient years for interstitial disease related to drugs over a 12-year period (1997–2008).[1] These data reflect only a portion of the impact of drug-induced respiratory disease, because the alveoli, upper and lower airways, pleura, pulmonary vasculature, muscles of respiration, and the central nervous system governing respiratory control are all susceptible to injury from ingested, inhaled, and parenterally administered agents. As the categories and varieties of therapeutic drugs continue to increase, clinicians will encounter disease from new culprit drugs in addition to well-established drug reactions. Web-based data repositories, such as www.pneumotox.com, can serve as useful tools for the clinician, as they provide frequent updates based on the emerging literature on drug toxicities.

As the clinician-scientist explores the literature on drug-induced lung injury, it is critical to recognize that not all associations between drug use and respiratory dysfunction imply a definitive causal link between a specific drug and the injury pattern described. The literature needs to be cautiously interpreted before concluding that the reported associations are actually due to the implicated drug rather than a confluence of clinical conditions. This chapter addresses a broad array of drug classes implicated in pulmonary toxicity. Chemotherapeutic agents are discussed separately.

GENERAL PRINCIPLES OF DRUG-INDUCED LUNG DISEASE

The lung has an enormous surface area on which blood-borne substances (therapeutic medications, nutritional supplements, illicit drugs, or toxins) actively interact with lung tissue. Drug-related pulmonary toxicity, however, is a rare event. Reactions typically occur in a small minority of individuals exposed to a given agent. In most cases, lung injury appears to be an idiosyncratic event and cannot be predicted by dose, latency from drug initiation, duration of exposure, or pharmacologic characteristics of the drug. Often, there is no characteristic clinical presentation or pathognomonic histologic pattern of injury associated with a given drug, although certain histologic patterns of lung injury may occur more frequently than others. Thus, establishment of a diagnosis of lung toxicity is frequently a diagnosis of exclusion (see Table 66-1).

It may be inferred from the idiosyncratic nature of toxicity that there are host-specific risk factors that influence development of pulmonary toxicity. The factors influencing individual susceptibility may be: (1) genetically determined, (2) due to concurrent exposures to medications or environmental factors, (3) related to the individual's comorbid disease, or (4) a function of a combination of these factors.

Genetic predisposition to drug-induced injury is not fully characterized. While drug metabolism occurs primarily in the liver, through the action of the cytochrome P450 family of enzymes, the lung also is an active site of drug biotransformation, with cytochrome P450 enzyme levels estimated as 10% to 15% of those in the liver. In addition, the existence of lung-specific cytochrome P450 isoenzymes implies lung-specific metabolism of drugs.[2] Host-specific enzyme polymorphisms affecting drug metabolism may confer increased risk of toxicity on certain individuals.[3,4]

MECHANISMS OF PULMONARY INJURY

Mechanisms of lung injury include: (1) oxidant injury, (2) immunological and inflammatory cell–mediated injury (including immune complex–mediated injury), (3) interference with matrix formation, (4) abnormal protease/antiprotease balance, and (5) interference with lipid metabolism.

Mechanisms of lung toxicity are less well characterized than are other organ toxicities. The role of drug-induced oxidant injury is well established for nitrofurantoin, and it may be the mechanism of injury of other drugs, as well. Biotransformation of these drugs results in generation of reactive oxygen species, including hydrogen peroxide (H_2O_2), the hydroxyl radical (•HO), and superoxide anion (O_2^-•), which promote lipid peroxidation, glutathione depletion, and, consequently, cellular dysfunction or cell death.[2]

Immunologically mediated injury is undoubtedly important as well. The observation that drug metabolite–protein adducts can act as immunogens, resulting in hypersensitivity reactions or other immunologically mediated tissue injury likely applies to the lung, as well as to other organs.[5,6] Lymphocytic or neutrophilic alveolitis and inflammatory cell interstitial infiltrates are present in many cases of drug-induced lung injury, and the elaboration of chemokines and proteases by these cells may lead to cellular injury. Complement-mediated injury has been implicated for drugs causing noncardiogenic pulmonary edema (ARDS), particularly opiates and β-agonists.

Amphiphilic compounds, such as amiodarone, quinidine, and some β-blockers are passively sequestered in the lung within macrophages and type II alveolar cells. The role of disruption of phospholipid metabolism as a consequence of this sequestration has been well established for amiodarone-mediated lung injury, as discussed below.

TABLE 66-1 General Principles of Drug-Induced Lung Injury

Clinical presentation is nonspecific
Injury occurs with variable latency from drug initiation
Lung injury is often dose-independent
Pulmonary toxicity may be unrelated to the drug's pharmacologic properties
Acute, subacute, and chronic reactions may be caused by a drug
A variety of histopathologic patterns may be induced by a drug
Diagnosis of drug-induced injury is often made by exclusion
Resolution of injury may occur with drug discontinuation alone
Rechallenge with the suspected culprit drug is *not* recommended

IMPACT OF CONCURRENT EXPOSURES OR CONDITIONS

The harmful effect of concurrent oxygen administration in association with the chemotherapeutic agent, bleomycin, has been well established. It has been suggested that the apparent increased risk of amiodarone toxicity in patients who have had thoracic surgery (see below) may be a result of the impact of intraoperative high oxygen tensions.[7] However, high oxygen tension does not substantially increase the risk of toxicity for most nonchemotherapeutic agents. It is plausible that the additive effect of oxidant injury may be more relevant for some individuals than others. There are evolving data that other exogenous factors, such as cigarette smoke, may influence lung injury through induction of cytochrome P450 enzymes.

DIAGNOSTIC APPROACH TO THE PATIENT WITH SUSPECTED DRUG-INDUCED LUNG DISEASE

Confirmation of suspected drug-induced pulmonary toxicity is often a diagnostic challenge. No definitive criteria exist by which to establish the diagnosis of drug-induced disease, but the diagnosis may be inferred if: (1) there is a history of drug exposure; (2) clinical, radiologic, and histopathology are consistent with previously reported toxicity; (3) alternate diagnoses are excluded (e.g., infection, systemic or idiopathic diseases); and (4) findings regress with drug discontinuation and/or treatment. Recrudescence of the lung injury following rechallenge with the culprit drug is further confirmation of drug-induced disease, but rechallenge is *not* recommended due to the substantial risk of morbidity and/or mortality.

Recognition of a patient's risk of drug-induced injury is the first step in the diagnostic process. Drug-induced lung disease occurs with prescribed drugs, over-the-counter drugs, herbal or alternative medicine preparations (many of which contain a variety of substances that could be implicated as culprit agents), and illicit drugs. Patients may be reluctant to offer accurate information about their use of alternative medicines or supplements, and the clinician must skillfully elicit the history.

The challenge of diagnosis is further compounded by the fact that the latency from the onset of drug use to development of a toxic reaction can be highly variable, such that the temporal relationship between the pulmonary findings and the culprit drug is not readily apparent. Furthermore, many drugs (e.g., amiodarone and nitrofurantoin) can cause acute, subacute, or chronic pulmonary toxicity. Moreover, new drugs will continue to come on the market, some of which will inevitably cause lung disorders. Often the potential for drugs to cause toxic reactions will only be recognized once the drug has been in use for a sufficient length of time to allow a low frequency event, such as drug-induced toxicity, to be recognized.

In many cases, drug reactions are idiopathic, rather than dose-dependent reactions, and are unpredictable in that they are unrelated to the drug's intended pharmacologic properties. Exceptions to these observations include (1) amiodarone, for which there is an increased risk of toxicity with higher daily maintenance dosages, and for which the associated histopathology is related to amiodarone's pharmacologic properties; and (2) heroin, methadone, aspirin, propoxyphene, ethchlorvynol, and colchicine that cause pulmonary toxicity only in the setting of overdose.

A diagnosis of drug-induced lung toxicity is often difficult to establish, because patients with this condition typically come to medical attention with nonspecific symptoms, radiologic findings, and laboratory data. The clinical presentation of drug-induced lung disease may be similar to that of other disorders, including infection, hypersensitivity pneumonitis due to environmental antigens, eosinophilic lung disease, systemic rheumatologic or collagen vascular disease, and idiopathic interstitial pneumonias. High-resolution computed tomography (HRCT) has utility in characterizing the lung injury, but it does not confidently predict the histologic pattern of drug-induced injury.[8,9] Even in cases in which lung tissue is obtained by biopsy, the histopathologic features may not fully distinguish drug-induced disease from the disorders or conditions mentioned earlier.

An additional consideration is that the underlying disease for which a drug is given may produce pulmonary findings similar to drug-induced lung disease. For example, rheumatoid arthritis may cause pulmonary infiltrates with similar radiographic appearance and histology to toxic reactions induced by the methotrexate, gold, or penicillamine used to treat the rheumatoid arthritis.

Once the clinician has established that a patient has (1) a recognized, identifiable risk of drug-induced lung toxicity, and (2) history, physical examination, laboratory data, and radiographic findings compatible with known patterns of lung injury, then further cytopathologic or histologic evidence may be warranted to further establish the diagnosis. The technique of bronchoalveolar lavage (BAL) is used in the diagnostic evaluation of patients with interstitial lung diseases (ILDs). Analysis of BAL fluid is most useful when it is used in conjunction with a comprehensive clinical history and HRCT.[10] BAL cytologic analysis and culture can be particularly useful to exclude typical or atypical bacterial, fungal, viral, or parasitic infections in patients with suspected drug-induced lung injury. BAL may be helpful in diagnosing diffuse lung malignancies, such as lymphangitic spread of tumor or diffuse pulmonary lymphoma.[11] BAL can also provide evidence of alveolar hemorrhage, whether bland or vasculitic in origin. The grossly cloudy BAL fluid that settles with gravity is consistent with pulmonary alveolar proteinosis, which is a reported pattern of injury associated with disease-modifying, antirheumatoid arthritis drugs.[12]

The cellular differential of the BAL fluid may help narrow the diagnosis in suspected drug-induced pulmonary disease. The most common BAL cellular profile in drug-induced disease is lymphocytosis; a cell differential of ≥25% lymphocytes should earn drug-induced ILD a place on the differential diagnosis of any presentation of ILD. Recent guidelines for the use of BAL do not recommend routine measurement of lymphocyte subsets on all patients with ILD. However, if a lymphocyte alveolitis is suspected or confirmed, the subset measurement may be justified.[10] The T suppressor (CD8+) lymphocyte subset is commonly reported in drug-induced lung disease, as seen in hypersensitivity pneumonitis. BAL T helper (CD4+) predominance has been associated with immunomodulatory drug injury, including methotrexate, sirolimus, and temsirolimus.[13,14] Other cellular profiles occur in drug-induced disease: Eosinophils and neutrophils are variably present.[15–17] A percentage of eosinophils ≥25% is consistent with acute or chronic eosinophilic pneumonia, which may be seen as a result of drug injury.

Lung tissue obtained bronchoscopically or surgically may help characterize the injury pattern and may support the diagnosis of drug-induced injury. However, lung biopsy is not essential to establish the diagnosis. The histologic patterns seen in drug-induced injury, whether usual or nonspecific interstitial pneumonia (NSIP), organizing pneumonia with or without bronchiolitis obliterans, eosinophilic pneumonia, or granulomatous inflammation are histologically indistinguishable from other etiologies of these lung injury patterns.

Adjunctive testing for serum markers has been studied in the context of drug-induced lung injury. Serum markers, including surfactant proteins (SP-A, SP-D), KL-6, and ADAM8 have been associated with drug-induced injury but have not entered into the diagnostic armamentarium for most routine clinical evaluations.[18–21] Similarly, drug-specific lymphocyte stimulation testing and lymphocyte migration inhibition testing have been shown to be useful in the diagnosis of drug-induced lung disease by some investigators, but have not been found to be sufficiently and clinically helpful to enter mainstream clinical practice.[22–25]

CLINICAL AND HISTOPATHOLOGIC PATTERNS OF INJURY

The entire respiratory system – upper and lower airway, pleura, lung parenchyma, pulmonary vasculature, muscles of respiration,

and the central nervous system governing respiratory control – is susceptible to the adverse effects of drugs. Of these areas, injury to the parenchyma is the most important cause of morbidity and mortality.

Respiratory disease may occur as the sole consequence of drug toxicity, or it may be one manifestation of a systemic drug-induced syndrome. For example, systemic hypersensitivity syndromes, such as drug rash with eosinophilia and systemic symptoms (DRESS), may be induced by drugs, particularly the aromatic anticonvulsants.[26] Drug-induced systemic lupus erythematosus (SLE) may occur, with or without pulmonary involvement, from exposure to β-blockers, amiodarone, angiotensin-converting enzyme inhibitors (ACEIs), hydralazine, procainamide, isoniazid, methyldopa, minocycline, and tetracycline, among others. In addition, drugs (e.g., phenytoin, hydralazine, propylthiouracil, D-penicillamine, and cocaine, among others) can cause the clinical picture of a pulmonary–renal syndrome, with evidence for pulmonary and renal vasculitis with renal failure.

Parenchymal injury may manifest itself in the interstitial, alveolar, and/or vascular compartments. Of the processes affecting the lung parenchyma, interstitial involvement is the most common. The major histopathologic forms of ILD – cellular and fibrotic NSIP and usual interstitial pneumonia (UIP) – have been reported to occur as an adverse effect of drugs. Unfortunately for diagnostic clarity, among the many case reports citing the presence of ILD, many have no tissue confirmation of the precise lung histology, and older case reports were published before the current guidelines for classification of ILDs were established. However, it seems likely that much of the previously reported drug-induced ILD would now be classified as either cellular or fibrotic NSIP. Virtually all histopathologic types of ILD have been reported to occur in association with drugs, including organizing pneumonia (with and without obliterative bronchiolitis), usual interstitial pneumonitis, eosinophilic pneumonia, desquamative interstitial pneumonitis, and hypersensitivity pneumonitis. It is important to recognize that few drugs have been reported to cause a single histopathologic pattern of parenchymal injury, and in the cases of many drugs, several patterns of injury may occur (Table 66-2).

NONSPECIFIC AND USUAL INTERSTITIAL PNEUMONIAS

The radiographic and histologic definitions of NSIP and UIP have been defined in the American Thoracic Society/European Respiratory Society (ATS/ERS) international, multidisciplinary consensus statements of 2002 and 2013.[27,28] Whether drug-induced, idiopathic, or due to systemic disease, the radiographic and histologic features are largely indistinguishable, and it is the clinical scenario that is critical to the differential diagnosis. Older literature on drug-induced lung disease does not necessarily conform to recent consensus definitions of NSIP, UIP, or otherwise unclassified interstitial pneumonias, making older case series somewhat difficult to interpret. Culprit drugs leading to these interstitial pneumonias include antimicrobials, antirheumatics, tumor necrosis factor (TNF) antagonsists, β-adrenergic antagonists, antiarrhythmics, anti-inflammatory drugs, antipyretics, and immunosupressants (see Table 66-2).

BRONCHIOLITIS OBLITERANS AND ORGANIZING PNEUMONIA

Organizing pneumonia (OP) with or without histopathologic evidence of obliterative bronchiolitis is a frequently reported pulmonary reaction to medications. The histologic pattern seen in drug-induced parenchymal injury is indistinguishable from cryptogenic organizing pneumonia (COP) or other causes of bronchiolitis obliterans organizing pneumonia (BOOP). The histology consists of plugs of loose connective tissue, or granulation tissue that fills respiratory bronchioles, alveolar ducts, and alveolar spaces. This may be accompanied by mild interstitial inflammation with preserved architecture. Radiographic findings of BOOP are typically bilateral, patchy areas of consolidation that are often subpleural, with a tendency to lower lobe predominance or distribution along the bronchovascular bundle.

Many of the drugs that have been reported to cause BOOP are commonly used medications. Among the implicated antimicrobials are cephalosporins, minocycline, nitrofurantoin, amphotericin B, and interferons. One of the most utilized antiarrhythmic agents, amiodarone, is known to cause BOOP, as are the anticonvulsants, carbamazepine and phenytoin, and the anti-inflammatory agents, gold, penicillamine, and sulfasalazine. In patients treated for rheumatoid arthritis (RA) with gold or penicillamine, it is important to distinguish between drug-induced OP and infiltrates reflecting a pulmonary manifestation of the underlying RA itself. A variety of other agents reported to cause obliterative bronchiolitis are listed in Table 66-2.

The clinical presentation of drug-associated OP or BOOP is similar to that of the idiopathic disease, which is now referred to as COP. Symptoms include shortness of breath, nonproductive cough, and, in some cases, low-grade fever and/or pleuritic chest pain. The chest radiograph typically shows bilateral patchy infiltrates that may be migratory over serial radiographs, with interval normal chest radiographs despite continuous drug exposure. As with other interstitial lung disease, the utility of BAL is primarily to exclude an infectious etiology of the infiltrates. There is no specific BAL cellular profile characteristic of OP or BOOP. Lung biopsy reveals characteristic histopathology, identical to that of COP. Patients with drug-induced OP or BOOP may have spontaneous resolution of disease when the offending drug is discontinued, but oral corticosteroids may be used to accelerate disease resolution if the patient is symptomatic.

EOSINOPHILIC LUNG DISEASE

Drug-induced eosinophilic lung disease may mimic other eosinophilic pulmonary syndromes, including simple eosinophilic pneumonitis (Loeffler's syndrome), chronic eosinophilic pneumonia, acute eosinophilic pneumonia, pulmonary infiltrates with peripheral eosinophilia (PIE), and Churg–Strauss syndrome (see Chapter 71). The differential diagnosis of eosinophilic lung disease includes drug-induced injury and a search for the culprit drug is an integral part of the diagnostic evaluation. Although the clinical presentation of drug-induced eosinophilic pneumonia may be identical to idiopathic conditions, several distinctions can be made. In idiopathic eosinophilic pneumonia, symptoms affect the lung exclusively, while in drug-induced eosinophilic pneumonia, respiratory symptoms may be accompanied by systemic symptoms, such as rash and fever. Marked peripheral blood eosinophilia (>1000 cells/mL) suggests drug-induced pneumonitis, rather than acute idiopathic eosinophilic pneumonia, in which the eosinophilia tends to be more modestly elevated or normal.

The diagnosis of drug-induced eosinophilic pneumonia is supported by peripheral blood and/or pulmonary eosinophilia in a setting of exposure to a suspect drug. The diagnosis may be established when other eosinophilic lung diseases are excluded. When evaluating a patient with pulmonary eosinophilia, it is particularly important to exclude infectious causes of eosinophilia so as to avoid promoting progressive infection and/or death by use of corticosteroid treatment for presumptive drug-induced eosinophilic pneumonia. Tropical pulmonary eosinophilia caused by filarial infection should be suspected if the patient has a consistent travel history. Schistosoma and Paragonimus westermani are other potential pathogens to be excluded. Strongyloides, Ascaris, and Toxocara are indigenous to the United States and are known to cause pulmonary

TABLE 66-2 Histopathologic Diagnosis or Clinical Syndrome and Strength of Association with Drug

Histopathologic Diagnosis or Syndrome	Drug	Strength of Association
Interstitial Infiltrate/ Fibrosis (acute, subacute, or chronic)	Amiodarone	++++

ACE, angiotensin converting enzyme; ARB, angiotensin II receptor blocker; ARDS, acute respiratory distress syndrome; BOOP, bronchiolitis obliterans organizing pneumonia; LTRA, leukotriene receptor antagonist; mTOR, mammalian target of rapamycin; NSAIDs, nonsteroidal anti-inflammatory drugs; OTC, over the counter; TNF, tumor necrosis factor.
[a]Withdrawn from the market.

infiltrates and peripheral blood eosinophilia. Missing the diagnosis of a fungal infection can be lethal. Aspergillus is a ubiquitous fungus that can be difficult to diagnose as a pulmonary pathogen. BAL eosinophilia may be present without definitive evidence of invasive fungal infection, which may require a tissue biopsy for diagnosis. Coccidioides immitis is endemic in the southwestern United States, and infection can result in peripheral blood eosinophilia and pulmonary infiltrates. Serologic testing for antibodies to Coccidioides and sputum or BAL cultures are useful studies to exclude coccidioidomycosis.

Specific testing for drug reactions, such as drug-specific lymphocyte transformation tests, has been used to implicate a culprit drug. However, the clinical utility of such tests is uncertain, especially because a negative assay does not exclude the diagnosis.

Successful management of drug-induced eosinophilic lung disease is achieved by identification and discontinuation of the inciting drug. Typically, resolution of symptoms in drug-induced eosinophilic lung disease occurs with discontinuation of the culprit drug, frequently without the need for corticosteroids. In contrast, idiopathic chronic eosinophilic pneumonia may require months of treatment with corticosteroids, and relapse may occur as steroids are tapered. Relapse of the disease as steroids are tapered is rare in drug-induced eosinophilic disease; recrudescence of the lung infiltrates suggests an alternate diagnosis.

■ HYPERSENSITIVITY SYNDROMES

Systemic hypersensitivity syndromes with granulomatous inflammation of the lung may be caused by a number of drugs, most commonly the aromatic anticonvulsants, phenytoin, and carbamazepine, as well as nonsteroidal anti-inflammatory drugs (NSAIDs), minocycline, and sulfonamides, among others. DRESS has been reported primarily with the anticonvulsants and, in some cases, is accompanied by pulmonary histopathology consistent with BOOP, ILD, or granulomatous inflammation.

Not all cases of pulmonary hypersensitivity are accompanied by rash or other systemic symptoms. The clinical presentation of drug-related pulmonary hypersensitivity typically consists of acute onset of dyspnea, cough, and fever. The radiographic pattern is one of diffuse reticular or peripheral alveolar infiltrates, sometimes accompanied by pleural effusion. In most cases, drug discontinuation results in disease resolution. A minority of individuals (10%) have persistent radiographic abnormalities after several months, and

rarely, progressive disease may occur despite drug withdrawal. In these cases, a trial of corticosteroids is reasonable if the diagnosis has been well established.

ALVEOLAR INJURY: NONCARDIOGENIC PULMONARY EDEMA AND ACUTE RESPIRATORY DISTRESS SYNDROME

Alveolar disease occurs in the form of noncardiogenic pulmonary edema, diffuse alveolar damage (DAD) or acute respiratory distress syndrome (ARDS), and both bland and vasculitic diffuse alveolar hemorrhage (DAH). (Vasculitis due to drugs is discussed in the separate section below.)

Noncardiogenic pulmonary edema may be precipitated by numerous drugs, including aspirin, opiates, calcium channel blockers, some diuretics (e.g., hydrochlorothiazide and acetazolamide), intravenous and inhaled pulmonary vasodilators (e.g., epoprostenol and nitric oxide), methotrexate, TNF-alpha radiographic contrast media, tocolytics, and oxytocin, among others.[29] The onset of drug-induced pulmonary edema typically occurs in close temporal proximity to ingestion of the culprit drug and does not have a variable latency of onset.

A variety of mechanisms are implicated in the development of pulmonary edema. Increased pulmonary capillary permeability is the likely cause of aspirin-induced, interleukin-2–induced, and ethchlorvynol-induced edema. Volume expansion and sodium retention likely cause the pulmonary edema associated with the use of β2-sympathomimetic tocolytic agents. Opioid-induced edema is mediated by neurogenic reflex and deposition of immunoglobulin and complement in the lung.[30] Although the mechanisms of pulmonary edema may vary, frequently the resolution of symptoms is prompt within days of drug discontinuation.

Pulmonary edema is common in salicylate intoxication, and the risk is correlated with the degree of intoxication. A prevalence of alveolar edema as high as 20% to 30% has been reported for aspirin-intoxicated adults. An increased risk of edema is associated with chronic aspirin ingestion, older age, positive smoking history, neurologic disease, and proteinuria.[31,32]

In many cases reported as drug-induced ARDS, this condition is considered as a clinical syndrome of lung injury, rather than a specific histopathologic pattern of disease. If we examine the more specific histopathology of DAD, many cases of drug-induced injury have been reported to have these histologic characteristics and diffuse ground-glass attenuation on CT imaging of the lung. The more commonly implicated drugs associated with DAD are amiodarone, methotrexate, rituximab, and many chemotherapeutic agents.

DIFFUSE ALVEOLAR HEMORRHAGE, VASCULITIS, AND PULMONARY–RENAL SYNDROMES

Drug-induced DAH is infrequently reported in the literature on drug-induced pulmonary disease. DAH should be suspected in patients with unexplained ground-glass infiltrates or consolidation, accompanied by anemia. Hemoptysis is not required for the diagnosis, and may be absent in as many as one-third of patients with DAH.

The classification of DAH is based on histopathologic findings and includes (1) capillaritis, (2) bland hemorrhage due to drug-induced coagulopathies, and (3) DAD, the histopathologic finding in ARDS.

Pulmonary capillaritis has been described as an adverse effect of many drugs, but strong associations with its development are reported for relatively few drugs. One of the best-characterized toxicities presenting as DAH is that from propylthiouracil.[33] The DAH is a manifestation of a systemic vasculitic syndrome characterized by leukocytoclastic vasculitis, glomerulonephritis, and pulmonary capillaritis. Use of propylthiouracil induces antineutrophil cytoplasmic antibodies (ANCAs) in as many as 46% of patients, although only a minority of these develop pulmonary toxicity; pathogenesis may be mediated by antimyeloperoxidase antibodies.[34,35] Cases of pulmonary or systemic vasculitis also have been reported for diphenylhydantoin, hydralazine, nitrofurantoin, and leukotriene receptor antagonists. In the case of the last group of drugs noted, there has been considerable discussion as to whether the vasculitis is a toxic effect of the leukotriene antagonists or whether withdrawal of oral corticosteroids leads to identification of pre-existing Churg–Strauss granulomatous vasculitis. At least some reported cases of Churg–Strauss syndrome are unrelated to steroid withdrawal and appear to represent a rare complication of leukotriene antagonists.

Bland hemorrhage without capillaritis can occur (1) in the setting of therapeutic and supratherapeutic anticoagulation, (2) with the use of inhibitors of platelet aggregation (e.g., clopidigrel), and platelet glycoprotein IIa/IIIb inhibitor therapy, and (3) as a complication of thrombolysis. Drug combinations may increase the risk of pulmonary hemorrhage. For example, when therapeutic anticoagulation is combined with epoprostenol for management of pulmonary hypertension, the risk of hemorrhage is compounded.[36] Bland DAH related to D-penicillamine, amiodarone, and cocaine is discussed in the sections on individual drugs in later sections.

Drug-induced DAD may lead to bland DAH and has been reported for amiodarone, nitrofurantoin, minocycline, methotrexate, gold, cocaine, and chemotherapeutic agents.

COUGH AND ANGIOEDEMA

Cough induced by ACEIs is well characterized in several case series.[36–40] The overall reported incidence of cough ranges from 5% to 25%. Women are more at risk of developing cough than are men.[37,39,41] The latency from initiation of use to the onset of cough is variable, ranging from 1 week to 15 months. A prior diagnosis of asthma has not been found to be a significant risk factor for the development of ACEI-associated cough. While some series have reported increased nonspecific bronchial hyperresponsiveness among subjects with cough, others have not. Symptoms typically resolve promptly after a week to 1 month after discontinuation of the drug, but occasionally resolution may take as long as 3 months.[41] Angiotensin receptor blockers induce cough in approximately one-third of patients in whom ACEI-induced cough has been diagnosed.[42] Less frequent side effects of ACEIs include PIE, SLE, and subacute ILD, but these do not typically appear in conjunction with ACEI-induced cough.

Angioedema to ACEIs is a potentially life-threatening complication of these medications. Edema more commonly affects the face (57%) and less commonly affects the floor or roof of mouth and tongue (26%). In 17%, the oropharynx and glottis are involved.[43] Presenting symptoms may range from simple edema of the lips and/or face to respiratory failure requiring ventilatory support. The latency for onset is even wider than that for cough, ranging from 4 weeks to 4 years after onset of ACEI use. In one series, 70% presented within the first month of treatment.[44]

Numerous case series have reported a higher incidence of angioedema among African Americans, and a higher risk of intubation among those affected in this racial group.[43,44] Angioedema formation is likely due to elevation of circulating bradykinin as a result of ACEI-induced inhibition of its degradation, leading to vasodilatation and capillary leak. The effect of impaired bradykinin degradation may be compounded in individuals with genetically based deficiency of other bradykinin metabolizing enzymes. Most experts recommend treatment for angioedema with corticosteroids, H1- and H2-blockers, and, in some case, epinephrine.

BRONCHOSPASM AND ANAPHYLAXIS

Drug-induced bronchospasm is a relatively common side effect of many categories of medications (see Table 66-2).[45] Bronchospasm is mediated by a variety of mechanistic pathways including (1) IgE-mediated anaphylaxis, (2) non–IgE-mediated anaphylactoid reactions, (3) alteration in the cyclooxygenase (COX) and

lipoxygenase pathways, and (4) other pharmacologic mechanisms, such as β-blockade.[46,47]

Brochospasm triggered by drugs is more common in subjects with underlying asthma, atopy, or bronchial hyperreactivity. These reactions are more common in women than in men, and there appears to be familial predisposition to reactions to some drugs.[48] Symptoms range from mild chest tightness and dyspnea on exertion to respiratory failure in susceptible individuals.

In the United States, medications are the primary cause of anaphylaxis in adults and antimicrobials have been implicated as the cause of 0.7% to 10% of cases of severe bronchospasm. Penicillin remains the most important cause of anaphylaxis, accounting for up to 75% of cases annually.[49,50] Aspirin and NSAIDs are commonly implicated in bronchospasm, in one series accounting for as many as 24% of bronchoconstrictive reactions, ranging from mild to severe reactions.[49,51] (Aspirin and NSAIDs are discussed in the sections below.) Other agents more commonly implicated in bronchospasm and anaphylaxis include sulfonamides, omalizumab, halothane, heparins, protamine, insulin, and neuromuscular blocking agents.

■ BRONCHIOLITIS

Agents that have been reported to cause small airway inflammation (bronchiolitis) include medications used in the treatment of RA, such as D-penicillamine, gold, and tiopronin. The bronchiolitis in these cases may be fatal.[52–55] Interpretation of earlier literature on D-penicillamine and gold-induced bronchiolitis is complicated by the fact that RA itself can cause bronchiolitis.[56] Use of these agents has been largely supplanted by disease modifying antirheumatic drugs, immunosuppressants, and biologics, but the implicated agents may still be used in certain cases. Drug-induced bronchiolitis typically causes shortness of breath, with or without wheezing, and cough. Spirometry may not detect small airway disease until obstruction is severe, but high-resolution CT imaging protocols may show centrilobular nodules and/or tree-in-bud opacities, as well as mosaic attenuation of the lung parenchyma, reflective of airtrapping.[57]

■ PULMONARY HYPERTENSION

Pulmonary hypertension (see Chapter 72) is a relatively infrequent complication of drug therapy, but because of the subtlety of the onset of disease, paucity of symptoms until significant vascular compromise has occurred, and potential for eventual vascular collapse and death, it is critical to recognize drug-induced pulmonary hypertension early in its course. Among the drugs known to cause pulmonary hypertension are cocaine, other illicit stimulants, anorexigens, and toxic contaminants of food and nutritional supplements (e.g., tryptophan).[58]

The association of appetite suppressants with pulmonary hypertension dates to the late 1970s when reports of unexplained "primary" pulmonary hypertension were first published. The "epidemic" of pulmonary hypertension was linked to the use of aminorex fumarate, an amphetamine-derived appetite suppressant that came into use because its potential for addiction and abuse was lower than that of amphetamine. The use of aminorex was associated with a significant rise in the incidence of pulmonary hypertension, primarily among women in Germany, Austria, and Switzerland. Development of disease occurred as early as weeks to months from the onset of use of the drug, with a dose-dependent risk as high as 2 in 100. The mechanism of action on the pulmonary vasculature is through the release of catecholamines, including dopamine. The epidemic subsided as the drug's use declined.

The aminorex epidemic was followed by the introduction of fenfluramine, a phenylethylamine, like amphetamine and aminorex. Fenfluramine had been shown to be equally effective for weight reduction as an amphetamine, without the potential for abuse.

Satiety is normally accompanied by the release of serotonin, which acts on central serotonin 2_C receptors. Fenfluramine and racemic dexfenfluramine mimic normal satiety through competitive inhibition of the serotonin transporter, leading to release of serotonin from intracellular stores. These agents were used primarily in Europe throughout the 1980s. Case reports of users with pulmonary hypertension were published in Britain as early as 1981, but use of these agents persisted through the 1980s.

Two landmark reports supported a causal relationship between pulmonary hypertension and the use of fenfluramine and dexfenfluramine. The first was published in 1993, describing a cohort of young-to-middle–aged users of the anorexigens who developed pulmonary hypertension indistinguishable from idiopathic primary arterial pulmonary hypertension.[59] This was followed in 1996 by the findings of the International Primary Pulmonary Hypertension Study Group, which published a case-control series of 95 patients with pulmonary arterial hypertension.[60] An odds ratio (OR) of 23.1 for development of disease was found among those who had used an anorexigen for more than 3 months, with an estimated incidence of one to two cases per million users per year. Further support for a causal link is contained in the surveillance study of pulmonary hypertension among anorexigen users in the United States. Fenfluramine was withdrawn from the market in 1995 due to its association with increased risk for pulmonary hypertension, as well as its role in the development of valvular heart disease in users of the fenfluramine–phentermine combination anorexigen, known as "fen-phen."[61]

Epidemics of pulmonary hypertension also have been reported due to contaminants in a specific manufacturer's rapeseed oil in Spain, and from use of an over-the-counter L-tryptophan preparation that resulted in the eosinophilic myalgia syndrome, characterized by a systemic syndrome, which included acute lung injury and pulmonary hypertension.

The reason(s) that some individuals develop drug-related pulmonary hypertension while others do not has not been clearly defined. One putative risk may be polymorphisms of a cytochrome P450 enzyme, CYP 2D6, which is the primary enzyme for metabolism of fenfluramine.[62] Other risk factors have yet to be characterized.

TOXICITY ASSOCIATED WITH SELECTED DRUGS

The following drugs have been selected for discussion because (1) they are very commonly used, or (2) have important forms of toxicity associated with their use, or (3) have more recently entered into our pharmacologic armamentarium and, therefore, are likely associated a lower level of awareness of their potential toxicity to the respiratory system.

■ CARDIOVASCULAR DRUGS

Important examples of cardiovascular agents associated with pulmonary toxicity are highlighted in the sections that follow.

Amiodarone

Amiodarone is an iodinated, benzofuran-derivative antiarrhythmic used for management of life-threatening supraventricular and ventricular arrhythmias. Both amiodarone and its major metabolite, desethylamiodarone, are cationic, amphiphilic compounds with high lipid solubility, causing the drug to accumulate in a variety of tissues. The elimination half-life of amiodarone is 30 to 60 days. However, the concentration of amiodarone in lung tissue can be 100- to 500-fold higher than serum levels and the drug has been found in lung tissue as long as 1 year after discontinuation of therapy. These pharmacokinetic characteristics contribute to the drug's potential toxicity and impact treatment strategies.

One of amiodarone's biochemical effects is to impair normal phospholipid catabolism by phospholipases, thereby leading to cellular phospholipidosis. The accumulation of phospholipids in the cell may cause direct cellular injury and secondary tissue inflammation. Evidence supports cellular injury through production of

the unstable aryl radical as amiodarone is deiodinated, leading to reactive oxygen species formation and cell death.[63] The impairment of phospholipid metabolism results in the lamellar inclusions and lipid-laden foamy macrophages that characterize the histology seen on lung biopsy and BAL. These findings are characteristic of amiodarone exposure and are not indicative of toxicity unless accompanied by the lung injury patterns discussed below.

Adverse reactions to amiodarone have been reported in a variety of tissues, including the lung, liver (liver function abnormalities and increased tissue attenuation on radiographic imaging), thyroid (thyrotoxicosis), skin (discoloration), and cornea. The first reports of amiodarone pulmonary toxicity were published in 1980 and were followed by larger series of patients as amiodarone was tested in the United States in early-to-middle 1980s. Based on two trials published in 1987, the clinical picture of amiodarone pulmonary toxicity emerged as a syndrome of pulmonary infiltrates and respiratory symptoms, most often cough and dyspnea of subacute or chronic onset, accompanied by fever, malaise, and chest discomfort in 50% of those affected. In one series, 11 of 171 patients (6.4%) treated with 400 to 1200 mg of amiodarone developed pulmonary disease. In the other series, 15 of 154 subjects (9.7%) developed disease.[64–66] The time from initiation of therapy to development of symptoms was 61 to 465 days in one series and 30 to 720 days in the other. Subsequent reports have further refined these initial observations.[67]

Disease Prevalence and Risk Factors for Amiodarone Toxicity Based on the analysis of administrative databases in Quebec, approximately 4% of amiodarone users with atrial fibrillation carry a diagnosis of pulmonary fibrosis, alveolar or interstitial lung disease or ARDS.[68] Earlier studies reported the incidence of pulmonary toxicity to range from 0.1% to 10%. Predisposing risk factors for the identification of amiodarone pulmonary toxicity include older age, higher daily dosages, male gender, renal disease, and pre-existing lung disease.[68] The risk of pulmonary toxicity is dependent on daily dose: In one series, 0.1% to 0.5% of patients on 200 mg per day developed amiodarone pulmonary toxicity, while as many as 50% of those using the highest dosages (e.g., 1200 mg per day) were affected.[69] Most reports of amiodarone toxicity have been of subjects receiving doses greater than 400 mg daily. The lower doses of amiodarone that are more commonly used are considered to be safer than higher doses; however, toxicity has been reported at doses as low as 200 mg per day.[68,70]

Pre-existing lung disease may enhance the risk of toxicity, but not all studies have shown this to be the case. It is not clear whether there is actually higher incidence of toxicity in those with pre-existing lung disease, or if prior disease results in earlier perception of symptoms and attention to pulmonary causes of dyspnea. The AFFIRM (Atrial Fibrillation Follow-up of Rhythm Management) trial reported a higher risk of diagnosis of amiodarone lung toxicity if the patient had pre-existing pulmonary disease; however, there was no higher risk of either pulmonary death or all-cause mortality.[71] Patients with atrial fibrillation and amiodarone used in the setting of chronic obstructive pulmonary disease (COPD) had a hazard ratio of 2.53 (2.2–2.89) compared to those without COPD.[68] It is acceptable to use amiodarone in the setting of pre-existing lung disease if vigilance is maintained for the development of symptoms suggestive of amiodarone toxicity. Prospective studies have suggested that a decrement in diffusing capacity from baseline is a poor predictor of amiodarone toxicity. Therefore, there are no formal recommendations for screening pulmonary function tests during amiodarone use. However, it is reasonable to obtain a baseline pulmonary function test, including diffusing capacity measurement, and to follow the patient with symptom-driven testing, thereafter.

Exposure to high concentrations of supplemental oxygen may increase the risk of amiodarone pulmonary toxicity. Several authors have suggested that amiodarone pulmonary toxicity may be triggered by administration of high concentrations of supplement oxygen, or that oxygen may act in synergy with amiodarone to enhance cellular injury.[72–74] A high index of suspicion for amiodarone toxicity, therefore, should be maintained especially if high concentrations of oxygen were used perioperatively, and if high loading doses of amiodarone were initiated for the management of perioperative cardiac arrhythmias. Similarly, serious consideration to amiodarone lung toxicity is warranted if high concentrations of oxygen are used for management of respiratory failure. A less substantiated risk factor may include use of intravenous iodinated contrast media. Rapidly progressive, fatal ARDS attributed to amiodarone toxicity has been reported following pulmonary angiography.[75] A protective effect against amiodarone pulmonary toxicity by ACEIs is supported in several publications.[76–78]

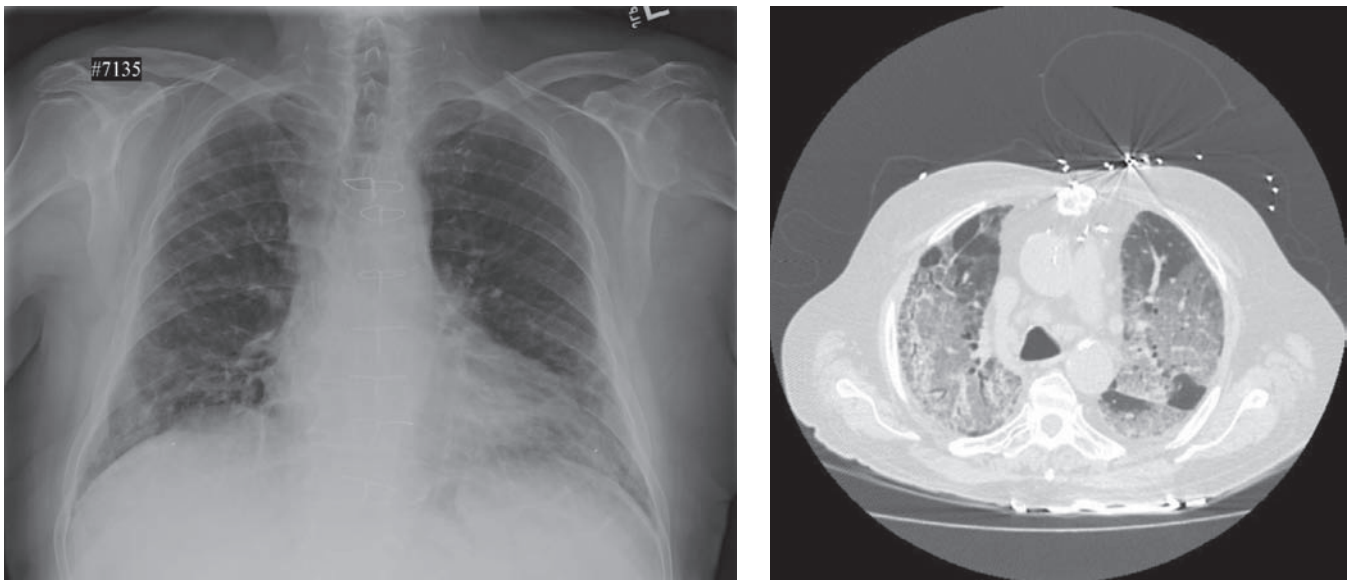
Clinical Presentation of Amiodarone Toxicity The typical clinical presentation of amiodarone pulmonary toxicity is nonproductive cough and dyspnea, sometimes accompanied by pleuritic chest pain, fever, malaise, and/or weight loss. Symptom onset is most often 6 to 24 months into treatment (100–150 g cumulative dose), but ranges from a few days to 10 years into therapy. Most subjects have an insidious onset of symptoms over several months, but fatal amiodarone-induced pulmonary toxicity occurring 2 weeks into therapy has been reported.[79]

The earliest abnormality identifiable on pulmonary function testing of affected individuals is impairment in diffusing capacity for carbon monoxide (D_{LCO}) There may be an accelerated decline in the D_{LCO} as the disease progresses, accompanied by mild restrictive physiology. Since a low D_{LCO} is not specific for amiodarone toxicity, a decline should not necessarily prompt discontinuation of the drug, but should trigger evaluation for possible cause(s) of the impairment.

Radiographic and Histologic Findings of Amiodarone Toxicity The radiographic and histologic findings associated with amiodarone pulmonary toxicity are not stereotypic (Fig. 66-1). While the most common pattern observed is subacute ILD, there are also many reports of organizing pneumonia and pulmonary fibrosis, and fewer reports of nodules (which can be fluorodeoxyglucose [FDG]-avid on PET imaging), ARDS, and SLE. Reports of PIE and DAH are rare.[67,80]

Typical radiographic findings in patients with subacute or chronic onset of disease are diffuse or patchy, interstitial or mixed alveolar–interstitial infiltrates, which are either bilateral or unilateral. Mild cases of toxicity may be characterized by a diffuse ground-glass pattern on HRCT, often in a peripheral, subpleural distribution.[81] Focal and patchy areas of higher attenuation may be superimposed on the ground-glass opacification. Alveolar opacities may correspond to areas of organizing pneumonia that are indistinguishable from idiopathic BOOP. Amiodarone toxicity should be considered in cases of migratory infiltrates that are consistent with BOOP but that are poorly responsive to steroids. Amiodarone-induced fibrosis occurs in 5% to 7% of patients diagnosed with amiodarone pneumonitis and may be present at disease presentation. A coarse interstitial pattern in the periphery of the lung, accompanied by traction bronchiectasis, is characteristic. Honeycombing is rare.

Laboratory Analysis in Amiodarone Toxicity Laboratory analyses have little utility in the differential diagnosis of amiodarone-associated lung toxicity. Common laboratory abnormalities include mild leukocytosis and elevation in serum lactate dehydrogenase (LDH). Earlier trials of amiodarone identified elevated sedimentation rates (ESRs) (i.e., a range of 39–150 mm/h) in 9 of 11 patients with pulmonary toxicity,[64] but nonspecificity of the ESR makes this test less useful in the clinical setting. Identification of a value for brain natriuretic peptide (BNP) that is normal, or at a patient's baseline, may be useful in distinguishing pulmonary causes of dyspnea from congestive heart



A B

Figure 66-1 **A.** Baseline chest radiograph before initiation of amiodarone. **B.** Amiodarone lung toxicity. ARDS superimposed on mild underlying fibrosis at 3 months after initiation of amiodarone in an 80-year-old man with progressive dyspnea. Dyspnea began insidiously approximately 1 month after amiodarone load.

failure. Laboratory findings that are investigational include elevated serum levels of KL-6, a mucin glycoprotein secreted by proliferating type II pneumocytes, and surfactant protein SP-D.[21,82] Elevations of the latter may be an early marker of amiodarone pulmonary toxicity, but the sensitivity and specificity of these tests is uncertain, and neither has a place in routine clinical evaluation of amiodarone toxicity.

Diagnostic Evaluation and Management of Amiodarone Toxicity The challenge to the practitioner considering the diagnosis of amiodarone pulmonary toxicity is that the differential diagnosis is extensive for dyspnea with pulmonary infiltrates in patients with known cardiac disease. Cardiogenic and noncardiogenic etiologies must be excluded. Consideration must be given to cardiac conditions, including ischemic and nonischemic cardiomyopathies, diastolic dysfunction, mitral valve disease, aortic stenosis, and atrial fibrillation. Noncardiogenic causes may include infections; the broad range of idiopathic interstitial pneumonias; malignant causes of infiltrates (e.g., lymphangitic spread of tumor or lymphoma); systemic diseases, such as sarcoidosis, amyloidosis, or autoimmune disease; exposures to inhaled agents (e.g., occupational inorganic dust exposures, or organic inhalations, with subsequent development of hypersensitivity pneumonitis); and exposures to drugs other than amiodarone.

The risk of invasive workup must be weighed against those of empiric therapy, which includes drug discontinuation and, possibly, corticosteroids. BAL may reveal a lymphocytosis, often with a predominance of CD8+ lymphocytes, reflective of a lymphocytic alveolitis. This finding, however, is not consistently reported, and some affected individuals may have elevated BAL neutrophils as well. Significant BAL eosinophilia is rare. Abundant alveolar macrophages with a "foamy" cytoplasm, indicative of undigested phospholipids, are found in all subjects chronically exposed to amiodarone and are not indicative of pulmonary toxicity per se. Hemosiderin laden macrophages are infrequently found, since alveolar hemorrhage is rare. As the BAL findings are neither sensitive nor specific for amiodarone pulmonary toxicity, the role of BAL in the diagnosis is controversial.

Lung biopsy findings, however, may support the diagnosis of amiodarone toxicity. Earlier reports of amiodarone pulmonary toxicity describe DAD of variable severity in all affected subjects. Those more severely affected had evidence of acute DAD, with abundant hyaline membranes and reactive type II pneumonocytes lining the alveoli, while others showed organizing DAD with interstitial and intra-alveolar proliferation of fibroblasts and prominent type II pneumocytes. All cases had abundant "foamy" macrophages in the alveolar spaces. The foamy appearance of the cytoplasm is due to the presence of lamellar bodies (~1 μm in diameter) containing lipid particles, reflecting the disrupted lipid metabolism caused by amiodarone. The foamy macrophages or histiocytes are not indicative of toxicity; in fact, similar vacuolated histiocytes and parenchymal cells may be found in the thyroid, liver, and skin of treated individuals without clinical evidence of cellular dysfunction.

The diagnosis of amiodarone pulmonary toxicity is supported by the presence of lamellar bodies in macrophages, pneumocytes, bronchiolar epithelium, and/or endothelial cells, but the diagnosis cannot be made unless there is also evidence of interstitial lymphocytic infiltrates or fibrosis with alveolar distortion. Histologic findings may also fit the description of fibrotic NSIP or bronchiolitis with organizing pneumonia, and combinations of histologic findings may occur. Despite the early reports, few patients with amiodarone pulmonary toxicity have DAD pathologically unless they fit the clinical picture of ARDS. Alveolar hemorrhage may be present, but it is not a common feature of amiodarone toxicity.[83]

In contrast to other types of drug-induced pulmonary toxicity, resolution of amiodarone-induced toxicity does not often occur with discontinuation of the drug alone. Amiodarone becomes sequestered in tissues and the clearance of drug is typically prolonged. Depending on the severity of respiratory symptoms, practitioners often may need to treat affected patients with corticosteroids. Specific dosages of prednisone have not been studied for efficacy, but 0.5 to 1 mg/kg is a reasonable starting point in most cases. Due to the pharmacokinetic characteristics of amiodarone, the required duration of therapy may be as long as several months, and recrudescent disease after tapering of corticosteroids is not uncommon.

β-Adrenergic Receptor Blockers

The most common adverse effect of β-adrenergic blockers on the respiratory system is precipitation of bronchospasm in asthmatics and patients with reactive airway disease. The high frequency of clinically significant bronchospasm in hypertensive

asthmatics treated with nonselective β-adrenergic blockers, such as propranolol, requires that these agents be avoided in asthmatics. β1-Receptor–selective agents and the mixed α- and β-receptor blockers, labetalol, are better tolerated but should be used with considerable caution in asthmatics. The use of β-adrenergic blockers is not contraindicated in patients with COPD. Many individuals with COPD tolerate β-adrenergic blockers without significant decrement in their lung function. Patients with COPD who have clinical or spirometric evidence of variable airflow obstruction responsive to bronchodilators should be observed carefully for bronchospasm upon initiation of these agents; the cardiac benefit of β-blockade in these subjects may outweigh any risk.

Pulmonary parenchymal injury associated with the use of β-adrenergic blockers is not common, but it warrants mention because of the ubiquitous use of these agents. Subacute interstitial infiltrates, PIE, and pulmonary edema have been reported in conjunction with the use of acebutolol, propranolol, labetalol, nadolol, and pindolol. Thus, the clinician should be vigilant for these reactions from using β-adrenergic blockers as a class. SLE has reported with the use of acebutolol, propranolol, labetalol, and pindolol.

Hydralazine

Hydralazine-induced pulmonary disease is not common, but it can be associated with systemic autoimmune disease that is potentially fatal even when recognized.[84] Half of the patients on daily doses of greater than 200 mg have a positive ANA, however only 10% of these patients develop clinical symptoms. The most important reported complication of long-term use of hydralazine is drug-inducedLE, which occurs more frequently if daily dosing is greater than 200 mg or the cumulative dose exceeds 100 g. In addition, there have been cases of pulmonary–renal syndrome associated with the use of hydralazine.[85] Pleuropulmonary manifestations occur in 30% of affected subjects, and isolated pulmonary parenchymal disease is rare. Subacute ILD/NSIP, organizing pneumonia, and DAH also have been documented.

Hydrochlorothiazide

The most commonly reported pulmonary side effect of the diuretic hydrochlorothiazide (HCTZ) is noncardiogenic pulmonary edema or ARDS.[86] Pulmonary edema was first reported in 1968 as a potentially life-threatening complication of HCTZ use. The onset of symptoms is typically acute and less often occurs later in the course of HCTZ use. Typical symptoms and signs include acute dyspnea and hypoxemia; fever, tachycardia, hypotension, and shock may accompany the dyspnea. Immunologically mediated capillary leak has been suggested as a possible mechanism of action. IgG deposition in the alveolar membrane and elevated serum IgM have been reported. Management is supportive, and symptom resolution typically occurs in a few days. Rechallenge with HCTZ can cause recrudescent pulmonary edema and is not recommended. Since HCTZ is a widely used diuretic, frequently used in patients with cardiovascular disease who are prone to pulmonary edema, the true incidence of drug-induced noncardiogenic pulmonary edema may be underreported.

Procainamide

Procainamide, used in the treatment of supraventricular and ventricular arrhythmias, is frequently cited as a cause of drug-induced lupus (DIL). Among patients using procainamide for over 2 months, as many as 50% to 90% develop serum antinuclear antibodies (ANAs), and of these, 10% to 30% may develop symptomatic DIL. Slow acetylators develop DIL at lower doses of procainamide and earlier in their course of treatment.[87] Symptoms associated with drug-induced disease are indistinguishable from those of idiopathic SLE, and may include fever, rash, arthralgias, Raynaud disease, myositis, vasculitis, and serositis. Among affected subjects, 40% to 80% exhibit pleuropulmonary manifestations characteristic of SLE, such as pleuritis, with pleural effusion and/or diffuse parenchymal infiltrates. Of these findings, pleural disease is more common, while parenchymal infiltrates are present in fewer than half of affected individuals.[88] The pleuritis of DIL may produce pleural fluid with characteristics indistinguishable from those of spontaneous SLE: high pleural fluid ANA (≥1:160), high pleural fluid to serum ratio of ANA (≥1), and LE cells. More severe myositis also may affect respiratory muscle function and result in ventilatory insufficiency, perhaps potentiated by competitive blockade of the acetylcholine receptor by procainamide. The absence of renal or central nervous system involvement is suggestive of DIL, but it is otherwise difficult to differentiate drug-induced disease from other SLEs on clinical grounds. The absence of anti–double-stranded DNA, normal complement levels, and identification of antibodies to histone complex H2A-H2B support the diagnosis of DIL.

Unlike idiopathic SLE, DIL may resolve over several weeks simply with discontinuation of the drug and without the use of corticosteroids or immunosuppressants. More severely affected patients may benefit from oral corticosteroids, which appear to accelerate symptom resolution. A positive ANA without signs or symptoms of local or systemic disease need not warrant discontinuation of procainamide. Relapse after symptom resolution does not occur unless the drug is reintroduced.

■ STATINS

Statins are widely used 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors. Injury has been reported for various statin compounds and appears to be a class effect. Clinicians are more familiar with the well-reported myositis and hepatotoxicity associated with statins than they are pulmonary side effects.[89] Based on Food and Drug Administration reports of adverse events and the medical literature, lung injury occurs in 0.01% to 0.04% of patients with side effects attributed to statin use.[90] Although the incidence of adverse pulmonary events among all statin users is low, the widespread use of this class of drugs makes lung injury a potentially important side effect.

As with other drugs, the latency, radiographic and histopathologic pleuropulmonary manifestations associated with statins are variable. The latency between initial use and onset of injury ranges from 1 week to 120 months (mean, 34 months; SD, ±35 months).[91] The most common presenting complaints are nonspecific: dyspnea, cough, and fever. The predominant radiographic findings are ground-glass and alveolar opacities that are diffuse in distribution, sometimes with patchy consolidation. Fewer subjects exhibit interstitial infiltrates or fibrosis, and pleural effusion is reported, but is rare.[91,92] Analysis of BAL fluid shows no characteristic predominant cellular profile. Foamy macrophages suggesting pulmonary phospholipidosis have been observed in some, but not all cases. When obtained, biopsies demonstrate histopathology consistent with NSIP or hypersensitivity pneumonitis.[90,92–94] The mechanism of lung injury from statins is not fully characterized, but a role of NLRP3 inflammasome activation has been proposed.[95]

Resolution of statin-induced lung disease has been achieved with drug discontinuation, with or without corticosteroid therapy.

■ ANTICONVULSANTS

Various types of pulmonary injury may result from exposure to phenytoin. Among the reported patterns of injury are pulmonary hypersensitivity reactions, which may be a component of systemic hypersensitivity (see the prior discussion of DRESS). Two fatal cases of apparent polyarteritis nodosum and necrotizing vasculitis have been reported. The histologic findings in subacute phenytoin lung toxicity are most consistent with NSIP, but lymphocytic interstitial pneumonitis and BOOP have been described, as well. In

some cases, parenchymal findings are accompanied by peripheral blood eosinophilia, suggesting PIE syndrome. The presence of cold hemagglutinins has been reported. Carbamazepine has also been reported to cause systemic and pulmonary hypersensitivity syndromes.

■ ANTIRHEUMATIC AND ANTI-INFLAMMATORY DRUGS

Pulmonary toxicity has been reported with aspirin non-steroidal anti-inflammatory drugs (NSAIDs), and a number of drugs used in the management of rheumatologic disorders.

Aspirin

The most common pulmonary reaction associated with aspirin use is bronchospasm, which may occur with therapeutic dosing in aspirin-sensitive individuals. Aspirin and NSAIDs induce bronchoconstriction by diverting arachidonic acid metabolites toward the lipoxygenase metabolic pathway, thereby leading to enhanced leukotriene-mediated airway inflammation and bronchoconstriction. Less commonly reported pulmonary complications of aspirin use include PIE syndrome, DAH, pulmonary hypersensitivity, vasculitis, and ARDS.

Acute salicylate poisoning produces symptoms of central nervous system toxicity (tinnitus, vertigo, nausea, vomiting, and hyperventilation) in mild to moderate overdose, and may result in coma, severe metabolic acidosis, and noncardiogenic pulmonary edema with critical overdoses. Pulmonary edema occurs in as many as 30% of patients with severe salicylate poisoning and may result in respiratory failure, often exacerbated by severe metabolic acidosis. Risk factors for salicylate toxicity include increased age and chronic aspirin ingestion. Management of severe toxicity includes supportive intensive care and sodium bicarbonate infusion to promote drug excretion.

Non-Steroidal Anti-Inflammatory Drugs

NSAIDs are widely used and generally well tolerated. However, NSAIDs may cross react with aspirin, producing a variety of allergic and pseudoallergic reactions affecting upper and lower airways.[96] NSAIDs cause bronchospasm in susceptible individuals with symptoms range from mild to severe. NSAIDs also cause anaphylactic reactions through the same mechanisms as that for aspirin.

The bleeding tendency induced by NSAIDs is well known, and reports exist of pulmonary hemorrhage associate with their use. DAH has been reported for ketorolac tromethamine in subjects without an underlying bleeding diathesis, but the histopathology leading to DAH has not been characterized.[97]

Methotrexate

Methotrexate is a dihydrofolate reductase inhibitor used as an anti-inflammatory and immunosuppressant, as well as a chemotherapeutic agent when used in higher doses. Despite the availability of newer antirheumatic drugs, methotrexate has retained its position as a first-line disease-modifying agent for the management of RA. Methotrexate affects cell replication through inhibition of dihydrofolate reductase, the enzyme that converts folic acid to its active coenzyme, tetrahydrofolate, allowing it to serve as one-carbon carriers in the synthesis and repair of DNA. The major nonpulmonary side effects of methotrexate correlate with the degree of folate deficiency. In contrast, pulmonary toxicity does not correlate with folate deficiency and may be seen at doses as low as 7.5 mg/wk, a conventional starting dose for treatment of RA. Conditions that have been identified as risk factors for toxicity include diabetes (OR, 35.6), hypoalbuminemia (OR, 19.5), rheumatoid pleuropulmonary disease (OR, 7.1), previous use of other disease-modifying agents (e.g., gold, sulfasalazine, or penicillamine), and older age (OR, 5.1).[98]

Methotrexate-induced pulmonary toxicity typically occurs within the first 2 years of treatment, but it can occur as early as 1 month into therapy. Pulmonary symptoms are most often subacute in onset, presenting over days to weeks, and include dyspnea, cough, fever, and less frequently, chest pain (<10%).[99] Symptoms may also develop acutely.[100] Radiographic changes are interstitial and bilateral in 50% of cases, but may also include a mixed alveolar–interstitial pattern that may appear as ground-glass opacities on high-resolution CT imaging.[99] Fibrotic changes are less common.

Diagnosis is challenging in cases of suspected methotrexate-induced pulmonary toxicity and RA, because similar clinical presentations may occur as a manifestation of RA itself. The most important diagnosis to exclude is infectious pneumonia, including that from opportunistic organisms. A diagnosis of methotrexate-induced lung disease is suggested by a predominance of lymphocytes, rather than neutrophils, on BAL.[14,22] The lymphocytic BAL fluid of methotrexate-induced hypersensitivity pneumonitis often has a CD8-predominant profile (low CD4:CD8 ratio), but not exclusively so. It appears that the type inflammatory cells may predict disease severity. In one study of 56 cases of methotrexate pulmonary toxicity, a lymphocyte-predominant BAL fluid was associated with late onset of symptoms (>6 months from drug initiation) and lower mortality than in those with neutrophil-predominant BAL.[101] Histopathology is varied and may demonstrate ill-formed granulomas suggestive of hypersensitivity pneumonitis, changes of chronic interstitial pneumonitis, BOOP, and/or DAD. PIE syndrome has also been reported.[99]

As with other pulmonary toxicities, prompt drug withdrawal is critical; resolution follows in the majority of patients. Corticosteroids may accelerate recovery in those with severe disease or symptoms refractory to drug withdrawal alone. Fatalities have been reported in subjects rechallenged with methotrexate, but rechallenge has been tolerated in others, arguing against hypersensitivity as the mechanism of injury in some subjects.

D-Penicillamine

D-Penicillamine is used as an anti-inflammatory agent in the management of rheumatoid arthritis. Although currently used less frequently than disease-modifying antirheumatic drugs (DMARDs), its pulmonary manifestations are important to recognize, as mortality from penicillamine pulmonary toxicity can be as high as 5%.

Penicillamine is a heavy metal chelating agent that has inhibitory effects on T-lymphocytes, impairs fibroblast proliferation, and decreases levels of rheumatoid factor and immune complexes. DAH and subacute interstitial infiltrates are the two most frequently reported histologic patterns of penicillamine-induced lung toxicity. Other patterns of pulmonary injury associated with its use include chronic alveolitis, PIE, and hypersensitivity pneumonitis.

Penicillamine is one of the few drugs that cause a pulmonary–renal syndrome, including a clinical presentation similar to Goodpasture syndrome.[102,103] The syndrome occurs infrequently among patients on penicillamine therapy for rheumatic disease, and also has been reported in patients given penicillamine as a chelating agent in Wilson disease—findings which support the hypothesis that the pulmonary findings are not simply a manifestation of the underlying collagen vascular disease.[104] Diagnosis is supported by high serum titers of ANA; antiglomerular basement membrane (anti-GBM) antibodies are typically absent from the serum. Pulmonary vasculitis is absent. Renal histopathology is that of crescentic glomerulonephritis, similar to that of Goodpasture syndrome; immunoglobulin deposition is absent. No specific risk factors have been identified for penicillamine-induced pulmonary–renal syndrome.

Symptoms at presentation include cough, dyspnea, hemoptysis, and hematuria. Symptom onset has been reported from 10 months to 20 years after drug initiation. No definitive dose–response relationship has been defined but there are reports of toxicity at doses as low as 300 mg

per day and as high as 3.5 g per day. Coalescing, bilateral alveolar infiltrates characterize the radiographic findings, resulting in severe hypoxemia. BAL reveals an increase in the concentration of red blood cells on serial lavage and the presence of hemosiderin-laden macrophages, both of which characterize DAH. The syndrome may progress to include respiratory and/or renal failure. Mortality from penicillamine-induced pulmonary–renal disease has been reported to be as high as 50%. Survivors in one series were all left with residual radiographic abnormalities. Many patients become hemodialysis dependent despite treatment. Therefore, prompt identification and treatment are warranted.

Drug withdrawal, accompanied by high-dose corticosteroids, is the cornerstone of therapy. Adjunctive treatment with cyclophosphamide or azathioprine is often offered, although studies definitively supporting their use do not exist. In the absence of anti-GBM antibodies, plasmapheresis is not warranted.

Penicillamine may also induce interstitial lung disease, including hypersensitivity pneumonitis and/or bronchiolitis obliterans. In some cases, the findings are accompanied by alveolitis. A sister drug, bucillamine, has also been reported to cause centrilobular, ground-glass opacities and thickening of interlobular septae.

Gold Salts

The immunomodulatory properties of gold have been recognized since the 1920s, when the first cases of RA treated with chrysotherapy were reported. The first reports of gold-induced pulmonary toxicity followed in 1948.

Gold remains a therapeutic option for the treatment of RA that is refractory to other agents. It also has a role in the management of juvenile RA, ankylosing spondylitis, and pemphigus. As with methotrexate and penicillamine, the toxic reaction of gold must be distinguished from pulmonary disease related directly to the underlying RA.

One of the largest reviews of 140 patients with gold-related pulmonary toxicity identified distinguishing features.[25] The pattern that emerged from this review is one of cough and dyspnea as the most common presenting symptoms, with half of the patients exhibiting fever, as well. More than one-third of patients have an erythematous skin rash. Peripheral blood eosinophilia is a common finding. The onset of symptoms is typically early in the course of treatment, often within the first 4 months. Gold-induced pulmonary toxicity affects women more often than men (4:1). The mean age of onset of disease is in the sixth decade of life. A restrictive ventilatory defect is characteristic. The diffusing capacity is reduced in over 90% of affected individuals. The radiographic injury patterns seen include ILD, hypersensitivity pneumonitis, and BOOP.[105,106]

Diagnostic evaluation may include BAL, which typically shows a lymphocytic-predominant fluid, including CD8+ lymphocyte predominance.[106,107] This finding, in conjunction with a positive in vitro gold lymphocyte proliferation assay, strongly supports the diagnosis of gold-induced pulmonary toxicity. The diagnostic features suggest that the gold-induced toxicity can be a hypersensitivity reaction.

Treatment of gold-induced lung toxicity necessitates discontinuation of the drug. Longitudinal data reveal that gold-induced impairments in diffusing capacity may take months to resolve. Rarely, disease progression may occur after discontinuation of the gold. Refractory or progressive symptoms may be treated with prednisone at 30 to 60 mg per day.

Sulfasalazine and Mesalazine

Sulfasalazine is used as a DMARD and also is commonly employed in the treatment of inflammatory bowel disease, as is mesalazine. Both agents have been associated with pulmonary toxicity, most commonly interstitial pneumonias, including NSIP.[108,109] Sulfasalazine has been reported to cause BOOP.[110,111] BOOP has been associated with mesalazine, as well.[112] Mesalazine has been associated with eosinophilic pneumonia when taken orally and when it is used as a suppository.[113]

Biologic Agents

Rituximab is a CD20-directed, B-cell–depleting monoclonal antibody used in the treatment of RA. granulomatosis with polyangiitis (formerly known as Wegener granulomatosis), and microscopic polyangiitis. Many case reports regarding its pulmonary toxicity have been reported in the literature, with clinical presentations ranging from dyspnea and mild hypoxemia to fatal respiratory failure.[114] Clinical disease occurs in three different time courses, most commonly as a subacute onset of dyspnea 2 weeks following rituximab infusion, often several cycles into therapy.[115–117] Radiographic imaging shows bilateral diffuse interstitial infiltrates or ground-glass opacities. Less common presentations include acute onset of ARDS within hours of first infusion of the drug and chronic, insidious onset of disease.[115] Histopathology may include obliterative bronchiolitis.[118]

TNF antagonists are used in the management of rheumatic diseases. The most important pulmonary side effects of these agents are pneumonias due to bacteria, mycobacteria, Pneumocystis jiroveci, and fungi, occurring in 1.4% of patients treated with etanercept and 2.4% of those treated with infliximab. Among noninfectious pulmonary disorders associated with the use of anti-TNF therapies, interstitial pneumonitis is the most common manifestation of drug-induced disease. Interstitial pneumonitis was reported in 0.5% of 5000 Japanese subjects treated with infliximab and in 0.6% of over 7000 subjects who received etanercept.[119,120]

The reliability of case reports for demonstrating a definite causal link between monoclonal antibody use and pulmonary toxicity is complicated by the fact that interstitial pneumonitis is part of the spectrum of disease in patients with rheumatologic disorders. In addition, biologics are often administered to those with more severe manifestations of disease in whom lung disease is often present. In a large case series of autoimmune disease induced by TNF antagonists, 24 cases of interstitial pneumonitis were noted among 233 subjects studied.[121] In a review summarizing case series and reports published between 1990 and 2010, the mean time of onset of respiratory symptoms for subjects receiving biologic was 26 weeks, with 50% of cases occurring within the first 2 months.[122] Sarcoid-like granulomatosis has been frequently reported with the use of etanercept.[122,123] Among cases of sarcoid-like disease associated with monoclonal antibody therapies, 50% were compatible with stage 2 sarcoidosis, and two-thirds of all cases resolved with discontinuation of biologic therapy.[122]

Etanercept and infliximab have also been associated with development of drug-induced lupus, presenting with pleural effusion and/or pericarditis, along with positive ANA and antihistone or anti–double-stranded DNA antibodies.[124,125] The lupus-like conditions subside with drug discontinuation.

Adalimumab, a new TNF-α antagonist used in management of RA , also has been reported to cause pulmonary toxicity. Reports indicate lung injury occurring months to years into therapy. Patients usually present with dyspnea, cough, and a radiographic pattern are consistent with interstitial pneumonitis. Acute onset of lung injury has reported within 1 hour of dosing of this agent.[126] Symptoms may begin subtly as mild cough following a treatment cycle and progress with each subsequent injection.[127] Imaging shows patchy ground-glass opacities, with or without consolidation and patchy fibrosis.[127,128] In one case, patchy fibrotic interstitial disease was seen initially, followed by resolution after drug withdrawal, and then recurrent injury characterized by areas of ground-glass opacification after rechallenge.[129] Patients usually require corticosteroids to achieve clinical resolution.

■ IMMUNOSUPPRESSANTS

Sirolimus and everolimus are immunosuppressive agents used in the management of patients with solid organ transplants. They function as inhibitors of mammalian target of rapamycin (mTOR)

and suppress organ rejection through inhibition of growth factor–induced smooth muscle cell proliferation and migration; they also inhibit T- and B-cell activation.

Sirolimus was introduced into clinical use in the late 1990s. Sirolimus-induced pneumonitis in solid organ transplant recipients is an important consideration in the differential diagnosis of dyspnea with interstitial infiltrates after exclusion of infection. Case reports of sirolimus-induced pulmonary toxicity began to appear in the literature in 2000, when the drug was first implicated as the cause of biopsy-proven BOOP in a renal transplant recipient. A dose–response relationship is suggested, because dose reduction appears to ameliorate the pneumonitis. However, toxicity may occur despite therapeutic serum sirolimus levels and can occur as early as 2 weeks into therapy. However, it occurs more often after at least 6 weeks of therapy.

A case series of 24 patients further characterized the drug reaction. Most patients in the series exhibited a radiographic pattern of patchy peripheral consolidations consistent with BOOP, while four patients had reticular and ground-glass opacities.[130]

The BAL of subjects with sirolimus lung toxicity is typically lymphocytic (19 of 24 subjects); ≥5% eosinophilia was present in four cases.[130] Lymphocyte subsets have not been consistently reported, but some authors have described CD4+ predominance in the BAL.

The histology is consistent with BOOP and/or granulomatous interstitial pneumonitis, characterized by noncaseating granulomas in the bronchial wall and surrounding granulomatous inflammation.[131,132]

Cases of DAH have also been reported associated with sirolimus, and in some cases have been fatal.[133,134]

Discontinuation of sirolimus is necessary for syndrome resolution. Complete recovery is typically achieved in all patients by 6 months.

Everolimus has been shown to cause mild, reversible pulmonary toxicity.[135] It has also been implicated in fatal respiratory failure presenting initially with cough and dyspnea and accompanied by patchy alveolar infiltrates. Despite drug withdrawal and treatment with corticosteroids, the patient described in the case report progressed to respiratory failure and DAH.[136]

ANTIMICROBIAL DRUGS

The most commonly reported clinical syndrome for all classes of antimicrobials is pulmonary infiltrates with PIE. Among the reports of antibiotic-associated PIE syndrome are many cases of minocycline- and erythromycin-induced PIE, and fewer cases associated with penicillins, tetracyclines, sulfonamides, and cephalosporins. Cases of PIE have also been reported with the use of antituberculous drugs, including isoniazid, rifampin, and ethambutol.

Nitrofurantoin

Nitrofurantoin is one of the most commonly implicated antimicrobial agents that causes pulmonary toxicity. Although its peak usage worldwide was probably in the 1980s, it remains a widely used antibiotic for management of chronic urinary tract infections. Pulmonary toxicity may have significant clinical impact if the affected patient has underlying cardiopulmonary disease. Since the drug is used primary in the elderly population, in whom cardiopulmonary disease is common, recognition of its potential contribution to a patient's respiratory decline is important.

The clinical spectrum of respiratory disease caused by nitrofurantoin is broad. The onset of symptoms is highly unpredictable and of variable latency. The severity of disease varies; and the histopathology is diverse. Ninety percent of the earliest reported cases of nitrofurantoin pulmonary toxicity were acute in onset, occurring within days to weeks of treatment initiation. These patients presented with fever (80%), cough, dyspnea, rash (20%), arthralgias, and peripheral eosinophilia. As reports of toxicity have continued to populate the literature, it has become clear that subacute and chronic presentations also are common (Fig. 66-2).

It is inevitable that many cases may be missed due to the long latency between the initial dose and the onset of clinical symptoms. The median time to diagnosis in one series was 4 months; however, some diagnoses were made as long as 5 years after drug initiation. Among those with chronic symptoms, the most common histopathologic pattern is that of chronic interstitial pneumonitis, with fewer reported cases of BOOP and granulomatous interstitial disease.[137] High-resolution CT findings in 18 patients with chronic nitrofurantoin lung injury showed bilateral ground-glass opacities in all subjects (diffuse in 30%, and with a middle to upper lung zone predominance in 40%). Irregular linear opacities were present in 30%, consolidation in 30%, and traction bronchiectasis in 10% (one subject).[138]

Many other histopathologic patterns and clinical syndromes have been reported, including pulmonary edema, ARDS, vasculitis, DAH, SLE, PIE, and nodules. Bronchospasm and anaphylaxis related to antimicrobials is discussed in the section on those conditions.

INTERFERON-α AND PEGYLATED INTERFERON-α_2b

The rising prevalence of chronic hepatitis C worldwide, and its treatment with interferon-α and pegylated interferon-α_2b, has brought with it reports of pulmonary toxicity, most commonly interstitial infiltrates and BOOP. Systemic side effects are common among patients using interferon, and typically include flu-like symptoms of fatigue, headache, anorexia and myalgias. Pulmonary symptoms occur infrequently. Ribavirin, a synthetic nucleoside analog is often used in conjunction with either interferon-α or pegylated interferon-α_2b to enhance the antiviral activity of the interferons. Ribavirin is associated with dyspnea and cough, but it has not been reported to cause pulmonary toxicity when used alone. The reported rate of significant pulmonary interstitial disease and/or BOOP is as high as 6% among patients receiving high-dose daily interferon for hepatitis C, and <1% among patients on conventional three-times-weekly dosing schedules of interferon-α and ribavirin.[139]

The occurrence of interstitial disease among users of interferon-α is not exclusive to those with hepatitis, and it has been reported in patients on interferon therapy for chronic myelogenous leukemia and myelofibrosis as well. Most cases of pulmonary toxicity occur within several weeks of initiation of therapy and resolve with discontinuation of the medications.

Several case reports or small series of cases characterize the association of de novo sarcoidosis or recrudescent sarcoidosis with interferon-α and interferon-α_2a used in chronic hepatitis C.[140] The incidence of sarcoidosis among patients receiving interferon is not well established, but has been reported to be as high as 5% among patients receiving treatment with interferon-α_2a for hepatitis C.[141]Although most of the reports of sarcoidosis have been in patients undergoing treatment for hepatitis C, it also can occur in the setting of treatment of hematological malignancy. Interferon-associated pulmonary sarcoidosis occurs along with manifestations of disease involvement of other sites, including cutaneous, parotid, liver, ocular, and cardiac diseases. Prompt withdrawal of the drug is advised, and corticosteroids may be necessary for disease resolution.

OPIATES AND ILLICIT DRUGS

Complications of illicit drug use are numerous and encompass toxic injury to the lung related to use of the drug itself, and the associated infectious sequelae of venous cannulation, including endocarditis, septic embolization, and HIV-associated opportunistic infection. The prevalence of tuberculosis among drug users puts these individuals at high risk of active tuberculosis as well. Opiates or other sedatives may cause altered mental status and impairment of the gag reflex, substantially increasing the risk of aspiration pneumonia. Pulmonary parenchymal disease may also be caused by talc or other inert substances used to "cut" the drugs. Recognition of these

conditions unrelated to direct toxicity of the drug broadens the differential diagnosis of respiratory symptoms in users of illicit drugs.[142]

Heroin

Overdoses of heroin and other narcotics have long been known to cause pulmonary edema. One of the earliest reports of drug-induced lung disease was by Osler in 1880, in which he described pulmonary edema in an opiate addict and ascribed the edema to the opiate use. For unknown reasons, the frequency with which heroin-induced pulmonary edema (HIPE) occurs appears to have decreased in recent decades. In one series of patients compiled between 1968 and 1970, 48% of 149 patients with heroin overdose had pulmonary edema on presentation.[143] The presence of pulmonary edema was associated with increased mortality (18.3% vs. 8.7% if pulmonary edema was absent). A more recent case series describes a much lower incidence of pulmonary edema: 2.1% cases of heroin overdose.[144] It is unclear whether the change in epidemiology of HIPE relates to a change in the additives to illicit heroin or other factors. In the latter series, one-third of the patients required intubation and mechanical ventilation, but the hypoxemia of HIPE resolved within 48 hours of presentation.

The literature does not conclusively indicate the mechanism of HIPE. Some studies have reported higher protein levels in pulmonary edema fluid of HIPE than in cardiogenic pulmonary edema, supporting increased capillary permeability as the mechanism.[145] There are reports of significant acute inflammation in the lung tissue of narcotic abusers who were examined postmortem.[146] Other reactions associated with heroin use include acute bronchospasm.

Pulmonary disease associated with illicit injection drug use may be unrelated to the drug itself. Talc used to cut heroin or inert substances used in pills that are crushed and injected produce foreign-body granulomatous reactions in the pulmonary vasculature and interstitium. A longitudinal study of six patients with pulmonary talcosis described characteristic radiographic findings, consisting of a diffuse, micronodular pulmonary infiltrate that evolved into coalescent conglomerates, often in the upper lobes, similar in appearance to those of progressive massive fibrosis. These alterations may be accompanied by emphysematous changes in the lower lobes, which may result in pneumothoraces. Other pulmonary complications of injection drug use include septic emboli, abscess formation, bronchiectasis, and bullae independent of apical fibrotic reactions.

Cocaine

Cocaine may be injected intravenously, inhaled nasally, or smoked. It is the last noted route that is most frequently associated with respiratory symptoms and pulmonary injury. Cocaine is typically smoked as "crack" cocaine, an alkaloid derivative of cocaine hydrochloride that is mixed with ether or alcohol. Respiratory symptoms typically develop acutely, within hours of use, and include cough, hemoptysis, chest pain, and shortness of breath. Bronchospasm, which may be severe enough to precipitate respiratory failure, has been reported with and without a prior history of asthma. The radiographic appearance may

be consistent with ARDS, and the histopathology that of DAD, with or without alveolar hemorrhage.[147] Capillaritis, accompanied by glomerulonephritis, has been reported, but is not typically present.

PRINCIPLES OF TREATMENT AND DISEASE RESOLUTION

Prompt recognition of drug-induced lung disease affords patients the greatest chance of clinical and radiographic recovery, before irreversible lung injury occurs. In most cases of drug-induced pulmonary injury, discontinuation of the culprit drug is sufficient for regression of clinical symptoms and most or all of the radiographic findings. The decision to treat with corticosteroids must be individualized, based on the severity of the clinical picture and the expected rapidity of symptom resolution. For example, amiodarone pulmonary toxicity frequently requires oral corticosteroid administration unless the symptoms are very mild, because of the long serum half-life of the drug. Recrudescence of lung injury is rare among other implicated drugs in the absence of reexposure to the culprit drug. Overall, corticosteroids are used with apparent success, but controlled studies to determine therapeutic efficacy are lacking, and the infrequent occurrence of most drug toxicities will not allow this treatment to be convincingly studied in clinical trials.

CHAPTER 67

The Lungs in Patients with Inborn Errors of Metabolism

Timothy Craig Allen

INTRODUCTION

Inborn errors of metabolism, also termed "inherited metabolic disorders," are a group of inherited systemic conditions involving various types of chemical imbalances that cause disease and affect essentially all organs to a greater or lesser degree.[1–9] Each of the diseases is characterized by a specific genetic defect that causes an abnormality of an enzyme necessary for the degradation of some chemical substance.[2] The disruption of degradation leads to disease due to the deficiency of a substance or to the pathologic accumulation of a substance.[2,5] The first inborn errors of metabolism were identified about a century ago. Sir Archibald Garrod coined the phrase in 1902.[10] Today, there are over 500 inborn errors of metabolism identified.[11]

The diseases that comprise the inborn errors of metabolism are individually rare; however, taken together, they affect about 1 in 1000 people.[2] The majority of the diseases making up the inborn errors of metabolism exhibit autosomal recessive inheritance; however, X-linked recessive inheritance occurs with some diseases, and, less commonly, autosomal dominant inheritance is seen.[5] The majority of these diseases are pediatric; however, with the identification of attenuated variants, and with improved survival, they are today's conditions that must be considered in patients of all ages.[2] Tissue biopsy may be necessary for specific diagnosis; however, given that these disorders typically present with unexpected findings, high clinical suspicion and careful radiologic evaluation are usually the key to faster and more accurate diagnoses. Particularly as newer and more effective therapies being designed require earlier diagnoses, radiology plays a central role in diagnosis, and clinical–radiologic correlations are increasingly important.[2] Although metabolic specialists with expertise in the various inborn errors of metabolism are present in large academic centers and tertiary care centers, pediatricians and primary care physicians are typically the first physicians to whom patients with these diseases present themselves.[5]

Some of the diseases that make up the inborn errors of metabolism can be placed into a few broad groups; these include disorders of amino acid metabolism, organic acidurias, urea cycle defects, disorders of ketogenesis and ketolysis, disorders of fatty acid oxidation, lysosomal storage disorders, and mitochondrial disease.[2] While the lung is not typically a primary site of clinical disease in patients with inborn errors of metabolism, the lungs are involved with many inborn errors of metabolism, and in some diseases, clinically significant lung disease may occur.[1,12] Of course, the lungs may be involved with infections as a secondary feature in many types of chronic diseases, including inborn errors of metabolism; however, this chapter focuses on several specific inborn errors of metabolism for which lung disease may be a clinically significant feature.

ACID SPHINGOMYELINASE DEFICIENCY (NIEMANN–PICK DISEASE TYPES A AND B)

Acid sphingomyelinase (ASM) deficiency, an autosomal recessive condition, has a phenotype that occurs in a continuum, with severe, neuropathic disease with early symptoms and resulting in death in infancy or early childhood designated as Niemann–Pick disease type A (NPA), and nonneuropathic disease with generally later onset and milder symptoms designated as Niemann–Pick disease type B (NPB).[13–17] Patients with NPA typically show hepatosplenomegaly by about 3 months of age. The hepatosplenomegaly may ultimately become massive, and children are often dead within 3 years. Psychomotor development in patients with NPA typically is limited to not more than the 12-month level, after which deterioration occurs. NPB patients generally show milder hepatosplenomegaly and may survive to adulthood; however, progressive and clinically significant pulmonary changes are frequent in these patients.[14,18,19] Diagnosis is made by showing less than 10% normal residual ASM activity in peripheral blood lymphocytes or cultured skin fibroblasts.

Patients with NPA often exhibit radiographic changes of interstitial lung disease due to sphingomyelin storage within pulmonary macrophages, and they may exhibit low arterial blood oxygen levels. Respiratory infections are common, and not infrequently culminate in respiratory failure and death.[13,20,21] Patients with NPB, who have generally milder disease, may develop pulmonary complications at any age.[21,22] Most patients with NPB exhibit radiographic changes of interstitial lung disease, even while their individual symptoms may vary dramatically; their radiographic changes often do not correlate with the severity of pulmonary function abnormalities.[14,18] Cystic lung disease has also been reported in association with NPB.[23] Whole lung lavage has been attempted for symptomatic treatment of patients with NPB.[24]

Radiographically, patients show nodular infiltrates and linear strands, with a predominantly basilar honeycomb pattern.[19,25] Histologically, the lungs demonstrate predominantly normal architecture, with airspaces filled with Niemann–Pick cells—enlarged histiocytes with finely vacuolated cytoplasm (Figs. 67-1 and 67-2).[26] If necessary, CD68 immunostain may be used to establish their presence. These collections of cells have been termed "sea blue histiocytosis," due to the vivid blue staining with May–Grunwald Giemsa stain. Pulmonary fibrosis may occur over time (Fig. 67-3).

NIEMANN–PICK DISEASE TYPE C

Niemann–Pick disease type C (NPC) is a rare, autosomal recessive inborn error of metabolism characterized by impaired intracellular lipid trafficking and accumulation of cholesterol and glycosphingolipids in the brain and other tissues.[27–34] It is diagnosed by

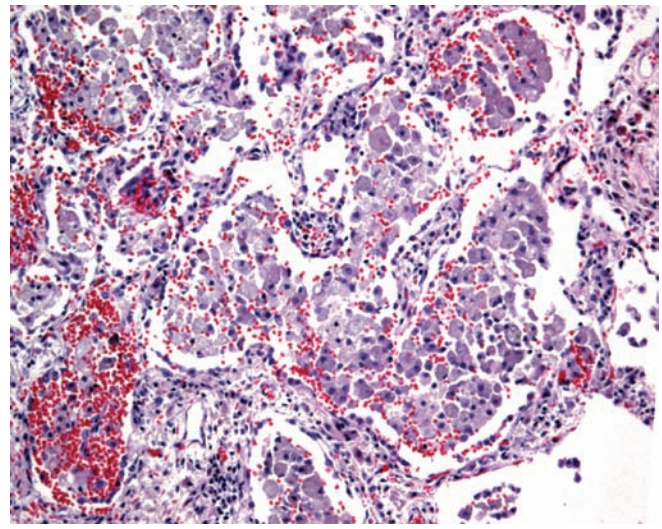

Figure 67-1 Low power image of lung in Niemann–Pick disease showing collections of foam cells within alveoli.

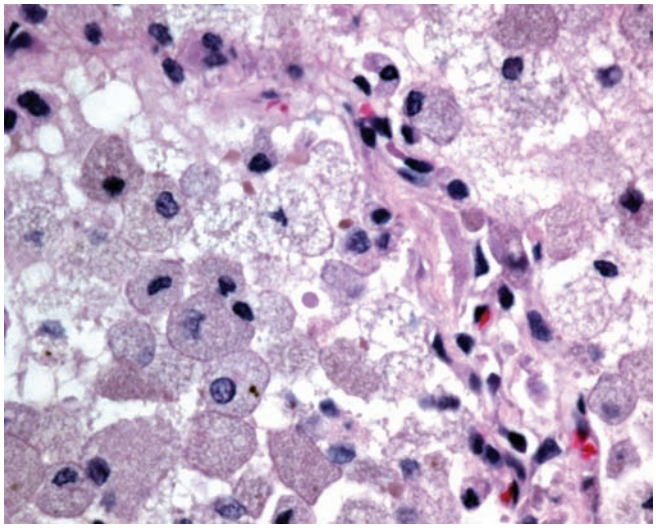

Figure 67-2 High power image of lung in Niemann–Pick disease showing enlarged histiocytes with finely vacuolated cytoplasm within the alveolar spaces.

biochemical tests that show impaired cholesterol esterification and positive filipin staining in cultured fibroblasts. Patients typically have saccadic eye movement abnormalities or vertical supranuclear gaze palsy; cerebellar signs, such as ataxia, dystonia/dysmetria, dysarthria, and dysphagia; gelastic cataplexy; and epileptic seizures[27,33] are given symptomatic treatment for cataplexy, dystonia, and seizures, as well as physical therapy to maintain as much independent mobility as possible. Approximately 95% of NPC cases are due to mutations of the NPC1 gene, with the remainder due to mutations of the NPC2 gene.[27]
