About 20% of patients have PGD, characterized by severe early abnormalities of lung function, with rapidly progressive pulmonary edema, persistent pulmonary hypertension, and markedly diminished pulmonary compliance that occurs rapidly after graft implantation (Table 107-7).[101] PGD is the most common cause of early mortality after lung transplantation and is associated with long-term sequelae including BOS and increased mortality.[101]

In some patients, acute graft dysfunction is due to unsuspected abnormalities in the donor lung, such as aspiration or contusion, volume overload, or venous outflow obstruction.

Management of PGD includes evaluation of the venous anastomoses with transesophageal echocardiography to rule out a potentially correctable technical complication, and maintenance of oxygenation using mechanical ventilation and PEEP. In severe cases associated with profound hypoxemia and/or hypercapnia, ECMO should be considered early in the perioperative period. In most patients, regardless of the supportive measure required, the process resolves over several days.

Pleural space complications are not uncommon after lung transplantation, although they are usually of minor significance. Pneumothorax may occur on either the side of a lung graft or on the side of a native lung. Pneumothoraces that arise from the lung graft are of greatest concern because of the possibility that airway dehiscence communicates with the pleural space. Fortunately, this is a rare occurrence. Nonetheless, flexible bronchoscopy is always indicated for diagnostic purposes in patients presenting with this problem. In most patients, placement of a chest tube with expansion of the lung limits the process acutely. More commonly, pneumothorax is the result of rupture of a bullous lesion in an emphysematous native lung after single-lung transplantation. Conservative management with chest tube drainage is indicated. Occasionally,

pneumothoraces are noted after bilateral-lung transplantation when a significant size discrepancy exists between the donor lungs and recipient thorax. In these patients, the space resolves spontaneously in a short time and specific interventions are not required.

Pleural effusions are common after lung transplantation, particularly when a significant size disparity exists between the donor lungs and the thorax. Management of these effusions is best done conservatively, with diuretic therapy and dietary salt restriction. Invasive measures, such as thoracentesis and tube drainage, are indicated only for enlarging effusions, particularly those that impact ventilatory function, and for large effusions that persist for more than 4 weeks after surgery.

The frequency of airway complications following lung transplantation has diminished in recent years. Bronchial ischemia is the most common cause of postoperative airway complications. The most common methods of lung transplantation do not provide direct revascularization of the bronchial arterial circulation, and the donor bronchus must rely entirely on collateral perfusion from the pulmonary circulation in the initial postimplantation period. Airway ischemia at this time may lead to mucosal ulceration followed by progressive mural necrosis. Localized bronchomalacia is frequently present adjacent to this region. A spectrum of abnormalities, ranging from anastomotic dehiscence to submucosal fibrosis, may occur as a result. Most commonly, partial anastomotic dehiscence occurs, followed by formation of granulation tissue and eventually some degree of anastomotic stenosis.

The reduced incidence of these complications has been attributed to methods of surgical anastomosis that limit the length of the donor bronchus, minimizing the amount of airway for which collateral perfusion is required. Most anastomotic techniques emphasize trimming the donor bronchus to within two rings of the upper-lobe orifice and the preservation of peribronchial tissues containing the collateral circulation. Telescoping the bronchi and covering the anastomosis with vascular tissue may be useful adjunctive measures. The effect of improved methods of lung preservation and of more specific immunosuppression on the decrease in airway complications is difficult to quantitate, but these factors are probably of some importance in the reduced incidence of this problem.

The overall incidence of airway complications in all lung transplant patients is 5% to 15%. In approximately half of these patients, the diagnosis is made from endoscopic surveillance alone, and healing occurs without further treatment or secondary complication. In the rest, the airway complication requires more specific management and may lead to secondary complications. Of these patients, 70% require anastomotic dilatation or stent placement and 20% develop a bronchopleural fistula that requires a chest tube and perhaps reoperation. Death due to extensive airway necrosis or secondary infectious complications occurs in about 10% of patients who develop symptomatic airway complications. Successful management of early strictures does not limit survival.

Atrial dysrhythmias are common in the early postoperative period, as with other types of cardiothoracic surgery, and are managed in a similar fashion. Transplant patients are also prone to significant gastrointestinal complications, whose manifestations may be obscured by the anti-inflammatory effects of immunosuppressive therapy. Hepatobiliary and pancreatic complications are especially common after intrathoracic transplantation, particularly when CPB has been required. Postoperatively, continued surveillance of pancreatic exocrine function, bilirubin, and liver function tests is indicated to allow prompt diagnosis and intervention for specific abnormalities. In view of the surgical stress and use of corticosteroids in these patients, all patients should receive H_2-blocking agents or proton pump inhibitors postoperatively to prevent upper gastrointestinal hemorrhage. Gastroparesis and pseudo-obstruction are common complications as is distal intestinal obstruction syndrome (DIOS) in patients with cystic fibrosis. Preventative strategies designed to promote bowel function are critical in this group. A prior history of DIOS is the greatest risk factor for the development of this complication post transplantation.

INFECTIOUS COMPLICATIONS

Lung transplant patients have several unique attributes that account for a rate of infectious complications that is higher than the rate for other transplant recipients. Before implantation, the donor lung may contain significant pathogens, owing to the changes in lung defense mechanisms that follow intubation and brain death. After the transplant, the lung allograft continues to be exposed both to the external environment and sites in the upper respiratory tract, such as the sinuses, that may contain significant pulmonary pathogens. Finally, the lack of a cough reflex and a disturbed pattern of mucociliary clearance in the donor lung after the transplant predispose to pulmonary infection. An aggressive approach to the evaluation of all new pulmonary infiltrates is required in these patients. Flexible bronchoscopy is often helpful for proper diagnosis of pulmonary infections after lung transplantation.

Bacterial pneumonia is the most commonly acquired infection after lung transplantation. It occurs most frequently within 2 months of transplantation and is usually due to gram-negative bacilli. Potential native sources of contamination of the respiratory tract should be evaluated, particularly in patients with cystic fibrosis or recurrent pneumonia. Chronic sinusitis is common in cystic fibrosis patients and may act as a source of contamination of the lower respiratory tract. Careful otolaryngologic evaluation and sinus drainage are indicated in selected patients. Gastroesophageal reflux (GERD) is common in lung transplant recipients and can lead to recurrent aspiration pneumonia in dependent regions of the lungs.[102–109] In most patients, conservative treatment with elevation of the head of the bed and the administration of promotility agents, in addition to the H_2-blocking agents or proton pump inhibitors taken by most transplant recipients, control the reflux. Reflux of pH-neutral or alkaline gastric contents may not be detected by standard esophageal pH probe monitoring and requires impedance monitoring. Early laparoscopic Nissan fundoplication seems to have an acceptable risk–benefit for selected patients with GERD not controlled by medical means and in certain series has been shown to reduce the risk of BOS.[110–113] The mechanism may relate to prevention of direct graft damage from bile acids or by preventing exposure of cryptic antigens that may elicit an autoimmune response.[114,115] In patients who have undergone single-lung transplantation, the native lung may occasionally be a site of graft contamination or, more commonly, may become the site of pneumonia or a lung abscess. Standard therapy is recommended for such cases, although a localized area of anatomic abnormality in the native lung (e.g., focal bronchiectasis) may require surgical excision if it proves to be the source of recurrent infection.

Viral infections can be a major source of morbidity or mortality for lung transplant patients. Previously, HSV infection was an occasional cause of tracheobronchitis or pneumonitis following lung transplantation. As stated above, the use of prophylactic acyclovir, ganciclovir, or more recently valganciclovir has substantially reduced the incidence of these infections. Community-acquired respiratory viruses represent a clear and present danger to the survival and quality of life of lung transplant recipients. Influenza in particular may carry an excess mortality so yearly vaccination is recommended despite the acknowledgment that seroconversion may only occur in 60% to 70% of subjects.[116–120] Other community-acquired respiratory viruses include the family of paramyxoviruses comprising respiratory syncytial virus (RSV), Parainfluenza 1,2,3, and the newly described human metapneumovirus, all of which can cause pneumonitis and bronchiolitis. RSV, human metapneumovirus, and influenza are more frequently identified in lung

transplant patients during the winter and early spring months but parainfluenza can occur all year round. Treatment of RSV has evolved at some centers to include both intravenous and oral ribavirin.[121–123] Although successful treatment of the acute disease has been reported, a major issue remains regarding the potential for later development of obliterative bronchiolitis following RSV as well as other viral respiratory tract infections.[124] The cost, complication rate, and cumbersome nature of RSV therapies have stimulated a search for alternative measures such as the recently described use of an inhaled small mRNAi molecule.[125]

CMV, a member of the human herpes virus family, is the second most frequent cause of infection in the lung transplant patient and the most important opportunistic infection that occurs in these patients.[46,74,76,126,127] Following infection with CMV, the virus remains in a latent state in the body; evidence of the infection can be identified from a positive serologic assay demonstrating anti-CMV antibodies. Approximately, 80% of adults are seropositive for CMV. Immunosuppression can cause reactivation of the latent virus and shedding of CMV into both the urine and sputum. Viremia may also be detected. CMV infection of a lung transplant recipient can occur either from reactivation of a recipient's latent virus or direct transmission to the patient of latent virus in the donor lung. Direct transmission, which occurs by the transfusion of blood products obtained from seropositive donors into seronegative recipients, has been essentially eliminated by administration of blood products only from seronegative donors to seronegative recipients.

The incidence of CMV infection in the lung transplant recipient is related to the serologic status of both the donor and recipient.[128] Recipients who are seronegative for CMV and receive seronegative lungs should not develop CMV infection, provided they are protected from transmission of the virus by blood transfusion. Conversely, seronegative recipients who receive lungs from a seropositive donor are at high risk for primary infection, which in the absence of preventive measures can lead to life-threatening pneumonitis and systemic disease. Recipients who are seropositive for CMV are at lower risk for serious CMV disease in the posttransplant period because of their preoperative immunity; nonetheless, they are at risk for both infection by the donor strain (if the donor is seropositive) and reactivation of their own latent strain.

The most serious form of CMV disease that threatens the lung transplant recipient is pneumonitis in the lung graft. This is an invasive infection, with evidence of viral-induced cytotrophic changes in the pulmonary parenchyma in addition to the presence of CMV in serum (Fig. 107-4). Other manifestations of CMV disease include hepatitis, encephalitis, retinitis, and enterocolitis as well as CMV syndrome (fever, malaise, and viremia without organ-specific signs or symptoms). The treatment of choice for CMV disease is ganciclovir 5 mg/kg intravenously twice a day, titrated for renal function. A viable alternative for milder presentations is oral valganciclovir at a dose of 900 mg daily titrated for renal function. Treatment with these agents is continued until CMV is shown to clear from the serum by PCR. However, CMV can be compartmentalized so that clearance from the lung may be delayed. Some centers use CMV hyperimmune globulin in conjunction with ganciclovir for severe infections but evidence documenting the benefits of combined therapy over ganciclovir alone is anecdotal. In addition to its acute impact, CMV pneumonitis in some series appears to be a risk factor for the subsequent development of BOS.

A major advance in the management of CMV has been the widespread implementation of viral prophylaxis with valganciclovir, for all patients who are at risk for CMV disease.[126] This approach has led to a marked decrease in the incidence of serious CMV disease, particularly for patients with disparate donor–recipient CMV status. Prolonged prophylaxis with valganciclovir appears to have an acceptable risk–benefit ratio but is associated with significant cost and the risk of selecting strains of resistant viruses.[48] Donor-positive/recipient-negative patients typically receive at least a year of prophylaxis while recipient-positive patients (independent of donor serologic status) typically receive a 6- to 12-month course.

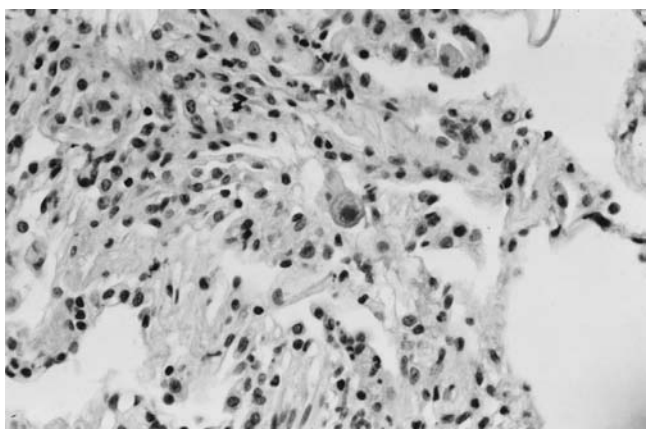

Figure 107-4 Cytomegalovirus (CMV) pneumonitis. A characteristic cytotrophic change in the pulmonary parenchyma is seen with invasive CMV infection.

■ REJECTION

Lung grafts contain a large population of immunocompetent cells, including lymphocytes and macrophages within the parenchyma, hilar and pulmonary lymph nodes, and bronchus-associated lymphoid tissue. Most of these cells are memory T cells. A prominent interaction occurs between donor and recipient immune cells during the early period after implantation. Analysis of cells obtained by BAL during the first month after transplant demonstrates donor-specific lymphocyte proliferation, suggesting in vivo mixed lymphocyte reactivity at a time when both donor and recipient immune-competent cells are present. Subsequently, rapid replacement of donor lymphocytes and macrophages occurs. By 90 days after transplantation, most of the parenchymal cells are of recipient origin and bronchus-associated lymphoid tissue has been markedly depleted.

In view of these rapid and profound changes in immune cell populations, it is not surprising that rejection is common in lung allografts and that, in the case of heart–lung grafts, lung rejection may occur more frequently than, and independent of, rejection of the heart. A protocol of routine transbronchial biopsy of the lung for identification of histologic evidence of lung rejection is usually recommended for both heart–lung and isolated-lung transplant recipients because of the likelihood of rejection that may occur with minimal clinical symptoms.[129–141] The frequency with which surveillance biopsies are performed is center dependent, and many centers stop this practice after the first year in patients who have not had significant episodes of rejection. Bronchoscopy and biopsy are, of course, also performed for clinical symptoms or for changes in spirometry.

AR is characterized by perivascular and subendothelial mononuclear cellular infiltrates (Fig. 107-5). Airway inflammation, particularly lymphocytic bronchiolitis, may also be seen as a component of AR.[142–145] Clinically, patients may manifest dyspnea, low-grade fever, hypoxemia, and pulmonary infiltrates on chest radiograph. More commonly, however, the patient is asymptomatic. Flexible bronchoscopy with BAL and transbronchial biopsy is the most useful method of differentiating AR from infection. BAL is most useful in excluding infection and is not generally helpful in confirming rejection. The transbronchial biopsy is assessed with a

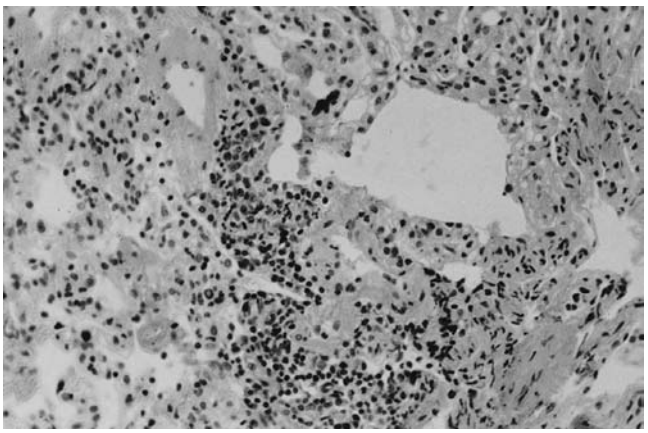

Figure 107-5 Lung allograft rejection–acute rejection, grade A2. Acute rejection is characterized by lymphocytic infiltration about pulmonary vessels. Grading of the rejection process is based on the extent of the lymphocytic infiltration into the surrounding lung parenchyma.

standard histologic grading of AR based on the degree of perivascular infiltrate, with an additional category for assessing the degree of airway inflammation (Table 107-8). Efforts are being made to improve kappa scores between pathologists grading rejection by the use of web-based digitized images based on the recognition that between pathologist grading was highly variable when compared with a central panel.[146] The severity of the perivascular process and the bronchiolar process determine the grade of AR and both processes have been identified as independent risk factors for the later development of BOS.[143]

The initial treatment of AR is administration of a brief course of high-dose corticosteroids (e.g., methylprednisolone 500–1000 mg intravenously every day for 3 days). CMV prophylaxis using oral valganciclovir is advisable for all mismatched and recipient-positive patients when antirejection therapy is initiated. In most patients, symptomatic and radiographic improvement is seen within 48 hours. Thereafter, the maintenance dose of steroids is usually increased for several weeks and then slowly reduced to maintenance levels. Repeat transbronchial biopsy to confirm resolution of the AR also allows the detection of other secondary infections or other unsuspected pathologies.[147] Occasionally, some patients with persistent findings require a second course of steroids, either as previously administered or as a slightly longer course of oral therapy. If persistent AR is identified, cytolytic therapy with OKT3 or antithymocyte globulin should be considered.

AMR is now recognized to play a significant role after lung transplantation. The ISHLT Pathology Council Working Group has outlined the histologic criteria for the determination of pulmonary AMR that are suggestive, if not wholly diagnostic of AMR.[148] Immunologic and clinical features of allograft dysfunction are needed to secure the diagnosis. The four diagnostic pillars that comprise AMR are histopathology (neutrophilic capillaritis or neutrophilic margination), C4d immunostaining involving 50% or greater interstitial capillaries, the presence of circulating donor-specific antibodies, and allograft dysfunction. Capillaritis is now the preferred term rather than the somewhat vague "capillary injury."

An important and not uncommon clinical question is how to manage the patient in whom there is discordance between the four pillars of the diagnostic criteria. Donor-specific antibodies are commonly present without demonstrable histologic change or C4d staining. Histologic change and C4d staining may be present without donor-specific antibodies raising the proposition of whether low-level phasic release of donor-specific antibodies is responsible, whether the antibodies are all tissue bound or indeed whether the presence of IgM is causing a false-negative donor-specific antibody assay. The possibility of non-HLA targets is not discounted.[149] Indeed, a number of authors have postulated that BOS is the result of humoral and cellular immune responses developed against non-major histocompatibility complex molecules expressed by airway epithelial cells of the lung allograft.[150] Irrespective of the type of antibody, allograft specificity is important and this raises the vexing question of how often to monitor for the presence of donor-specific antibodies and what the threshold for commencing treatment should be. The development of donor-specific antibodies has been shown to be associated with an inferior outcome due to the development of BOS. This has prompted some centers to initiate therapy intended to remove these circulating antibodies. There is preliminary evidence that therapy with intravenous gamma globulin combined with therapeutic plasma exchange with or without rituximab or bortezomib may be beneficial but further corroboration is required before this approach can be considered to be standard of care.[151–157]

CR in the lung may affect either the pulmonary vasculature or the airway.[158–160] Occasionally, accelerated sclerosis of the pulmonary arteries and veins may be encountered in lung allografts. These changes are analogous to the CR identified in many isolated cardiac allograft recipients. In fact, when this type of CR is identified in the lungs of heart–lung transplant recipients, it appears to correlate with similar changes in the coronary arteries of these patients.

More typically, CR in the lung is manifested histologically by obliterative bronchiolitis and consists of dense eosinophilic scarring of the membranous and respiratory bronchioles (Fig. 107-6). This is accompanied physiologically by evidence of airflow obstruction as assessed by simple spirometry. Clinically, progressive dyspnea occurs, although a gradual decline in FEV_1 or in expiratory flow rates often precedes symptoms. The lung has a great deal of physiologic reserve so that by the time the patient is symptomatic the process is usually far advanced. Further progression of this process leads to worsening dyspnea and bronchiectasis with secondary

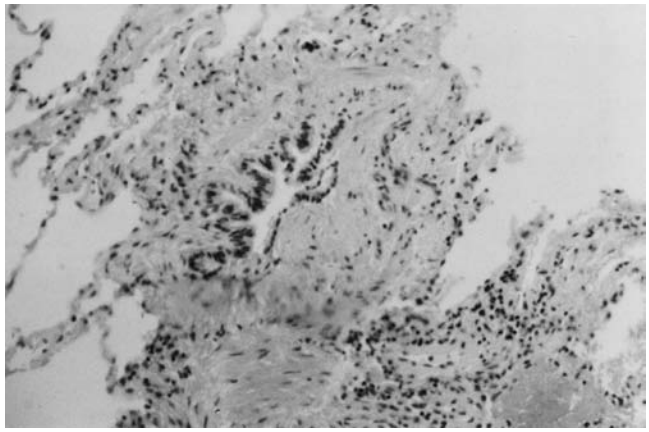

Figure 107-6 Lung allograft rejection–obliterative bronchiolitis. Chronic rejection in the lung most commonly involves the small airways, resulting in obliterative bronchiolitis. Dense submucosal scarring occurs and may completely obstruct the lumen of small airways. The process may be categorized as active or inactive, depending on the degree of associated inflammation.

infection. Although this form of CR is uncommon in the first 3 months after lung transplantation, up to 50% of patients develop it within 5 years and the mortality at 3 years after diagnosis is 40% or higher. Risk factors for the development of this process include episodes of severe AR, three or more episodes of mild AR, and, in some centers, the occurrence of CMV pneumonitis.[161–165] Lymphocytic bronchiolitis appears to be the most important risk factor, which makes sense as this process targets the same airways involved with scar tissue in established obliterative bronchiolitis.[143]

The term *BOS* has been introduced as a noninvasive means to identify patients thought to have CR of the lung involving the airways.[1] Sampling limitations of transbronchial biopsy and the risk of surgical lung biopsy result in many patients with CR not having histologic proof of obliterative bronchiolitis despite a course of progressive deterioration. Therefore, the diagnosis of BOS is based on objective changes in pulmonary function and does not require histologic evidence of obliterative bronchiolitis. The severity of BOS is graded on a scale from 0 to 3 (Table 107-9) depending on the magnitude of the fall in FEV_1 from a baseline determined as the mean of the two best FEV_1 value measures (without the use of a bronchodilator) taken at least 3 weeks apart.[2] In brief, the assignation of a particular grade of BOS is made retrospectively at the time of the first of two FEV_1 measurements at least 3 weeks apart, both of which show a percentage fall in FEV_1 from the baseline value. Although some patients with BOS will remain stable within a given grade, most demonstrate evidence of disease progression. Some evidence suggests that augmented immunosuppression may stabilize the BOS process, particularly if initiated early in its evolution. Augmented corticosteroid therapy (including inhaled steroids), cytolytic agents, tacrolimus, and sirolimus have been used for this purpose but the level of evidence supporting efficacy of these strategies is low. The lack of a uniformly accepted therapy for BOS speaks to the lack of proven benefit of therapies. Azithromycin has shown great promise in a number of studies for patients with BOS associated with BAL neutrophilia, although at least one study found patients without a predominant neutrophil population on BAL also responded.[166–172] Azithromycin has multiple sites of action including as a prokinetic agent and anti-inflammatory agent, but it also has significant antimicrobial activity, particularly against *Chlamydia pneumonia*, which has been associated with graft dysfunction and rejection.[173–175]

Management of progressive BOS in its later stages is mostly palliative unless retransplantation is possible. At its most advanced stage, BOS may have similar features of an acquired form of septic lung disease, including the development of bronchiectasis and recurrent airway infections with *Pseudomonas aeruginosa*. Management is similar to that required for other patients with septic lung disease. Salvage therapies such as total lymphoid irradiation and extracorporeal photopheresis have met with some success but must be commenced prior to the development of terminal respiratory failure, for which only redo lung transplantation has been shown effective.[176,177] Retransplantation has been performed for a number of patients with BOS.[178] The results demonstrate significantly increased perioperative mortality for such patients. One-year survival is approximately 60% to 70% in well-chosen subjects, a rate lower than that associated with primary lung transplantation. Approximately 30% of patients surviving retransplantation develop recurrent BOS by 3 years—an incidence similar to that following primary lung transplantation.

TABLE 107-9 Staging Classification of Bronchiolitis Obliterans Syndrome

Stage	Severity	FEV_1 (% baseline)
0	Nil	>80
1	Mild	66–80
2	Moderate	51–65
3	Severe	≤50

■ NEOPLASTIC COMPLICATIONS

Immunosuppression increases the risk of development of neoplasms after lung transplantation.[179,180] The risk applies to a specific group of solid tumors, including squamous cell cancers of the lip and skin, Kaposi sarcoma, soft tissue sarcomas, carcinomas of the vulva and perineum, and hepatobiliary tumors.[181,182] Colon cancer appears to be more common in cystic fibrosis patients after transplant.[179] Transplant recipients are not at increased risk for developing the more common cancers encountered in the general population, such as carcinoma of the lung, breast, or prostate, and some of the newer agents, such as mycophenolate mofetil and sirolimus may have antitumor properties, although they have yet to be studied long term to determine whether they will reduce malignancy-related mortality.

The most common malignancy seen after lung transplantation is a type of B-cell lymphoid proliferation known as PTLD. PTLD represents a morphologically diverse group of polyclonal lymphoid proliferations. The pathogenesis of PTLD appears to be related to EBV infection of B lymphocytes that are free to proliferate as a result of the recipient's immunosuppression.[97,183] Clinically, a distinction can be made between patients presenting with PTLD within 1 year after transplantation and those presenting with PTLD at later times. Patients presenting early tend to have disease localized to the allograft that responds to a temporary reduction in immunosuppression; their long-term prognosis is excellent. Patients who present after 1 year often have extrapulmonary or disseminated disease that does not respond to reduced immunosuppression and requires tumor-specific therapies to control. The mortality from lymphoma in these patients is 50% to 60%. Epstein–Barr virus seronegative recipients, particularly those treated with cytolytic induction therapy, are at highest risk for developing PTLD.[95] Of interest is that the use of valganciclovir and ganciclovir for prophylaxis against CMV disease in lung transplant patients may also help to control the incidence of PTLD, since these agents also have significant activity against EBV. Rituximab and chemotherapy have been shown to be effective in EBV-positive patients with PTLD who fail or do not tolerate reduction in immunosuppression. Rituximab is well tolerated

and is considered first-line therapy for CD-20 positive tumors. In contrast, chemotherapy is associated with marked toxicity and appreciable mortality but may induce an enduring remission.

RESULTS

The success of lung transplantation is assessed by both survival and functional metrics, as discussed below.

SURVIVAL

Early mortality following lung transplantation has decreased significantly over the past decade. The cause of this reduction is probably multifactorial—that is, the result of technical improvements in the procedure, of improved recipient selection and preoperative management, and increasing experience in perioperative management of these patients. In the ISHLT database, 90-day mortality following lung transplantation is 10%. Short-term mortality after heart–lung transplantation is usually slightly higher. PGD is the major cause of early mortality followed by infection.[101,184,185]

Longer-term survival data indicate a cumulative survival rate above 80% at 1 year. Survival curves vary significantly at 1 year, depending on the disease for which transplantation was performed.[4] Patients with emphysema and those with cystic fibrosis appear to have a survival advantage over patients with pulmonary fibrosis at this time point. Beyond the first year, BOS begins to have a significant impact on survival, leading to an overall survival rate of only approximately 65% at 5 years.[4] Causes of death in this period include infection and BOS, which can be identified in up to half of the patients who survive to 5 years. Malignancy, usually PTLD, is the third most common cause of late mortality following lung transplantation.

FUNCTIONAL RESULTS

Most patients surviving lung transplantation experience a highly significant improvement in their functional capability over their preoperative state. Typically, patients can resume an exercise program without oxygen supplementation by 6 weeks after transplantation. However, the occurrence of severe PGD may delay full recovery for 2 to 3 months. Survivors of severe PGD are frequently left with significant functional deficits, though recovery of normal allograft function is possible.

Improvements occur regardless of the native disease that led to transplantation. Unless BOS occurs, functional capacity based on the standards of reproducible exercise testing remains stable for at least 3 years. Controversy exists over the potential functional benefit of single-lung transplantation as compared to the bilateral procedure for younger patients with emphysema and most centers now offer bilateral transplantation to this group.[53,186,187] Although the results of spirometry are obviously better in bilateral recipients, exercise tolerance is similar in the two groups.

RETRANSPLANTATION

Pulmonary retransplantation has been undertaken with increasing frequency in recent years.[188] Retransplantation has been used either as a method to correct an acute complication, such as graft failure or severe bronchial dehiscence, or as a treatment for a chronic process in the graft, such as BOS or airway stenosis. The benefits of emergent retransplantation for early, acute complications appear very limited while patients transplanted for BOS generally do well, albeit with slightly lower survival rates compared to primary transplantation. At the present time, BOS is the most common indication for retransplantation. Novick described the largest pooled data series but many centers have reported individual results with variable success rates.[189–203] Ipsilateral single-, contralateral single-, and bilateral-lung transplantation all have been used for retransplantation following initial single or bilateral transplantation; the superiority of one approach over another has not been demonstrated. These are technically challenging procedures, with a surgical mortality of nearly 20%. Factors contributing to a more favorable outcome include retransplantation beyond the first 30 days, an ambulatory status before retransplantation and prior institutional experience with retransplantation. In the early days of retransplantation, the long-term results of retransplantation were far worse than those of initial lung transplantation. However, results have improved so that 1-year survival is now about 70%.

SUMMARY

Lung transplantation is now an established therapy for advanced lung diseases for which no other therapy is applicable. A shortage of donor organs, however, remains the most significant obstacle to wider use of this method of treatment. Nevertheless, there are now almost 10,000 living recipients within the United States alone, which is a testament to the growth of the discipline and the durability of the outcome in selected recipients. There are now a number of long-term survivors who continue to enjoy good health and an excellent quality of life, which no other therapy could have provided. Techniques of donor lung preservation and implantation allow ischemic intervals of 6–8 hours for reasonable postoperative function, with the hope of extended periods afforded by the newly developed technique of ex vivo lung perfusion. Surgical mortality has declined considerably over the years. Functional results in survivors of the operation are excellent. PGD and infection remain significant causes of morbidity and mortality in both the early and late postoperative periods. The most significant impediment to long-term survival is the development of chronic allograft dysfunction, often manifested as BOS, in almost half of the patients by 5 years after transplantation. Further measures to prevent and manage BOS and other forms of CR are critical to improving long-term survival rates following lung transplantation.

ACKNOWLEDGMENT

The author thanks John C. Wain, MD, for his contributions to this chapter in the last edition.

CHAPTER 108

Genetic and Molecular Changes in Lung Cancer: Prospects for a Personalized Pharmacological Approach to Treatment

Howard Li
Jeffrey A. Kern

INTRODUCTION

Lung cancer is the most common cause of cancer-related death in men and women worldwide, responsible for over 1 million deaths annually.[1] Each year, more people die of lung cancer than of the next three leading causes of cancer death combined: breast, colon, and prostate cancer. Despite advances in surgical techniques and combined therapies, lung cancer remains a disease with a dismal prognosis. Although 1-year survival has improved over the past few decades, overall 5-year survival has remained relatively unchanged at 12% to 16% over the past 30 years.[2] These data underscore the need to develop new diagnostic modalities and therapeutic approaches to target lung cancer.

Lung cancer therapy is in the midst of a revolution toward personalized therapy. A key discovery in the past decade has been that some lung cancers harbor specific mutations that are essential for malignant growth (i.e., "driver mutations"), which lead to gain of function of oncogenes or loss of function of tumor suppressor genes (TSGs). In contrast, lung cancers also harbor mutations that are functionally insignificant (i.e., "passenger mutations"). While clearly promoting the oncogenic state, driver mutations are also commonly associated with "oncogene addiction," or dependency of some cancers on one gene for the maintenance of the malignant phenotype. These dependencies, which are specific to an individual's cancer, are absent in normal cells. Inhibition of "druggable" proteins coded for by driver mutations, such as the BCR-ABL fusion protein with imatinib in chronic myelogenous leukemia or human epidermal growth factor receptor 2 (HER2)/Neu with trastuzumab in breast cancer, are prime examples of successful therapeutic targeting of critical signaling nodes in cancer.

Historically, nonsmall cell lung cancer (NSCLC) has been classified histologically as squamous cell carcinoma, adenocarcinoma, and large cell carcinoma, and various chemotherapeutic regimens have been used to treat different histological subtypes. But with the realization that NSCLC is a collection of diseases that are identifiable by specific molecular abnormalities, personalized therapy became a goal – and now a reality – for patients with NSCLC. Between 1980 and 2000, NSCLC driver lesions that were investigated included mutations in the Kirsten rat sarcoma viral oncogene homolog *(KRAS)* and protein 53 *(p53)* genes, loss of specific chromosomal loci, loss of heterozygosity, and DNA methylation of TSGs. In 2004, driver mutations in the epidermal growth factor receptor *(EGFR)* gene, a membrane-bound receptor tyrosine kinase (RTK) that regulates cell growth, were discovered in NSCLC, especially in adenocarcinomas.[3–5] These *EGFR* driver mutations resulted in a receptor with deregulated signaling driving cell growth and the oncogenic phenotype, but also led to a cellular dependence on EGFR RTK signaling. Thus, these mutations were strongly associated with therapeutic sensitivity to tyrosine kinase inhibitor (TKI) drugs that inhibited the tyrosine kinase (TK) function of EGFR. In 2007, the existence of the echinoderm microtubule-associated protein-like 4 *(EML4)* translocation to the anaplastic lymphoma kinase *(ALK)* gene resulting in an *EML4-ALK* fusion gene was discovered in NSCLC.[6] As with EGFR, this translocation resulted in deregulated TK signaling by ALK, again driving cell growth and the oncogenic phenotype, as well as a cellular dependence on EML4-ALK signaling. Targeting the TK domain of ALK with ALK inhibitors has been found to be highly effective in lung cancers that have this translocation.

The observation that the response rates with EGFR TKIs are higher in never smokers than in smokers with advanced NSCLC led to the realization that lung cancer in never smokers is a distinct disease from tobacco-associated lung cancer, with unique molecular and biological characteristics. Tobacco components promote lung carcinogenesis through the accumulation of mutations in key genes in the growth regulatory pathways, leading to uncontrolled cellular proliferation and tumorigenesis. Although tobacco use is the oldest and the most well-established risk factor for lung cancer, lung cancer can also occur in patients who have no history of smoking. A "never smoker" is commonly defined as an individual who has smoked less than 100 cigarettes over his or her lifetime.[7] The World Health Organization estimates that 25% of lung cancer worldwide occurs in never smokers,[8] but in Western countries this percentage is closer to 10% to 15%.[7,9–11] Histologically, the most frequent type of lung cancer in never smokers is adenocarcinoma.[7] In all series of never smokers, lung cancer is much more frequent in women than in men, and generally occurs at an earlier age.[7,9,12–14] Although lung cancer in never smokers occurs worldwide, geographic and ethnic variation is striking, with 30% to 40% of Asian patients with lung cancer having never smoked, compared with 10% to 20% of Caucasians.[7,15–17] In the United States, African American never smokers have greater incidence and mortality rates of lung cancer compared with Caucasian never smokers.[15,18] As the molecular drivers in lung cancer have been identified, it has become clear that driver mutations in never smokers are distinct from those in smokers. For example, patients with lung cancer who have never smoked are more likely to have *EGFR* gene mutations and *EML4-ALK* gene fusions, and have better response to inhibitors of these pathways than do patients with tobacco-associated lung cancer. Moreover, in patients with NSCLC, the average mutation frequency is more than 10-fold higher in smokers than in never smokers.[19] Thus, it is clear that lung cancer in never smokers is a very different disease than that seen in tobacco-associated lung cancer (Table 108-1).

These discoveries illustrate that molecular biological findings can be directly linked to the development of novel chemotherapies and thereby improve the survival rates of lung cancer patients. As new pathways and mechanisms that drive lung cancer are identified, existing agents that have not been previously considered for lung cancer can now be tested, or new drugs targeting the affected pathways can be developed. These discoveries allow a patient's therapy to be individualized to the molecular elements that drive their disease

TABLE 108-1 Clinical and Molecular Characteristics of Lung Cancer in Smokers and Never Smokers

	Smokers	Never Smokers/ Light Smokers
Age	Older (>60)	Younger (<60)
Gender	Male > Female	Female > Male
Ethnicity	Caucasian predominant	East Asian > Caucasian
Histological subtype	All	Adenocarcinoma
Associated mutations/ alterations	KRAS, PIK3CA, RB, p53	EGFR, EML4-ALK

and treatment with agents that best target the characteristics of their cancer, potentially offering higher response rates and improvements in survival. Because these therapies are targeted to mutations that are only present in cancer cells, normal tissues are relatively unaffected, resulting in fewer side effects. However, hundreds of mutations occur in a cancer cell and not all of them are functionally important or suitable targets for personalized therapy. To improve the chances of success in the development of personalized medicine for lung cancer, we need to identify a functionally important target or pathway, a biomarker to identify and follow therapeutic response, the appropriate therapeutic end point, and the mechanisms of resistance to personalized therapy, both primary and acquired.

REGULATION OF CELL GROWTH AND SURVIVAL

Lung cancer results from the deregulation of cellular processes that control cell cycling and death, allowing unrestricted cell growth. Dysfunctional signaling pathways and proteins that promote carcinogenesis include membrane-bound RTKs such as EGFR, guanosine triphosphatases (GTPases) such as RAS, and nuclear proteins that contribute to cell mitosis and abrogate the appropriate apoptotic (programmed cell death) pathway such as Myc and p53, respectively.

MEMBRANE-BOUND RECEPTOR TYROSINE KINASES

Membrane-bound RTKs share a common general structure composed of an extracellular region that contains a ligand-binding domain, an extracellular juxtamembrane region, a hydrophobic transmembrane domain, a cytoplasmic TK domain, and a cytoplasmic tail with tyrosine residues that serve as sites for receptor phosphorylation (Fig. 108-1). Ligand-binding results in activation of the receptor's TK domain, leading to phosphorylation of the receptor's tyrosine residues. This, in turn, results in recruitment of signaling molecules to the phosphorylated tyrosine residues and coupling to downstream effectors, eventually leading to biological responses. RTK activity in nonmalignant cells is normally under tight temporal and spatial regulation by the receptor and its ligand, which act as safeguards against unwanted activation. Driver lesions in the membrane-bound RTKs result in deregulated signaling or in a receptor that cannot be shut off. RTK activation in cancer may occur via overexpression of wild-type receptor due to gene amplification (resulting in excess signaling), excess ligand production, ligand overstimulation, activating mutations, translocations resulting in activated fusion proteins, or reduced receptor downregulation.

The prototypical RTKs involved in lung cancer are members of the ErbB family. The ErbB family of RTKs includes ErbB1 (EGFR; HER1), ErbB2 (HER2/Neu), ErbB3 (HER3), and ErbB4 (HER4). In the lung, these RTKs are expressed by the pulmonary epithelium (e.g., alveolar type II cells and bronchial cells) and fibroblasts. Members of the epidermal growth factor (EGF) family of peptide hormones serve as ligands for ErbB RTKs, and include EGF, transforming growth factor-α, betacellulin, and epiregulin for ErbB1; and the neuregulins for ErbB3 and ErbB4. Ligand-binding activates the receptor and multiple intracellular signaling pathways that govern fundamental cellular processes including proliferation, cell migration, metabolism, and survival. For example, phosphorylation of ErbB RTKs results in activation of growth factor receptor–bound protein 2 (Grb2) and Son of Sevenless (SOS), which ultimately leads to phosphorylation and activation of RAS. Activation of the RAS/RAF/MEK/extracellular signal–regulated kinase (ERK) pathway leads to cell proliferation. In contrast, activation of the phosphoinositide 3-kinase (PI3K)/AKT pathway by ErbB RTK signaling results in prolonged cell survival via the expression of mitochondrial antiapoptotic proteins. Thus, deregulation in an RTK pathway can give a selective growth and survival advantage to a cell, resulting in clonal expansion and tumorigenesis. Sequencing a patient's lung cancer for *EGFR* or *ErbB2* gene mutations can identify specific alterations in this pathway, allowing the use of targeted chemotherapy agents.

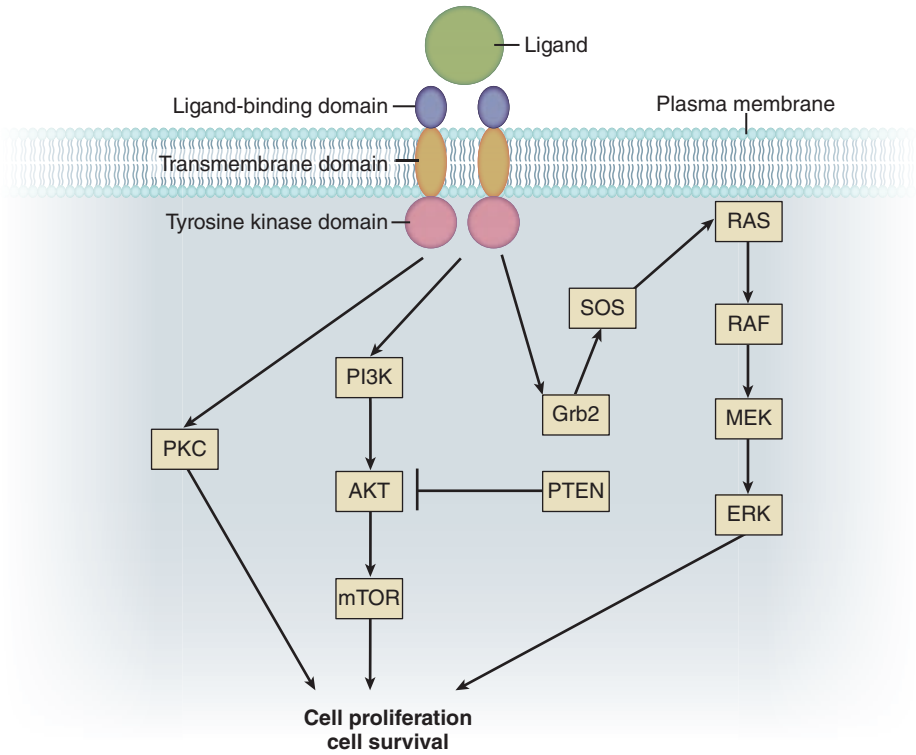

Figure 108-1 Simplified schematic of receptor tyrosine kinase (RTK) and downstream signaling pathways. Binding of ligand to the RTK leads to activation of the RAS/RAF/MEK/ERK signaling cascade, which is involved in cell proliferation. Similarly, RTK phosphorylation can also signal through the PI3K/AKT/mTOR pathway, which is involved in cell survival.

■ INTRACELLULAR KINASES AND TARGETS: RAS/RAF/MEK/ERK PATHWAY

Downstream of membrane-bound RTKs is the RAS/RAF/MEK/ERK pathway, which is a pivotal intracellular signaling pathway that transmits RTK signals to the nucleus via a cascade of specific protein phosphorylation (Fig. 108-1). When activated, ERK translocates to the nucleus, where it induces regulatory proteins such as the nuclear transcription factors Elk-1, Fos, Jun, activator protein 1 (AP-1), and Myc, which regulate genes that play key roles in proliferation, angiogenesis, metastasis, and chemotherapy resistance.

RAS

The *RAS* family of oncogenes includes neuroblastoma RAS viral oncogene homolog *(NRAS)*, *KRAS*, and Harvey rat sarcoma viral oncogene homolog *(HRAS)*. *KRAS* is the gene that is most commonly involved in lung cancer. *RAS* genes encode a family of membrane-bound GTPases, or G proteins, whose signaling regulates cell growth, differentiation, and apoptosis. Similar to RTKs, G proteins can be thought of as "on/off switches" for signaling (Fig. 108-2). In the "off" state RAS is bound to the nucleotide guanosine diphosphate (GDP), while in the "on" state it is bound to guanosine triphosphate (GTP). A phosphate group is then transferred from GTP to a RAS effector molecule, activating the downstream signaling process. The remaining GDP is incapable of signaling, and thus puts the RAS complex in an "off" state. Activation and deactivation of RAS and other small G proteins are thus controlled by cycling between the active GTP-bound and inactive GDP-bound forms. Activated RAS stimulates RAF protein kinases, which in turn initiates the MEK cascade leading to ERK activation and ultimately activation of transcription factors that regulate cell cycle progression. Other effectors of activated RAS include signal transducer and activator of transcription (STAT) and PI3K signaling cascades.

Approximately 20% to 30% of NSCLC harbor activating point mutations in *RAS* genes.[20–23] Mutations occur most frequently in the *KRAS* gene (90%), specifically in codons 12, 13, and 61.[24] These mutations result in compromised GTPase activity, causing mutant RAS protein to favor its active GTP-bound state. Therefore, mutant RAS protein results in continuous signaling even in the absence of growth factor stimulation, conferring a proliferative advantage to tumor cells.

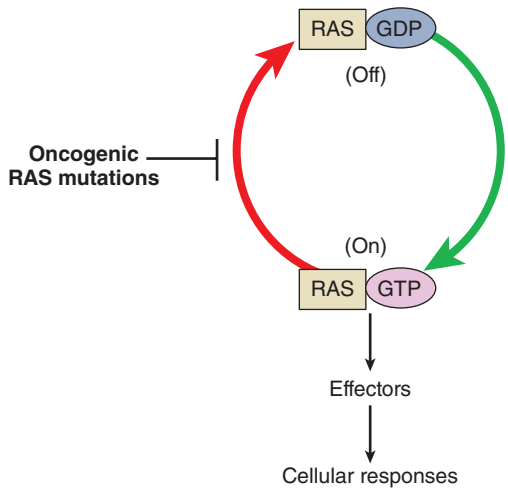

Figure 108-2 Activation cycle of Ras proteins. Growth factor stimulation leads to activation of RTKs, which causes the adaptor protein growth factor receptor–bound protein 2 (Grb2) to bind to Ras and recruit Son of Sevenless (SOS), which stimulates the conversion of Ras from the inactive guanosine diphosphate (GDP)-bound form to the active guanosine triphosphate (GTP)-bound form. Stimulation of Ras activates a mitogen-activated protein kinase cascade, leading to cell growth and differentiation. Oncogenic Ras mutations result in compromised GTPase activity, causing mutant RAS to favor its active GTP-bound state. Therefore, mutant RAS results in continuous signaling even in the absence of growth factor stimulation, conferring a proliferative advantage to tumor cells.

RAF

Next in the RAS signaling cascade is RAF, which is a family of serine–threonine kinases that includes A-RAF, B-RAF, and RAF-1 (also known as C-RAF). Although RAF is activated by RAS, activation can also occur independently of RAS through other activators such as Src, c-Jun NH2-terminal kinase, interferon-β, protein kinase C-α (PKC-α), or through dimerization between RAF isoforms. Activating mutations of the *B-RAF* gene have been reported in up to 3% of NSCLC tumors, most of which are adenocarcinoma.[25,26]

ERK/MEK

To date, no activating mutations have been identified in *ERK* or *MEK* genes. However, activation of ERK/MEK signaling is a result of upstream pathway activation, and tumor cells often have coactivation of ERK/MEK and either RAS or RAF.[27]

■ SERINE–THREONINE KINASES

Membrane-bound RTKs also couple to serine–threonine kinases, which are a second class of regulatory molecules (Fig. 108-1). These enzymes also function through phosphorylation and subsequent activation of their substrate, but unlike RTKs, they phosphorylate serine and threonine residues instead of tyrosine.

Protein Kinase C

Protein kinase C (PKC) is a major component of downstream signaling pathways activated by various RTKs, including VEGF receptor (VEGFR), EGFR, and c-MET. PKC transduces signals that initiate cellular events important for carcinogenesis, including cell growth, cell cycle progression, drug efflux, apoptosis, and angiogenesis. PKC-α and PKC-β isoforms are highly expressed in approximately 20% of NSCLC tumors.[28,29]

PI3K/AKT/mTOR

The PI3K pathway is a complex pathway with numerous feedback loops that is fundamental for cell development, growth, and survival. Activation of the PI3K pathway is also important in the development of lung cancer. Many cell surface receptors activate second messengers that in turn activate PI3K. In addition, activation of the PI3K pathway can occur through loss of phosphatase and tensin homolog (PTEN), a lipid phosphatase that inactivates phosphatidylinositol (3,4,5)-triphosphate (PIP3). Loss of PTEN expression by immunohistochemistry or quantitative real-time polymerase chain reaction (PCR) occurs in up to 73% of NSCLC patients.[30–33] PI3K generates phosphorylated phosphatidylinositides (e.g., PIP3) that bind to phosphoinositide-dependent kinase, which subsequently phosphorylates AKT at the threonine 308 residue. The resultant activation of AKT in this pathway promotes cell survival through inhibition of apoptosis and promotion of cell cycle progression, and leads to phosphorylation of mammalian target of rapamycin (mTOR), which is a serine–threonine kinase that mediates cell growth and proliferation.

By sequencing *RAS*, *RAF*, *PI3K*, *mTOR*, and *PTEN* genes, a specific mutation in this signaling pathway can be identified, leading to tumor-specific targets for personalized therapy. In addition, knowledge of where driver mutations occur in a signaling pathway is critical to define appropriate therapy. For example, identification of a *KRAS* driver mutation would suggest that therapy targeted to

molecules upstream of KRAS, such as EGFR, HER2, or c-MET, would be ineffective. Clinically, this has been well confirmed.

CELL CYCLE REGULATION

In nontransformed pulmonary epithelial cells, cell division is a tightly regulated process with multiple checkpoints that assess extracellular growth signals, cell size, and DNA integrity (Fig. 108-3). Cyclins and their associated cyclin-dependent kinases (CDKs) are the central machinery that control cell cycle progression. Alterations in these proteins may lead to a bypass of the checkpoints that assess a cell's readiness to divide. These are critical checkpoints, because any mutation that is not identified and corrected by DNA repair mechanisms will be incorporated into the genome through DNA replication during S (synthesis) phase. At the next replication cycle, the cell will "read" this mutation as normal and it is subsequently fixed into the cell's genome.

Rb

The product of the retinoblastoma susceptibility gene, Rb, plays a central role in the G_1-S transition, and *Rb* is considered a tumor suppressor gene. Therefore, loss of normal function of this gene removes its suppressor effect leading to cellular transformation. In its unphosphorylated state, Rb protein prevents progression from G_1 to S phase by binding the key transcription factor E2F/DP-1. Once the Rb protein is phosphorylated by the cyclin D/CDK complex, E2F is released allowing transcription of a battery of genes that regulate DNA metabolism. Mutation of the *Rb* gene can result in a protein that does not require phosphorylation and is constitutively activated. In this case, cell cycle arrest does not occur at the G_1-S transition. Alternatively, alterations in the mechanisms that phosphorylate Rb can inappropriately activate Rb, again leading to loss of the G_1-S restriction point. For example, the cyclin E/CDK2 complex is an important regulator of entry into the S phase through Rb phosphorylation. Disruption of this complex regulation by increased cyclin production or loss of endogenous cell CDK inhibitors, such as the Cip/Kip family (p21, p27, p57) and the INK4 family (p16, p18, p19), can result in unregulated progression through the G_1-S checkpoint.

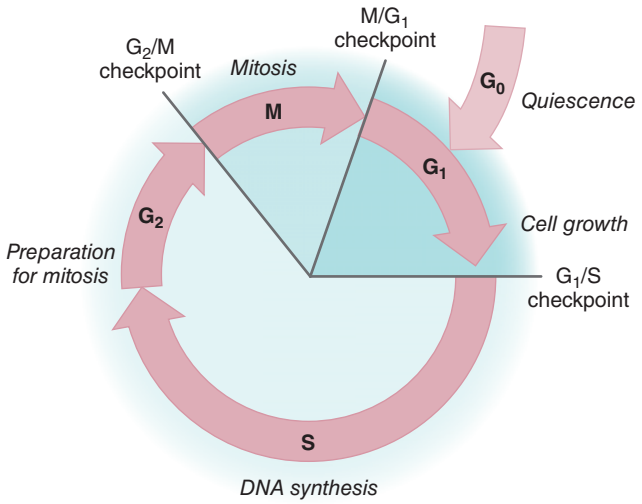

Figure 108-3 Cell cycle regulation. The cell cycle is an ordered process of events that occurs in four stages. During the two gap phases, G_1 and G_2, the cell is actively metabolizing but not dividing. In S (synthesis) phase, the chromosomes duplicate as a result of DNA replication. During the M (mitosis) phase, the chromosomes separate in the nucleus and the division of cytoplasm occurs. There are checkpoints in the cycle at the end of G_1 and G_2 that can prevent the cell from entering the S or M phases of the cycle. Cells that are not in the process of dividing are in the G_0 stage.

p53

p53 is a transcription factor that can activate the transcription of numerous genes, including the CDK inhibitor p21. Under normal conditions, p53 is rapidly degraded and therefore not detectable within the cell. Mutation of the *p53* gene results in a protein that fails to bind DNA effectively. Therefore, expression of the CDK inhibitor *p21* gene is decreased, and p21 protein production is decreased. p21 protein is not available to stop the entry of the cell into S phase, again resulting in unregulated cell cycle progression. Mutations of the *p53* gene occur in nearly 50% of NSCLC,[34,35] and abnormalities of p53 protein may play an important role in the tumorigenesis of lung epithelial cells.

Disruption of the normal regulation of cell growth lies at the heart of the events leading to lung cancer. Complex networks of regulatory factors dictate whether lung cancer cells proliferate or die. Knowledge of these regulatory networks has led to identification of key pathways involved in the development of lung cancer. A detailed understanding of the molecular changes underlying lung cancer offers the prospect of specifically targeting malfunctioning pathways to achieve more rational lung cancer therapy.

PERSONALIZED THERAPY IN LUNG CANCER

EGFR

Small-molecule agents have been developed to inhibit EGFR kinase signaling by blocking the intracellular TK domain (Table 108-2). The first of these EGFR TKIs, gefitinib and erlotinib, began testing in clinical trials in the early 2000s. Both gefitinib and erlotinib are orally administered agents that bind at the catalytic cleft of EGFR in competition with ATP, suppressing EGFR phosphorylation and downstream signaling.[36–38] Initial randomized studies in NSCLC with EGFR TKIs in combination with standard first-line platinum-based chemotherapy were all negative. However, in the TRIBUTE trial of carboplatin and paclitaxel with erlotinib or placebo, 116 patients who reported that they had never smoked had a prolongation in survival with erlotinib treatment (22.5 months) compared to placebo treatment (10.1 months, $p = 0.01$), suggesting treatment with erlotinib improved survival in never smokers.[39]

In 2004, as a result of basic research to understand the dramatically different response rates to EGFR TKI therapy, several academic groups reported the discovery of a collection of activating mutations in the TK domain of EGFR that correlated with a high likelihood of response to EGFR TKIs.[3–5] Many of the patients harboring these mutations demonstrated rapid, nearly complete reduction of their cancers that persisted for up to several years. *EGFR* gene mutations were much more commonly found in female never smokers of East

TABLE 108-2 Targeted Therapies Against Oncogenic Pathways in Lung Cancer

Gene	Drug
ALK	Crizotinib
EGFR	EGFR TKIs: erlotinib, gefitinib, afatinib
	EGFR monoclonal antibodies: cetuximab, matuzumab, necitumumab, panitumumab
MEK	AZD6244
MET	Tivantinib, cabozantinib, foretinib, crizotinib, MetMAb
mTOR	Everolimus
RAF	Sorafenib

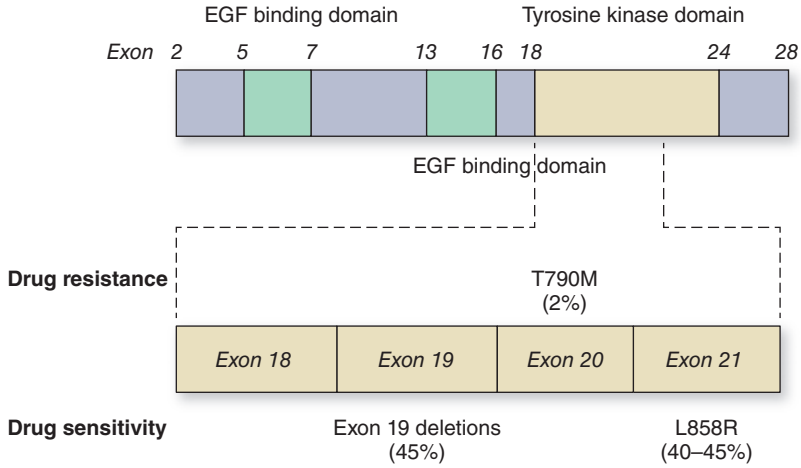

Figure 108-4 Epidermal growth factor receptor (EGFR) mutations in NSCLC. A cartoon representation of EGFR showing the distribution of exons in the epidermal growth factor (EGF) binding and tyrosine kinase domains. Exons 18 to 21 in the tyrosine kinase region where the relevant mutations are located are expanded and the most common mutations associated with drug sensitivity and drug resistance are shown.

Asian origin with adenocarcinoma histology. Whereas the incidence of *EGFR* mutations in Asians is 25% to 35%, the incidence in North American and Western European patients is approximately 15%. However, the strongest predictor of *EGFR* mutation status appears to be absent or low smoking history.[40,41]

Approximately 90% of observed *EGFR* gene mutations are either small in-frame deletions in exon 19 clustered around the catalytic site of the receptor, or an amino acid substitution from a leucine to an arginine at position 858 in EGFR (L858R), which lies within the TK activation loop in exon 21 (Fig. 108-4).[3–5,42–45] In cells harboring *EGFR* gene mutations, the mutated receptor leads to enhanced AKT signaling and downstream activation of antiapoptotic and prosurvival signals. The location of *EGFR* gene mutations within critical residues of the catalytic domain leads to altered physical structure, enhanced drug binding, and sensitivity to EGFR TKIs.[46] Other types of *EGFR* TK domain mutations have been reported. In contrast to the more common exon 19 deletions and L858R mutation, some of these minor mutations are associated with resistance to EGFR TKIs.[47–49]

The rapid and dramatic clinical responses to EGFR TKI therapy seen in patients with *EGFR* gene mutations have led to the "oncogene addiction" hypothesis,[50,51] which states that because EGFR-mutant lung cancers develop in a setting in which the mutated receptor is constantly transducing high levels of antiapoptotic signals, the cancer cells are "addicted" to EGFR kinase prosurvival signaling. As a result, sudden interruption of EGFR signaling by EGFR TKIs causes massive cell death. Another hypothesis, termed the "oncogenic shock" hypothesis,[52] states that proapoptotic signals are still present in EGFR-mutant lung cancer cells. When receptor signaling is inhibited by EGFR TKIs, both antiapoptotic and proapoptotic signals are blocked. However, antiapoptotic signals decay much more rapidly than proapoptotic signals, leading to a temporary predominance in proapoptotic signaling and cell death.

A large number of retrospective series have demonstrated that the response rate of *EGFR* mutation-positive patients to EGFR TKIs exceeds 60%,[5] which is markedly higher than the typical 20% response rate to combination chemotherapy in NSCLC.[53] Several studies have also shown that NSCLC patients harboring *EGFR* mutations survive longer with EGFR TKI therapy than wild-type EGFR patients, with median survivals of 11 to 30 months.[43,54–60] Thus, personalized therapy targeting the specific genetic changes in a patient's lung cancer is critical for improving response rates and overall survival.

Several randomized phase III trials comparing gefitinib to platinum-based chemotherapy in patients with advanced NSCLC have been reported. Although participants were not selected based on *EGFR* gene mutation status, the IPASS trial enriched its study population for subjects with *EGFR* mutations by selecting patients according to clinical factors known to be associated with higher prevalence of *EGFR* mutation: East Asian patients, adenocarcinomas, and never smokers or former light smokers.[61] The IPASS trial was designed with progression-free survival (PFS) as the primary end point to assess the noninferiority of gefitinib compared with carboplatin/paclitaxel. The study met its primary objective demonstrating noninferiority and showed superiority of gefitinib for PFS, objective response rate (ORR), and quality of life for the entire cohort. However, results depended upon the *EGFR* mutation status. For patients whose tumors contained an *EGFR* mutation, PFS was significantly prolonged with gefitinib (9.5 months) in contrast to carboplatin/paclitaxel (6.3 months). In comparison, for those without an *EGFR* mutation, PFS was significantly shorter with gefitinib (1.5 vs. 6.5 months). Two additional randomized phase III trials of patients with advanced NSCLC selected for *EGFR* mutations (either the exon 19 deletion or L858R point mutation) also demonstrated a significant increase in PFS with gefitinib compared to platinum-based chemotherapy as first-line treatment.[62,63] Similarly, a multicenter, open-label, randomized phase III trial of erlotinib versus standard chemotherapy as first-line treatment for Caucasian patients with advanced *EGFR* mutation-positive NSCLC (EURTAC) reported a median PFS of 9.7 months in the erlotinib group, compared with 5.2 months in the standard chemotherapy group.[64] These studies confirm that treatment of *EGFR* mutation-positive patients with first-line EGFR TKI therapy is superior to standard chemotherapy and represents one of the most promising advances in the field of lung cancer in recent years.

Another strategy to block EGFR kinase function in patients with NSCLC focuses on the use of monoclonal antibodies directed against EGFR. Cetuximab, a chimeric anti-EGFR monoclonal antibody, has been studied in combination with different chemotherapy protocols in both phase II and phase III trials in patients with advanced NSCLC. In the phase III FLEX trial, cetuximab added to cisplatin and vinorelbine in patients with advanced *EGFR* mutation-positive NSCLC resulted in an absolute overall survival benefit of 1.2 months.[65] Additional anti-EGFR monoclonal antibodies under study include matuzumab and panitumumab, which have been evaluated in phase II trials, and necitumumab, which is currently being evaluated in combination with chemotherapy in phase III trials.

Unfortunately, virtually all patients who initially respond to EGFR TKI therapy will develop resistance and suffer a clinical relapse. Approximately 50% of the cases of acquired TKI resistance are attributed to a secondary *EGFR* gene mutation, the threonine to methionine point mutation at amino acid 790 (T790M) in exon 20 (Fig. 108-4).[49] The threonine residue at position 790 is highly conserved across the oncogenic RTKs EGFR, ABL, and KIT, and mutations of this residue often lead to resistance to kinase-targeted drugs.[66] The T790M mutation in EGFR kinase causes drug resistance by increasing the receptor's affinity for ATP at the ATP-binding pocket, thereby minimizing the effects of EGFR TKIs.

Several second-generation EGFR TKIs have been developed with a specific focus on the T790M mutation. Typically, these are small molecules that covalently bind to the intracellular kinase domain of the EGFR protein. In addition to binding irreversibly to wild-type

EGFR, HER2, and HER4, these novel agents also bind to receptors carrying the T790M mutation. The LUX-Lung 1 trial[67] studied 585 patients with lung adenocarcinoma who had progressed after treatment with a platinum-based regimen followed by at least 12 weeks of erlotinib or gefitinib, which are criteria for acquired resistance proposed by Jackman et al.[68] Treatment with the second-generation TKI afatinib tripled PFS from 1.1 to 3.3 months, suggesting afatinib may have a role in the treatment of NSCLC patients with *EGFR* gene mutations who acquire resistance to EGFR TKIs. The LUX-Lung 3 trial investigated the efficacy and safety of afatinib compared with pemetrexed/cisplatin in patients with *EGFR* mutation-positive stage IIIB/IV lung adenocarcinoma.[69] Treatment with afatinib led to a significantly prolonged PFS versus pemetrexed/cisplatin (median 11.1 vs. 6.9 months) and significantly higher ORR (56% vs. 23%), indicating afatinib may also be a first-line treatment option in NSCLC patients with *EGFR* gene mutations.

Blocking both the intracellular and extracellular domains of the EGFR kinase ("vertical blockade") by combining a TKI and an EGFR antibody concurrently may offer an additional strategy to overcome TKI resistance. Vertical blockade of the EGFR receptor with the combination of the dual EGFR/HER2 inhibitor lapatinib and the monoclonal antibody trastuzumab has been shown to significantly improve PFS and disease control rate in HER2-positive metastatic breast cancer patients.[70] In preclinical studies, dual targeting with the EGFR TKI afatinib and the anti-EGFR monoclonal antibody cetuximab was able to induce near complete responses in T790M transgenic mouse models.[71] A phase 1 trial of afatinib and cetuximab in NSCLC patients with clinically defined acquired EGFR TKI resistance is currently ongoing. Further studies are underway to clarify the roles of second-generation TKIs and vertical inhibition in the treatment of EGFR TKI-resistant patients.

In addition to secondary resistances caused by T790M, several other mechanisms of resistance to EGFR TKIs have been described. MET protein overexpression or *MET* gene amplification was observed in up to 20% of tumor samples after treatment with EGFR TKI.[72] Cells with *MET* gene amplification are capable of maintaining AKT activation in the presence of EGFR TKIs. In these cases, inhibition of signaling by a TKI may result in the cell switching to an alternate signal pathway, undergoing a "kinase switch" to ensure their survival. In theory, kinase switching might be counteracted by concurrent blockade of EGFR and MET kinase signaling.

EML4-ALK

In 2007, Soda et al.[6] reported a new molecular abnormality involving the fusion of ALK with EML4 in lung adenocarcinoma. The fusion protein results from an inversion in the short arm of chromosome 2 that fuses the N-terminal domain of EML4 to the intracellular kinase domain of ALK, leading to constitutive activation of the ALK kinase (Fig. 108-5). In the original report by Soda and colleagues, 6.7% of unselected NSCLC patients had the EML4-ALK fusion protein. Similar to the clinical phenotype seen in patients with *EGFR* mutations, the EML4-ALK fusion protein occurs more commonly in younger patients who are never or former smokers and is predominantly associated with adenocarcinoma.[73,74] However, patients with *EML4-ALK* translocation have characteristics that distinguish them from patients with *EGFR* mutations. EML4-ALK-positive patients are younger than patients with *EGFR* mutations, with a median age of 52 years compared to 66 years.[74,75] Most reports show that *EML4-ALK* translocations are mutually exclusive of *EGFR* and *KRAS* mutations.[75–79]

In preclinical studies, the ALK kinase inhibitor TAE684 was shown to inhibit the growth of an EML4-ALK containing NSCLC cell line, both in vitro and in vivo.[6,80–83] These findings led to the testing of crizotinib, a small-molecule competitive inhibitor targeted to the ATP-binding pocket of the ALK TK. A phase 1 study of patients with EML4-ALK-positive stage III or IV NSCLC treated with crizotinib demonstrated an overall response rate of 60.8%, including three complete responses.[74] Median time to first documented objective response was 7.9 weeks. Median PFS was 9.7 months, and estimated overall survival at 6 and 12 months was 87.9% and 74.8%, respectively. These data show convincingly that ALK inhibition is effective in patients with NSCLC carrying an ALK rearrangement.

Similar to EGFR-targeted therapy, resistance to crizotinib in EML4-ALK-positive NSCLC has been reported. A patient on the original phase 1 study of crizotinib developed resistance after 5 months of therapy.[84] Deep sequencing of complementary DNA comparing *EML4-ALK* translocation before and after resistance identified two independent events in the resistant cancers: point mutation of residue 1156 from cytosine to tyrosine (C1156Y) and at residue 1196 from leucine to methionine (L1196M). In vitro, these new mutations decreased the fusion protein's sensitivity to crizotinib. Structural analysis of these mutants showed that C1156Y was close to the edge of the ATP-binding pocket. Interestingly, L1196M corresponds to the T790M gatekeeper mutation in EGFR, suggesting a common mechanism for the development of resistance in TKs. Doebele et al.[85] analyzed tissue obtained from patients with *ALK* gene rearranged NSCLC who showed radiological progression while on crizotinib, and found that mechanisms of resistance to crizotinib included secondary mutations in the TK domain of *ALK*, new onset *ALK* copy number gain, and outgrowth of either *EGFR*- or *KRAS*-mutant NSCLC. Novel inhibitors of ALK kinase are in development that can decrease ALK protein phosphorylation, induce apoptosis, and reduce cell survival in crizotinib-resistant EML4-ALK-mutant cell lines. These inhibitors represent potentially novel treatment options for patients with EML4-ALK fusion proteins that develop crizotinib resistance.

KRAS

In 1984, a human lung cancer specimen was found to contain an activating *KRAS* mutation that was not found in corresponding normal tissue.[86] Subsequently, investigators have found that 20% to 40% of NSCLC tumors harbor somatic *KRAS* mutations.[87–89] *RAS* gene mutations are found in approximately one-third of all human malignancies, with *KRAS* accounting for the majority of *RAS* mutations.[90] Whereas *KRAS* accounts for 90% of *RAS* mutations in lung adenocarcinomas, *KRAS* mutations are uncommon in lung squamous cell carcinomas.[20,21] *KRAS* mutations are more common in NSCLC tumors from smokers than from never smokers.[91] A meta-analysis of 53 studies on lung cancer assessing prognostic value of *RAS* mutation on survival found a worse survival for NSCLC with *KRAS* mutations, particularly in adenocarcinomas.[23] Because the RAS protein is a downstream effector of EGFR, *KRAS* mutations have been assessed as a primary mechanism of resistance to EGFR TKIs, and the presence of *KRAS* mutations predicts that a patient will not respond to EGFR TKIs.[92,93]

Due to the frequency of *KRAS* mutations in NSCLC, development of agents to inhibit mutated RAS proteins has been widely pursued. However, the search for RAS inhibitors has proven challenging. Whereas RAS binds GTP with picomolar affinities, the concentration of GTP in cells approaches micromolar levels.[94] Thus, targeting mutant RAS with nucleotide analogs is unlikely to be successful. Moreover, RAS does not have an accessible active site or pocket to which molecules are likely to bind, and the search for small molecules that bind to the surface of RAS has been unsuccessful. Current therapeutic approaches targeting RAS fall into three major categories: inhibition of RAS protein synthesis, alteration of RAS membrane localization, or inhibition of effector molecules downstream of mutant RAS. Although *RAS* antisense oligonucleotides can block protein synthesis in vitro, drug delivery issues have led to difficulty developing effective agents for use in humans. Considerable

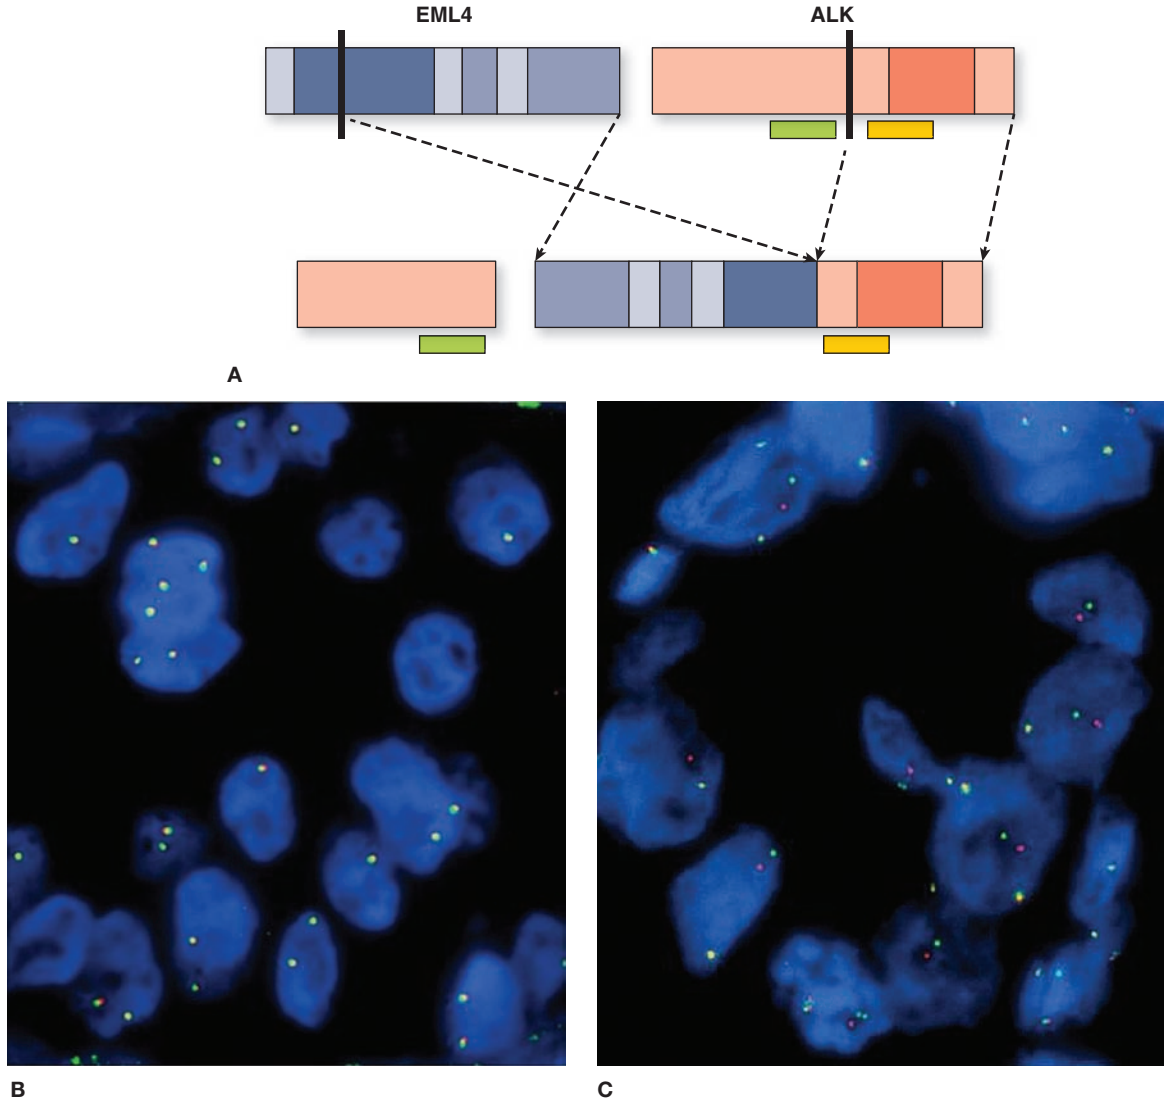

Figure 108-5 Schematic of echinoderm microtubule–associated protein-like 4 (EML4) translocation to the anaplastic lymphoma kinase (ALK) and its detection by fluorescence in situ hybridization (FISH). **A.** Both *EML4* (depicted in *blue*) and *ALK* (depicted in *red*) genes are located on the short arm of chromosome 2. A chromosomal inversion leads to *EML4-ALK* rearrangement and generation of a fusion protein. Green and orange bars represent DNA probes corresponding to the 5′ and 3′ fragments of the *ALK* gene. FISH detection of *EML4-ALK* rearrangement uses break-apart technology (ALK Break Apart FISH Probe, Abbott Molecular), which detects the adjacently located *EML4* and *ALK* genes in wild-type signals (**B,** adjacent green–orange probes) and break-apart signals caused by chromosomal inversion (**C,** separated green–orange). *(FISH images used with permission of Dr. Marileila Garcia, University of Colorado Anschutz Medical Campus.)*

research went into the development of farnesyl transferase inhibitors to alter RAS membrane localization such as farnesylthiosalicylic acid (Salirasib), which mimics the carboxy terminal amino acid of RAS and dislodges activated RAS from the membrane. However, farnesyl transferase inhibitors failed to demonstrate efficacy in clinical trials against tumors containing mutant KRAS, likely due to alternative pathways for farnesyl modification of KRAS. Two promising approaches to inhibiting KRAS that are currently under investigation involve the inhibition of downstream proteins RAF kinase and MEK. For example, sorafenib is a multikinase inhibitor of RAF, inhibiting wild-type B-RAF, oncogenic B-RAF, C-RAF, VEGF receptors 1 to 3, platelet-derived growth factor receptor-β, c-Kit, Fms-like TK 3, and rearranged during transfection protein (RET).[95] Unfortunately, clinical trials of sorafenib in unselected NSCLC patients have shown no clinical efficacy. However, in the BATTLE trial, sorafenib was active against tumors with mutated or wild-type KRAS, but had a worse disease control rate (compared with other study agents) in patients with *EGFR* mutations. MEK inhibitors are also being tested. A selective MEK inhibitor, AZD6244, showed clinical activity as second- or third-line therapy for patients with advanced NSCLC.[96] Based on preclinical data and clinical observations, multiple clinical trials are ongoing of AZD6244 for the treatment of *KRAS* and *B-RAF*-mutant NSCLC.

PI3K/AKT/mTOR

Investigators have hypothesized that PI3K signaling activity is induced by cigarette smoking before the development of lung cancer. In vitro, activation of the PI3K/AKT pathway by nicotine and a tobacco carcinogen in normal human bronchial and small airway epithelial cells has been shown to be an early event promoting cell survival.[97] Similarly, PI3K pathway activation has been identified in normal and premalignant bronchial airway epithelial cells of smokers with airway lesions.[98] Finally, inhibition of the PI3K/AKT pathway abrogates nicotine-triggered antiapoptotic

signals and blocks human lung cancer cell growth, suggesting that the PI3K/AKT pathway mediates the antiapoptotic effects of nicotine.[99,100]

AKT can be activated by amplification of upstream molecules of the PI3K pathway, directly through AKT overexpression, or overactivation of the AKT protein itself. Overexpression of PI3K and AKT has been demonstrated in primary NSCLC lung tumors and their metastases.[101] Moreover, genomic amplification of *PIK3CA* has been shown to occur in NSCLC tumors and preinvasive lesions.[102,103] However, mutations in the *PIK3CA* gene are rare in NSCLC.[103]

Targeting PI3K signaling with pharmacological inhibitors has become an important experimental therapeutic approach, and several direct PI3K inhibitors are under development. In phase I trials of patients with advanced solid tumors (including patients with advanced lung cancer), PI3K inhibitors decreased levels of phosphorylated AKT, MEK, and ERK in tumor biopsies.[104] Clinical trials of PI3K inhibitors in combination with platinum-based chemotherapy or with EGFR inhibitors are currently underway.

Another approach to targeting PI3K signaling has focused on inhibitors of its downstream target mTOR. In preclinical studies, the orally available mTOR inhibitor everolimus has been shown to have antitumor activity in both in vitro and in vivo models of NSCLC.[105] Upregulation of the PI3K/AKT/mTOR pathway is an important mechanism for resistance to chemotherapy targeting RTKs, such as EGFR TKI resistance in EGFR-mutant lung cancer and resistance to crizotinib in EML4-ALK-positive lung cancer. Thus, mTOR inhibition by everolimus is currently being studied as a therapeutic approach to overcome acquired resistance to RTK TKIs in patients with NSCLC.

MET

The MET pathway is activated in a number of human malignancies, including lung cancer. MET receptor overexpression by immunohistochemistry has been reported in NSCLC, in particular lung adenocarcinoma.[106,107] Using fluorescence in situ hybridization (FISH), the Lung Cancer Mutation Consortium reported that 4.1% of lung adenocarcinomas have *MET* gene amplification.[108] *MET* gene mutations have also been reported in human lung cancer, mainly clustered in the juxtamembrane domain, which enhance oncogenic signaling, tumorigenicity, cell motility, and migration.[109,110] MET kinase domain mutations are also somatically selected in metastatic tumors compared with the primary tumors.[111]

In preclinical studies, small-molecule MET inhibitors decrease cell viability and growth, and induce apoptosis in NSCLC cells via inhibition of MET/hepatocyte growth factor (HGF) signaling.[112–115] Although there are many MET-targeting agents under development, only one, tivantinib, is currently in phase 3 testing for advanced nonsquamous NSCLC. Tivantinib targets the MET RTK by locking the kinase in an inactive conformation. The combination of erlotinib and tivantinib prolonged PFS compared to erlotinib alone in a phase II trial of advanced NSCLC patients.[116] Interestingly, tivantinib combined with erlotinib inhibited tumor metastases in this phase II study, supporting the concept that the MET pathway plays an important role in human lung cancer metastasis.

Other MET agents include the multitargeted small-molecule kinase inhibitors cabozantinib, foretinib, and crizotinib. Since these agents also target kinases other than MET, it is difficult to determine the degree to which their efficacy is due to MET inhibition alone in lung cancer therapy. A recombinant, humanized, monoclonal antibody antagonist of the MET receptor (MetMAb) that inhibits HGF-induced MET signaling has been tested in a phase II study (ClinicalTrials.gov NCT00854308). The combination of erlotinib and MetMAb resulted in a statistically and clinically significant improvement in both PFS and overall survival compared to erlotinib alone in NSCLC patients with high MET protein expression by immunohistochemistry. Although MET-targeting agents show promise for the treatment of lung cancer, analysis of MET expression and amplification needs to be optimized and standardized.

Rb

Impairment of the Rb pathway has been shown to occur in almost all lung tumors.[117] Deregulation at any level of the Rb pathway mimics loss of Rb, leading to failure of cell cycle arrest and uncontrolled cellular proliferation. Rb protein expression varies with different lung cancer types. Whereas small cell lung cancer and large cell neuroendocrine carcinomas are characterized by loss of Rb expression, NSCLC is typically characterized by loss of p16 (an endogenous CDK inhibitor that prevents entry to cell cycle) or overexpression of CCND1 (an activator of CDK kinases that promotes entry into cell cycle), both of which lead to inactivation of the Rb pathway.[118–122]

In vitro, forced expression of p16 or constitutive activation of Rb potently inhibits cellular proliferation and can induce persistent cell cycle arrest in cancer cells.[123,124] However, reactivation of compromised tumor suppressors in the clinical setting has proven challenging. Inhibitors of DNA methylation or histone deacetylases can lead to activation of epigenetically silenced *p16*.[125] Unfortunately, these agents are cytotoxic and can lead to numerous other end points. CDK inhibitors, which prevent Rb phosphorylation, have also been studied as a way to reactivate Rb function in tumor cells, thereby inhibiting cell cycle entry.[126–128] However, these compounds are also relatively toxic due to effects on CDKs involved in normal transcriptional regulation. Finally, the optimal method to evaluate Rb pathway activity in biopsy specimens has not been standardized.

p53

Loss of heterozygosity in lung cancer cell lines and tumor samples at the location of the *p53* gene on chromosome 17p13 suggested that *p53* was likely to be involved in the pathogenesis of lung cancer. Genetic abnormality of the *p53* gene in lung cancers has been shown to be associated with poor prognosis and increased resistance to chemotherapy.[129,130] Among NSCLC tumor samples, the frequency of *p53* gene mutations is higher in squamous cell carcinomas than in adenocarcinomas.[131,132] Patients with tobacco-associated lung cancer have a higher frequency of *p53* gene mutations than patients who never smoked.[133–135] Lung cancer from smokers also shows a specific spectrum of *p53* gene mutations that is rarely observed in never smokers.[136] Although *p53* has been extensively studied as a prognostic marker in NSCLC, there is no evidence that *p53* status plays a role in the management of patients with NSCLC.

Aberrant p53 protein expression predicts clinical resistance to cisplatin-based chemotherapy in locally advanced NSCLC.[137] Similarly, tumors containing *p53* gene mutations are more resistant to ionizing radiation than those with wild-type *p53*. One strategy for therapeutic targeting of the p53 pathway is use of adenovirus-based gene therapy to introduce a copy of wild-type *p53* complementary DNA into tumor cells with mutant *p53*. In preclinical studies with lung cancer cell lines expressing mutant *p53*, *p53* replacement therapy improved responses to chemotherapy and radiotherapy.[138,139] *p53* gene therapy via bronchoscopic intratumoral injection is also being evaluated in clinical trials of patients with NSCLC.

FUTURE DIRECTIONS: EMERGING MOLECULAR MARKERS

Novel molecular alterations have been identified in a subset of NSCLC patients involving other RTKs, including ROS1, fibroblast growth factor receptor 1 (FGFR1), HER2, RET, and discoidin domain receptor 2

(DDR2).[23,140–155] These RTK mutations and gene amplifications represent excellent therapeutic targets. Inhibition of these pathways with a number of agents is being actively investigated, such as the use of the ALK inhibitor crizotinib for treatment of patients with advanced-stage NSCLC harboring *ROS1* gene rearrangements. Interestingly, *ROS1* gene fusions, *FGFR1* gene amplification, and *DDR2* gene mutations have been identified in squamous cell lung carcinomas, and kinase inhibitors directed against these molecules may represent targeted therapy for patients with squamous cell lung cancer.

Loss of heterozygosity involving several chromosome 3p regions accompanied by chromosome 3p deletions is frequently detected in NSCLC. These changes appear early in the pathogenesis of lung cancer and are found as clonal lesions in respiratory epithelium damaged by smoking. These 3p genetic alterations led to the discovery that the short arm of human chromosome 3 contains several TSGs. It has become apparent that genetic and epigenetic abnormalities of several genes residing in chromosome region 3p are important for the development of lung cancer. Tumor-acquired promoter DNA methylation is an important epigenetic mechanism for inactivation of these TSGs in lung cancer. However, which of the numerous candidate TSGs on chromosome 3p that have been identified play a key role in lung cancer pathogenesis remains unclear. Since epigenetic changes in chromosome 3p are early events in the development of lung cancer, improvements in the ability to detect acquired abnormalities of gene-specific methylation could lead to earlier diagnosis of lung cancer. Reversal of tumor-acquired promoter methylation of chromosome 3p TSGs with demethylating agents may also prove promising for the treatment of lung cancer.

MicroRNAs (miRNAs) are small noncoding, endogenous, single-stranded RNAs that regulate gene expression.[156] By regulating gene expression at the posttranscriptional level, miRNAs influence a wide variety of oncogenic pathways. Human miRNA genes are frequently located within or near chromosomal fragile sites, common breakpoints, minimal regions of loss of heterozygosity or amplification, and other genomic regions involved in cancers.[157] Accumulating evidence shows that miRNAs are profoundly deregulated in human NSCLC, and may serve as either oncogenes or tumor suppressors. These properties make miRNAs attractive targets in lung cancer therapy. However, one miRNA may target hundreds of messenger RNAs, which could lead to unpredictable side effects. Emerging data suggest that in addition to their potential use in NSCLC therapy, miRNAs may also be useful for classification and risk stratification of patients with NSCLC.[158–161] In the future, miRNAs may assist in patient selection for targeted therapy and form the basis for the development of novel therapeutics and/or early disease biomarkers.

CLINICAL PERSPECTIVE

Below are considered several important clinical aspects of molecular testing, including methods employed, the importance of adequate tissue sampling, initial studies, and acquired resistance to targeted therapy.

MOLECULAR TESTING METHODS

The identification of new genetic changes in patients with NSCLC signals a new era of personalized medicine for patients with lung cancer, in which it will be imperative to match the specific mutations of a patient's tumor with a specific therapy. An important issue to consider is which method will be used for molecular testing. Direct sequencing of PCR-amplified regions is the most common method of identifying *EGFR* and *KRAS* gene mutations. Testing for rearrangements and amplification is typically performed using FISH, but other approaches are possible, including chromogenic in situ hybridization and real-time quantitative PCR. In the future, as the cost of genome-wide screening decreases, methods such as comparative genomic hybridization and nucleic acid microarrays are likely to become commonly used techniques for molecular testing of lung cancer.

IMPORTANCE OF SATISFACTORY BIOPSIES FOR MOLECULAR TESTING OF LUNG CANCER

A satisfactory biopsy that allows for both histological characterization and mutation analysis is becoming increasingly important, both for the diagnosis of lung cancer and for molecular testing. The analytic sensitivity of an assay dictates the quantity of tumor that must be present in the tested sample. For FISH and immunohistochemical analysis, the Molecular Assays in NSCLC Working Group has recommended that a tumor tissue section should contain at least 1 to 2 mm^2 of tumor area to provide enough tumor cells for reliable interpretation.[162] FISH results should include hybridization signal counts from at least 100 to 200 tumor cells. Larger amounts of tissue may be required to ensure that sufficient DNA is obtained for mutational analysis. However, the minimum number of cells needed for mutational analysis by direct sequencing has not been determined.

Although surgical resection remains the gold standard, the techniques most commonly used for the diagnosis of lung cancer are fiberoptic bronchoscopy and CT-guided transthoracic needle aspiration. Because the majority of patients with NSCLC have advanced disease and are not candidates for surgery, nonsurgical biopsy procedures are preferable. For endobronchial tumors, four specimens have been shown to be adequate for optimal diagnostic yield.[163] However, biopsy specimens are generally small, averaging approximately 300 malignant cells in aggregate biopsies. In addition, not every biopsy contains tumor cells. Although four specimens may be sufficient to make a diagnosis of lung cancer, they may not provide enough tissue to perform a more detailed molecular analysis. Thus, some authors have recommended that six specimens be obtained from central, endobronchial lesions.[164]

Transbronchial needle aspiration (TBNA) of intrathoracic lymph nodes under endobronchial ultrasound (EBUS) has an increasingly important role in the diagnosis and staging of lung cancer. Several authors have described the successful use of EBUS-TBNA specimens for molecular analysis for *EGFR*, *EML4-ALK*, and *KRAS* gene mutations.[165–167] The concordance rate of mutation analysis between EBUS-TBNA cytological aspirates and histological samples obtained by surgical resection have been compared, and all mutations detected in the histological material of primary tumors were also identified in the cytological samples.[168] Three needle aspirates from each lymph node stage has been recommended for optimal diagnostic yield. However, the number of needle aspirates needed to obtain sufficient cellular material for molecular analysis has not been determined. Although bronchial washes and bronchial brushes can be useful for the diagnosis of lung cancer, they often will not provide enough tumor cells for molecular testing.

For patients with peripheral lung nodules or masses, transthoracic needle aspiration and biopsy are useful procedures. Core-needle biopsy specimens usually contain enough cellular material for molecular analysis (approximately 500 cells per core biopsy). In comparison, a transthoracic needle aspirate obtained using a 21-gauge needle yields approximately 100 cells.[169] Discordance between transthoracic needle aspiration and surgical pathology may be as high as 39%.[170]

INITIAL MOLECULAR TESTING

As we evolve toward a personalized pharmacological approach to the treatment of lung cancer, it will be necessary to determine the situations in which molecular testing of tumor specimens should be prioritized in addition to standard histological examination. At this time, molecular testing is not recommended for small cell or neuroendocrine lung cancers. However, all adenocarcinomas should undergo molecular testing when chemotherapy is being considered. Although mutation rates for driver mutations with

effective therapy are low in squamous cell carcinoma, there have been reports describing *EGFR* gene mutations in squamous cell carcinoma.[171–174] Automatically excluding all lesions classified as squamous cell carcinoma from molecular testing would potentially prevent these patients from receiving beneficial targeted therapies. Moreover, a small biopsy sample showing squamous morphology does not exclude the possibility of an adenocarcinomatous component elsewhere in the lesion. We therefore favor molecular testing of squamous cell carcinoma when chemotherapy is being considered, especially in younger patients with little or no smoking history. At a minimum, testing for *EGFR* mutation, *EML4-ALK* rearrangement, and *KRAS* mutation should be performed. Many argue that it is more cost effective to test only the patients most likely to have a specific mutation, such as *EGFR* in never smokers, and *KRAS* in patients being considered for EGFR TKI therapy, because the presence of *KRAS* mutations predicts lack of response to these agents. However, serial analysis for each mutation will take longer to define the cancer's mutational profile, thereby delaying treatment or potentially starting a harmful therapy. Thus, another challenge will be to develop testing platforms to simultaneously detect multiple somatic mutations. Newer technologies such as SNaPshot (Life Technologies, Carlsbad, CA) and MassARRAY (Sequenom, San Diego, CA) allow testing of multiple mutations at the same time and with little additional expense compared to testing for a single mutation. As more driver mutations are identified, we can expect overlapping mutations to be identified. In the future, it is likely that routine simultaneous testing of multiple markers will be conducted on all patients before initiation of therapy, irrespective of their clinical features.

■ ACQUIRED RESISTANCE TO TARGETED THERAPY

As described above, although most NSCLC patients with *EGFR* mutations or *ALK* rearrangements respond clinically and radiologically to targeted therapy, the disease always progresses due to acquired resistance. Thus, defining resistance to targeted therapy will be critical for determining whether treatment should be terminated. Jackman et al. proposed four criteria for the clinical definition of acquired resistance to EGFR TKIs: clinical exposure to an EGFR TKI, benefit from an EGFR TKI, evidence of disease progression by the RECIST criteria (an increase of 30% in summed maximum diameter or occurrence of new metastatic lesions), and lack of exposure to other drugs.[68] In patients who develop a growing lesion or new metastatic lesion on targeted therapy, we recommend that biopsies be obtained to confirm the presence of disease. Molecular testing should be repeated on these biopsy specimens to identify mechanisms of resistance, such as T790M mutations in the *EGFR* gene, and to direct further therapy. As we learn more about the mechanisms of resistance to targeted therapy, we will be able to provide alternative therapies to patients who have disease progression.

CONCLUSIONS

The past decade has witnessed dramatic success with personalized cancer therapy, and this paradigm shift has led to tremendous improvements in clinical outcomes in patients with molecularly defined subsets of lung tumors. Notably, the identification of a variety of molecular and genetic alternations in NSCLC has provided the opportunity for targeted therapy, such as EGFR TKIs for activating *EGFR* mutations in NSCLC, and the ALK inhibitor crizotinib for NSCLC harboring *ALK* fusions. The discovery of novel "druggable" driver mutations can lead to swift development of inhibitors of these targets and improved rational combinations of drugs. Despite initial responses to molecular-targeted therapy, however, the development of secondary resistance inevitably leads to treatment failure. Irreversible TKIs, combined approaches using multiple kinase inhibition, and vertical inhibition by combination of small molecules and antibodies are promising approaches to overcoming secondary drug resistance. A greater understanding of tumor resistance mechanisms will also provide additional therapeutic opportunities, leading to improved responses with targeted therapy.

CHAPTER 109

Epidemiology of Lung Cancer

Charles S. Dela Cruz
Lynn T. Tanoue
Richard A. Matthay

THE EPIDEMIOLOGY OF LUNG CANCER

Lung cancer is the leading cause of cancer death in the United States and worldwide. Siegel et al.[1] estimated a total of 246,210 new lung cancer cases and 163,890 deaths from lung cancer in the United States in 2013.[1,2] These statistics reflect data ending in 2009, and likely underestimate the current lung cancer burden.

In the United States, more Americans die of lung cancer every year than from prostate, breast, and colon cancer combined.[1] Cancer of the lung and bronchus ranked second in cancer incidence in both sexes, with an estimated 118,080 new cases in males (14% of all new cancers) and 110,110 in females (14% of all new cancers).[1] The age-adjusted incidence rate of lung cancer was 62 per 100,000 men and women per year in the United States, with the incidence rate much higher in men than in women (75.2 vs. 52.3 per 100,000).[3] Lung cancer ranked first in both sexes in the number of estimated deaths yearly[1] (87,260 or 28% of all cancer deaths for males and 72,220 or 26% of all cancer deaths for females) (Fig. 109-1). The current 5-year survival rate in the United States for lung cancer is 17%; while this rate has actually increased over the past few decades, it lags behind survival advances in other common malignancies.[1]

Globally, lung cancer has been the most common cancer since 1985, both in terms of incidence and mortality rate. Worldwide, lung cancer is the largest contributor to new cancer diagnoses (1,350,000 new cases; 12.4% of total new cancer cases) and to death from cancer (1,180,000 deaths; 17.6% of total cancer deaths).[2] Worldwide, it was also the most commonly diagnosed cancer and

Estimated new cases

Males				Females		
Prostate	238,590	28%		Breast	232,340	29%
Lung & bronchus	118,080	14%		Lung & bronchus	110,110	14%
Colorectum	73,680	9%		Colorectum	69,140	9%
Urinary bladder	54,610	6%		Uterine corpus	49,560	6%
Melanoma of the skin	45,060	5%		Thyroid	45,310	6%
Kidney & renal pelvis	40,430	5%		Non-Hodgkin lymphoma	32,140	4%
Non-Hodgkin lymphoma	37,600	4%		Melanoma of the skin	31,630	4%
Oral cavity & pharynx	29,620	3%		Kidney & renal pelvis	24,720	3%
Leukemia	27,880	3%		Pancreas	22,480	3%
Pancreas	22,740	3%		Ovary	22,240	3%

Figure 109-1 Ten leading cancer types for the estimated new cancer cases and deaths categorized by sex. *(Reproduced with permission from Siegel R, Naishadham D, Jemal A. Cancer statistics, 2013. CA Cancer J Clin. 2013;63(1):11–30.)*

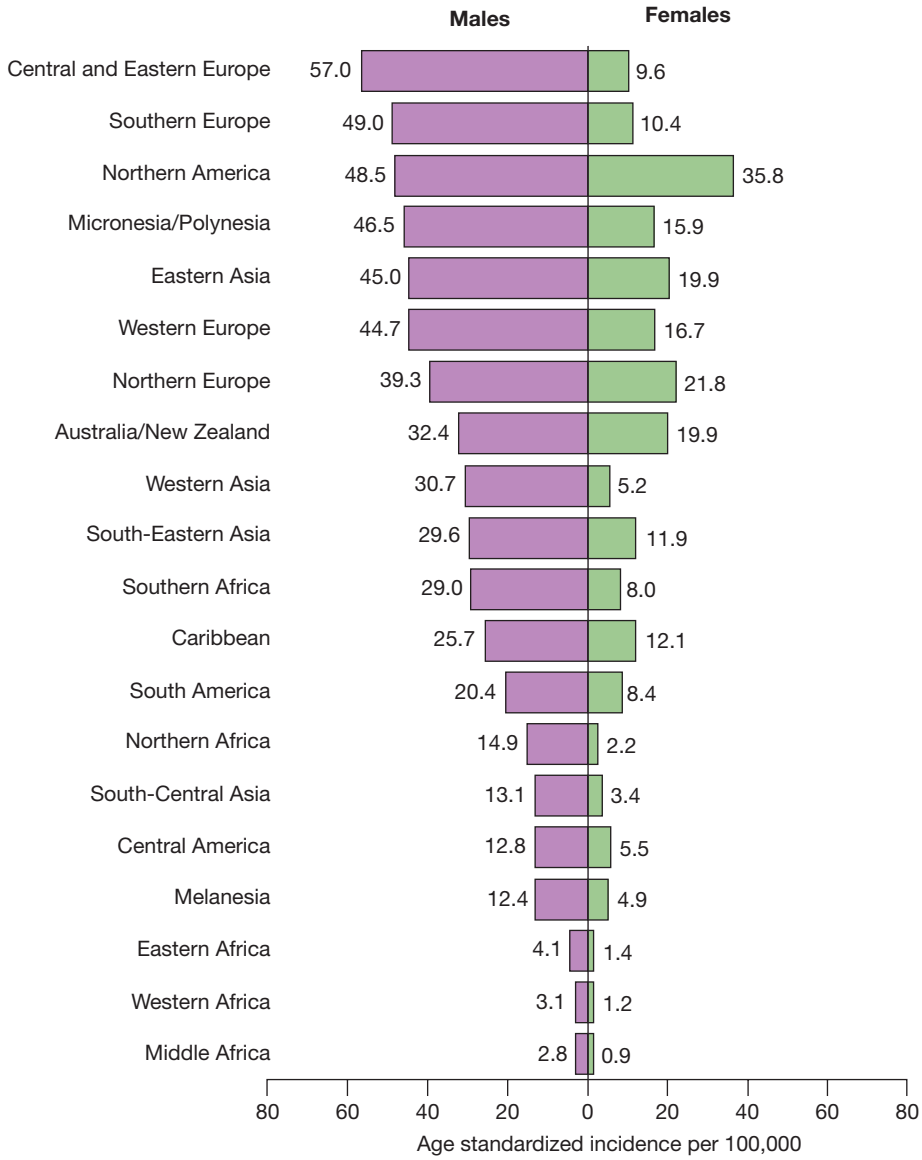

Figure 109-2 Age-standardized lung cancer incidence and mortality rates by sex and world area. Lung cancer incidence by sex and world area. Rates are standardized to the world standard population, in 2008. *(Adapted with permission from Jemal A, Bray F, Center MM, et al. Global cancer statistics. CA Cancer J Clin. 2011;61(2):69–90.)*

the leading cause of cancer death in males in 2008.[2] For females, lung cancer was the fourth most commonly diagnosed cancer and the second leading cause of cancer death. Lung cancer incidence and mortality rates are highest in the United States and the developed countries, and relatively lower in Central America and most of Africa (Fig. 109-2). However, there has been a large relative increase in the numbers of cases of lung cancer in developing countries. Almost half (49.9%) of the cases now occur in developing countries, whereas in 1980, 69% of cases were in developed countries. The estimated numbers of lung cancer cases worldwide has increased by 51% since 1985 (a 44% increase in men and a 76% increase in women).[2] The World Health Organization estimates that lung cancer deaths worldwide will continue to rise, largely as a result of an increase in global tobacco use, especially in Asia.[2]

Lung cancer incidence in males in the United States has been decreasing since the early 1980s (Fig. 109-3). The incidence and mortality rates for lung cancer tend to mirror one another because most patients diagnosed with lung cancer eventually die of the disease. Siegel et al.[4] noted decreases in death rates from lung cancer in men by 2.0% per year from 1994 to 2006 (Fig. 109-4). In women, lung cancer death rates instead increased by 0.3% per year from 1995 to 2005; however, more recent data from 2003 to 2006 show a decline of 0.9% per year (Fig. 109-4). Because of the change in lung cancer incidence in women, recent figures show that lung cancer death rates have decreased in women for the first time, more than a decade after the beginning of the decreasing trend in men.[5] The difference between the sexes in the onset of decline in lung cancer may be attributable to the fact that cigarette smoking in women peaked two decades later than in men. Lung cancer mortality rates thus appear to be reaching a plateau for women, which is an encouraging change from the steep rise in the 1970s.

The Surveillance, Epidemiology, and End Results (SEER) data from 2004 to 2008 report the median age at diagnosis for cancer of the lung and bronchus to be 71 years. No cases were diagnosed in patients younger than 20 years.[3] Approximately 0.2% of cases were diagnosed in patients between age 20 and 34 years; 1.5% between 35 and 44 years; 8.8% between 45 and 54 years; 20.9% between 55 and 64 years; 31.1% between 65 and 74 years; 29% between 75 and 84 years; and 8.3% at 85 years and older.

There are two broad categories of lung cancer: small cell lung cancer (SCLC) and nonsmall cell lung cancer (NSCLC). SCLC, which is a highly malignant tumor derived from cells exhibiting neuroendocrine characteristics, accounts for 15% of lung cancer cases. NSCLC, which accounts for the remaining 85% of cases, is further divided into three major pathologic subtypes: adenocarcinoma, squamous cell carcinoma, and large cell carcinoma. Adenocarcinoma by itself accounts for 38.5% of all lung cancer cases, with squamous cell carcinoma accounting for 20%, and large cell carcinoma accounting for 2.9%.[3,6] In the past several decades, the incidence of adenocarcinoma has increased greatly, and it has replaced squamous cell carcinoma as the most prevalent type of NSCLC.

Despite the availability of new diagnostic and genetic technologies, advancements in surgical techniques, and the development of new biologic treatments, the overall 5-year survival rate for lung cancer in the United States remains at a dismal 17%.[7] The 5-year survival rate in Europe, China, and developing countries is estimated at only 8.9%.[2] Lung cancer stage is often advanced at the time of diagnosis; 30% to 40% of cases of NSCLC and 60% of SCLC are stage IV at presentation. Patients with stage I disease at diagnosis have a 5-year survival rate of approximately 50%. In stark contrast, patients with advanced stage disease and distant metastasis at diagnosis have a dismal 5-year survival rate of 1% to 2%, which argues strongly for the need for better screening methods to detect early stage cancers.[8,9]

ETIOLOGY OF LUNG CANCER —TOBACCO SMOKING AND LUNG CANCER

Tobacco smoking is the most important modifiable risk factor for lung cancer. It has been estimated that up to 20% of all cancer deaths worldwide could be prevented by the elimination of tobacco smoking.[10] More than 80% of lung cancers develop in smokers, and one in nine smokers develops lung cancer.[11] The cumulative lung cancer risk among lifelong heavy smokers can be as high as 30% compared with a lifetime risk of less than 1% in nonsmokers.[12,13] Smoking cessation, especially at a younger age, is associated with many health benefits including lowering the risk of lung cancer; cessation before the age of 40 years reduces the risk of death associated with continued smoking by about 90%.[14] Lung cancer risk is proportional to the magnitude of cigarette consumption, as factors such as the number of packs per day smoking, the age of onset of smoking, the degree of inhalation, the tar and nicotine content of cigarettes, and use of unfiltered cigarettes are important.[15,16] Individual susceptibility, which is a function of environmental factors and genetic predisposition, is a factor in carcinogenesis.

In 1912, Adler in an extensive review of autopsy reports from hospitals in the United States and western Europe identified 374 cases of primary lung cancer, representing <0.5% of all cancer cases.[17] He concluded at the time that "primary malignant neoplasms of the lung are among the rarest forms of disease." In 1920, lung cancer constituted only 1% of all malignancies in the United States, but over the next several decades, the incidence of lung cancer increased disproportionately to the incidence of all other cancers.[18] The first report linking cigarette smoking with an increased risk of premature death was in 1938 when Pearl showed that cigarette smoking had a dose-related adverse effect on longevity.[19] The finding that tar (the total particulate matter in cigarette smoke after water and nicotine are removed) applied to the skin of animals produced skin cancer raised concern that inhalation of tar products could be an important etiologic factor in lung cancer. Subsequent studies in patients and experimental animals demonstrated that tar from the burning of tobacco was carcinogenic.[20] Ochsner and DeBakey[21] stated in their 1941 review of lung carcinoma that "it is our definite conviction that the increase in the incidence of pulmonary carcinoma is due largely to the increase in smoking."

In 1950, two large landmark epidemiologic studies established the causal role of tobacco smoking in bronchogenic carcinoma.[22,23] In the United Kingdom, Doll and Hill described an association between carcinoma of the lung and cigarette smoking, and the effect of the number of cigarettes smoked on the development of lung cancer.[19,22,24] In the United States, Wynder and Graham examined 605 cases of lung cancer in men and found that 96.5% of lung cancers were in men who were moderate to heavy smokers for many years.[19] They concluded that (1) the excessive and prolonged use of tobacco was an important etiologic factor in lung cancer; (2) lung cancer in nonsmokers was rare; and (3) the onset of carcinoma could occur 10 years or more after the cessation of smoking.

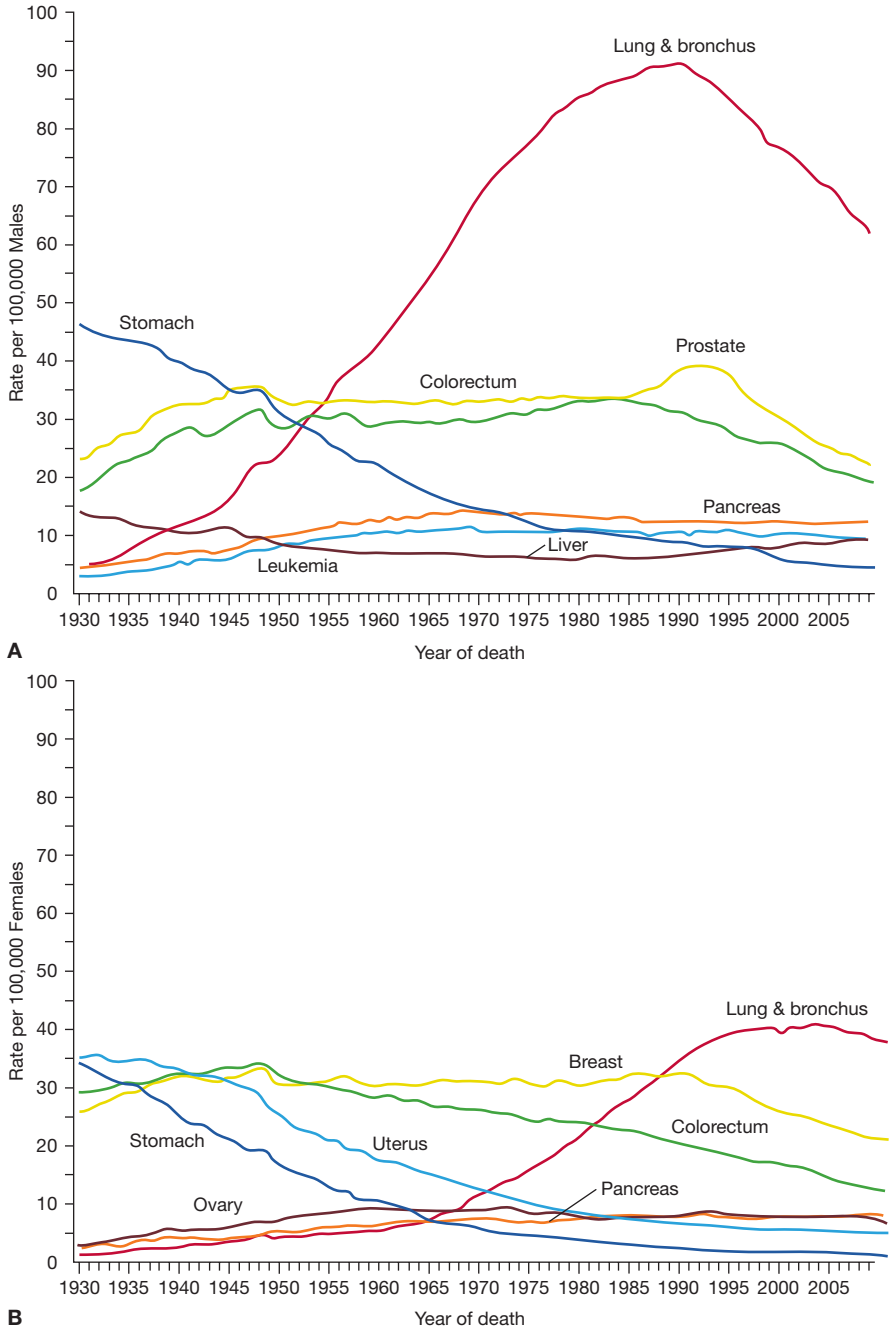

Figure 109-4 Death rates trend for selected cancers including cancer of the lung and bronchus in the United States. Cancer statistics, 2013. CA Cancer J Clin. 2013;63(1):11–30.)*

In 1964, the United States Surgeon General issued a landmark report on smoking and its effects on health that included a number of key observations and conclusions. First, cigarette smoking was associated with a 70% increase in the age-specific death rates of men and a lesser increase in the death rates of women. Second, cigarette smoking was causally related to lung cancer in men. The magnitude of the effect of cigarette smoking far outweighed all other factors leading to lung cancer. The risk for lung cancer increased with the duration of smoking and the number of cigarettes smoked per day. The report estimated that the average male smoker had an approximately 10-fold risk for lung cancer, whereas heavy smokers had at least a 20-fold risk. At that time, the relative risk for lung cancer death among smokers was five times as high for men than for women; however, these differences between men and women are no longer as evident.[25] Third, cigarette smoking was believed to be much more important than occupational exposures in the causation of lung cancer in the general population. Fourth, cigarette smoking was the most important cause of chronic bronchitis in the United States. Finally, male cigarette smokers had a higher death rate from coronary artery disease than male nonsmokers. The report concluded that: "Cigarette smoking is a health hazard of sufficient importance in the United States to warrant appropriate remedial action." Despite efforts to curb tobacco smoking, there are approximately 1.1 billion smokers worldwide, and if the current trends continue, that number will increase to 1.9 billion by the year of 2025.[26] Wynder and Graham estimated that the average American adult smoked fewer than 100 cigarettes per year in 1900.[27] Fifty years later, the number smoked had risen to approximately 3500 cigarettes per person per year and reached a maximum of approximately 4400 cigarettes per person per year in the mid-1960s (Fig. 109-5).[28] Since the 1964 publication of the Surgeon General's first report on the health consequences of smoking, yearly per capita consumption of cigarettes has been declining in the United States (Fig. 109-5).[28] As of 2008, it is estimated that 20.6% of American adults over age 18 years old (46.0 million) are habitual smokers, an improvement from 24.1% a decade previously.[29,30] Of these, 79.8% (36.7 million) smoke every day and 20.2% (9.3 million) smoke some days. Unfortunately, the rate of decline in smoking prevalence has slowed recently, with 19.5% of American adults habitually smoking in 2009.[31] More than 80% of adult smokers begin before the age of 18 years. In 2009, one in five American high school students reported smoking cigarettes in the preceding 30 days.[32] Several factors identify populations more likely to smoke. Prevalence is higher in men (23.5%) than in women (17.9%). Socioeconomic influences contribute. Among persons below the federal poverty level, the prevalence of smoking is 31.1%. In the population of adults older than 25 years, the prevalence of smoking among persons with educational status less than a high school diploma is 28.5% compared with 5.6% among persons with a graduate degree.[30] There are also regional differences in the United States, with lowest smoking prevalence in western states (16.4%) compared to southern (21.8%) and midwest states (23.1%).[29]

Cigarette smoke is a complex aerosol composed of more than 4000 gaseous and particulate compounds. *Mainstream smoke* is produced by inhalation of air through the cigarette and is the primary source of smoke exposure for the smoker. *Sidestream smoke* is produced from smoldering of the cigarette between puffs and is the major source of environmental tobacco smoke (ETS). The primary determinant of tobacco addiction is nicotine; exposure to tar appears to be a major

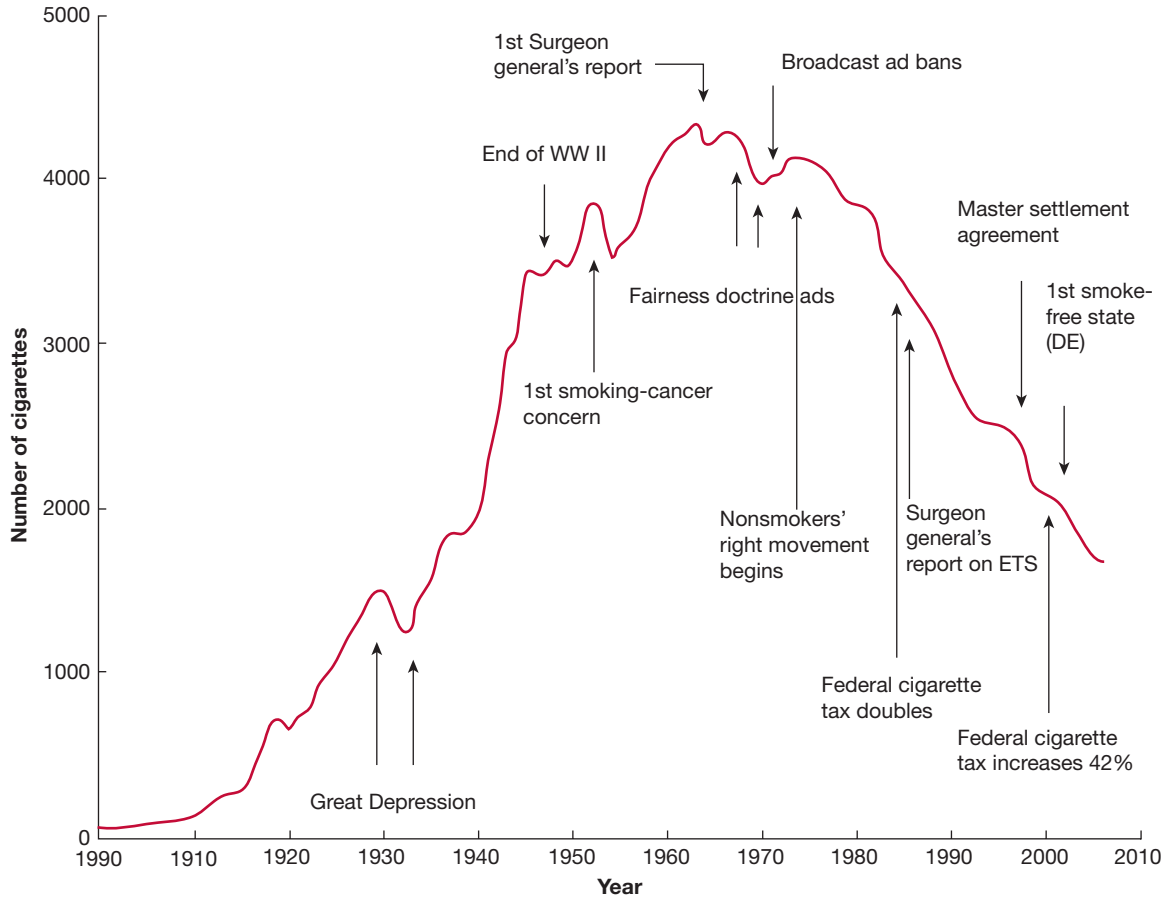

Figure 109-5 The adult per capita cigarette consumption in the United States, 1900 to 2006, with historical highlights. *(Adapted with permission from Warner KE, Mendez D. Tobacco control policy in developed countries: yesterday, today, and tomorrow. Nicotine Tob Res. 2010;12(9):876–887.)*

component of lung cancer risk. The nicotine and tar composition of mainstream smoke can vary greatly depending on the intensity of inhalation by the smoker. Although the use of filter tips decreases the amount of nicotine and tar in mainstream smoke, the effect of filter tips also varies in relation to differences in the compression of the filter tips by lips or fingers and the depth of inhalation of the smoker.

The primary factor determining intensity of cigarette use is the nicotine dependence of the smoker, and although cigarettes now contain less nicotine and tar than in the past, smokers tend to take more puffs per minute and inhale more deeply to satisfy their nicotine need. Low-yield filtered cigarettes have been hypothesized to contribute to the increase in the incidence of adenocarcinoma of the lung.[33] The nicotine-addicted smoker smokes low-yield cigarettes far more intensively than nonfiltered higher-yield cigarettes. With deeper inhalation, higher-order bronchi in the peripheral lung, which lack protective epithelium, are exposed to carcinogen-containing smoke, rather than simply the major bronchi.

The International Agency for Research on Cancer (IARC) has identified at least 50 carcinogens in tobacco smoke.[34,35] The agents that appear to be of particular concern in lung carcinoma are the tobacco-specific N-nitrosamines (TSNAs) formed by nitrosation of nicotine during tobacco processing and during smoking. Eight TSNAs have been described, including 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), which is known to be an important inducer of lung cancer. Mainstream smoke contains other potential carcinogens, including polycyclic aromatic hydrocarbons (PAHs), aromatic amines, and other organic and inorganic compounds such as benzene, vinyl chloride, arsenic, and chromium. The PAHs and TSNAs require metabolic activation to become carcinogenic. Metabolic detoxification of these compounds can also occur, and the balance between activation and detoxification likely affects individual cancer risk.

Tobacco carcinogens such as NNK can bind to DNA and form DNA adducts. Failure of the normal DNA repair mechanisms to remove DNA adducts can lead to permanent mutations. NNK can mediate signaling pathway activation that includes modulation of critical oncogenes and tumor-suppressor genes that promote uncontrolled cellular proliferation and tumorigenesis.[36] NNK is associated with DNA mutations resulting in the activation of K-*ras* oncogenes.[37,38] K-*ras* oncogene activation has been detected in 24% of human lung adenocarcinomas,[39] and is present in adenocarcinoma of the lung in ex-smokers, suggesting that such mutations persist even after smoking cessation.[40] This finding may explain the persistent elevation in lung cancer risk in ex-smokers even years after discontinuing cigarette use. Similarly, benzo(a)pyrene metabolite, a specific chemical constituent of tobacco smoke, can damage various *p53* tumor-suppressor gene loci that are known to be abnormal in approximately 60% of primary lung cancer cases.[41] Related PAHs in tobacco smoke can also target other lung cancer mutational hot spots.[42]

OTHER TYPES OF SMOKING

Cigar smoking and pipe smoking have been associated with increased risk for lung cancer, although seemingly not as great a risk as with cigarette smoking. The tobacco content of cigars can vary from 1 g to 20 g. Smoking five cigars a day on average is equivalent to smoking one pack of cigarettes a day. Cigar smokers have a

relative risk of lung cancer of 2.1 to 5.1 compared to nonsmokers; men who smoked five or more cigars a day have the greatest risk.[43] The risk for lung cancer in pipe smokers is similar to that in cigar smokers.[44,45] The effects of smoking marijuana and cocaine have not been extensively studied, and an association has not been fully established between such inhalant drug use and lung cancer. There have, however, been reports of increased risk for lung cancer in marijuana smokers; and metaplastic, histologic, and molecular changes similar to premalignant alterations have been detected in the bronchial epithelium in habitual smokers of marijuana or cocaine.[46,47]

NEVER SMOKERS

Never smokers are defined as persons who have smoked fewer than 100 cigarettes in their lifetime, including lifetime nonsmokers. An estimated 15% of lung cancers in men and up to 53% in women worldwide occur in never smokers, accounting for 25% of all lung cancer cases.[48] Lung cancer in never smokers considered as a distinct group would rank as the seventh most common cause of cancer death worldwide, ahead of cervical, pancreatic, and prostate cancer.[49] In countries in South Asia, up to 80% of women with lung cancer are never smokers.[50] In the United States, one study estimated that 19% of lung cancers in women and 9% in men occur in never smokers.[51] The age-adjusted rate for lung cancer in never smokers (aged 40–79 years) ranges from 11.2 to 13.7 per 100,000 person-years for men and from 15.2 to 20.8 per 100,000 person-years for women. The rates are 12 to 30 times higher in current smokers of the same age group.[52]

Adenocarcinoma of the lung is more common than squamous cell carcinoma in never smokers,[50] and recent data suggests that adenocarcinoma is also becoming more common in smokers.[53,54] Risk factors considered to be important for never smokers include environmental tobacco exposure ("secondhand smoke"); environmental exposures to carcinogens such as radon, outdoor and indoor air pollution, asbestos, and arsenic; a history of lung disease including interstitial lung disease; and genetic factors.[55] A population-based case-control study in Canada found that occupational exposures, history of lung disease, and family history of early-onset cancer were important risk factors for lung cancer among never smokers.[56] In this study, potential environmental sources of increased risk included exposure to solvents, paints or thinners, welding equipment, and smoke, soot, or exhaust. Other studies have implicated a genetic role in lung cancer in light of associations between lung cancer in never smokers and a family history of lung cancer.[57–59] Genes implicated include the epidermal growth factor receptor (EGFR) gene, the human repair gene (*hMSH2*), and various cytochrome P450, and glutathione-*S*-transferase (GST) enzymes. A case-control study following 2400 relatives of 316 never smokers with lung cancer cases showed a 25% excess risk for cancer in first-degree relatives.[58]

The investigation threshold in symptomatic never smokers might be higher than in smokers, leading to diagnosis at later stages in never smokers.[60] Despite this potential delayed diagnosis and later presentation of lung cancer in never smokers, the survival rate for never smokers is better than for smokers, independent of stage of disease, treatment received, and presence of comorbidities.[61–63] A multivariate analysis of lung adenocarcinoma found that never smoking status was an independent predictor of improved survival (23% overall 5-year survival rate for never smokers; 16% for current smokers).[61] Such findings have suggested that the cancer in never smokers may display a distinct biologic behavior and natural history. Microarray gene profiling studies have found that lung adenocarcinomas are heterogeneous, and the profiles of cancer in smokers and never smokers are quite different.[64,65] In 2010, the first genome-wide association study (GWAS) reported genetic variations in never smoking females in chromosome 13q31.3 that altered the expression of glypican 5 (*GPC5*), a heparin sulfate proteoglycan with many known functions involving cell growth and differentiation and tissue responses.[66] Another GWAS, focusing on lung adenocarcinomas in female Han Chinese never smokers in Taiwan, identified genetic variation in the *CLPTM1L-TERT* locus of chromosome 5p15.33 to be associated with risk for lung cancer in this population.[67] This 5p15.33 chromosome contains two genes implicated in carcinogenesis, telomerase reverse transcriptase (*TERT*) and cleft lip and palate transmembrane 1-like (*CLPTM1L*).

GENETIC FACTORS

The genetic component of lung cancer relates to host susceptibility with or without exposure to cigarette smoke, the development of certain types of lung cancer, and the patient's responsiveness to biologic therapies. A lung cancer risk prediction model developed by Spitz et al. incorporated such variables as smoking history, exposure to ETS, occupational exposures to dusts and to asbestos, and family history of cancer.[68,69] Their analysis showed the influence of family history of cancer on the risk for lung cancer in never smokers, former smokers, and current smokers (Table 109-1). Cassidy et al.[70] also highlighted a significantly increased risk for lung cancer specifically for persons with a family history of early-onset lung cancer (<60 years of age) (Table 109-2).

TABLE 109-1 Multivariable Logistic Model for Lung Cancer by Smoking Status

Risk Factor	*P* Value	OR (95% CI)
Never smoker

Recent reviews have examined the molecular epidemiology and biology of lung cancer, focusing on genetic markers of host susceptibility to lung carcinogens and their clinical implications.[71,72] The susceptibility genetic factors include high-penetrance low-frequency genes, low-penetrance high-frequency genes, and acquired epigenetic polymorphisms. There are associations of lung cancer with rare Mendelian cancer syndromes such as Bloom and Werner syndromes. Familial aggregation studies have demonstrated a hereditary component to the risk for lung cancer and have been used to discover high-penetrance, low-frequency genes. There is a twofold increased risk for lung cancer in persons with a family history of lung cancer, with an increased risk also present in nonsmokers.[73] There have also been numerous studies on candidate susceptibility genes that are of low penetrance and high frequency. The approach has been to target genes known to be involved in the absorption, metabolism, and accumulation of tobacco or other carcinogens in lung tissue. For example, genetic polymorphisms encoding enzymes involved in the activation and conjugation of tobacco smoke compounds, including PAHs, TSNAs, and aromatic amines have been widely studied. Some of the frequently studied enzymes in this system include CYP1A1, the GSTs, microsomal epoxide hydrolase 1 (mEH/EPHX1), myeloperoxidase (MPO), and NAD(P)H quinine oxidoreductase 1 (NQO1). A GWAS of tagged single nucleotide polymorphisms (SNPs) in histologically confirmed NSCLC was recently performed to identify common low-penetrance alleles that influence lung cancer risk. This study identified a susceptibility locus that contains the nicotinic acetylcholine receptor genes.[74] Polymorphisms in genes involved in DNA repair enzymes active in base excision repair (XRCC1, OGG1), nucleotide excision repair (ERCC1, XPD, XPA), and double-strand break repair (XRCC3) and different mismatch repair pathways have been studied as they relate to lung cancer risks.[75,76] Chronic inflammation in response to repetitive tobacco exposure has been theorized to be involved in lung tumorigenesis.[77] Genes encoding for the interleukins (IL-1, IL-6, IL-8) or the cyclooxygenase enzymes (COX2) involved in inflammation, or the metalloproteases (MMP-1, -2, -3, -12) involved in repair during inflammation, and more recently NFKB1 have been associated with lung cancer risk.[78] Various cell cycle–related genes have also been implicated in lung cancer susceptibility, including the tumor-suppressor genes *p53* and *p73*, mouse double minute 2 (*MDM2*), and the apoptosis genes encoding FAS and FASL.[79,80] Acquired or epigenetic changes to DNA chromosome can also lead to increased lung cancer susceptibility. These events include changes such as DNA methylation, histone deacetylation, and phosphorylation, all of which can affect gene expression.[81] Despite numerous genetic association studies, the specific genes responsible for the enhanced risk for lung cancer have not been identified. Collaborative efforts such as the Genetic Susceptibility to Environmental Carcinogens and the International Lung Cancer Consortium are attempting to pool findings to achieve greater study sample sizes.[82]

GENDER

In the late 1980s, lung cancer surpassed breast cancer as the leading cause of cancer death in women in the United States. At present, nearly twice as many American women die annually of lung cancer than succumb to breast cancer.[4] Since 1950 there has been a more than 600% increase in the lung cancer mortality rate in women. In the United States, the cigarette smoking rate for women increased during the period from 1930 to 1960; this increase was followed by an increase in lung cancer in women starting around 1960.[83,84] Smoking prevalence is higher among men (23.1%) than women (18.3%), but the difference is narrowing.[29] In 2009, lung cancer death rates for women declined for the first time in four decades, along with a decrease in the overall cancer death rate.[5] This trend varies geographically; for example, the rate of lung cancer is increasing among women in southern and midwestern states.[85]

Whether women are more or less susceptible than men to the carcinogenic effects of cigarette smoke is controversial. While lung cancer in never smoking women is more common than in never smoking men, up to 80% of lung cancer cases in women are related to smoking.[82] A recent study from the U.S. National Health Interview Survey showed a staggeringly high hazard ratio for lung cancer mortality of 17.8 for female smokers, compared to 14.6 for male smokers.[14] Recent analysis of the SEER data from 1997 to 2006 showed that the lung cancer mortality rate is 74.08 per 100,000 man-years compared to 40.81 per 100,000 woman-years.[86] However, other studies have suggested that women may be actually more vulnerable to carcinogens in tobacco smoke than men.[87–90] A study using the American Health Foundation data found that the odds ratio for the major lung cancer types has been consistently higher for women than for men at every level of exposure to cigarette smoke.[90] The dose-response odds ratios for lung cancer in women were 1.2- to 1.7-fold higher than in men. A Canadian case-control study of male–female differences in lung cancer covering the period 1981 to 1985 showed that with a history of 40 pack-years of cigarette smoking relative to lifelong nonsmoking, the odds ratio for women developing lung cancer was 27.9 versus 9.6 in men. The gender differences in susceptibility may be related to differences in nicotine metabolism and in metabolic activation or detoxification of lung carcinogens; women have higher levels of DNA adducts than men, which may result in greater susceptibility to carcinogens.[91] Hormonal factors may also play a role in susceptibility. A case-control study showed that estrogen replacement therapy was significantly associated with an increased risk for adenocarcinoma (odds ratio 1.7), and the combination of cigarette smoking and estrogen replacement increased that risk substantially (odds ratio

32.4).[92] Conversely, early menopause (age 40 years or younger) was associated with a decreased risk for adenocarcinoma (odds ratio 0.3). More recent large randomized studies suggest that the use of hormonal therapies such as estrogen and progestin may be associated with an increased risk of lung cancer in women.[93]

A separate but related issue is whether cigarette smoking may be associated with a higher risk of nonmalignant lung disease in women than in men. Neither the British Physicians Study in the United Kingdom[94,95] nor the Lung Health Study in the United States[96] found gender differences in mortality from smoking-related chronic obstructive pulmonary disease (COPD). However, other studies, including a report by Chen et al.,[97] suggest that cigarette smoking may be more harmful to pulmonary function in women compared with men. In this study, changes in forced expiratory volume in 1 second (FEV_1) and maximal midexpiratory flow rate increased with increasing pack-years more rapidly in women smokers than in their male counterparts. These changes were independent of age, height, and weight. Beck and colleagues in a study of 4690 Caucasians found that for a given level of smoking, women had greater decline in FEV_1 and maximal expiratory flow at 25% and 50% of vital capacity at a younger age (15–24 years) than men (40–45 years).[98] Because smokers with spirometric evidence of airway obstruction are at higher risk for lung cancer, the suggestion that women have increased susceptibility to smoking-induced airway disease may be important in the consideration of their risk for lung cancer.[98]

Finally, it also appears that lung cancer is more common in nonsmoking women than in nonsmoking men. For example, in never smokers, the age-adjusted incidence rate of lung cancer is much higher for women than men (14.4–20.8 per 100,000 person-years for women, compared with 4.8–13.7 per 100,000 person-years for men).[51] The proportion of never smoking lung cancer patients was more than twice as high for women than for men in a case-control study.[90]

RACE AND ETHNICITY

Race is a complex variable that often has a strong socioeconomic association. However, notable racial differences in disease states can shed light on the specific issues of a particular subpopulation. In general, the incidence of lung cancer is substantially higher among blacks, Native Hawaiians, and other Polynesians, and lower among Japanese Americans and Hispanics than among whites in the United States.[99] These differences initially have been attributed to the variations in cigarette smoking pattern among the different ethnic and racial groups. Recent smoking data show that among the different groups, Asians (9.9%) had the lowest smoking prevalence in the United States, whereas American Indians and Alaska Natives (32.4%) had significantly higher prevalence than the other groups.[29] Smoking prevalence among whites (22%) and blacks (21.3%) was significantly higher than among Hispanics (15.8%). Black smokers have higher rates of lung cancer than white smokers, even though only 8% of black smokers smoked at least 25 cigarettes per day compared with 28% of white smokers.[29] Native Hawaiians had higher rates of lung cancer than whites and Asians despite having similar smoking habits.[29] The relative risk for lung cancer among subjects smoking less than 20 cigarettes per day were 0.21 to 0.39 for Japanese Americans and Latinos, and 0.45 to 0.57 for whites as compared with black Americans.[29] However, the differences in lung cancer risks were not significant among all racial groups who exceeded 30 cigarettes per day of smoking. A recent SEER report specifically showed that black men, but not black women, in the United States had a higher age-adjusted incidence of lung cancer than their white counterparts at all age groups. Hispanics in the United States have lower incidence and death rates than non-Hispanic whites for lung cancer; however, they have higher rates for other organ cancers.[100] Further, first-degree relatives of black persons with early-onset lung cancer have a much greater risk of lung cancer than their white counterparts (25.1% vs. 17.1%, respectively).[101]

The explanation for these racial or ethnic variations in risk for lung cancer is not known. Black Americans also have higher mortality rates from lung cancer than white Americans.[29] This difference in mortality rates has been attributed not only to the higher incidence rates but also to the poorer survival of black patients with lung cancer than white patients. For example, the 5-year survival rate was 14.3% lower in black Americans compared to white Americans.[29] The reasons for these racial differences are not known. Some have hypothesized a potential role for greater use of menthol cigarettes among black Americans than among white Americans (69% vs. 22%), or the deeper inhalation of menthol cigarettes compared to nonmenthol cigarettes.[102]

AGE

Although smoking prevalence is lowest among persons aged 65 years and older (9.3%) compared to persons aged 18 to 24 years (21.4%), 25 to 44 years (23.7%), and 45 to 64 years (22.6%),[29] more than 65% of patients with lung cancer are older than 65 years.[3] Specifically, 31.1% of patients with lung cancer are between 65 and 74 years; 29% between 75 and 84 years; and 8.3% are 85 years old and older.[3] The mean age at the time of diagnosis is 71 years old. This difference between relatively lower current smoking prevalence and the higher cancer rate in the elderly population likely reflects the effects of prior smoking. In the past decade, the incidence and mortality from lung cancer have decreased among persons aged 50 years and younger, but have increased among persons aged 70 years and older.[103] The 5-year survival rate for lung cancer decreases incrementally with age for both sexes. Patients older than 80 years constitute 14% of all patients with lung cancer in the United States but account for almost a quarter of all lung cancer deaths.[103] It has been estimated that the number of lung cancer patients aged 85 years and older will quadruple by 2050.[104]

DIET AND OBESITY

It has been suggested that diet is responsible for approximately 30% of all cancers.[105] For example, low serum concentrations of antioxidants, such as vitamins A, C, and E, have been associated with the development of lung cancer.[106,107] The carotenoid component of vitamin A, in particular β-carotene, has been shown to have protective effects against lung cancer in dietary studies. Vitamins C and E (α-tocopherol) have also been shown to have some protective effect.[108,109] Based on those observations, several large intervention trials have been conducted to examine the relationship between vitamin supplementation and lung cancer. The Alpha-Tocopherol, Beta-Carotene Cancer Prevention (ATBC) Study (daily supplementation of a-tocopherol, β-carotene, or both) and the Beta-Carotene and Retinol Efficacy Trial (CARET) (β-carotene, vitamin A, or both) found that vitamin supplementation did not reduce lung cancer risk, and in some circumstances, actually increased the incidence of lung cancer.[110,111] Therefore, the use of supplemental β-carotene and vitamin A is discouraged. There have also been suggestions that low dietary intake of certain minerals, including magnesium, zinc, copper, and iron, is associated with increased lung cancer risk; however, a prospective cohort study observed no significant associations between total mineral intake and lung cancer risk.[112,113]

A diet rich in fruits and vegetables has been linked to decreased cancer incidence, and the protective effects are stronger in current than in former smokers.[114] Although no specific type of vegetable or fruit has been shown to be particularly responsible for the effect, consumption of cruciferous vegetables, such as broccoli and cabbage that are rich in isothiocyanates, has some protective effect against lung cancer.[115] Low or no intake of fruits or vegetables has

been associated with up to threefold risk for lung cancer.[116] It has been also further suggested that consuming fruits or vegetables raw rather than cooked is associated with a further reduction in risk for lung cancer because important carotenoids can be destroyed with cooking.[117] A large prospective NIH-AARP Diet and Health Study showed no relation between total intake of fruit and vegetables with lung cancer risk.[118] However, the study showed that higher consumption of several botanical groups such as rosaceae (apples, peaches, strawberries), convolvulaceas (sweet potatoes and yams), and umbelliferae (carrots), was significantly and inversely associated with lung cancer risk in men and in former smokers.[118] Flavonoid plant metabolites have antioxidant and antiproliferative properties and can be found in food such as berries, citrus fruits, tea, dark chocolate, and red wine. A prospective study showed that the risk for lung cancer was lower in men with the highest total flavonoid intake compared to those with the lowest intake.[119] Certain dietary items including red meat, dairy products, saturated fats, and lipids, have been reported to be associated with an increased risk of lung cancer.[120–123] Other foods found to have an adverse effect on lung cancer risk include items that contain nitrosodimethylamines and nitrites, such as those found in salami and salted and smoked meat products.[124,125]

In the United States, 35.1% of adults are classified as obese.[126] Excessive body weight has been associated with increased risk for endometrial, breast, and colorectal cancers but not for lung cancer. A meta-analysis reported that an inverse association between body mass index (BMI) and lung cancer risk, and obesity may even have a protective role.[127] However, in the absence of cigarette smoking, the association between BMI and lung cancer was not significant. It has been proposed that the observed BMI and cancer association may be related to residual strong confounding effects of smoking itself.[128] For example, smokers tend to have lower mean BMI than age- and sex-matched nonsmokers.[129] Smokers have a notably lower BMI than nonsmokers, and they gain weight when they quit smoking. More recent studies that adjusted for pack-years of smoking and other relevant covariates in a female cohort showed an inverse association of BMI and lung cancer risk in current and former smokers, whereas BMI was positively associated with lung cancer in never smokers.[130] Other studies have shown that waist circumference was positively associated with lung cancer risk in smokers.[131]

OTHER LUNG DISEASES AND AIRWAYS OBSTRUCTION

Some nonmalignant lung diseases have been associated with an increased risk for lung cancer, the strongest association being with COPD. Cigarette smoking is the primary cause of both lung cancer and COPD. COPD affects an estimated 40% to 70% of patients with lung cancer, a finding that reflects a common smoking history. Some evidence suggests an association between the presence of airflow obstruction and the development of lung cancer.[132] A recent study evaluated 602 patients with lung cancer and found that 50% of them had prebronchodilator pulmonary function test results consistent with a diagnosis of COPD GOLD stage 2 and higher, independent of age, sex, and smoking history, with an odds ratio of 11.6.[133] The prevalence of COPD in patients with newly diagnosed lung cancer was sixfold greater than matched smokers, suggesting that COPD itself is an important independent risk factor with potential relationship to the pathogenesis of lung cancer.

COPD is characterized by chronic inflammation, which, in turn, has been suggested as a risk factor for lung cancer. A Dutch study found that the likelihood of developing lung cancer was increased in patients with an elevated serum C-reactive protein, a marker of generalized inflammation. A large retrospective study of patients with COPD found that the risk for lung cancer was lower in patients who took high-dose inhaled corticosteroids than in patients taking lower doses or none at all.[134] These results suggest that inhaled corticosteroids may have a chemoprotective role in lung cancer in patients with COPD. A study of α_1-antitrypsin deficiency carriers found that they have an approximately twofold higher risk for lung cancer, after adjusting for the effects of tobacco smoke exposure and COPD.[135]

The incidence of lung cancer has been demonstrated to be increased in patients with pulmonary fibrosis, even after adjustment for smoking.[136] In a population-based cohort study, patients with pulmonary fibrosis had an odds ratio for lung cancer of 8.25 compared with control subjects. Other fibrosing diseases, including asbestosis and scleroderma-related lung disease, also appear to be associated with an increased risk of lung cancer.[136,137] The mechanism by which pulmonary fibrosis may predispose to pulmonary malignancy is not clear.

INFECTIONS

Oncogenic viruses have been proposed as a cause of lung cancer. The possible involvement of human papillomavirus (HPV), which is known to cause carcinoma in other tissues, in bronchial squamous cell lesions was first suggested because the epithelial changes in bronchial carcinomas resemble those of established HPV condylomatous lesions in the female genital tract.[138] HPV DNA has been detected in lung squamous cell carcinoma tissues.[139] However, there is inconsistency in the reported prevalence of HPV infection in patients with lung cancer in different countries, with racial and geographic variations. Studies to date testing lung cancer specimens for HPV have yielded mixed results because of variability in genetic susceptibility, method of HPV detection, and environmental and high-risk behavior variables. Epstein–Barr virus (EBV), which is associated with Burkitt lymphoma and nasopharyngeal carcinoma, has been strongly associated with lymphoepithelioma-like carcinoma (LELC), a rare form of lung cancer in Asian patients, but this association has not been observed in the Western population.[140] Other viruses suggested as etiologic for lung cancer include BK virus, JC virus, the human cytomegalovirus, simian virus 40 (SV40), and measles virus; however, the evidence of causality is inconclusive.[141–144] More recently, DNA from Torque teno virus (TTV), a relatively new virus, has been detected at high levels in idiopathic pulmonary fibrosis patients with lung cancer, but more studies are needed to confirm these findings and determine their clinical significance.[145] It has also been suggested that *Chlamydia pneumoniae*, a common cause of acute respiratory infection, especially in patients who smoke cigarettes, might be involved in lung carcinogenesis.[146] If such an association were established, it could have profound implications, particularly for lung cancer prevention. *Chlamydia* is not a known oncogenic pathogen, but some have hypothesized that the inflammation resulting from the infection can lead to reactive oxygen species that damage DNA and cause cell injury, resulting in mutations that may lead to an increased risk of tumorigenesis.

Some studies have also reported an association of pulmonary tuberculosis with lung cancer.[147,148] A cohort study showed an increased risk for lung cancer in tuberculosis patients with hazard ratio of 3.3 after adjusting for confounding factors such as COPD and smoking-related cancers other than lung cancer. The effect of tuberculosis was even greater when combined with COPD or with other smoking-related cancers.[148] Some have speculated that tuberculosis-related inflammation and scarring contribute to lung cancer pathogenesis.[147]

AIDS-related mortality has dramatically decreased since the advent of highly active antiretroviral therapy; however, this decrease has been accompanied by an increase in the proportion of deaths attributable to non-AIDS defining tumors, especially lung cancer.[149,150] The increased risk of lung cancer relative to the general population of the same age seems to be due in part to the higher

prevalence of smoking among HIV-infected patients. HIV was associated with a hazard ratio of 3.6 for lung cancer after controlling for smoking status.[151] Although smoking is a key risk factor for lung cancer in HIV-infected patients, several other factors may contribute to the higher incidence of lung cancer. These include greater prevalence of coinfection with oncogenic viruses such as human herpesvirus 8, HPV, and EBV and the potential direct effects of the HIV virus and the consequences of long-term immunosuppression.[152] For example, the HIV tat protein can transactivate cellular genes or proto-oncogenes, while other HIV genes inhibit tumor-suppressor genes.[153] HIV-infected patients with lung cancer have a worse prognosis than similarly staged non–HIV-infected patients.[154] They are also more likely to have more advanced stage lung cancer at diagnosis.[155] Studies have reported that HIV-infected patients were much younger, were more likely to be smokers, and had significantly reduced median survival.[155,156]

ENVIRONMENTAL TOBACCO SMOKE

ETS, also referred to as "secondhand smoke," contributes to an increased risk for lung cancer with a notable dose-dependent relationship.[157] ETS consists of both mainstream (exhaled) smoke and sidestream smoke. In one study, household exposure of 25 or more smoker-years before adulthood doubled the risk for lung cancer; exposure of less than 25 smoker-years did not increase risk.[158] At least 17% of lung cancers in nonsmokers are thought to be attributable to exposure to high levels of ETS during childhood and adolescence.[158] The Surgeon General's 1976 report raised concerns about hazards relating to such environmental smoke exposure.[159] Nonsmokers exposed to ETS have an increased rate of smoke-related problems, including upper respiratory symptoms and eye irritation, and exposed children have an increased frequency of respiratory illnesses. Therefore, the report suggested that the acknowledged carcinogenic effect of active tobacco smoking might also be present in those involuntarily exposed. The risk for lung cancer is increased in nonsmoking women married to men who smoke.[160,161]

The risk of lung cancer related to ETS has been studied, though quantification of the magnitude of exposure is problematic. In an analysis of 37 epidemiologic studies of the risk of lung cancer in nonsmokers who did or did not live with a smoker, encompassing 4626 cases, a lifetime nonsmoker had an estimated 24% greater risk of lung cancer if he/she lived with a smoker.[157] It is important to note that this should be interpreted from the perspective that the background risk for lung cancer in a nonsmoker is very low, and so a 24% increase will not substantively change that risk.[157] Similarly, in 1986, the National Research Council commissioned a review of the effects of ETS as a potential causal agent of lung cancer in nonsmokers exposed to household cigarette smoke.[162] Review of all the available evidence yielded an overall odds ratio of 1.34 in lung cancer risk associated with ETS. In nonsmokers, this translates into an approximately 30% increase of risk for lung cancer, which, as already noted, should be interpreted in the context of a low background risk.[162]

Many government agencies, including the U.S. Department of Health and Human Services, Environmental Protection Agency, and the IARC, classify ETS as containing lung carcinogens. The presence of ETS is pervasive and harmful. There are reports that suggest as many as 88% of nontobacco users have detectable levels of serum cotinine, a metabolite of nicotine, presumably from exposure to ETS.[163] Therefore, efforts to limit public smoking will be of great benefit in this regard. Given that 20.6% of the American adult population still smoke, ETS will continue to be a major public health issue until cigarette smoking altogether is eliminated.[164]

ENVIRONMENTAL POLLUTION

Outdoor air pollution has long been thought to increase the risk for lung cancer. Advances in analytical methods used to detect specific pollutants have helped investigators study the effects of airborne particulates. Early studies involving urban–rural comparisons have shown that an "urban factor" is associated with a 10% to 40% increase in lung cancer deaths.[165] Two large US cohort studies suggest that there is an excess risk for lung cancer of about 19% per 10 $\mu g/m^3$ increment in the long-term average exposure to fine particulates, after adjustments for multiple confounding factors. The Cancer Prevention II study found that fine particulate and sulfur oxide–related pollution were associated with 8% increased risk for lung cancer mortality for each 10 $\mu g/m^3$ elevation in long-term average ambient concentration of fine particles less than 2.5 μm in diameter.[166]

However, it is difficult to determine the carcinogenicity of single constituents of air pollution. Other sources of fossil fuel combustion products can also have potential carcinogenic components. Estimates of relative risks for lung cancer associated with exposure to combustion products range from 7.0 to 22.0 in cigarette smokers, 2.5 to 10.0 in coke oven workers, and 1.0 to 1.6 in residents of areas with high levels of air pollution.[167] Diesel exhaust, which is composed of a complex mixture of gases and fine particles, is also an important component of air pollution. Some of the gaseous components of diesel exhaust, including benzene, formaldehyde, and 1,3-butadiene, are suspected of causing or known to cause cancer in humans. There is strong support that occupational exposure to diesel exhaust, particularly in persons in the trucking industry, is associated with an approximately 30% to 50% increase in the relative risk for lung cancer.[168] Data linking gasoline engine exhaust and lung cancer are less compelling. In many parts of the world, solid fuels such as wood are burned as primary sources of domestic energy for cooking and heating. Incomplete combustion of coal in homes in China has been linked with lung cancer.[169] The IARC has classified indoor emission from household coal combustion as a human carcinogen and emissions from biomass fuel, primarily from wood, as a probable human carcinogen.

OCCUPATIONAL CARCINOGENS

The IARC has identified arsenic, asbestos, beryllium, cadmium, chloromethyl ethers, chromium, nickel, radon, silica, and vinyl chloride as carcinogens. The occupations associated with exposure to these agents are shown in Table 109-3. It has been estimated that 10% of lung cancer deaths in men and 5% in women worldwide could be attributable to exposure to eight occupational lung carcinogens, namely asbestos, arsenic, beryllium, cadmium, chromium, nickel, silica, and diesel fumes.[170,171] Worldwide, lung cancer related to occupational carcinogen exposures is estimated to be responsible for 152,000 deaths, and a loss of nearly 1.6 million disability-adjusted life years (DALYS).[170] The National Institute for Occupational Safety and Health (NIOSH) estimated that approximately 9000 to 10,000 men and 900 to 1900 women per year in the United States develop lung cancer from exposure to occupational carcinogens.[172]

Asbestos is the most common occupational cause of lung cancer. Asbestos, a naturally occurring fibrous mineral, can be classified as serpentine (chrysotile) or amphibole (amosite, crocidolite, tremolite). Asbestos has been used in construction and as insulating material for its fire-retarding qualities and strength since the 1800s, but its role as lung carcinogen was not known until the 1940s. Fortunately, asbestos use has precipitously declined in the United States since the 1970s.[173,174]

Asbestos exposure has been reported to be associated with a relative risk of lung cancer of 3.5 after adjusting for age, smoking, and vitamin intake.[175] Risk may be dose dependent, as well as influenced by the type of asbestos fiber. For example, the risk of lung cancer appears to be higher for workers exposed to amphibole fibers than for those exposed to chrysotile fibers, after adjusting for similar exposure level.[176] Notably, it remains unclear whether asbestos exposure alone or asbestosis in particular is the actual risk factor

TABLE 109-3 Occupational Carcinogens and Associated Occupational Exposures

Known Carcinogen	Occupational Exposure	Suspected Carcinogens	Occupational Exposures
Arsenic	Copper, lead, or zinc ore smelting	Acrylonitrile	Textile manufacture
	Manufacture of insecticides		Plastics, petrochemical manufacture
	Mining		
Asbestos	Asbestos mining	Cadmium	Electroplating
	Asbestos textile production		Pigment production
	Brake lining work		Plastics industry
	Cement production		
	Construction work		
	Insulation work		
	Shipyard work		
Beryllium	Ceramic manufacture	Formaldehyde	Formaldehyde
	Electronic and aerospace equipment		Resin production
	Mining		Synthetic fibers
			Insulation work
			Insulation production
Chloromethyl ethers	Chemical manufacturing	Vinyl chloride	Plastic production
			Polyvinyl chloride production
Chromium	Chromate production		
	Chromium electroplating		
	Leather tanning		
	Pigment production		
Nickel	Nickel mining, refining, electroplating		
	Production of stainless and heat-resistant steel		
	Polycyclic aromatics		
	Aluminum production		
	Hydrocarbon compounds		
	Coke production		
	Ferrochromium alloy production		
	Nickel-containing ore smelting		
	Roofing		
Radon	Mining		
Silica	Ceramics and glass industry		
	Foundry industry		
	Granite industry		
	Metal ore smelting		
	Mining and quarrying		

for lung cancer. Two reviews discussing the extensive available epidemiologic data illustrate this controversy.[173,177] First, it is widely recognized that lung fibrosis of many causes, including idiopathic pulmonary fibrosis and interstitial disease associated with connective tissue disease, is associated with an increased risk for lung cancer.[171] Second, asbestos-exposed animals developed lung cancer only when they also developed pulmonary fibrosis.[178,179] Third, pleural plaques have not proved to be a reliable marker for increased risk for lung cancer. Fourth, the presence of asbestosis is associated with increased likelihood of lung cancer compared to patients with asbestos exposure without associated fibrosis.[175] Nonetheless, at present the issue of whether asbestosis is a necessary precursor to asbestos-attributable lung cancer is not definitively settled.[173,180] The risk for lung cancer from nonoccupational asbestos exposure in the general environment is extremely low.[181]

It is important to recognize that cigarette smoking contributes significantly to the lung cancer risk profile in asbestos-exposed individuals. Smoking cessation is especially important for cancer prevention programs in workers exposed to asbestos, and probably even more important for workers with asbestosis. In a study of 17,800 individuals with more than 20 years of occupational asbestos exposure, Hammond et al. obtained information on the combined effects of cigarette smoking and asbestos dust exposure on lung cancer mortality. The risk for death from lung cancer increased by 16-fold in asbestos workers who smoked more than one pack of cigarettes per day and by ninefold in workers who smoked less than one pack per day, compared to asbestos workers without significant smoking history.[182] The relative risk for lung cancer with asbestos exposure alone is sixfold, with cigarette smoking alone 11-fold, but with exposure to both asbestos and cigarette smoke, the increase

may be as high as 59-fold.[182] This study did not distinguish individuals with asbestos exposure alone from those who also had asbestosis and thus was unable to identify the contribution of the latter factor to lung cancer risk and mortality.[182]

Radon and its decay products are carcinogens associated with one of the world's oldest occupation, mining. Initially known as a wasting pulmonary disease of miners and metal smelters, radon-induced lung cancer was first attributed to dust or metal exposure, or infections such as tuberculosis, but later linked to radioactive materials.[183] Radon is a natural decay product of radium 226, itself a decay product of uranium 238. Ultimately, radon decay produces lead 210, which has a half-life of 22 years. Both uranium and radium are ubiquitous in soil and rock, though in highly variable concentration. At usual temperatures, radon is released as an inert radioactive gas. Radon has a half-life of 3.82 days and decays into radioisotopes known as radon decay products (or radon daughters) that have half-lives measured in seconds to minutes. These products include polonium 218 and polonium 214, which emit α particles. It is the α radiation that is highly damaging to tissues including the respiratory epithelium. Inhalation of these radon decay products and subsequent α-particle emission in the lung can cause damage to cells and genetic material. Evidence from epidemiologic studies of underground miners shows a linear relationship between radon exposure and lung cancer risk.[184,185] Uranium miners exposed to radon and its decay products have an increased risk for lung cancer, peaking 15 to 24 years after exposure.[186] Lubin et al.[187] pooled 11 cohort studies, examining 2700 lung cancer deaths occurring in 65,000 miners. They concluded that the relative risk for lung cancer was linearly related to cumulative radon progeny exposure, and that 40% of all lung cancer deaths in their cohort might be due to such exposure.[187] There is an increased risk of lung cancer in uranium miners who smoke, with smoking and uranium exposure acting in at least an additive fashion.[188,189] In addition, there appears to be an increased risk of lung cancer in nonsmoking uranium miners who have higher levels of uranium exposures.[190] In the study by Lubin et al.,[187] 70% of lung cancer deaths in never smokers were thought attributable to radon progeny exposure.

Uranium mining has ceased in the United States. However, radon exposure continues to be an occupational concern in nonuranium mining and underground work as well as in uranium and nonuranium mines around the world.[191] In the United States, occupational exposure to radon is legislatively controlled. It has been estimated that a 40-year radon exposure at the maximum allowed level by occupational standards would increase a person's lifetime risk for lung cancer twofold.[192] Continued longitudinal evaluation of occupationally exposed persons is needed to improve our understanding of the carcinogenic effects of radon.

There is legitimate concern about the possible risk for lung cancer in the general population associated with domestic radon exposure. The National Council on Radiation Protection and Measurements has identified radon and its decay products as the largest component of environmental radiation to persons living in the United States.[185] Radon is a ubiquitous indoor domestic air pollutant. The concentration of radon gas in an environment depends on the richness of the source of radium and the degree to which the air around that source is ventilated. The primary factor determining radon gas concentration in homes is the concentration of radium in the soil and rock beneath those structures.[188] Building materials, well water, and natural gas are less common sources, usually contributing only minimally to indoor radon concentrations.

It has been proposed that radon is the second leading attributable cause of lung cancer after smoking.[193] Smokers and nonsmoking residents of smoking households are at potentially increased risk for lung cancer even when radon levels are low.[191] However, the potential for mutagenic and carcinogenic effects of low-level radon has been an area of controversy, and the risk associated with exposure to radon in the home remains uncertain. One meta-analysis concluded that greater residential exposure levels were associated with a relative risk of lung cancer of 1.14, a number consistent with extrapolation of risk from studies performed in miners as well as with actual calculated risks in miners with low cumulative radon exposure.[191] However, other studies have demonstrated no increased risk even with high indoor domestic radon levels.[193–195] It has been pointed out that the effects of low-dose, low-level radiation have never been adequately evaluated, which contests the assumptions inherent in extrapolation of high radon exposure in miners to domestic situations. However, even low-dose α radiation from domestic radon exposure could very conceivably lead to cellular genetic mutation, an early step in the induction of cancer. From a practical standpoint, radon can usually be readily eliminated from domestic sites, and so testing and abatement should be encouraged. Environmental and indoor radon exposure should continue to be carefully assessed as a public health problem.

CONCLUSIONS

Most lung cancer deaths are attributable to cigarette smoking, and curtailing the rates of cigarette smoking continues to be an important global imperative. Insights into the epidemiology and causal factors of lung cancer provide additional foundation for disease prevention. Likewise, ionizing radiation and certain occupational exposures have been recognized as carcinogenic. At present, the 5-year survival rate for lung cancer is only 17%.[1] This is in stark contrast to the 5-year survival rates for the other leading causes of cancer death in the United States.[4] The absolute number of lung cancer cases continues to be alarming, with the incidence of lung cancer in women only now beginning to decline. The challenge in the future will be to modify the impact of identified external sources of risk while continuing to expand our knowledge of the genetic and molecular basis of lung carcinogenesis. With one-fifth of the American population still smoking cigarettes, continued efforts must be directed at smoking cessation and at preventing persons from becoming addicted to smoking. Although work in advancing the field of lung cancer treatment is critically important, the dismal survival rate associated with this disease demands that the medical profession contribute to efforts aimed at limiting its primary cause. If tobacco smoking could be eliminated, and if we address some of the other known exposure risks of lung cancer, then might we be able to return lung cancer to its designation by Adler at the turn of the 20th century as "among the rarest forms of disease."

CHAPTER 110

Approach to the Patient with Pulmonary Nodules

David Ost

INTRODUCTION

The radiographic finding of a pulmonary nodule, formerly known as a *coin lesion,* has long challenged the clinician. At the heart of the dilemma, the question remains unchanged: "Is it malignant or benign?" When faced with a pulmonary nodule, the clinician and the patient usually have one of three choices: (1) observe it with serial chest computed tomography (CT), (2) perform additional diagnostic tests (imaging and/or a biopsy), or (3) remove it surgically.

The proper choice depends on epidemiology, radiographic appearance, assessment of surgical risk, and patient preferences. For malignant lesions, early surgical resection still represents the best chance for cure. On the other hand, unnecessary resection of benign nodules exposes patients to the morbidity and mortality of a surgical procedure. The aim of this chapter is to review what is known about the pulmonary nodule to formulate a diagnostic approach to this often controversial problem. The goal will be to arrive at a systematic approach that will promptly identify and bring to surgery all patients with operable malignant nodules while avoiding thoracotomy in patients with benign nodules. To do this we need to have a clear definition of pulmonary nodules, information on their incidence and prevalence, the causes of malignant and benign nodules, the available imaging techniques, a method of estimating the probability of cancer, the strengths and weakness of serial CT imaging versus different biopsy techniques, and the impact of surgical risk and comorbidities on diagnostic strategies. These various considerations can then be integrated into an algorithm providing a unified approach to diagnosis and management.

DEFINITION

Pulmonary nodules should be characterized on the basis of number, size, and density as determined by CT. A solitary pulmonary nodule is defined as a single discrete pulmonary opacity that is surrounded by normal lung tissue that is not associated with adenopathy or atelectasis.[1,2] Previously there was controversy as to what constituted the upper size limit for defining a solitary pulmonary nodule. Some early series included lesions up to 6 cm in size.[3,4] However, it is now recognized that lesions larger than 3 cm are almost always malignant, so current convention is that solitary pulmonary nodules must be 3 cm or less in diameter.[5,6] Larger lesions should be referred to as pulmonary masses and should be managed with the understanding that they are most likely malignant; prompt diagnosis and resection is usually advisable.[7]

The term "solitary pulmonary nodule" was originally used when most nodules were detected incidentally by chest radiography. Today, most nodules are detected by CT, which greatly enhances nodule detection and characterization. However, we now recognize that many nodules that would have been characterized previously as "solitary" by chest radiograph are actually not solitary, since there may be other small nodules present. Thus, the classical definition of pulmonary nodules needs to be revised to take into account data from more recent CT-based studies.[1,7] As such, the term "solitary" should not be used for nodules accompanied by additional nodules or associated findings, or for nodules not completely surrounded by aerated lung.

CT has also increased awareness of subcentimeter nodules, which are defined as those ≤8 mm in diameter.[1,8–10] Subcentimeter nodules may be spherical or nonspherical, and malignant nodules may have either shape.[10] CT has also led to a more precise and nuanced classification of nodules according to their density. Nodules may have a pure solid appearance, a pure ground-glass appearance, or a mixed ground-glass and solid appearance. These characteristics can be used to help estimate the probability of cancer in the nodule.

INCIDENCE AND PREVALENCE

The incidence of pulmonary nodules and the probability of malignancy in those nodules vary widely, depending on the patient population; thus, many case series may not be directly comparable. This is a critical distinction when reviewing the literature. So the clinical context that led to nodule detection is a key factor to consider. Surgical case series, in which the denominator consists entirely of resected lung nodules, have a much higher prevalence of malignancy as compared to studies that use all nodules detected by chest radiograph or CT. Note that the prevalence of cancer seen in these surgical case series is not the same as the pretest probability of cancer for a newly identified lung nodule. Cancer prevalence in surgical series is high because the population being studied consists entirely of patients in whom the clinical suspicion of cancer based on prior testing has been deemed high enough to warrant the risk of surgery. Nodules unlikely to be malignant tend to be excluded from surgical case series. Given these limitations, surgical case series data can still be useful to gain insight into the factors that impact the probability of cancer, but the prevalence of cancer will be higher than in other clinical situations.

The frequency with which a pulmonary nodule is identified on chest radiography is on the order of 1 to 2 per 1000 chest radiographs.[11] Most of these are clinically silent, and about 90% are noted as an incidental finding on radiographic examination. Younger patients from areas where granulomatous diseases such as tuberculosis, histoplasmosis, and coccidioidomycosis are endemic can be expected to have a lower malignancy rate. In an Air Force Medical Center study from Illinois of 137 patients, only 22 (16%) had a malignancy.[12] Granulomas were diagnosed in 103 (75%) patients; 53 of them were attributable to histoplasmosis endemic to the area. Most of these patients (77%) were under age 45, and no malignant nodules were diagnosed in patients less than 35 years of age. This series predated the use of chest CT.

Importantly, the incidence of nodules and the probability of malignancy in the nodules are very different in more recent studies of low-dose CT screening for lung cancer among high-risk patients than in surgical case series. The prevalence of noncalcified nodules in observational studies of low-dose CT screening ranges from 13% to51%.[13–15] Among nodules that are identified on the first screening study, the prevalence of cancer ranges from 3% to 12%.[16] On follow-up CT imaging of the same population (i.e., incidence screens), the probability of new noncalcified nodules has varied widely, from 2.5% to 13%. The probability of cancer in these incidence nodules has varied from 5% to 23%.

MALIGNANT PULMONARY NODULES

Risk factors for malignancy have been identified from studies of pulmonary nodules and include patient age, smoking history, nodule size, and prior history of malignancy. Age is one of the most consistent risk factors. In a series of 370 resected indeterminate solitary pulmonary nodules, the incidence of malignancy increased from 63% for patients age 45 to 54 to 74% for ages 54 to 64 and continued to rise with age to 96% for those above the age of 75.[17] Since this was a surgical case series, in which the denominator consists of

resected lung nodules, the prevalence of malignancy is much higher as compared to studies of nodules detected by chest radiograph or during lung cancer screening, in which the denominator consists of all nodules detected. These findings correlate with those of previous studies, which also show that malignancy is very rarely found in patients under the age of 35.[12,18,19]

Smoking is closely correlated with the development of lung cancer, particularly squamous and small cell carcinoma. The Surgeon General's report of 1964 and subsequent studies have demonstrated that the risk of lung cancer increases with the duration of smoking and the number of cigarettes smoked. Average smokers have about a 10-fold risk and heavy smokers a 20-fold risk of developing lung cancer when compared to nonsmokers. Smoking is responsible for about 85% of the cases of bronchogenic carcinoma. Cessation of smoking will reduce this risk after 10 to 20 years, but it now appears that former smokers have a slightly higher risk of cancer throughout their lifetimes.

Nodule size is closely correlated to risk of malignancy. Several series have demonstrated an increased incidence of malignancy with increasing nodule size. Nodules larger than 3 cm will be malignant 80% to 99% of the time. In seven studies of nodules detected in lung cancer screening trials, the prevalence of malignancy was 0% to 1% in patients with nodules <5 mm in diameter, 6% to 28% for 5- to 10-mm nodules, 33% to 64% for 11- to 20-mm nodules, and 64% to 82% for nodules measuring >20 mm.[12,17,20–23]

Primary bronchogenic carcinoma is the most common malignant tumor that presents as a pulmonary nodule.[5,17,21,24] Histologically, adenocarcinoma and squamous cell carcinoma make up the majority; of the two, adenocarcinoma is the more common (Table 110-1). Of note, tumors that used to be called bronchioloalveolar cell carcinoma (BAC) have now been reclassified and the term adenocarcinoma in situ is used for BAC tumors once they have been confirmed by surgical resection. Small cell carcinoma presenting as a solitary pulmonary nodule is rare. Other rare primary lung tumors that may present as solitary pulmonary nodules are bronchial carcinoids, lymphomas, hemangioendotheliomas, and sarcomas.

Metastases may present as solitary pulmonary nodules in patients who have known primary malignancies or in whom the presence of primary malignancy is unknown. In up to 40% of such patients, who manifest only a single nodule on chest radiograph, CT scan may show other nodules that are not disclosed by plain chest radiograph.[25,26] Even though a lesion is solitary, 33% to 95% of nodules in patients with an established diagnosis of cancer will be malignant.[27–31] The most common histologic types of metastatic nodules are adenocarcinomas of the colon, breast, and kidney; head and neck tumors; sarcoma; and melanoma. Because of the high likelihood of malignancy, a nodule in a patient with an established diagnosis of cancer should be treated differently from other solitary nodules. Assuming no other obvious metastatic spread, one should consider proceeding directly to biopsy. Even in the presence of a known lung cancer, some of these nodules may represent a second primary pulmonary malignancy that is similar in histologic appearance. Immunohistochemistry and other confirmatory marker studies may be indicated to determine the nature of the nodule. A solitary pulmonary nodule in a patient with a history of malignant disease should be resected as long as there is no other evidence of recurrent or metastatic disease.

BENIGN PULMONARY NODULES

Benign solitary pulmonary nodules are more common in the young and in nonsmokers. Causes include benign tumors such as hamartomas, both infectious and noninfectious granulomas, vascular lesions, and rare miscellaneous conditions (Table 110-1).

Hamartomas are the most common benign tumors presenting as solitary pulmonary nodules. They are believed to be developmental malformations composed mainly of cartilage, fibromyxoid stroma, and adipose tissue. A review of six series with 3802 resected solitary pulmonary nodules found that 5% were hamartomas.[12,17,19,32–34] In a series of 215 hamartomas resected at the Mayo Clinic, the peak incidence was in the seventh decade of life; male-to-female ratio was 1:1; and the average size was 1.5 cm, although some were as big as 6 cm.[35] Most hamartomas were asymptomatic (97%), and 17% were noted to grow slowly on serial radiographic examination. They may be identified radiographically by a pattern of "popcorn" calcification, which is often intermixed with areas of low attenuation on CT scan representing fat deposits within the nodule. CT appearance will be diagnostic in about 50% of hamartomas (Fig. 110-1).[36]

Infectious granulomas make up more than 90% of all benign nodules. They arise as a result of healing after infection from a variety of organisms. The offending agents will vary, depending on geographic

TABLE 110-1 Differential Diagnosis of Solitary Pulmonary Nodules

Malignant Tumors
Bronchogenic carcinoma (adenocarcinoma, large cell, squamous, small cell)
Carcinoid
Pulmonary lymphoma
Pulmonary sarcoma
Plasmacytoma
Solitary metastases (colon, breast, kidney, head and neck, germ cell, sarcoma, thyroid, melanoma, others)
Benign Tumors
Hamartoma
Adenoma
Lipoma
Infectious Granulomas
Tuberculosis
Histoplasmosis
Coccidioidomycosis
Mycetoma
Ascaris
Echinococcal cyst
Dirofilariasis (dog heartworm)
Noninfectious Granulomas
Rheumatoid arthritis
Wegener granulomatosis
Sarcoidosis
Paraffinoma
Others
Miscellaneous
Bronchiolitis obliterans organizing pneumonia
Abscess
Silicosis
Fibrosis/scar
Hematoma
Pseudotumor
Spherical pneumonia
Pulmonary infarction
Arteriovenous malformation
Bronchogenic cyst
Amyloidoma

Figure 110-1 Benign pulmonary nodules and their radiographic patterns: **A.** Hamartoma with fat density within the nodule. **B.** Pseudotumor due to fluid in a fissure, the result of both pleural disease and fluid overload, has the appearance of a pulmonary mass. **C.** Noncontrast CT shows a round 1-cm nodule, with relatively high radiographic density, proven on resection to be a granuloma. **D.** Nodule with smooth border, diagnosis histoplasmosis.

location. Among the most common causes are histoplasmosis, coccidioidomycosis, and tuberculosis. Other, less common causes are dirofilariasis (dog heartworm), mycetoma, echinococcal cyst, and ascariasis. A history of exposure is important in establishing a possible infectious origin. Clues such as tuberculosis exposure history and skin test results, prior travel history, places of residence, occupation, and pets may be invaluable in some instances.

A variety of inflammatory diseases can also cause benign pulmonary nodules. Noninfectious granulomas sometimes present as pulmonary nodules in systemic diseases such as sarcoidosis, in which nodules are not invariably accompanied by hilar adenopathy. Rheumatoid arthritis may also be associated with pulmonary nodules, usually in patients with active rheumatoid disease who will also have subcutaneous nodules. Granulomatosis with polyangiitis (formerly Wegener's granulomatosis) can also present with pulmonary nodules, which are often cavitary. In such cases there are usually multiple nodules and there may be concurrent renal disease.

Miscellaneous causes of benign pulmonary nodules have been described. Some of the more common conditions are lung abscess; rounded or spherical pneumonia; pseudotumor, which represents fluid in an interlobar fissure (Fig. 110-1); hematomas after thoracic trauma or surgery; and fibrosis or scars resulting from the resolution of infectious or inflammatory process. Rarer conditions presenting as pulmonary nodules include silicosis, bronchogenic cyst, amyloidosis, pulmonary infarct, and vascular anomalies. Arteriovenous malformations may also present as pulmonary nodules. They may grow slowly, and have a characteristic appearance on contrast-enhanced CT scan, with identification of afferent and efferent vessels emanating from and heading toward the hilum, respectively.

IMAGING TECHNIQUES

Imaging techniques are often helpful in distinguishing benign from malignant causes of pulmonary nodules, and as such they play a key role in their evaluation and management. During the last decade,

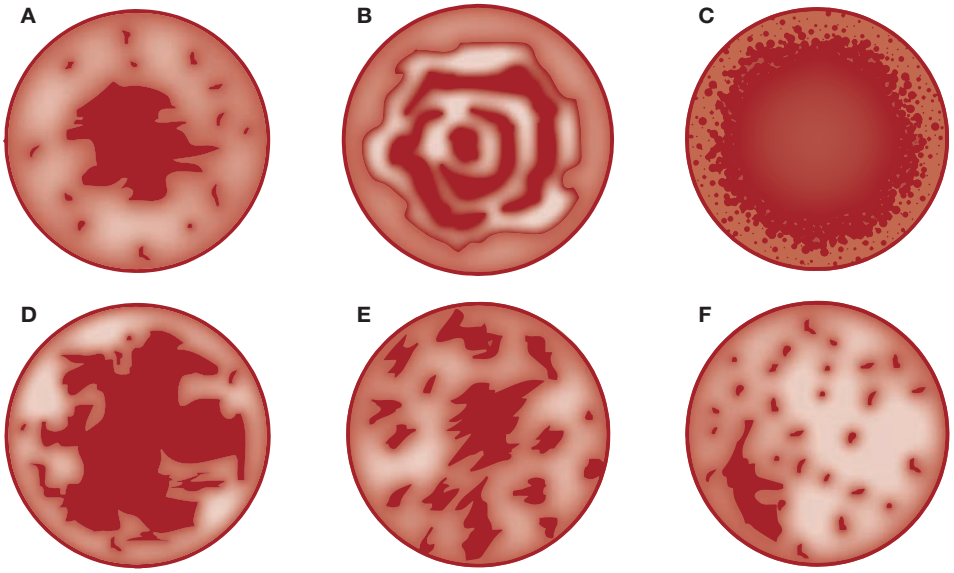

Figure 110-2 Patterns of calcification in nodules. **A.** Central. **B.** Laminated. **C.** Diffuse. **D.** Popcorn. **E.** Stippled. **F.** Eccentric. Patterns A, B, C, and D generally indicate a benign process; E and F suggest malignancy. *(Data from Lillington GA. Management of solitary pulmonary nodules. Dis Mon. 1991;37(5):271–318.)*

rapid advances in both CT and positron emission tomography (PET) have dramatically changed the diagnostic approach to pulmonary nodules. However, this does not mean that these techniques should be used indiscriminately. Cost-effective strategies to manage pulmonary nodules require that we understand the performance characteristics (sensitivity, specificity), strengths, and weaknesses of each of these technologies, so that they can be applied properly.[37] The primary technologies that need to be considered are plain chest radiography, CT, and PET.

■ PLAIN CHEST RADIOGRAPHY

Many pulmonary nodules are discovered on routine plain chest radiograph while asymptomatic. Nodules are usually identifiable on chest radiograph by the time they are 0.8 to 1 cm in diameter, although nodules 0.5 to 0.6 cm can occasionally be seen.[11] Most will be identified on posteroanterior (PA) projection, but some will be seen only on lateral projection, so standard PA and lateral chest radiography should be obtained whenever possible. When a nodule can be seen only on one projection, the clinician should question whether it is truly in the lung parenchyma. Structures overlying the lungs, such as leads used for cardiac monitoring, nipple shadows, skin lesions, and rib lesions can all mimic a pulmonary nodule, as can pulmonary vessels viewed end on. If in doubt, a CT should be done. Once it has been ascertained that a true nodule exists, the first step is to make every effort to obtain previous radiographs for comparison. A solid nodule that has remained stable with no increase in size for 2 years by CT is very likely benign and warrants no further investigation. Conversely, a nodule that was not present on a comparable radiograph within the past 2 months is unlikely to be malignant, having grown so rapidly.

■ COMPUTED TOMOGRAPHY

Chest CT should be part of the evaluation of all lung nodules, either alone or as part of a combined PET-CT. As with chest radiography, comparison with old films is critical, since it can provide an estimate of the growth rate over time. CT can pinpoint the exact location of the nodule and provide three-dimensional images of the lesion. Thin-section high-resolution CT can better define the borders and the nodule's relation to adjacent structures, such as vessels and the pleura.[23,38] CT is also more sensitive than standard chest radiographs in detecting calcifications and can quantify calcification in nodules even when they are not readily visible to the naked eye.[23,39] Nodules with higher radiographic density are more likely to be benign (Fig. 110-1).

Calcification is generally an indication of benignity in a pulmonary nodule. Infectious granulomas tend to calcify with central, diffuse, or stippled patterns (Fig. 110-2). Laminar or concentric calcification is characteristic of granulomas caused by histoplasmosis. A popcorn calcification pattern is typically seen in hamartomas and when coupled with fat density within the same nodule is highly specific. Eccentric calcification patterns should make one suspicious for malignancy. It should be noted that, in general, 6% to 14% of malignant nodules exhibit calcification. When calcifications are present in malignant lesions, they are usually eccentric and few. Benign patterns of calcification (central, diffuse, laminar, or popcorn) are very rare in malignant nodules. In one study of 1267 solitary pulmonary nodules, only seven malignant nodules (0.6%) had a benign calcification pattern.[40] Most nodules with a benign calcification pattern can be observed with serial CT scans.

The edge characteristics of nodules can also offer insight into whether or not a lesion is malignant. Benign lesions are often well circumscribed with a round appearance whereas malignant nodules tend to have irregular or lobulated borders (Fig. 110-3). CT imaging characteristics that suggest malignancy include spiculated margins (likelihood ratio [LR] 5.5),[23,24,38] pleural retraction (LR 1.9), and a vessel sign (LR 1.7). The feeding vessel sign consists of a vessel leading directly to a nodule. This is often associated with septic embolism but also occurs with metastasis, arteriovenous fistulas, and rarely in lung cancer. Lobulated margins (LR 1.1) are associated with malignancy but the predictive value is low.[41] Other patterns that have been reported to be associated with malignancy include vascular convergence (which suggests vascular and/or lymphatic invasion),[42] a dilated bronchus leading into the nodule,[43] pseudocavitation ("bubbly" appearance thought to represent air bronchiolograms),[38] and true cavitation when it is associated with a thick and irregular wall.[44] However, none of these radiographic signs is entirely specific for malignancy. Malignancy is somewhat less likely if a bronchus sign is present although its predictive value is low. An air-bronchus sign can be seen in primary pulmonary lymphoma, but this is a very rare disease, accounting for less than 1% of all lung cancers. Malignancy is much less likely if a nodule has smooth or polygonal margins (LR 0.2).

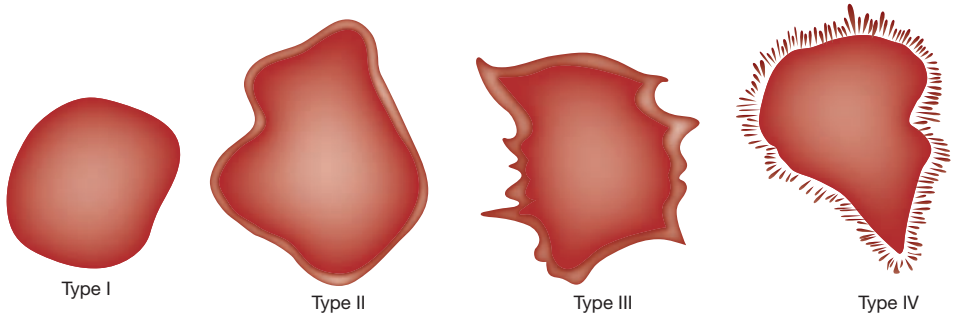

Figure 110-3 Characteristic appearance of nodule edges. Type I is sharp and smooth, type II is lobulated, type III has irregular undulations, and type IV is grossly irregular with many spiculations. *(Data from Siegelman SS, Khouri NF, Leo FP, Fishman EK, Braverman RM, Zerhouni EA. Solitary pulmonary nodules: CT assessment. Radiology. 1986;160(2):307–312.)*

Rapid advances in CT technology have also led to more precise characterization of the density of lung nodules. It is now appreciated that nodules may be characterized as solid, partly solid, or pure ground-glass opacities (defined as focal densities in which underlying lung morphology is preserved) (Fig. 110-4). This is particularly useful for categorizing small nodules (<1 cm) since these categories can help to distinguish benign from malignant nodules. The percentage of pure ground-glass opacities that are malignant varies significantly in the literature, from 18% to almost 60%.[45–47] For subcentimeter nodules, the likelihood of malignancy is similarly high in partly solid lesions, but much lower (<10%) in solid nodules.[45,47]

Ground-glass nodules may represent either atypical adenomatous hyperplasia (AAH) or adenocarcinoma in situ (formerly BAC).[42,48–55] In contrast, partly solid or solid nodules usually represent adenocarcinoma, but can also be caused by squamous cell carcinoma or small cell carcinoma. When pure ground-glass opacities start to grow and become more solid, demonstrating a replacement growth pattern, this should be considered highly suspicious for adenocarcinoma.[1,56,57] Of note, observed growth rates are often very slow for malignant ground-glass opacities, intermediate for partly solid nodules, and relatively fast for solid nodules.[58]

The superior resolution of multidetector scanners has also facilitated the development of volumetric CT. Volumetric CT may allow growing lesions to be identified earlier than conventional transverse CT. Preliminary studies demonstrated that three-dimensional volume analysis enabled tumor growth to be detected in 5-mm diameter nodules as early as 30 days after the initial CT.[59,60] Volumetric CT was successfully used to guide evaluation of small lung nodules in the NELSON trial.[8,61] In that trial, the investigators used serial volumetric CT measurements to calculate the doubling time of indeterminate lung nodules. CT volume doubling time of <400 days or a new solid component in a previously nonsolid nodule was defined as positive.[8] Follow-up imaging could detect growth as early as 6 weeks after imaging of an indeterminate nodule. The second round screening in this study had a sensitivity of 96.4%, specificity of 99.0%, positive predictive value of 42.2%, and a negative predictive value of 99.9%.

A complementary technique is dynamic CT, which uses iodinated IV contrast to look for enhancement of nodules.[62] Although malignant nodules enhance more than benign ones, benign lesions, such as

hamartomas and tuberculomas, may also enhance. Median sensitivity and specificity in seven studies from a systematic review were 96% and 75%, respectively.[20,62–68] In a multicenter trial using dynamic CT the negative predictive value was 97%. However, lack of specificity has limited the utility of this test, since it cannot reliably distinguish between malignant and active inflammatory or infectious nodules.[2] As a result few centers at the present time are using this approach.

■ POSITRON EMISSION TOMOGRAPHY

PET can be used to help differentiate noninvasively between malignant and benign nodules. PET takes advantage of the fact that tumor cells have increased glucose uptake and metabolism. A D-glucose analog labeled with a positron-emitting fluorine-18 radioisotope (FDG) is injected into the patient, and uptake by the nodule is then measured. Malignant nodules have a higher uptake of FDG. Sensitivity of PET in systematic reviews has ranged from 87% to 95%.[2,20,69] Integrated PET-CT scanners combine the CT and FDG imaging gantry, allowing more precise anatomic localization of areas of FDG uptake than dedicated PET imaging alone.[70–72] PET imaging also provides useful information regarding lung cancer staging, since it will occasionally detect unsuspected distant metastases.[73]

It is important to recognize that most studies of PET have used a single threshold level for discriminating malignant from benign nodules, typically a standard uptake value (SUV) of 2.5.[2,73] However, PET images actually provide a range of possible results, depending on the amount of uptake in the nodule as compared to that of the mediastinal blood pool. In a study of 344 patients undergoing PET-CT, the likelihood ratios (LRs) for benign, probably benign, indeterminate, probably malignant, and definitely malignant were 0.03, 0.15, 1.01, 3.2, and 9.9, respectively.[74] When FDG uptake was slightly greater than the mediastinal blood pool, this was considered as probably malignant. Substantially greater uptake was considered

as definitely malignant. Indeterminate readings were rare (1%). This study suggests that greater FDG uptake is more strongly associated with malignancy. Clinically, the implication is that physicians should consider not only whether a PET scan is positive, but should also consider the degree of FDG uptake when estimating the posterior probability of disease after PET imaging.

However, PET appears to be less sensitive for lesions less than 8 mm in size, so its use should be limited to those lesions ≥8 mm in size.[2,75] While there is limited preliminary evidence that PET may be useful for lesions as small as 8 to 10 mm in size, there are still too many false negatives reported to make PET useful for smaller lesions outside of a clinical trial at the current time.[76–78] False-negative findings have also been seen in patients with lepidic predominant adenocarcinomas (formerly BAC, also minimally invasive or adenocarcinoma in situ), carcinoids, and mucinous adenocarcinomas.[78,79] False positives have been seen in patients with granulomatous infections, such as tuberculosis, atypical mycobacterial disease, and endemic mycoses, as well as in patients with inflammatory conditions, such as rheumatoid arthritis and sarcoidosis.[80,81] Theoretically, false-positive results can also be caused by uncontrolled hyperglycemia.[82]

DISTINGUISHING BETWEEN BENIGN AND MALIGNANT NODULES

ESTIMATING PROBABILITY OF MALIGNANCY

Epidemiology, knowledge of the different causes of malignant and benign nodules, and the imaging characteristics of the nodule all serve to inform the physician as to the probability of malignancy in a given nodule. While physicians often estimate pretest probability of cancer intuitively, several investigators have attempted to develop mathematical models to estimate the probability of malignancy of indeterminate pulmonary nodules.[83–86] Using clinical and radiographic characteristics of malignancy derived from the literature, these authors have analyzed some combination of the following risk factors by Bayesian, neural network, and other methods to obtain a mathematical estimate of the probability of malignancy: nodule size, location, growth rate, margin characteristics, age of the patient, smoking history, prevalence of malignancy in the community, and occult calcification on CT densitometry.[83–85,87–90]

For example, in the Bayesian approach, each risk factor for a particular patient and nodule is assigned a LR of malignancy derived from published data. In one model, overall prevalence of malignancy, diameter of the nodule, patient's age, and smoking history were considered.[84] The LRs for malignancy of each of these factors were then multiplied to provide odds of malignancy, which are then converted into a percent probability of cancer. In a computerized neural network model that utilizes nonlinear mathematics to analyze input data, risk factors for malignancy were used and compared to the results of Bayesian analysis.[85] The authors found that their neural network was not as accurate as Bayesian analysis in predicting malignancy.

One of the problems with these and other methods is the quality of the input data (i.e., the LRs), which may not be representative of all patient populations. In addition, Bayesian analysis presupposes that the LRs for a particular risk factor are not affected by the presence or absence of any other factor. It is not clear that this is true of the LRs. Therefore, although mathematical models to predict probability of malignancy may seem attractive, the complexity of the issue once again leaves us with an uncertain answer. This may explain why the previously described methods are not in widespread clinical use. It is worth noting that the accuracy of models for predicting malignancy appears to be similar to that of expert physicians, although the correlation is poor, which suggests that models may provide additional insights.[87]

However, assessment of the pretest probability of malignancy is central to optimal strategy selection when managing pulmonary nodules.[1,2,37,56,91] While these formulas and neural networks may lack precision on an individual patient level, they can serve to inform decision making as to what risk factors to pay attention to and how important they are relative to each other.[5] Risk factors associated with a low probability of malignancy include diameter less than 1.5 cm, age less than 45 years, absence of tobacco use, having quit for 7 or more years, and a smooth appearance on radiographic imaging. Risk factors associated with a moderately increased risk of malignancy include diameter 1.5 to 2.2 cm, age 45 to 59, smoking up to 20 cigarettes per day or being a former smoker within the last 7 years, and a scalloped edge appearance on radiography. Risk factors associated with a high risk of malignancy include a diameter of 2.3 cm or greater, age greater than 60 years, being a current smoker of more than 20 cigarettes per day, a history of prior cancer, and a corona radiata or spiculated appearance on radiography.[4,5,87,92–94]

After consideration of these risk factors and possibly using one of the validated models to arrive at an estimate of the pretest probability of malignancy, physicians must then choose between alternative strategies. The main alternatives are (1) careful observation with serial CT imaging; (2) nonsurgical biopsy using CT guidance or bronchoscopy; or (3) surgery. The results of each strategy help to further refine the probability of malignancy, either up or down. As such, it is important to consider the strengths and weaknesses of each of these approaches.

CAREFUL OBSERVATION WITH SERIAL CT IMAGING

Careful observation with serial CT is predicated on the ability of the imaging technology to detect nodule growth. The fundamental assumption is that by comparing serial images over time a nodule's growth rate can be determined and this in turn can be used to help distinguish between benign and malignant nodules. Squamous and large cell tumors have an average doubling time (i.e., the time for a nodule to double in volume) of 60 to 80 days. Adenocarcinomas double at about 120 days, and the rare small cell carcinoma that presents as a solitary pulmonary nodule can have a doubling time of less than 30 days.[27] A nodule that has doubled in weeks to months is probably malignant and should be removed when possible.[5] Benign nodules have doubling times of less than 20 days or more than 400 days. A nodule that doubles in size in less than 20 days is usually the result of an acute infectious or inflammatory process, while those that grow very slowly are usually chronic granulomatous reactions or hamartomas. Nodules with doubling times over 400 days can be observed with serial radiographs.[1,2,5] This is the basis for the clinical axiom that 2-year radiographic stability is strong presumptive evidence that a nodule is benign.

It should be noted that controversy remains regarding how long follow-up should be continued. While traditional teaching has recommended observing lesions for a maximum of 2 years, it is now recognized that for some lesions longer follow-up may be warranted. Long doubling times have been observed in malignant lesions that presented as ground-glass nodules or as partially solid nodules.[48,54,58] As a consequence, longer follow-up extending over years may be appropriate in patients with pure ground-glass nodules, especially if there is an antecedent history of lung cancer.[95] However, for most solid nodules, 2 years of follow-up without evidence of growth is sufficiently long to warrant discontinuation of CT imaging.

Determination of nodule growth is based on the assumption that nodules are more or less spherical. Growth of a sphere must be considered in three-dimensional volume, not in two-dimensional diameter. The formula for volume of a sphere is $4/3(\pi)r^3$, or $1/6(\pi)d^3$, where r = radius and d = diameter. A nodule originally 1 cm in diameter whose diameter is now 1.3 cm has actually more than doubled in volume. Similarly, a 2-cm nodule has doubled in volume by the time its diameter reaches 2.5 cm. A nodule that has doubled in diameter has undergone an eightfold increase in volume. When

old radiographs are available, growth rate and nodule doubling time can be estimated. If the diameter of a nodule is measured at two different points in time (first t1 and later at t2), then doubling time in days = (t × log 2)/[3 × log (d2/d1)]. In this formula t is the number of days between t2 and t1; d1 and d2 are the diameters of the nodule at times t1 and t2, respectively. It is therefore critical that old radiographs and CT scans be obtained for comparison when evaluating pulmonary nodules, since they can provide valuable insights into the doubling time and natural history of the nodule.

Accepting the assumption that a tumor arises from serial doublings of a single cancerous cell, we can estimate that it will take 27 doublings for it to reach 0.5 cm. By the time a nodule is 1 cm in diameter, it represents 30 doubling times and about 1 billion tumor cells. Depending on the exact growth rate, this theoretical 1-cm nodule has probably existed for years before it is detected, as malignant bronchogenic tumors have doubling times estimated at between 20 and 400 days. The natural history of a tumor usually spans about 40 doublings, whereupon the tumor is 10 cm in diameter and the patient has usually died.[96]

Nodule growth rate and doubling times become clinically relevant when deciding how often to order follow-up imaging when observing a pulmonary nodule. The question often arises whether observing a pulmonary nodule for an extra 3 to 6 months increases the likelihood of metastatic disease, since that nodule has probably been growing for years. There is no convincing empiric evidence to support this hypothesis. Whether delays longer than 3 to 6 months are safe is unknown. However, estimating this hazard of delay is clinically relevant, since the optimal frequency of serial CT follow-up imaging to monitor nodules for growth is predicated on limiting this hazard of delay. The question is, how frequently do follow-up scans need to be done to minimize the hazard of delay while containing costs and avoiding excessive radiation exposure?

Traditional practice, based on little empiric evidence, recommended that when a careful observation strategy was warranted, repeat CT scans be done at 3, 6, 12, and 24 months.[5] However, more recent data from lung cancer screening trials using CT imaging suggests that a less aggressive practice may be reasonable in some patients with very small nodules.[1,2,8,92,97–99] Therefore, decisions about the frequency and duration of follow-up for patients with pulmonary nodules need to consider multiple dimensions of the problem, including clinical risk factors, nodule size, radiation dose, surgical risks, patient preferences, cost, and the limits of imaging technology resolution (especially at sizes less than 5 mm).[100–102] All of these can affect the optimal frequency of CT follow-up.

The ability to detect nodule growth is a function of image resolution. CT imaging greatly improved the ability to detect nodule growth as compared to conventional chest radiographs. This has made the careful observation strategy with serial imaging more effective, since it limits the hazard of delay by allowing earlier detection of growth. However, the accuracy of size measurements is still a problem when nodules are small. There is poor inter- and intraobserver variability when size differences of <1.5 mm are being assessed with two-dimensional (2D) CT.[103,104] As a result, 2D measurements of small nodules may not always be reliable. The presence of growth was incorrectly assessed in 27% to 37% of CT scan pairs when diameters or cross-sectional areas were used as compared to a reference standard of volumetric measurement.[2,101,105,106] Limited data suggests that volumetric measurements may provide a better alternative. When evaluated retrospectively, volumetric measurements using two CT scans performed a median of 3.7 months apart with a threshold volume doubling time >500 days was found to be 91% sensitive and 90% specific for malignancy. Another small study of predominantly solid nodules found that volumetric imaging changed management strategy in 10% of cases.[107] Volumetric imaging and doubling times were also used successfully to guide management in the NELSON lung cancer screening trial.[8] Unfortunately, volumetric measurement is time consuming and labor intensive and therefore has not yet become the standard of care.

TABLE 110-2 Schedule for Conducting Serial CT Imaging on Solid Nodules

Nodule Size	Solid Nodule and No Lung Cancer Risk Factors	Solid Nodule with Lung Cancer Risk Factors
≤4 mm	No follow-up needed	• CT in 12 mo • No additional imaging if there is no change
>4–6 mm	• CT in 12 mo • If no change then no additional follow-up	• CT at 6–12 mo • Repeat CT at 18–24 mo provided there is no change
>6–8 mm	• CT in 6–12 mo • Repeat CT at 18–24 mo provided there is no change	• CT at 3–6 mo • Repeat CT at 9–12 mo and 24 mo provided there is no change
>8 mm	• CT imaging at 3–6 mo • Repeat CT at 9–12 and 18–24 mo provided there is no change	• CT at 3 mo • Repeat CT at 6 mo, 12 mo, and 24 mo provided there is no change

Source: Data from Gould MK, Donington J, Lynch WR, et al. Evaluation of individuals with pulmonary nodules: when is it lung cancer? Diagnosis and management of lung cancer, 3rd ed. American College of Chest Physicians evidence-based clinical practice guidelines. Chest. 2013;143(5 Suppl):e93S–e120S.

Given this framework, it is reasonable to apply more recent expert consensus-based guidelines to help guide the frequency of follow-up CT imaging for the pulmonary nodule.[2,95,108] For follow-up studies, imaging should be performed without contrast with thin sections using low-dose techniques.[2] Where available, volumetric CT may further facilitate growth detection and limit the hazard of delay. In all cases patients should be informed about the potential benefits and harms including the hazard of delay versus the risks of unnecessary testing. The frequency and duration of CT imaging for solid nodules in patients who are potentially treatable is shown in Table 110-2. For patients with indeterminate pure ground-glass nodules and patients with part-solid nodules the frequency and duration of surveillance is different (Table 110-3).

Patients with a solid indeterminate nodule or a part-solid, part ground-glass nodule that shows evidence of growth on serial imaging should have a nonsurgical biopsy or surgical resection. Similarly, any patient with a pure ground-glass nodule that develops a solid

TABLE 110-3 Schedule for Conducting Serial CT Imaging on Non-Solid Nodules

Pure Ground-glass Nodules	Part-solid, Part Ground-glass Nodules
Nodule size ≤5 mm: no follow-up needed	Nodule size ≤8 mm: CT imaging at 3, 12, and 24 mo with follow-up annual CT for 1–3 additional years
Nodule size >5 mm: re-evaluate at 3 mo. If there is no change then follow-up annually for 3–5 y	Nodule size >8 mm: CT imaging at 3 mo followed by PET and/or biopsy if nodules persist

component should have a nonsurgical biopsy or surgical resection. If a nonsurgical biopsy is chosen, then either a specific benign diagnosis (e.g., hamartoma) or a diagnosis of malignancy must be made. If the biopsy is nonspecific (e.g., inflammation) then surgical resection should be considered.

NONSURGICAL BIOPSY TECHNIQUES: CT-GUIDED TRANSTHORACIC NEEDLE BIOPSY

CT-guided transthoracic needle biopsy is most useful for peripheral lesions in the outer third of the lung, and in lesions under 2 cm in diameter. The sensitivity of CT-guided transthoracic needle biopsy for malignancy is 90%.[109] The major limitation of CT-guided transthoracic needle biopsy is its high rate of pneumothorax, with reported rates ranging from 10% to 35% overall.[42,110] In a recent cross-sectional analysis of 15,865 patients, the rate of any pneumothorax was 15% and the rate of pneumothorax requiring a chest tube was 7%.[111] Risk factors associated with pneumothorax include older age, smoking, emphysema, smaller lesions, deeper locations, lateral puncture site, proximity to fissures, and low entry angle to the pleura.[1,112,113] Because of the high rate of pneumothorax and its possible complications, the following patients should not undergo percutaneous needle aspiration: those with severely limited pulmonary reserve, those with bullous emphysema or blebs in the needle path, and postpneumonectomy patients. Other relative contraindications are bleeding diathesis, inability to hold breath, and severe pulmonary hypertension. Bronchoscopy can sometimes be used when percutaneous needle aspiration is contraindicated.

Importantly, CT-guided transthoracic needle biopsy does not always provide a specific benign or malignant diagnosis. Such nondiagnostic results occur in 4% to 41% of cases.[2] Because of this, if the pretest probability of cancer is high, then a nondiagnostic result does not necessarily rule out malignancy and additional testing or observation with serial CT may be warranted.

NONSURGICAL BIOPSY TECHNIQUES: BRONCHOSCOPY

Traditionally, bronchoscopy has been regarded as a procedure of limited usefulness in the evaluation of solitary pulmonary nodules.[114,115] Studies have shown variable success rates, with an overall diagnostic yield of 36% to 68% in nodules greater than 2 cm with bronchoscopic biopsy, brushings, and washings.[116,117] In general, the yield for specific benign diagnoses has ranged from 12% to 41%.[32,116] Complication rates are low at about 1% to 2%, with most of the risk being associated with the transbronchial biopsy component of the bronchoscopy.[118,119]

Factors to consider when deciding on the suitability of bronchoscopy for diagnosis of a pulmonary nodule include the size of the nodule, its location, the presence of air bronchograms, and the availability of new bronchoscopic technologies. In terms of nodule size, the sensitivity of conventional bronchoscopy is significantly worse for smaller lesions. The overall sensitivity when combining cytology brushing, transbronchial biopsy, and bronchoalveolar lavage was 34% for lesions <2 cm in diameter and 63% for lesions >2 cm.[109,120] Location also matters: nodules located in the inner or middle one-third of the lung have the best diagnostic yield; nodules in the outer one-third have a much lower diagnostic yield and as such are often best approached with CT-guided transthoracic needle aspiration if biopsy is needed. Another characteristic of pulmonary nodules to consider when deciding on the role of bronchoscopy is the relation of the nodule to neighboring bronchi.[109,121] Tsuboi et al. described four types of tumor–bronchus relationships: (1) the bronchial lumen is patent up to the tumor; (2) the bronchus is contained in the tumor mass; (3) the bronchus is compressed and narrowed by the tumor, but the bronchial mucosa is intact; and (4) the proximal bronchial tree is narrowed by peribronchial or submucosal spread of the tumor or by enlarged lymph nodes (Fig. 110-5). The presence of types I and II, a bronchus leading to or contained within the body of a nodule or mass on CT, has subsequently been termed a positive bronchus sign. When a bronchus sign is present on CT, the diagnostic yield of bronchoscopy can be as high as 60% to 90%.[109,122,123] With a negative bronchus sign, the yield drops to 14% to 30%. Signs and symptoms of airway involvement (cough, hemoptysis, localized wheezing), although rare in solitary pulmonary nodules, will increase diagnostic yield when present.

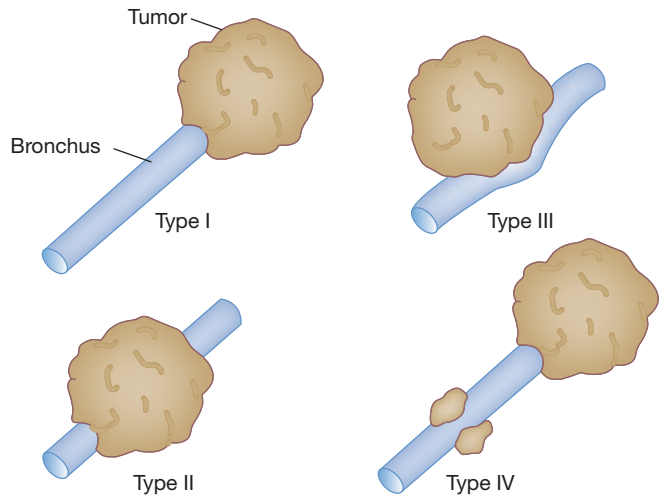

Figure 110-5 Schematic illustration of tumor–bronchus relationships (see text). *(Data from Tsuboi E, Ikeda S, Tajima M, Shimosato Y, Ishikawa S. Transbronchial biopsy smear for diagnosis of peripheral pulmonary carcinomas. Cancer. 1967;20(5):687–698.)*

New bronchoscopic technologies include electromagnetic navigation and guidance (EMN), radial endobronchial ultrasound (EBUS), ultrathin bronchoscopy, guide sheath techniques, and virtual bronchoscopic navigation. Importantly, many of these techniques can be used together. A systematic review of radial EBUS with transbronchial biopsy demonstrated 73% sensitivity for all lesions and 71% sensitivity for nodules <25 mm in size.[124] EMN with transbronchial biopsy for peripheral lesions has been reported to have a sensitivity ranging from 44% to 75%.[2,125–127] In a systematic review the diagnostic yield of EMN was 67%, radial EBUS was 71%, ultrathin bronchoscopy was 70%, guide sheath techniques was 73%, and virtual bronchoscopy 72%.[118] Note that in many of the studies cited, investigators would use multiple modalities concurrently—for example, a study using radial EBUS with a guide sheath and virtual bronchoscopy would be included in all three categories. As such, it is difficult to tell the contribution of individual system components, since what is truly relevant is overall aggregate system performance. In addition, many of the studies did not report on the method of patient selection, but it is clear that proper patient selection is vital if high diagnostic yields are to be obtained with these technologies, since they are not suitable for all patients. The presence of an air-bronchus sign significantly increases the yield of these technologies and is probably among the best predictors of success.[127]

On balance, EMN, EBUS, and VB appear to increase the diagnostic yield of bronchoscopy in select centers with the appropriate expertise, although the magnitude of the benefit for each of these technologies is difficult to quantify and there is a paucity of randomized controlled data. In cases in which there is an air-bronchus sign, or in cases in which there are very central lesions abutting the large airways, bronchoscopy may be of use. Similarly, if there is a suspicion for unusual infections (e.g., tuberculosis or fungal infections), then bronchoscopy may be warranted. The complication rate of bronchoscopy is also significantly lower than that of CT-guided biopsy.

As with CT-guided biopsy, bronchoscopy does not always provide a specific benign or malignant diagnosis. Because of this, if the pretest probability of cancer is high, a nondiagnostic bronchoscopy result does not necessarily rule out malignancy and additional testing or observation with serial CT may be warranted. It should also be mentioned that routine preoperative staging bronchoscopy is of no value in asymptomatic patients with a solitary pulmonary nodule smaller than 3 cm because it has not been shown to alter management decisions.[114,115] For most patients with pulmonary nodules without mediastinal adenopathy bronchoscopy will not play a major role since the sensitivity of CT-guided biopsy is considerably higher.

SURGERY: THORACOTOMY AND THORACOSCOPY

Surgical biopsy can be achieved with video-assisted thoracoscopic surgery (VATS), traditional thoracotomy, or a combination of both. If the frozen section demonstrates a benign lesion, then only a wedge resection may be required and if that is the case then operative mortality will be low (~0.5%).[56] Conversely, if the lesion is malignant and the patient has sufficient pulmonary reserve a lobectomy using either open thoracotomy or VATS with systematic lymph node sampling remains the standard of care.

Lobectomy mortality is 1% to 4%.[1] Mortality is higher in patients over age 70 and in patients with malignancy. These patients will often have other coexisting illness, such as chronic obstructive pulmonary disease (COPD) or coronary artery disease. The mortality risk increases with the extent of the procedure. In one series by Ginsberg et al.,[128] the mortality was 1.4% for wedge resection, 2.9% for lobectomy, and 6.2% for pneumonectomy. A more recent observational study of lung cancer surgery reported similar 30-day mortality rates.[129] Of note, this study indicated that there may be a relationship between volume of surgeries performed and outcome. Hospitals that performed the highest volume of lung cancer surgeries had lower 30-day mortality than those that had the lowest volume (3% vs. 6%).

VATS uses fiberoptic telescopes and miniaturized video cameras to facilitate biopsies and resection. VATS represents a complementary approach to traditional thoracotomy and can be very useful in some patients. This approach still requires general anesthesia but does not require a full thoracotomy incision or spreading of the ribs. VATS allows the experienced surgeon to identify and wedge out peripheral nodules in many cases with minimal morbidity and mortality. In a series by Mack et al.,[130] 242 nodules were resected with no mortality and minimal morbidity. Average hospital stay was 2.4 days. VATS can spare some patients with benign nodules the risks of open thoracotomy and can be useful for wedging out nodules in patients who have limited pulmonary reserve who cannot otherwise tolerate a lobectomy. However, in up to 12% of cases conversion from VATS to a minithoracotomy will still be required.[131–135]

Whether resection is performed by VATS or by thoracotomy, lobectomy with systematic lymph node sampling remains the procedure of choice for malignant solitary pulmonary nodules.[136] Wedge excisions or segmental resections for smaller cancers have been evaluated, but the role of these limited pulmonary resections in the management of lung cancer remains controversial. The Lung Cancer Study Group evaluated this in a study of 276 patients with T1N0 lesions that were strictly staged to prove N0 status. Patients were randomized to lobectomy or limited resection.[137] In patients undergoing limited resection, there was an observed 75% increase in recurrence rates ($p = 0.02$) attributable to an observed tripling of the local recurrence rate ($p = 0.008$), an observed 30% increase in overall death rate ($p = 0.08$), and an observed 50% increase in death with cancer rate ($p = 0.09$) compared to patients undergoing lobectomy. Because of the higher death rate and locoregional recurrence rate associated with limited resection, lobectomy has been recommended as the surgical procedure of choice for patients with peripheral T1N0 nonsmall cell lung cancer.

For patients with insufficient pulmonary reserve to tolerate a lobectomy, segmentectomy or wedge resection remains a viable alternative. In addition, whether or not very small malignant lesions, less than 2 cm in size, can be managed with segmentectomy, radiation, or some combination thereof, remains controversial and is the subject of ongoing research. The original randomized trial used both wedge resections and segmentectomy, but more recent data suggests that segmentectomy is superior to wedge resection for tumors <2 cm in size.[138–140] At the present time, it is reasonable to recommend lobectomy with systematic lymph node dissection for all patients with malignant solitary pulmonary nodules who have sufficient pulmonary reserve to tolerate the procedure, with consideration of segmentectomy for those patients with inadequate pulmonary function to tolerate a lobectomy.

THE IMPACT OF SURGICAL RISK ASSESSMENT ON DIAGNOSTIC STRATEGY

For patients with pulmonary nodules, optimal management strategy depends on both probability and consequences. Factors to consider when calculating the probability of cancer have been reviewed earlier. If the probability of cancer is very close to 0, then a careful observation strategy with serial CT imaging will be superior. At the other extreme, if the probability of cancer is very close to 1, proceeding directly to surgery after an appropriate staging work-up will be best. When the probability of cancer is in the intermediate range, a nonsurgical biopsy will be warranted.

Clearly there must be some probability threshold at which the optimal strategy changes from one option to another (i.e., going from careful observation with serial CT scanning to nonsurgical biopsy to surgical biopsy). These probabilities are called decision thresholds.[1] The lower probability, when strategy changes from careful observation to nonsurgical biopsy we will call the "observation threshold." If the probability of cancer is below the observation threshold, careful observation will be warranted. The upper probability, when strategy changes from nonsurgical biopsy to surgical biopsy, we will call the "surgical threshold." If the probability of cancer is above this probability, then surgical biopsy with frozen section, usually followed by lobectomy if malignant, is warranted.

The factors that determine these decision thresholds are treatment consequences, specifically the relative potential for benefit and harm.[1,141] The benefit of treatment is defined as the difference in outcome between *patients with the disease* who receive treatment and similar patients who do not receive treatment. Harm is defined as the difference in outcome between patients *without the disease* who receive no treatment and similar patients who receive treatment. The treatment threshold probability is defined as the probability of disease at which the expected outcome of treatment and no treatment are exactly equal. As applied to pulmonary nodules, treatment usually refers to surgery and no treatment refers to careful observation with serial CT scans. The treatment threshold probability is equal to harm/(harm + benefit) which is the same as 1/(1 + [benefit/harm]).[141]

A useful way to conceptualize the treatment threshold is to imagine that there are no diagnostic tests available. At what probability of disease would empiric treatment be warranted? If a disease can be effectively treated (i.e., high benefit) and the impact of accidentally treating a patient without disease is minimal (i.e., low harm) then the treatment threshold will be low. An example would be using antibiotics to treat suspected meningitis. Conversely, if the treatment is not that effective (i.e., low benefit) and the consequences of accidentally treating a patient without disease are very bad (i.e., high harm) then the treatment threshold will be very high. A high burden of proof would be warranted in this case, for example, when using chemotherapy for cancer.

Once the treatment threshold has been determined the decision thresholds, including both the observation threshold and the

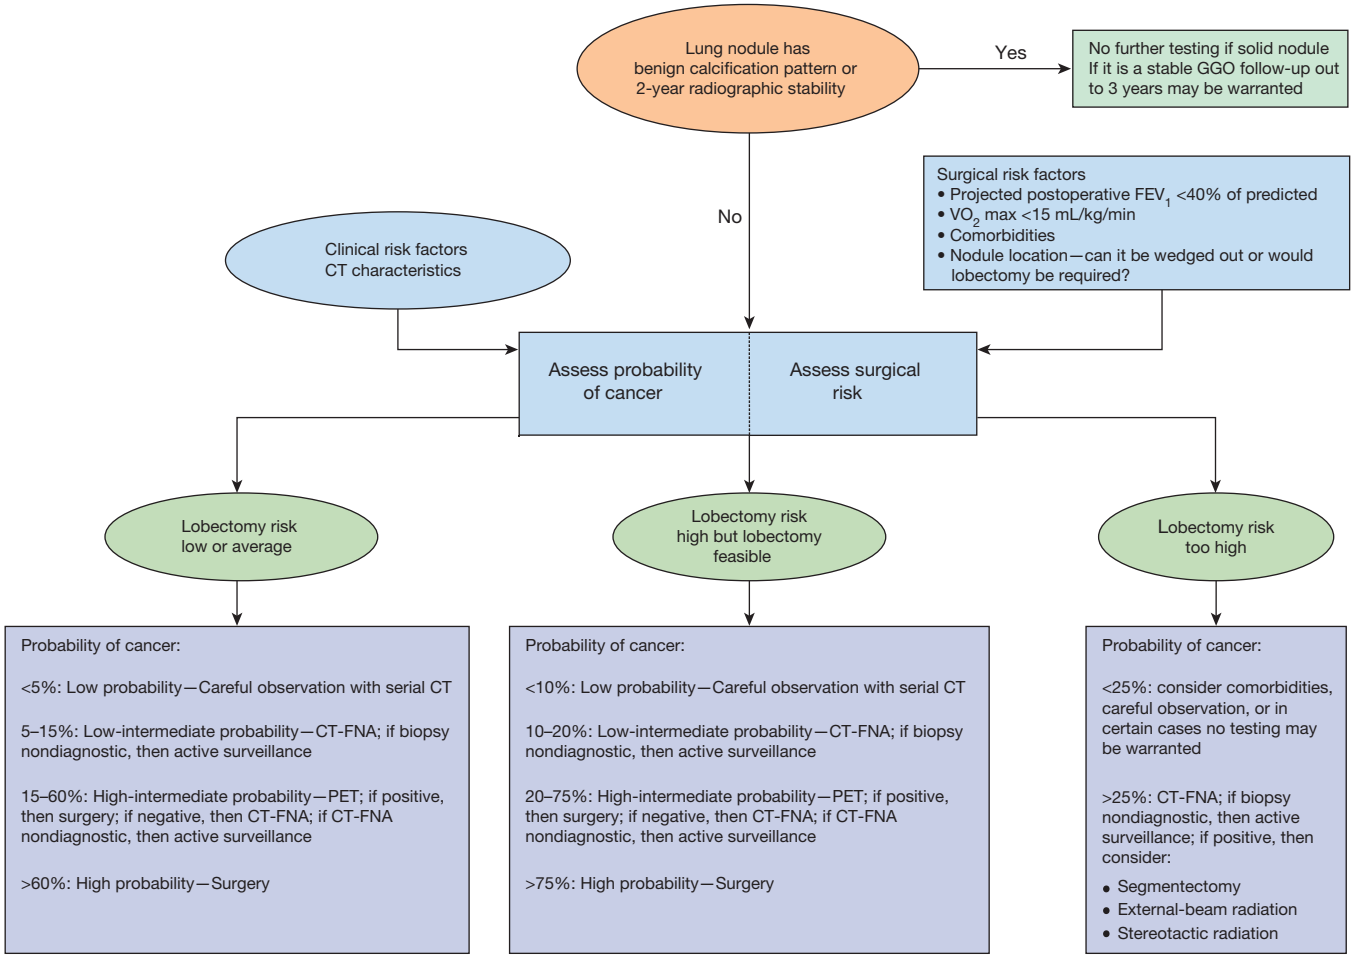

Figure 110-6 Systematic approach to the pulmonary nodule.

surgical threshold, can be calculated.[1,141] While the derivation of these thresholds is complex and has been published elsewhere,[1] it is conceptually easier to grasp the concept of decision thresholds by asking this question: Is there any test result that would shift the pretest probability of cancer from one side of the decision threshold to the other? For patients with a pretest probability that is above the treatment threshold, one possible strategy is to select a test (or tests) that if negative would result in a posttest probability of cancer below the treatment threshold. Alternatively, for patients with a pretest probability below the treatment threshold, a test(s) could be selected that if positive resulted in a posttest probability above the treatment threshold. Note that in the absence of perfect tests, there are some instances in which the pretest probability of cancer is so high that even if all tests were negative the resulting posttest probability would be greater than the treatment threshold. However, as the pretest probability decreases, it must reach some point at which a negative test result would indeed lower the posttest probability below the treatment threshold. For pulmonary nodules this is the surgical threshold. The opposite scenario is when the pretest probability of disease is exceedingly close to 0 such that even a positive test will yield a posttest probability less than the treatment threshold. As the pretest probability increases, there must be some point at which a positive test will indeed result in a posttest probability greater than the treatment threshold. This is the observation threshold.

Importantly the treatment threshold varies not only by disease, but also among patients with the same disease. Imagine two patients with the same probability of cancer with the same exact lung nodule in the same location. If one patient has normal pulmonary function and no comorbidities, the treatment threshold will be low. This is because the harms of accidentally doing surgery if he does not have cancer are relatively low. Conversely, if a patient has very limited pulmonary reserve and is much more likely to have complications, then the treatment threshold will be higher, because the potential for harm is higher. Note that we are not dealing with the probability of cancer here, but rather the severity of the consequences of treating or not treating. Of course, since the treatment threshold varies between patients, so too must the observation and surgical decision thresholds.

When we apply this to the pulmonary nodule, it becomes apparent that in addition to considerations about the probability of cancer, we must also consider the consequences of surgery and coexisting comorbidities. Assessing surgical risk is critical because it determines the benefits and harms, which will in turn determine the treatment threshold, the observation threshold, and the decision threshold. Patients with severe comorbidities (e.g., severe COPD, severe heart disease) will have higher treatment thresholds than patients who have good pulmonary reserve with little comorbidity. Differences in treatment thresholds will in turn change what constitutes optimal diagnostic strategy (Fig. 110-6).

SYSTEMATIC APPROACH TO THE PULMONARY NODULE

The goal is to promptly identify and bring to surgery all patients with operable malignant nodules while avoiding thoracotomy in patients with benign nodules. Based on the previous discussion, the systematic approach to the pulmonary nodule should begin with a history and physical. The history and physical should focus on addressing the following questions: (1) What is the pretest probability of cancer? (2) What is the patient's surgical risk? This should include a detailed history of relevant comorbidities. These include

comorbidities that impact on surgical risk as well as severe competing diseases (e.g., severe Alzheimer's) that significantly limit life expectancy independent of cancer and surgical risk.

Surgical risk assessment should include spirometry and diffusion capacity for carbon monoxide (D_{LCO}). If pulmonary function is not normal, then quantitative perfusion scans may be warranted to calculate the projected postoperative FEV1 and D_{LCO}. If the projected postoperative FEV_1 and D_{LCO} are ≥40% of predicted the risk of pulmonary complications following surgery is acceptable. If one of the two measures is <40% while the other is ≥40%, pulmonary exercise testing may be useful to further risk stratify the patient. A $VO_{2\ max}$ ≥15 mL/kg/min is associated with a low risk of pulmonary complications following lobectomy. Other factors to consider include the location of the nodule. If the nodule is very peripheral and easily reached by VATS and wedge resection is feasible, then the potential harm of resecting a benign lesion will be relatively low. Conversely, if the nodule is very central, such that the only way to obtain a surgical biopsy is to do a lobectomy, then the potential harm of resecting a benign lesion will be high. These considerations in turn will impact the treatment threshold and hence optimal strategy.

A chest CT should be ordered if not already available and compared to all old chest radiographs and CT images (if available). A pretest probability of cancer should be estimated, based on clinical and radiographic features. If the lesion is a solid nodule and has demonstrated radiographic stability for 2 or more years no additional evaluation is warranted. If the lesion is a pure ground-glass nodule and has been unchanged for 2 years or less, serial CT may still be warranted.

At this point the physician should integrate the probability of cancer with the relative consequences of treatment. Treatment consequences should be considered by comparing the benefits of surgery if the patient has cancer with the potential harm of surgery if the patient does not have cancer. This determines the treatment threshold, which is the point around which the decision centers. These thresholds vary significantly between patients depending on their cardiopulmonary reserve, comorbidities, and individual preferences. Patient preferences for certain outcomes can play an important role in strategy selection, so physicians should discuss the risks and benefits of alternative strategies and elicit patient preferences.[2,37,88,142]

Management strategies can then be selected based upon the patient's surgical risk, probability of disease, and patient preferences (Fig. 110-6). Since individual patients vary widely, the probability thresholds provided are only estimates of a typical case – they represent an "average" case drawn from the body of evidence and derived from decision analysis studies.[37,88,143,144] However, it is important to remember that the median and mean are characteristics of populations, not individuals. The probability threshold for a given individual patient may be very different from those shown.

This is not to say that the probability thresholds are arbitrary but rather that for a given patient they are determined by multiple factors, including the individual patient's preferences, estimates of the effectiveness of surgery, the risks of surgery, the long-term consequences of surgery, estimates of the hazard of delay, the patient's comorbidities, the range of alternative diagnostic tests and their performance characteristics (sensitivity and specificity), and the range of alternative treatments.[145] The value of probability thresholds lies not in their precision, but in the underlying systematic approach that they represent and the recognition that careful assessment of the probability of cancer as well as the relative consequences of treatment is critical to determining optimal strategy.

Indeed there have been many decision analysis studies of solitary pulmonary nodules published over time, and the probability of cancer that defines low, intermediate, and high probability risk groups vary between studies.[37,88,143,144] In part, this is because diagnostic tests and treatments have changed over time so the underlying probability thresholds will of course vary over time. As new diagnostic and treatment alternatives become available, these thresholds need to be periodically reassessed.[145] However, even if technology were unchanging, patient preferences vary significantly, so defining a single "optimal answer" for all patients is not feasible. Given these constraints, all of the decision analyses published are fairly consistent, with low probability being approximately 5% to 12% or less, and high probability being approximately 60% to 72%.[37,88,143,144]

Keeping this in mind, we can gain some useful insights of a more general nature from a careful examination of Figure 110-6. While decision thresholds for individual patients vary because of the surgical risk, and hence the potential benefit and harm of surgery vary, the order of the preferred strategies is the same when going from lowest to highest pretest probability of cancer: careful observation with serial CT, then CT-FNA, then PET with possible CT-FNA, and then surgery. This is a consequence of the sensitivity and specificity of CT-FNA and PET as well as the risks associated with them.

The reason is as follows: Imagine the pretest probability is just above the observation threshold in the low-intermediate range. If a CT-FNA is done and it is nondiagnostic, the posttest probability of cancer will be somewhat lower, so careful observation will be warranted. The finding of a specific benign diagnosis (e.g., endemic mycosis) would lead to appropriate treatment. Because CT-FNA has close to 100% specificity for cancer, a positive result will raise the posttest probability of cancer high enough to warrant surgery.[20] In contrast, when the pretest probability is low, a PET will not be as useful because the specificity of PET is only 83%.[20,56] A positive PET scan increases the posttest probability of cancer, but the posttest probability of cancer will not be above the surgical threshold so it is not high enough to make a definitive treatment decision.

We can use the same approach to understand why PET is preferred when the pretest probability is in the high-intermediate range. Imagine that the pretest probability is just below the surgical threshold. The pretest probability is so high that any single negative test will not result in a posttest probability below the observation threshold. Thus a second negative test would be needed to lower the probability below the observation threshold. However, PET carries much less risk to the patient than CT-FNA. If PET is performed first when the pretest probability of cancer is high the posttest probability will be high enough to warrant surgery and the risks of CT-FNA will be avoided.

SUMMARY

Providing cost-effective, patient-centered care for patients with pulmonary nodules can be challenging because many factors must be considered simultaneously and technologies are constantly developing. Integrating current evidence with fundamental concepts from decision theory suggests that management of pulmonary nodules should begin with estimating the pretest probability of cancer. The consequences of treatment should be considered by comparing the benefits of surgery if the patient has cancer with the potential harms of surgery if the patient does not have cancer. This determines the treatment threshold. These thresholds vary widely among patients depending on their cardiopulmonary reserve, comorbidities, and individual preferences. For patients with a very low probability of cancer, careful observation with serial CT is warranted. For those with a very high probability of cancer, surgery is preferred. For patients with an intermediate probability of cancer, either CT-FNA or PET possibly followed by CT-FNA is best. Patient preferences should be considered because the absolute difference in outcomes between strategies may not be large. [2,88] Although the specific algorithms may change as technologies develop, the underlying principles remain the same. No set of guidelines can encompass all possible scenarios that occur in day-to-day clinical practice. It is important to recognize that the body of evidence is based on studies of populations, but that individual patients vary significantly in terms of their risks, potential

for benefit, and preferences. Applying these first principles in a systematic fashion will be useful for physicians, especially in challenging cases. Understanding the underlying concepts allows physicians to view the patient management process as a unified whole – a system of principles rather than a multitude of isolated facts.[1,145] Guidelines and algorithms are useful and provide a conceptual framework, but rote memorization and dogmatic adherence need to be avoided. Individualization of guidelines and application of their underlying principles to particular patients is the goal.

CHAPTER 111

The Pathology of Bronchogenic Carcinoma

Leslie A. Litzky

There have been profound and fundamental changes in the significance of the histologic classification of bronchogenic carcinoma since the previous edition of this book. The past practice of simply dividing lung tumors into non–small-cell and small-cell lung carcinoma, particularly when evaluating small specimens in patients with advanced disease, was nearly always sufficient for providing the clinically relevant pathologic information that was necessary for treatment purposes. The development of new classes of drugs and targeted therapy for lung cancer has not only prompted an extensive reevaluation of the pathologic classification but has also affected strategies for tissue acquisition and routine processing. Rather than diminishing the traditional role of the pathologist in lung cancer treatment, the advent of what has been termed "personalized" or "precision" medicine has only made pathologic assessment more crucial to patient management.[1,2] This chapter focuses on the major histologic subtypes of malignant pulmonary epithelial tumors and includes carcinoid tumors, sarcomatoid carcinoma, and salivary gland tumors. Other unusual tumors, both benign and malignant, are covered in a separate chapter and there is a separate chapter on the genetic and molecular changes in lung cancer. The extremely rapid pace of developments in molecular diagnostics and therapy makes it quite difficult to make enduring summary statements about the prognostic and therapeutic implications for specific histologic subtypes. The overall intent of the chapter is to provide a broad overview of the current histologic classification with its controversies and to provide a deeper understanding of the current issues regarding the preanalytic steps of sampling, processing, and evaluating lung cancer specimens for molecular analysis.

GENERAL CONSIDERATIONS IN HISTOLOGIC CLASSIFICATION AND THE CURRENT CLASSIFICATION OF LUNG TUMORS

Pathologic assessments are continually refined to reflect changes in surgical and medical management, as well as to incorporate an improved understanding of basic tumor biology. Once the diagnosis of malignancy has been made, the pathologic evaluation of lung cancer has traditionally focused on histologic subtyping and, for the minority of patients undergoing surgical resection, determining the extent of disease. Histologic classification is essentially predicated on the assumption that the quantitative predominance of a particular histologic pattern reflects distinctive biologic characteristics. It has been gratifying to note that concurrent developments in other disciplines such as molecular biology have substantiated many aspects of the currently accepted framework for histologic classification. The 2004 World Health Organization (WHO) classification of lung tumors was the first edition to extensively summarize the molecular biology of different tumor subtypes.[3] Nevertheless, the main purpose of the 2004 WHO classification was to provide reproducible criteria to pathologists worldwide by using recognizable architectural patterns and individual cellular features that can be appreciated by routine light microscopy and standard hematoxylin- and eosin-stained slides. The use of ancillary techniques, such as immunohistochemistry or molecular biology, is not required in most instances, thereby making the classification accessible to all pathologists for diagnosis and fostering consistency in treatment and research protocols. Although this approach might seem antiquated, it should be noted that the incorporation of data from ancillary studies such as immunohistochemistry or molecular analysis has broad implications, not the least of which is the expense of the laboratory tests, which require additional time, special equipment, technical expertise, and the possibility of exhaustion of small tumor samples that are then no longer available for future testing. Criteria for the interpretation of some of these emerging molecular tests have yet to be well defined and the clinical significance addressed within the confines of prospectively designed, large clinical studies with standardized laboratory analysis.

The 1999 WHO classification introduced significant changes in the classification and nomenclature of malignant epithelial lung tumors from the previous 1982 WHO classification.[4] These changes reflected the substantial amount of pathologic observation and translational research that had ensued in the intervening 17 years. The 2004 revision made some minor changes in nomenclature but preserved the overall classification scheme that had been established in 1999. Major changes in the 1999 revision included the introduction of new variants of squamous cell carcinoma, adenocarcinoma, and large-cell carcinoma, as well as new or refined definitions for bronchioloalveolar carcinoma (BAC) and solid adenocarcinoma. The 1999 revisions also incorporated consensus criteria for neuroendocrine tumors and biphasic or pleomorphic tumors. Although it is beyond the scope of this chapter to discuss in detail, it is worth noting that 1999 WHO revisions also added and defined two other preneoplastic processes – atypical adenomatous hyperplasia (AAH) and diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH) – to the previously recognized squamous dysplasia/carcinoma in situ.

Tumor classification and associated generalizations pertaining to tumor type are often made to seem relatively straightforward but, in practice, it is always a challenge for any proposed scheme of histopathologic classification to ensure the reproducible recognition of tumor subtypes. One of the major criticisms of the current WHO classification is that the classification of lung cancer cell types is based on a detailed histologic examination of resection specimens despite the unfortunate fact that the majority of lung cancer patients present with advanced disease and never undergo resection. The 1999 and then the 2004 WHO classifications also had attempted

to reconcile the often bewildering heterogeneity of pulmonary adenocarcinomas by introducing the term "mixed" type. In practice this term ended up obscuring major differences between minimally and predominantly invasive adenocarcinomas and the potential prognostic significance of different histologic patterns in adenocarcinomas. The 2011 International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society (IASLC/ATS/ERS) International Multidisciplinary Classification of Lung Adenocarcinoma addressed these two major issues by proposing terminology for small biopsies/cytology specimens and by proposing a new classification for adenocarcinomas.[5] The overall framework of this classification has been generally accepted and adopted but with some criticism, particularly in regard to the new category of "lepidic predominant adenocarcinoma."[6] Despite these refinements, the degree to which histologic heterogeneity is recognized and tumors classified depends to some extent on sampling techniques, and that may, in turn, have implications for protocol design and data evaluation. The effects of prior therapy must also be considered in subsequent biopsies.

Lung carcinomas are classified according to the best differentiated component and pathologists assign a degree of differentiation to tumors that show differentiation, such as squamous cell carcinoma and adenocarcinoma. This is also known as histologic grading and it is used in tumor pathology as a way of attributing prognostic significance to a specific histologic pattern. It is an assessment as to how much the tumor cells phenotypically resemble a normal cell type, such as a squamous cell or a glandular cell. Histologic grading should not be viewed as a histogenetic determination, that is, that a tumor is derived from a specific cell of origin, such as a squamous cell, or that the tumor cell has "dedifferentiated" from a cell of origin. There are three histologic degrees of differentiation: well differentiated, moderately differentiated, and poorly differentiated. Many lung tumors show a wide variation in differentiation. If a tumor is largely undifferentiated but contains recognizable foci of squamous cell carcinoma or adenocarcinoma, it is classified as a poorly differentiated squamous cell carcinoma or adenocarcinoma, respectively. Some tumors, such as small-cell carcinoma or sarcomatoid carcinoma are, by definition, poorly differentiated. In recent years, the most intense focus has been on developing a standardized histologic grading system for pulmonary adenocarcinomas and these efforts will be summarized in the subsequent section on adenocarcinoma.

Only one study to date has provided data on the interobserver reproducibility for non–small-cell lung carcinomas with routine hematoxylin–eosin slides for the current 2004 WHO classification.[7] In this study, which included both community pathologists and expert pulmonary pathologists, overall interobserver reproducibility was only fair ($\kappa = 0.25$) when using all 44 diagnostic categories of malignant epithelial tumors, with improvement following consolidation into 10 diagnostic categories ($\kappa = 0.48$) or the therapeutically relevant small-cell/non–small-cell distinction ($\kappa = 0.55$). Not surprisingly, the study identified better differentiation, in addition to slide quality and pathologist expertise, as important predictive factors for increased interobserver reproducibility. The results help to define a baseline diagnostic agreement that might be used in the validation of other ancillary techniques such as immunohistochemistry or molecular analysis that are proposed to further refine diagnostic criteria.

The histologic subtyping of pulmonary carcinomas on the basis of morphology alone is even more challenging in small samples. With the advent of targeted therapies for non–small-cell carcinoma, further pathologic subclassification beyond the traditional distinction between small-cell carcinoma and non–small-cell carcinoma is now considered critical for selecting appropriate treatment for patients.[1] Subsequent sections will address the expanded use of immunohistochemical stains for further histologic subclassification as well as the competing priority of preserving sufficient tumor for molecular analysis.

INVASIVE ADENOCARCINOMA, INCLUDING ADENOCARCINOMA IN SITU AND MINIMALLY INVASIVE ADENOCARCINOMA

Adenocarcinoma is the most common histologic subtype in the United States and in most countries.[8] Adenocarcinoma is also the most frequently diagnosed subtype in nonsmokers.[9] The classification of pulmonary adenocarcinoma has long been a source of controversy—not only because of its diversity in histologic appearance but also because of a wide spectrum of clinical behavior, radiographic findings, and molecular characteristics associated with the entity. It is worth reviewing a concise history of the revisions in lung adenocarcinoma classification to understand the conceptual framework of 2011 IASLC/ATS/ERS multidisciplinary classification and current unsettled issues. The inherent histologic heterogeneity of many primary pulmonary adenocarcinomas has always made reproducible subclassification difficult and even small adenocarcinomas (<2 cm) can contain more than one histologic pattern.[10] This practical problem was addressed by the 1999 WHO revision, which introduced for the first time a *mixed* subtype to the four previously recognized subtypes of *acinar, papillary, bronchioloalveolar,* and *solid*.[4] In addition, a strict definition for BAC was adopted in the 1999 revision and retained in the 2004 classification. The definition required that the tumor have a pure lepidic growth pattern without evidence of stromal, vascular, or pleural invasion.[3,4] The term "lepidic" means that the proliferation of tumor cells should line the alveolar walls in a uniform manner, using the alveolar walls as a supporting scaffold. It should be noted that prior to the 1999 revision, pathologists widely varied in their assessments. Adenocarcinomas with a minor, usually central, and often more poorly differentiated invasive glandular component along with a peripheral bronchioloalveolar pattern are frequently encountered. In instances in which the peripheral BAC component predominated, it had been a common practice to designate the tumor either as a BAC or an "adenocarcinoma with a BAC pattern/features." The stricter definition of BAC prevailed in the revisions because of evidence demonstrating that small (<2 cm) solitary tumors with a pure lepidic growth pattern had a 100% 5-year survival.[11] Histologically, BACs were divided into two major subtypes, *nonmucinous* and *mucinous,* and were grouped together because of a similar "lepidic" growth pattern along alveolar septa. The more common nonmucinous type consists of cuboidal, columnar, or so-called "hobnail" cells with apical nuclei. The mucinous type consists of tall columnar cells with abundant apical pale mucinous cytoplasm and basally located nuclei, sometimes resembling goblet cells. A rare *mixed nonmucinous and mucinous* or *indeterminate* subtype was also recognized in the 1999/2004 revisions.

While this classification of BAC made sense from a histologic pattern perspective, it did not really encompass the variability in clinical presentation, radiographic features, or prognosis. Although practice patterns changed somewhat after these revisions, the diagnosis of BAC continued to be used for both small and well-differentiated adenocarcinomas as well as for more advanced stage tumors with obvious diffuse pneumonic spread or lymph node involvement. Moreover, in the years following the publication of the 2004 WHO classification, it became increasingly apparent that the nonmucinous and mucinous cell types have distinctive clinical, radiographic, immunophenotypic, and molecular correlations.[12,13] In 1995, Noguchi et al. had suggested that even small foci of invasion in what would otherwise be a pure BAC were associated with a 100% disease-free survival and, following the publication of the 2004 WHO classification, there were a number of other studies that similarly supported quantitation of the lepidic growth pattern and the area of invasion within these "mixed" type adenocarcinomas. These studies focused on a cutoff of 5 mm or less of

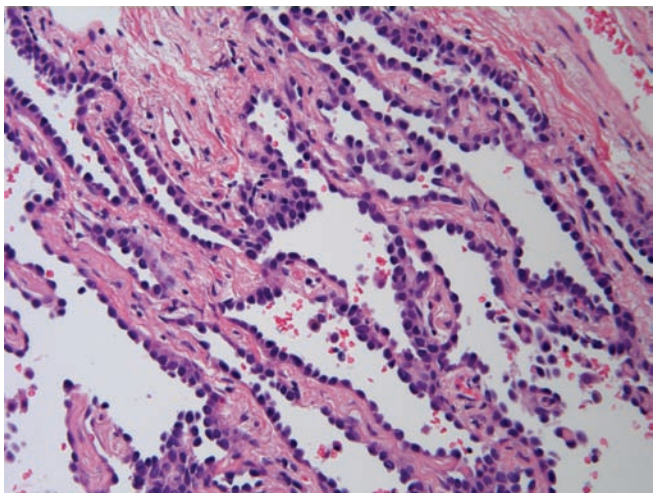

Figure 111-1 Adenocarcinoma in situ, nonmucinous. Uniform proliferation of atypical nonciliated columnar cells with apical nuclei. The tumor cells are growing along the alveolar septa without invasion. (H&E, 200×).

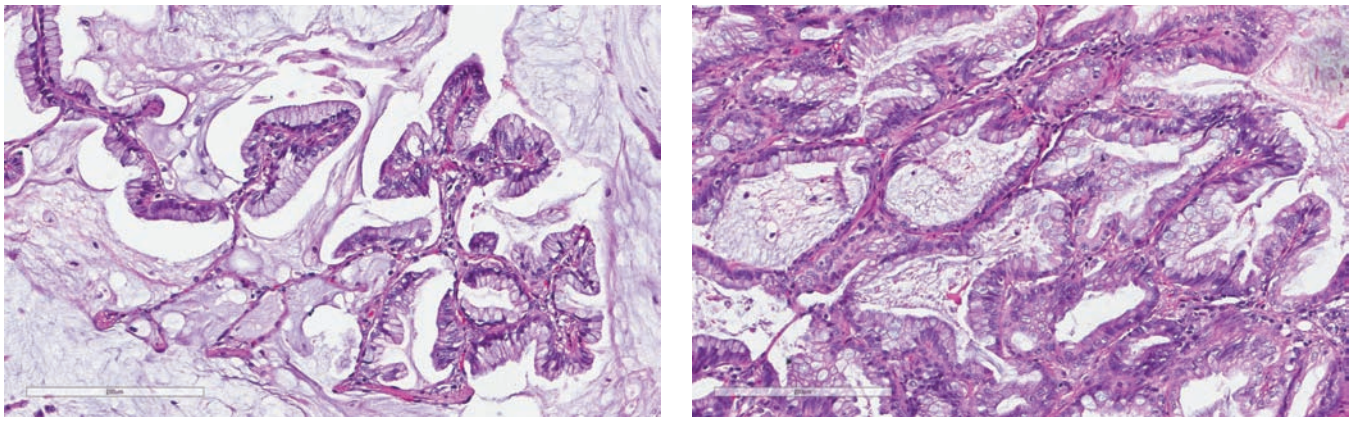
invasion as a way of defining a "minimally invasive adenocarcinoma" (MIA) with an excellent survival.[14,15]

The evidence from these and other studies culminated in the comprehensive 2011 IASLC/ATS/ERS International Multidisciplinary Classification of Lung Adenocarcinoma.[5] The 2011 classification completely discards the term BAC in favor of "adenocarcinoma in situ" (AIS). For small (≤3 cm) solitary adenocarcinomas with predominant lepidic growth and small foci of invasion measuring ≤0.5 cm, the term "minimally invasive adenocarcinoma" is recommended. By definition, MIA, can only be applied to a solitary and discrete lesion unless it is clear, in the instance of multiple tumors, that they are synchronous primaries.[5] Although the new terminology is a bit unsettling to pathologists and clinicians who have long been used to the entity of BAC, the terms AIS and MIA were favored because they more accurately reflect both the histologic growth pattern and survival statistics. AIS and MIA will typically present as pure ground-glass opacities without a solid component on computed tomography (CT) scans.[16] The majority of AIS and MIA cases are nonmucinous, although some cases of mixed nonmucinous and mucinous MIA have been reported (Fig. 111-1).[17] Most lesions with a mucinous "BAC" histologic pattern, if carefully examined and sampled, will have invasive foci and, therefore, are classified as "invasive mucinous adenocarcinoma" (Fig. 111-2A,B).

The IASLC/ATS/ERS consensus panel further proposed that invasive adenocarcinomas be characterized by a predominant subtype and recognized five patterns: Lepidic predominant, acinar predominant, papillary predominant, micropapillary predominant, and solid predominant with mucin production. The introduction of a "predominant" pattern was intended as a practical way to evaluate the characteristic heterogeneity of many adenocarcinomas and to allow for better stratification than the "mixed subtype."[5] The recommendation was based on studies in stage I tumors that had suggested that these different histologic patterns had prognostic value in a grading system and that these different patterns can be reproducibly recognized.[17–19] Other studies have further validated the prognostic significance of the predominant histologic pattern using this classification system or have evaluated other potential parameters for a grading system including mitotic rate and high thyroid transcription factor-1 (TTF-1) expression within this framework.[20–23] *Lepidic predominant adenocarcinoma* consists mainly of tumor cells growing along alveolar septa (previously referred to as a nonmucinous BAC pattern) but with greater than 5 mm invasion. *Acinar predominant adenocarcinoma* consists of irregularly contoured but nonetheless recognizable glandular structures and is often associated with a desmoplastic stroma (Fig. 111-3A). *Papillary predominant adenocarcinoma* consists of malignant cuboidal or columnar cells that line the surface of fibrovascular cores (Fig. 111-3B). *Micropapillary predominant adenocarcinoma* consists of small papillary clusters of glandular cells growing within airspaces (Fig. 111-3C). The micropapillary pattern was not recognized as a formal histologic subtype in the 2004 WHO classification but has since been recognized in IASLC/ATS/ERS adenocarcinoma classification.[5] *Solid predominant adenocarcinoma with mucin* consists of sheets of tumor cells without an acinar, papillary, or lepidic growth pattern (Fig. 111-3D). The tumor cells have abundant cytoplasmic and mostly vesicular nuclei with prominent nucleoli. Multiple tumor cells have basophilic cytoplasmic vacuoles that suggest intracytoplasmic mucin, which then may be confirmed by a special stain for mucin. The 2004 WHO classification requires that be there five or more mucin-positive cells in at least two high power fields for the diagnosis of *solid adenocarcinoma with mucin production*. This criterion was adopted because it is not uncommon for squamous cell or large-cell carcinomas to have rare mucin droplets and this is retained in 2011 IASLC/ATS/ERS classification. By definition, given the solid pattern of the tumor, solid adenocarcinomas are poorly differentiated.

The variants of invasive adenocarcinoma that were defined in the 1999/2004 WHO classifications were reconsidered in the 2011 update and four variants are now recognized: *invasive mucinous*



A **B**

Figure 111-2 Invasive mucinous adenocarcinoma. **A.** Tall columnar cells with abundant mucinous cytoplasm line the alveolar septa (former mucinous bronchiolalveolar carcinoma). **B.** Invasive pattern in same tumor. (H&E, 200×).

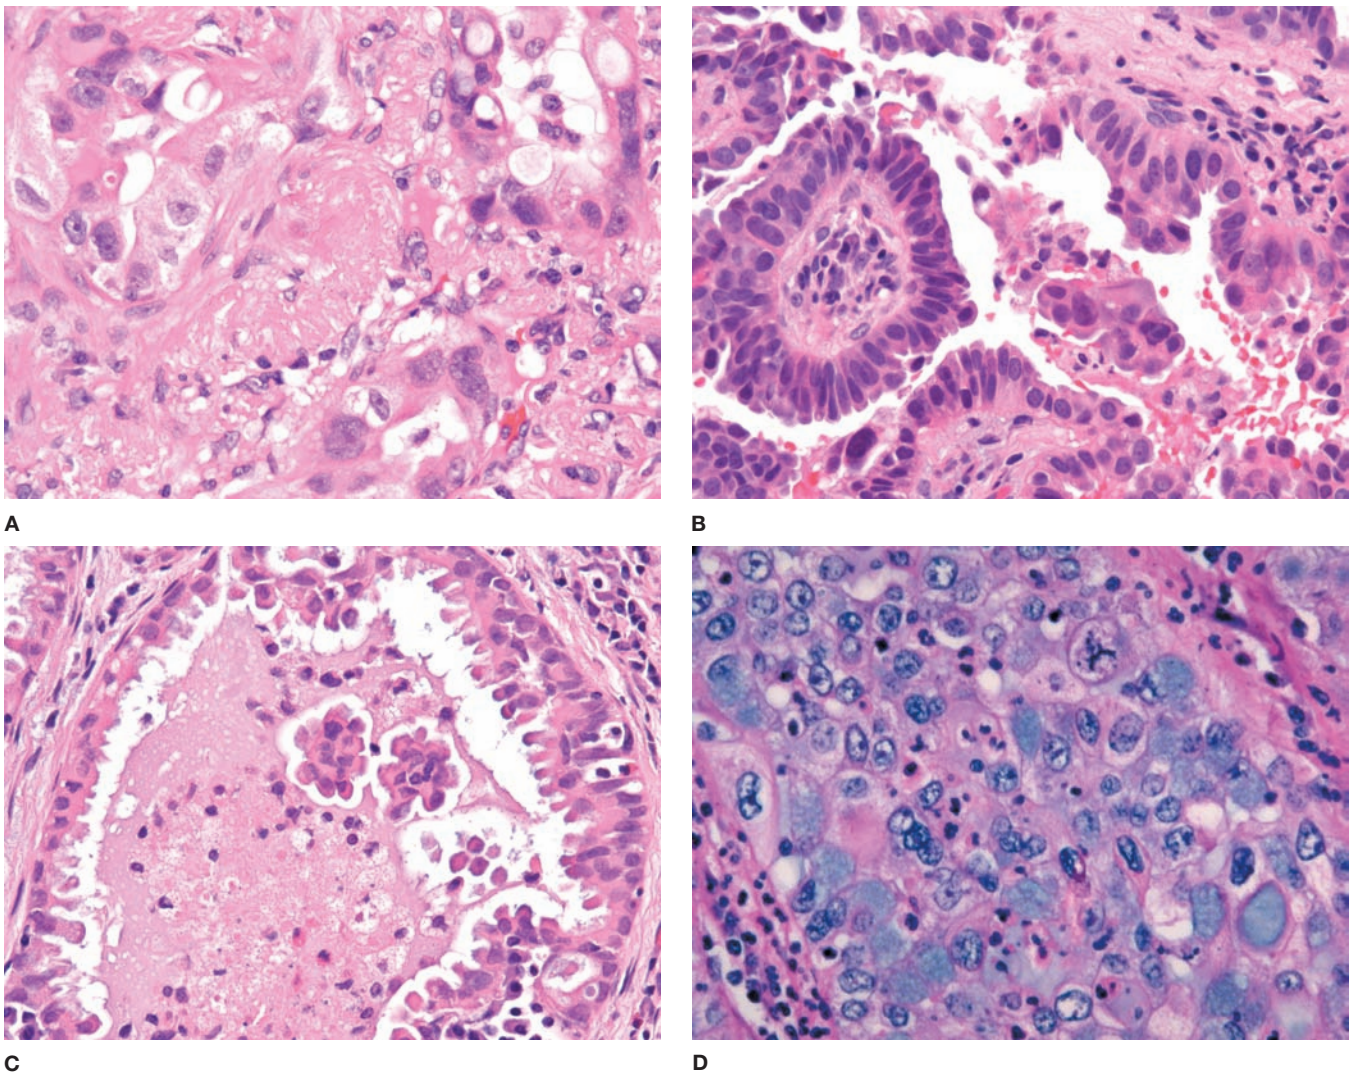


Figure 111-3 **A.** Invasive pulmonary adenocarcinoma, acinar predominant. adenocarcinoma (formerly mucinous BAC), *colloid adenocarcinoma*, *fetal adenocarcinoma* (low and high grade), and *enteric adenocarcinoma*.[5] The previously recognized variants of *signet-ring adenocarcinoma,* and *clear cell adenocarcinoma* were discarded as discrete entities and are now viewed as cytologic changes that can occur in association with multiple histologic patterns. Although echinoderm microtubule–associated protein-like 4 and anaplastic lymphoma gene fusions (*EML4-ALK*) may be seen in other histologic subtypes, a significant number of patients with this fusion will demonstrate a solid signet-ring cell pattern (Fig. 111-4).[24,25] *Enteric adenocarcinoma* was added because of its morphologic and immunohistochemical overlap with colorectal adenocarcinomas, thereby necessitating a clinical evaluation to exclude a gastrointestinal primary.[5]

The reproducibility of histopathologic subtype and invasion in pulmonary adenocarcinomas has been studied.[26] In pulmonary adenocarcinomas with classic morphology, there is good reproducibility in identifying a predominant pattern but only fair reproducibility in distinguishing invasion from in situ (wholly lepidic) patterns. Specifically recognizing stromal invasion is still somewhat problematic in practice, even among expert thoracic pathologists. Many adenocarcinomas have areas of fibrosis due to alveolar wall collapse or septal fibrosis with some observers interpreting an individual case as tumor-related stroma with fibroblasts (desmoplastic stroma) and others interpreting as benign fibroelastotic scarring. Histologic criteria for true invasion include single cell infiltration, a fibromyxoid stromal response, high-grade cytology, and a cribriform

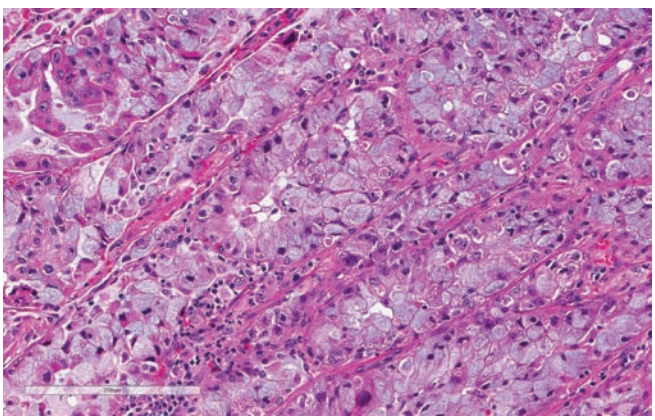

Figure 111-4 Numerous tumor cells with abundant intracellular mucin (signet-ring cells) that can be seen in association with *EML4-ALK* fusion. (H&E, 200×).

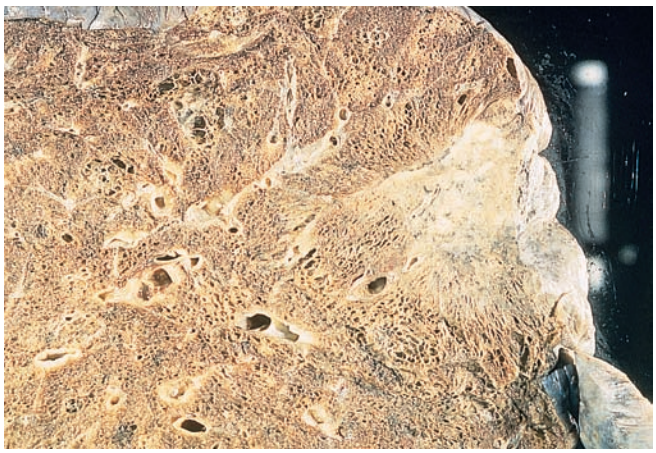

Figure 111-5 Peripheral adenocarcinoma of the lung with pleural puckering.

or acinar growth pattern. This lack of clarity and reproducibility in defining what constitutes invasion in well-differentiated adenocarcinomas makes the subtype of "lepidic predominant adenocarcinoma" the most controversial and there remains some work to be done in terms of refining, standardizing, and improving the recognition of purely in situ disease.[6,26]

The majority of adenocarcinomas arise in the periphery of the lung and are often associated with parenchymal scarring or puckering of the overlying pleura (Fig. 111-5). It is now a standard recommendation for accurate staging to use elastin stains in the evaluation of visceral pleura invasion in any lesion that approaches the visceral pleura (Fig. 111-6).[27,28] Although there are associations of specific subtypes of adenocarcinoma with, for example, *EGFR* mutations or the *EML4-ALK* fusion gene, histology is not robust enough to replace molecular analysis in predicting which lung cancers have mutations and are likely to respond to targeted therapy. However, the recognition of these subtypes by the pathologist may play a role in suggesting which molecular tests are most likely to yield positive results for a given cancer and this may be important if there are restrictions due to sample size, test availability, and turnaround time.[1]

The histologic heterogeneity of adenocarcinomas is such that the exclusion of metastatic disease or malignant mesothelioma is often an important consideration. As mentioned previously in the enteric variant of adenocarcinoma, the exclusion of a colorectal primary may be important. Other features such as signet-ring cytology raise

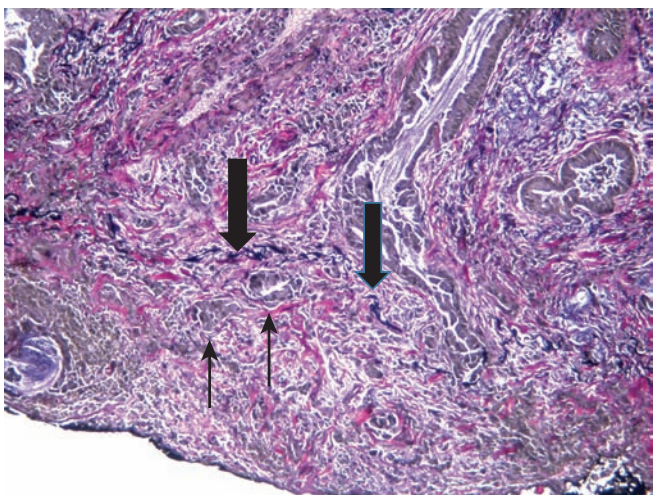

Figure 111-6 Visceral pleural invasion. Tumor cells *(thin black arrow)* are present beyond the black elastic layer of the visceral pleura *(thick black arrow)*. (Elastin, 100×).

the possibility of a gastric or appendiceal tumor as well as other primary sites. Mucinous carcinomas, particularly of pancreatic or ovarian origin, may metastasize to the lung and mimic a mucinous adenocarcinoma. All of the classic growth patterns – acinar, papillary, micropapillary, or solid – may be seen in any number of extrapulmonary primaries and clinicoradiologic correlation is always essential. The distinction between peripheral adenocarcinomas with extensive pleural involvement, diffuse carcinomatous involvement of the pleura by metastatic tumor, and malignant mesothelioma may be similarly problematic. Some carcinomas grow in a manner virtually identical to malignant mesothelioma, with extensive pleural involvement and limited parenchymal invasion.[29] Clinically, radiographically, and macroscopically, these tumors are indistinguishable from malignant pleural mesothelioma. The histologic appearance may be equally confusing, requiring the use of immunohistochemical stains. As will be discussed further in the general section on immunohistochemistry, there are multiple antibodies that will stain adenocarcinomas of the lung. Many of these antibodies (CEA, MOC31, B72.3, LeuM1, and BerEP4) recognize glycoproteins and are not specific for the lung. Surfactant protein A (SP-A), TTF-1, and Napsin A are the three commercially available markers that can be useful in the diagnosis of lung adenocarcinomas, with the latter two markers (TTF-1 and Napsin A) having higher sensitivity for lung adenocarcinomas.[30,31] It is important to recognize that neither TTF-1 nor Napsin A are entirely specific for lung adenocarcinomas and pathologists must still consider within the differential diagnosis a number of extrapulmonary tumors, depending on the clinical circumstances. The combined use of TFF-1 and Napsin A does result in improved sensitivity and specificity for identifying primary pulmonary adenocarcinomas.[32]

SQUAMOUS CELL CARCINOMA

Despite its replacement as the leading lung cancer cell type among both men and women in the United States and in many other countries, squamous cell carcinoma remains an important histologic subtype. Squamous cell carcinoma is seen more commonly in men and is still very strongly correlated with cigarette smoking.[33] About two-thirds of squamous cell carcinomas occur centrally, where involvement of a mainstem, lobar, or segmental bronchus may be demonstrated but squamous cell carcinoma may also present as a peripheral mass (Fig. 111-7A,C).[34] As would be expected from an endobronchial growth pattern, squamous cell carcinomas frequently are associated with bronchial obstruction and postobstructive pneumonia. Cavitation is seen more frequently in squamous cell carcinoma than in the other histologic subtypes (Fig. 111-7B).[3]

In the 2004 WHO classification, squamous cell carcinoma is defined as a malignant epithelial tumor showing keratinization and/or intercellular bridges. Keratinization may be in the form of squamous pearls or individual cells with dense eosinophilic cytoplasm. Intercellular "bridges" are seen in paraffin sections due to cell shrinkage caused by fixation and correspond to the desmosomal attachments that can be appreciated ultrastructurally (Fig. 111-8B,C). A desmoplastic (i.e., fibrotic) response is often associated with the invasive nests of tumor cells (Fig. 111-8A). As is true of other histologic types, squamous cell carcinomas often show areas of histologic heterogeneity. There are four histologic variants within the 2004 WHO classification of squamous cell carcinoma: papillary, clear cell, small cell, and basaloid patterns.[3] On occasion, a tumor may consist entirely of one of these variants, but it is far more common for these patterns to be focal. The *papillary variant* is characterized by an exophytic growth pattern and papillary cores. The classic tumor cells of a squamous cell carcinoma are large and polygonal with eosinophilic cytoplasm, but in the *clear cell variant*, as the name suggests, cells with clear cell cytoplasm can be seen (Fig. 111-8D). In the basaloid variant, the nests of tumor cells have prominent peripheral palisading and have less cytoplasm toward the

periphery, but the more centrally located cells have more obvious keratinization. In the *small-cell variant* of squamous cell carcinoma, the tumor cells are relatively smaller and can have granular nuclear chromatin, but there is some chromatin variation with more coarse or vesicular chromatin and prominent nucleoli. A careful search shows cytoplasmic evidence of squamous differentiation in the form of focal keratinization or intracellular bridges. A familiarity with these variant patterns is useful for the practicing pathologist, but at the current time there is no evidence that these variant patterns have any clinical significance. The basaloid and small-cell variants of squamous cell carcinoma can pose a diagnostic dilemma in small, poorly preserved biopsies when their relatively scant cytoplasm mimics small-cell carcinoma. In this instance, a panel of immunohistochemical stains that includes markers of squamous and neuroendocrine differentiation can be useful in interpretation.

Although not invariably demonstrated, it is easiest to identify a trend in tumor progression with the squamous cell histologic subtype. Sampling of a resected specimen may show changes in the adjacent bronchial mucosa ranging from squamous metaplasia to dysplasia to carcinoma in situ. If identified, the presence of an in situ component helps to differentiate a primary squamous cell carcinoma from a metastatic lesion. Aside from a clear-cut transition from in situ to invasive squamous cell carcinoma, there is no other conclusive morphologic means of differentiating a primary pulmonary squamous cell carcinoma from a metastasis. There is a tendency for metastatic tumors from the head and neck to be better differentiated (i.e., show more extensive keratinization) than their primary pulmonary counterparts, but reliably distinguishing a primary squamous cell carcinoma of the lung from other primary sites, particularly from the head and neck, continues to be an ongoing issue. There are studies that have used various molecular techniques to separate a primary squamous cell carcinoma of the lung from a metastasis from the head and neck or addressed these diagnostic issues within the broader context of synchronous or metachronous tumors and metastases.[35,36] It is anticipated that additional studies will further validate molecular techniques and facilitate their transition into routine clinical assays that can be used in equivocal clinicopathologic circumstances and when the distinction is critical for treatment or prognosis.

ADENOSQUAMOUS CARCINOMA

This tumor consists of well-defined squamous carcinoma and adenocarcinoma components, with each component comprising at least 10% of the whole tumor.[3] The areas of glandular and squamous differentiation may be located in different areas of the tumor or may be intimately admixed. In the past, different criteria had been used for this histologic subtype and these differences in definition, in addition to its low incidence, have made it extremely difficult to compare survival rates with other non–small-cell carcinomas. Prior to the widespread use of immunohistochemistry, the incidence of adenosquamous carcinoma was estimated at 1%.[37] It is unclear how the increasing use of immunohistochemistry for histologic subtyping will impact the incidence of this rare tumor. The 2004 WHO criterion of 10% was intended to foster more uniformity in clinical trials and research studies but there is still only a limited amount of data available on this histologic subtype. There are studies that have reported a worse prognosis with adenosquamous carcinoma when compared to other non–small-cell carcinomas of the lung.[38–40] The question as to whether adenosquamous carcinomas are a simple mix of adenocarcinoma and squamous cell carcinoma or whether they are more complex at a molecular level is an interesting one that may have a significant impact on targeted therapy selection. There is a limited amount of data that

suggests that these tumors are not simple mixtures of two histologic components but rather behave as their own unique entity.[41,42]

LARGE-CELL CARCINOMA

Large-cell carcinomas account for a little less than 10% of all lung cancers.[37] Large-cell undifferentiated carcinoma is defined in the 2004 WHO classification as "an undifferentiated malignant epithelial tumor that lacks the cytologic features of small-cell carcinoma and glandular or squamous differentiation."[3] The tumor cells typically have large nuclei, prominent nucleoli, and a moderate amount of cytoplasm (Fig. 111-9). As is evident from this description, this tumor is defined more by what it is not than what it is. For practical purposes, it is a diagnosis of exclusion, and the diagnosis of large-cell carcinoma requires morphologic examination of the resected tumor to rule out areas of squamous or glandular differentiation. The WHO criteria for large-cell carcinoma are based on conventional microscopy, the occasional use of mucin stains, and the required use of immunohistochemistry for one variant (large-cell neuroendocrine carcinoma). Melanoma, malignant large-cell lymphomas, and epithelioid sarcomas also can mimic large-cell carcinoma, typically requiring the use of immunohistochemistry to exclude these diagnoses. The major change in the 1999/2004 WHO revisions was to expand the number of variants included within the category of large-cell carcinoma and transfer others, namely giant cell carcinoma and spindle cell carcinoma, into the sarcomatoid carcinoma category. The large-cell carcinoma variants now include *large-cell neuroendocrine carcinoma* and *combined large-cell neuroendocrine carcinoma* (to be covered in the section on neuroendocrine tumors) in addition to *basaloid carcinoma,*

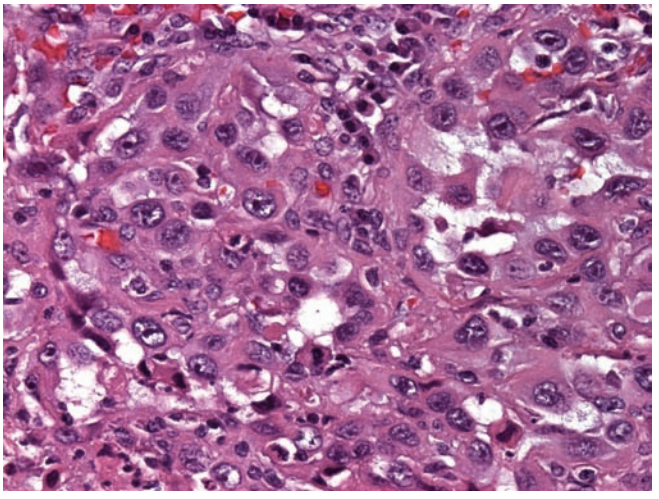

Figure 111-9 Large-cell carcinoma of the lung. There is no obvious squamous differentiation in the form of keratinization or intercellular bridges and a mucin stain was negative (H&E, 400×).

lymphoepithelioma-like carcinoma, clear cell carcinoma, and large-cell carcinoma with rhabdoid phenotype (discussed below).

Despite this definition of large-cell carcinoma based solely on morphology, it has long been known and generally acknowledged that the majority of these tumors represent either very poorly differentiated adenocarcinomas or squamous cell carcinomas. By electron microscopy, many large-cell carcinomas show focal ultrastructural features consistent with adenocarcinoma or a poorly differentiated squamous cell carcinoma.[43] Similar subsets within large-cell carcinoma can be defined using the same immunohistochemical stains that are routinely employed to distinguish between adenocarcinoma and squamous cell carcinoma and the distribution of targetable mutations can be generally correlated with the immunophenotyping profile.[44] The extent to which morphologically identifiable large-cell carcinomas with immunohistochemical marker profiles of adenocarcinoma or squamous cell carcinoma should be reclassified for prognostic and therapeutic purposes has not been resolved. It is nevertheless clear that there are therapeutically relevant genetic alterations within these "undifferentiated" carcinomas that have practical implications for predictive molecular testing strategies and individualized therapy.

■ OTHER VARIANTS OF LARGE-CELL CARCINOMA

In the 1999/2004 WHO revisions, *basaloid carcinoma of the lung* is considered to be a variant of large-cell carcinoma. The basaloid histologic features in lung carcinomas are similar to those also seen in other extrapulmonary sites such as the head and neck or cervix. Basaloid cells are typically described as relatively small monomorphic cuboidal to fusiform cells with moderately hyperchromatic nuclei, finely granular chromatin, absent or focal nucleoli, scant cytoplasm, and a high mitotic rate. Intercellular bridges and/or individual cell keratinization should not be present. The tumor cells are usually arranged in lobular, trabecular, or palisading growth patterns (Fig. 111-10). Since these types of histologic patterns can also be seen in neuroendocrine tumors, immunohistochemical stains for neuroendocrine markers should be negative or extremely focal. If the basaloid component is less than 50% and combined with a squamous cell carcinoma, the tumor is classified as squamous cell carcinoma (basaloid variant). One large series of basaloid carcinomas that included both tumors as a variant of large-cell carcinoma and those associated with a squamous cell component suggested that the basaloid pattern itself confers a poor prognosis.[45]

Lymphoepithelioma-like carcinomas are extremely rare in the Western population but are more frequently reported in Chinese patients.[46] This rare pulmonary tumor was first reported in the lung in 1987 and the morphologic features are identical to undifferentiated nasopharyngeal carcinoma of the head and neck.[47] Large malignant cells with prominent nucleoli are arranged in nests within a lymphoid-rich stroma (Fig. 111-11). In Eastern Asian patients, Epstein–Barr virus EBER-1 RNA has been demonstrated to be present in the large tumor cells.[46]

The *clear cell carcinoma variant* consists of a pure clear cell carcinoma without evidence of squamous or glandular differentiation. The tumor consists of large polygonal cells with clear or foamy cytoplasm.[3] In addition to other primary lung tumors, the differential diagnosis of a large-cell carcinoma with prominent clear cells should include tumors from other primary sites such as the kidney.

Large-cell carcinoma with rhabdoid phenotype, that is, a large-cell carcinoma with cells showing prominent eosinophilic cytoplasmic globules, is extremely rare. Although this variant is included under large-cell carcinoma, mixtures of rhabdoid tumor cells with other recognizable components such as adenocarcinoma have also been reported. In the limited number of cases that have been reported in the literature, this rhabdoid phenotype is associated with a poor prognosis.[48]

SARCOMATOID CARCINOMA

Tumors that have sarcoma-like elements such as malignant spindle or giant cells or have a sarcomatous component that consists of a neoplastic but differentiated connective tissue phenotype such as neoplastic bone, cartilage, and striated muscle have been described in many primary organ sites, including the lung. The proliferation of terms in past literature and even the variations in nomenclature that have characterized revisions in the WHO classification have generated a disproportionate degree of confusion when compared with the actual incidence of these relatively rare lung tumors. Various terms in the literature have included spindle cell carcinoma, sarcomatoid carcinoma, carcinosarcoma, pleomorphic carcinoma, giant cell carcinoma, and pulmonary blastoma. The 1999 revision established a minimum requirement of 10% for certain elements, such as spindle cells or giant cells, for a tumor to be appropriately classified.[4] The most recent 2004 WHO revision has settled on the term *sarcomatoid carcinoma* to categorize these tumors, which are by definition poorly differentiated non–small-cell carcinomas that have a histologic appearance that suggests mesenchymal differentiation. The current

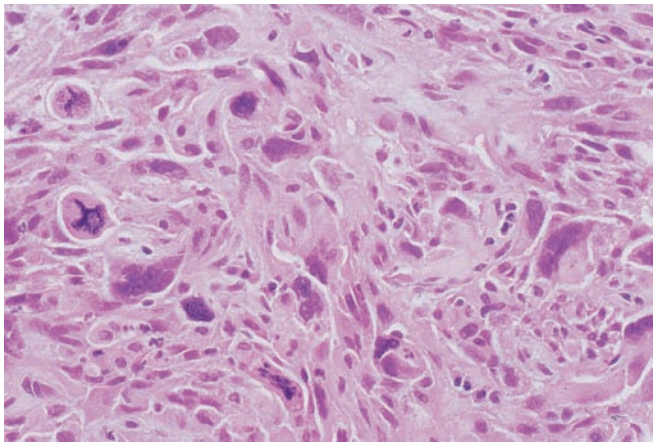

Figure 111-12 Pleomorphic carcinoma of the lung. The spindle cell and giant cell component in this large-cell carcinoma comprise at least 10% of the tumor (H&E, 400×).

variants of sarcomatoid carcinoma include *pleomorphic carcinoma, spindle cell carcinoma, giant cell carcinoma, carcinosarcoma,* and *pulmonary blastoma.*[3] It is now accepted that these variants are phenotypic variations that can occur within the spectrum of epithelial-derived lung tumors. Careful sampling of these tumors will often demonstrate an identifiable component of squamous cell carcinoma, adenocarcinoma, or large-cell carcinoma. The rarity of these tumors (<2%) and previous confusion in terminology have made it difficult to characterize clinical characteristics and outcome.[49] These tumors have no distinguishing radiologic features and have been reported in both central and peripheral locations. With the exception of pulmonary blastoma, which appears to be most frequent in the fourth decade and occurs slightly more in women, the other variants occur primarily in men in the sixth and seventh decade and have the same general association with tobacco use as other more common lung tumors.[3] As with other entities in the WHO classification, the diagnosis of sarcomatoid carcinoma cannot be made on the basis of a cytology or small biopsy specimen. Features suggestive of the tumor in a small sampling may be mentioned on a descriptive basis, that is, poorly differentiated non–small-cell lung cancer with spindle and/or giant cell carcinoma.[5]

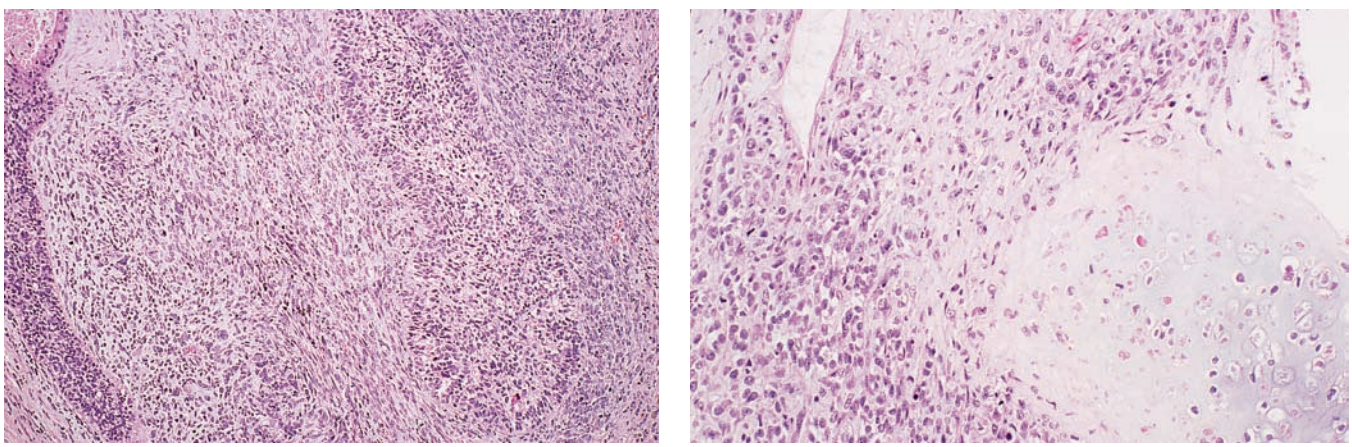
Pleomorphic carcinoma is defined as a poorly differentiated non–small-cell carcinoma containing spindle cells and/or giant cells. As mentioned, the spindle cell and/or giant cell component should comprise at least 10% of the tumor (Fig. 111-12). *Spindle cell carcinoma* and *giant cell carcinoma* are terms that are reserved for the extremely rare instance in which the tumor is shown to consist entirely of spindle cells or giant cells, respectively. The tumor giant cells are bizarre, dyscohesive, and multinucleated and often associated with an inflammatory infiltrate that includes increased numbers of neutrophils.

In the pathology literature, tumors that contain cells with a neoplastic but differentiated connective tissue phenotype are said to have "heterologous elements." *Carcinosarcoma* refers to a lung tumor that has recognizable heterologous elements such as rhabdomyosarcoma, osteosarcoma, or chondrosarcoma (Fig. 111-13). Rather than terminology, the more significant issues confronting the pathologist are exclusion of metastasis from another site and avoiding the misdiagnosis of a primary pulmonary sarcoma.

Pulmonary blastoma is a biphasic tumor that contains a primitive epithelial component that resembles well-differentiated fetal adenocarcinoma and a primitive mesenchymal stroma, which occasionally has foci of osteosarcoma, chondrosarcoma, or rhabdomyosarcoma.[3] The term pulmonary blastoma had been used historically to describe tumors that have been reported in all age groups. Manivel et al.[50] argued that the childhood intrathoracic tumor was a distinct clinicopathologic entity that differed from the adult type, particularly in the absence of a carcinomatous component and its variable anatomic location. They proposed the alternate nomenclature of *pleuropulmonary blastoma* for these pediatric tumors, which occur almost exclusively in children of 6 years of age or younger, and in the 2004 WHO classification, this tumor is recognized as a distinct entity in the mesenchymal tumor category.[3] *Pulmonary blastoma* mainly occurs in adults. Although uncommon, pulmonary blastomas composed exclusively of embryonal-like epithelial and mesenchymal elements do occur. Adult tumors consisting entirely of malignant primitive glandular epithelium have also been described and are termed *fetal adenocarcinomas,* now classified as a variant of adenocarcinoma. Pulmonary blastomas have a histologically distinct, malignant glandular component that resembles the developing fetal lung at an early gestational age and malignant cellular stroma with an embryonic appearance (Fig. 111-14). The treatment is surgical and there is no good data on adjuvant therapy.[51]

PULMONARY NEUROENDOCRINE TUMORS—OVERVIEW

The 2004 WHO classification includes four tumor subtypes with neuroendocrine differentiation: carcinoid tumor (typical), carcinoid tumor (atypical), large-cell neuroendocrine carcinoma, and small-cell carcinoma[3] Collectively, these neuroendocrine tumors



A B

Figure 111-13 **A.** Carcinosarcoma showing a mixture of sarcoma (center) and carcinoma (periphery) (H&E stain, 100×). **B.** Tumor includes a malignant cartilaginous component (H&E stain, 100×).

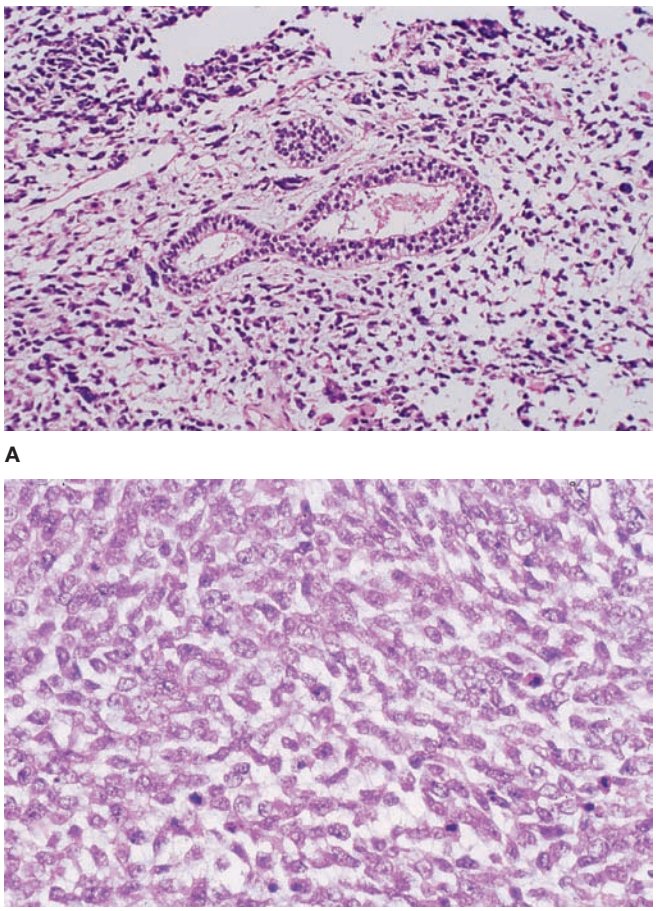


Figure 111-14 **A.** Pulmonary blastoma, showing a characteristic endometrioid-type gland, composed of cells with clear cytoplasm and basally oriented nuclei (H&E, 200×). **B.** Malignant stroma in a pulmonary blastoma (H&E, 400×).

represent about 25% of all primary pulmonary carcinomas with small-cell carcinoma being by far the most common. Typical carcinoid tumors are reasonably represented in surgical series but the relative rarity of atypical carcinoid tumors and the low incidence and controversies surrounding the definition of large-cell neuroendocrine carcinoma make it more difficult to establish treatment guidelines and prognosis for those entities. Historically, the recognition of "neuroendocrine differentiation" was based on morphologic characteristics as assessed by traditional light microscopy and hematoxylin and eosin sections. The subsequent introduction of electron microscopy and then the widespread use of immunohistochemistry (which has become the standard in routine clinical practice) led to a broader identification of "neuroendocrine differentiation" and, inevitably, debates about classification, therapeutic implications, and prognosis ensued. As is to be expected with any framework for classification, the WHO classification for neuroendocrine tumors is not without controversy and practical difficulties. Although it has been intellectually appealing to view the pulmonary neuroendocrine tumors along a continuous spectrum from low grade (typical carcinoid) to intermediate grade (atypical carcinoid) to high grade (large-cell neuroendocrine carcinoma and small-cell carcinoma), current epidemiologic, clinical, and molecular data suggest that this is not the case. Review of the data suggest a clear-cut separation of carcinoid tumors from the high-grade neuroendocrine carcinomas and anticipate that advances in molecular genetics may further impact the classification of the high-grade neuroendocrine tumors.[52] In the 2004 WHO classification, large-cell neuroendocrine carcinoma has been categorized as a non–small-cell carcinoma with a distinct morphologic appearance and immunohistochemical evidence of neuroendocrine differentiation. Some authors have challenged the reproducibility of this entity.[53] Other authors have suggested extrapolation from treatment paradigms for small-cell carcinoma in the management of large-cell neuroendocrine carcinoma, further blurring the clinical utility of the traditional separation of the two high-grade neuroendocrine tumors into small-cell carcinoma and non–small-cell carcinoma (large-cell neuroendocrine carcinoma).[54]

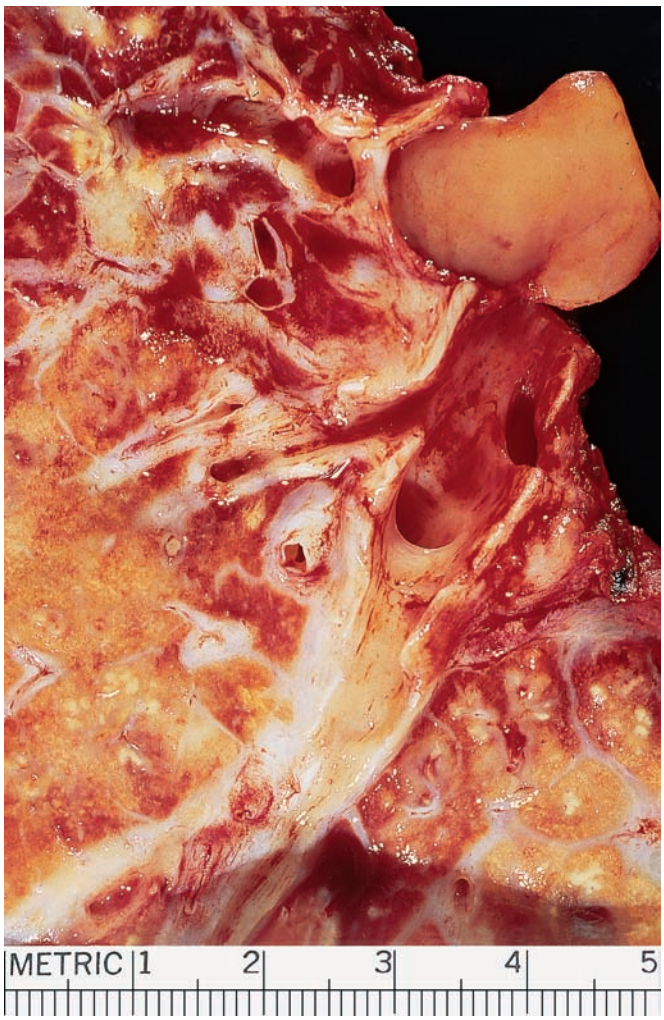
CARCINOID TUMORS

The 2004 WHO classification recognizes two distinct subtypes of carcinoid tumor—typical carcinoid tumor and atypical carcinoid tumor.[3] Both tumors are recognized by their low power architectural pattern and characteristic cytologic features that are familiar to pathologists and are similar in appearance to carcinoid tumors that occur in other primary sites such as the gastrointestinal tract. However, in contrast to the terms low grade or intermediate grade or well-differentiated neuroendocrine carcinoma that are now used in extrapulmonary sites, carcinoid tumor has been retained in the lung tumor nomenclature because of its familiarity to clinicians and because of the well-established clinical behavior associated with the terminology. In the intervening years between the 1981 WHO revisions and the 1999/2004 revisions, there was a significant amount of debate regarding the diagnostic criteria for these lesions, the most appropriate terminology, and their clinical behavior within the broader context of pulmonary neuroendocrine tumors. It should be noted that there is still no uniform agreement on one of the major criteria for separating typical from atypical carcinoid tumors – that of mitotic activity – usually expressed as the number of mitoses per 2 mm^2 or per 10 high power fields. Some authors have challenged the current WHO mitotic cutoff of <2 mitoses per 10 high power fields and have advocated a cutoff of <3 per 10 high power fields.[53] Even more problematic than mitotic counts is the fact that these criteria were established on resected specimens and therefore, it may be impossible to separate an atypical carcinoid from a typical carcinoid tumor on the basis of a small biopsy or to apply this criterion to a cytology specimen. The distinction may not affect initial surgical management but it may significantly impact subsequent prognosis.

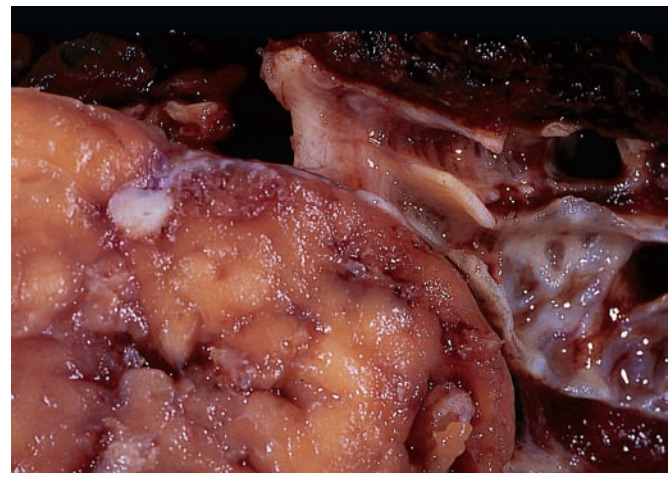
TYPICAL CARCINOID

Typical carcinoid tumors can be divided into central and peripheral variants. Both variants can be asymptomatic but central carcinoids, which characteristically grow as an endobronchial mass, may present clinically with recurrent pneumonias or hemoptysis. Typical carcinoid tumors are not associated with tobacco use, but there is an association with multiple neuroendocrine neoplasia (MEN)1 syndrome in about 5% of cases and screening for pulmonary carcinoids with CT imaging is recommended in patients with MEN1.[55] The incidence of bronchial carcinoid tumors with carcinoid syndrome at presentation is low (1%–3%) and most typically occurs in the presence of metastatic liver disease.[56] Cushing syndrome due to ectopic production of ACTH is similarly rare.

Central carcinoids grossly appear as yellow or fleshy, polypoid masses (Fig. 111-15). The tumor usually has a significant exophytic endobronchial component but the tumor can infiltrate between cartilaginous rings to extensively involve the bronchial submucosa. The tumor cells form diverse patterns such as organoid nests, trabeculae, insular islands, ribbon, or rosette-like arrangements. Carcinoids can also have papillary, sclerosing, follicular, and glandular patterns. The tumor cells are generally uniform in appearance and have a low nuclear:cytoplasmic ratio with round to oval nuclei and eosinophilic



A



B

Figure 111-15 **A.** Large endobronchial carcinoid. **B.** Endobronchial carcinoid. Grossly, the tumor is yellow, fleshy, and vascular.

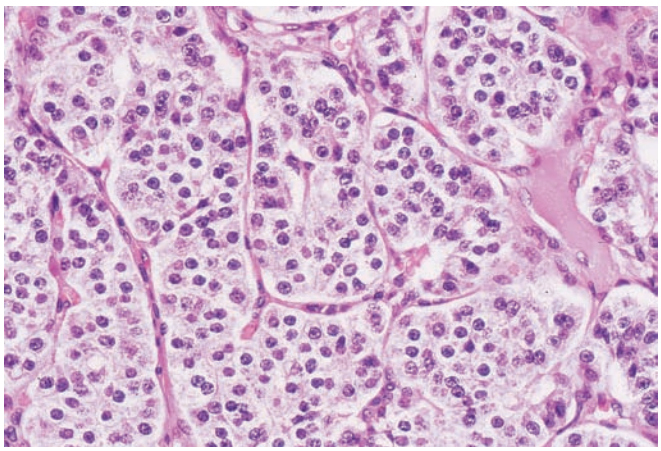
cytoplasm (Fig. 111-16). The tumor cells have characteristic neuroendocrine tumor chromatin that is finely granular or classically described as "salt and pepper."

Peripheral carcinoids are frequently subpleural and can be associated with a scar (Fig. 111-17A). Unlike the cells of central tumors, which are usually round or polygonal in shape, the tumor cells of peripheral carcinoids tend to have prominent spindle cell features (Fig. 111-17B). These fusiform cells have less cytoplasm than central tumors, but this feature should not be considered a sign of atypia. There is a subset of patients with one or more peripheral carcinoid tumors who have multiple tumorlets (defined as small neuroendocrine cell proliferations <0.5 cm) and DIPNECH. In these patients, it is believed that the neuroendocrine cell hyperplasia represents a preneoplastic condition. The most significant complication for this subset of patients is airway fibrosis, which can progress to severe obstructive lung disease.

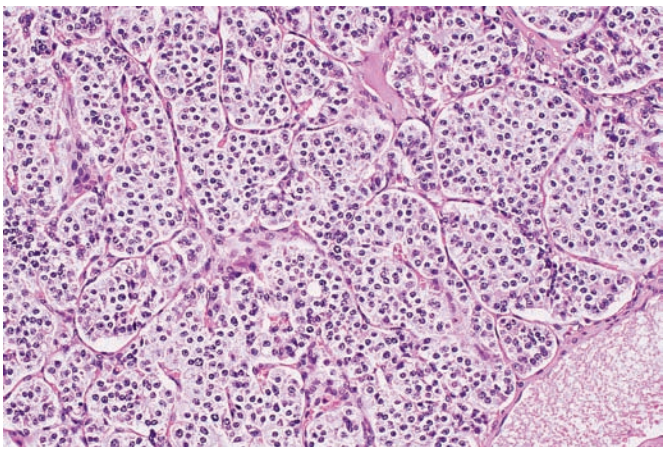
The pathologic attributes of typical carcinoid tumors have been examined in numerous histologic, immunohistochemical, and molecular studies. The only consistent prognostic indicators have proved to be mitotic rate and necrosis—although as previously discussed there is still disagreement about what is the best prognostic cutoff for mitotic activity. The current 2004 WHO criteria for the diagnosis of carcinoid tumor require fewer than 2 mitoses per 10 high power fields of viable tumor and no necrosis. Cytologic atypia, increased cellularity, and lymphovascular invasion are not predictive features. Although carcinoid tumors have a generally excellent prognosis with reported 5-year survival rates of 87% to 100%, it is critical to understand that typical carcinoids are low-grade but malignant tumors. One large study and review of the literature reported a 5% to 15% incidence of lymph node metastasis and 3% incidence of distant metastasis at presentation.[57] The new seventh TNM classification is useful for staging bronchopulmonary carcinoid tumors.[58] There are currently no histologic characteristics that reliably predict which typical carcinoid tumors will behave more aggressively and go on to develop systemic disease.

■ ATYPICAL CARCINOID

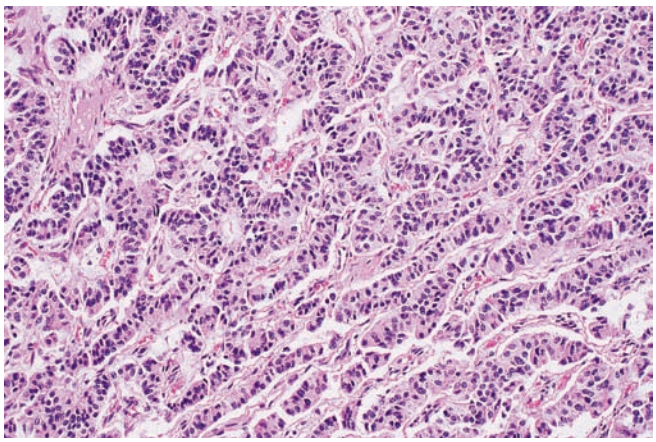
The term "atypical carcinoid" was first introduced by Arrigoni et al.[59] in 1972. Twenty-three tumors were described that appeared to have a general resemblance to carcinoid tumors but that also had a focally disorganized growth pattern, areas of tumor necrosis, increased mitoses, and cellular pleomorphism. Dissension was immediately generated by the use of the word "atypical," given the aggressive biologic behavior in their series. Many other terms were introduced into the literature in the 1980s as more published reports detailing this entity appeared. The tumors described in these initial papers were a heterogeneous group, in part due to the subjective interpretation of features such as "architectural distortion." In defending atypical carcinoids as a distinct clinicopathologic entity, Travis et al.[60] emphasized that the overall architecture should be that of a recognizable carcinoid tumor with a predominantly organoid growth pattern. In the 2004 WHO classification, an atypical carcinoid tumor is defined as a carcinoid tumor with between 2 and 10 mitoses per 10 high power fields and/or with



A



B



C

Figure 111-16 **A.** Cytologic features of carcinoid tumor with small, uniform cells. The nuclei are round to oval with a "salt and pepper" chromatin pattern (H&E, 400×). **B.** Carcinoid tumor, nested pattern of carcinoid tumor (H&E, 200×). **C.** Carcinoid tumor, ribboned pattern in carcinoid tumor (H&E, 200×).

foci of necrosis.[3] The necrosis in these tumors is usually punctate (Fig. 111-18) and one should be careful to exclude the possibility of a large area of necrosis that is secondary to a previous needle biopsy. Although cytologic atypia, lymphovascular invasion, nucleoli, increased cellularity, and disorganized architecture may be seen, these features are not a part of the classification system. Like typical carcinoid tumors, atypical carcinoid tumors can occur centrally as well as in the periphery. It is appropriate to consider atypical carcinoid tumors as an intermediate grade malignant tumor with an increased capacity for progression. Atypical carcinoids have a higher incidence of lymph node metastases at presentation (40%–50%) and of distant metastases at presentation (20%) than typical carcinoid tumors.[57] Stratified for stage, patients with tumors showing a higher mitotic rate (6–10 mitoses/2 mm^2) have a significantly worse survival rate than those patients with tumors with a lower mitotic rate (2–5/2 mm^2).[61]

SMALL-CELL CARCINOMA OF THE LUNG

The 2004 WHO classification defines small-cell carcinoma as a malignant epithelial tumor consisting of small cells with scant cytoplasm, ill-defined cell borders, finely granular nuclear chromatin, and absent or inconspicuous nucleoli.[3] The tumor cells can be round, oval, or spindle shaped. The criterion for cell size is given as "usually less than the size of three small resting lymphocytes" but there is no absolute criterion for cell size and cell size can vary from less than the diameter of three resting lymphocytes (10 μm) to that of a larger tumor cell (45 μm) depending on the type of specimen, the quality of fixation/processing, and inherent tumor heterogeneity.[62–64] Nuclear molding is commonly seen as is crush artifact with basophilic nuclear DNA encrustation of the vessel walls (Azzopardi effect). There is usually a high mitotic rate, averaging over 60 mitoses per 2 mm^2, but a significant mitotic rate may not be discernible in some small biopsy cases.[65] Extensive necrosis and numerous apoptotic cells are frequently seen but again may be absent in smaller biopsies (Fig. 111-19). While this definition can be simply summarized and the most classic appearance of small-cell carcinoma easily recognized with a high degree of interobserver agreement, diagnostic difficulties and issues of reproducibility do occur—even among experts.[66] Some of these difficulties are related to the sampling problems inherent in the small biopsies that are obtained by fiberoptic bronchoscopy and which are further discussed in the section on small biopsies. Some of these difficulties are related to the qualitative rather than quantitative criteria that have been set forth as distinguishing features between small-cell carcinoma and large-cell neuroendocrine carcinoma and which will be further discussed in the section on large-cell neuroendocrine carcinoma.

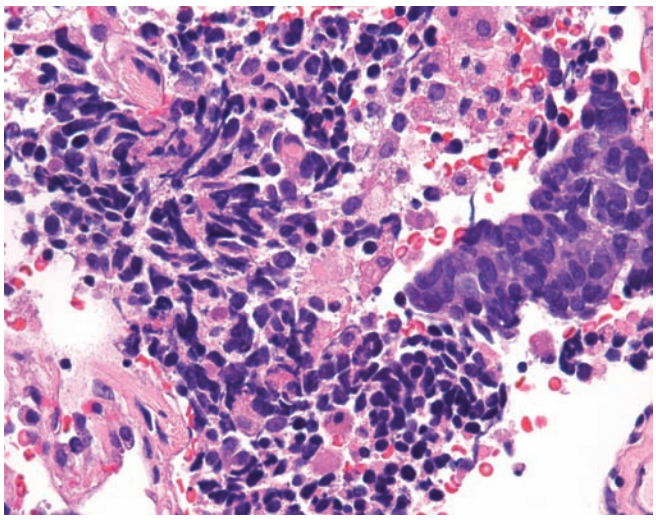

Figure 111-19 Small-cell carcinoma. Classic tumor cell appearance with scant amounts of cytoplasm, hyperchromatic nuclei, nuclear molding, crush artifact, and necrosis. (H&E, 400×).

Small-cell lung carcinoma has decreased in incidence in the United States where it now represents about 13% of all lung cancers but is still the most common of the pulmonary neuroendocrine tumors.[67] A significant smoking history is present in the vast majority of cases, such that the diagnosis of small-cell carcinoma should be seriously reconsidered in a patient without current or former heavy tobacco use. The current male:female ratio is about 2:1 and the average patient presents in their 60s. There are several different presentations that are familiar to most clinicians. Patients may present with pulmonary symptoms related to a large central mass that include cough, wheezing, dyspnea, and hemoptysis. Mediastinal extension may cause superior vena cava syndrome, recurrent laryngeal nerve paralysis, or dysphagia. Constitutional symptoms such as pain, decreased appetite, and weight loss are also common. A significant number of patients present with widespread metastases involving the liver, brain, bone, and adrenal glands. Paraneoplastic syndromes include the syndrome of inappropriate secretion of antidiuretic hormone, Eaton–Lambert syndrome, and ectopic Cushing syndrome. Despite the fact that less than 10% of patients with small-cell carcinoma limited to the lung are surgical candidates, the IASLC staging system is useful in predicting prognosis for small-cell carcinoma and the IASLC staging project has recommended the adoption of this staging system rather than the traditional limited versus extensive stage disease that has been used for staging small-cell carcinoma.[68] The 2009 College of American Pathologists (CAP) protocol for the examination of resected pulmonary specimens has been extended to include small-cell carcinoma and can be used as a template for pathologic evaluation as with non–small-cell carcinomas.[28]

Small-cell carcinoma can present as a solitary pulmonary nodule and early-stage small-cell carcinomas are occasionally resected. In the gross descriptions of surgically resected small-cell lung carcinomas, the gross appearance does not differ significantly from many other lung carcinomas.[64] The tumors are described as well circumscribed, often lobulated with others as endobronchial and some as subpleural. The cut surface is described as white to tan to yellow and gray with necrosis recorded in only a small number of cases.

In addition to other neuroendocrine tumors, the differential diagnosis of small-cell carcinoma might include nonspecific chronic inflammation, other small "round blue cell tumors" and poorly preserved, often necrotic non–small-cell lung carcinomas. The general use of immunohistochemistry in the differential diagnosis of lung tumors is discussed in a separate section, but two points deserved to be emphasized here. One point is that a positive TTF-1 stain cannot be used to support a diagnosis of a primary pulmonary small-cell carcinoma or to exclude a metastatic small-cell carcinoma from an extrapulmonary primary.[69] The second point is that it is a mistake to rely on neuroendocrine markers alone for the diagnosis of small-cell carcinoma. Not only are neuroendocrine markers negative in about 10% of small-cell carcinomas but other tumors within the differential diagnosis may be positive for neuroendocrine markers. The difficulties that can be encountered in separating out small-cell carcinoma from carcinoid tumors and other non–small-cell carcinomas in a small biopsy are discussed in greater detail in a separate section, as is the distinction from large-cell neuroendocrine carcinoma. But in general, it might be considered that the name itself, "small-cell" carcinoma, has led to a relative overemphasis on cell size in comparison to other criteria. From a therapeutic point of view, the recognition of any small-cell component has significant

clinical implications, but interpretative disagreements as to whether the tumor is a combined small-cell carcinoma or a pure small-cell carcinoma may not.

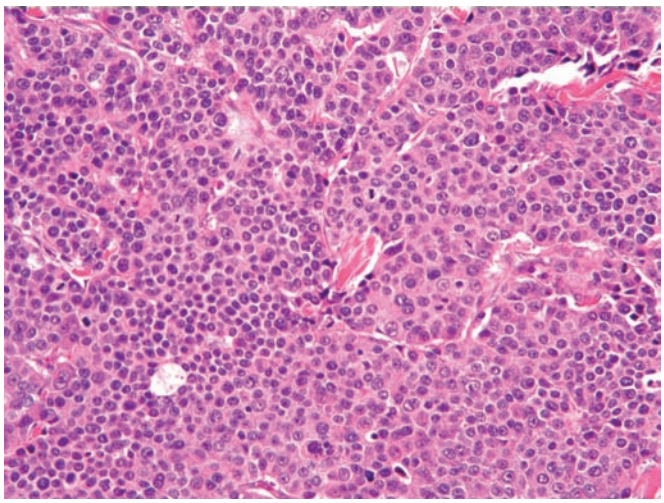
LARGE-CELL NEUROENDOCRINE CARCINOMA OF THE LUNG

In 1991, Travis et al.[70] first proposed criteria for this entity, which was considered to be histologically distinct from atypical carcinoid tumor or small-cell carcinoma. A great deal of controversy ensued over that following decade and continues to the current time. As mentioned in the introduction to this section on pulmonary neuroendocrine tumors, one controversy centers on the reproducibility of the diagnosis of large-cell neuroendocrine carcinoma. One study has demonstrated substantial agreement, at least among experienced lung pathologists.[66] In this study, a majority consensus diagnosis was achieved for 50% of the cases of large-cell neuroendocrine carcinoma, which is no worse than other categories of lung tumors. However, there are a number of other studies that question the reproducibility of the diagnosis and have highlighted the considerable overlap in cell size and the substantial degree of subjective interpretation that is required for categorization.[64,71–74] Also problematic, as it is for other WHO lung tumor entities, is that the definition of large-cell neuroendocrine carcinoma applies to resected tumors and not to smaller samples.

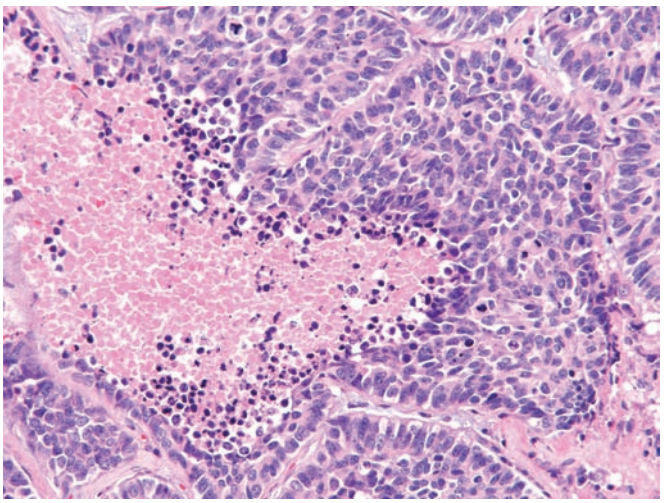
A third controversy has focused on the clinical significance of the diagnosis, particularly in relationship to small-cell carcinoma. From an epidemiologic perspective, both tumors are associated with heavy tobacco use and both tumors can occur in combination with other non–small-cell lung cancers.[63] Both tumors are aggressive high-grade neuroendocrine tumors and have a very poor prognosis.[75]

Large-cell neuroendocrine carcinoma is defined as "a large-cell carcinoma showing histologic features such as organoid nesting, trabecular, rosette-like and palisading patterns that suggest neuroendocrine differentiation and in which the latter can be confirmed by immunohistochemistry or electron microscopy."[3] The cells are relatively large in size, often polygonal in shape, with moderate to abundant cytoplasm. The nuclear chromatin ranges from vesicular to finely granular. Nucleoli are frequent and often prominent (Fig. 111-20A). The presence of nucleoli tends to be a critical feature in the separation from small-cell carcinoma (Fig. 111-20B) but some large-cell neuroendocrine carcinomas lack this criterion. Mitoses should be greater than 10 mitoses/10 high power fields. As mentioned previously, neuroendocrine differentiation must be demonstrated by ancillary techniques such as immunohistochemistry. Chromogranin and synaptophysin are the two stains that are most frequently used and are considered to be more specific than neuron-specific enolase. In order for a tumor to be designated as a large-cell neuroendocrine carcinoma, the tumor must have both neuroendocrine morphology and positive staining. Tumors that otherwise look like squamous cell carcinomas, adenocarcinomas, or large-cell carcinomas but have focal neuroendocrine staining have been termed "non–small-cell lung carcinoma with neuroendocrine differentiation." Although this designation appears in the literature, particularly in studies that have sought to determine whether non–small-cell lung carcinoma with neuroendocrine differentiation has a worse prognosis or differs in its response to chemotherapy, it is actually not formally part of the WHO classification. Similarly problematic are those tumors that show the histologic features of a large-cell neuroendocrine tumor but which fail to stain with neuroendocrine markers and have been classified as *large-cell carcinoma with neuroendocrine morphology or pattern,* with some authors suggesting that these are likely the same tumors as large-cell neuroendocrine carcinomas.[54] *Combined large-cell neuroendocrine carcinoma* refers to a large-cell neuroendocrine carcinoma with components of another non–small-cell carcinoma such as, for example, squamous cell carcinoma or adenocarcinoma.

The controversies in diagnosis and treatment of large-cell neuroendocrine carcinoma have been recently summarized.[54,75] The low incidence of the tumor (estimated as 2%–3% of non–small-cell carcinomas) combined with the limitations of the current WHO classification have resulted in a lack of robust evidence for stage-based treatment strategies. What can be concluded at this point in time is that the molecular genotype and phenotype of large-cell neuroendocrine carcinoma and small-cell carcinoma are similar enough to support at least some extrapolation from treatment paradigms for small-cell carcinoma and, as has been suggested, to include unresectable disease large-cell neuroendocrine carcinoma patients within clinical trials for small-cell carcinoma to obtain prospective data.[54] It is possible that in the future this data may demonstrate that the clinical and pathologic distinction between the two high-grade neuroendocrine carcinomas is of minimal significance.



A



B

Figure 111-20 Side by side comparison of large-cell neuroendocrine carcinoma (**A**) with small-cell carcinoma (**B**). The large-cell neuroendocrine tumor cells have more cytoplasm and there are more prominent nucleoli. The small-cell carcinoma tumor cells have less cytoplasm and the nuclear chromatin is finely granular. (H&E, 200×).

SALIVARY GLAND TUMORS

Mixed seromucinous glands are found in the tracheal and large bronchial submucosa and are believed to give rise to a variety of salivary gland–like tumors, histologically indistinguishable from their major salivary gland counterparts. The 2004 WHO revision recognizes three major subtypes of malignant salivary gland tumors: mucoepidermoid carcinoma, adenoid cystic carcinoma, and epithelial–myoepithelial carcinoma.[3] Other salivary gland–like tumors such as acinic cell carcinoma or carcinoma ex pleomorphic–mixed tumor do occur in the lung but are exceptionally rare. Salivary gland carcinomas represent less than 1% of all lung carcinomas, with mucoepidermoid carcinoma and adenoid cystic carcinoma being the most common subtypes.[33] Although uncommon, their distinctive morphology, growth pattern, and clinical presentation make these salivary gland–type tumors of the lung an important subgroup of malignant epithelial tumors of the lung.

■ ADENOID CYSTIC CARCINOMA

Adenoid cystic carcinoma is the most common of the tracheobronchial gland tumors but is still quite rare, representing less than 0.2% of all primary lung tumors.[33] There is a wide age range from young adults to older patients but the tumor tends to occur in the fourth and fifth decades of life.[76] The incidence is equal among men and women. The vast majority of cases originate intraluminally and the typical presenting symptoms such as wheezing, progressive dyspnea, stridor, cough, and hemoptysis reflect this intraluminal tumor growth. Unlike carcinoid tumors and mucoepidermoid carcinomas, which usually present as intraluminal endophytic masses, adenoid cystic carcinomas have a more variable growth pattern. Some tumors are grossly nodular with minimal invasion of the bronchus, whereas others have a mixed nodular/infiltrative or predominantly infiltrative growth pattern (Fig. 111-21A,B). More infiltrative tumors appear as small nodules within the airway or cause a generalized constriction of the airway. There may be lymph node involvement, usually by direct extension, and higher-grade tumors have a tendency to radially spread into the adjacent parenchyma rather than along the airways.

The microscopic level of invasion nearly always exceeds that which is grossly apparent. Negative resection margins often are difficult to achieve. Complete resection may be quite difficult and can require multiple frozen sections to confirm clear surgical margins. The tumor cells are small with a relatively high nuclear:cytoplasmic ratio but nuclear pleomorphism and mitoses are rare. Characteristic mucinous cysts of varying size are present within the tubular and cribriform patterns (Fig. 111-21C). Poorly differentiated tumors have a significant component of solid tumor nests. As is characteristic of their salivary gland counterparts, adenoid cystic carcinomas are notorious for perineural spread. Long-term survival can be achieved with adequate resection but local recurrence may occur even late (>10 years) following resection. The most common site of disseminated disease is the lung parenchyma, but extrathoracic metastases do occur.[77]

■ MUCOEPIDERMOID CARCINOMA

Mucoepidermoid carcinomas account for approximately 0.1% to 0.2% of lung cancers.[33] Patients with this tumor may be asymptomatic, but it is far more common for patients to present with symptoms of bronchial obstruction due to the tumor's characteristic endobronchial location.[78] These symptoms include wheezing, cough, and hemoptysis, and patients may present with postobstructive pneumonia. The age at presentation varies, but almost half of the cases of mucoepidermoid carcinoma occur in patients under 30 years of age and it is common in the pediatric population. There is no significant association with tobacco use. Although the radiographic findings may be subtle and identified in retrospect, a solitary, centrally located mass with distal pneumonia or atelectasis is typical.

Mucoepidermoid carcinomas usually arise from segmental and subsegmental bronchi, but can involve the trachea as well.[33] They range in size from a few millimeters to up to 6 cm and grow as polypoid masses with a tan or gray surface (Fig. 111-22A,B). On cross section, the tumor may appear more mucoid or cystic than the more common non–small-cell carcinomas of the lung. Histologically, mucoepidermoid tumors of the lung are separated into low- and high-grade tumors.[79,80] An "intermediate grade," which is used for tumors within the salivary gland, has not been formally recognized with the WHO classification but has been used.[77] The tumors are composed of a mixture of mucin-secreting cells, squamous cells, and what are termed "intermediate cells." The intermediate cells have a polygonal shape and eosinophilic cytoplasm, but lack obvious squamous or glandular differentiation. The mucinous component consists of well-differentiated glands, with both intracellular and extracellular mucin (Fig. 111-22C). Some tumors are associated with a prominent lymphocytic infiltrate.[81] Thus far, these tumors have been reported to be TTF-1 negative.[81] In low-grade tumors, the cells have minimal pleomorphism, rare mitoses, and minimal necrosis. Suggested criteria for high-grade tumors include an increased mitotic rate (average of 4 per 10 high power fields), necrosis, and nuclear pleomorphism. High-grade mucoepidermoid carcinomas may be difficult to distinguish from adenosquamous carcinomas. High-grade mucoepidermoid carcinomas still retain a characteristic admixture of mucin-containing cells, squamoid cells, a central endobronchial location, and transitional areas from low-grade mucoepidermoid carcinoma. There should be no keratinization, squamous pearl formation, or in situ squamous cell carcinoma. These features, if present, are more consistent with a diagnosis of squamous or adenosquamous carcinoma.

The clinical behavior of these neoplasms had been controversial, mainly due to past ambiguities regarding the definition of high-grade mucoepidermoid carcinomas and their distinction from adenosquamous carcinomas. Low-grade tumors, which are usually confined to the bronchus, have an excellent prognosis following complete excision. High-grade tumors, which tend to invade the adjacent lung parenchyma, carry a worse prognosis and tend to behave in a manner similar to more common non–small-cell carcinomas. The data suggest that long-term clinical follow-up is indicated for these patients. There is a low reported incidence of lymph node metastases and local recurrence has been reported with incomplete excision.

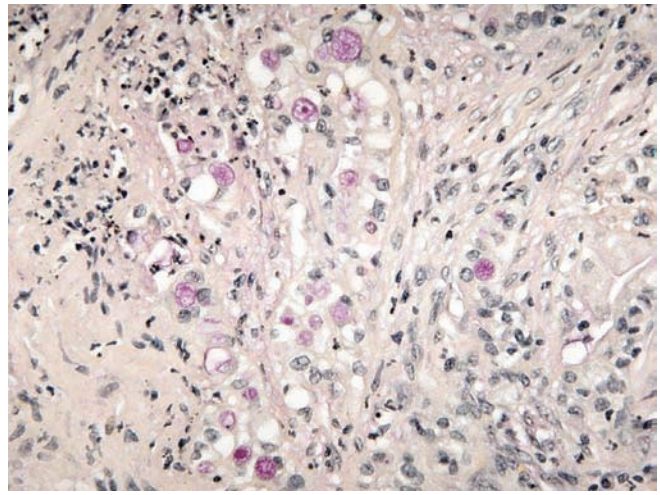

Figure 111-24 Positive mucin stain in a poorly differentiated non–small-cell carcinoma with clear cell change, supporting the diagnosis of adenocarcinoma (400×).

■ EPITHELIAL–MYOEPITHELIAL CARCINOMA

The 2004 WHO classification defines epithelial–myoepithelial carcinoma as a tumor that consists of "myoepithelial cells with spindle cell, clear cell or plasmacytoid morphology and varying amounts of duct-forming epithelium" (Fig. 111-23).[3] The tumor is extremely rare with 25 cases reported in the literature to date.[82] Nearly all of the tumors have been endobronchial and reported within the adult population with no known risk factors. There has been a wide range of terminology associated with this lesion in the literature including adenomyoepithelioma, myoepithelioma, epithelial–myoepithelial tumor of unproven malignant potential, and malignant mixed tumor comprising epithelial and myoepithelial cells. Grossly the tumor is well circumscribed but unencapsulated, with a size range of 1.2 to 5.0 cm. Microscopically, the tumor consists of duct-like structures that are lined by a double layer of cells with an inner layer of cuboidal cells with eosinophilic cytoplasm and an outer layer of cells with predominantly clear cell cytoplasm. There is often eosinophilic material in the luminal spaces. The outer layer of cells and more solid components typically stain positively for SMA, S-100, p63, and calponin, which is characteristic of myoepithelial cells. The inner layer of tumor cells stains positively with cytokeratins (CAM5.2, AE1/3, CK7, and CK903) as well as EMA and TTF-1.[83] The positive TTF-1 staining is of interest in that other salivary gland–type tumors such as adenoid cystic carcinoma and mucoepidermoid carcinoma are reported to be TTF-1 negative. Most of the cases reported (with limited follow-up) have been free of disease following complete surgical resection with a minority of cases showing lymph node involvement or recurrent disease.[82–84]

ANCILLARY STUDIES

The lung is a common site for both primary tumors and metastases and the pathologist must consider a broad differential diagnosis when analyzing a cytologic or tissue preparation. Ancillary studies typically are used to narrow the differential diagnosis or demonstrate differentiation. The appropriate use of ancillary studies is grounded in a well-formulated differential diagnosis based on the tumor's histologic appearance. The clinician contributes greatly by providing the details of a complete clinical history, thorough physical examination, and high-quality radiographic imaging. This helps direct the diagnostic workup and avoids unnecessary tests that will delay the diagnosis or exhaust the tumor contained in that specimen.

■ HISTOCHEMICAL STAINS

The most commonly used histochemical stains in tumor evaluation are those that demonstrate intracellular mucins – periodic acid-Schiff (PAS) after diastase and mucicarmine – characteristic of adenocarcinomas. Mucin stains are typically performed on poorly differentiated carcinomas that appear as solid carcinomas lacking glandular differentiation but prove to have numerous mucin-positive tumor cells and therefore would be best classified as adenocarcinomas, solid type (Fig. 111-24). While helpful in some instances, mucin stains have a low sensitivity for glandular differentiation (about 30%).[85] Although practice patterns vary somewhat, pathologists will often forego a mucin stain in small biopsies in an effort to preserve as much tissue as possible and do a limited panel of immunohistochemical stains instead. Stains for neutral mucins are still occasionally used to distinguish adenocarcinoma from epithelial mesothelioma. Alcian blue staining with hyaluronidase treatment can be used to distinguish the acid mucin of mesothelial cells from the epithelial mucin associated with adenocarcinomas, but its use has largely been supplanted by immunohistochemistry.

■ IMMUNOHISTOCHEMISTRY

Immunohistochemistry is based on a primary antigen–antibody reaction and a secondary antibody–enzyme complex that interacts with a chromogen for a microscopically visible color reaction. Since its introduction into diagnostic pathology in the early 1980s, immunohistochemistry has become an integral part of tumor diagnosis. Unfortunately, there are very few antibodies that approach 100% sensitivity and specificity. As experts on immunohistochemistry have emphasized, it is diagnostically irrelevant to speak of overall sensitivity and specificity for a particular antibody. Rather it is more appropriate to speak of relative sensitivity and specificity within a particular differential diagnosis. This requires clinical interaction and morphologic expertise in generating a differential diagnosis in addition to critical assessment of the immunohistochemical results with appropriate controls. New antibodies are developed, evaluated, and introduced at a fairly constant rate. The following summary remarks are meant only as broad overview of current practice with the understanding that the field is constantly evolving and that all of the markers mentioned have utility both in and outside of the lung.[86]

Immunohistochemistry is often used in the workup of an undifferentiated large-cell carcinoma, usually to exclude melanoma and lymphoma, which can mimic a highly pleomorphic epithelial

tumor. Within this differential diagnosis of an undifferentiated tumor comprised of large cells, cytokeratin antibodies such as AE1/3, CAM5.2, and pancytokeratin are used to support the diagnosis of carcinoma. Cytokeratin antibodies will at least focally stain most non–small-cell carcinomas of all histologic subtypes, in addition to a wide variety of carcinomas from other primary sites. There are, however, potential pitfalls. Cytokeratin antibodies stain benign bronchial and alveolar epithelia, which can be entrapped within tumors and lead to a false-positive interpretation. Reactive mesothelial cells and malignant mesotheliomas are cytokeratin positive as well. Cytokeratin positivity, usually focal, also has been demonstrated in sarcomas and melanomas. S100, HMB45, melan-A, MITF, and tyrosinase are markers of melanocytic differentiation; a panel using at least two or three of these is often employed when malignant melanoma is a strong consideration. Although sensitive, S100 is less specific for melanoma and stains other tumors, including those of neural origin and some adenocarcinomas of both primary pulmonary and extrapulmonary origin, such as the breast. The range of markers used to evaluate lymphoid neoplasms is extensive but include leukocyte common antigen (LCA), CD30, and B and T cell markers. There are antibodies to glycoproteins such as CEA, MOC31, B72.3, LeuM1, Bg8, and BerEP4, which stain a high percentage of adenocarcinomas, including adenocarcinomas of the lung. Recommended guidelines on the use of immunohistochemistry when the differential diagnosis includes malignant mesothelioma have been published and updated.[87] When the differential diagnosis centers on an epithelioid malignant mesothelioma versus adenocarcinoma, a panel of at least two affirmative markers for malignant mesothelioma and two affirmative markers for adenocarcinoma is recommended.

Immunohistochemistry is similarly used in the workup of an undifferentiated small-cell carcinoma, usually to exclude melanoma and other so-called "small round blue cell tumors" such as lymphoma, Merkel cell carcinoma, and other primitive neuroectodermal tumors. In this instance, attention to subtle differences in nuclear cytology, chromatin pattern, and mitotic activity is essential, as is a targeted immunohistochemical panel that might include (depending on the circumstances) pancytokeratin, synaptophysin, chromogranin, CD56, TTF-1, CK7, CK20, CD99, S-100, desmin, WT-1, LCA, myogenin, and TLE. Unusual clinical circumstances or radiographic imaging, particularly in a younger patient or a nonsmoker, should prompt consideration of a broad immunohistochemical workup as well as molecular tests for characteristic cytogenetic abnormalities for tumors such as a poorly differentiated synovial sarcoma, desmoplastic small round cell tumor, Ewing sarcoma, and rhabdomyosarcoma.

The use of immunohistochemistry has not eliminated the challenges of distinguishing a primary lung carcinoma from metastatic disease. There are only a limited number of instances in which immunohistochemical stains are useful in differentiating a pulmonary primary from a metastatic tumor. With the exception of thyroglobulin for the majority of thyroid tumors and prostate-specific antigen for the majority of prostatic adenocarcinomas, many other antibodies have too much overlap in specificity to be conclusive. There has been some qualified success in instances when the differential diagnosis includes other common solid organ malignancies such as breast or gastrointestinal carcinomas. Staining with a panel of antibodies to bolster one's diagnostic certainty in the differential diagnosis of primary lung carcinoma versus metastasis can certainly enhance diagnostic accuracy. Fundamentally, however, this type of immunohistochemical analysis remains an exercise in probabilities and may not be sufficient for certain clinical circumstances. It is most often the case that new markers are introduced into the literature with initial reports of high sensitivity and specificity. After a time, with additional studies and incorporation into daily practice, more exceptions appear. A good example is TTF-1. On average, TTF-1 stains about 75% of primary pulmonary adenocarcinomas, although the percentage is lower in more poorly differentiated tumors, some subtypes of adenocarcinoma, and better differentiated neuroendocrine tumors.[31] It was initially believed that the only extrapulmonary tumor that was as frequently positive for TTF-1 was thyroid carcinoma. Now there are reports of TTF-1 positivity in extrathoracic tumors that would not be expected – such as ovarian epithelial tumors – making the marker less specific than was initially asserted although often still useful.[31] The same can be said of gastrointestinal profile panels that use CK7, CK20, TTF-1, Napsin A, and CDX2 to support a luminal GI primary. Although many GI primaries will have a CK20, CDX2 positive and CK7, TTF-1, Napsin A negative staining pattern, a small subset of primary lung tumors with an "enteric" differentiation will show an overlapping staining pattern.[88] Whether "molecular profiles" will be able to improve diagnostic accuracy or supplant the relatively rapid turnaround time and low cost of immunohistochemistry remains to be seen.

As discussed in the section on pulmonary neuroendocrine tumors, the artifacts that are often present in small samples can make it difficult to separate out small-cell carcinoma from other non–small-cell carcinomas or to apply the criteria for separating out carcinoid tumors from the higher-grade neuroendocrine carcinomas. In addition to some of the other immunohistochemical stains mentioned for supporting neuroendocrine differentiation (synaptophysin, chromogranin, and CD56), an extended panel might also include CK5/6, p63 (or p40), and TTF-1 to exclude the possibility of a basaloid or small-cell variant of squamous cell carcinoma.[89] The proliferation marker, ki-67, is sometimes used in smaller specimens as a surrogate for identifying mitoses, which may be absent or infrequent. Although not completely standardized or reproducible, an increased proliferation index can be helpful in favoring a lower- or higher-grade neuroendocrine tumor.[65,90]

The need for a more precise classification of poorly differentiated non–small-cell carcinoma into squamous or nonsquamous histology has further expanded the use of immunohistochemistry within pulmonary pathology. A significant proportion of small biopsies (and some large resections) will not have obvious evidence of squamous differentiation, as defined by keratinization or intercellular bridges, or obvious features of adenocarcinoma, as defined by gland formation or intracellular mucin. In these instances when the tumor cells are arranged in solid nests and there is no specific evidence of differentiation, a panel of immunohistochemical stains can be used for further subclassification. There are numerous studies that have looked at the utility of immunohistochemistry in reducing the category of "non–small-cell lung carcinoma, not otherwise specified" and the minimum number of stains needed for evaluation. The latter point, of using the least number of stains with the most specificity and sensitivity, is not a trivial issue in the usual case of advanced disease patient who will have an initial biopsy that will likely be triaged for targeted therapy. At the current time, the data support at minimum a panel that includes TTF-1, CK5/6, and p63 (or p40), with addition of stains such as Napsin A or CK7 if there is sufficient tissue (Fig. 111-25A–D).[85,91–93] Beyond using evidence to construct the best limited immunohistochemical panel to determine differentiation, other techniques such as dual antibody staining cocktails can reduce the amount of tissue used (Fig. 111-26). As discussed in greater detail in the following section, processing decisions must be made up front to ensure that there is sufficient material for diagnosis, immunohistochemical stains if necessary, and residual tissue for molecular testing.

The increased use of immunohistochemistry for histologic subclassification has generated debate, particularly in the context of clinical trials for advanced disease patients, as to what exactly it means – biologically, therapeutically, and prognostically – for a tumor to only have immunohistochemical evidence of differentiation. These issues were further complicated by the conspicuous historic lack of any

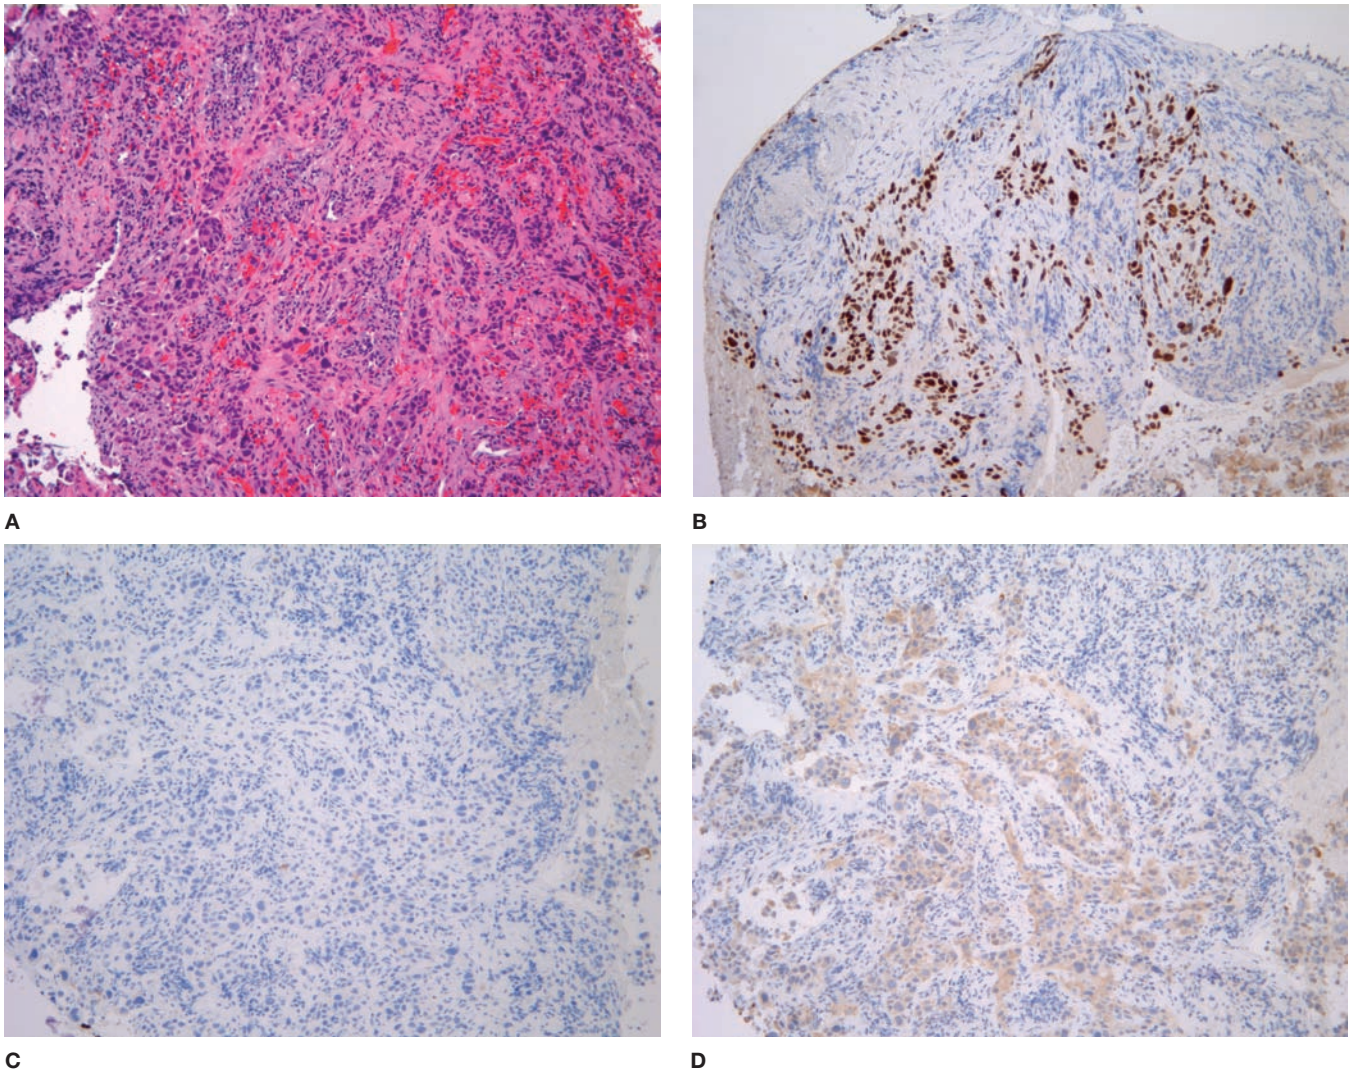

Figure 111-25 Small biopsy showing poorly differentiated non–small-cell carcinoma and immunohistochemical stains supporting the diagnosis of pulmonary adenocarcinoma. **A.** H&E (100×). **B.** TTF-1 antibody positive (100×). **C.** CK5/6 antibody negative (100×). **D.** p63 antibody negative in tumor nuclei (100×).

standard nomenclature for small biopsies. The 2011 IASLC/ATS/ERS International Multidisciplinary Classification of Lung Adenocarcinoma proposed terminology for small biopsies/cytology specimens in these instances[5] although the adoption of this terminology in general practice and even within academic medical centers has been inconsistent.

ADEQUACY OF SMALL SPECIMENS FOR DIAGNOSIS, TREATMENT, AND MOLECULAR ANALYSIS

Small specimens occupy a central role in the majority of patients with lung cancer – often at multiple time points during the course of their disease – and the clinical relevance of these small specimens has led to a "paradigm shift" in the way these small specimens are processed and interpreted.[94] Bronchoscopic biopsies with or without endobronchial ultrasound guidance, fine-needle aspiration, or body fluid cytologic examination are all acceptable as minimally invasive procedures for the initial diagnosis of a primary lung carcinoma or to document metastasis. With the emerging emphasis on the importance of histologic subtyping in non–small-cell lung cancer and the need for molecular analysis for "personalized" or "precision" medicine, the debate in recent years had focused on whether small specimens are adequate for these purposes. Numerous studies have

now established that a variety of specimens, ranging from small biopsies to cytology cell blocks to cytology touch imprints or aspirates, are potentially suitable for molecular testing and the practical considerations for testing have been recently and comprehensively reviewed.[95] The essential point is that small diagnostic specimens must be handled carefully from the outset of any procedure with the understanding that the specimen may be the only specimen available for molecular analysis. Within each specific practice setting, an algorithm should be established that emphasizes the need for communication between the pathologist and the clinical care team *before* the specimen is processed.[96] This clinical information should include such information as whether the biopsy is for initial diagnosis, whether the patient is a candidate for surgical resection, whether the patient is a candidate for targeted therapy, whether the biopsy is for molecular prioritization in a patient with an established diagnosis of lung cancer, or whether the biopsy is a rebiopsy for resistance testing. All of this information will in turn allow the pathologist to communicate with molecular and histology laboratories to ensure that the specimen is appropriately triaged and that the optimal material is selected for diagnosis, ancillary immunohistochemical testing, and molecular prioritization.

CONCLUSION

In addition to the clinicopathologic features and histologic subtyping of primary pulmonary carcinomas, recent changes and current controversies in tumor classification have been reviewed. The pathologist makes a critical contribution to the management and treatment of lung carcinoma, but the final pathologic interpretation should not be rendered in a clinical vacuum. It is incumbent upon the clinician caring for the patient to be sure that the pathologist has the benefit of complete clinical information. Nowhere is this clinical information and communication more critical than in the processing of small specimens in this era of personalized medicine. The inclusion of the pathologist as an integral part of what is now a multidisciplinary evaluation team for a thoracic malignancy enhances the quality of care for the individual patient and refines the general practice of thoracic oncology.

CHAPTER 112

Clinical Evaluation, Diagnosis, and Staging of Lung Cancer

Lydia Chang
M. Patricia Rivera

INTRODUCTION

Patients who present with suspected lung cancer require a detailed clinical evaluation followed by noninvasive testing and invasive procedures to establish both the histopathologic diagnosis as well as disease stage. Historically, great emphasis has been placed upon the differentiation of small-cell lung cancer (SCLC) from non–small-cell lung cancer (NSCLC). SCLC, which accounts for 14% of bronchogenic carcinomas, is histologically and clinically distinct from NSCLC.[1] NSCLCs have been traditionally regarded as a fairly uniform group of cancers. However, it has become increasingly evident that NSCLCs are comprised of clinically, pathologically, and molecularly diverse tumors that respond to different therapeutic agents based on specific histologic phenotypes and molecular characteristics.

The clinician evaluating the patient with suspected lung cancer must take into account several factors, including the likelihood of SCLC versus NSCLC, probability of metastatic disease, comorbid illness and functional status, presence of paraneoplastic syndromes, and treatment preferences of the patient. Good decision making regarding appropriate diagnostic test selection must incorporate: (1) careful assessment of pretest probabilities based upon clinical evaluation and initial radiographic features, and (2) understanding of specific test characteristics. The main objectives of the diagnostic and clinical staging evaluation are to obtain adequate tissue to establish the histopathologic diagnosis and, when indicated, molecular characterization of the tumor, and to ascertain the extent of disease to determine candidacy for specific therapies. These twinned goals should be accomplished in the safest, least invasive, and most cost-effective manner possible.

INITIAL CLINICAL EVALUATION

A detailed history and physical examination are of key importance in assessment of the patient's overall health status and medical appropriateness for specific therapies.[2] Certain comorbid conditions may reduce therapeutic options. Limited cardiopulmonary reserve may preclude surgical intervention. A thorough history can also assist a physician in determining overall extent of disease. At the time of presentation, it is most useful to consider the clinical stage using the International Association for the Study of Lung Cancer (IASLAC) 7th edition of the tumor, node, and metastasis (TNM) classification system (Table 112-1); pathologic stage is established only after surgical resection.[3]

Only 7% to 13% patients are asymptomatic at the time of initial diagnosis as lung cancer is usually a diagnosis made during its later stages.[4,5] A recent national cancer database survey of patients diagnosed from 1998 to 2006 demonstrates that the majority of patients have either locally advanced or metastatic disease at the time of diagnosis. Only 26% of patients have stage I disease and 8.3% have stage II, whereas 27.6% have stage III disease and 38.1% have metastatic disease (Fig. 112-1).[6]

Patients often have had symptoms for months prior to diagnosis.[7,8] Symptoms, particularly those associated with localized disease such as cough, wheezing, and dyspnea, are often attributed to comorbid illnesses by both patients and their physicians. In one study in the United Kingdom of newly diagnosed lung cancer patients, symptom duration ranged from 4 to 24 months with a median of 12 months.[9] In one of the earliest series describing the relationship of presenting symptoms to stage and prognosis, about a third of patients (27%) presented with symptoms related to primary tumor only (Table 112-2), another third (34%) presented with nonspecific symptoms concerning for metastatic disease, and the final third (32%) presented with symptoms attributable to a distant metastatic site.[10] Only 6% were asymptomatic.

TABLE 112-1 TNM Staging System for Lung Cancer

Primary tumor (T)	T1	Tumors ≤3 cm that do not invade the lobar bronchus and do not invade the visceral pleural
	T1a	Tumors ≤2 cm
	T2a	Tumors >2 cm but ≤3 cm
	T2	Tumors >3 cm but ≤7 cm OR invades the visceral pleural OR invades the mainstem bronchus OR associated with atelectasis or obstructive pneumonia extending from the hilum
	T2a	Tumor >3 cm but ≤5 cm
	T2b	Tumor >5 cm but ≤7 cm
	T3	Tumors >7 cm OR • Direct invasion of chest wall, diaphragm, phrenic nerve, mediastinal or parietal pleural, parietal pericardium, OR mainstem bronchus to within 2 cm carina OR • Atelectasis or obstructive pneumonia of whole lung OR • Satellite tumor nodules within same lobe
	T4	Direct invasion mediastinal structures OR trachea OR recurrent laryngeal nerve OR carina OR vertebral body OR Satellite tumor nodule within a different lobe of the ipsilateral lung
Regional lymph nodes (N)	N0	No regional lymph node metastases
	N1	Metastases or involvement by direct extension of ipsilateral peribronchial, intrapulmonary, or hilar nodes
	N2	Metastases to ipsilateral mediastinal or subcarinal lymph node
	N3	Metastases to any scalene or supraclavicular lymph node or to contralateral mediastinal or hilar nodes
Distant metastases (M)	M0	No distant metastases
	M1	Distant metastases present
	M1a	Satellite tumor nodule(s) in contralateral lung, pleural nodules, or malignant pleural or pericardial effusion
	M2a	Extrathoracic metastases

The IASLC Lung Cancer Staging Project: proposals for the revision of the TNM stage groupings in the forthcoming (seventh) edition of the TNM Classification of malignant tumours. Journal of Thoracic Oncology. 2007;2(8):706–714.

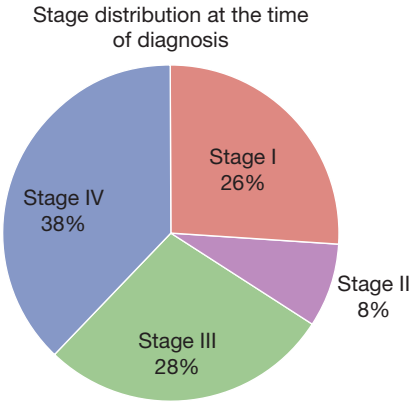

Figure 112-1 Stage distribution at the time of diagnosis.

Local symptoms can include cough, hemoptysis, dyspnea, chest pain, and wheezing.[5,11] Cough is the most frequently encountered presenting symptom and can be the result of endobronchial or parenchymal involvement by the primary tumor, regional lymph node enlargement, or postobstructive complications. Hemoptysis is the symptom that typically results in the most expeditious evaluation; about 5% of patients with hemoptysis and a normal chest x-ray will ultimately be diagnosed with lung cancer.[12] Chest discomfort and pain may indicate pleural involvement or direct tumor invasion of the chest wall or thoracic cage. Hoarseness, which can occur in up to 5% lung cancer patients at presentation, can be concerning for laryngeal nerve palsy, which can occur in 2% to 18% of lung cancer patients.[5] This is more commonly seen with left-sided tumors, which can involve the recurrent laryngeal nerve as it loops under the aortic arch.[11] Lung cancer accounts for up to 75% of all cases of superior vena cava (SVC) syndrome due to local compression or invasion.[13] Signs and symptoms of SVC syndrome include swelling of the face, neck, upper torso and arms, and dyspnea. Up to 4% of patients with NSCLC and 10% of patients with SCLC can develop SVC syndrome. Dysphagia can suggest extrinsic compression of the esophagus due to bulky mediastinal disease, particularly involving the subcarinal lymph node, or it can result from direct esophageal invasion. Central tumors such as squamous cell carcinoma may cause airway obstruction resulting in a localized or unilateral wheeze, atelectasis, or postobstructive pneumonia.[14,15] Cancers arising in the lung apex (superior sulcus tumors) can present with the Pancoast syndrome, an assortment of clinical manifestations due to invasion or compression of local structures. Characteristic signs and symptoms include shoulder pain due to invasion of the brachial plexus and/or ribs and vertebrae, upper extremity weakness and paresthesias, and Horner syndrome (unilateral ptosis, meiosis, and lack of facial sweating on the involved side) due to compression or invasion of the sympathetic chain.[16]

Focal symptoms of metastatic disease are fairly common at presentation: 25% of patients present with bone pain, 20% of patients present with symptoms associated with bulky mediastinal adenopathy such as cough and hoarseness, and 10% of patients have neurologic symptoms that may include headache, nausea and emesis, seizures and/or mental status changes at the time of diagnosis.[5,11] Lung cancer accounts for 70% of the cancers that first present as symptomatic brain metastases.[17] The presence of nonspecific constitutional symptoms (weakness, weight loss, fever, and anorexia) is worrisome for metastatic disease; often, patients with hepatic metastases present with symptoms of weakness and weight loss. Standard laboratory testing should include a complete blood count as well as chemistries that include liver function testing. Anemia (hematocrit less than 40% in men and less than 35% in women) can indicate higher likelihood of metastatic disease. Similarly, elevated liver function tests can be worrisome for hepatic metastases.

Hooper et al.[18] have enumerated a standard set of clinical features found to be associated with metastatic disease (Table 112-3). Systematic review suggests that absence of all of these features makes metastatic disease highly unlikely with a negative predictive value exceeding 90%.[19,20]

Initial clinical evaluation of the patient with suspected lung cancer should also include an assessment for paraneoplastic syndromes (Table 112-4), clinical disorders associated with malignant disease that are not directly attributable to the physical effects of the tumor. They may be seen in up to 10% patients with lung cancer.[5] The most commonly recognized paraneoplastic syndromes are hormonally mediated; tumor cells secrete hormones or hormonal analogs. The syndrome of

TABLE 112-2 Initial Signs and Symptoms of Lung Cancer[5]

Signs and Symptoms	Range of Reported Frequencies (%)
Cough	8–75
Weight loss	0–68
Dyspnea	3–60
Chest pain	20–49
Hemoptysis	6–25
Bone pain	6–25
Fever	0–20
Weakness	0–10
Superior vena cava obstruction	0–4
Dysphagia	0–2
Wheezing	0–2

inappropriate antidiuretic hormone (SIADH) is seen in 10% to 45% of patients with SCLC and 0.7% to 1% of patients with NSCLC (squamous cell and adenocarcinoma) although symptoms related to hyponatremia are present in just 1% to 5% of patients.[21,22] Hyponatremia is associated with decreased survival in SCLC.[23] Ectopic production of adrenocorticotropin hormone (ACTH) can be found in up to 50% of patients with lung cancer, but true Cushing syndrome is seen in only 1% to 5% of patients with SCLC.[5,21] Ectopic Cushing syndrome is also associated with a poor prognosis in SCLC, in part related to an increased susceptibility to opportunistic infection in patients given chemotherapy.[21,24–26]

Hypercalcemia is seen in 2% to 6% of all lung cancer patients at presentation, and in up to 10% to 25% during their clinical course.[5,21] Etiology of hypercalcemia can be due to direct tumor effect on local osteolytic activity when there are bony metastases. However, in a substantial fraction of patients, typically those with squamous cell histopathology and less commonly in SCLC, hypercalcemia is due to tumor cell–elaborated parathyroid hormone related peptide (PTHrP).

Digital clubbing and hypertrophic osteoarthropathy (HOA) are two paraneoplastic syndromes of the musculoskeletal system commonly associated with NSCLC. Clubbing manifests as enlargement of the terminal tufts of the fingers and toes. It results from the proliferation of connective tissue beneath the nail matrix and can be seen in up to 29% of patients with adenocarcinoma or squamous cell carcinoma histopathology.[27] HOA, which occurs in fewer patients (<4%), presents as painful symmetric arthropathy, usually involving the ankles, wrists, and knees, and is caused by new periosteal bone formation at the distal long bones, resulting in vascular hyperplasia and edema. It is postulated that HPO occurs due to overexpression of vascular endothelial growth factor (VEGF).[28]

Other paraneoplastic syndromes associated with lung cancer occur due to the development of autoantibodies that can cause neurologic disease or rheumatologic disease. Dermatomyositis and polymyositis are autoimmune inflammatory myopathies characterized by progressive symmetrical proximal muscle weakness associated with various malignancies. Patients with dermatomyositis additionally may have Gottron's papules, and a heliotrope rash with poikiloderma. In two series, lung cancer accounted for 17.4% and 18%, respectively, of new cancer diagnoses within the first year of diagnosis of dermatomyositis.[29,30] The diagnosis can be confirmed by muscle or skin biopsy. Polymyositis is similarly associated with an increased risk of malignancy, with lung cancer accounting for 20% of newly diagnosed cancers during 5-year follow-up.[29]

There are a large number and variety of paraneoplastic neurologic syndromes (Table 112-3).[31] Lambert Eaton myasthenic syndrome (LEMS) is one of the better defined; it occurs due to the development of autoantibodies against presynaptic voltage-gated calcium channels. These circulating autoantibodies can be found in up to 5% to 8% patients with SCLC although clinical LEMS occurs in only 1% to 3% of patients.[32–34] Other paraneoplastic neurologic syndromes occur due to the presence of circulating neuronal autoantibodies (including anti-Hu, anti-Yo, and anti-Ri antibodies) and have a myriad of clinical manifestations.[21] Up to 20% patients with SCLC have circulating anti-Hu antibodies although paraneoplastic syndromes do not occur in the majority.[35] The related syndromes can include autonomic overactivity, corticocerebellar degeneration, brainstem encephalitis, limbic encephalitis, myelopathy, and peripheral nerve palsies. Autopsy studies have revealed that patients suffering from these syndromes have lymphocytic inflammatory infiltration in areas of the nervous system corresponding to their neurologic deficits.

While paraneoplastic syndromes manifest systemically, they are not always indicative of advanced malignant disease. Indeed, syndromes may regress with appropriate treatment of the tumor. Approximately 70% of patients with neurologic paraneoplastic syndromes have limited stage SCLC.

IMAGING EVALUATION

Following the initial intake evaluation, further noninvasive and invasive work-up should be undertaken with paired goals of (1) definitive establishment of histopathologic diagnosis and, when indicated, molecular characterization of the tumor, and (2) determination of disease stage in the most cost effective and least invasive manner possible. Given the myriad of diagnostic modalities available, it is often advisable that patients suspected of having lung cancer undergo this phase of the evaluation at an established multidisciplinary lung cancer center.

Unless a patient is clearly not a candidate for any treatment, all patients should undergo a chest computed tomography (CT) scan appropriately modified for the purposes of lung cancer assessment. The lung cancer CT scan includes the chest and the upper abdomen such that the liver and the adrenal glands are visualized in their entirety. The administration of intravenous contrast facilitates better characterization of hilar and mediastinal lymph nodes by differentiating them from vascular structures and also helps to better characterize hepatic and adrenal lesions. CT is most useful in delineating the key features of the primary tumor (size, presence of satellite nodules, associated atelectasis and infection, and invasion of adjacent structures); these features are essential in establishing the clinical T stage.

Regional lymph node involvement can also be evaluated on chest CT. Lymph nodes are deemed to be enlarged when they measure greater than 1 cm in short-axis diameter on transverse images. Likelihood of metastatic involvement increases with the degree with mediastinal enlargement: 62% of lymph nodes measuring 10 to 15 mm are malignant versus 90% of nodes measuring >15 mm.[36] However, in most patients, lymph node staging cannot be accurately undertaken based upon CT findings alone. In a meta-analysis of 35 studies (5111 patients, 28% of whom had mediastinal metastases), the pooled sensitivity of CT scanning for mediastinal nodal metastases was found to be 51% and pooled specificity 86%.[37] About 20% of nodes deemed to be benign on chest CT were actually malignant and 40% of nodes deemed abnormal on chest CT were actually benign. On occasion, there are CT findings that demonstrate mediastinal tumor invasion convincingly enough that further staging is unnecessary. These findings include extensive infiltration of mediastinal structures such that discrete anatomic landmarks are lost, matting of nodal tissue such that boundaries become indistinct, and encircling of mediastinal structures by infiltrating tumor. In the absence of these findings, further studies need to be undertaken to adequately stage the mediastinum.

Chest CT can also often demonstrate findings that may be suggestive of metastatic disease. CT may better delineate pleural disease; the majority of these effusions are malignant. In addition, CT may reveal pericardial effusion, pleural nodularity, or nodules in the contralateral lung, all of which may indicate metastatic disease. Bony involvement of the thoracic cage may be seen. Adrenal lesions can be identified in up to 10% of patients, however, many of these are ultimately found to be benign.[38]

Positron emission tomography (PET) with 18-fluoro-2-deoxyglucose (FDG) has assumed an increasingly prominent role in the initial noninvasive evaluation of the patient with suspected lung cancer.[39] Metabolically active tissues take up FDG, a glucose analog, avidly and appear bright on PET scan. Strongly hypermetabolic activity raises suspicion of malignancy. However, hypermetabolic activity can also be seen in inflammatory processes related to infections or recent surgery, raising the specter of false positivity. False negatives can occur with low-grade malignancies or small foci of malignancy. Lesions less than 0.8 to 1.0 cm may be too small for accurate assessment. High-level physiologic uptake within the brain, heart, gastrointestinal, and genitourinary tracts may compromise precise evaluation of tumor invasion in these areas. In addition, the presence of hyperglycemia can interfere with the uptake of FDG and thus increase the likelihood of false-negative examinations. Integrated PET/CT allows more detailed evaluation of abnormal tissues and surrounding structures and it is more helpful than full-body PET, which has limited anatomic resolution, to elucidate specific tumor characteristics as well as surrounding structures.

The PET scan is more sensitive and specific than CT in regional lymph node assessment with a pooled sensitivity of 74% and specificity of 85% in the identification of mediastinal lymph node metastases.[37] In patients with enlarged mediastinal nodes, the sensitivity has been estimated to be as high as 100% with a specificity of 78%.[40] Thus the false-positive rate ranges between 13% and 25% in patients with nodal enlargement. In those with normal-sized nodes on CT, PET sensitivity is 82% but specificity is higher at 93%.[41] Approximately 20% of patients with normal mediastinal nodes on CT and PET will actually have malignant disease within the mediastinum.

PET scanning can disclose unsuspected metastatic disease (M1) in 6% to 37% of cases, depending on clinical pretest probability. Rates are lower in earlier-stage disease: 1% to 8% of patients with clinical stage I disease and 7% to 18% in patients with clinical stage II disease.[37] Liver metastases, adrenal metastases, and bone metastases can be diagnosed with good accuracy. A recent study of PET-CT in the evaluation of adrenal lesions detected in patients with lung cancers reported an overall sensitivity and specificity of 97% and 94%, respectively.[42] Two systematic reviews suggest that PET scanning has higher diagnostic value than bone scintigraphy for the detection of bone metastases from lung cancer, with >90% sensitivity and specificity for PET-CT.[40,43]

PET has been the most helpful in decreasing the frequency of understaging in patients at risk for advanced lung cancer. Clinical trials have suggested that addition of PET imaging to the evaluation results in a reduction of the rates of noncurative surgery for NSCLC from 40% down to 20%.[44,45] The frequency of understaging disease decreases from 30% to 15%. The beneficial impact of PET diminishes in patient with early-stage disease. In patients with clinical stage I disease, PET correctly detects N2, N3, or M1 disease in 7% to 10%.[46] However, this comes at a cost of increased false-positive rate of up to 14%. PET should not be used alone to confirm advanced stage disease as patients may be erroneously directed away from curative therapies.

MRI scanning is the test of choice when assessing for intracranial metastatic disease. It is more sensitive than CT scan of the brain.[47] Staging brain MRI should be considered in patients who present with locally advanced or advanced NSCLC on chest CT or PET scanning, patients with neurologic signs or symptoms, patients presenting with nonspecific constitutional symptoms of fevers, weight loss, anorexia, and weakness and in patients with SCLC. MRI scanning is also often the test of choice for focused examination for extent of chest wall invasion, diaphragmatic involvement, superior sulcus tumors, brachial plexus invasion, or invasion of the spine (T4 disease).

Any extrathoracic lesion detected on imaging studies in a patient suspected of having lung cancer should be biopsied first, if feasible. This will accomplish not only tissue diagnosis but also confirmation of advanced disease in both SCLC and NSCLC.

ESTABLISHING THE TISSUE DIAGNOSIS

Methods employed in establishing a tissue diagnosis SCLC and NSCLC are discussed below.

SCLC

Specific imaging characteristics on chest CT can be indicative of SCLC. In particular, the findings of massive lymphadenopathy, direct mediastinal invasion, or hilar masses can suggest SCLC. The suspicion should be raised if clinical evaluation is worrisome for SIADH, ectopic ACTH production, or neurologic paraneoplastic syndromes. If SCLC is suspected, then tissue diagnosis should be established utilizing the least invasive test feasible.

In 1989, the International Association for the Study of Lung Cancer modified the Veterans Administration Lung Study Group (VALSG) two-stage classification of SCLC; this modified classification system is currently the widely accepted clinical staging system for SCLC.[48] Patients with limited stage disease have disease confined to one hemithorax, the mediastinum, and ipsilateral supraclavicular lymph nodes. In other words, limited stage defines a primary tumor and regional nodes that can be incorporated into in a reasonably safe radiation port. Patients with extensive stage disease have malignant pleural and pericardial effusions, contralateral hilar or supraclavicular nodes, and/or distant metastases. Given the high likelihood of extensive disease at the time of presentation, all patients should undergo a full staging evaluation that

traditionally included a contrast-enhanced CT of the chest and abdomen, bone scan, and MRI or contrast-enhanced CT scan of the brain. MRI scanning, the preferred imaging modality, will detect brain metastasis in 10% to 15% of asymptomatic patients with SCLC at the time of diagnosis, and in 12% of patients with otherwise limited stage SCLC.[34,49] Routine bone marrow aspiration is not indicated. The use of PET scan in the initial stating of SCLC has been evaluated in several small studies.[50–54] Because SCLC is a highly metabolic malignancy, PET scan is 100% sensitive for the detection of primary tumor. In addition, PET is superior to standard imaging in both sensitivity and specificity for detection of non-CNS metastatic foci. In patients with radiographic evidence of extensive stage SCLC, tissue diagnosis, and stage confirmation should be accomplished by biopsy of a metastatic focus if feasible.

NSCLC

In the case of NSCLC, the primary goals in tissue sampling selection are more complicated. These goals are to (1) obtain a tissue specimen adequate for histopathology and genetic analysis and (2) establish the clinical stage of disease in the least invasive manner feasible. If imaging tests suggest a site of distant metastatic disease, then that site should be sampled first, if accessible.

Sputum cytology is the least invasive way of achieving a histologic diagnosis. However, yield is clearly center dependent and requires a highly trained respiratory cytologist to process and analyze specimens appropriately. Sensitivity of sputum cytology has been reported to be as low as 42% and as high as 97%.[55] Yield increases with number of specimens submitted: 68% for one specimen, 78% for two, and 86% when three or more specimens are submitted.[56] Diagnostic yield is higher in patients with central tumors, tumors >2.4 cm, squamous cell histopathology, and those with hemoptysis.[55] Diagnostic yield is lowest in patients with peripheral lesions.

Thoracentesis is indicated when a pleural effusion is present as a significant proportion of pleural effusions seen in patients with lung cancer are malignant. Positive pleural fluid cytology not only establishes the diagnosis but also establishes stage IV disease in NSCLC and extensive stage SCLC. Thoracentesis is best accomplished utilizing bedside ultrasound guidance, as this appears to improve the safety and yield of the procedure. Furthermore, ultrasound imaging can reveal findings that raise the suspicion for malignant disease, including pleural thickening and nodularity. A volume of at least 50 mL should be sent; diagnostic yield does not appear to increase with larger volume of fluid analyzed.[57] If the initial thoracentesis is negative, a second thoracentesis should be performed. A second thoracentesis has a diagnostic yield of 27% when the first is negative. Sensitivity of pleural fluid cytology can be as high as 72% when at least two separate specimens are sent.[55]

When pleural disease is present and thoracentesis is negative, additional diagnostic strategies include blind pleural biopsy, percutaneous image-guided biopsy, and thoracoscopic biopsy. Non-image guided closed pleural biopsy using an Abrams needle probably no longer has a role as it increases diagnostic yield over thoracentesis by only 7% to 27%.[55] Image-guided pleural biopsy has clear advantages in diagnostic yield, particularly when there are abnormal findings, with a sensitivity of 84%.[55] Thoracoscopy has a reported sensitivity of 80% to 99% in the diagnosis of malignant pleural disease.[55] However, when there is CT evidence of pleural thickening or nodules, the diagnostic yield of image-guided percutaneous biopsy is similar to thoracoscopy. Thus, medical or surgical thoracoscopy may be reserved for patients with pleural fluid but without a discrete target for CT-guided pleural biopsy.[58]

HISTOLOGIC SAMPLING OF THE PRIMARY TUMOR

There are numerous procedures presently utilized to sample the primary tumor with varying diagnostic yields depending on tumor characteristics and adjunct technologies (Table 112-5). Bronchoscopy enables sampling of the primary tumor as well as the mediastinum for regional lymph node staging. Overall sensitivity of endobronchial forceps biopsy of directly visualized central tumor is 74% with yield increasing with the number of biopsy passes.[55] It is recommended that at least three biopsies be taken. The yield of endobronchial washes and brushes is lower (sensitivity 47% and 61%, respectively) but may have additive benefit.[55] Endobronchial needle aspiration further increases yield as forceps biopsies of endobronchial lesions can sometimes sample areas of necrosis and may result in nondiagnostic biopsies.[59–61] When all techniques are utilized, reported yield of bronchoscopic sampling of endobronchial lesions can be as high as 91% to 96%. Bronchoscopic visualization of endobronchial disease is also the best way to estimate the extent of proximal tumor invasion, specifically if tumor invasion occurs proximal to a lobar bronchus (T2b lesion) or invades the mainstem bronchus to within 2 cm of the carina (T3 disease).

The utility of bronchoscopic sampling in patients with peripheral primary tumor is much lower. When lesions are sampled utilizing multiple techniques (transbronchial biopsy, transbronchial brush, lavage, and wash as well as transbronchial needle aspiration), the overall pooled sensitivity is 78% on recent comprehensive review of bronchoscopic techniques to diagnose lung cancer.[55] The sensitivity of transbronchial biopsy is 57% with the yield higher in larger lesions: 63% in lesions measuring at least 2 cm and only 34% in lesions measure <2 cm. When only one pass is made, the sensitivity is 45%. Sensitivity increased to 70% when at least six passes are made.

Adjunctive new technologies, including electromagnetic navigational (EMN) bronchoscopy and radial probe endobronchial ultrasound (R-EBUS), may also improve the yield of transbronchial biopsy of peripheral lesions. EMN bronchoscopic technology creates a real-time virtual thoracic map that helps the bronchoscopist steer an extended guidance sheath through subsegmental airways toward the target lesion. The utilization of this tool increases the diagnostic yield of bronchoscopic biopsy of peripheral lesions from 57% overall to 70%.[63] When CT scanning demonstrates that a subsegmental bronchus leads directly into the lesion, yield increases up to 79%.[63] One study suggests that the addition of needle aspiration further improves the yield.[64] R-EBUS permits direct real-time ultrasound imaging of target lesions; this can increase overall sensitivity of bronchoscopic biopsy of peripheral lesions up to 73%.[62] Lesion size, as with fluoroscopically guided procedures, continues to influence test performance, with a sensitivity of 56% for lesions measuring 2 cm or less and a much higher sensitivity of 78% for lesions measuring greater than 2 cm. Procedural complications are minimal with an overall rate of pneumothorax of 1% and pneumothorax requiring catheter drainage of 0.4%.[63] When R-EBUS is utilized in conjunction with EMN, reported diagnostic yield has been as high as 93%.[65]

Image-guided transthoracic needle aspiration has excellent sensitivity for peripheral lesions, with a pooled sensitivity of approximately 90%.[55] However, a negative biopsy does not rule out malignant disease. The false-negative rate can range between 20% and 30% depending on patient population and disease characteristics.[55] CT guidance is clearly superior to fluoroscopic guidance. The addition of transthoracic core biopsy does not increase sensitivity but can help establish specific histopathologic diagnosis by improving tissue acquisition for immunohistochemical staining and molecular characterization. In addition, a core biopsy may be helpful in ascertaining specific benign diagnoses.

The complication rate of transthoracic needle biopsy or aspiration is higher than that seen with bronchoscopy. The incidence of pneumothorax is 15% and the incidence of severe hemorrhage is 1%.[66] Risk factors for complications include tobacco use and underlying chronic obstructive pulmonary disease. Video-assisted thoracoscopic surgery (VATS) biopsy has the highest yield but also requires hospitalization and carries higher attendant risk. Therefore, despite overall lower yield, bronchoscopic sampling may be preferable, particularly in centers where advanced diagnostic technologies including R-EBUS and EMN are available. Furthermore, bronchoscopic techniques can also be utilized to stage the mediastinum.

TABLE 112-5 Sampling of Primary Tumor

Tumor Characteristics	Procedure	Sensitivity (%)	Comments
Directly visualized endobronchial tumor	Bronchoscopy with forceps biopsy	74[55]	
	Bronchoscopic washes	47[55]	
	Endobronchial brush	61[55]	
	Needle aspiration	75–96[59–61]	
Peripheral lesions	Transbronchial biopsy	57[55]	Yield increases with number of biopsy passes: 45% for one sample and 70% for six samples[55]
	Overall	34[55]	
	Lesions <2 cm	63[55]	
	Lesions >2 cm		
	Transbronchial brush	54[55]	
	Bronchoalveolar lavage/wash	43[55]	
	Transbronchial needle aspiration	65[55]	
	Combination of all modalities	78[55]	
	Radial EBUS	73[62]	Yield increases to 79% if subsegmental bronchus leads to lesion on chest CT[62]
	Overall	56[62]	
	Lesions ≤2 cm	78[62]	
	Lesions >2 cm		
	Transthoracic needle aspiration	90[55]	Pneumothorax rate 15%
	CT guided	92[55]	Use of core biopsy similar sensitivity to FNA for detection of malignancy but better able to determine specific benign diagnoses
	Fluoroscopically guided	88[55]

MEDIASTINAL STAGING

Lung cancer staging is based upon the tumor node metastasis (TNM) staging system last updated on January 1, 2010 (Table 112-1) by the International Association for the Study of Lung Cancer. Extent of disease is categorized by the characteristics of the primary tumor (T), the involvement of regional lymph nodes (N), and the presence of absence of distant metastases (M). Disease stage is the key determinant of candidacy for tumor resection. Patients with stage I and II diseases and otherwise adequate cardiopulmonary reserve should undergo surgery. Unfortunately, only 20% of patients are ultimately deemed operable after thorough clinical staging.

Nearly a third of patients with lung cancer have locally advanced disease with mediastinal involvement (N2 or N3) at the time of presentation.[4,6] Mediastinal staging is crucial in determining stage of disease and candidacy for surgical resection once metastatic disease has been ruled out. Tissue confirmation of mediastinal nodal metastasis becomes unnecessary only in situations where distant metastatic disease has already been confirmed or when the patient is clearly not a candidate for any treatment. Patients with NSCLC fall into four categories in regard to approach to clinical staging of the mediastinum based on the radiographic findings (Table 112-6).[67] Radiographic group A includes patients who have imaging characteristics that are unequivocally consistent with malignant invasion of the mediastinum (mediastinal infiltration with loss of normal tissue boundaries, nodal tissue is no longer discrete and can be matted together, and vascular structures are often encircled) (Fig. 112-2). In this group of patients, the goal is to obtain tissue by the least invasive procedure to establish the diagnosis. Group B includes patients with discrete lymph node enlargement (Fig. 112-3). Discrete enlargement of lymph nodes on a CT scan, even massive enlargement, is inadequate evidence for mediastinal metastases as up to 40% of these nodes are actually benign.[37] Conversely, group C includes patients with central lesions or N1 disease with radiographically normal mediastinal lymph nodes (Fig. 112-4). In this group, 20% to 25% are found to have nodal involvement.[37] Finally, the last group of patients, group D, includes those with peripheral clinical stage I lesions with radiographically normal mediastinal

TABLE 112-6 Classification of Mediastinal Disease by Radiographic Characteristics

Group	Description
A	Mediastinal infiltration: tumor invasion such that normal anatomic boundaries cannot be distinguished
B	Enlarged discrete mediastinal lymph nodes: lymph nodes measuring ≥1 cm in short-axis diameter on transverse CT scan
C	Clinical stage II or central stage I tumor: normal-sized mediastinal lymph nodes but enlarged N1 nodes or central tumor
D	Peripheral clinical stage I tumor: normal mediastinal and hilar nodes with a peripheral tumor

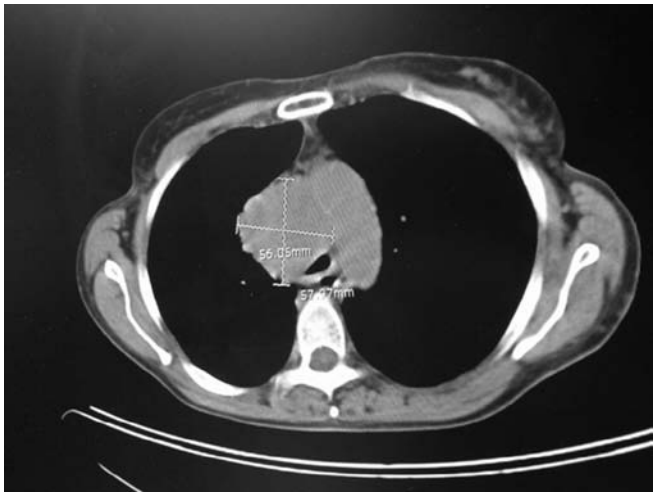

Figure 112-2 Example of radiographic group A disease: mediastinal infiltration with loss of normal anatomic boundaries.

and hilar lymph nodes. These patients have a sufficiently low pretest probability for mediastinal involvement that invasive mediastinal sampling becomes unnecessary. In patients with radiographic group B or C disease, adequate staging of the mediastinum is mandatory.

Mediastinal staging procedures include transthoracic needle aspiration (TTNA), transbronchial needle aspiration (TBNA) with or without endobronchial ultrasound (EBUS), endoscopic ultrasound (EUS) needle aspiration, cervical mediastinoscopy, anterior mediastinoscopy, and thoracoscopy. Selection of appropriate procedure is made based upon nodal station (Table 112-7), pretest probability of disease, and medical appropriateness for surgical resection.[68] The diagnostic yield of each procedure (Table 112-8) should also be taken into account.

TTNA of mediastinal nodal tissue is possible when anterior mediastinal lymph nodes are enlarged. Recent systematic review reported a pooled sensitivity of 94%.[39] As with TTNA of peripheral lesions, the risk of pneumothorax is fairly high. In fact, chest tubes are required for evacuation of pneumothorax in 10% of procedures.[67] TTNA of the mediastinum is primarily utilized in patients with fairly bulky anterior mediastinal lymph node enlargement.

Bronchoscopic sampling with TBNA without image guidance is of variable yield. Nodal stations accessible to TBNA include stations 2, 4, 7, and 10. Sensitivity ranges from 14% to 100% in published studies, with an overall pooled sensitivity of 78%.[39,67] This technique is primarily

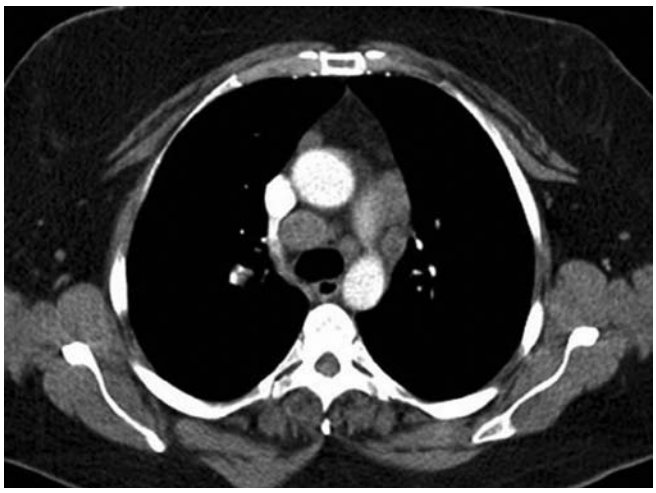

Figure 112-3 Example of radiographic Group B disease: discrete mediastinal (4R) nodal enlargement.

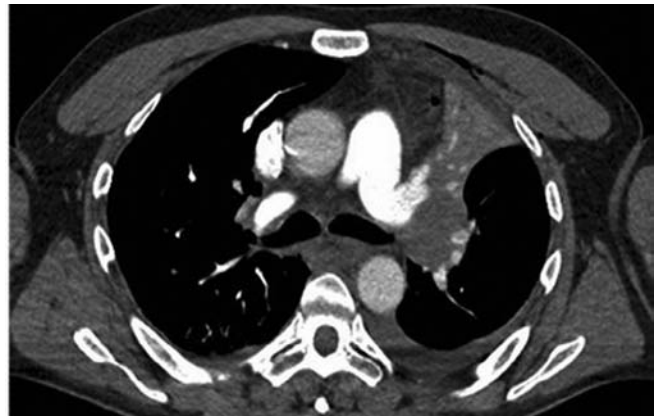

Figure 112-4 Example of radiographic group C disease: central lesion with N1 disease but no enlarged mediastinal lymphadenopathy.

utilized in patients with mediastinal lymph nodes large enough to be amenable to non–image-guided sampling. The availability of rapid on-site cytologic evaluation also improves diagnostic yield and decreases the number of biopsy passes needed.[72] The advent of convex probe EBUS has significantly improved the diagnostic yield of TBNA sampling of the mediastinum. EBUS allows for real-time visualization of the target nodal tissue with improved sensitivity to 88% to 93% on systematic review and it is recommended as the first procedure, if available, for sampling the hilar and mediastinal nodes. EBUS-FNA provides the ability to access nearly all lymph node stations, combine diagnosis and staging in a single procedure and results in equivalent if not better diagnostic yield when compared with mediastinoscopy.[39,69,70] Performance is best in patients with positive CT or PET results, with a sensitivity of

TABLE 112-7 Regional Lymph Node Stations (International Association for the Study of Lung Cancer)

Zone	Lymph Node Station	
Supraclavicular zone	1	Low cervical, supraclavicular, sternal notch
Superior mediastinal nodes	2R	Right upper paratracheal
	2L	Left upper paratracheal
	3a	Prevascular
	3p	Retrotracheal
	4R	Right lower paratracheal
	4L	Left lower paratracheal
Aortic nodes/aortopulmonary window nodes	5	Subaortic
	6	Para-aortic
Interior mediastinal nodes	7	Subcarinal
	8	Paraesophageal nodes
	9	Pulmonary ligament
Hilar nodes	10	Hilar nodes
	11	Interlobar nodes
Peripheral nodes	12	Lobar nodes
	13	Segmental nodes
	14	Subsegmental nodes

American College of Chest Physicians evidence-based clinical practice guidelines. Chest. 2013;143(5):e211s–e250s; Adams K, Shah PL, Edmonds L, Lim E. Test performance of endobronchial utlrasound and transbronchial needle aspiratiopn biopsy for mediastinal staging in patients with lung cancer: a systematic review and meta-analysis. Thorax. 2009;64(9):757–762; Gu P, Zhao YZ, Jiang LY, Zhang W, Xin Y, Han BH. Endobronchial ultrasound-guided transbronchial needle aspiration for staging of lung cancer: a systematic review and meta-analysis. European Journal of Cancer. 2009;45(8):1389–1396; Micames CG. Endoscopic Ultrasound-Guided Fine-Needle Aspiration for Non-small Cell Lung Cancer Staging A Systematic Review and Metaanalysis. Chest. 2007.

94% in that population.[70] The false-negative rate remains substantial at 24%. Evaluation of tissue adequacy for immunohistochemical testing (IHC) and molecular characterization suggests that EBUS-TBNA can result in satisfactory sampling in up to 67% to 79% of cases. Diagnostic yield is clearly related to expertise of the bronchoscopist and there is significant heterogeneity in yield across hospitals.[73] Therefore, negative sampling should be followed by mediastinoscopy for patients who are candidates for surgical resection.

EUS-FNA can access the inferior mediastinal nodal stations as well as nodal tissue in the subaortic stations: 9, 8, 7, and 5 for fine-needle aspiration. Like bronchoscopy, EUS-FNA is minimally invasive and is an outpatient procedure. In addition, the left adrenal gland, celiac lymph nodes, and lesions involving the left lobe of the liver can be sampled utilizing this technique. The sensitivity for accessible mediastinal lymph nodes is excellent at 83% with an overall false-negative rate of 19%.[71] Yield is highest with enlarged nodes with a sensitivity of 90% and a false-negative rate of 22%.[71] In the hands of expert endoscopists, normal-sized nodes may also be sampled with a reported sensitivity of 58% for metastatic disease.[71] While a negative test impels further testing, a positive study obviates the need for more invasive evaluation.

When EUS is combined with EBUS, the mediastinum can be much more extensively sampled than with either modality alone. In the studies investigating this combined approach, sensitivity ranged between 72% and 100% with 98% to 100% specificity.[74–80] Negative predictive value ranged between 80% and 100%. This combined approach requires highly specialized expertise and is available only at selected centers.

Cervical mediastinoscopy is typically a same-day surgical procedure where an incision is made just above the suprasternal notch and a mediastinoscope inserted. It is a low morbidity procedure with complication rates of 2% and mortality of 0.08%.[67] The high and low paratracheal nodes (station 2R, 2L, 4R, and 4L), pretracheal (stations 1 and 3) and anterior subcarinal (station 7) nodal stations can be sampled. Mediastinoscopy is the procedure of choice to demonstrate node negativity prior to surgical resection of the primary tumor. Test sensitivity has been reported to be overall 80% with a false-negative rate as high as 10%.[67] The lymph nodes identified as false negatives are often located in nodal stations not accessible to the mediastinoscope. The addition of video mediastinoscopy may further improve test performance with sensitivity increasing to 80%.[67]

A Chamberlain procedure (i.e., anterior mediastinoscopy) can be performed to sample aortopulmonary and anterior mediastinal nodal stations (stations 5 and 6), commonly involved with left upper lobe cancers.

VATS can be utilized to sample multiple lymph node stations, including the right paratracheal (station 4R) nodes, stations 5 and 6 nodes, paraesophageal nodes, and stations 9 and 10 nodes. The left paratracheal lymph nodes are much more difficult to access. VATS sampling also provide the most reliable information short of full thoracotomy regarding extent of primary tumor invasion of the chest wall and mediastinal structures as well as pleural and pericardial involvement.

TISSUE ACQUISITION FOR HISTOPATHOLOGY AND GENETIC TESTING

It has become increasingly evident that NSCLCs encompass a heterogeneous group of cancers with not just different histologies but also different genetics. In addition, NSCLCs respond differently to therapeutic agents depending on histology and molecular characteristics. Significant positive outcomes have been reported when certain adenocarcinomas are combined with specific chemotherapy agents (pemetrexed) and tyrosine-kinase inhibitors (erlotinib), while patients with squamous cell histology are clearly at higher risk of toxicity from bevacizumab.[81–83]

The identification of specific driver mutations has provided new targets for molecular therapies. Epidermal growth factor receptor (EGFR) tyrosine-kinase inhibitors are now considered first-line therapy for patients with advanced NSCLC whose tumors have EGFR mutations. Testing for EGFR mutations in advanced NSCLC is now the standard of care.[84] Two other driver mutations, EML4 and anaplastic lymphoma kinase (EML4-ALK) oncogenic fusion gene, and ROS1 translocations are present in 7% and 2%, respectively, of adenocarcinomas of the lung. The use of crizotinib, an oral agent, in patients with either one of these genetic alterations has been shown to result in dramatic treatment response.[85,86]

The emergence of individually tailored therapy based on histology and molecular characteristics has served to emphasize how important adequate tissue acquisition is when diagnosing lung cancer. In patients who are candidates for treatment, it is no longer adequate to simply differentiate between SCLC and NSCLC. It has become incumbent upon clinicians who perform diagnostic studies to obtain sufficient tissue to perform IHC and molecular analysis in order to accurately ascertain the histologic subtype and molecular characterization of NSCLC. The impetus to obtain larger pieces of tissue can often seem discordant with the other objective of tissue acquisition, which is to achieve diagnosis and staging in the least invasive manner possible. In an era of minimally invasive procedures, several studies have reported high feasibility (range

67%–100%) of performing IHC and molecular analysis on specimens obtained via EBUS-TBNA.[84,87–94] Tissue adequacy depends on center expertise, and one study reported that IHC analysis was feasible in all studied specimens obtained by EBUS-TBNA from mediastinal nodes.[87]

Success rates in performing molecular testing for EGFR and Kras mutations on cytologic material obtained by EBUS-TBNA have been reported to be as high as 72% to 77%.[89,92] ALK fusion genes were detected in 6% of 109 samples obtained by EBUS-TBNA of lymph node metastases through IHC, fluorescence in-situ hybridization (FISH) and polymerase chain reaction (PCR) in one published series.[94] DNA sequencing for EGFR and Kras mutations was demonstrated to be feasible in cytologic specimens acquired through a number of means, including body fluid aspiration, TTNA, and EBUS-TBNA, with a very low specimen insufficiency rate of only 6.2%; the lowest specimen insufficiency rates were seen in EBUS-TBNA (4%) and body fluid (3.7%).[93] Preservation of material from needle aspirates in cell block can store tumor cells for future IHC and molecular studies. How much tissue is needed to accurately diagnose the lung cancer histologic type and assess molecular markers has not been formally studied. It has been reported that one aspiration per lymph node station during EBUS-TBNA without rapid on-site cytology results in a sample adequacy of 90% compared to 100% for the three aspirations.[95]

SUMMARY

- Initial clinical evaluation of a patient with suspected lung cancer should focus upon presenting symptomatology as well as signs and symptoms suggestive of advanced stage disease. History and laboratory testing may also be revealing for paraneoplastic syndromes.
- Initial imaging evaluation should include a CT scan for all patients who may be candidates for treatment. PET scanning is indicated for the majority of patients, particularly for those who are at risk for mediastinal involvement as well as those patients with advanced thoracic disease and thus are at risk for distant metastatic disease. Integrated PET/CT scanning may be the initial study of choice at centers with available technology. CT with contrast or MRI of the brain should be performed to assess for intracranial metastases in those patient with neurologic symptoms or to screen for intracranial metastases in patients with locally advanced or advanced NSCLC, and in those with SCLC.
- When SCLC is suspected, tissue diagnosis should be obtained in the least invasive manner possible. Staging classification is either limited stage or extensive stage disease and if feasible, a suspicious metastatic lesion should be biopsied first to confirm diagnosis and stage. In selected cases, staging can be accomplished through imaging evaluation alone (patient with multiple brain lesions or multiple bone lesions).
- Multiple diagnostic modalities are available to establish tissue diagnosis and to confirm clinical stage. Selection should be based upon diagnostic yield, procedure safety, and ability to simultaneously establish stage. Thus, priority should be given to procedures that sample foci of metastatic disease detected on imaging evaluation (e.g., thoracentesis when pleural effusions are present, biopsy of PET avid adrenal, bone or hepatic lesions).
- Tissue sampling from the primary tumor can be accomplished percutaneously, bronchoscopically, and surgically. Yield of bronchoscopic biopsy for peripheral lung lesions is still not as high as that seen with TTNA. However, the advent of new techniques such as R-EBUS and EMN has improved test performance. Bronchoscopy remains the procedure with the lowest complication rate and should be strongly recommended as the procedure of choice in centers with local expertise.
- EBUS-FNA is the procedure of choice for sampling hilar and mediastinal lymph nodes.
- In the absence of M1 disease, clinical staging of the mediastinum becomes crucial unless the patients has radiographic findings of mediastinal invasion or the patient has a sufficiently low pretest probability of mediastinal metastasis (peripheral T1N0 lesion). Ultrasound-guided bronchoscopic and endoscopic techniques have resulted in much improved diagnostic yield with excellent procedural safety. However, negative results should prompt surgical mediastinal sampling.
- The emergence of therapies tailored to tumor histology and genetics has resulted in greater emphasis upon adequate tissue acquisition for molecular analysis.

CHAPTER 113

Treatment of Non–Small-Cell Lung Cancer: Surgery

Scott I. Reznik
W. Roy Smythe

Lung cancer represents the most common cause of cancer-related death in the world. It was considered a rare disease until the early part of the 20th century. In 1879, lung cancer represented only 1% of cancers identified at autopsy compared to 14% in 1927.[1] The famous surgeon, Alton Oschner reported that as a medical student in 1910, he was called to the autopsy suite to see a case of lung cancer, since it was so rare he was likely to never see another case. Seventeen years passed before he saw another case of lung cancer and then he saw 8 cases in 6 months.[2] The link between tobacco use and lung cancer has been common knowledge since the surgeon general's report in 1964, and despite that knowledge, the death rate continued to rise in men until 1991 and in women until 2003. The treatment of lung cancer has evolved from a single modality, surgery, to a multimodality approach that calls upon the skills of numerous specialists. Physicians, who diagnose and treat lung cancer, must work together to define the role that surgery plays in the modern management of lung cancer. Surgery, when appropriate remains the cornerstone of therapy, and surgeons play an integral role in the diagnosis and treatment of patients with lung cancer.

DIAGNOSIS

The diagnosis and staging of lung cancer is covered elsewhere in the text. It is illustrative to consider the route taken by most patients before being referred to a surgeon and the qualifications that the surgeon should ideally possess to contribute optimally to the management of the patient with lung cancer. Patients with lung cancer may present with obvious symptoms such as hemoptysis or chest wall pain. The most common presenting complaints are respiratory symptoms that prompt a chest radiograph. From the surgeon's viewpoint, the evaluation of patients with abnormal imaging studies depends on the likelihood of malignant disease. In patients with a history of smoking the level of suspicion is higher. Lung cancer is seen in nonsmokers, but the suspicion for cancer is significantly lower in this group than in smokers, in whom an abnormal chest radiograph is lung cancer until proved otherwise. If previous chest imaging is available those studies should be compared with the current imaging. A lesion that appears unchanged from older films, particularly those obtained more than 2 years previously, markedly diminishes, but does not eliminate, the probability that the current finding represents a lung cancer.

When a surgical referral is indicated, the surgical specialist should offer a complete armamentarium of surgical options and techniques as well as an understanding of the principles of lung cancer treatment. The technical ability to perform lung resection is the minimum requirement but by itself is not sufficient. There is an increasing trend toward thoracoscopic techniques such as video-assisted thoracic surgery (VATS) or robot-assisted surgery. At least 30% of lobectomies are performed using minimally invasive techniques but this proportion is rising rapidly.[3] Thoracoscopic lung resection has been shown to be associated with a decreased length of stay, decreased complication rate, and decreased need for blood transfusion.[4,5] The lymph node harvest is equivalent if not superior.[3] The thoracic surgical specialist should be proficient in staging procedures including mediastinoscopy and endobronchial ultrasound (EBUS) although in many hospitals, a pulmonologist performs this latter procedure. The critical element is the willingness of the surgical specialist to participate in coordinated multidisciplinary care. Patients with advanced disease, who may be candidates for resection after induction therapy, should be referred early in the process so that decisions about potential fitness for operation from oncologic, medical, and technical perspectives can be made.

As critical care and anesthetic techniques continue to improve and minimally invasive surgery advances, all patients with lung cancer should be considered for therapy by the treating specialists. Age bias against treatment including chemotherapy, radiation, and surgery has been documented across many fields of medicine.[6] Age alone should not be the basis for ruling out definitive treatment and each patient must be evaluated individually.

Patients may present with symptoms either referable to the chest or related to the presence of metastatic disease. The initial evaluation should be directed toward an explanation of the symptoms. A complete discussion of the clinical presentation is available in Chapter 112. Patients with evidence of metastatic disease still require a tissue diagnosis. The method employed to obtain the tissue diagnosis should have the highest probability of success. Whereas

bronchoscopy has a high likelihood of yielding a diagnosis in the patient who presents with cough or hemoptysis and a central lesion, it is less likely to be successful when the lung findings are confined to a peripheral small nodule. In these cases, transthoracic needle biopsy may have the highest yield. When a patient presents with presumed metastatic disease that is accessible, such as a palpable supraclavicular lymph node, a fine-needle aspirate, done in the office, may yield the diagnosis and obviate the need for mediastinal staging. Consideration must be given to tissue yield, since ideally a biopsy sample should have sufficient tissue to allow for the ever-expanding array of genetic testing such as for EGFR mutations or ALK gene rearrangements. Some patients with metastatic disease may require wedge resection or other excisional biopsy to obtain enough tissue to allow for extensive molecular testing. A percutaneous biopsy of an adrenal lesion may also provide both a diagnosis and stage; however, prior to biopsy, the likelihood of pheochromocytoma should be considered. Previously the only question of significance in the patient with metastatic disease was the differentiation between small cell and non–small-cell lung cancer (NSCLC). However, current adjuvant or definitive treatment algorithms differ considerably between the different histologic types of NSCLC. Occasionally mediastinoscopy may be required to obtain enough tissue and very rarely video thoracoscopic excision of a lung nodule may be needed. Exploratory thoracoscopy or thoracotomy has no place in the management of these patients.

For patients who present with a solitary pulmonary nodule, chest computed tomography (CT) should be performed to determine if the nodule is solitary as well as to assess the status of the mediastinum, liver, and adrenal glands. When the risk of malignancy is low, such as in nonsmokers with a small nodule, it is reasonable to follow the lesion over a period of time. A repeat chest CT in 3 to 12 months, depending on the size of the nodule, is the recommended approach in the low-risk candidate. If the lesion has increased in size, then excision is carried out. If there is no change in size continued observation with repeated chest imaging is warranted. Conversely, in a smoker in whom there is a high probability that the nodule is malignant, excision may be justified without a prior needle biopsy.

The role of percutaneous needle biopsy of the solitary pulmonary nodule remains controversial. Diagnostic accuracy of CT-guided biopsy has been reported as high as 93.5% but this is due largely to its ability to diagnose malignant as opposed to benign processes.[7] The accuracy can be improved with increasing use of core needles and on-site cytologic analysis. In a patient at high risk for cancer, a positive biopsy confirms what we already suspected; however, the patient has been exposed to the risk of the needle biopsy, namely, a 10% to 15% incidence of pneumothorax with a need for a chest tube in 2% to 5% of cases.[8] The National Lung Screening Trial reported a 21.2% complication rate of needle biopsy with one death.[9] A negative biopsy does not negate the fact that a suspicious nodule remains and is of little help. More definitive information has to be obtained, such as cartilage or fungal elements, for the biopsy to obviate the need for resection in a high-risk patient with a suspicious lesion. If biopsy is inconclusive or the patient has significant anxiety regarding the possibility of a pulmonary nodule being an occult cancer, then resection may be indicated. Most peripheral lesions can be resected thoracoscopically and sent for frozen section. If the nodule proves to be benign, then thoracoscopic excision both makes the diagnosis and completes the therapy. If the nodule is malignant, an anatomic or other therapeutic resection and lymph node sampling can be performed during the same operative session. A biopsy consistent with small cell cancer should not preclude resection if there is no mediastinal adenopathy. T1-2N0-1 small cell lung cancers are optimally treated with anatomic resection and mediastinal lymph node dissection or sampling.[10] Most thoracic surgeons would perform mediastinoscopy and/or EBUS prior to resection to confirm that the mediastinum is not involved with tumor. If the final pathology reveals small cell carcinoma, resection is followed by chemotherapy.

STAGING

A discussion of noninvasive staging is beyond the scope of this chapter and is dealt with elsewhere in this volume; however, the role of invasive staging and specific procedures utilized deserve mention. Staging determines the appropriate surgical and medical treatment plan. Therefore, thorough staging is mandated. In discussing stage, distinction must be made between *clinical* and *pathologic* stage. The former is based solely on noninvasive imaging studies, whereas the latter depends on actual histologic material obtained either by invasive staging studies or at the time of the surgical resection. The accuracy of clinical staging depends upon the accuracy of the study. A chest CT scan provides excellent visualization of the contents of the superior mediastinum. Typically, mediastinal lymph nodes are considered suspicious if they are greater than 1 cm in short axis. However the CT must always be considered in context of the remainder of the mediastinum. Volterrani et al.[11] have suggested creating size cutoffs for each of the mediastinal lymph node stations to improve diagnostic accuracy of CT alone. Fused CT-PET provides information on the metabolic activity of the primary lesion and the mediastinal lymph nodes and may detect occult distant metastases. A recent study in patients with clinical stage I NSCLC, who underwent staging with PET followed by resection and lymphadenectomy revealed the sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of PET to be 68%, 95%, 31%, 99%, and 94% respectively.[12] Thus PET is a highly specific test. However, a patient without obvious distant metastatic disease and a PET or CT that is concerning for mediastinal metastasis should not be deemed inoperable based on imaging alone. Patients with granulomatous lymphadenitis from sarcoidosis or histoplasmosis frequently have hypermetabolic lymph nodes not due to malignancy. These patients should undergo invasive mediastinal staging. In addition, patients with postobstructive pneumonia often have enlarged or hypermetabolic mediastinal lymph nodes as a reaction to infection. At our institution, in these cases, we perform EBUS and if negative for malignancy, we perform mediastinoscopy at the time of planned resection. EBUS followed by mediastinoscopy provides a greater sensitivity than either test alone and helps eliminate sampling error.[13] When performing EBUS for staging and diagnosis a logical progression from N3 to N2 to N1 nodes should be followed, minimizing the need for sampling nodal stations that would not affect the stage and preventing upstaging through needle contamination.[14]

With the constantly improving resolution of CT imaging and the increasing availability of EBUS, the need for routine mediastinoscopy for all patients with lung cancer must be questioned. While still considered a definitive staging technique, there are nodal stations that cannot be accessed by standard cervical mediastinoscopy. These include the subaortic nodes (level 5) and para-aortic nodes (level 6), both of which are located in the aortopulmonary window (Fig. 113-1). They are a common site for lymph node involvement in left upper lobe tumors but when involved in the absence of other lymph node disease, the prognosis is equivalent to N1 (hilar) disease. These nodes are not accessible through standard EBUS techniques and are difficult to access via the esophagus although transarterial sampling has been described but is rarely performed.[15]

Mediastinoscopy is performed through a small (2.5-cm) incision made in the neck 1 cm above the sternal notch. The area explored by mediastinoscopy, the superior mediastinum, is palpated first by inserting a finger along the anterior aspect of the trachea, which also serves to develop the space and facilitate insertion of the mediastinoscope (Figs. 113-2 and 113-3). Obviously involved lymph nodes often may be palpated, but palpation alone is insufficient,

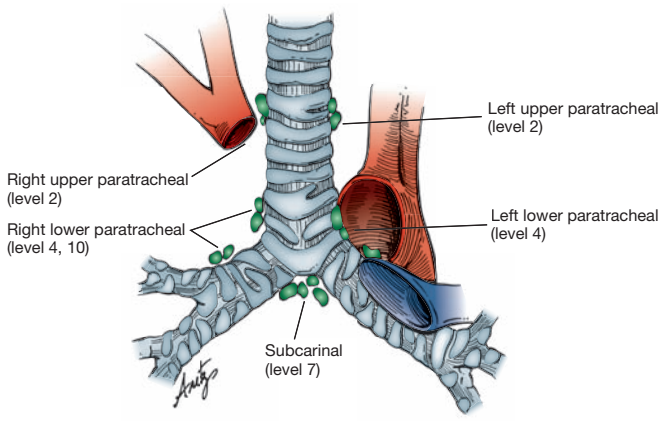

Figure 113-1 Lymph node stations accessible by cervical mediastinoscopy. For consistency the levels should be labeled with the appropriate number when submitted to surgical pathology.

since microscopic disease may be present that can only be identified if representative biopsies of the important nodal stations are taken following insertion of the mediastinoscope. Visual inspection without histologic confirmation is also to be scrupulously avoided. Of major importance are the ipsilateral nodes, but just as important is the status of the contralateral lymph nodes, especially in left lower lobe lesions, in which right paratracheal lymph nodes are commonly involved. Despite notions to the contrary, left-sided lymph nodes are readily accessible at mediastinoscopy but are somewhat more difficult to identify. In fact the left paratracheal lymph nodes are much more easily sampled at mediastinoscopy than at left thoracotomy because of the location of the aortic arch relative to the left mainstem bronchus. Because of this we have a much lower threshold for performing mediastinoscopy for left-sided lesions. Nodal stations most frequently sampled include levels 2 (upper paratracheal) and 4 (lower paratracheal) on the right, level 3 (pretracheal), level 7 (subcarinal), and level 4 on the left. Because the left level 4 lymph nodes occur at a slightly higher location, identifying separate level 2 nodes on the left can be difficult. It is not necessary always to sample all nodal stations; if there are nodes obviously involved, these, along with contralateral nodes, are all that are necessary to adequately stage the patient.

Mediastinoscopy is a technically demanding procedure that requires significant training to perform correctly. The close proximity of a number of major vascular structures makes it daunting even to the experienced practitioner. Major vessels within the operative field and therefore at risk include the innominate artery, aortic arch, superior vena cava, azygous vein, and right main pulmonary artery (Fig. 113-4). The left recurrent laryngeal nerve and esophagus are also subject to injury. A recent meta-analysis of the complications of mediastinoscopy reported a morbidity of 0% to 5.3% and a mortality of 0% to 0.05%.[16] Despite the stakes of the procedure, in experienced hands, the actual risk of the procedure is quite low and all but the most debilitated and infirm patients tolerate the procedure well. Inability or reluctance to adequately stage the mediastinum may result in unnecessary or unsuccessful thoracotomy or thoracoscopy.

Although mediastinoscopy is the mainstay of invasive staging for lung cancer, other procedures provide additional information that often complements that obtained at mediastinoscopy. The aortopulmonary window, a common site of nodal spread from tumors of the

left upper lobe, and one that cannot be reached with conventional mediastinoscopy or EBUS without traversing the left main pulmonary artery, may be reached with an anterior mediastinotomy, also known as the Chamberlain procedure. An incision is made over the left second costal cartilage, the cartilage is excised, and the pleural reflection is swept laterally to access the aortopulmonary window in an extrapleural plane. Typically, anterior mediastinotomy is performed in conjunction with cervical mediastinoscopy, and the mediastinoscope is used for visualization. Tube thoracostomy is rarely needed and this procedure can be performed as an outpatient. The involvement of lymph nodes at this level (level 5) in the absence of other nodal disease is associated with a 5-year survival that approaches 50% if the disease can be completely resected, a survival that is almost identical to that seen with N1 (hilar) disease. The rationale, then, behind performing parasternal mediastinotomy either is to assess resectability or document mediastinal nodal disease to justify placing the patient into an experimental protocol of neoadjuvant chemotherapy, radiation therapy, or both.

Similarly, video-assisted thoracoscopic surgery (VATS) aids in the staging of lung cancer, as an occasional adjunct to, but not in lieu of, mediastinoscopy. VATS offers an opportunity to sample nodes on the right and left through one incision and provides access to aortopulmonary window (level 5), ascending aortic (level 6), paraesophageal (level 8), and inferior pulmonary ligament (level 9) nodal stations. It is notable that levels 4R, 2R, 7, 8, and 9 nodes are often easily biopsied via esophageal endoscopic ultrasound. VATS also visualizes the pleural space, especially useful in the patient with a pleural effusion and negative fluid cytology, so as to rule out diffuse pleural involvement and prevent an unnecessary thoracotomy. Other nodules seen on CT scan that may have an impact on treatment planning also may be excised and defined histologically prior to formal thoracotomy.

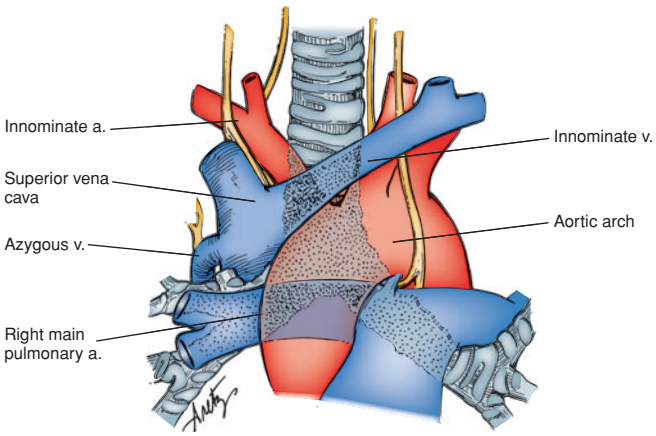

Figure 113-4 The relationship of major vascular structures potentially encountered during mediastinoscopy to the trachea and main bronchi.

Usually the ultimate decision regarding resectability of a locally invasive lesion must be made at the time of thoracotomy when the lesion itself may be palpated and the dissection conducted under greater control. Direct invasion into mediastinal structures including the superior vena cava or vertebral bodies is not a contraindication to resection. As imaging has evolved, the rate of exploratory thoracotomies has dropped. A logical progression from the less invasive to the more invasive procedures guided by the imaging studies often results in the patient being spared a procedure from which there will be no significant benefit.

SURGICAL TREATMENT OF LUNG CANCER

When evaluating a patient with lung cancer for possible resection there are three different criteria that must be satisfied: (1) Is resection oncologically beneficial, (2) is resection technically feasible, and (3) does the patient have the physiologic fitness to tolerate resection?

Staging studies and procedures determine the oncologic benefit of therapy. The feasibility of resection is typically a decision made by the operating surgeon. Involvement of ribs, vertebral bodies, or mainstem bronchi does not preclude resection. Extended resections are discussed later in this chapter. The final and often most difficult criterion to satisfy is the patient's physiologic fitness to undergo surgery. Factors that must be considered include pulmonary reserve, exercise capacity, heart disease, and other medical comorbidities. Frailty indices can be calculated and correlate with postoperative complications.[17] Cardiac risk factors should be identified and evaluated per published guidelines.[18] Often borderline patients benefit from functional testing such as stair climbing or shuttle walking. These tests are easily performed in the office and are associated with minimal cost. The height climbed or speed at which the patient climbs a set number of stairs can predict postoperative complications.[18,19] Formal exercise testing with measurement of oxygen consumption may help quantify the risk of lung resection in selected patients. Quantitative perfusion lung scans have allowed us to better select borderline patients for pulmonary resection, especially when pneumonectomy is a possibility. This information has all but eliminated the "pulmonary cripple" as a result of a lung resection. Quantitative split perfusion testing may identify poorly perfused lung tissue, especially in the setting of upper lobe tumors surrounded by severe upper lobe predominant emphysema. Those patients may tolerate resection because of a volume reduction effect. Experience with lung transplantation has shown that deconditioned patients benefit from at least a 6-week period of pulmonary rehabilitation, and selected patients with otherwise operable disease may be placed in a rehabilitation program before undergoing surgery.[20] Smoking cessation is of paramount importance.

Thoughtful and thorough evaluations combined with less invasive surgical approaches have allowed many patients who previously were not considered surgical candidates to undergo surgery. All but the frailest patients should be referred to a thoracic surgeon to allow this determination.

In spite of recent advances in nonoperative therapy, surgery remains the best treatment for early-stage disease. It is important that the

appropriate procedure be performed. The types of resection include anatomic resection such as segmentectomy, lobectomy, bilobectomy, and pneumonectomy; and nonanatomic wedge resections. Anatomic resections involve the individual ligation of the feeding pulmonary artery, vein, and bronchus to the region of the lung to be resected. Wedge resections are nonanatomic operations where lung parenchyma is divided without ligation of the feeding vasculature or bronchi. Extended resections include an anatomic resection with associated structures that are involved with the cancer. These can include portions of the chest wall resected *en bloc*, vertebral bodies, diaphragm, pericardium, left atrium, or superior vena cava. Also included in extended resections are bronchoplastic resections or pulmonary artery reconstruction procedures. The choice of resection is multifactorial based on the location and stage of the tumor and the patient's physiologic fitness.

OPEN VERSUS MINIMALLY INVASIVE TECHNIQUES

The role of minimally or less invasive surgical techniques in lung cancer resection continues to evolve. Currently most pulmonary resections are performed by thoracotomy but an increasing number of thoracic surgeons now perform these oncologic procedures using VATS or robotically assisted resections. VATS is analogous to laparoscopic surgery wherein operative visualization is provided by an endoscopic camera as opposed to direct visualization through the incision. Currently at least 30% of lobectomies for lung cancer are performed using VATS.[21] It should be emphasized that although the approach is different, the principles of anatomic lung resection should remain the same. Anatomic lung resections most typically performed by VATS include lobectomy and segmentectomy. Pneumonectomy has been reported as well as bronchoplastic procedures.[22,23] The key elements of these procedures involve the identification and individual ligation of the relevant branches of the pulmonary artery, pulmonary veins, and bronchi. A thorough mediastinal lymph node sampling should also be performed. In experienced hands, VATS lymph node harvest is equivalent when compared to thoracotomy.[24,25] The perioperative outcomes have been superior to thoracotomy for quality of life and pain.[26] Multiple studies have demonstrated oncologic equivalency, decreased complication rate, and decreased levels of inflammatory mediators.[27,28] Minimally invasive approaches to lobectomy are associated with decreased pain and length of stay.[28,29] There is increasing evidence that patients who undergo VATS lobectomy are better able to tolerate adjuvant chemotherapy and receive a greater proportion of the planned dose.[26,30] Robotic-assisted surgery continues to evolve; multiple case series have been reported and a retrospective multi-institutional review of robotic lobectomy revealed perioperative and long-term outcomes to be equivalent to VATS lobectomy.[31] Although VATS techniques are associated with improved outcomes in selected patients, many patients are best treated with open surgery. The decision of whether to employ a minimally invasive technique versus thoracotomy depends on many factors such as tumor size and location, extent of chest wall involvement, the presence of calcified lymphadenopathy, and surgeon experience.

TYPE OF RESECTION

Surgical considerations in management of lung cancer include lobectomy versus a lung-sparing resection.

Lobectomy

Lobectomy remains the definitive resection for most lung cancers, since it is an anatomic resection that removes the regional lymph nodes located along the lobar bronchus. Other choices include limited resections such as wedge resection, and segmentectomy. Some hilar tumors or those involving the chest wall or other structures may require pneumonectomy or extended resections. Doing less than a lobectomy may represent a compromise, although a nonanatomic wedge excision may be considered for small primary tumors. Tumors located within the center of the lobe or near the hilum typically require lobectomy.

Limited Resection: Wedge Resection and Segmentectomy

Smaller tumors that are peripherally situated may be candidates for lesser resections. Only patients with clinical stage I cancer (T1N0, T2N0) are possible candidates for a curative limited or sublobar resection. Tumor characteristics and location also play an important role in decision making. Pure ground-glass opacities on CT scan often are revealed to be adenocarcinoma in situ, adenocarcinoma with lepidic growth pattern, and minimally invasive adenocarcinoma with pure lepidic growth; this group of tumors was formerly known as bronchioloalveolar carcinoma (BAC). These lesions, if small, can be considered for limited resection, since resection yields almost 100% survival and may have equivalent survival after wedge resection.[32,33] Combining CT and PET characteristics such as percent ground-glass opacity and standardized uptake value (SUV) can aide in predicting who would benefit from limited resection.[34]

Wedge resection crosses lymphatic channels, does not remove the originating bronchus, and does not permit adequate regional lymph node resection, and parenchymal margins may be limited. These factors limit the value of wedge resection as a planned curative procedure for most primary lung cancers. Wedge resection is, at best, a compromise, and patients who otherwise could tolerate an anatomic resection are not well served by having less done. External beam radiation has been used in an attempt to augment the efficacy of wedge resection but it has been associated with increased pulmonary toxicity in a patient population that typically has compromised pulmonary function. Several groups have reported decreased local recurrence with adjuvant brachytherapy at the time of resection. ^{125}I seeds embedded in an absorbable mesh are applied to the line of resection.[35] A randomized phase III trial comparing sublobar resection with and without brachytherapy (ACOSOG Z4032) in high-risk patients has completed enrollment but the results are still maturing at the time of publication. Perioperative morbidity and mortality were not increased in patients receiving brachytherapy.[36]

Segmentectomy represents a more favorable option for limited resection than wedge resection. As an anatomic resection, segmentectomy provides a wider parenchymal margin and encompasses the regional lymphatics, which drain centrally, and permits regional lymph nodes to be evaluated during the resection. Parenchymal margins of resection are identified more clearly when an anatomic resection is accomplished and a longer length of bronchus is removed, minimizing the opportunity for local bronchial recurrence. Anatomic segmentectomy is the operation of choice in patients with marginal pulmonary function because mortality is lower, and long-term survival is almost comparable to lobectomy.

Segmentectomies are often more technically demanding to perform compared to lobectomy. Many surgeons who do not perform a high volume of pulmonary surgery may not possess the expertise required to perform this procedure. Segmentectomy can be performed by open or VATS techniques. The prototype segmental resection is the superior segment of the lower lobe, but any lung segment may be removed anatomically. Typically the basilar segments of either lower lobe are resected as a unit. The lingular segments or the upper division of the left upper lobe are often resected together. Segmentectomy of the middle lobe is rarely performed.

The key to segmental resection is the identification of the segmental artery, which, once ligated and divided, reveals the location of the segmental bronchus that is taken next. The segmental vein is divided last, and the parenchyma is divided with a stapler or stripped by dividing the lung parenchyma in the intersegmental plane using a combination of blunt and sharp dissection (Fig. 113-5). When properly performed, this technique is not associated with significant blood loss or air leak.

Most surgeons would consider limited resection only for tumors ≤2 cm. Tumors ≤2 cm and those presenting as ground-glass opacities offer better long-term prognosis in association with a limited

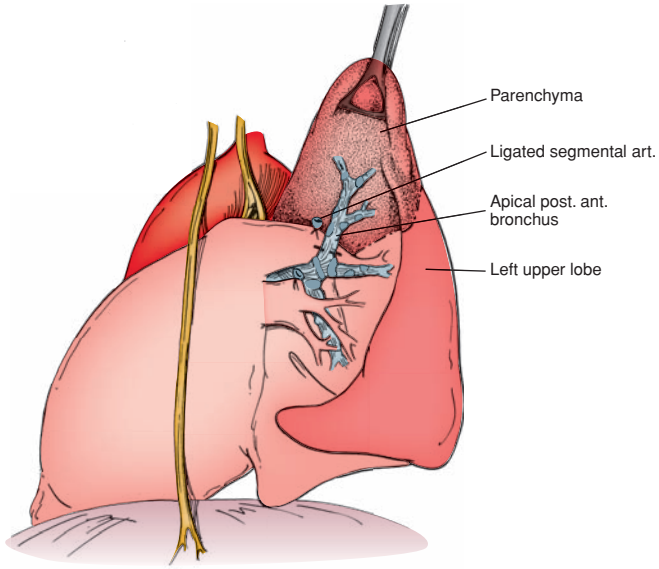

Figure 113-5 Segmental resection. The example shown here is the resection of the apical–posterior segment of the left upper lobe. The segmental pulmonary arterial branch is shown ligated and divided. The segmental bronchus has been dissected out and is the next structure to be divided.

resection. The perioperative risk needs to be balanced against the oncologic benefit of limited resection, especially wedge resection. Nonoperative therapy should be considered for any patient who is not a candidate for segmentectomy. A recent phase II trial of stereotactic body radiation therapy (SBRT) in medically inoperable early-stage cancers reported a 3-year locoregional control rate of 87% and overall a survival of 56%.[37] One drawback of nonoperative therapy is the lack of a pathologic sample, which may provide additional staging information such as pleural invasion, lymph node status, and more detailed histopathologic analysis. A prospective study of sublobar resection with or without brachytherapy versus SBRT is currently enrolling to evaluate these therapies in operable patients.

The Lung Cancer Study Group (LCSG) addressed the question of lobectomy versus limited resection for T1N0 lesions (tumor >3 cm, negative lymph nodes) in a prospective randomized trial.[38] The initial analysis of the data demonstrated an increased incidence of local recurrence in the limited resection group but no difference in survival. Subgroup analysis revealed superior survival for patients in the lobectomy group. This remains the only randomized prospective trial of lobectomy versus sublobar resection. The LCSG has been criticized extensively and many other studies have looked retrospectively at patients undergoing limited resection, which includes segmental resection, and have demonstrated long-term survivors. In a 2010 review of the SEER database of tumors ≤1 cm, Kates et al.[39] were not able to detect a survival difference in patients undergoing lobectomy versus sublobar resection. A new prospective randomized trial to address the issue of lobar versus sublobar resection for peripheral tumors ≤2 cm is currently accruing. The type of limited resection (wedge vs. segmentectomy) is at the surgeon's discretion. Most enrolling surgeons have opted to perform segmentectomy if possible.

In summary lobectomy remains the operation choice in most fit patients; in compromised patients, or those with peripheral tumors segmentectomy, when applicable, yields nearly equivalent results. Patients who are only candidates for wedge resection should be considered for nonoperative therapy such as SBRT.

Pneumonectomy and Extended Resections

Depending mainly on the location of the tumor, more extensive and complex resections than lobectomy may be required. The final determination to perform a pneumonectomy is made at the time of operation. Attempts should be made to perform parenchymal-sparing resections using bronchoplasty and arterioplasty if possible. Recognizing that even today pneumonectomy carries a perioperative mortality of at least 5%, most thoracic surgeons strive to avoid pneumonectomy. There are only a few absolute indications for performing pneumonectomy for the experienced surgeon. These include such proximal involvement of the main pulmonary artery that it is difficult to place a clamp on the artery, endobronchial tumor so extensive as to preclude sleeve resection, and involvement of the confluence of the pulmonary veins or of the left atrium. There is reason for concern if a surgeon is performing an abundance of pneumonectomies. A "difficult" fissure, unless tumor involves the artery in the fissure, is not an indication for pneumonectomy, nor is tumor crossing a fissure an absolute indication. Pneumonectomy, technically, is an easier operation to perform than lobectomy, requiring very little dissection and only several applications of the stapler.

Sleeve resections, or bronchoplastic procedures, are technically more demanding procedures that result in the same bronchial resection as a pneumonectomy, yet preserve lung tissue. The prototypical bronchoplastic procedure is the right upper lobe sleeve resection, in which the main bronchus is divided just proximal to the right upper lobe takeoff and the bronchus intermedius is divided just distal to the upper lobe bronchus (Fig. 113-6). The right upper lobe, with tumor present at the lobar orifice, is thus removed with a portion of the mainstem bronchus, and the bronchus intermedius is anastomosed to the mainstem bronchus. Thus the proximal bronchial

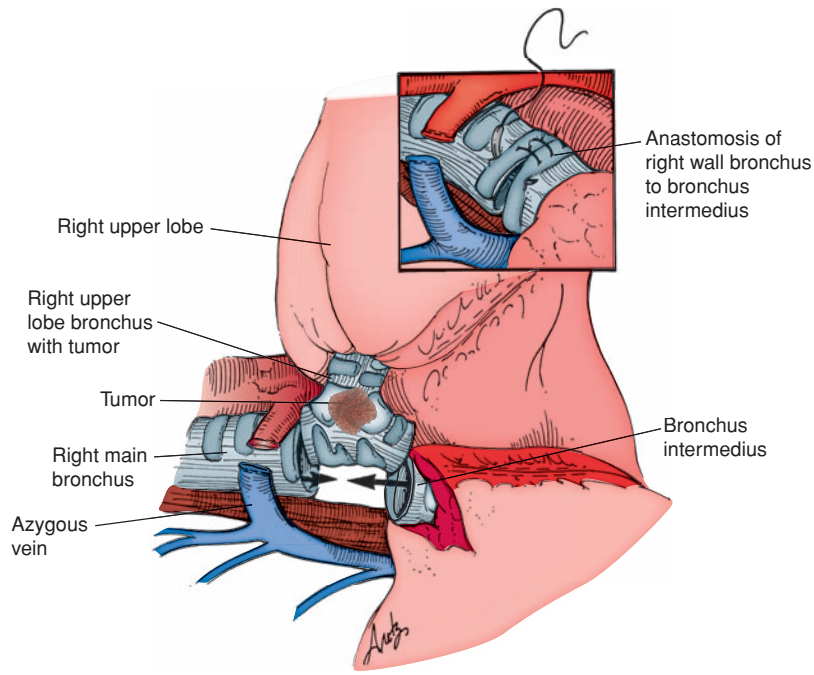

Figure 113-6 Right upper lobe sleeve resection. The right main bronchus has been divided just proximal to the right upper lobe takeoff where the tumor is located. The bronchus intermedius has been divided just distal to the right upper lobe bronchus. The bronchus intermedius is anastomosed to the right main bronchus *(inset)*.

division occurs essentially at the same site as if a pneumonectomy had been performed. Other sleeve resections are possible on both the right and the left side. All bronchoplastic resections result in lung conservation and are associated with long-term survival equivalent to pneumonectomy without the attendant morbidity of pneumonectomy and with the added bonus of preserved lung parenchyma. Even with proximal involvement of the pulmonary artery, partial resection or sleeve resection of the artery is possible to avoid removal of the entire lung. A patch angioplasty with pericardium may be utilized if a significant enough portion of the anterior wall of the artery is taken so as to narrow it. Alternatively a segment of the artery may be removed and an end-to-end anastomosis completed. Sometimes a pneumonectomy must be done, but the complete thoracic surgeon always looks to see if alternatives exist while preserving the principles of the cancer operation and not compromising margins. With any lung-conserving procedure, the margins of the resection should be sent for frozen section confirmation that no tumor is present.

The designation *locally advanced* includes a wide variety of lesions that extend outside of the lung parenchyma, whether by direct extension or nodal involvement to involve other structures within the hemithorax. Certain criteria need to be fulfilled before considering extending the indications for resection, since the intent is to maximize survival. The most obvious criterion is the exclusion of disseminated disease; thus, it is vital to complete an extent-of-disease evaluation before embarking upon a complex resection in which the indications for resection have been extended.

LYMPH NODE SAMPLING

A complete pulmonary resection requires more than simply excision of the tumor and the surrounding lung parenchyma, whether lobe or entire lung. The operation is incomplete without excision of lymph nodes to complete the staging assessment. The appropriate extent of lymph node harvest, ranging between systematic sampling and complete dissection, has been the subject of debate among thoracic surgeons. A randomized trial of over 1000 patients with T1 or T2 tumors was reported in 2011. There was no significant survival advantage to lymph node dissection as long as systematic and thorough lymph node sampling was performed. Systematic sampling included levels 2R, 4R, 7, and 10R for right-sided tumors and levels 5, 6, 7, and 10L for left-sided tumors. Mediastinoscopy was performed at the surgeon's discretion.[40] It is notable that this study was conducted in high-volume centers with dedicated general thoracic surgeons. Also these patients had relatively small tumors and underwent intraoperative frozen section analysis of N2 nodes, which is not common practice. Typically, most nodes are sent for routine pathologic analysis. Other groups continue to advocate formal lymph node dissection.[40,41] During anatomic resection, multiple inter- and intralobar lymph nodes are encountered, these N1 nodes are labeled by their anatomic location and sent for pathologic examination. Many surgeons perform frozen section on N1 nodes during segmentectomy and if positive for cancer, the operation is converted to lobectomy. Any sampling procedure of mediastinal lymph nodes depends on how the nodes to be sampled are chosen. The failure to include mediastinal lymph nodes as part of a resection results in incomplete information. More accurate staging through appropriate lymph node harvest improves prognostic accuracy and determines which patients should be considered for adjuvant treatment.

It is not uncommon to find microscopic disease in a node that grossly appears normal at the time of surgery. Finding tumor in mediastinal lymph nodes portends a significantly worse prognosis and at least prompts consideration of postoperative treatment. Postoperative adjuvant therapy, usually chemotherapy with or without radiation therapy, is now recommended for patients with positive lymph nodes.[42,43] This is in contrast to several previous studies and meta-analyses that did not show a survival benefit to adjuvant therapy.[44] All patients with pathologically determined stage II or III disease should be referred to a medical oncologist for evaluation for systemic therapy.

N2 DISEASE

Involvement of ipsilateral paratracheal or subcarinal lymph nodes classifies the patient as having N2 disease. Most experts believe that these patients are best treated with induction (neoadjuvent) therapy or definitive nonoperative therapy at the time of presentation since overall survival after primary resection is poor. Thorough evaluation of the mediastinum is mandatory to optimize the outcomes of patients with advanced disease. Contralateral or N3 disease, carries a significantly worse prognosis than ipsilateral disease, may also be detected at mediastinoscopy or EBUS and usually renders the patient inoperable, even if combined with neoadjuvant therapy.

Perhaps the first recognition that a subset of patients with mediastinal lymph node involvement could benefit from surgery came from the work of Martini, who was able to completely resect 151 patients out of approximately 500 with N2 disease. Many of these patients were treated with postoperative radiation therapy. For the group of completely resected patients he found a 28% 5-year actuarial survival and subsequently a 26% absolute survival. All the patients with N2 disease, resected or not, were identified at the time of thoracotomy, as mediastinoscopy was not performed.[45] Breaking the patients down into two groups yielded those staged as N0 or N1 preoperatively, and those with bulky disease, so-called clinical N2, noted either on preoperative chest radiograph or at bronchoscopy when carinal splaying was noted. Those patients thought to have N0 or N1 disease preoperatively had a 35% 5-year survival, and those with clinical N2 disease had 0% 5-year survival. Fewer than 10% of patients with clinical N2 disease could be completely resected.

In recognition that patients with bulky N2 disease not only had a low rate of resectability but also a poor long-term outlook, an attempt was made to improve the resectability rate and, it was hoped, survival in this patient group by employing preoperative (neoadjuvant) chemotherapy. In one study, there was a 77% response rate to the chemotherapy regimen of vinblastine and cisplatin with 10% complete responders.[45] Sixty-five percent of patients, who underwent surgery, after induction therapy, were able to have complete resection, a significant improvement over the rate of complete resection when no preoperative therapy was employed. All patients entered into this trial were those with bulky mediastinal disease. The overall survival was 28% at 3 years and 17% at 5 years, with a median survival of 19 months. Patients who were able to undergo a complete resection had a mean survival of 27 months and 3- and 5-year survival of 44% and 26%, respectively.[46] In another randomized trial of patients with N2 disease, 28 patients were randomized to receive three cycles of preoperative chemotherapy with cyclophosphamide, etoposide, and cisplatin followed by surgery, and 32 patients underwent operation without preoperative therapy.[47] Significant survival advantage was conferred upon those who received preoperative therapy. Median survival in the combined therapy group was 64 months compared to only 11 months for the surgery-only group, despite the fact that the percentage of patients able to have complete resection in each group was similar (39% vs. 31%). Although this trial clearly demonstrated an advantage to neoadjuvant therapy in a group of patients with locally advanced disease, survival in the surgery-only group was significantly shorter than expected, making the survival difference between the groups more striking. Excluded from the trial were patients with left lung tumors in conjunction with left paratracheal disease, as these patients were felt to be unresectable. A randomized trial of patients with stage IIIa disease included 25 patients with N2 disease who received chemotherapy followed by an operation and 19 patients with N2 disease who underwent operation as their only therapy. As in the other trials, there was a significant survival benefit in the group that received combination therapy (median, 26 vs. 8 months).[48]

In light of the previously mentioned studies, a phase III prospective, multicenter, randomized trial, Intergroup 0139 trial, compared induction chemoradiation followed by surgery with definitive chemoradiation.[49] Although overall survival was similar in the two groups, progression-free survival was significantly improved in association with the combined use of chemoradiation and surgery. Notably, perioperative mortality in the surgical patients who underwent pneumonectomy approached 26%. When the analysis was restricted to the subgroup of patients who underwent lobectomy, overall survival was improved compared to the group receiving definitive chemoradiation (Fig. 113-7). In an observational study of over 39,000 patients from the National Cancer Database of patients with clinical stage IIIa-N2 disease, Koshy et al.[50] reported improved survival in patients receiving neoadjuvant chemoradiation followed by lobectomy.

Subsequently, several groups have reported excellent results of patients undergoing pneumonectomy after induction therapy with perioperative mortality less than 5%.[50–53] Pneumonectomy can be considered in the setting of induction therapy in appropriate patients when performed in centers with experience in the management of these patients.

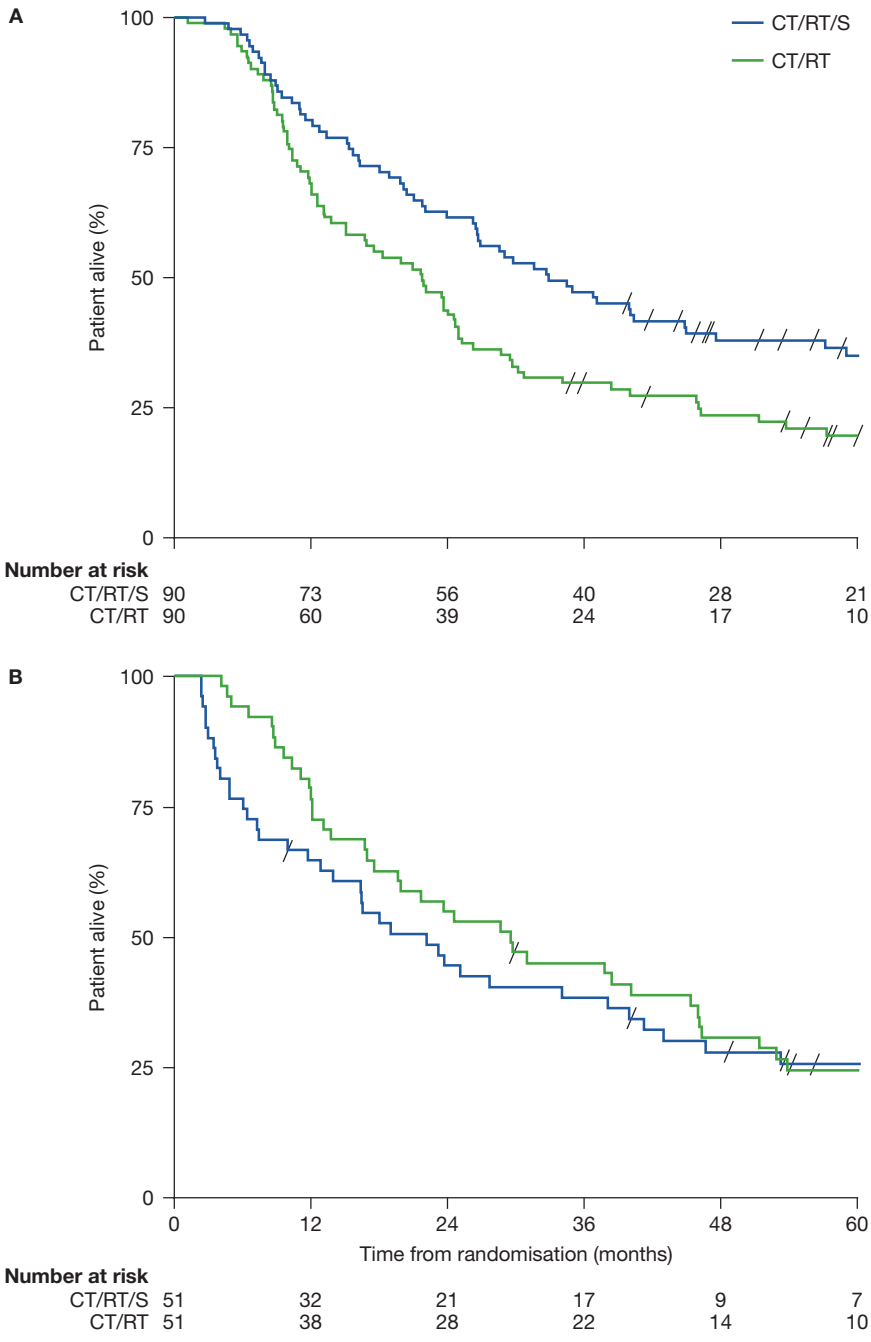

Figure 113-7 Overall survival of a subset of patients from Intergroup 0319 trial the intention-to-treat population given lobectomy (**A**) or pneumonectomy (**B**) in group 1 versus matched cohorts in group 2. *Slash marks* represent censored results. Radiotherapy plus chemotherapy with or without surgical resection for stage III non-small-cell lung cancer: a phase III randomised controlled trial. Lancet. 2009;374(9687):379–386.)*

Resections following preoperative therapy can be extremely difficult and hazardous because of the fibrosis that often results as a response to the therapy. This is especially significant when there has been a response in involved lymph nodes, since the nodes are intimately associated with the pulmonary artery and its branches, often making resection quite treacherous. It is particularly important to have proximal control of the pulmonary artery before undertaking a resection in a patient with N2 disease who has received preoperative therapy. Ideally, resections of this type should only be undertaken by a surgeon with experience in dealing with complex resections.

CHEST WALL RESECTION

Approximately 5% of lung cancers involve the chest wall by direct extension. This involvement may be limited to the parietal pleura or may invade the endothoracic fascia, intercostal muscle, or ribs. Chest wall involvement by direct extension is *not* a contraindication to resection unless vertebral bodies are invaded, and even then, under some circumstances, resection may still be completed. The optimal treatment for tumors involving the chest wall that do not involve the superior sulcus is resection followed by adjuvant therapy.[43,54] Chest wall pain is the most sensitive predictor of chest wall involvement in a patient with a peripheral lung lesion in which there is a question of chest wall invasion. Neither CT scan nor MRI can distinguish between abutment and invasion unless there is gross invasion of bone. PET or bone scan cannot absolutely predict chest wall involvement, especially if only the parietal pleura and muscle are involved. Lesions involving parietal pleura or other chest wall structures are clinically staged as T3 primary tumors, but definitive staging cannot be accomplished until the time of operation.

As with any lung cancer it is important to rule out disseminated disease before considering surgery in a patient with chest wall involvement. It is particularly important to assess the mediastinum in these patients, since mediastinal lymph node involvement is the single best prognostic indicator. Three-year survival approaches zero in patients with chest wall and mediastinal lymph node involvement, underscoring the importance of accurate mediastinal lymph node staging before considering thoracotomy in this

patient group. Conversely, greater than 50% 5-year survival can be expected in patients with chest wall involvement with negative mediastinal lymph nodes as long as the resection margins are negative.

The operation performed in a patient with suspected chest wall involvement begins by assessing the pleural space to rule out diffuse pleural disease and then defining whether the chest wall is invaded. Before beginning the chest wall resection it is important to assess the hilum of the lung to ensure that there is not such extensive disease as to preclude resection, though this should usually be apparent on a preoperative chest CT performed with contrast. Resection should begin in the extrapleural plane, thus separating the parietal pleura from the endothoracic fascia in the area of the lesion. If this plane is easily developed, it may be that the parietal pleura are not invaded but the adhesion is inflammatory. If there is any question at all about invasion when attempting to develop the extrapleural plane, then chest wall resection is performed (Fig. 113-8). Ideally the chest wall resection is performed in continuity with the parenchymal resection; the portion of chest wall resected remains attached to the underlying lung and the specimen is removed *en bloc*. The chest wall resection should include at least one rib and preferably two above and below the area of chest wall invasion. Three- to 5-cm margins should also be taken anteriorly and posteriorly. The intent is to achieve negative margins, so the resection margin should be wide; there is little if any additional morbidity to taking a somewhat larger piece of chest wall. For posteriorly based tumors the rib may be disarticulated and the nerve root ligated at its origin. Once the chest wall block is totally mobilized, the lobectomy and mediastinal lymph node dissection are completed. A mediastinoscopy should be performed prior to resection and a lymph node dissection should be completed with the anatomic resection. A posterior chest wall defect is reconstructed with polypropylene mesh or expanded polytetrafluoroethylene, and a defect in the anterior chest wall should be reconstructed. Many surgeons recommend a sandwich of methyl methacrylate cement and polypropylene mesh, which creates a rigid prosthesis. In posteriorly based tumors, the defect may be covered by the scapula, which obviates the need for reconstruction. Anterior rigid fixation provided by the methyl methacrylate and mesh eliminates any paradoxical motion that might interfere with mechanics of breathing. Interference with the mechanics of breathing is much less likely to occur with posterior defects. Chest wall resection, reconstruction, and anatomic resection can be accomplished in selected patients without formal thoracotomy, using VATS techniques and a variety of bone-cutting instruments.[55]

En bloc resection of the chest wall typically adds little, if any, additional morbidity to a pulmonary resection. Patients tend to have the chest tubes in a few days longer following chest wall resection because of increased fluid drainage. Pain in the early postoperative period is best controlled with a thoracic epidural catheter, which allows patients to be comfortable enough to maintain a good cough for clearance of secretions. There is no evidence that patients undergoing chest wall resection are subject to more pain than those who have a simple lobectomy. Many patients with bony erosion report a decrease in pain after resection. Aggressive pulmonary toilet is mandatory. If the cough is ineffective, and lobar collapse ensues, then bronchoscopy may be indicated.

Postoperative treatment for patients who have undergone chest wall resection with pulmonary resection includes adjuvant chemotherapy for margin-negative patient.[43] Currently no evidence exists that postoperative radiation therapy prolongs survival in patients with negative margins, but local recurrence may be problematic. Thus there may be a role for radiation therapy in some of these patients—in particular those with disease close to the spine, in whom local recurrence presents major management problems. If negative margins cannot be achieved, reresection or adjuvant radiation can be considered.[43] Anything less than a complete resection is associated with poor long-term survival.

TUMORS OF THE SUPERIOR SULCUS

Tumors of the superior sulcus can represent an oncologic and surgical challenge. Therapy for these difficult tumors has evolved from palliative care to induction chemoradiation followed by surgery with curative intent.[56] Patients with superior sulcus tumors may present with the Pancoast syndrome, which includes pain, Horner syndrome, and neurologic deficits in the intrinsic muscles of the hand.[57] These patients should undergo extensive evaluation including MRI of the thoracic inlet, spinal imaging as appropriate, MRI of the brain, and invasive mediastinal staging. The presence of N2 disease generally remains a contraindication to surgery. Typical treatment regimens include induction chemoradiation with cisplatin and etoposide and 45 Gy of radiation followed by resection and planned follow-up chemotherapy.[58] These tumors may be approached using an anterior cervicothoracotomy, an extended posterolateral thoracotomy, or a combined anterior and posterior approach.[56,59] Involved vertebral bodies may be resected at the time of surgery.[60]

TUMORS INVOLVING THE MEDIASTINUM BY DIRECT EXTENSION

Some centrally located primary tumors may involve structures in the mediastinum by direct extension (Fig. 113-9). The assessment of this involvement, whether there is true invasion or just abutment and adherence, cannot be determined until the findings are seen intraoperatively and then often only as the dissection proceeds. The presence of a central tumor that appears on CT scan to be close to the mediastinum is not justification for ruling out resection. In the absence of frank invasion, this is a judgment that can only be made intraoperatively, since no imaging modality readily distinguishes abutment from invasion. There may be other reasons why the patient should not be operated on, but it is dangerous to simply assume that a lesion is unresectable. The distinction between a T3 tumor involving the mediastinum and a T4 tumor depends on the mediastinal structure invaded. Tumors invading structures such as the phrenic nerve, mediastinal pleura, the pericardium, or the diaphragm that may be readily removed are classified as T3 primary tumors and if N0 or N1 should be considered for primary resection. T4 primary tumors invade the mediastinum, heart, great vessels, esophagus, vertebral bodies, carina, and recurrent laryngeal nerve. There are occasions when tumors involving these structures are resected, most commonly with lesions involving the vena cava or left atrium. Rarely, if ever, is a portion of aorta resected for excision of a lung tumor, but a lesion may involve only the muscular wall of the esophagus and thus may be amenable to resection. T4N0-N1 tumors are staged as IIIa and should be evaluated and treated as such.[61] What is important to recognize is despite the seeming ability to remove some of these invasive lesions, the prognosis for long-term survival is dismal. For T4 lesions, fewer than 10% of patients are alive at 5 years.

Vertebral body invasion is not a contraindication to resection. Tumors that involve the transverse process or anterior aspect of the vertebral body can be approached with a partial resection of the vertebral body. If there is extensive involvement of one or more vertebral bodies or if resection could lead to spinal instability, a combined procedure with a neurosurgeon or orthopedic spine surgeon is planned in one or two stages. There are multiple reconstructive and stabilization techniques available. These complex procedures may be performed from a single approach or with posterior spinal stabilization either preceding or following en bloc resection of the lung parenchyma and involved vertebral bodies. These procedures can be performed primarily or preferably after induction therapy.[62] Excellent results have been reported in highly selected patients.[63]

Tumors preoperatively identified as involving the left recurrent laryngeal nerve are generally considered inoperable. This situation should be considered in any patient who presents with the new onset of hoarseness and is found to have paralysis of the left vocal cord. Almost always a tumor will be found in the left chest, usually the left upper lobe. The left recurrent nerve is in a position of great vulnerability, since it arises after the vagus nerve crosses the aortic arch and recurs around the ligamentum arteriosum (Fig. 113-10). The left recurrent nerve may be involved either by a primary tumor, which encases the vagus nerve as it crosses the aortic arch, or more commonly by lymph node disease in the aortopulmonary window. Because of the depth of the aortopulmonary window, there can be gross mediastinal lymph node involvement and a sheet of tumor despite minimal plain radiographic evidence, since tumor underneath the aortic arch is not easily seen. CT scan usually confirms extensive involvement. Involvement of the left recurrent laryngeal nerve represents a contraindication to operation, since these lesions are rarely able to be completely resected. Left recurrent laryngeal nerve involvement should exclude patients from participating in neoadjuvant trials as well. The only exception is the occasional situation in which the primary tumor involves the vagus nerve as it crosses the aortic arch, a situation that may prove to be resectable and justifies exploration. Rarely, if ever, does lung cancer involve the right recurrent laryngeal nerve, which "recurs" around the right subclavian artery above the apex of the chest.

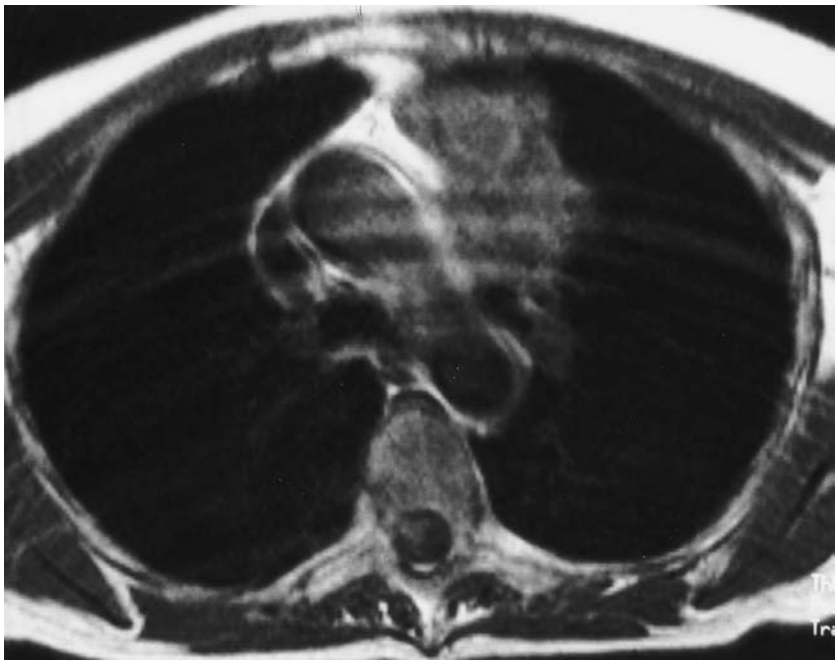

Figure 113-9 MRI scan showing a primary lung tumor involving the aorta by direct extension (T4 primary). The distinction between abutment and invasion often cannot be made until the findings are seen at operation. MRI is no better at delineating invasion than CT.

PALLIATIVE RESECTIONS

There is only a very limited role for palliative resections in the modern management of NSCLC; this is principally confined to select cases of massive hemoptysis or superinfection of necrotic tumors. Morbidity resulting from the primary tumor usually can be managed using

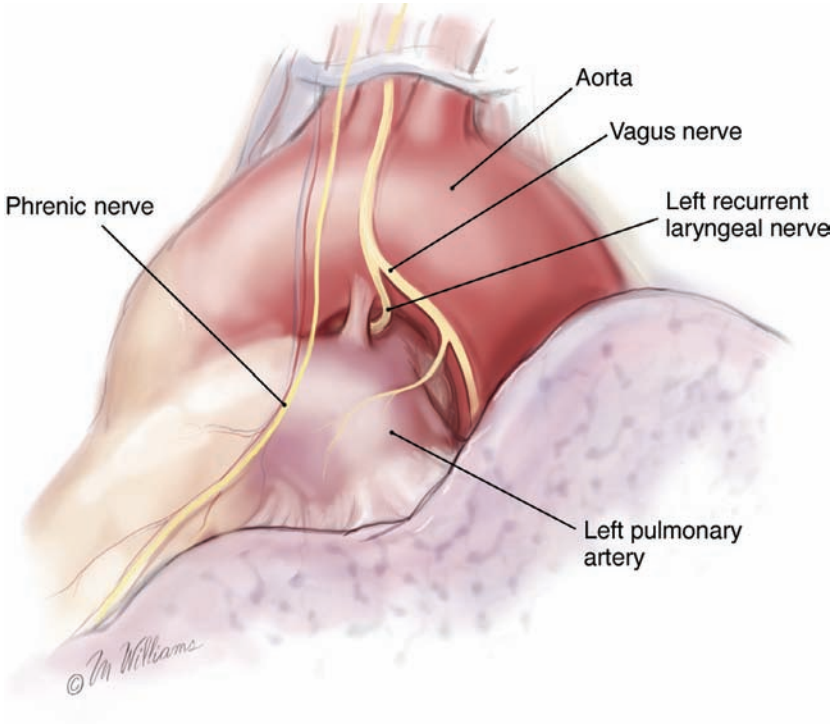

Figure 113-10 The anatomy of the aortopulmonary window showing the relationship of the left recurrent laryngeal nerve to the aortic arch and ligamentum arteriosum. The nerve is easily damaged in this location. Hoarseness may result from tumor involvement of the nerve in this location or from involvement of the vagus nerve at the level of the aortic arch proximal to the location where the recurrent laryngeal nerve originates. *(Used with permission of Marcia Williams.)*

modalities other than surgery. At the present time there is no role for surgical "debulking" in the management of the patient with unresectable disease. With the newer treatment planning modalities available, radiation therapy can be given accurately and in high doses to patients who are inoperable or unresectable. Patients with hemoptysis or postobstructive pneumonia may benefit from bronchoscopic debulking of endobronchial disease possibly combined with stent placement to maintain patency of the obstructed bronchus or trachea, followed by external beam radiation therapy or endobronchial brachytherapy. Chest wall pain usually is readily controlled by a course of radiation therapy.

RESULTS OF TREATMENT

Postoperative complications and morbidity, as well as prognosis, tumor recurrence, and post-operative follow-up are discussed below.

■ POSTOPERATIVE COMPLICATIONS

Major improvements in perioperative care of patients undergoing thoracic surgical procedures have led to decreased morbidity and mortality when compared with only 10 to 20 years ago. Improved preoperative evaluation of patients has allowed us to identify risk factors associated with morbidity and address these early on. The further refinement of lung-conserving procedures and the use of minimally invasive techniques such as VATS along with better perioperative pain management provided by continuous epidural administration of narcotic have provided the incentive to offer surgery to many patients previously thought not to be candidates because of poor pulmonary function. A greater recognition of the importance of preoperative teaching of postoperative maneuvers such as coughing and the use of chest physiotherapy given by expertly trained individuals also has contributed to decreasing respiratory complications. With the proliferation of general thoracic surgeons, dedicated service lines and inpatient units to care for patients undergoing pulmonary resections have emerged.

In spite of the advances in surgical and anesthetic techniques thoracic surgery remains a significant physiologic stress. Patients should be counseled that they may not achieve full physiologic and psychological recovery for several months. Serial quality-of-life measurements reveal progressive improvement at 3, 6, and 9 months after surgery.[64] Most patients have returned to baseline by 9 months.[65] Postthoracotomy pain, even in patients who underwent less invasive approaches, may persist for several weeks after surgery. For patients who still require narcotics beyond this point, referral back to the operating surgeon should be made to rule out postoperative problems. These patients often benefit from the use of nonnarcotic analgesics such as gabapentin. In addition, consideration should be given to referral to a pain specialist for comprehensive evaluation and treatment including epidural steroid injection and narcotic weaning.

■ POSTOPERATIVE MORTALITY

Recent analyses document that lobectomies and lesser resections have a mortality between 1% and 2%; notably, pneumonectomies still carry a mortality of 5% to 7%.[66,67] The mortality rate is directly proportional to increased age, associated diseases, and the extent of resection. Respiratory complications, not surprisingly, are the most common cause of postoperative mortality in patients undergoing pulmonary resection. Cardiac complications also account for a significant percentage of mortality, and technical problems such as hemorrhage, bronchopleural fistula, and empyema account for a small but significant percentage of complications leading to death.

■ POSTOPERATIVE MORBIDITY

Approximately 30% to 40% of patients undergoing pulmonary resection sustain a postoperative complication, of which approximately two-thirds are minor and the other one-third nonfatal major complications.[66] The most common complication is supraventricular arrhythmia, which occurs in up to 20% of patients, depending on how closely patients are monitored. Most of these respond to simple pharmacologic manipulation and rarely are hemodynamically significant at onset. With appropriate treatment the rhythm reverts to sinus rhythm quickly, and patients may be taken off the antiarrhythmic drugs usually after 1 month. Other minor complications include postoperative air leaks lasting greater than 7 days and atelectasis. Major nonfatal events most commonly are respiratory related, principally aspiration pneumonitis and nosocomial pneumonia. A small percentage of patients require reintubation in the postoperative period for respiratory failure. There are no definitive predictors for postoperative pulmonary complications, although significant risk factors for major complications include increasing age, FEV_1 less than 2 L, and diminished diffusing capacity (D_{LCO}).[68–70] Oxygen consumption less than 10 mL/kg/min on preoperative cardiopulmonary exercise testing is associated with an increased risk of major pulmonary complications. The use of VATS rather than standard thoracotomy may decrease the risk of pulmonary complications in patients with limited pulmonary reserve undergoing lobectomy.[71]

Pulmonary complications can be minimized with meticulous attention to postoperative respiratory maneuvers, including chest physiotherapy and preoperative teaching. Other complications of pulmonary resection include wound infections and disturbances in mental status, especially in older patients.

Complications specific to pneumonectomy include postpneumonectomy pulmonary edema and empyema with or without a bronchial stump leak. Postpneumonectomy edema is characterized by tachypnea, low-grade fever, and noncardiogenic pulmonary edema and hypoxemia in the absence of pneumonia. Supportive care, gentle diuresis, and protective ventilation strategies are the mainstays of care. The mortality can approach 50%.[72] Postpneumonectomy empyema is a devastating complication. In the early postoperative period it can be caused by contamination at the time of surgery or from a bronchial stump leak. A falling air–fluid level on chest radiograph and a cough productive of thin brownish sputum should trigger a prompt investigation.

PROGNOSIS FOLLOWING RESECTION

Outcomes following pulmonary resection for lung cancer have been well analyzed. Prognosis depends mainly on TNM stage, a classification that was revised as recently as 2009.[61] Short of disseminated disease, prognosis mainly depends on the status of the regional lymph nodes. Prognostic data are only as good as the sampling done at the time of operation, and lymph node dissection is the only sure way to ascertain definitively the status of the lymph nodes. Histologic type also has some prognostic significance but to a lesser extent, and histologic grade, according to present knowledge, has little prognostic significance. The presence of neuroendocrine features in what is otherwise an NSCLC, however, may have prognostic significance.

SITES OF RECURRENCE

Patients with lung cancer frequently die of disseminated disease, and it is a distant site that most commonly is the first site of recurrent disease. In a series from Memorial Sloan Kettering of patients who underwent resection for early-stage cancers, 44% of recurrences involved distant sites, 30% involved both distant and locoregional sites, and only 26% were locoregional.[73] Over 30% of patients with adenocarcinomas develop brain metastases, a percentage significantly higher than for patients with squamous carcinoma. Other common sites of metastatic disease include bone, lung, liver, and adrenals. Patients with higher-stage disease have a significantly greater likelihood of developing disseminated disease. This recognition has led to the development of neoadjuvant treatment regimens following surgical resection. As earlier, isolated local recurrence accounts for only a minority of events but sometimes is amenable to resection. This underscores the importance of a complete resection at the time of the initial operative procedure. Sites of local recurrence that may cause symptoms include the chest wall (pain), mediastinum (SVC syndrome, dysphagia), and involvement of the left recurrent laryngeal nerve (hoarseness). Symptomatic local recurrence is often treated with radiation therapy, and chemotherapy is employed for some patients who develop disseminated disease, while recognizing that cure is usually not possible in patients who have developed distant disease.

POSTSURGICAL FOLLOW-UP

Recognizing that essentially no patient is cured once distant disease is present might raise the question of why patients should be followed at all after pulmonary resection. Is there an advantage to recognizing the development of distant disease early rather than late? Actually there may be some advantage, especially when it comes to preventing some of the morbidity that may accompany disseminated disease if treatment begins early. Also the occasional patient presents with an isolated local recurrence that may be amenable to surgery. In addition, second primary cancers may be identified.

Current recommendations include a history and physical examination every 6 to 12 months with a chest CT with contrast for 2 years, followed by a yearly examination and noncontrast CT for an additional 2 years.[43] In light of the recent National Lung Screening trial results, the American Association for Thoracic Surgery recommends an annual low-dose screening CT for lung cancer survivors between the ages of 50 and 79 years who have completed 4 years of standard follow-up.[74,75] Additional studies such as PET and MRI are ordered based on patient symptoms or findings elicited by a careful history and physical examination.[74]

FUTURE DIRECTIONS

The role of surgery in the management of NSCLC has been well defined and remains the standard therapy for patients with localized disease. The challenge for all who deal with lung cancer is the problem of disseminated disease. Perhaps the better way to deal with the problem is to identify risk factors in addition to the already well-defined risk of cigarette smoking. Thus far a "lung cancer susceptibility" gene has not been demonstrated; however, based on the recent explosion of knowledge related to breast cancer, the identification of one or more genes involved in the genesis of certain lung cancers is at hand. Cigarette smoking has been identified as a major risk factor, yet only a small percentage of patients who smoke develop lung cancers. Efforts to identify such susceptibility genes have been hampered by the relative lack of families with a genetic predisposition. The issue of smoking as a risk factor only serves to confound the search.

Molecular markers to identify patients at increased risk of developing recurrent disease are also desperately needed. Once identified, these patients would begin adjuvant therapy designed to prevent recurrence in this high-risk group, sparing those patients who are at lower risk. This further underscores the need for better adjuvant therapy. Mutation-specific drugs and assays continue to proliferate and promise to achieve this goal. Major strides have been and continue to be made in the molecular biology and genetics of tumors, and we can expect lung cancer to be the beneficiary of some of these developments.

In the meantime, refinements in surgical techniques and perioperative management of patients with lung cancer have allowed greater numbers of patients with localized and locally advanced disease to benefit from operative intervention. Many patients with mediastinal lymph node disease previously thought not to be operative candidates now can be operated upon with improved survival after a course of neoadjuvant therapy. Many patients with severely compromised pulmonary function previously thought not to be surgical candidates may be considered for resection using minimally invasive techniques. In combination with advances in diagnosis and medical therapy, it is hoped that surgery will offer the promise of cure to an increasing number of patients with NSCLC.

CHAPTER 114

Treatment of Non–Small-Cell Lung Cancer: Chemotherapy

Laurie L. Carr
James R. Jett

Historically, lung cancer is associated with high mortality rates and little effective therapy. Because this disease predominately affects those of advanced age with significant comorbidities, treatment can be difficult to deliver safely with manageable adverse effects. All of these factors can lead to a sense of futility among clinicians and patients when discussing lung cancer therapy. However, in the last several years novel therapies have emerged to make lung cancer therapy better tolerated and more effective, even among those with significant comorbidities. The introduction of better-tolerated cytotoxic chemotherapy and targeted agents has made lung cancer therapy tenable for many more patients. In addition, the improved response rates seen by matching targeted drugs to specific genetic alterations driving tumor growth have led to improved quality of life and survival among patients with these specific tumors. Thus, although the morbidity and mortality of lung cancer remain high, novel approaches to therapy and improved supportive care have begun to make a significant impact in the burden of this disease.

Chemotherapy, whether an oral targeted drug or an intravenous cytotoxic agent, is used for three main reasons in the treatment of non–small-cell lung cancer (NSCLC): (1) As adjuvant therapy in early-stage disease following potentially curable surgical resection to prevent disease recurrence, (2) as concurrent therapy with radiation in locally advanced disease to radiosensitize the tumor and prevent metastatic disease recurrence, and (3) as palliative therapy in the setting of advanced disease to ease symptoms and prolong survival. This chapter will focus on the role of systemic chemotherapy in the treatment of NSCLC in each of these settings.

EARLY-STAGE NON–SMALL-CELL LUNG CANCER

Surgery remains the standard of care for patients with early-stage disease who do not have medical contraindications. In this setting, surgery provides definitive treatment and allows for more accurate pathologic staging. Staging is central to the therapeutic approach to NSCLC. This entails determination of the extent of invasion of the mediastinal lymph nodes. Mediastinoscopy or fine-needle aspiration (FNA) of lymph nodes by endobronchial ultrasound (EBUS) can be used to sample mediastinal lymph nodes before a surgical resection. As for all surgical interventions for thoracic malignancy, complete nodal sampling or lymph node dissection is an integral part of the procedure. Reliance on noninvasive imaging alone may be inadequate for accurate assessment of the mediastinum (Fig. 114-1).

■ ADJUVANT CHEMOTHERAPY

It is well recognized that despite complete resection, most patients with locally advanced NSCLC will develop disseminated disease. The risk of developing disseminated disease can be predicted, with some accuracy, on the basis of the stage of the disease determined at the time of the initial resection. However, the value of the staging information depends on the completeness of the staging procedures carried out at the time of resection. Even with stage I disease, as many as 20% of patients die of disseminated disease within 5 years. With stage II disease, less than 50% of patients are alive at 5 years;

Figure 114-1 Computerized tomography (CT) scan of a 59-year-old female with ongoing smoking and chronic cough. The image shows a large nodule in the left lower lobe extending into the pleura. The patient underwent a mediastinal lymph node dissection and left lower lobectomy. She was found to have several hilar lymph nodes involved with tumor at the time of resection, (stage IIA). She received four cycles of cisplatin-based adjuvant chemotherapy following surgical resection.

TABLE 114-1 Randomized Trials for Adjuvant Chemotherapy

Trial	Number of Patients	Stage	Therapy	Overall Survival (mo)	Survival (%) 2 y	3 y	5 y
International Adjuvant Lung Cancer Trial[2,3]	1867	IA, IB, II, III	Observation	45	66.7		40.4
			Chemotherapy	54	70.3		44.5
CALGB 9633[4]	344	IB–T2N0	Observation	78[a]	84	73	58[a]
			Chemotherapy	95[a]	90	80	60[a]
NCIC JBR 10[5]	482	IB, II (no T3N0)	Observation	73			54
			Chemotherapy	94			69

with stage IIIA (N2) disease, at best, 30% of patients are alive at 5 years. These numbers make clear the need for additional therapy to improve on the overall survival (OS) achieved by surgery.

To this end, there has been an emergence of a body of data to better define the role of chemotherapy in the adjuvant setting. The rationale behind this approach is to treat patients who are deemed to be at high risk for recurrence and dissemination of disease in the hope of eliminating micrometastatic disease. Early trials to study adjuvant chemotherapy were negative, possibly either due to the use of less effective chemotherapy regimens, the increased morbidity of treatment with fewer supportive care options, or the lack of statistical power. However, interest in studying adjuvant chemotherapy reemerged with presentation of a meta-analysis in 1995 in which 52 randomized trials were reviewed.[1] The authors concluded that the trials that compared cisplatin-based adjuvant chemotherapy to no further treatment favored the use of chemotherapy with an absolute survival benefit at 5 years of 5%. Since then, more homogeneous trials randomizing patients to surgery versus surgery followed by platinum-based chemotherapy have been conducted. These studies are outlined in Table 114-1.

International Adjuvant Lung Cancer Trial

The International Adjuvant Lung Cancer Trial (IALT) randomized 1867 patients with stage I, II, or III NSCLC to observation or chemotherapy after surgical resection.[2] The two groups were evenly matched with regard to age, sex, stage, performance status (PS), type of surgery, and histologic subtype. Due to the lack of consensus regarding the use of adjuvant radiotherapy, the choice of specific regimen was made by each participating institution at the time of protocol development. The chemotherapy regimens used consisted of cisplatin 80, 100, or 120 mg/m^2 offered on one of four different schedules with vindesine, vinblastine, vinorelbine, or etoposide. Patients were treated with three or four cycles. Of the various choices, the combination of cisplatin and etoposide was used to treat nearly 50% of the patients. When offered, radiation was given after chemotherapy in the group randomized to postoperative treatment. Radiation was planned for about 30% of the patients in the trial, with two-thirds of these having N2 disease. It was actually delivered to slightly more patients in the control group compared with the chemotherapy group (28% vs. 23%). Overall, the results favored the use of adjuvant chemotherapy, with a hazard ratio (HR) for death of 0.86 (0.76–0.98). At 5 years, the group that received chemotherapy had a statistically significant improvement in survival of 44.5% versus 40.4%. The toxicities associated with chemotherapy included the expected risks of neutropenia and nausea/vomiting. However, seven patients, (0.8%) died due to chemotherapy-related acute toxicities; this was predominately seen in those who received cisplatin at 120 mg/m^2. Long-term follow-up, (median 7.5 years) of this study was reported in 2009.[3] Although the benefit of cisplatin-based adjuvant chemotherapy on disease recurrence did not decrease with long-term follow-up, there was an increase in nonlung cancer–related death seen after 5 years in the treatment group. This positive trial demonstrated an absolute benefit at 5 years that was consistent with the previous meta-analysis and provided support for the use of cisplatin-based treatment in the adjuvant setting.

Retrospectively, tissue samples collected from patients participating in the IALT have been analyzed by immunohistochemistry to assess which biomarkers may predict a response to cisplatin therapy. Specifically, investigators have assayed for the enzyme excision repair cross-complementation group 1 (ERCC1).[8] Cisplatin acts by directly binding to DNA and forming platinum-DNA adducts, which prevents DNA replication. It is known that the presence of high levels of ERCC1 is associated with cisplatin resistance due to DNA repair of cisplatin adducts. To study this in the context of the IALT results, 761 tumor samples from that trial were assayed for ERCC1 expression by immunohistochemistry; half of these patients received chemotherapy and the remainder was in the control group. Of the tumors analyzed, 44% were ERCC1 positive. Expression was more common in patients over the age of 55 and those with squamous cell histology. Notably, there was a benefit from adjuvant chemotherapy in patients with ERCC1-negative tumors, with a statistically significant improvement in OS and disease-free survival due to chemotherapy (HR 0.65). In contrast, patients with ERCC1-positive tumors did not achieve a survival benefit from adjuvant chemotherapy compared with the control group. Among patients in the control group, those with ERCC1-positive tumors had an increased survival compared with patients with ERCC1-negative tumors. Although these results are intriguing, ERCC1 levels are difficult to quantify and it is currently not routinely tested in the clinical setting. Its use as a predictive marker for cisplatin-based adjuvant therapy needs to be validated in a prospective clinical trial.

CALGB 9633

The Cancer and Leukemia Group B (CALGB) conducted a trial to test the benefit of carboplatin-based adjuvant chemotherapy

exclusively in stage IB (T2N0) patients.[4] Other studies have included these patients along with those with more advanced disease, and in subset analyses the true benefit of chemotherapy after surgery in this population has been questioned. Originally, this study was intended to enroll 500 patients. However, due to poor accrual, this number was modified and in the final analysis, 344 patients were treated. Patients randomized to the chemotherapy arm received carboplatin dosed to a target area under the curve (AUC) of 6 mg/mL/min and paclitaxel 200 mg/m^2 every 3 weeks for four cycles. This study has been provocative in that it was initially reported in 2004 to be a positive trial with a statistically significant survival advantage, after a median follow-up of 34 months. This prompted the study to be terminated early, and the National Comprehensive Cancer Network (NCCN) practice guidelines adopted the use of adjuvant chemotherapy in stage IB patients. In 2008, when the results were updated after longer follow-up, (mean 74 months), the difference in 5-year survival between the chemotherapy and observation arms (59% vs. 57%, HR 0.83) was no longer statistically significant. However, the 3-year survival difference remained statistically significant, and there was a trend favoring a benefit in OS in the patients who received chemotherapy. Despite this, the routine practice of treating patients with stage IB disease is no longer recommended. In a subset analysis, there was a statistically significant benefit overall, (HR 0.69, $p = 0.43$), in patients with tumors over 4 cm in size who received chemotherapy. This benefit was not shared in those with tumors less than 4 cm in size. Therefore, in practice, many oncologists choose to treat patients with large-stage IB tumors, based on this subset analysis. The reason why the results are negative is not known and may be due to the population of patients being treated, the choice of a carboplatin-based regimen rather than cisplatin, or the abridged number of patients who were treated.

NCIC JBR 10

In this intergroup study, 482 patients with stage IB or II (excluding T3N0) NSCLC were randomized to either surgery or surgery followed by four cycles of chemotherapy.[5] Again, the treatment studied included cisplatin (50 mg/m^2 days 1 and 8) and vinorelbine (25 mg/m^2 weekly); one cycle was 4 weeks. This also was a positive study, with the 5-year survival favoring the chemotherapy group (69% vs. 54%), as well as a statistically significant improvement in disease-free and OS. Toxicity was associated with this regimen with two treatment-related deaths and over 70% of patients experiencing either grade 3 or 4 neutropenia. Other toxicities included fatigue, anorexia, and vomiting.

ANITA

The most recent study of interest is the Adjuvant Navelbine International Trialist Association (ANITA) study, in which 799 patients with stage IB, II, or IIIA NSCLC were randomized to four cycles of chemotherapy or observation after surgery.[6] Similar to the other trials, the chemotherapy regimen consisted of cisplatin (100 mg/m^2, day 1) and vinorelbine (30 mg/m^2, weekly) for a 4-week cycle. The choice of radiotherapy was left to the discretion of the treating physicians, and in the final analysis 24% of patients in the chemotherapy arm and 33% of patients in the observation arm received radiation. Patients who were randomized to chemotherapy had a significant improvement in median survival to 66 months, compared with 44 months in the control group. At 5 years, the absolute benefit in survival was 8.6%, and in a subset analysis this benefit seemed to be mainly noted in stage II and IIIA patients.

Lung Adjuvant Cisplatin Evaluation Meta-Analysis

In 2008, the Lung Adjuvant Cisplatin Evaluation (LACE) Collaborative Group published results of a pooled analysis of large trials (>300 subjects) investigating the use of cisplatin-based adjuvant chemotherapy versus no further therapy following complete resection of NSCLC.[7] The individual data from over 4500 subjects was analyzed with a median of 5.2 years follow-up. The investigators found an absolute benefit of 5.4% improvement in OS at 5 years in the treatment group. There was no interaction seen in regards to gender, age, histology, or type of surgery. However, the degree of benefit varied with stage; the HR for stage IB was 0.93 (95% CI: 0.78–1.10), for stage II HR = 0.83 (95% CI: 0.73–0.95), and for stage III, HR = 0.83 (95% CI: 0.72–0.94). In this analysis, a significant benefit from adjuvant chemotherapy was seen in those with better PS. In patients with Eastern Cooperative Oncology Group (ECOG) PS of 2 – defined as "ambulatory and capable of all self-care but unable to carry out any work activities; up and about more than 50% of waking hours," – chemotherapy may be detrimental and is not recommended. This analysis confirmed the benefit of cisplatin-based adjuvant chemotherapy following complete resection in fit patients with stage II and III NSCLC. Currently the NCCN and American Society of Clinical Oncology (ASCO) guidelines recommend cisplatin-based adjuvant chemotherapy for stage II and IIIA NSCLC.

Future Directions

Adjuvant cisplatin doublet chemotherapy is currently the standard of care for stage II and IIIA patients. The role of adjuvant treatment of stage IB patients has yet to be defined more clearly, but based on subset analyses, it is possible that patients with tumors greater than 4 cm will benefit from chemotherapy. Given the now-negative results of the CALGB 9633 study, carboplatin cannot be recommended as a standard choice for adjuvant treatment. Hopefully future studies will provide further data to guide the therapy of stage IB patients. Also, although molecularly targeted agents have been studied in the advanced disease stage (as detailed in the following sections), the utility of these agents in the early-stage setting is unknown. To begin to answer this question, the current large intergroup effort that is underway will randomize patients with stage IB (tumor >4 cm), II, and IIIA NSCLC to a cisplatin-based doublet either with or without the antiangiogenesis agent bevacizumab. Adjuvant trials are also underway to assess the role of erlotinib in patients with a sensitizing mutation in EGFR.

LOCALLY ADVANCED NSCLC

The term *locally advanced* includes several different presentations of primary lung cancer, but all have in common the absence of disease outside of the chest. Included in this category are those with stage IIIA or IIIB disease. These tumors involve mediastinal lymph nodes, either ipsilateral (N2) or contralateral (N3), and/or large primary tumors that directly invade important thoracic structures. For example T3 tumors involve the chest wall, the main bronchus less than 2 cm from the carina, or are greater than 7 cm in size. T4 tumors invade the mediastinum and affect structures that are not usually considered resectable (e.g., aorta, esophagus, and vertebral bodies). Mediastinal lymph node invasion should be determined before surgical resection by way of mediastinoscopy or EBUS with FNA, which also allows contralateral mediastinal lymph nodes to be sampled.

About 40,000 cases of stage IIIA and IIIB disease occur per year in the United States. The best treatment approach to locally advanced disease has not yet been determined. A wide array of combined modality approaches have been used in stage IIIA patients (particularly those with N2 nodes). These include varying combinations of chemotherapy, radiation, and surgery. Many studies in which patients with locally advanced disease were treated with chemotherapy, radiotherapy, or a combination of the two have relied on noninvasive determination of the extent of the disease. Thus, on the basis of enlarged ipsilateral mediastinal lymph nodes seen on a computed tomographic (CT) scan, patients were assumed to have N2 disease and were treated without histologic documentation of mediastinal lymph node

impairment. Such studies are seriously flawed. For meaningful interpretation, accurate histologic staging has to be included as an entry criterion for any study of locally advanced disease.

LOCALLY ADVANCED INOPERABLE OR UNRESECTABLE STAGE III NSCLC

Below are considered treatment approaches based on sequential or concurrent chemotherapy and radiation therapy in the management of locally advanced, inoperable or unresectable Stage III NSCLC.

Chemotherapy Followed by Radiation Therapy

Several prospective, randomized studies have compared radiation therapy alone and radiation therapy in sequence with chemotherapy in the setting of unresectable stage III disease. Le Chevalier et al.[9] randomized 353 patients to radiation alone (6500 cGy) or to cisplatin-based chemotherapy followed by radiation. One-, 2-, and 3-year survival rates all favored the combined therapy arm (51%, 21%, and 12% vs. 41%, 14%, and 4%, respectively). However, using repeat biopsies, the study found only a 17% incidence of local control in the radiation arm and a 15% incidence of local control in the chemotherapy and radiation arm.

In a trial conducted by CALGB, 155 patients were randomized to either radiation alone (6000 cGy) or a cisplatin-based regimen followed by radiation.[10] The median survival favored the combination therapy arm (13.8 vs. 9.7 months). The results at 1 and 2 years were so striking for the combined therapy group that the study was terminated early—a decision that subsequently prompted considerable criticism. The 3- and 5-year survival rates also favored the combination therapy (25% and 19%) over radiation therapy alone (11% and 7%). Unfortunately, the study was limited to patients with a high PS and less than 5% weight loss in the 6 months before enrollment in the trial. Limiting a study to the most favorable patients begs the question of the applicability of the results to the general group of patients with locally advanced lung cancer, many of whom have a decrease in their PS and have lost considerable weight.

A study seeking to confirm the CALGB report was initiated by the Radiation Therapy Oncology Group (RTOG), which randomized patients to the same two arms, in addition to a third arm using hyperfractionation radiation (69.6 cGy twice daily fractions) as the only treatment modality.[11] This study demonstrated that chemotherapy given prior to radiation was indeed superior to radiation alone in the patients with good PS (i.e., loss of weight of less than 5% in the previous 3 months). Analysis at 1 year showed the median survival to be statistically longer for those in the combined chemotherapy and radiation arm. At 3 years follow-up, however, no difference in survival (14%) was observed between the chemotherapy and radiation arm and the hyperfractionated arm. Both of these treatment regimens were better than standard radiation alone (Table 114-2).

Concurrent Chemotherapy and Radiation Therapy

The rationale for concurrent therapy, that is, chemotherapy given during a course of radiation therapy, is based on the concept that some drugs or drug combinations (notably cisplatin) may increase the radiosensitivity of tumor cells. The trade-off, however, is an increase in toxicity and a regimen that is not well tolerated by all potentially eligible patients. A meta-analysis of randomized trials directly comparing platinum-based chemotherapy given concurrently with thoracic radiation to chemotherapy given sequentially with thoracic radiation was performed in 2010.[16] Data from six trials (1205 individual patients) were analyzed. There was a significant benefit to concurrent therapy with an absolute OS benefit of 5.7% at 3 years (HR = 0.84, 95% CI: 0.74–0.95, $p = 0.004$). The primary effect was seen in control of locoregional disease, with no difference in risk of distant recurrence over sequential therapy. The risk of severe esophagitis was increased with concurrent therapy, although pulmonary toxicity was not different. Concurrent platinum chemotherapy and radiation therapy is the treatment of choice for patients with locally advanced, inoperable disease, provided their PS and comorbidities do not limit their ability to withstand the toxicities associated with this approach. Based on small phase II trials conducted by the Southwest Oncology Group (SWOG), a favored regimen for concurrent therapy utilizes cisplatin (day 1, 8, 29, 36) and etoposide (days 1–5, 29–33) with conventional RT.[17–19] For those patients unable to receive cisplatin, due to renal insufficiency or hearing loss, weekly carboplatin and paclitaxel has demonstrated activity in this setting. The OS seen with carboplatin and paclitaxel treatment is less than the control arms of the cisplatin/etoposide studies, although these two chemotherapy regimens have not been directly compared in a randomized trial. For those unable to tolerate a concurrent approach, sequential chemotherapy followed by radiation is a reasonable alternative.

Induction or Consolidation Chemotherapy in Addition to Concurrent Chemoradiation

Although the addition of concurrent platinum-based chemotherapy to thoracic radiation for unresectable stage III NSCLC has been proven to improve local control and OS, disease recurrence at distant

sites remains high. With concurrent therapy, only two cycles of chemotherapy are given during the course of radiation. This is fewer than the four cycles of cisplatin-based chemotherapy that has proven benefit to lessen disease recurrence in the adjuvant setting. This has led to an interest in increasing the amount of chemotherapy given for patients receiving concurrent therapy in locally advanced disease by adding several additional cycles of chemotherapy either prior to (induction) or after (consolidation) the concurrent chemoradiation.

Multiple randomized clinical trials have studied each of these approaches. In a nonrandomized phase II study, concurrent chemoradiation was followed by two cycles of consolidation cisplatin and etoposide, resulting in a median survival of 15 months and a 5-year survival of 15%.[18] A subsequent trial used the same combined treatment regimen, but then switched to docetaxel for consolidation.[19] This yielded a median survival of 26 months and a 3-year survival of 37%. However, a randomized study performed by the Hoosier Oncology Group in which patients received cisplatin, etoposide, and radiation, either with or without consolidation docetaxel, failed to show a benefit from consolidation treatment.[20] This is the first and only randomized study of consolidation therapy after concurrent therapy and radiation. Another favored regimen utilizes low-dose carboplatin and paclitaxel with radiation, followed by consolidation therapy with the same agents. Noncomparative phase II studies of this regimen have demonstrated a median survival of 16 months.[21] CALGB published findings of a phase III randomized study of two cycles of induction chemotherapy with full-dose carboplatin and paclitaxel followed by concurrent weekly dosing with radiation versus concurrent therapy alone.[22] Overall survival was not significantly improved with induction therapy (14 vs. 12 months, $p = 0.3$). Multiple studies have attempted to integrate targeted agents into the treatment of patients with unresectable, locally advanced disease, as consolidation following chemotherapy and radiation, with disappointing outcomes to date.

New Approaches to Concurrent Chemoradiation

Novel approaches to the treatment of locally advanced, nonresectable NSCLC include addition of pemetrexed and/or the monoclonal antibody, cetuximab as radiosensitizers and increasing the dose of radiation to 74 Gy. In 2011, the results of CALGB Trial 30407, a phase II study of pemetrexed and carboplatin administered with concurrent radiation ± cetuximab, were reported.[23] The combination of pemetrexed, carboplatin, and concurrent radiation with an additional four cycles of pemetrexed alone as consolidation met the primary end point of an 18-month survival rate of 58% and was recommended for further study; the addition of cetuximab did not meet statistical significance. The results of PROCLAIM, a phase III study of pemetrexed, cisplatin, and concurrent radiation with pemetrexed consolidation versus cisplatin and etoposide with concurrent radiation and consolidation is awaited. This study will determine if pemetrexed improves outcomes in stage IIIB in those patients with predominately nonsquamous histology. Finally, results of the RTOG 0617 study randomizing patients to standard dose (60 Gy) versus high dose (74 Gy) of chemoradiation ± cetuximab are awaited. The initial planned interim analysis for OS was recently reported, with discontinuation of the high-dose radiation arm due to inferior survival.[23] The results of the addition of cetuximab are pending.

■ LOCALLY ADVANCED RESECTABLE NSCLC

The roles of sequential chemotherapy followed by surgery and concurrent chemoradiation followed by surgery in treating locally advanced, resectable NSCLC are described below.

Chemotherapy Followed by Surgery

Neoadjuvant therapy, also referred to as *induction therapy,* has been applied to the treatment of NSCLC. It entails treating patients with chemotherapy even though there is no clinical evidence that the primary cancer has spread. Lung cancers are particularly attractive targets for neoadjuvant therapy because even though many present as locally advanced disease confined to the chest, patients run a considerable risk of developing distant disease within a short time. Neoadjuvant therapy affords a unique opportunity to assess the sensitivity of the cancer to the drug regimen. This information may be useful in the postoperative period when the possibility of adjuvant therapy is under consideration. Moreover, preoperative neoadjuvant therapy may render resectable a tumor that would otherwise be regarded as unresectable. Another consideration is that the required dose-intensive regimens are apt to be tolerated better before than after surgery. Finally, neoadjuvant therapy may allow for improved drug delivery due to the preserved vasculature of the tumor, and thus may decrease the prospect of developing drug resistance. However, the possibility exists that delaying surgery may be disadvantageous. In patients with locally advanced disease who are at high risk for developing disseminated disease, the delay imposed by the administration of chemotherapy provides an additional period of observation during which a nonresponder may manifest distant disease, thereby precluding surgery.

There have been two phase III randomized trials of neoadjuvant chemotherapy in patients with locally advanced lung cancer (stage IIIA). Some patients had N2 disease alone, while others had T3N0 disease (now considered stage IIB by the 7th edition TNM staging).[24,25] In contrast to results in patients with disseminated NSCLC in whom the response to chemotherapy at best approaches 30%, 60% to 70% of patients with locally advanced disease responded favorably. Also, in both trials, the median survival was improved in the group of patients who received neoadjuvant treatment. The explanation for this difference in responsiveness may be the better overall status of patients who are regarded as candidates for surgery and the smaller tumor burden that these patients bear. Alternatively, qualities inherent in the primary tumor that differ from those in the tumor that has metastasized may contribute to a better response to chemotherapy. Currently, there is no way of assessing the response of micrometastatic disease other than the disease-free interval after resection and the OS.

Another experience with neoadjuvant chemotherapy for NSCLC was reported from the Memorial Sloan Kettering Cancer Center.[26] The study was prospective but nonrandomized. It included 41 patients with "clinical N2" disease defined as bulky mediastinal adenopathy that could be seen on the conventional chest radiograph or was manifested at bronchoscopy by widening of the carina. Patients received a cisplatin-based regimen plus mitomycin. The overall response rate was 77%; 19 of the patients achieved a complete response that was confirmed by histologic examination. Seventy-five percent of patients were able to undergo resection, even though resectability based on previous experience would have been anticipated to be about 10%. It must be emphasized that these patients had bulky mediastinal lymph node disease, not lymph nodes that appeared grossly normal but in whom disease was subsequently detected. The authors concluded that the results obtained paralleled those noted in neoadjuvant studies with other solid tumors in that response rates to chemotherapy were high, and complete resection rates were high after response to chemotherapy. They identified response to chemotherapy as a significant prognostic indicator for survival.

Concurrent Chemoradiation Followed by Surgery

Various theoretical considerations have led to trials of chemotherapy and radiation followed by surgery (trimodality therapy): (1) Tumor cell subpopulations in locally advanced NSCLC may respond differently to radiation and chemotherapy, and cells resistant to one treatment method may be sensitive to the other; (2) chemotherapy may promote the emergence of radiosensitive cells, thereby increasing the total number of cells killed by continued radiation treatments; and (3) induction of cell cycle synchronization by certain drugs may increase cell killing by radiation and induce recruitment of tumor cells in G_0.

SWOG conducted a trial using the cisplatin/etoposide regimen that they had developed with concurrent radiotherapy; the trial included both stage IIIA and IIIB patients.[17] All 126 patients underwent mediastinoscopy for histologic evaluation of mediastinal lymph nodes. The response rate to the preoperative therapy was 59%, with 29% having stable disease. The resection rate was 85% in the stage IIIA patients, and 80% in the stage IIIB patients. The 3-year survival was similar in both stage IIIA and IIIB patients at 27% and 24% respectively. The absence of tumor in the mediastinal nodes at the time of surgery was associated with improved survival. Failure was more common in distant, rather than locoregional, sites with relapse occurring in 26 patients.

It remains to be proven that surgery is a necessary part of the treatment of these patients. The high response rate to chemoradiotherapy in the high-performance patients entered into these clinical trials raises the question of whether chemotherapy and radiation might be able to achieve a similar end point with regard to local control. A large intergroup study addressed this question.[27] In this trial, 396 patients with stage IIIA pathologic N2 disease were randomized to either concurrent chemotherapy with cisplatin/etoposide and radiation to 4500 cGY followed by surgery or the same chemotherapy regimen with radiation to higher doses of 6100 cGy. The patients who were randomized to surgery had a statistically significant improvement in progression-free survival (12.8 vs. 10.5 months); while there was a trend toward an improvement in OS in the surgery group, this was not statistically significant. In an unplanned subset analysis, patients who seemed to do better were those who had a lobectomy rather than a pneumonectomy, as well as those who had obtained a pathologic response in the mediastinal nodes. Although there was no significant benefit in OS, surgery is still often offered to medically fit patients after induction chemoradiotherapy.

In summary, major issues remain concerning the sequence and type of treatment for locally advanced disease. Although some permutation of combined modality treatment is clearly needed in patients with locally advanced disease, we currently do not have data in the form of randomized control studies that compare the efficacy of the varying combinations of chemotherapy, radiation, and surgery. In patients who can tolerate the added toxicity, combined concurrent chemoradiotherapy is more effective than sequential therapy. Although it has not been proven that surgery after induction chemoradiotherapy confers a survival benefit compared to definitive chemoradiotherapy, surgery is still a preferred approach in many institutions if patients can tolerate trimodality treatment. It remains unclear how combined chemoradiotherapy compares to induction chemotherapy followed by surgery or chemoradiotherapy followed by surgery. At the present time, this is a matter of institutional preference as well as the particular characteristics of individual patients.

METASTATIC NSCLC

Cytotoxic chemotherapy remains the recommended first-line therapy for those with metastatic disease without activating mutations in epidermal growth factor receptor (EGFR) or anaplastic lymphoma kinase (ALK) translocations, and for all patients as second-line therapy. Because the choice of treatment of metastatic NSCLC is based upon the presence of driver mutations, prompt molecular testing of the tumor biopsy material is of increasing importance. Currently the NCCN recommends the testing of all newly diagnosed nonsquamous cell NSCLC (and all cell types in never-smokers) for EGFR mutations and ALK translocations.[28] If these molecular targets are not identified, standard first-line therapy is a platinum (cisplatin or carboplatin)-based doublet with consideration for adding bevacizumab, a monoclonal antibody that targets vascular endothelial growth factor (VEGF). In metastatic lung cancer, the goals of chemotherapy are to improve the duration of survival and to palliate the symptoms of disease. The decision to use chemotherapy in the setting of incurable disease is based on patient preference, comorbidities, and PS and requires an ongoing dialogue between the patient and physician throughout the disease course.

FIRST-LINE CHEMOTHERAPY

For patients with adequate PS, the standard first-line chemotherapy recommendations currently consist of a platinum doublet, with several reasonable non-platinum combinations as an alternative. Numerous randomized studies have been conducted that compare the benefits of single-agent versus doublet regimens. A meta-analysis that reviewed 65 of these trials found a significant benefit in response and median survival with a cytotoxic doublet. There was no survival benefit with the addition of a third cytotoxic agent at the time of this analysis. Although there are several cisplatin or carboplatin backbone doublets to consider, carboplatin tends to be favored in the palliative setting due to its better toxicity profile. A large study that was conducted by the ECOG randomized 1207 patients with advanced disease to either cisplatin/paclitaxel, cisplatin/gemcitabine, cisplatin/docetaxel, or carboplatin/paclitaxel.[29] The median survival among all four treatment groups was 7.9 months, with a 1-year survival of 33% and a 2-year survival of 11%. There was no clear survival benefit with any one regimen compared with the others. Carboplatin/paclitaxel did seem to have a slightly better toxicity profile. Hence, this is a common regimen in use, but the other doublets are acceptable as well.

Pemetrexed, an antifolate, is a relatively new addition to the available agents in the first-line setting. This cytotoxic agent is unique in that efficacy varies by the histology of the NSCLC and it is labeled by the FDA for use in nonsquamous cell NSCLC only. This labeling is based on a phase III trial in which newly diagnosed patients with advanced NSCLC were randomized to either cisplatin/gemcitabine or cisplatin/pemetrexed in the first-line setting.[30] This trial was designed as a noninferiority study and did demonstrate that the doublet cisplatin/pemetrexed was noninferior to a standard doublet with a median OS of 10.3 months. When given with the appropriate folic acid and B12 supplementation, the cisplatin/pemetrexed doublet was associated with less cytopenia and led to a decrease in the need for growth factors and blood transfusions. There was a prespecified histology stratification performed, nonsquamous NSCLC (including adenocarcinoma, large cell carcinoma, and others) versus squamous cell NSCLC. Median OS for the nonsquamous NSCLC histology was 11.0 months for those who received cisplatin/pemetrexed versus 10.1 months for cisplatin/gemcitabine (HR = 0.84, 95% CI: 0.74–0.96). Those with squamous cell histology had a median OS of 9.4 months with cisplatin/pemetrexed versus 10.8 months with cisplatin/gemcitabine (HR = 1.22, 95% CI: 0.99–1.5). As pemetrexed is well tolerated and not associated with alopecia, carboplatin with pemetrexed is a widely used first-line regimen in nonsquamous cell NSCLC.

Two randomized phase III studies have addressed the use of non–platinum-based regimens as first-line treatment. The first, by Kosmidis et al., randomized patients to paclitaxel and gemcitabine versus paclitaxel and carboplatin.[31] The study showed similar efficacy with respect to median survival, 1-year survival, and response rate. Both regimens were well tolerated. The largest study to address the role of non-platinum doublets randomly allocated 929 patients to carboplatin/paclitaxel, carboplatin/gemcitabine, or gemcitabine/paclitaxel.[32] Again, the results indicated similar efficacy in all three arms. There were differences in toxicities in that anemia and thrombocytopenia were more common in the carboplatin/gemcitabine arm, although peripheral neuropathy and alopecia were more common in the paclitaxel containing groups. For chemotherapy-naive patients, treatment choices tend to be heavily dependent on a patient's comorbidities and the toxicity profile of each regimen.

The monoclonal antibody bevacizumab, which targets the VEGF, is approved for first-line treatment of NSCLC when combined with cytotoxic chemotherapy. VEGF, a circulating ligand that promotes angiogenesis, is not mutated in NSCLC, and this therapy, though molecularly targeted, is not specific to the tumor. A large randomized phase III study published in 2006 demonstrated an improvement in OS, 12.3 versus 10.3 months (HR = 0.79, $p = 0.003$) for those patients who received bevacizumab in addition to carboplatin and paclitaxel for advanced NSCLC.[33] Due to the high risk of life-threatening hemoptysis seen in early clinical trials, patients with squamous cell lung cancer or a history of hemoptysis were excluded from this study. As an antiangiogenesis agent, bevacizumab has several unique adverse effects including hemoptysis, hypertension, and proteinuria.[34] When carefully used in patients with advanced lung cancer, bevacizumab is a novel targeted agent that can improve survival.

■ ELDERLY PATIENTS WITH ADVANCED NSCLC

The median age at diagnosis for patients with NSCLC is 65 years; therefore, a significant number of patients diagnosed with advanced disease are elderly (≥70 years). Chemotherapy has been demonstrated to improve survival in the elderly with advanced disease to the same extent as those who are young.[35] Although there is an increase in side effects, particularly cytopenias, advanced age is not a contraindication to chemotherapy. Randomized studies dedicated to the treatment of elderly patients with advanced NSCLC are few, but several have provided needed data for this group. In 1999 a randomized study of vinorelbine versus best supportive care in those ≥70 years demonstrated improved survival in those patients who received single-agent chemotherapy.[36] A follow-up study compared combined vinorelbine and gemcitabine to either agent alone.[37] The combination did not improve outcomes over using single-agent treatment. Due to these findings, national treatment guidelines recommended the use of single agents in the first-line treatment of elderly (70–89 years) with advanced disease. More recently, results of a randomized trial using a carboplatin-based doublet for elderly patients have changed this approach. This study randomized elderly patients to single-agent vinorelbine or gemcitabine versus carboplatin and weekly paclitaxel.[38] Those who received the platinum-based doublet had a higher response rate (27% vs. 10.2%, $p < 0.0001$) and better OS (10.3 vs. 6.2 months, $p < 0.001$). Higher rates of febrile neutropenia were seen with the doublet therapy. This study supports the use of carboplatin and weekly paclitaxel in elderly patients with good PS with close monitoring for associated cytopenia.

■ PATIENTS WITH POOR PERFORMANCE STATUS

Patients with poor PS represent another common group in need of treatment for advanced lung cancer, but underrepresented in randomized clinical trials. Patients with ECOG PS of 2 – defined as "ambulatory and capable of all self-care but unable to carry out any work activities; up and about more than 50% of waking hours," – often are included in first-line trials, although they represent a small proportion of those enrolled. In 2012 data from a randomized clinical trial dedicated to first-line treatment of patients with ECOG PS 2 was presented.[39] In this study, patients were randomized to pemetrexed alone versus carboplatin and pemetrexed. Those who received the platinum-based doublet had an improved response rate (24% vs. 20%) and an improvement in median OS (9.1 vs. 5.6 months, $p = 0.001$). For those patients with ECOG PS 3 – "capable of only limited self-care, confined to bed or chair more than 50% of waking hours" – cytotoxic chemotherapy is of no known benefit, and best supportive care is recommended.

■ MOLECULAR TARGETED THERAPY

Advances in molecular biology have enabled the search for novel molecular abnormalities in lung cancer that provide insights into tumorigenesis as well as potential therapeutic targets. The identification of "driver mutations," those mutations that drive neoplastic transformation and contribute to tumor progression, has provided at least two clinically important targets to date. The epidermal growth factor receptor (EGFR) is a member of the human epidermal growth factor receptor (HER) family, a group of four transmembrane tyrosine kinase receptors expressed on epithelial cells of many organs, including the lung. In response to ligand binding, EGFR (HER1) forms a homodimer with another EGFR molecule or heterodimerizes with a different HER family receptor (HER 2, 3, or 4). This leads to tyrosine phosphorylation on the EGFR intracellular domain and activation of EGFR's kinase activity, resulting in phosphorylation of target proteins and initiation of downstream signaling. Normal functions of EGFR include epithelial growth and differentiation, cell–cell adhesion, and cell migration.[40]

Many NSCLCs harbor at least one EGFR mutation. Most EGFR mutations are in the tyrosine kinase domain and result in activation of EGFR and unregulated signaling.[41,42] The discovery of these mutations forms the basis for the use of erlotinib and gefitinib, EGFR tyrosine kinase inhibitors (TKI), as a treatment for lung cancer. Certain clinical characteristics are associated with EGFR mutation-positive lung cancer. Mutation-positive cancers are almost exclusively NSCLC, specifically adenocarcinoma.[41] EGFR mutations have been reported in 10% to 15% of Western and 25% to 30% of Asian lung cancer patients. EGFR mutations are significantly more common in women and nonsmokers. The presence of EGFR mutations strongly predicts a response to TKI therapy. One pooled analysis of three prior studies demonstrated a response rate to TKI treatment of 81% in mutation-positive cancers compared to <10% in mutation-negative cancers.[43] Given the poor response of mutation-negative cancers, therapy selection based on molecular characteristics is superior to using standard clinical criteria. However, further analyses have revealed growing complexity and certain EGFR mutations are associated with resistance to TKI treatment. In addition, over time almost all TKI-responsive lung cancers acquire secondary mutations rendering them resistant to further treatment and relapse is inevitable.[44]

The presence of driver mutations allows targeting of mutant proteins that are only present in the lung cancer, avoiding systemic toxicity seen in nontargeted therapy. An oral TKI, erlotinib, received FDA approval based on an improvement in OS seen in a randomized phase III trial of erlotinib versus best supportive care in heavily pretreated NSCLC patients.[45] The identification of specific activating mutations within EGFR that predict disease response to EGFR inhibitors has made routine genetic testing feasible.[46] Multiple randomized clinical trials have demonstrated that patients with activating mutations within EGFR have significant improvement in disease response with decreased toxicity when treated with erlotinib, compared to traditional chemotherapy, as first-line therapy.[47] Due to these findings, it is recommended that all patients with newly diagnosed advanced adenocarcinoma of the lung have their cancer tested for EGFR-activating mutations and treated with erlotinib if a mutation is identified.[48] The most common toxicities seen with EGFR inhibitors are acneform-type rash, diarrhea, and a small risk of interstitial lung disease (<1% in Caucasian patients). Patients treated with EGFR TKIs develop drug resistance on average about 1 year after treatment.[47] Mechanisms of resistance are being studied to provide future targeted therapy in this setting.

Another clinically relevant molecular subset of NSCLC is the one driven by the newly discovered echinoderm microtubule–associated protein-like 4 (EML4) and ALK translocation.[49] The EML4–ALK translocation in NSCLC leads to the constitutive activation of the ALK domain and promotes cell growth and survival. More recently additional fusion partners have been identified with ALK. ALK translocations are found in approximately 2% to 5% of NSCLC,

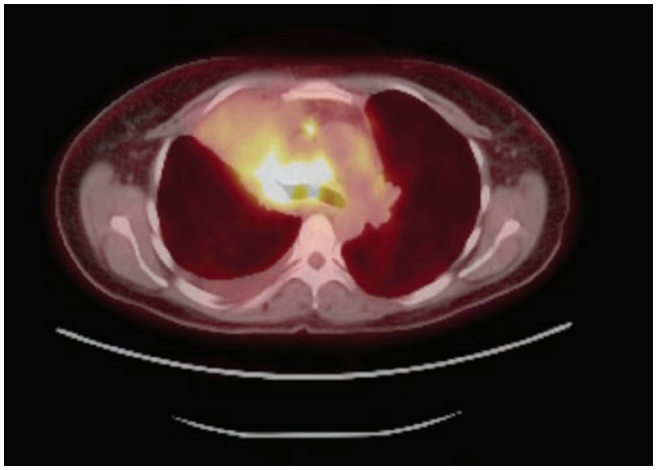

Figure 114-2 CT scan combined with fluorodeoxyglucose positron emission scan (FDG-PET) of a newly diagnosed metastatic lung adenocarcinoma in a never-smoker. This tumor was found to have an echinoderm microtubule–associated protein-like 4 (EML4) and anaplastic lymphoma kinase (ALK) translocation upon fluorescence in situ hybridization (FISH) analysis.

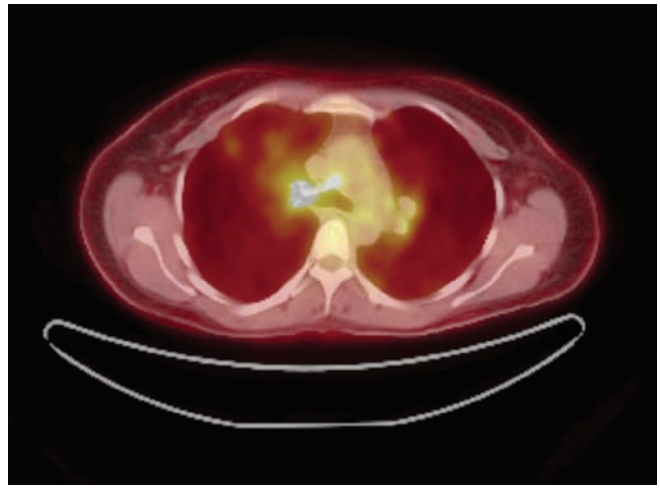

Figure 114-3 CT/FDG-PET scan of the same patient after 3 months of treatment with crizotinib, an oral tyrosine kinase inhibitor. The imaging shows marked disease response. The patient had progressive disease 9 months after starting crizotinib.

most commonly in never-smokers or light smokers with adenocarcinomas. These translocations are rarely found in tumors that harbor activating mutations in EGFR. A recently reported nonrandomized clinical trial of crizotinib, a TKI that targets the ALK kinase domain, demonstrated encouraging rates of disease control (90%) in patients with advanced lung cancer with EML4–ALK translocations.[50] In October 2011, the FDA gave crizotinib approval for treatment of NSCLC with ALK–EML4 translocations (Figs. 114-2 and 114-3).

■ MAINTENANCE THERAPY

Historically, first-line chemotherapy for NSCLC was given for four to six cycles then held, as there was no proven benefit to extending treatment with a doublet past six cycles. If the disease was under control (responded to therapy or stable), all treatment was held and the patient was followed clinically until disease progression. At that time, the patient would be considered for second-line chemotherapy. Over the past few years the availability of drugs that are better tolerated, such as pemetrexed and erlotinib, has enabled investigators to reevaluate this approach and consider maintenance therapy for those with disease control following first-line treatment. Maintenance therapy is given to keep cancer from progressing after response to initial treatment. In NSCLC, maintenance therapy has been divided into two general approaches: Switch maintenance and continuation maintenance. Recent clinical studies have demonstrated an OS benefit with use of maintenance therapy and it has become the standard of care in advanced NSCLC treatment (Table 114-3).

The NCCN defines switch maintenance as "the initiation of a different agent, not included as part of the first-line regimen, in that absence of disease progression, after 4 to 6 cycles of initial

TABLE 114-3 Randomized Trials of Maintenance Therapy in Advanced NSCLC

Trial	Therapy	Number of Patients	Progression-Free Survival (mo)	Median Overall Survival (mo)

Pem, pemetrexed; G, gemcitabine; C, carboplatin; Cis, cisplatin; B, bevacizumab.

therapy."[28] Pemetrexed and erlotinib have been shown to improve progression-free survival and OS as maintenance therapy following disease control with platinum-based doublet chemotherapy. Ciuleanu et al.[51] investigated the use of pemetrexed as switch maintenance in nonsquamous NSCLC and reported an improvement in OS of 13.4 months versus 10.6 months ($p = 0.012$) in those who did not receive further treatment until disease progression. In a similar study design SATURN, a randomized placebo-controlled trial, demonstrated OS improvement in an unselected patient population that received erlotinib as switch maintenance following first-line chemotherapy.[52] For the overall patient population the progression-free survival in the erlotinib group was 12.3 weeks versus 11.1 weeks for the control group ($p < 0.0001$), with OS of 12 months versus 11 months ($p = 0.0088$). The improvement in progression-free survival, in a subgroup of those with an activating mutation in EGFR, was dramatic, 44.6 weeks versus 13 weeks ($p < 0.0001$). Overall survival benefit was not seen in this subgroup, presumably due to crossover to a TKI in the placebo arm upon progression.

Docetaxel has also been studied as a switch maintenance therapy compared to docetaxel upon disease progression.[53] This study essentially compared immediate versus delayed docetaxel and found an improvement in progression-free survival and OS for those who started docetaxel immediately following first-line treatment. However, the difference in outcome could be explained by the low number (60%) of patients in the delayed arm who actually received drug. When subjects who received docetaxel in the delayed arm were compared to those in the immediate docetaxel arm, no difference was seen. Careful monitoring of patients while on a treatment break following first-line therapy with prompt administration of second-line docetaxel is a reasonable alternative approach, particularly for patients with squamous cell cancer when pemetrexed is not a maintenance option.

Continuation maintenance is "the use of at least one of the agents given in the first line, beyond four to six cycles, in the absence of disease progression."[28] There are several agents that were originally approved for use in the first line that have been used in this fashion. For example, in ECOG 4599, bevacizumab is continued until disease progression even after the carboplatin and paclitaxel are held after four to six cycles. This is also true of the TKIs, erlotinib and crizotinib, when used as first-line treatment for those with target mutations. Pemetrexed has been studied as a single agent given as continuous maintenance when used as part of platinum-based doublet in the first line.[51] PARAMOUNT, a randomized trial of continuous maintenance pemetrexed following first-line treatment with cisplatin/pemetrexed, demonstrated an improvement in performance-free survival when compared with placebo: 4.1 months versus 2.8 months ($p < 0.001$) after randomization.[54] There is also preliminary data to suggest an OS advantage to the continuous use of pemetrexed (13.9 vs. 11.0 months).[54] As a result, the current recommendation is to continue pemetrexed until disease progression in those with disease control following cisplatin (or carboplatin) and pemetrexed. As many oncologists are now using carboplatin, pemetrexed, and bevacizumab as first-line treatment of nonsquamous NSCLC, studies are currently underway to determine the best continuous maintenance strategy in this setting. One of these studies, AVAPERL, randomized patients to bevacizumab/pemetrexed versus bevacizumab alone as continuous maintenance in this setting.[56] Preliminary data from this trial suggested that the use of pemetrexed and bevacizumab together in the maintenance setting was associated with superior progression-free survival (10.2 vs. 6.6 months). However POINTBREAK, an open-label, randomized, phase III study comparing carboplatin, paclitaxel and bevacizumab with bevacizumab as maintenance to carboplatin, pemetrexed and bevacizumab with bevacizumab and pemetrexed as maintenance found no difference in OS.[57] Finally, a recently published study investigated the use of gemcitabine as continuous maintenance following cisplatin/gemcitabine induction chemotherapy.[58] This study included a significant number of patients with squamous cell carcinoma. Progression-free survival was significantly improved in those who received gemcitabine versus placebo following induction chemotherapy. Overall survival benefit was seen in those who received gemcitabine after an objective response to induction therapy, but not those with stable disease. This suggests that gemcitabine is a reasonable agent to use as continuous maintenance in patients with squamous cell carcinoma with response to platinum-gemcitabine in the first line.

SECOND-LINE THERAPY

Ultimately, patients with advanced disease will progress after receiving first-line therapy, with or without maintenance treatment. There are several options to consider in the second-line setting, and selection of the appropriate agent depends on histology, ECOG PS, and previous treatment. Docetaxel was one of the first agents approved for this indication. In the first trial of interest, 104 previously treated patients were randomized to docetaxel every 3 weeks at 100 mg/m^2, 75 mg/m^2, or to supportive care.[59] Docetaxel therapy resulted in an improvement in median survival (7.5 vs. 4.6 months) and 1-year survival (37% vs. 11%). The lower dose of docetaxel was better tolerated. In another study, 373 patients who progressed after platinum therapy were randomized to docetaxel at one of two schedules, ifosfamide or vinorelbine. Treatment with docetaxel at 75 mg/m^2 was associated with a higher response rate as well as an improvement in 1-year survival.[60] Interestingly, there was no difference in OS between the four groups.

In a phase III trial of pemetrexed in NSCLC, 571 patients were randomized to docetaxel or pemetrexed in the second-line setting.[61] Survival was similar in each arm with a median survival of 8.3 and 7.9 months for pemetrexed and docetaxel, respectively. The 1-year survival was 29.7% in both groups. Although survival with pemetrexed was not improved compared to docetaxel, pemetrexed was better tolerated with a significant decrease in the incidence of grade 3 or 4 neutropenia and febrile neutropenia events.

Erlotinib has also proven to be beneficial in the second- and third-line setting and is the only agent with data to support its use in those with ECOG PS 3.[45] In a large multicenter trial, 731 patients with stage IIIB or IV disease who were previously treated with first- or second-line therapy were randomized to either erlotinib or placebo in a 2:1 randomization favoring erlotinib. Patients with an ECOG PS of 0, 1, 2, and 3 were eligible. The response rate to erlotinib was 8.9%, with an OS of 6.7 versus 4.7 months in the placebo arm. In addition, there was an improvement in cancer-related symptoms in patients who received erlotinib. This was a significant survival benefit, and based on this study, erlotinib obtained FDA approval in the second-line setting. A small percentage of patients required dose reductions or were taken off of therapy due to drug-related toxicity. This study was performed prior to routine molecular testing for activating mutations within EGFR. In a subgroup analysis of this study, patients who had an increased likelihood of a response included those who were never-smokers, of Asian origin, female, or who had the adenocarcinoma histology.

FUTURE DIRECTIONS IN THE TREATMENT OF METASTATIC NSCLC

The integration of agents that target signal transduction and other biologically relevant pathways are beginning to make an impact in the care of patients and in the design of future trials for NSCLC. Although responses and survival benefits are currently modest, one avenue of research is to combine multiple agents with nonoverlapping mechanisms of action and toxicity profiles to have obtained a

greater clinical benefit. Now that the number of biologic agents in development is increasing at a faster pace, future research will focus heavily on learning more about patterns of resistance and determining which biomarkers will predict responsiveness to each agent and regimen. In addition, unique immunotherapeutic agents that facilitate an autoimmune response to solid tumors are showing promise in NSCLC and further clinical studies are eagerly awaited with this novel class of drugs.

CONCLUSION

Chemotherapy has an established role in the adjuvant therapy of stage II and IIIA NSCLC. Randomized clinical trial data demonstrate improved median and long-term survival when antineoplastic agents are used as part of a multimodality approach. The next step in the development of adjuvant regimens will be to add molecular targeting agents; these trials are already underway.

Response rates to chemotherapy are higher in patients with localized disease than in those with disseminated disease. Some of these differences may be related to tumor burden or overall PS. Questions that need to be addressed in future and ongoing trials include the optimal sequence for various modalities and the best modalities for each situation in locally advanced disease. For advanced-stage NSCLC, there is now a growing list of active agents. However, especially for heavily pretreated patients and those with a poor PS, response rates and overall prognosis are still limited. There are data to suggest that cytotoxic and biologic agents can modestly increase survival and improve a patient's quality of life. However, even in the most recent phase III trial with bevacizumab in the advanced setting, the median survival barely increased over the 1-year mark. Thus, there is still considerable room for improvement. Cost/benefit analysis is another consideration, as the newer agents are especially expensive. With the development of molecular agents and the future potential to select treatment options based on genomic and proteomic profiles, there is cautious optimism that the treatment of NSCLC will continue to improve in the future.

CHAPTER 115

Treatment of Non–Small-Cell Lung Cancer: Radiation Therapy

Tithi Biswas
Mitchell Machtay

Lung cancer is the second most common malignancy in the United States, after prostate cancer among men and breast cancer among women, but the number one cause of cancer-related mortality in both genders. Non–small-cell lung cancer (NSCLC) accounts for 80% to 85% of all lung cancers.[1] Most patients with NSCLC receive radiotherapy as part of their treatment, either as initial management or later in the course of their disease. This may include thoracic radiotherapy and/or irradiation of sites of metastatic disease.

Thoracic radiotherapy for NSCLC can be categorized as follows:

- Neoadjuvant = preoperative
- Adjuvant = postoperative
- Definitive = cure without surgery as treatment goal; with or without chemotherapy
- Palliative = directed at relief of thoracic symptoms

There is some overlap in these categories with respect to the goals of treatment. For example, most patients treated with definitive intent are not cured but do achieve palliation of thoracic symptoms. Similarly, a few patients originally considered to be technically unresectable may have a dramatic response to irradiation and/or chemotherapy, and the goal of treatment may then change from palliative to neoadjuvant or definitive intent.

The size of the primary lesion, stage, and total dose of radiation are important factors in determining the likelihood of achieving local control. A summary of radiotherapy for lung cancer is provided in Table 115-1.

The decision to utilize thoracic radiotherapy as part of the therapeutic regimen, and the treatment goals of such therapy, depend not only on tumor-related factors such as stage but also on patient-related factors such as pulmonary reserve and performance status. All these factors need to be considered when deciding whether to irradiate. Although radiotherapy might be appropriate for a patient with a postoperative forced expiratory volume (FEV_1) of 2 L and pathologic stage T2N2M0 disease, the same treatment would be problematic in a patient with a postlobectomy FEV_1 of 1.1 L who has had a series of postoperative complications. Of course, such clear-cut cases usually are the exception rather than the rule in clinical oncology. Table 115-2 lists the relative contraindications to thoracic radiation for lung cancer.

Finally, it must be remembered that the prognosis for most patients with lung carcinoma remains poor with standard therapy, and a concerted effort should be made to enter patients into clinical trials that are investigating new treatments or combinations of treatments for this disease.

THORACIC RADIOTHERAPY MANAGEMENT STRATEGIES

Surgery, irradiation, and chemotherapy are all used in the treatment of NSCLC and are based on the stage of the disease at presentation. Staging for all patients should include PET-CT scan, and selected patients should have bronchoscopy with endobronchial ultrasound (EBUS)-guided sampling of intrathoracic lymph nodes

TABLE 115-1 Summary of Radiotherapy for Lung Cancer: Indications and Treatment

Type	Indication(s)	Dose[a]
Preoperative (with chemotherapy)	Pancoast tumor; clinical N2	45–50 Gy
Postoperative	N2 disease; T4 tumors; selected T3 and/or N1 disease; incomplete resection	50–66 Gy (depends on surgical pathology findings)
Definitive medically inoperable	T1–2N0–1 not surgical candidate or refuses surgery	60–74 Gy (conventional fractionation) or 40–60 Gy (accelerated hypofractionation with stereotactic techniques)
Definitive unresectable (with chemotherapy)	Selected stage III patients; performance status high	56–74 Gy
Palliative unresectable	Other stage III and IV patients with local symptoms	20–50 Gy with accelerated hypofractionation (2.5–4 Gy fraction size)
Small cell (with chemotherapy)	Limited stage with good performance status	45–55 Gy or in 1.5 Gy bid fractionation

[a] *1.8–2 Gy once daily fractionation unless otherwise indicated.*

or mediastinoscopy, and MRI of the brain. Surgical resection remains the primary curative modality and may be the only treatment required in early-stage disease. The local failure rate in stage I patients after lobectomy or pneumonectomy is less than 10%. With such a low incidence of local failure the addition of postoperative irradiation is unnecessary if resection margins are negative. Unfortunately, many patients present with locally advanced, unresectable, or marginally resectable disease. In marginally resectable NSCLC, the addition of radiation and chemotherapy is aimed at decreasing the high frequency of failure due to local and distant spread that occurs with surgery alone. However, progress has been slow, and the overall survival of patients with locally advanced lung cancer has only increased modestly over the past 20 years.

NEOADJUVANT THERAPY

The current use of preoperative radiotherapy in the management of NSCLC falls into two categories: (1) as part of neoadjuvant chemoradiotherapy for N2 (IIIA) disease; and (2) as part of neoadjuvant chemoradiotherapy for superior sulcus (Pancoast) tumors (T3-4NxM0). For patients who are otherwise surgical candidates but are found at mediastinoscopy to have positive mediastinal lymph nodes (N2 disease), it is not clear whether neoadjuvant chemoradiotherapy is superior to neoadjuvant chemotherapy; either is an acceptable option.

N2 Disease

Conceptually, it has become attractive to attempt to convert bulky mediastinal nodal disease to microscopic mediastinal nodal disease, thereby rendering the patient suitable for surgical resection. Two large randomized trials were conducted to compare surgical versus nonsurgical management for highly selected patients with stage III disease.[2,3] These studies demonstrated the safety and feasibility of the surgical approach, but no definitive improvement in survival by adding surgery to chemoradiotherapy. However, secondary analyses suggested a favorable outcome in patients who had a pathologic complete response after neoadjuvant therapy. Patients undergoing lobectomy after neoadjuvant therapy appear to have better outcomes than patients who require pneumonectomy. Despite several large phase III randomized trials, the optimal approach remains unclear. Options include chemotherapy followed by surgery, chemoradiotherapy followed by surgery, and definitive chemoradiotherapy alone. The median and 5-year survival rates for these three options appear to be similar. There is evidence that induction chemotherapy or chemoradiotherapy followed by pneumonectomy (particularly right pneumonectomy) may be excessively toxic, with the previously mentioned studies reporting treatment-related mortality rates above 20%. In contrast, induction therapy (chemotherapy or chemoradiotherapy) followed by lobectomy appears to be well tolerated.[2–4]

Chemoradiotherapy followed by thoracotomy is an intensive treatment with considerable morbidity and mortality. Its use should be limited to patients with excellent cardiac and pulmonary reserve and a high performance status. Preferably this combination should be used in the context of a prospective clinical trial. Only patients with reasonable expectation of benefit should receive this form of aggressive management; thorough staging workups for metastatic disease should be performed prior to the start of preoperative treatment and in the "window" period (i.e., after this therapy has been administered and before surgery). Lesions that are suspected of being distant metastases should be investigated by tissue biopsy. The radiotherapy dose should be moderate, approximately 45 to 50 Gy, with standard fractionation (1.8–2 Gy once daily). An interval of approximately 3 to 8 weeks between completion of irradiation and surgery is advised to minimize the risk of difficulties in wound healing. Bronchial stump reinforcement at the time of surgery is strongly encouraged. As noted, right pneumonectomy after neoadjuvant chemoradiotherapy has a high mortality rate and should be avoided.

Preoperative radiotherapy carries with it the potential disadvantage of limiting the ability to give additional radiotherapy if the tumor proves to be unresectable or if residual disease remains after resection. After 45 Gy preoperatively, only about 30 Gy of additional irradiation can be safely administered postoperatively. Thus, it may be preferable to defer additional radiotherapy unless or until there is clear evidence of local progression. Chemotherapy may be offered, although in general, the patient left with residual or unresectable

TABLE 115-2 Relative Contraindications to Thoracic Radiotherapy for Lung Cancer

Prior high-dose thoracic radiotherapy (RT)
Connective tissue disease
FEV_1 <800 cc
Tracheobronchial–esophageal fistula
Projected RT fields to include >35% of normal lung volume (i.e., >40% of normal lung volume is projected by three-dimensional treatment plan to receive >20 Gy)
Projected RT fields to include >50% of heart volume
Patient expected to be noncompliant with treatment or follow-up visits

disease after preoperative chemoradiotherapy has a low likelihood of achieving long-term disease-free survival.

Superior Sulcus (Pancoast) Tumor

Superior sulcus tumors are uncommon lung cancers and account for only 3% of all lung cancer cases. They deserve special consideration as they can invade blood vessels if located anteriorly, brachial plexus if located in the middle or the stellate ganglion, or vertebral bodies if located posteriorly. These syndromes can cause extremely debilitating symptoms that are difficult to manage. In addition to the routine staging workup, MRI scan of the chest and/or spine may be very valuable to rule out any brachial plexus or vertebral body invasion.

Treatment depends on the extent of the disease. Presence of hilar or mediastinal nodal involvement is associated with poorer outcome. Single center studies have reported improved outcome using preoperative radiotherapy with or without chemotherapy. A phase II study by SWOG (SWOG 9416/INT0160) showed 2-year overall survival of 55% in T3–4N0 superior sulcus tumors.[5] In most institutions, preoperative chemoradiotherapy is standard management for superior sulcus tumors, with excellent outcome. However, selected patients may undergo surgery first followed by adjuvant treatment. In patients who are not candidate for surgical resection, concurrent chemoradiation is the preferred treatment approach.

■ ADJUVANT THERAPY

The primary tumor-related factors considered in decisions about the need for postoperative radiotherapy (PORT) are the pathologic stage and the completeness of the surgical resection. PORT is generally considered to be the standard of care for patients with resected ipsilateral mediastinal node–positive (N2) NSCLC, based in part on a Lung Cancer Study Group Trial that demonstrated a longer relapse-free survival with PORT in this subgroup.[6] There is no role for PORT for T1-2N0 tumors completely resected by lobectomy or pneumonectomy. The role of PORT for T1-2N1 tumors is questionable; in fact, there is the suggestion of a slight detrimental effect of PORT on overall survival. It is less clear whether radiotherapy should be administered after a wedge resection, although in selected patients, the high local failure rate after this procedure suggests a possible role for adjuvant radiotherapy.[7] Phase II data suggest that the combination of wedge resection plus brachytherapy results in local failure rates below 5%, comparable to that of lobectomy, and this approach can be considered in this situation. A multicenter phase III trial suggested sublobar resection with brachytherapy is feasible without any increase in morbidity compared to sublobar resection alone, and with low mortality at 30 and 90 days in high-risk patients with NSCLC.[8]

Whether PORT for stage IIIA NSCLC (N2-positive disease) has any impact on survival is debatable. Although many retrospective studies have shown a survival benefit to PORT, prospective, randomized trials have not. In fact, a highly publicized meta-analysis of randomized trials of surgery alone versus surgery plus PORT showed a detrimental effect of PORT on survival for lower stage.[9] This negative effect of PORT was very strong for stage I disease and modest for stage II disease; there was no evidence of any detrimental effect of PORT in stage III disease. The reasons for excess deaths in the PORT arm were not addressed, though likely attributable to radiation-induced cardiopulmonary toxicity. It should be noted that the legacy randomized trials included in the PORT meta-analysis and also in the Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute all used radiotherapy techniques that would be considered outdated by modern standards.

A more recent study utilizing the SEER database looked at the role of PORT in resected NSCLC. There was no difference in survival for the overall group but a subgroup analysis suggested increased survival with PORT in the N2 subgroup and decreased survival in N0–1 subgroups.[10] Douillard et al.[11] retrospectively analyzed patients in the Adjuvant Navelbine International Trialist Association (ANITA) trial, and found a benefit to PORT in patients with IIIA/N2 disease.

Future studies of PORT should focus on stage III disease and selected stage II disease, and on coordinating selective use of PORT with adjuvant chemotherapy. The majority of patients with node-positive resected NSCLC probably harbor micrometastatic disease outside of the thorax and thus adjuvant chemotherapy is appropriate. However, the risk for potentially morbid local–regional recurrence also exists in these patients. Further research is needed to better identify which patients are at very high risk for local–regional recurrence and thus most likely to benefit from PORT. If more effective therapy to prevent distant disease is developed, then the improvement in local control may lead to consistent significant increases in survival.

When employing PORT, meticulous radiotherapy treatment planning is essential to minimize risks of toxicity. Radiotherapy fields should be relatively modest in size, yet include the high-risk regions of the bronchial stump, ipsilateral hilum, and the portion(s) of the mediastinum considered high risk for regional recurrence. If resection margins are negative and if there is no chest wall invasion, there is no reason to irradiate the "tumor bed"; doing so would only increase toxicity by irradiating that portion of remaining lung that has filled into the space left by the lobectomy. A radiation dose of 50 to 55 Gy using a standard fractionation schedule (1.8–2 Gy per day) should provide excellent local and regional control. Higher doses may be reasonable if resection margins are compromised and the patient has excellent underlying cardiopulmonary function.

Patients who undergo incomplete resection (gross residual disease) or suffer local recurrence after surgery alone have a poor prognosis, although radiation is usually used in an attempt to maximize local control. These patients should be considered to have the equivalent of locally advanced, nonoperative NSCLC and treated accordingly, potentially with definitive intent (see the following).

■ DEFINITIVE THERAPY (LOCALLY ADVANCED, NONOPERATIVE NON–SMALL-CELL LUNG CANCER IIIA OR IIIB)

Patients who do not have demonstrable distant metastases but have locally advanced, unresectable disease are often referred for radiation therapy, with or without chemotherapy. For nonoperable (stage IIIA and IIIB) patients, combined chemotherapy and radiation therapy is often considered as the standard of care in patients with good performance status and no other significant medical comorbidities.[12] Because combined modality therapy has considerable toxicity and requires a high level of patient time, commitment, and expense, intensive chemoradiotherapy generally should be limited to patients whose Karnofsky scores are 70% or greater. Significant weight loss, defined in most cooperative group trials as greater than 5%, is also a relative contraindication to aggressive combined modality therapy as it carries a poor prognosis. Although age itself is not a contraindication to combination therapy, intensive regimens should be applied cautiously in patients more than 70 years old. Notably, the median age averaged 60 years in most of the trials utilizing chemoradiotherapy. Although large tumor size is not a contraindication to definitive treatment, larger tumors generally result in a larger portion of normal tissue (lung, heart, and esophagus) being included in a radiotherapy portal, and the resultant high-dose irradiation may carry an unacceptable risk of complications. The location of the tumor (e.g., proximity to the heart and/or extensive involvement of the right lower lobe of the lung) and the patient's pulmonary reserve may also influence the decision regarding definitive irradiation. Supraclavicular adenopathy (N3 disease) is not an absolute contraindication for definitive therapy, although its presence is a poor prognostic indicator.

There is now strong evidence that concurrent chemoradiotherapy is better than sequential induction chemotherapy followed by

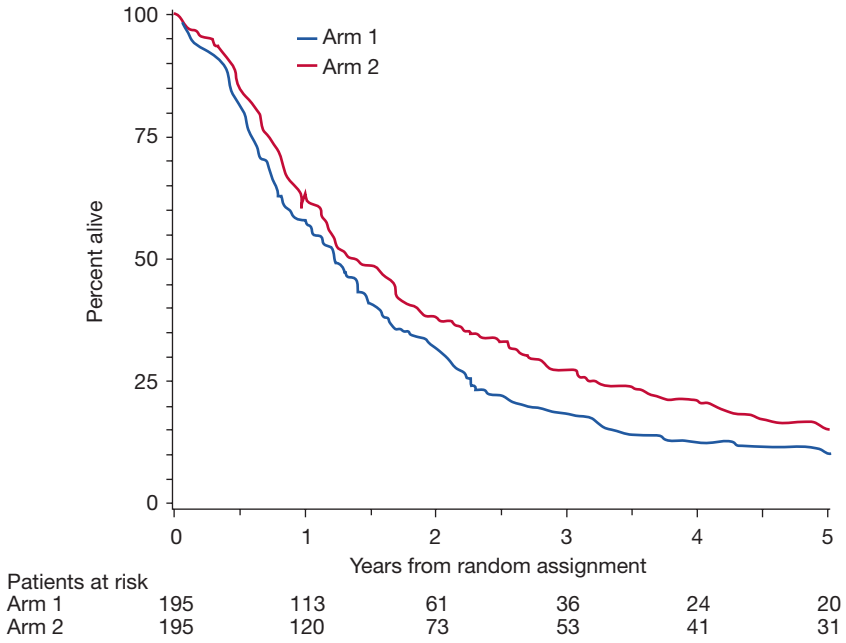

Figure 115-1 Five-year survival results for patients assigned to recrive standard radiation with concurrent chemotherapy compared with patients assigned to receive sequential chemotherapy and radiotherapy. Hazard ratio for death = 0.812, 95% confidence interval = 0.663 to 0.996, $P = .046$, two-sided log-rank test. radiotherapy. Several randomized trials have addressed this topic, and most show a clear benefit in local–regional control, median survival, and 2- and 3-year survival in favor of concurrent therapy (Fig. 115-1).[13–15] A meta-analysis showed significant overall survival benefit with an absolute benefit of 5.7% at 3 years and 4.5% at 5 years. The concomitant treatment also reduced locoregional progression significantly but there was no difference in distant progression between the sequential or concurrent treatment.[16] Long-term toxicity rates appear similar between sequential versus concurrent chemoradiotherapy; however acute toxicity with esophagitis is markedly increased with concurrent therapy without any increase in acute pulmonary toxicity.[16]

The conventional dose fractionation schedule used for definitive irradiation is 60 to 66 Gy in standard fractionation (1.8–2 Gy once daily). The maximum tolerated dose of irradiation is probably higher than that for small- to medium-sized tumors in which the amount of normal tissue in the field is low. However, preliminary results from a randomized trial did not show a benefit to 74 Gy as compared with 60 Gy.[17] The standard chemotherapy drugs are a platinum-based doublet regimen. Figures 115-2 and 115-3 show examples of radiographic response to combined chemoradiotherapy in two patients with NSCLC.

For many years, the fields to be treated in the definitive therapy of NSCLC have followed the Halsted principle of "radical en bloc" locoregional therapy (Fig. 115-4). The typical radiotherapy field encompassed the primary tumor (with approximately 2 cm margin), both the ipsilateral and contralateral hila, and the entire mediastinum from the thoracic inlet to a point at least 5 cm below the carina. Elective supraclavicular nodal irradiation was also typically used for upper lobe cancers. This usually results in a field size measuring approximately 16 ×20 cm, which incidentally irradiates a large amount of normal tissue. With this technique, it has been estimated that greater than 30% of a patient's normal lung tissue is exposed to a dose of irradiation expected to cause permanent fibrosis.

Because of these issues, in recent years there has been a trend toward smaller field size in definitive radiotherapy, encompassing gross disease with an appropriate margin and fewer areas of "prophylactic" nodal stations (Fig. 115-5). This evolution has been accelerated by improvements in preradiotherapy imaging (e.g., PET scan–based treatment planning) and the addition of chemotherapy to control microscopic disease).[18] Several studies have confirmed nodal failure to be 7% to 10% if prophylactic nodal irradiation has been omitted.[19,20] The use of smaller field sizes makes radiotherapy better tolerated and offers the possibility for higher doses of radiotherapy in

combination with chemotherapy. A concern about local failure just outside of the irradiated volume (also known as "marginal miss") with these newer techniques exists; however, the risk of this kind of failure appears to be relatively low compared with central local or distant failure. Most studies show that the risk for a marginal miss recurrence is between 5% and 10%, compared with 30% to 60% risk for central local recurrence and/or distant metastases. A randomized trial that enrolled 200 patients with inoperable stage III NSCLC showed similar 5-year survival rates with "involved field" irradiation versus elective nodal/comprehensive irradiation. Notably, overall response rates and local control rates were better, and toxicity lower, in association with use of the smaller fields.[21]

Through advances in chemoradiotherapy over the past 20 years, there have been improvements in the prognosis for locally advanced, unresectable NSCLC, as reviewed in Table 115-3. With supportive care alone (e.g., antibiotics, expectorants, oxygen, etc.) expected survival is less than 6 months and only about 5% of patients are alive at 2 years. Single-agent radiotherapy improves the median survival to about 9 months, with approximately 20% of patients alive at 2 years. Sequential induction chemotherapy followed by radiotherapy further improves these values to approximately 14 months and 33%, whereas concurrent chemoradiotherapy increases these values to 17 months and 40%, respectively. Several phase II studies incorporating newer chemotherapy agents/schedules with modern radiotherapy have reported median survival of about 2 years, with approximately 20% 5-year survival. Interpretation of these improved outcomes is confounded by patient selection bias and stage migration, particularly with the widespread use of PET scan–based staging. Improvement in supportive care is also likely a contributing factor. However, the improvements in the prognosis for stage III nonoperative NSCLC are well documented by large, prospective randomized trials and should be considered valid. It must be stressed that the trials in which the outcomes were positive involved patients with good performance status, absence of malignant pleural effusions, and minimal weight loss.[22] Not all patients with presumed unresectable disease would benefit from highly aggressive concurrent chemoradiotherapy.

Current research efforts are focused on optimizing radiation techniques and integrating new molecularly targeted therapies into the treatment of locally advanced NSCLC. As noted, there has been a paradigm shift away from large-field/medium-dose radiotherapy toward small-field/high-dose radiotherapy. This will hopefully continue to improve the therapeutic ratio of radiotherapy while making it more feasible to introduce new agents with less concern about excessive overlapping toxicities. Preclinical data suggest a benefit from combining radiotherapy with agents that target signal transduction and/or angiogenesis pathways. While this approach has been validated in some extrathoracic tumor sites (e.g., head and neck cancer), it is still investigational in lung cancer.

■ DEFINITIVE THERAPY (NONOPERATIVE NON–SMALL-CELL LUNG CANCER STAGE I)

Patients with "medically inoperable" (i.e., with medical contraindications to definitive surgery) stage I NSCLC who are treated with radiotherapy have a significantly improved prognosis compared with locally advanced "technically unresectable" stage II/III NSCLC. This is a major argument in favor of intervention with radiotherapy prior to disease progression to stage III. Relatively small radiotherapy fields can be safely used for most patients with stage I disease, and high doses can be administered. A traditional radiotherapy course consists of 60 to 66 Gy in conventional fractionation (1.8–2 Gy once daily). With this approach, reported 5-year local control rates are in the range of 30% to 50%, with 5-year survival ranging from 10% to 30%.[23,24] Even though the local control rate is inferior to surgical series, many of these patients die from intercurrent disease rather than their lung cancer. Since early-stage NSCLC is not inherently a systemic disease, there is interest in escalating the radiation dose to improve the local control rate.

Stereotactic Body Radiotherapy

The combination of multiple beam angles to achieve sharp dose gradients, high-precision localization, and a high dose per fraction in extracranial location is referred to as stereotactic body radiotherapy (SBRT) (Fig. 115-6). This technique allows precise targeting and delivery of high-dose radiation. SBRT for lung cancer

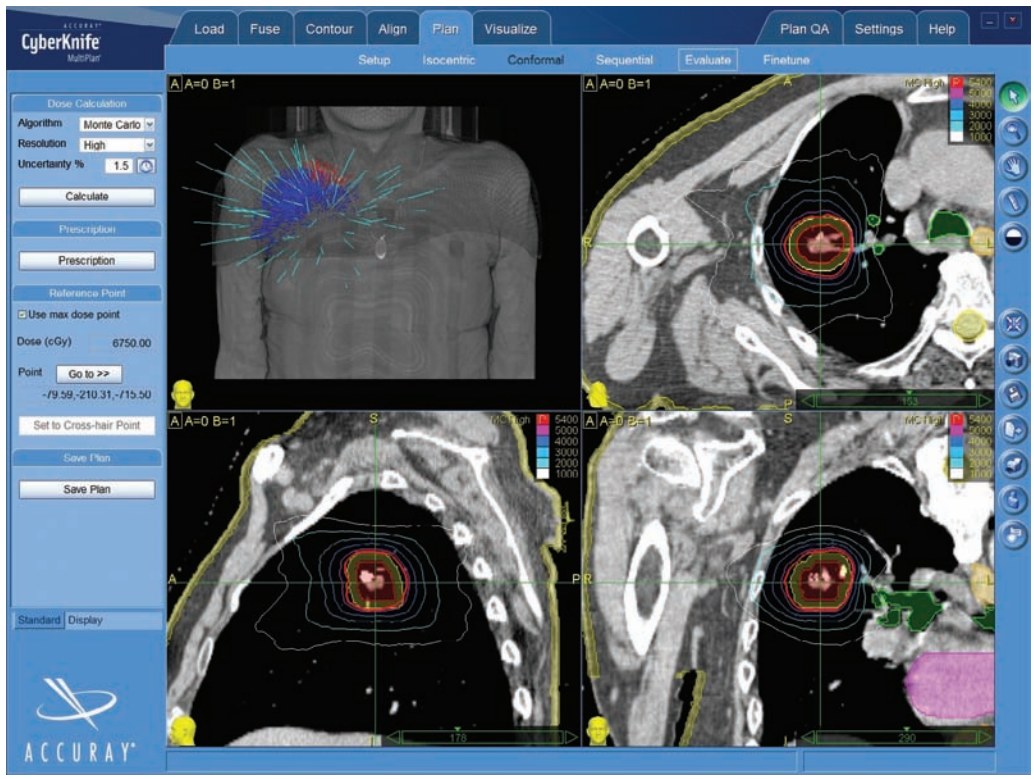

Figure 115-6 This figure illustrates the multiple beam arrangement and the radiation isodose distribution in treatment for medically inoperable peripheral stage I non–small-cell lung cancer using SBRT technique.

incorporates various systems to take tumor motion into consideration along with image guidance to decrease the set-up uncertainty. Both these components allow reduction in treatment volume, which enables delivery of markedly higher doses with fewer treatment fractionations. There have been several reports showing effectiveness of this treatment approach with very high local control rate. The only prospective multi-institutional study showed feasibility of delivering 20 Gy in 3 fractions (60 Gy total), a dose of radiation that is generally considered uniformly ablative of malignant cells.[25] Preliminary results suggest that SBRT offers extremely high local control rates approaching those achievable with lobectomy. However, long-term data are still pending, and at this time relatively few centers have extensive experience in this highly complex treatment. Furthermore, the optimal dose and fractionation are not clear because of the variation in dose and fractionation schedule used by different groups. Based on the RTOG phase II prospective study, for peripherally located stage I medically inoperable tumor, 54 Gy in 3 fractions is currently considered to be the standard.[25,26]

PALLIATIVE THERAPY

Palliative radiation therapy is most often used in situations in which the patient's quality of life is, or could be, substantially compromised. Situations in which thoracic radiotherapy is commonly applied for palliation include locally advanced disease with superior vena cava syndrome, hemoptysis, dyspnea, pain, or obstructive pneumonia, and metastatic disease.[27,28] Cough, often due to partial bronchial obstruction, is frequently palliated by radiotherapy. Atelectasis is rarely reversed by radiotherapy, although consideration should be given to irradiation to prevent refractory postobstructive atelectasis and pneumonia when impending obstruction of a mainstem or lobar bronchus is identified by bronchoscopy. A summary of the response rate (partial relief) of symptoms is shown in Table 115-4.

Palliative radiotherapy generally involves lower total doses and smaller fields than does definitive radiotherapy. Larger daily fraction size is used (2.5–4 Gy once daily) in the attempt to achieve relatively rapid palliation and minimize the number of trips to the radiotherapy department. In addition, late radiotherapy complications (which are related to larger fraction size) are less relevant in this patient population. There is no standard palliation regimen, and treatments have ranged from a single fraction of 8 to10 Gy (a very popular European regimen) to a full course of 60 Gy in standard 2 Gy once daily fractions. A typical palliative radiotherapy schema in the United States is to deliver 3 Gy × 10 fractions (30 Gy total), which may be followed by a second similar course of treatment, either after a several week break, or later, at the time of further local progression.

TABLE 115-4 Response Rate to Palliative Radiotherapy

Symptom	Response Rate (%)
Atelectasis	20
Cough	35–65
Dyspnea	35–50
Hemoptysis	75–85
Pain	50–75
SVC syndrome	60–80
Weight loss/anorexia	30–50
Vocal cord paralysis	5
Overall symptomatic response	60–75

SVC, superior vena cava.

After full-course external-beam irradiation, patients commonly develop symptoms associated with recurrent disease. Occasionally, it may be appropriate to offer reirradiation. If this is purely due to endobronchial obstruction, the patient may be a candidate for endobronchial irradiation.[29] This bronchoscopically guided treatment uses an Iridium-192 source, with a depth penetration that is superior to current laser or photodynamic treatments. However, it does carry a 5% to 10% risk of massive hemoptysis (presumably the result of tumor lysis with bronchovascular fistula).

Finally, radiotherapy plays an important role in the palliation of metastatic sites, including brain and bone metastases. Whole-brain irradiation is appropriate therapy for multiple brain metastases. In addition to palliating neurologic symptoms in many patients, it marginally improves survival compared with steroids alone. In addition, patients with limited brain metastases and a good performance status appear to benefit from a combination of whole-brain irradiation plus either surgical resection or stereotactic radiosurgery boost.[30] For bony metastases, most patients achieve at least partial pain relief from palliative radiotherapy. In some cases this can be given in a single 8 Gy × 1 fractionation. Other cases may require a 1- to 2-week course of radiotherapy. Disfiguring metastases to the skin, subcutaneous tissues, and/or lymph nodes can be improved by similar modest dosages of irradiation. Pain from adrenal metastases can be palliated with radiotherapy in patients in whom the radiotherapy field would not include an excessive amount of liver, kidney, or bowel. Radiotherapy is not generally useful for diffuse metastatic disease to the liver or bilateral lungs.

TOXICITY OF THORACIC RADIOTHERAPY

Toxicity from radiotherapy occurs both as *acute* side effects, generally defined as those occurring during or within 90 days after the completion of a course of irradiation, and *late* effects, which do not develop until at least 90 days after the completion of irradiation.[31–35] Although some of the same factors that predict acute effects also increase the likelihood of late effects, the acute effects themselves do not necessarily lead to the late, long-term complications. Conversely, some patients who experience minimal to no acute side effects may nonetheless be at risk for significant late complications. Most radiation toxicities reflect localized damage to tissue within the irradiated portal. However, some effects are more generalized (e.g., fatigue, immunosuppression, and the rare complication of acute respiratory distress syndrome). The grade of radiation toxicity is generally reported on a 1 to 5 scale, with grade 1 toxicity representing mild effects (e.g., dyspnea on exertion) and grade 5 representing fatal toxicity.

In the treatment of thoracic malignancies, where high irradiation doses and large fields are often used, the organs of greatest concern for both acute and late complications are the lung, esophagus, and heart. Significant dermatologic toxicity has been virtually eliminated by the use of megavoltage equipment. Likewise, with modern treatment planning techniques, spinal cord complications should be extremely rare. Other structures at risk for injury by thoracic irradiation include the brachial plexus, the tracheobronchial tree, the great vessels, the ribs, and the sternum. Although many complications of thoracic irradiation are manageable, the most important strategy is prevention through sophisticated treatment planning and appropriate selection of patients for treatment.

LUNG COMPLICATIONS

Radiation pneumonitis and pulmonary fibrosis are the most common serious complications of thoracic irradiation. Radiation pneumonitis represents acute/subacute lung injury. It usually occurs from 1 to 4 months after irradiation, although it may occur during a course of particularly intensive radiotherapy, often when combined with chemotherapy. Dyspnea is the most characteristic symptom;

Figure 115-7 Prechemo radiotherapy chest radiograph of a patient with limited-stage small-cell carcinoma of the right lower lobe.

cough, low-grade fever, and pleuritic chest pain often are also present (Figs. 115-7–115-9). Although infiltrates outside of the radiation portal do not completely rule out radiation pneumonitis, they make the diagnosis less likely. Community-acquired pneumonia and opportunistic infections as well as progressive malignancy can mimic radiation pneumonitis. Therefore, appropriate testing and consultation with the patient's radiation oncologist and/or a pulmonologist are indicated before empiric corticosteroids are begun. Mild cases should be treated supportively, reserving steroids for more severe symptoms. For severe radiation pneumonitis, prednisone 20 mg, three times per day, for approximately 2 weeks is a suggested regimen; tapering is done slowly during the subsequent 2 to 4 weeks.

The incidence of serious (≥grade 3) radiation pneumonitis ranges from 5% to 15%, and the risk depends on several variables. The most important factor appears to be the amount of normal lung tissue irradiated. Other factors that appear to increase the risk of radiation pneumonitis include radiation dose and dose per fraction (i.e., larger fraction size increases the risk) and tumor location

Figure 115-8 Chest radiograph 1 month after definitive radiotherapy and chemotherapy for the patient shown in Figure 115-5.

Figure 115-9 Chest radiograph 4 months after completion of radiotherapy for the patient shown in Figures 115-7 and 115-8. He presented with severe dyspnea on exertion. Radiographic infiltrates conform to the shape of his radiation portal. He responded promptly to steroids but soon developed fatal brain metastases.

(i.e., lower lobe lesions have a higher risk). The use of chemotherapy (particularly the anthracyclines, methotrexate, bleomycin, and mitomycin) and poor pulmonary function before treatment also increase the risks of serious damage to the lungs by radiation.

On rare occasion, patients may develop acute respiratory distress syndrome shortly after irradiation. The chest radiograph reveals

Figure 115-10 Chest radiograph of a patient 6 years after definitive radiotherapy for stage III unresectable non–small-cell lung carcinoma. Radiation fibrosis in the right upper lobe with mediastinal shift to the treated side and an ipsilateral pleural effusion and thickening is evident. Patient remained asymptomatic.

diffuse infiltrates both within and outside of the radiotherapy portal. It has been hypothesized that a severe autoimmune response may be involved; whereas mild and moderate radiation injury becomes manifest only in the irradiated portion of lung, a severe autoimmune response results in generalized bilateral lung injury.

The late complication of radiation fibrosis develops from 3 to 18 months after radiotherapy. All patients irradiated definitively for lung carcinoma develop some degree of radiologic radiation fibrosis in the portion of the lung that was heavily irradiated (Fig. 115-10). If this is a small volume, it should be asymptomatic, and the major difficulty is in distinguishing between fibrosis and residual, or recurrent, tumor. In clinically significant radiation fibrosis, however, there is usually a progressive decrease in the diffusing capacity, which may be combined with a more modest decrease in the FVC, reflecting the restrictive nature of radiation fibrosis. Unfortunately, established fibrosis does not respond to corticosteroids or any other therapy. Longitudinal studies in Hodgkin disease patients suggest that some recovery of lung function is possible by approximately 3 years after treatment. It is less clear if lung cancer patients, who are far older and more chronically ill than most lymphoma patients, can expect appreciable recovery.

■ ESOPHAGEAL COMPLICATIONS

Most patients receiving moderate- to high-dose radiotherapy for centrally located lung cancer experience an acute mucositis of the esophagus (and/or tracheobronchial tree) that is similar to that seen with other epithelial surfaces after radiation therapy. With standard radiotherapy (60 Gy in standard fractionation) this mucositis is almost always self-limited and usually responds to topical agents, such as sucralfate slurry or "magic mouthwash" combinations (e.g., antacid, viscous lidocaine, and diphenhydramine) with or without nonopioid and/or mild opioid pain medications. However, with more intensive radiotherapy or with concurrent chemotherapy, the incidence of grade 3 inflammation is higher, the recovery period is longer, and the need for aggressive pain management is greater.

Esophageal stricture is a late complication following thoracic radiotherapy. The risk of esophageal stricture is strongly related to the dose to the esophagus, approximately 1% with 50 Gy, 10% with 60 Gy, and as high as 50% with 70 Gy. It is likely that the concurrent use of chemotherapy potentiates this effect. Most cases of radiation esophageal stricture respond well to endoscopic dilatation although the procedure may have to be repeated. More severe complications, such as tracheoesophageal fistula or perforation, fortunately are rare.

■ HEART AND GREAT VESSELS

Acute effects of radiotherapy on the heart during treatment are uncommon, with cardiac events more commonly related to the tumor itself (e.g., atrial fibrillation due to invasion of the pericardium). Radiation pericarditis occurs during or after treatment in about 5% of patients, depending upon the radiation dose and volume of pericardium irradiated. As in the case of radiation pneumonitis, distinguishing between radiation pericarditis and tumor progression can be difficult. Most cases are self-limited and are treated supportively with antipyretics, analgesics, and occasionally with antiarrhythmic agents. Pericardiocentesis for tamponade is rarely required. Occasionally, severe constrictive changes may develop, leading to signs and symptoms of heart failure and necessitating pericardiectomy. In addition to the risk of radiation pericarditis, irradiation has increased long-term morbidity and mortality from heart disease in patients cured of Hodgkin disease, seminoma, and breast cancer, presumably due to accelerated coronary artery disease. Long-term cardiac complications of radiotherapy are less commonly encountered in patients with lung cancer, since few patients survive long enough to manifest these effects. Nonetheless, it is important to keep in mind that mediastinal irradiation is a risk factor for coronary disease, and should be taken into account in lung cancer survivors when deciding on screening and management of cardiac issues.

With the use of higher-dose radiotherapy, such as with SBRT, a small but finite number of patients can suffer injury to the mediastinal/hilar great vessels, including a risk of life-threatening hemorrhage. Although this is a rare complication, it has led to caution with the use of SBRT for centrally located and/or larger lung tumors.

■ BRACHIAL PLEXUS AND CHEST WALL

Radiation-induced inflammation and fibrosis of nerves, muscle, or bone can lead to long-term complications. Brachial plexopathy is uncommon with radiation doses of less than 60 Gy, but can be a concern in long-term survivors of superior sulcus tumors. More recently, it has become apparent that some patients successfully treated with SBRT for peripheral lung cancer experience chronic chest wall pain and/or rib fracture. As with other radiation toxicities, the dose to the chest wall and volume of the chest wall irradiated are important predictors. Treatment is symptomatic and supportive, including opioid and nonopioid pain medications.

ADVANCES IN RADIOTHERAPY

"Several recent advances in the field include radiation dose-fractionation modulation, enhancements in technical planning and delivery of radiation, combined modality therapy, and use of radiosensitizers. Each is discussed below."

■ RADIATION DOSE–FRACTIONATION MODULATION

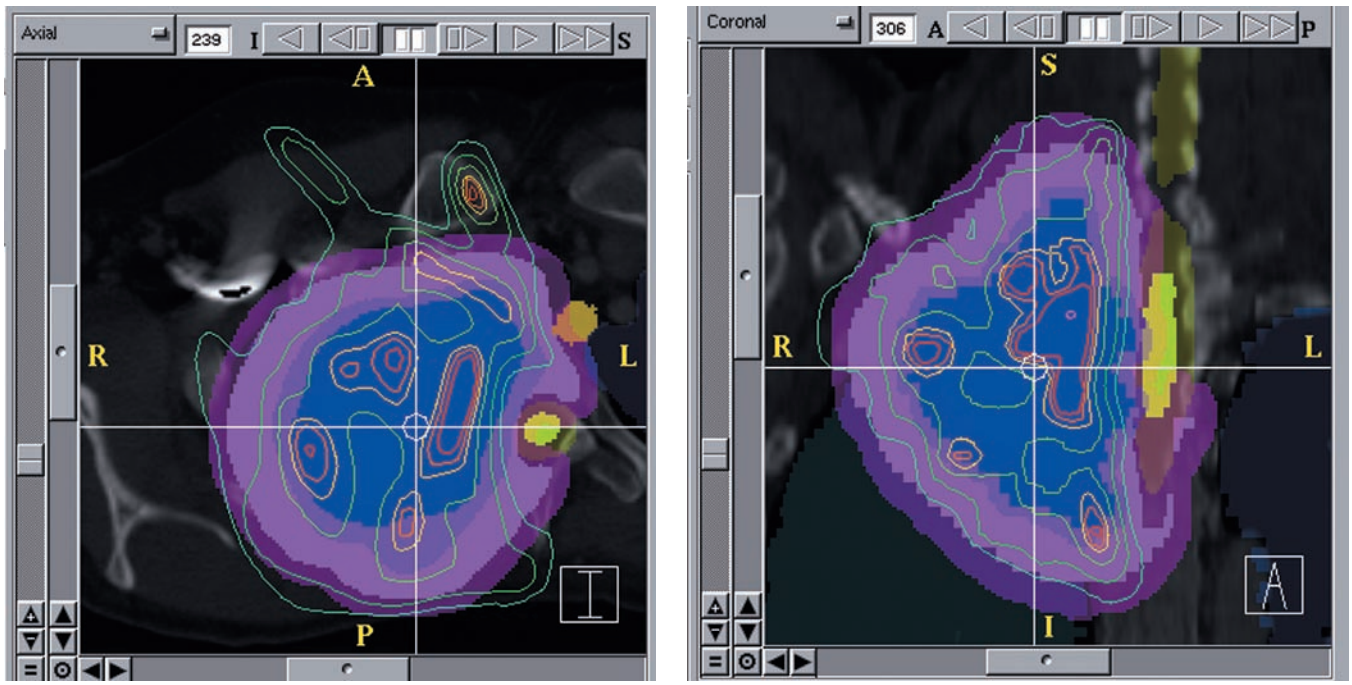
As the understanding of the relationship between radiation and cellular kinetics has grown, mathematical models have been developed to predict the responses of both normal tissue and tumor to radiation. This capability has led to many creative new fractionation schemes designed to maximize the destruction of tumor while minimizing damage to normal tissue. The difference in cellular kinetics between tumor cells and normal cells makes these new schemes possible and attractive. Both tumor cells and normal cells are injured by radiation; however, normal cells usually have a greater ability to repair this damage than do the tumor cells and can repopulate more between fractions.

Hyperfractionation utilizes multiple daily fractions in an effort to reduce the late effects in normal tissue without decreasing tumor control. The overall treatment time is the same as conventional schedules, but multiple smaller fractions are given each day, and total doses are increased. By giving multiple smaller fractions, the normal tissues are able to repair a greater percentage of the damage during the course of treatment. This may allow higher total cumulative doses of radiotherapy to be safely administered.

Accelerated treatment administers a larger total dose of radiation per day and also decreases the overall treatment time.[36] The final dose of radiotherapy may be similar to or even somewhat less than that of conventional treatment. Accelerated treatment may be given via hyperfractionation (e.g., 1.5 Gy BID-TID) or as hypofractionation (e.g., 4 Gy once daily). It is designed to reduce the amount of tumor repair and repopulation that occurs during treatment of rapidly dividing tumors and, therefore, improve local control.

Extreme hypofractionated treatment, as given with SBRT administers a very large dose of radiotherapy each day, typically for only three to five total treatments. This type of treatment does not discriminate well between tumor and normal cells, and is sometimes also known as "ablative" radiotherapy. For this treatment, to be safe, extremely small radiation fields must be used, and critical uninvolved organs must be carefully avoided, using stereotactic techniques.

In some settings, altered fractionation appears to increase local–regional control compared with standard fractionation. Because of toxicity concerns, it is usually not combined with concurrent chemotherapy in the treatment of NSCLC.



A B

Figure 115-11 High-technology radiation therapy involves the design of multiple conformal radiation beams directed in three-dimensional space from various angles and using variable field shapes and intensities. These slides illustrate the radiation dosimetry for a patient with a Pancoast tumor (T4N2M0) of the right upper lobe (**A**, axial view of radiation treatment planning CT scan; **B**, coronal view). The spinal cord is (relatively) spared from maximal radiation doses.

■ TECHNICAL PLANNING AND DELIVERY OF RADIATION

Complementing the advances in dose–fractionation schedules in radiotherapy are advances in technical planning and delivery of radiotherapy. Specifically, three-dimensional conformal radiation therapy, which includes newer techniques such as intensity-modulated radiation therapy (IMRT), proton-beam radiotherapy, and SBRT, is used in efforts to improve local control while minimizing toxicity. Utilizing three-dimensional planning of the tumor and surrounding normal tissue, the radiation beam(s) can be precisely conformed and modulated to the shape and size of the tumor volume (Fig. 115-11). Powerful computer software allows for detailed analysis of anticipated radiation dose/volume distributions, so that adjustments in the treatment plan can be made if necessary (Fig. 115-12). This information includes comprehensive dose–volume histograms, which quantitatively plot the volume of a given organ (or tumor/target) receiving a given dose of radiation. Dose–volume histogram analysis has demonstrated a powerful relationship between the risk of radiation pneumonitis and the amount of lung tissue irradiated to a certain threshold dose, usually considered to be 20 Gy in most studies.

In the future, these techniques may simultaneously allow a higher dose to the tumor and lower dose to normal tissues such as the spinal cord, esophagus, heart and great vessels, tracheobronchial tree, and normal lung tissue, offering an improved therapeutic ratio. Technologies investigating this include SBRT, respiratory-gated radiotherapy, and proton-beam radiotherapy.

■ COMBINED MODALITY THERAPY/RADIOSENSITIZERS

The rationale for combining radiotherapy with other anticancer treatments is twofold. First, it is expected that the nonradiotherapy treatment can sterilize tumor cells located outside of the radiation field (this is also known as spatial cooperation). Second, it is hypothesized that these other treatments act as radiosensitizers, turning a sublethal dose of radiation into a lethal dose of radiation. Both concepts apply to standard cisplatin-based polychemotherapy.

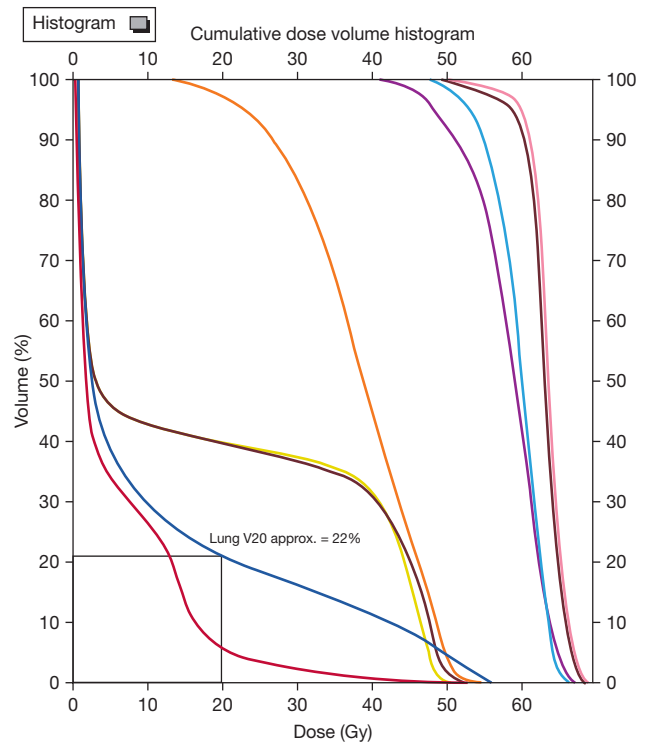


Figure 115-12 This figure illustrates the cumulative radiation dose–volume histogram plots for the patient from Figure 115-7. This graph includes the DVH curves for multiple normal organs (lung, heart, esophagus, spinal cord) as well as DVH curves for the tumor itself and electively irradiated targets adjacent to the gross tumor. The degree of radiation exposure to the normal lung tissue is expressed as the lung V20, the percent of the patient's total lung volume that receives a dose of at least 20 Gy, which is expected to devitalize that portion of lung. In this case the V20 is approximately 20%, which is generally considered a "safe" amount of radiation lung exposure and low risk for clinical radiation pneumonitis.

However, the toxicity of combined chemoradiotherapy appears to be at the limits of acceptability. In addition, conventional chemoradiotherapy has suboptimal effects against lung cancer. Thus, less toxic and better targeted drugs are needed. It is increasingly recognized that some cases of NSCLC are "driven" by a specific gene, such as an EGFR mutation or EML–ALK rearrangement. The corresponding proteins can be inhibited by a small molecule drug (e.g., erlotinib for EGFR-mutated NSCLC or crizotinib for EML–ALK rearranged NSCLC). These two drugs have demonstrated efficacy as single agents in stage IV NSCLC, but have not been adequately tested in cases of stage I to III NSCLC in which the appropriate gene aberration has been detected. Early phase research is ongoing.

SUMMARY

External-beam radiotherapy plays a major role in the treatment of NSCLC. It improves local control and enhances curability in patients with marginally resectable NSCLC. Patients with medically inoperable NSCLC have a good chance for durable local control with high-dose radiotherapy, particularly with modern technology including SBRT. In patients with unresectable NSCLC, radiotherapy (combined with chemotherapy) maximizes the median survival and offers occasional cure. Finally, radiotherapy often provides good palliation for patients with incurable and/or metastatic lung cancer.

CHAPTER 116

Small Cell Lung Cancer: Diagnosis, Treatment, and Natural History

Jonathan E. Dowell
David E. Gerber
David H. Johnson

Small cell lung cancer (SCLC) is, in many ways, a unique tumor. Untreated, it is a highly virulent malignancy, with a life expectancy best measured in weeks. Conversely, it displays exquisite chemosensitivity, resulting in partial or complete responses in the majority of cases. Unfortunately, these responses are typically short-lived, and as a result, more than 95% of SCLC patients die from their disease. Over the past 25 years, little progress has been made in prolonging the survival of patients with SCLC, despite numerous attempts to refine and improve the present therapy. This chapter reviews the biology, epidemiology, diagnosis, clinical presentation, staging, and current management of this difficult disease.

EPIDEMIOLOGY

Lung cancer remains the leading cause of cancer death in men and women in the United States. In 2012, estimates called for 226,160 cases of newly diagnosed lung cancer (116,470 men and 109,690 women) and 160,340 deaths (87,750 in men and 72,590 in women) from this disease.[1] A review of data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) Cancer Incidence Public Use database found that the proportion of lung cancer cases ascribed to SCLC has declined from a peak of 17.62% in 1986 to 12.95% in 2002.[2] A similar review of the National Cancer Database (NCDB) identified that SCLC constituted 19.5% of all new lung cancer diagnoses in 1992 and that this had decreased to 15.7% by 2007.[3] Of note, women now make up approximately 50% of SCLC cases, which is up from 28% in 1973.

The primary etiologic agent responsible for SCLC is tobacco smoke. A recent meta-analysis of nine case-control studies that included 11 European countries and Canada reported that the odds ratios in current smokers for the development of SCLC are 45.7 and 21.7 in men and women, respectively.[4] In the analysis, the risk increased markedly with both the intensity and duration of smoking, with males currently smoking >30 cigarettes daily having an odds ratio of 111.3 of developing SCLC. While >95% of cases of SCLC occur in current or former smokers, other etiologic agents including bischloromethyl esters, nickel, vinyl chloride, asbestos, cadmium, radon, arsenic, and radiation have been implicated as possible contributors to the development of this disease.[5] However, the true impact of exposure to each of these agents is not well quantified in the literature.

PATHOLOGY

Barnard[6] published the first report of SCLC in 1926, in which he described mediastinal tumors of epithelial origin that he called "Oat Cell Sarcoma" due to the histologic resemblance of the cells to oat grains. Since that description, the pathologic classification of SCLC has undergone frequent and extensive revision. Specifically, over the past five decades, the World Health Organization (WHO) proposed several different classification schemas that divided SCLC into a variety of subtypes that were, in retrospect, of limited utility in defining entities with truly different biologic behavior.

In 1999, the WHO joined with the International Association for the Study of Lung Cancer (IASLC) pathology panel to develop a revised classification of lung and pleural tumors. In the updated classification schema, neuroendocrine tumors are viewed as a spectrum extending from low-grade typical carcinoid to intermediate-grade atypical carcinoid to high-grade neuroendocrine tumors, a new entity called large

TABLE 116-1 Features of Neuroendocrine Lung Tumors

	Typical Carcinoid	Atypical Carcinoid	LCNEC	SCLC
NE features	Well differentiated	Well differentiated	Poorly differentiated	Poorly differentiated
Cell size	Intermediate	Intermediate	Large to intermediate	Small to intermediate
Mitotic rate	Low <2 mitoses/2 mm^2	Intermediate 2–10 mitoses/2 mm^2	High Median 70 mitoses/2 mm^2	High Median 80 mitoses/2 mm^2
NE markers by IHC	+++	++–+++	+–+++	±
Necrosis	—	+ (focal)	+++	+++
KI-67 index	≤5%	5–20%	50–100%	80–100%
5-y survival	90–95%	60–70%	10–40%	≤5–10%

IHC, immunohistochemistry; LCNEC, large cell neuroendocrine carcinoma; NE, neuroendocrine; SCLC, small cell lung cancer.

cell neuroendocrine carcinoma (LCNEC) and SCLC (Table 116-1).[7] This schema also identifies only one variant of SCLC ("SCLC combined"), which should be utilized when at least 10% of the tumor is composed of non–small-cell carcinoma elements.

Light microscopy is typically sufficient for making a diagnosis of SCLC. The cells are generally small (<4 lymphocytes or 20 μm in diameter) with scant cytoplasm, poorly defined borders, absent or inconspicuous nucleoli, and fine granular nuclei (so called "salt and pepper" chromatin).[7] The cells also often display nuclear molding, which is the propensity of the nuclei to be deformed by contact with adjacent cells or structures (Fig. 116-1). SCLC is quite proliferative and there are, therefore, rarely fewer than 10 mitoses per 10 high power fields. The cells are also quite fragile, and as a result, crush artifact is frequently observed on SCLC biopsies.[8] Inflammatory response and desmoplastic reactions are usually absent. Although biopsy specimens are ideal, cytologic specimens alone are often sufficient for diagnosis, with a sensitivity of 60% to 90% and a specificity of greater than 95%.[8,9]

While a diagnosis of SCLC can typically be made with morphology alone, immunohistochemical stains can assist in confirmation and can differentiate SCLC from lymphomas and other thoracic malignancies that can have a similar histologic appearance (Table 116-2). SCLC usually stains positive with epithelial markers (keratin, epithelial membrane antigen, and BER-EP4). In contrast, lymphoma is suggested by antibodies against the common leukocyte antigen, with negative epithelial markers. In addition, evidence of neuroendocrine differentiation is almost universal with >75% of SCLC staining positive with at least one neuroendocrine marker (neuron-specific enolase, chromogranin A, CD56 [neural cell adhesion molecule {NCAM}], synaptophysin). CD56, cytokeratins, TTF-1, and CD45 are useful in the diagnosis of SCLC in biopsies with extensive crush artifact and can help confirm the diagnosis in cases with equivocal features.[10] Other neuroendocrine markers that can be found include dopa decarboxylase, calcitonin, Leu-7, gastrin-releasing peptide (GRP), and insulin-like growth factor-1 (IGF-1).[8,11,12]

TUMOR BIOLOGY

Most cancers arise as a consequence of genetic abnormalities caused by exposure to environmental carcinogens. Both activation of a dominant oncogene and inactivation of a tumor suppressor

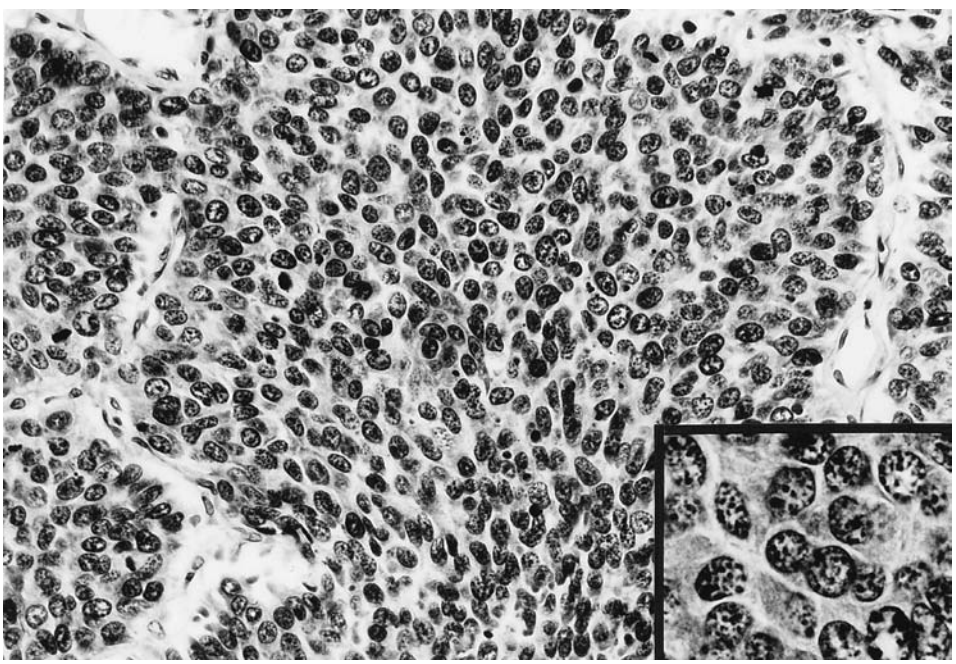

Figure 116-1 Photomicrograph of pure small cell carcinoma, demonstrating a homogeneous cell population with salt and pepper chromatin and moderately prominent nucleoli (H&E, 250×; *inset* 400×). *(Used with permission of Dr. Michael T. Lomis, Vanderbilt University.)*

TABLE 116-2 Immunohistochemical Profile of Small Cell and Other Primary Lung Cancers

	Positive Cases (%)			
		Non–Small Cell		
	Small Cell	Adenocarcinoma (Nonmucinous)	Adenocarcinoma (Mucinous)	Squamous Cell
CK-7	35	>95	90	40
CK-20	<5	10	50	<5
TTF-1	85	80	30	5
Napsin A	<5	85	<5	20
Synaptophysin	55	15	N/A	5
Chromogranin A	40	<5	N/A	5
CD56	95	<5	N/A	10
P63	<5	25	N/A	>95
CK 5/6	<5	15	N/A	90
34βE12	<5	55	N/A	>95
CDX-2	<5	<5	45	<5

CD, cluster of differentiation; CK, cytokeratin; TTF, thyroid transcription factor.

gene can lead to the development of a malignant phenotype. Recent genomic analyses of SCLC have revealed this malignancy to have one of the highest mutational rates of any cancer (7.4 mutations per million base pairs, compared to 6.3 for melanoma and 0.4 to 1.5 for various other solid and liquid tumors).[13] In SCLC the most common genetic abnormalities include loss of chromosomal material associated with inactivation of specific tumor suppressor genes.[14] Specific molecular aberrations identified in SCLC are listed in Table 116-3.

TUMOR SUPPRESSOR GENES

Mutations of the TP53 gene at 17p13.1, the most common gene abnormality in all human cancers, are found in 75% to 80% of SCLC.[13,15] Loss of heterozygosity of chromosomes 9p and 10q (the site of the PTEN gene) is present in the majority of cases.[13,16] The retinoblastoma gene *(RB1)* at 13q14.11 encodes a nuclear protein involved in cell-cycle control, and inactivating mutations of this gene are found in more than 90% of SCLC.[13,15,17]

Deletions in 3p are found in nearly all (90%) SCLC tumors and cell lines. Three tumor suppressor genes of particular interest are located in this region: Fragile histidine triad gene (*FHIT*) at 3p14.3 encoding the enzyme diadenosine triphosphate hydrolase, RAS effector homolog *(RASSF1A)* at 3p21.3 encoding a microtubule-binding protein, and *RARB* at 3p24 encoding the retinoic acid receptor β.[18–20] All three gene products are important in cell cycle control or induction of apoptosis.

ONCOGENES

Dominant oncogene abnormalities are less common in SCLC. Overexpression of myc oncogene through gene amplification is seen in approximately 25% of SCLC patients.[21,22] The myc oncogenes *c-myc, n-myc,* and *l-myc* are closely related nuclear DNA-binding phosphoproteins involved in gene regulation. In two retrospective studies, the presence of *myc* DNA amplification in tumor cell lines and *myc* family DNA amplification was associated with shortened survival in SCLC patients. In laboratory studies, transfection of *myc* into a SCLC cell line was found to be associated with faster growth, a greater cloning efficiency in soft agarose, altered cell structure, and altered histology in athymic nude mice. These findings connote a more aggressive form of SCLC in association with *myc* amplification.

In contrast to non–small-cell lung cancer (NSCLC), mutations in the EGFR and K-ras oncogenes are rare in SCLC. However, it has recently been demonstrated that histologic evolution from NSCLC to SCLC may account for some cases of acquired resistance to EGFR inhibitors. In a series of 37 cases of *EGFR*-mutant NSCLC that developed acquired resistance to EGFR tyrosine kinase inhibitors, drug resistance mechanisms included expected genetic changes such as *EGFR* T790M mutations (49% of cases) and *MET* amplification (5%). Somewhat unexpectedly, transformation to SCLC was noted in 14% of cases.[23] These cases were sensitive to standard SCLC treatments, stressing the importance of repeatedly assessing tumor histology and biology throughout the course of treatment as these may dictate needed modifications in therapy.

TABLE 116-3 Molecular Abnormalities in Small Cell Lung Cancer

Gene	Chromosome	Protein	Frequency
Fragile histidine triad (FHIT)	3p14.3	Diadenosine triphosphate hydrolase	~90%
RAS effector homolog (RASSF1A)	3p21.3	Microtubule-binding protein	~90%
Retinoic acid receptor β (RARB)	3p24	Retinoic acid receptor β	~90%
Retinoblastoma (RB1)	13q14.11	Nuclear protein involved in cell-cycle progression	~90%
TP53	17p13.1	P53: multifunctional transcription factor	75–80%
c-kit receptor	4q12	Transmembrane receptor tyrosine kinase	70%
c-myc/N-myc/L-myc (amplification)	8q24/2p24–25/1p34–35	Nuclear DNA–binding phosphoproteins	~25%
K-ras (point mutation)	12p11–12	G-protein regulator of cellular signal transduction	Rare

AUTOCRINE GROWTH PATHWAYS

SCLC has long been associated with the production of numerous peptides, including antidiuretic hormone (ADH), adrenocorticotropic hormone (ACTH), and calcitonin. The autocrine growth promotion potential of these peptides was first proposed almost 25 years ago. The classic autocrine agent in SCLC is GRP, a mammalian analog of the amphibian hormone bombesin.[24] SCLC cells produce GRP, as well as neuromedin B, which bind to one of three receptors (GRP receptor, neuromedin B receptor, and bombesin receptor subtype 3) to activate the autocrine-stimulated growth loop.

A second autocrine growth loop involves the c-kit receptor, which is found in the majority of gastrointestinal stromal tumors (GIST), as well as up to 70% of SCLC tumors.[25] The ligand stem-cell factor is produced by small cell cancers, which in turn binds to the c-kit receptor to stimulate cell growth. The tyrosine kinase inhibitor imatinib, although effective in GIST, was not shown to have any antitumor activity in two phase II trials in SCLC. Elevated levels of IGF-1 have been detected in more than 90% of SCLC tumors and cell lines, and receptors for IGF-1 are found on SCLC cell lines, suggesting autocrine growth activity.[26]

NATURAL HISTORY

The natural history of untreated SCLC is characterized by early dissemination and death. Unlike NSCLC, it is always considered a systemic disease at diagnosis, even if it appears clinically confined to the chest. Postmortem examinations performed on patients who died from other causes shortly after the "complete" surgical resection of their SCLC have demonstrated identifiable metastases in up to 70% of cases.[27] Evidence of distant spread can be found in virtually any organ system. The most common sites of involvement, however, are the liver, bone and bone marrow, and central nervous system (CNS) (Table 116-4).[28] This pattern of spread dictates how the search for metastatic disease is undertaken (see "Section Staging and Pretreatment Evaluation").

Patients with SCLC have a short life expectancy if therapy is not initiated in a timely fashion. The median survival for untreated patients is 4 to 6 months if they have disease that is apparently confined to the chest, and 5 to 9 weeks if they present with metastatic disease. With therapy, survival improves significantly (see Section "Treatment"). Chemotherapy with or without irradiation can extend median survival to an average of 14 to 20 months for those with thorax-confined disease and 7 to 10 months for those with more extensive spread. At 2 to 3 years, a consistent 10% to 25% of limited-stage (LS) patients will still be alive, although cure is not guaranteed even in these relatively long-term survivors (see Section "Late Complications"). Recent trials indicate that 2-year survival may be as high as 40% for aggressively treated LS patients. Two- to three-year survival remains under 5% for those with metastatic disease.

TABLE 116-4 Involvement of Extrathoracic Sites at Diagnosis after Pretreatment Staging Studies in Small Cell Lung Cancer

Extrathoracic Site	Patients with Finding (%)
Final stage	
Limited stage	30–40
Extensive stage	60–70
Bone	19–38
Liver	17–34
Bone marrow	17–23
Brain	0–14
Lymph nodes	7–25
Soft tissue	3–11

Staging evaluation and prognostic factors in small cell lung cancer In Aisner J, ed. Lung cancer. New York, NY; Churchill Livingstone; 1985:241–268.

STAGING AND PRETREATMENT EVALUATION

Staging a cancer defines the anatomic extent of the tumor, helps determine prognosis, and guides treatment options. The official staging for SCLC is the same as for NSCLC and utilizes the American Joint Cancer Commission staging system, which defines stage based on the extent of the primary tumor, the degree of nodal involvement, and the presence or absence of distant metastasis (TNM staging). Virtually all clinicians, however, prefer the original staging system for SCLC proposed several decades ago by the Veterans Affairs Lung Cancer Study Group as it better segregates patients into two groups with clearly different prognoses and treatment options. In this system, disease confined to one hemithorax that is able to be encompassed by a single, tolerable radiation port is considered LS.[29] This typically includes patients with hilar, mediastinal, and ipsilateral supraclavicular lymphadenopathy. There is debate regarding whether patients with contralateral hilar and supraclavicular lymphadenopathy or those with ipsilateral pleural effusion should be placed in the LS category. However, most clinical trials for LS disease exclude these patients. Any spread of disease beyond the extent described earlier is defined as extensive stage (ES) disease. A third stage ("very limited stage [VLS] disease") has been proposed by some to define those patients with small primary tumors and no identifiable regional lymphadenopathy or distant metastases, as this group of patients may be considered for surgery (see Section "Treatment"). In most modern series, the majority of patients (60%–65%) present with ES disease, with LS (30%–35%) and (<5%) making up the remainder.[2,3]

Once a diagnosis of SCLC is established the initial pretreatment evaluation should include a complete history and physical examination, and basic laboratory studies including a complete blood count (CBC), serum electrolytes, and liver and renal function tests. A serum lactate dehydrogenase (LDH) level may provide additional prognostic information (see Section "Prognostic Factors"). Current guidelines call for computed tomography scans of the chest (including the liver and adrenal glands) as initial imaging.[30,31] Ten to 18% of SCLC patients have brain involvement at presentation,[32,33] and it is therefore recommended by many that all patients with SCLC undergo imaging of the brain at diagnosis, preferably magnetic resonance imaging (MRI). Certainly, those patients with symptoms suggesting brain involvement require prompt evaluation.

Bone metastases from SCLC are also frequent at presentation. Historically, bone scan was the study of choice to evaluate those patients with bony symptoms or an elevated alkaline phosphatase suggesting possible spread of disease to the bone. More recently, fluorodeoxy glucose positron emission tomography (FDG-PET) has supplanted bone scan at many centers. SCLC is a highly metabolically active tumor, and is therefore typically quite FDG avid at both the primary and metastatic sites. Case series suggest that PET scan can improve staging accuracy in SCLC and that PET will correctly upstage as many as 19% of patients previously thought to have LS disease.[34–39] While the U.S. Centers for Medicare & Medicaid Services (CMS) does not consider SCLC an appropriate indication for PET scanning, most payors will cover this procedure in SCLC, and the National Comprehensive Cancer Network recommends PET, if available, as an initial staging study for all SCLC patients.

Another staging study of historical interest is bone marrow biopsy and aspiration. SCLC is one of a few cancers known to commonly cause bone marrow metastases and, as a result, bone marrow evaluation was standard in SCLC patients for many years. However, most patients with bone marrow involvement have significant

abnormalities on their CBC (notably leukoerythroblastosis), and exceedingly few patients have bone marrow as the only site of metastasis. Therefore, the utility of this test appears limited to those few patients with LS disease after complete radiographic staging and an abnormal CBC.

In general, with the possible exception of brain imaging to rule out occult disease, once the presence of metastatic SCLC has been established, further radiographic evaluation to identify additional sites of metastatic disease is not warranted. In that setting, subsequent evaluation should be symptom guided.

CLINICAL PRESENTATION

No aspect of the clinical presentation of SCLC distinguishes it from NSCLC or even from neoplasms metastatic to the lungs. However, the duration of symptoms of SCLC tends to be very short, due to the rapid dissemination of the disease. The typical patient is a middle-aged or elderly smoker who presents with symptoms attributable to his or her pulmonary and mediastinal disease: Cough, dyspnea, chest pain, hoarseness, and/or hemoptysis. Because of the usual endobronchial location of the tumor, patients often have accompanying postobstructive pneumonia.

Constitutional symptoms may include weakness, anorexia, weight loss, and, rarely, fever. Symptoms may also arise from distant metastases, including headache or seizures in patients with CNS disease, and abdominal or bone pain with hepatic and osseous metastases; or from regional disease with attendant superior vena cava obstruction, manifesting as facial fullness, upper extremity swelling, headache, and dysphagia. In rare instances, patients present with symptoms from a paraneoplastic syndrome. The more common of these rare presentations are inappropriate secretion of ADH (syndrome of inappropriate antidiuretic hormone secretion [SIADH]) and other causes of hyponatremia, Cushing syndrome, Lambert–Eaton syndrome, and other paraneoplastic neuropathies or neurologic disorders (see Section "Paraneoplastic Phenomena").

Physical examination may yield only the stigmata of chronic obstructive pulmonary disease, or it may demonstrate lymphadenopathy, hepatomegaly, bone tenderness, or neurologic findings. Signs of the superior vena cava syndrome include venous distention of the neck and chest wall, cyanosis, facial plethora, and upper extremity edema.

Figure 116-2 Chest radiograph of a patient with SCLC demonstrating increased right paratracheal soft tissue prominence. Note that the right paratracheal line is greater than 3 mm. *(Used with permission of Dr. Matthew J. DeVries, University of Nebraska Medical Center.)*

Radiographic studies typically demonstrate a central mass (75% of patients) with or without hilar nodal involvement (Figs. 116-2–116-4). Postobstructive atelectasis and pneumonia are very common with SCLC, but cavitation on chest radiograph suggests the alternative diagnosis of squamous cell lung cancer.

Laboratory evaluation reveals mild abnormalities of liver function (usually elevated alkaline phosphatase, and less commonly SGOT, SGPT, or bilirubin) and/or elevated LDH in about 50% of patients. Leukopenia and thrombocytopenia are unusual.

Two special situations warrant brief discussion. Organ involvement from SCLC can lead directly to failure of that organ, but SCLC may also impact organ function indirectly. For example, hepatic insufficiency from frank neoplastic involvement, based on the clinical picture of jaundice and abnormal liver function, is a well-described phenomenon and usually signals a poor outcome. If the same clinical picture is a result of extrahepatic biliary obstruction from nodal metastases, also well described in the literature, the patient has a better prognosis than one with diffuse liver replacement.[40] Horner syndrome, with ptosis, anhydrosis, facial edema, and sensory neuropathic pain and functional loss, is more commonly associated with NSCLC, but it has also been reported in patients with small cell disease. Obtaining a tissue diagnosis from an apical pulmonary mass is thus mandatory before radiotherapy or other treatment is started.

PARANEOPLASTIC PHENOMENA

Certain cancers cause various symptoms not attributable to direct tumor invasion or compression. Labeled *paraneoplastic syndromes* in the 1940s, these conditions are primarily due to tumor secretion of functional peptides and hormones (as occurs in endocrine paraneoplastic syndromes (Table 116-5)) or immune cross-reactivity between tumor and normal host tissues (as occurs in neurologic paraneoplastic syndromes (Table 116-6)). Paraneoplastic syndromes may be seen in any type of cancer but historically are most frequently associated with SCLC.

PARANEOPLASTIC ENDOCRINE SYNDROMES

Because paraneoplastic endocrine syndromes are generally due to tumor production of hormones or peptides that lead to metabolic derangements, successful treatment of the underlying tumor often

TABLE 116-5 Selected Paraneoplastic Endocrine Syndromes Occurring in Small Cell Lung Cancer

Syndrome	Presentation/Symptoms	Laboratory Values	Management/ Treatment[a]
SIADH	Gait disturbances, falls, headache, nausea, fatigue, muscle cramps, anorexia, confusion, lethargy, seizures, respiratory depression, coma	Hyponatremia Mild = serum sodium 130–134 mmol/L Moderate = serum sodium 125–129 mmol/L Severe = serum sodium less than 125 mmol/L Increased urine osmolality (>100 mOsm/kg in the context of euvolemic hyponatremia)	Fluid restriction (and encourage adequate salt and protein intake) Discontinuation of offending drugs Demeclocycline Vasopressin-receptor antagonists Conivaptan Tolvaptan Hypertonic (3%) saline **(if acute onset)**
Cushing syndrome	Muscular weakness, peripheral edema, hypertension, weight gain	Hypokalemia typically less than 3.0 mmol/L Elevated baseline serum cortisol greater than 800 nmol/L Normal to elevated midnight serum ACTH (not suppressed with dexamethasone) greater than 100 ng/L	Ketoconazole Octreotide Aminoglutethimide Metyrapone Mitotane Etomidate Mifepristone

[a] *In addition to treating the underlying malignancy.*

ACTH, adrenocorticotropic hormone; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

TABLE 116-6 Selected Paraneoplastic Neurologic Syndromes Occurring in Small Cell Lung Cancer

Syndrome	Clinical Presentation	Associated Antibodies	Additional Diagnostic Studies	Management/ Treatment
Limbic Encephalitis (LE)	Mood changes, hallucinations, memory loss, seizures, less commonly hypothalamic symptoms (hyperthermia, somnolence, endocrine dysfunction); onset over days to months	anti-Hu (ANNA-1) anti-CRMP5 (anti-CV2) anti-Ma anti-amphiphysin	**EEG** epileptic foci in temporal lobe(s); focal or generalized slow activity **FDG-PET** increased metabolism in temporal lobe(s) **MRI** hyperintensity in medial temporal lobe(s) **CSF** pleocytosis, elevated protein, elevated IgG, oligoclonal bands	IVIG Corticosteroids Plasma exchange Cyclophosphamide Rituximab
Paraneoplastic Cerebellar Degeneration (PCD)	Ataxia, diplopia, dysphagia/ dysarthria; prodrome of dizziness, nausea, vomiting	anti-Hu (ANNA-1) anti-Yo anti-CRMP5 (anti-CV2) anti-Ma anti-Tr anti-Ri anti-VGCC anti-mGluR1	**FDG-PET** increased metabolism (early stage) and then decreased metabolism (late stage) in cerebellum **MRI** cerebellar atrophy (late stage)	IVIG Corticosteroids Plasma exchange Cyclophosphamide Rituximab
Lambert–Eaton Myasthenic Syndrome (LEMS)	Lower extremity proximal muscle weakness, fatigue, diaphragmatic weakness, bulbar symptoms (usually milder than in myasthenia gravis); later in course, autonomic symptoms (ptosis, impotence, dry mouth) in most patients	anti-VGCC (P/Q type)	**EMG** low compound muscle action potential amplitude; decremental response with low-rate stimulation but incremental response with high-rate stimulation	3,4-Diaminopyridine (DAP) Guanidine Pyridostigmine Corticosteroids Azathioprine IVIG Plasma exchange
Subacute (Peripheral) Sensory Neuropathy	Paresthesias/pain (typically upper extremities before lower) followed by ataxia; multifocal/asymmetric distribution; all sensory modalities decreased but especially deep sensation/pseudoathetosis of hands; deep tendon reflexes decreased/absent; onset over weeks to months	anti-Hu (ANNA-1) anti-CRMP5 (anti-CV2) anti-amphiphysin	**NCS** reduced/absent sensory nerve action potentials **CSF** pleocytosis, high IgG, oligoclonal bands	Corticosteroids Cyclophosphamide IVIG Plasma exchange
Autonomic Neuropathy	Panautonomic neuropathy, often subacute (weeks) onset, involving sympathetic, parasympathetic, and enteric systems: Orthostatic hypotension, GI dysfunction, dry eyes/mouth, bowel/ bladder dysfunction, altered pupillary light reflexes, loss of sinus arrhythmia *Chronic Gastrointestinal Pseudoobstruction* *(CGP):* Constipation, nausea/vomiting, dysphagia, weight loss, abdominal distension	anti-Hu (ANNA-1) anti-CV2 (CRMP5) anti-nAchR anti-amphiphysin	**Abdominal x-ray/barium studies/CT** GI dilatation but no mechanical obstruction (for CGP) **Esophageal manometry** achalasia or spasms (for CGP)	*For orthostatic hypotension:* Water, salt intake Fludrocortisone Midodrine Caffeine *For pseudoobstruction:* Neostigmine

ANNA, antineuronal nuclear antibody; CRMP, Collapsin Response Mediator Proteins; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; EMG, electromyography; FDG-PET, fluorodeoxyglucose positron emission tomography; IVIG, intravenous immunoglobulin; mGluR1, metabotropic glutamate receptor subtype 1; MRI, magnetic resonance imaging; nAchR, nicotinic acetylcholine receptor; NCS, nerve conduction study; VGCC , voltage-gated calcium channel.

improves these conditions. These disorders are typically detected after a cancer diagnosis. Development of a paraneoplastic endocrine syndrome does not necessarily correlate with cancer stage or prognosis.[41]

Syndrome of Inappropriate Antidiuretic Hormone Secretion

SIADH is characterized by hypo-osmotic, euvolemic hyponatremia. Although it affects only 1% to 2% of all patients with cancer, SCLC accounts for most of these cases, with approximately 10% to 45% of all patients with SCLC developing SIADH.[42] In SIADH, tumor cells produce ADH (also known as arginine vasopressin or vasopressin) and atrial natriuretic peptide.[43,44]

The symptoms of SIADH depend on the degree and rapidity of onset of hyponatremia. Mild symptoms include headache, memory difficulties, and weakness. More severe symptoms (altered mental status, seizures, coma, respiratory collapse, death) may be seen with

serum sodium levels less than 125 mEq/L, especially if developing within 48 hours.[45] If hyponatremia develops over a longer time period, neurologic complications may not develop.

The time course of hyponatremia also impacts treatment. With symptomatic hyponatremia developing within 48 hours, the serum sodium level may be raised 1 to 2 mEq/L/h and usually no more than 8 to 10 mEq/L in the first 24 hours. With chronic hyponatremia, due to the brain generating endogenous osmoles to minimize intracellular swelling, rapid correction may lead to water egress, brain dehydration, and *central pontine and extrapontine myelinolysis*. This condition, which may be irreversible, features lethargy, dysarthria, spastic quadriparesis, and pseudobulbar palsy. Accordingly, a correction goal of 0.5 to 1.0 mEq/L is recommended for these patients.[42,45]

Successful treatment of the underlying tumor (which is frequently attainable given the chemosensitivity of SCLC) may normalize sodium levels in days to weeks.[42] In the short-term, fluid restriction (usually <1000 mL/d) along with adequate dietary protein and sodium (with the use of salt tablets if needed) may be implemented. In many instances, administration of standard intravenous fluids may exacerbate SIADH. Normal (0.9%) saline has an osmolality of 308 mOsm/kg, which is often less than urine osmolality in SIADH. Thus, normal saline infusion will result in free water retention and worsening of the hyponatremia. By contrast, hypertonic (3%) saline has an osmolality of 1026 mOsm/kg, which almost always exceeds that of the urine. The primary pharmacologic treatment of SIADH is demeclocycline (usually given at a dose of 300–600 mg per day, but can be increased to 1200 mg per day), an antibacterial agent that interferes with the renal response to ADH. In patients on demeclocycline responding to chemotherapy, careful monitoring is required to ensure against overcorrection and resulting hypernatremia.

Cushing Syndrome

Approximately 5% to 10% of cases of Cushing syndrome (hypercortisolism) are paraneoplastic, and 50% to 60% of these paraneoplastic cases occur with neuroendocrine lung tumors (SCLC and bronchial carcinoids).[46] Paraneoplastic Cushing syndrome is due to tumor secretion of ACTH or corticotropin-releasing factor (CRF). In turn, this results in adrenocortical hyperplasia and release of cortisol. Clinical features include hypertension, hypokalemic metabolic alkalosis, hyperglycemia, edema, and muscle weakness. Compared to Cushing disease (i.e., hypercortisolism due to a pituitary adenoma) onset is often more abrupt and weight gain with centripetal fat distribution is less common.

Ectopic (i.e., paraneoplastic) Cushing syndrome is distinguished from a pituitary source by failure to respond to high-dose dexamethasone suppression. For this test, 2 mg of dexamethasone is administered orally every 6 hours for 72 hours. Levels of urine 17-hydroxycorticosteroid (an inactive product of cortisol metabolism) are measured at 9 am and midnight of days 2 and 3 of the test. The test is considered positive if 17-hydroxycorticosteroid levels are reduced by 50% or more. The primary tumor is then located using CT, MRI, or somatostatin receptor scintigraphy (i.e., octreotide scan). Due to the distinct biochemical profile of paraneoplastic Cushing syndrome, inferior petrosal sinus sampling (to rule out a pituitary etiology) is generally not required.[46]

Therapy includes treatment of the underlying tumor and agents that inhibit steroid production. These include ketoconazole, mitotane, metyrapone, and aminoglutethimide. Ketoconazole is usually the best tolerated of these options, despite nausea, hepatotoxicity, and potential for drug–drug interactions. Supportive care includes antihypertensive agents and diuretics, with careful monitoring of serum potassium. Adrenalectomy may be considered when medical therapy is not successful.

Other Paraneoplastic Endocrine Syndromes

Although paraneoplastic hypercalcemia can be seen with several malignancies (including squamous NSCLC, breast, renal, and lymphoma), it is extremely unusual in patients with SCLC, even among cases with skeletal involvement. Similarly, tumor-associated hypoglycemia, a rare paraneoplastic phenomenon occurring most commonly in sarcomas, mesothelioma, and gastrointestinal cancers, is also unusual in SCLC.

PARANEOPLASTIC NEUROLOGIC SYNDROMES

Immune cross-reactivity between tumor cells and components of the nervous system gives rise to paraneoplastic neurologic syndromes. *Onconeural antibodies* are produced by a patient in response to a developing cancer. Due to antigenic similarity, these onconeural antibodies and associated T lymphocytes inadvertently attack the nervous system as well.[47] Although paraneoplastic neurologic syndromes occur in less than 1% of cancer patients overall, they are seen in up to 5% of patients with SCLC and up to 10% of patients with lymphoma or myeloma.[48] Overrepresented malignancies either produce neuroendocrine proteins (e.g., SCLC), contain neuronal components (e.g., teratomas), involve immunoregulatory organs (e.g., thymomas), or affect immunoglobulin production (e.g., lymphoma, myeloma). The potential for immune cross-reactivity with SCLC is apparent through its immunophenotypic profile. CD56, which is positive in the majority of SCLC cases, is also known as NCAM.

In direct contrast to paraneoplastic endocrine syndromes, over 80% of cases of paraneoplastic neurologic syndromes are detected prior to a cancer diagnosis.[41] Because most patients diagnosed with an apparent paraneoplastic neurologic syndrome will not have known cancer at the time, screening for an underlying tumor is indicated. This process includes complete history and physical examination, as well as imaging studies. If chest, abdomen, and pelvic CT scans are negative, FDG-PET or combined PET-CT may identify the underlying tumor, particularly in the case of an early central SCLC, which may be difficult to identify anatomically amid surrounding mediastinal structures.[49] Occasionally, the clinical syndrome and associated antibodies may sufficiently suggest a particular cancer to prompt disease-specific imaging modalities such as mammography. If no malignancy is identified, it is reasonable to consider clinical and radiographic surveillance every 3 to 6 months for 2 to 3 years. Beyond that time, the likelihood of a subsequent cancer diagnosis decreases substantially.[50]

Because tumor cells do not directly produce the causative agents (i.e., onconeural antibodies) and because these antibodies may cause permanent neuronal damage, successful cancer treatment does not necessarily result in neurologic improvement. Immunosuppressive therapy – including corticosteroids, other agents, intravenous gamma globulin, and plasma exchange – is a principal component of therapy.

Establishing a diagnosis of a paraneoplastic neurologic syndrome may require imaging, serologies, electroencephalography, electromyography, nerve conduction studies, and cerebrospinal fluid (CSF) analysis for signs of inflammation. Onconeural antibodies lack both sensitivity and specificity, as up to 30% of patients with apparent paraneoplastic neurologic syndromes do not have detectable antibodies and well-defined onconeural antibodies may be detected in individuals with no neurologic illness.[51]

The impact of these conditions on prognosis is complex and multifactorial. Development of a paraneoplastic neurologic syndrome may result in diagnosis of a cancer at an otherwise clinically occult and highly treatable stage. Conversely, the syndrome itself may cause substantial morbidity, independent of the underlying malignancy. Finally, onconeural antibodies may indicate an antitumor immunologic effect; patients with SCLC who have anti-Hu antibodies are more likely to have complete response to therapy and have longer survival than patients without anti-Hu antibodies.[52] While such observations raise the question whether treatment of paraneoplastic neurologic syndromes with immune modulation could lead to cancer progression, this hypothetical scenario has not been reported clinically.[41]

In SCLC, well-described paraneoplastic neurologic syndromes include limbic encephalitis (LE), cerebellar degeneration,

Lambert–Eaton myasthenic syndrome (LEMS), subacute (peripheral) sensory neuropathy, and autonomic neuropathy.

Limbic Encephalitis

LE features mood changes, hallucinations, memory loss, seizures, and less commonly hypothalamic symptoms (hyperthermia, somnolence, endocrine dysfunction), with onset over days to months. In SCLC, which accounts for 40% to 50% of LE cases, the associated antibody is usually anti-Hu (also known as antineuronal nuclear antibody-1 [ANNA-1]). Characteristic findings may also be seen on electroencephalogram, MRI, and CSF analysis.[53]

Paraneoplastic Cerebellar Degeneration

Paraneoplastic cerebellar degeneration (PCD), manifesting with ataxia, dysarthria, and diplopia, is seen with SCLC (incidence approximately 2%), as well as with gynecologic malignancies and lymphomas. Antibodies that react against cytoplasmic proteins of cerebellar Purkinje cells are often found in these patients. One such antibody, anti-Yo, attacks the cdr2 proteins in the Purkinje cells. Treatment may include steroids, plasmapheresis, and chemotherapy.

Lambert–Eaton Myasthenic Syndrome

LEMS is a result of IgG autoantibodies directed against presynaptic P/Q-type voltage-gated calcium channels. These antibodies are estimated to occur in 5% of patients with SCLC. Clinically, the syndrome presents with proximal muscle weakness, usually in the lower extremities, occasional autonomic dysfunction, and rarely with cranial nerve symptoms. As contrasted with patients with myasthenia gravis, strength *improves* with serial effort, and the weakness associated with LEMS improves over the course of the day. Plasma exchange and intravenous immunoglobulin can provide short-term benefit, whereas 3,4-diaminopyridine (which enhances the release of acetylcholine from presynaptic terminals), prednisone, and azathioprine can provide limited long-term benefit. Some patients who respond to chemotherapy have resolution of the neurologic abnormalities.

Subacute (Peripheral) Sensory Neuropathy

With onset over weeks to months, this syndrome initially features paresthesias and pain (typically multifocal, asymmetric, with upper extremities involved before lower), followed by ataxia. Nerve conduction studies demonstrate reduced or absent sensory nerve action potentials. A number of onconeural antibodies, including Anti-Hu, may be seen. Lung tumors (principally SCLC) account for 70% to 80% of cases.

Autonomic Neuropathy

Paraneoplastic autonomic neuropathy typically has a subacute onset over weeks and may involve sympathetic, parasympathetic, and enteric systems.[54,55] Symptoms include orthostatic hypotension, gastrointestinal dysfunction (pseudoobstruction), and dry eyes and mouth. A number of onconeural antibodies, including anti-Hu and anti-CRMP5 (anti-CV2), may be detected.[56] Other findings suggestive of this condition are loss of sinus arrhythmia (naturally occurring variation in heart rate that occurs during a breathing cycle) on EKG, GI dilatation without obstruction on abdominal imaging, and achalasia or spasms on esophageal manometry. Supportive care may include fludrocortisones, midodrine, caffeine, and neostigmine (for pseudoobstruction).[57]

EXTRAPULMONARY SMALL CELL CARCINOMA

The knowledge that small cell cancers can arise from tissues other than the lungs has existed since 1930.[58] Extrapulmonary small cell cancer (EPSCC) remains relatively rare, accounting for <5% of diagnosed small cell cancers.[59] EPSCC can arise from a variety of primary sites, including the female genital tract (commonly the uterine cervix), the genitourinary organs (primarily bladder and prostate), the head and neck, the gastrointestinal tract, and breast.[60,61]

Staging of EPSCC is similar to that of SCLC. LS is defined as disease confined to the primary site and regional lymph nodes. Any spread beyond the regional lymph nodes is ES disease. Most authorities would perform the same staging evaluation on these patients as in those with SCLC.

Due to the rarity of this entity, the optimal treatment of EPSCC is not clearly defined. Most case series are from single institutions and include EPSCC from a variety of primary sites. In general, the treatment approaches have been adapted from those utilized in SCLC. Surgery has been shown to be curative in selected patients with organ-confined disease. Unfortunately, as with SCLC, EPSCC is often characterized by early metastasis and a fairly aggressive course. Combined chemotherapy and radiation can be utilized for LS disease. ES EPSCC responds to platinum-based chemotherapies in approximately 75% of the cases, but these responses are typically short-lived. In a recent large retrospective single institution review from Australia, those EPSCC patients with LS disease had a median survival of 1.4 years and a 1-year survival rate of 63%, while those with ES stage disease had median and 1-year survivals of 0.7 years and 24%, respectively.[60] In their cohort, patients with a primary lesion in the female genital tract or the head and neck had superior outcomes when compared to other primary sites.

PROGNOSTIC FACTORS

A variety of pretreatment factors have been reported as having value in predicting therapeutic outcomes for patients with SCLC. Since the aggressiveness of therapy may depend on this perceived outcome, it is important to determine before treatment how a patient is *likely* to do. The strongest and most consistent prognosticators from nearly all studies have been stage of disease (limited vs. extensive) and performance status at presentation. The importance of stage has already been mentioned. ES patients have a lower chance of achieving a complete response to chemotherapy and a much shorter survival than those with LS disease. The performance status or ability of the patient to carry out normal daily activities has a profound effect both on the ability to tolerate chemotherapy and the efficacy of the drugs that are administered (Table 116-7). In general, SCLC patients with a poor performance status have a lower chance of response to chemotherapy, a higher probability of experiencing clinical toxicity, and a worse overall survival.[62–64] However, as opposed to NSCLC patients, poor performance status does not automatically exclude SCLC patients from receiving aggressive treatment. The occasional SCLC patient with significant functional impairment can experience improvement with chemotherapy.

The impact of gender on prognosis is debated. Some, but not all, studies have found that female gender is an independent predictor of better survival in SCLC.[62–65] In several of these series, the improved prognosis seen in women was limited to those with LS disease and those of younger age (<60 years old).[64,65]

The only serum marker consistently shown to be of prognostic value in SCLC is the serum concentration of LDH. This enzyme is known to be a nonspecific marker of cell turnover and pulmonary inflammation. A baseline (pretreatment) serum LDH is elevated in 33% to 57% of all SCLC patients and in as many as 85% of patients with ES disease. In most SCLC series, a normal baseline LDH is an independent predictor of better outcome, with hazard ratios of 1.6 to 1.9 for overall survival.[62,64]

The continued use of tobacco is also a potential adverse prognostic factor. Videtic et al.[66] evaluated the impact of continued smoking in patients with LS SCLC. In a retrospective review of 215 patients who received curative intent chemotherapy and radiation for LS disease from 1989 to 1999 patients who continued to smoke during treatment had a significantly inferior survival to those who quit smoking (median survivals 13.6 months and 15.8 months; 5-year survival rates of 4% and 8.9%, respectively). Though one might assume that those patients who continued to smoke tolerated treatment more poorly, the authors found no statistical differences between the groups in the numbers of patients that required breaks in treatment due to toxicity.

TABLE 116-7 Performance Status Scales

KARNOFSKY			ECOG	
Able to carry on normal activity and to work; no special care needed	100	Normal no complaints; no evidence of disease	0	Fully active, able to carry on all predisease performance without restriction
	90	Able to carry on normal activity; minor signs or symptoms of disease	1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work
	80	Normal activity with effort; some signs or symptoms of disease		
Unable to work; able to live at home and care for most personal needs, varying amount of assistance needed	70	Cares for self; unable to carry on normal activity or to do active work	2	Ambulatory and capable of all self-care but unable to carry out any work activities. Up and about more than 50% of waking hours
	60	Requires occasional assistance, but is able to care for most of his personal needs		
	50	Requires considerable assistance and frequent medical care	3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours
Unable to care for self; requires equivalent of institutional or hospital care; disease may be progressing rapidly	40	Disabled; requires special care and assistance		
	30	Severely disabled; hospital admission is indicated although death not imminent	4	Completely disabled. Cannot carry on any self-care. Totally confined to bed or chair
	20	Very sick; hospital admission necessary; active supportive treatment necessary		
	10	Moribund; fatal processes progressing rapidly		
	0	Dead	5	Dead

There are several possible explanations for these results. Nicotine has been shown to serve as a growth factor for some SCLC cell lines.[67] Smokers often have increased carboxyhemoglobin levels with resultant lower oxygen saturations than nonsmokers, and this may reduce the antitumor effects of radiation, which are at least partially oxygen dependent.[68–70] Lastly, it is well established that SCLC patients who survive are at increased risk of developing additional smoking-related malignancies, as well as other smoking-related illnesses. It is likely that continued smoking further increases these risks. Though this retrospective study has limitations, it suggests a compelling rationale for aggressive attempts at smoking cessation in this population.

TREATMENT

The roles of surgery, chemotherapy, and radiation in the treatment of SCLC are considered below. In addition, special circumstances, including treatment in the elderly and in those with poor performance status, are discussed.

■ SURGERY

Surgery was abandoned as a standard treatment modality for the majority of patients with SCLC in the 1970s following the publication of the results of a trial by the British Research Medical Council randomizing patients with LS disease to single modality treatment with radiation or surgery. Though outcomes were poor in both treatment arms, the 5- and 10-year survivals were significantly inferior with surgery.[71] A subsequent Lung Cancer Study Group trial also failed to demonstrate a benefit to surgery when compared with radiation in 340 LS patients following induction chemotherapy.[72] A legitimate criticism of these trials is that patients were inadequately staged when compared with modern standards. In addition, in both trials, only a small fraction of eligible patients had clinical stage I and II disease, which are the groups theoretically most likely to benefit from resection.

Over the past decade, there has been a renewed interest in surgery as a potential treatment modality for highly selected patients with very limited stage (VLS) SCLC. A number of primarily retrospective single institution series have reported outcomes with surgery followed by adjuvant chemotherapy (and sometimes radiation) in patients with LS SCLC. In patients with pathologic stage I disease, the ~5-year survival ranges from 40% to 86%.[73–75] In addition, analyses of the SEER database and the NCDB have shown improved outcomes for those patients with VLS SCLC that are treated with surgery.[3,76,77] Unfortunately, interpretation of these retrospective series and database reviews is hampered by inherent selection bias as well as by the heterogeneity of adjuvant treatment (chemotherapy and radiation) utilized. Ultimately, only randomized trials comparing surgery followed by adjuvant chemotherapy to definitive chemotherapy and radiation in SCLC patients with VLS disease will clearly define the role of surgery in this population.

Current guidelines suggest that surgical resection should be considered only in patients with clinical stage I (T1 or T2, N0, M0) SCLC and with adequate cardiac and pulmonary function to tolerate a thoracotomy. Patients should undergo rigorous staging, including invasive evaluation for mediastinal nodal disease as well as extensive radiographic assessment for distant metastases. Following complete resection, it is recommended that patients without nodal metastases receive adjuvant chemotherapy and that those with nodal metastases receive concurrent chemotherapy and radiation. Prophylactic cranial irradiation (PCI) can also be considered in selected patients (see below). At most centers, fewer than 5% of SCLC patients will be considered candidates for a surgical approach.[73]

■ CHEMOTHERAPY

Chemotherapy for SCLC can be considered with regard to first-line and second-line regimens.

First-Line Chemotherapy

In contrast to NSCLC, SCLC is classically associated with exquisite chemosensitivity, which may reflect its rapid doubling time and high growth fraction. In reality, the difference in treatment outcomes is modest with comparable median survivals in SCLC and NSCLC following chemotherapy for metastatic disease. Numerous chemotherapeutic agents have demonstrated activity in SCLC (Table 116-8). Untreated, patients with SCLC rarely survive more than a few months. Chemotherapy markedly prolongs survival compared to best supportive care.[78] In LS disease, chemotherapy combined with thoracic

TABLE 116-8 Chemotherapeutic Agents with Activity in Small Cell Lung Cancer

Platinum compounds (cisplatin, carboplatin)
Podophyllotoxins (etoposide, teniposide)
Camptothecins (irinotecan, topotecan)
Alkylating agents (ifosfamide, cyclophosphamide)
Anthracyclines (doxorubicin, epirubicin, amrubicin)
Taxanes (paclitaxel, docetaxel)
Vinca alkaloids (vincristine, vinorelbine)
Nitrosoureas (lomustine [CCNU])
Antimetabolites (methotrexate, gemcitabine)

radiation achieves a response in 80% to 90% of patients, and a complete response in the range of 40% to 60%. In LS disease, median survival in treated patients is 15 to 20 months, with 5-year survival rates of 10% to 13%. In ES disease, the response rate is 60% to 80%, with a complete response rate around 15% to 35%. The median survival for ES patients treated with chemotherapy remains 7 to 9 months, with few long-term survivors. Patients with bulky or ES disease may be considered at risk for tumor lysis syndrome, although this event is quite rare in clinical practice. Prophylaxis against this complication, which generally includes hydration and allopurinol, may be considered.[79] It should also be noted that systemic chemotherapy frequently yields intracranial responses in patients with brain metastases, with response rates ranging from 27% to 85%.[80,81]

The earliest treatments for SCLC included alkylating agents, such as nitrogen mustard and subsequently cyclophosphamide, given as monotherapy. As responses to single agents were rare, the focus changed to combinations of drugs, each with independent activity against SCLC. When given in combination, these drugs had synergistic activity, and lowered the likelihood of complete tumor resistance. Until the mid-1980s the combination of cyclophosphamide, doxorubicin (Adriamycin), and vincristine (CAV) was commonly used as first-line therapy. For the past three decades, platinum-based regimens have become the most frequently used combinations. A meta-analysis of 19 randomized trials encompassing over 4000 cases demonstrated an increase in response rates and decrease in risk of death for patients receiving cisplatin-containing chemotherapy.[82]

Currently, the two-drug regimen of cisplatin and etoposide (PE) is considered the standard of care for SCLC chemotherapy. In randomized trials, this combination appears to be at least as effective as CAV and has less toxicity.[83,84] The PE regimen is typically given over 3 days (cisplatin on day 1, etoposide on days 1–3) every 3 weeks for four to six cycles. Modifications to the PE regimen have included the substitution of carboplatin for cisplatin, replacing etoposide (a topoisomerase II inhibitor) with irinotecan or topotecan (topoisomerase I inhibitors), adding other agents, increasing dose intensity, and prolonging the duration of chemotherapy.

Carboplatin has a more favorable toxicity profile than cisplatin, with less nephrotoxicity, ototoxicity, neurotoxicity, and emetogenicity. Because pre- and posthydration are not required, its administration is also more convenient (typically 45 minutes for carboplatin vs. 4–6 hours for cisplatin, including hydration). In a randomized trial comparing the two agents, cisplatin demonstrated slightly higher overall and complete response rates than did carboplatin: Overall response 64% versus 50%; complete response 16% versus 10%. However, there was no significant difference in overall survival.[85] Based on a more favorable toxicity profile, most clinicians in the United States employ carboplatin–etoposide for the treatment of ES SCLC, with cisplatin–etoposide preferred for the treatment of LS SCLC due to the possibility of a higher response rate.

Cisplatin plus irinotecan has been compared to cisplatin plus etoposide in a number of clinical trials. In a Japanese study, the irinotecan-containing arm demonstrated a significantly higher response rate (84% vs. 68%), longer median survival (12.8 months vs. 9.4 months), and higher 2-year survival rate (19.5% vs. 5.2%).[86] However, three larger studies performed in Western populations did not confirm these findings, raising the possibility of pharmacogenomic differences between the populations.[87–89]

Three- and four-drug regimens, in which agents such as paclitaxel, ifosfamide, cyclophosphamide, and epirubicin are added to PE have yielded mixed results. Some studies have demonstrated higher response rates and modest prolongation of survival, but often at the cost of increased toxicity, including higher rates of treatment-related mortality in some instances.[90–92] Administration of non–cross-resistant regimens such as PE and CAV in alternating or sequential fashion has not consistently demonstrated a survival benefit.[93] Several studies have explored increasing chemotherapy dose intensity via dose escalation, shortening the interval between cycles, and providing hematopoietic support through growth factor administration or stem cell transplantation.[94–96] None of these approaches has demonstrated consistent benefit.

Maintenance chemotherapy, which has recently emerged as a new standard of care for advanced NSCLC, has also been studied in SCLC. In these trials, patients with nonprogressing disease after four cycles of combination induction therapy immediately proceed to maintenance monotherapy with agents such as topotecan or etoposide.[97,98] Individual trials have not demonstrated a significant increase in overall survival. Although a meta-analysis has suggested a modest survival advantage,[99] few if any oncologists employ this approach in the management of SCLC.

Based on the extant literature, it appears the optimal therapy for a majority of SCLC patients is PE with the addition of thoracic radiotherapy for those with LS disease (vide infra). Treatment beyond four to six cycles is unwarranted in the first-line setting. There is little support for the use of dose intensification or so-called "dose dense" therapy as a course of routine treatment. Furthermore, the need for expensive supportive care drugs such as colony-stimulating factors or erythropoietin is greatly diminished if one uses EP at standard dosing.

Second-Line Chemotherapy

Although the majority of SCLC patients treated with first-line chemotherapy demonstrate tumor shrinkage, most eventually relapse. Response to first-line therapy tends to be brief, with median duration 6 to 8 months. Along with performance status and tumor extent (i.e., limited vs. extensive), the time to relapse after first-line therapy is among the most important prognostic factors in SCLC.[100] The timing of relapse also has implications when considering further treatment options. Patients with disease progression can be categorized as *sensitive relapse* (tumor progression >90 days after last day of initial treatment), *resistant relapse* (tumor progression ≤90 days after last day of initial treatment), or *refractory* (tumor progression during initial therapy or unresponsiveness to initial therapy). For patients with sensitive relapse, response rates to second-line chemotherapy are 30% to 40%, and median survival is approximately 6 months. For those with resistant relapse or refractory disease, responses occur in less than 10% of cases.

In the United States, the topoisomerase I inhibitor topotecan is currently the only drug FDA approved for second-line treatment. Oral and intravenous topotecan formulations used as a single agent exhibit response rates of 11% to 37%.[101–103] Modest response rates have also been demonstrated with the use of single agents such as irinotecan, paclitaxel, docetaxel, oral etoposide, vinorelbine, gemcitabine, and amrubicin. These responses are rarely durable.

While molecularly targeted therapies (namely monoclonal antibodies and small molecule inhibitors) now have an established role in the treatment of NSCLC, these agents have demonstrated little activity against SCLC. Because c-Kit is frequently overexpressed in

SCLC, the c-Kit inhibitor imatinib has been studied in SCLC but has not demonstrated a response rate or survival benefit, even in populations selected according to tumor c-Kit status.[104,105]

Antiangiogenic agents such as the antivascular endothelial growth factor (VEGF) monoclonal antibody bevacizumab – which is approved for nonsquamous NSCLC – have also been evaluated in SCLC. While efficacy data were promising in LS SCLC, concerns emerged over the possibility of increased rates of tracheoesophageal fistula formation.[106] For ES SCLC, the combination of PE plus bevacizumab yielded a response rate of 64%, median progression-free survival of 4.7 months, and median overall survival of 10.9 months.[107] Bcl-2, an antiapoptotic protein found in high concentrations in SCLC cell lines and tumors, has been targeted with the antisense nucleotide oblimersen. Despite extensive preclinical data supporting this approach, in a phase II trial of carboplatin–etoposide plus oblimersen or placebo, outcomes were worse with the addition of oblimersen (1-year survival 24% vs. 47%).[108]

■ RADIATION THERAPY

The role of radiation in treatment of SCLC may be considered with respect to thoracic radiation and prophylactic cranial irradiation.

Thoracic Radiation Therapy

SCLC is a malignancy that is sensitive to radiation. Thoracic radiation therapy (TRT) as a single modality results in an objective tumor response rate of 75% in LS disease, and may cure as many as 5% of these patients.[71] Initial clinical trials combining TRT with chemotherapy yielded mixed results. For the most part, these early trials demonstrated a decrease in local recurrence but no clear survival benefit. However, two meta-analyses published in 1992 reported a statistically significant 5% improvement in overall survival with the addition of radiation to chemotherapy in SCLC patients with LS disease.[109,110] These reports established concurrent chemotherapy and radiation as the standard of care for fit patients with LS SCLC. Significant questions remained regarding the optimal timing, dose, and fractionation of radiation. A number of trials have evaluated early (typically <30 days after initiation of chemotherapy) versus late radiation and have yielded conflicting results. Both a subsequent meta-analysis and systematic review of the available data concluded that early radiation resulted in a small, but significant, improvement in overall survival and have established early TRT as the preferred approach for patients with LS disease.[111,112]

The optimal fractionation and dose of TRT are also unknown. The Eastern Cooperative Oncology Group conducted a randomized trial in LS SCLC patients comparing twice-daily TRT to 45 Gray (Gy) with the prior standard of once-daily TRT to 45 Gy. Both treatment arms received standard EP chemotherapy. They reported a significantly improved median (23 vs. 19 months) and 5-year (27% vs. 11%) survival favoring twice-daily TRT.[113] Despite these results, this strategy has not been widely adopted, presumably due to the inconvenience of administering twice-daily TRT. Many experts advocate once-daily TRT to 60 to 70 Gy, a radiobiologic dose that is similar to 45 Gy administered twice daily, although there are not yet data to definitively validate this approach.

Radiation plays primarily a palliative role in ES disease, and can be used for symptomatic control in bony, pulmonary, and brain metastases. One randomized trial from Europe evaluated the addition of TRT to patients with ES disease and reported an improvement in median overall survival from 11 to 17 months favoring those who received TRT.[114] In this study, patients with ES disease who experienced a complete response at all distant metastatic sites after three cycles of chemotherapy were randomized to TRT and continued chemotherapy or chemotherapy alone. However, the results of this trial are inconsistent with multiple other studies that failed to demonstrate a survival benefit with TRT. Nonetheless, ongoing trials are attempting to confirm a benefit to TRT in highly selected ES patients with an excellent response to chemotherapy.

Prophylactic Cranial Irradiation

As detailed earlier, the brain is a frequent site of metastatic spread in SCLC. Ten percent to 18% of patients have brain involvement at presentation, and 60% to 80% of SCLC patients who survive at least 2 years will develop brain metastases.[32,33,115] The prevailing assumption is that micrometastases in the brain are relatively protected from systemic chemotherapy by the blood–brain barrier. Given these facts, a number of randomized trials evaluated PCI in LS SCLC patients who had a complete or near-complete response with chemotherapy and TRT. These studies reproducibly showed significant reductions in the incidence of brain metastases with PCI but had conflicting results regarding the impact of PCI on overall survival. In 1999, an individual patient data meta-analysis of all available randomized trials reported a 5.4% increase in overall survival at 3 years (15.3% vs. 20.7%) favoring PCI. PCI also reduced the cumulative risk of brain metastases at 3 years from 58.6% to 33.3%.[116]

Until recently, the consensus opinion was that patients with ES disease were not likely to benefit from PCI. Given the poor prognosis in ES patients and the relatively limited ability to control their generally widespread metastatic disease, it was presumed that they would succumb to their systemic disease prior to occult micrometastatic disease in the brain producing a significant clinical impact. However, a trial from Europe has challenged that assumption. Patients with ES disease who experienced at least a partial response to chemotherapy were randomized to PCI or observation. The primary end point, symptomatic brain metastases, was reduced from 41.3% in the observation arm to 16.8% with PCI. Surprisingly, both median survival (6.7 months vs. 5.4 months) and 1-year survival (27.1% and 13.3%) were significantly improved with PCI.[117] In short-term quality-of-life analyses, overall functioning was similar between the two groups, but fatigue and hair loss were more frequent with PCI.

Current guidelines recommend consideration of PCI for all LS patients with a good performance status who have attained a complete or near-complete response after chemotherapy and radiation. In addition, fit ES patients whose disease responds to initial chemotherapy are also candidates for PCI. Concern has been raised about long-term neurocognitive impairment from PCI, which includes potential effects on communication and memory that may be dose dependent.[118,119] Therefore, before undergoing PCI, patients should be counseled regarding the expected risks and benefits of this intervention.

■ TREATMENT IN THE ELDERLY AND PATIENTS WITH A POOR PERFORMANCE STATUS

In most patients with metastatic solid tumors and a poor performance status, chemotherapy is felt to be of limited benefit given the high likelihood of severe toxicity and the low chance of a significant durable tumor response. As noted earlier, given the relative chemosensitivity of SCLC, an impaired performance status does not necessarily preclude treatment. Some SCLC patients with functional impairment can experience significant tumor response and resultant modest improvements in their performance status after treatment with chemotherapy.

Similarly, age should not be the sole criterion by which treatment decisions in SCLC are based. In recent series, the median age at diagnosis in SCLC is >65 years and approximately 40% of patients are ≥70 years.[3] Clearly, elderly (typically defined as >70 years old) patients with SCLC will be encountered frequently in clinical practice. Treatment of these patients is complicated by underlying comorbidities as well as decreased organ function that may lead to poor tolerance of treatment. Unfortunately, the elderly are typically underrepresented in clinical trials in SCLC and therefore there is little definitive prospective data on the appropriate management of this group. The available information suggests that elderly patients who are able to tolerate standard treatment for SCLC fair as well as their younger counterparts.[120] In addition, prospective randomized trials of "less intensive treatment" in those felt to be at risk for excess

toxicity from standard therapy found inferior survival and palliation on the "less intensive" treatment arms.[121] Current recommendations are to consider comorbidities and functional capacity, rather than age alone, when making treatment recommendations for these patients.

LATE COMPLICATIONS

The treatment of SCLC can cause more morbidity than the neoplasm itself. Both radiotherapy and chemotherapy cause side effects specific to the agent used. Irradiation can have early (esophagitis, pneumonitis, superficial skin burns) and late (pulmonary fibrosis, late cardiac disease, myelitis) toxicities. Chemotherapy toxicities depend on the specific regimen used, but they generally include alopecia, nausea and vomiting, and myelosuppression. Bone marrow suppression can lead to life-threatening bleeding episodes (from thrombocytopenia), but more commonly is associated with neutropenic fevers, and occasionally fatal infections. Published series have demonstrated that episodes of febrile neutropenia occur in roughly 30% of treated patients, documented infection in 5% to 15%, and fatal infection in 7%. Prevention of infection in patients treated with chemotherapy with or without irradiation has received significant attention. Measures have included prophylactic use of antibiotics and granulocyte colony-stimulating factor (GCSF). Recently, a large randomized trial showed that GCSF in addition to chemotherapy led to a reduction of the number of episodes of neutropenic fever and documented infections. Many oncologists do not agree that this is a cost-effective measure, however.

Given that the majority of patients with SCLC are older and have extensive smoking histories, it is not surprising that cardiovascular, cerebrovascular, and pulmonary diseases are extremely common in this population. Thus, a large portion of long-term survivors of SCLC succumb to these other diseases. Up to one-third of all long-term surviving patients, especially those who continue to smoke, have recurrence of their SCLC, or more rarely, develop a new SCLC. Other aerodigestive cancers, particularly NSCLC, are extremely common, leading some investigators to propose trials of chemoprevention agents in long-term survivors of SCLC. Finally, patients with SCLC have an increased risk of developing a hematologic malignancy. Secondary leukemias are believed to be related to treatment, especially if chemotherapy with alkylating agents was employed. Some of these posttreatment leukemias have also shown a deletion of chromosome 3, suggesting an underlying predisposition or common ancestor cell to both cancers, instead of a secondary leukemia arising from alkylating chemotherapy-induced genetic damage. Overall, 2-year survivors of SCLC face a 3.5-fold increased risk of a second cancer (mostly NSCLC) compared to the general population. The risk of a second lung cancer is increased 13-fold among those patients who received TRT and sevenfold among those who did not undergo radiation, with ongoing smoking further escalating risk.[122] Accordingly, long-term surveillance is mandatory in these otherwise cured patients.

CONCLUSION

SCLC is distinct from the other three major histologic varieties of pulmonary malignancies, which tend to behave similarly and are lumped together under the generic rubric "NSCLC." It is biologically more active, secreting multiple hormones and neural markers, resulting in a number of paraneoplastic syndromes. It is thought of as a systemic disease, and treatment nearly always includes chemotherapy. Although the tumor is highly responsive to chemotherapy, and survival is markedly prolonged with drug treatment, the complete eradication of SCLC remains a relatively rare event. Long-term survivors are still subject to a host of cardiopulmonary conditions, as well as second malignancies and recurrence of their SCLC. Over the last 30 years, clinical trials have made little progress in prolonging the survival of SCLC patients, and developments clearly lag behind those made in the more common NSCLC. In the era of tumor genomic profiling and molecularly targeted therapies, there is hope that new insights into tumor biology and novel therapies may show promise in the treatment of this aggressive and often fatal cancer.

CHAPTER 117

Primary Lung Tumors Other than Bronchogenic Carcinoma: Benign and Malignant

Alla Godelman
Steven M. Keller

Bronchogenic carcinoma represents the overwhelming majority of pulmonary neoplasms. However, a great variety of tumors originate in the lung.[1] Benign neoplasms (Table 117-1) comprise less than 1% of all resected lung tumors and nonbronchogenic primary pulmonary malignancies (Table 117-2) account for 3% to 5% of all lung tumors. Numerous classifications of these rare tumors have been devised, though none are widely accepted. Due to the disparate histogenesis of these varied tumors, it is best to discuss them individually.

BENIGN TUMORS

A broad array of benign primary lung tumors has been recognized, as discussed below.

MUCUS GLAND ADENOMA

Mucus gland adenoma, also known as bronchial cystadenoma, is a benign epithelial tumor that originates in the bronchial submucus glands and presents as an exophytic endobronchial mass.[2] Mucus gland adenoma occurs in adults and children and has no gender predilection.[3] The tumor occurs in the segmental or lobar bronchi and symptoms are due to obstruction or hemorrhage. Histologically, mucus-filled acini are lined with well-differentiated mucus-secreting cells, without any evidence of invasion. Radiographically, mucus gland adenomas appear as coin lesions on chest radiograph, or with an "air-meniscus" sign on CT scan. Treatment is endoscopic local excision. However, lobectomy may be required if the distal lung is destroyed.

SQUAMOUS PAPILLOMA

Tracheal papillomatosis, a form of recurrent respiratory papillomatosis (RRP), occurs in both children and adults.[4] When symptomatic, patients can present with dyspnea, cough, hemoptysis, and symptoms simulating reactive airway disease.[5] Histologically, papillomas consist of stratified squamous epithelium with a fibrovascular core. Imaging studies demonstrate lesions within the trachea and bronchi. Bronchoscopy is the diagnostic modality of choice. Squamous metaplasia and malignant transformation occur in 0.3% to0.5% of patients with RRP and have been linked to radiation exposure, tobacco use, and bleomycin.[4] Infection with HPV 11, HPV 16, or HPV 18 rather than HPV 6 is associated with a worse prognosis. Endoscopic excision is the treatment of choice for tumors with malignant transformation or causing airway obstruction.

Solitary bronchial papillomas affect adults in their fifth to seventh decades. When present, obstructive bronchiectasis may necessitate resection of distally destroyed lung. Parenchymal lesions are rare and can be associated with diffuse viral contamination or dissemination of fragments related to prior tracheostomy or surgical excision.[6,7] Lung involvement manifests as multiple slow-growing solid or cavitary nodules and carries a poor prognosis (Fig. 117-1).[7]

CAVERNOUS HEMANGIOMA

Cavernous hemangiomas of the lung are found in all age groups and may be single or multiple.[8,9] They may cause symptoms of hemoptysis, respiratory distress, or congestive heart failure. Histologically, cavernous hemangioma consists of flattened endothelial cells lining dilated vascular spaces. These cells stain positive for anti-von

TABLE 117-1 Benign Tumors of the Lung

Solitary Tumors	Other Solitary Tumors	Multiple Tumors
Epithelial tumors	Alveolar adenoma	Benign metastasizing leiomyoma
Clara cell adenoma	Pulmonary paraganglioma—chemodectoma	Lymphangioleiomyomatosis
Mucus gland adenoma	Glomus tumor	Cystic fibrohistiocytic tumors
Oncocytoma	Nodular amyloid	
Squamous papilloma	Pleomorphic adenoma—mixed tumor	
Soft tissue tumors	Pulmonary meningioma	
Cavernous hemangioma	Sclerosing hemangioma—pneumocytoma	
Chondroma	Sugar tumor—benign clear cell tumor	
Fibroma fibrous polyp	Teratoma	
Fibromyxoma		
Inflammatory myofibroblastic tumor/ plasma cell granuloma		
Granular cell myoblastoma		
Hamartoma		
Leiomyoma		
Lipoma		
Neurilemmoma—schwannoma		
Neurofibroma		
Pulmonary hyalinizing granuloma		

TABLE 117-2 Rare Primary Malignant Neoplasms of the Lung

Blastoma
Carcinoid tumors
Carcinosarcoma
Epithelioid hemangioendothelioma (IVBAT)
Malignant lymphoreticular disorders
Hodgkin disease
Non-Hodgkin lymphoma
Plasmacytoma
Malignant melanoma
Malignant germ cell tumors
Malignant teratoma
Choriocarcinoma
Salivary gland-type tumors
Adenoid cystic carcinoma
Mucoepidermoid carcinoma
Acinic cell tumor
Sarcoma
Chondrosarcoma
Osteosarcoma
Soft tissue sarcoma
Miscellaneous
Ependymoma, malignant
Ewing sarcoma
Lymphoepithelioma
Pseudomesotheliomatous carcinoma

Willebrand factor antibody and CD34, identifying them as endothelial in origin. Treatment for solitary lesions is excision.

SCLEROSING HEMANGIOMA

Sclerosing hemangioma (SH) is an epithelial tumor arising from respiratory epithelium. Histologically, the tumor has four components: solid, papillary, sclerotic, and hemorrhagic.[10] The majority of patients are women, predominantly middle-aged.[10–14] There is a higher incidence in Asia. Most patients are asymptomatic, but can present with chest pain, cough, pleurisy, and hemoptysis. SH appears as a solitary, juxta-pleural, well-defined nodule (Fig. 117-2) with smooth margins and strong enhancement. Calcifications are reported in 30% to 40%.[11,12] Tumors can be multiple and bilateral. There are very rare reports of lymph node metastases. Imaging and bronchoscopy are often not sufficient to make the diagnosis and resection is indicated. PET can show false-positive results. Limited, but complete resection is usually curative.

CHONDROMA

Chondromas of the lung may be solitary or multiple, unilateral or bilateral, and are usually asymptomatic slow-growing tumors. The association of multiple peripheral pulmonary chondromas with gastric stromal sarcoma and extra-adrenal paraganglioma has been described as the "Carney triad".[15] The majority of patients with Carney triad are young women. Chondromas consist almost exclusively of cartilage that may be calcified or ossified. The presence of a fibrous pseudocapsule and the absence of fat and entrapped epithelium distinguish chondroma from pulmonary hamartoma.[16] Chondromas present as calcified nodules and can sometimes be mistaken for gastric sarcoma metastases. Lung-sparing resections are curative in 44% of patients, the rest develop new chondromas. MRI-guided laser thermotherapy has been described for ablation of multiple chondromas.[17]

INTRAPULMONARY SOLITARY FIBROUS TUMOR

Solitary fibrous tumors (SFTs) are distinct spindle cell neoplasms that usually grow on a stalk arising from the visceral pleura[18,19] and are almost always diagnosed following resection of an asymptomatic lung mass found on routine radiography. These tumors are classified as benign or malignant based on histologic findings such as mitotic activity, pleomorphism, presence of necrosis, and invasiveness.[19] Tumor cells are immunoreactive for vimentin but not keratin, desmin, or actin, suggesting fibroblastic differentiation from a submesothelial origin.[18] They are also positive for CD34.

SFTs that arise within the lung parenchyma without histologic continuity with the pleura are extremely rare. Intrapulmonary SFTs may contain entrapped alveolar epithelium within the spindle cell proliferation.[19] Clinically, intrapulmonary SFTs are assumed to behave similarly to the pleural tumors. Radiographically, the

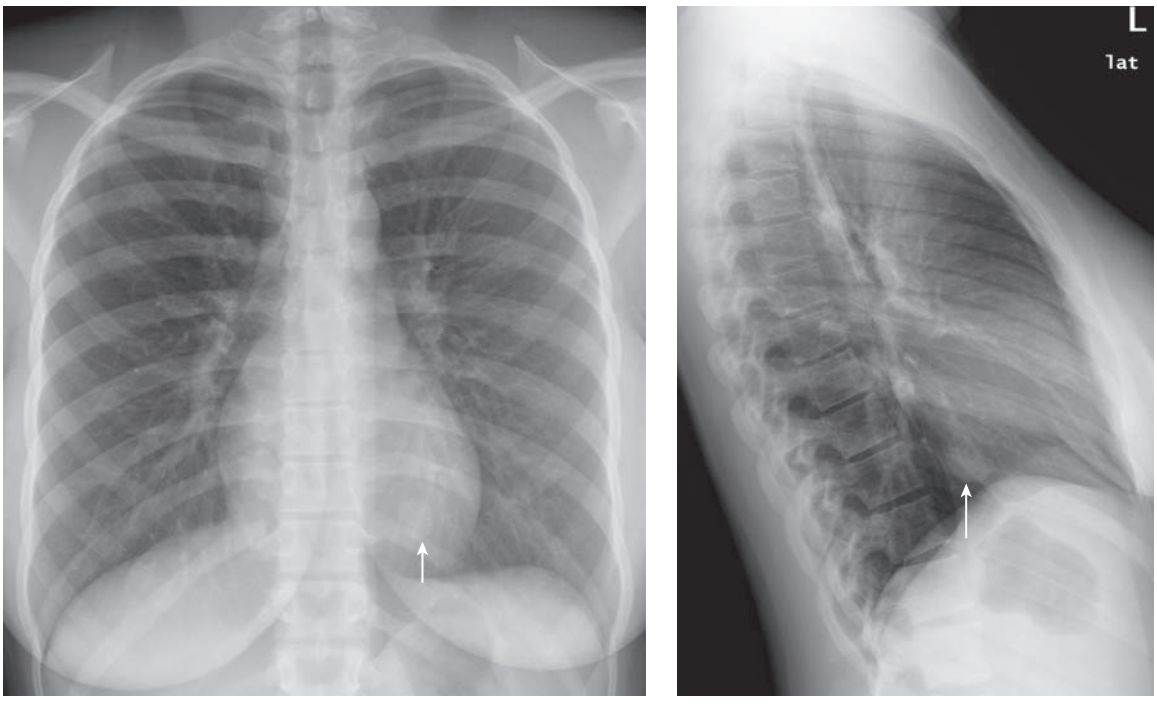
tumor appears as an oval or round nodule or mass of variable size. Treatment is resection and prognosis is generally good. It has been reported, however, that neither the size of the tumor nor its morphology is reliable predictor of clinical behavior and biologic potential of these tumors.[20] Adequate excision and follow-up are necessary.

■ INFLAMMATORY MYOFIBROBLASTIC TUMOR (PLASMA CELL GRANULOMA)

Inflammatory myofibroblastic tumor (IMT) is more commonly seen in children and adolescents, though it is also found in adults and has no gender predilection.[7,21–23] Patients are usually symptomatic, presenting with cough, fatigue, or weight loss. Previously thought to be an unchecked inflammatory response to viral/foreign antigens, IMT has been confirmed to be of neoplastic origin. Rearrangement of the anaplastic lymphoma kinase gene on chromosome 2p23 results in the expression of the ALK-1 protein. IMT is locally aggressive, can be multifocal, relapse and even metastasize. Radiographically, IMT presents as a mass or nodule with lobulated or spiculated borders closely related to the airways (Fig. 117-3). Calcification and cavitation are rare.[7] Histologically, plasma cells and spindle cells are seen with varying degrees of mitosis, necrosis, and vascular invasion. Tumors stain for vimentin, actin, and epithelial membrane antigen. Transbronchial/transthoracic biopsy often reveals mixed inflammatory cells with predominantly plasma cells in a background of fibroblastic proliferation, granulation tissue, and histiocytes with nuclear atypia. Thus, both fine-needle aspiration and frozen section are nonspecific and complete



A B

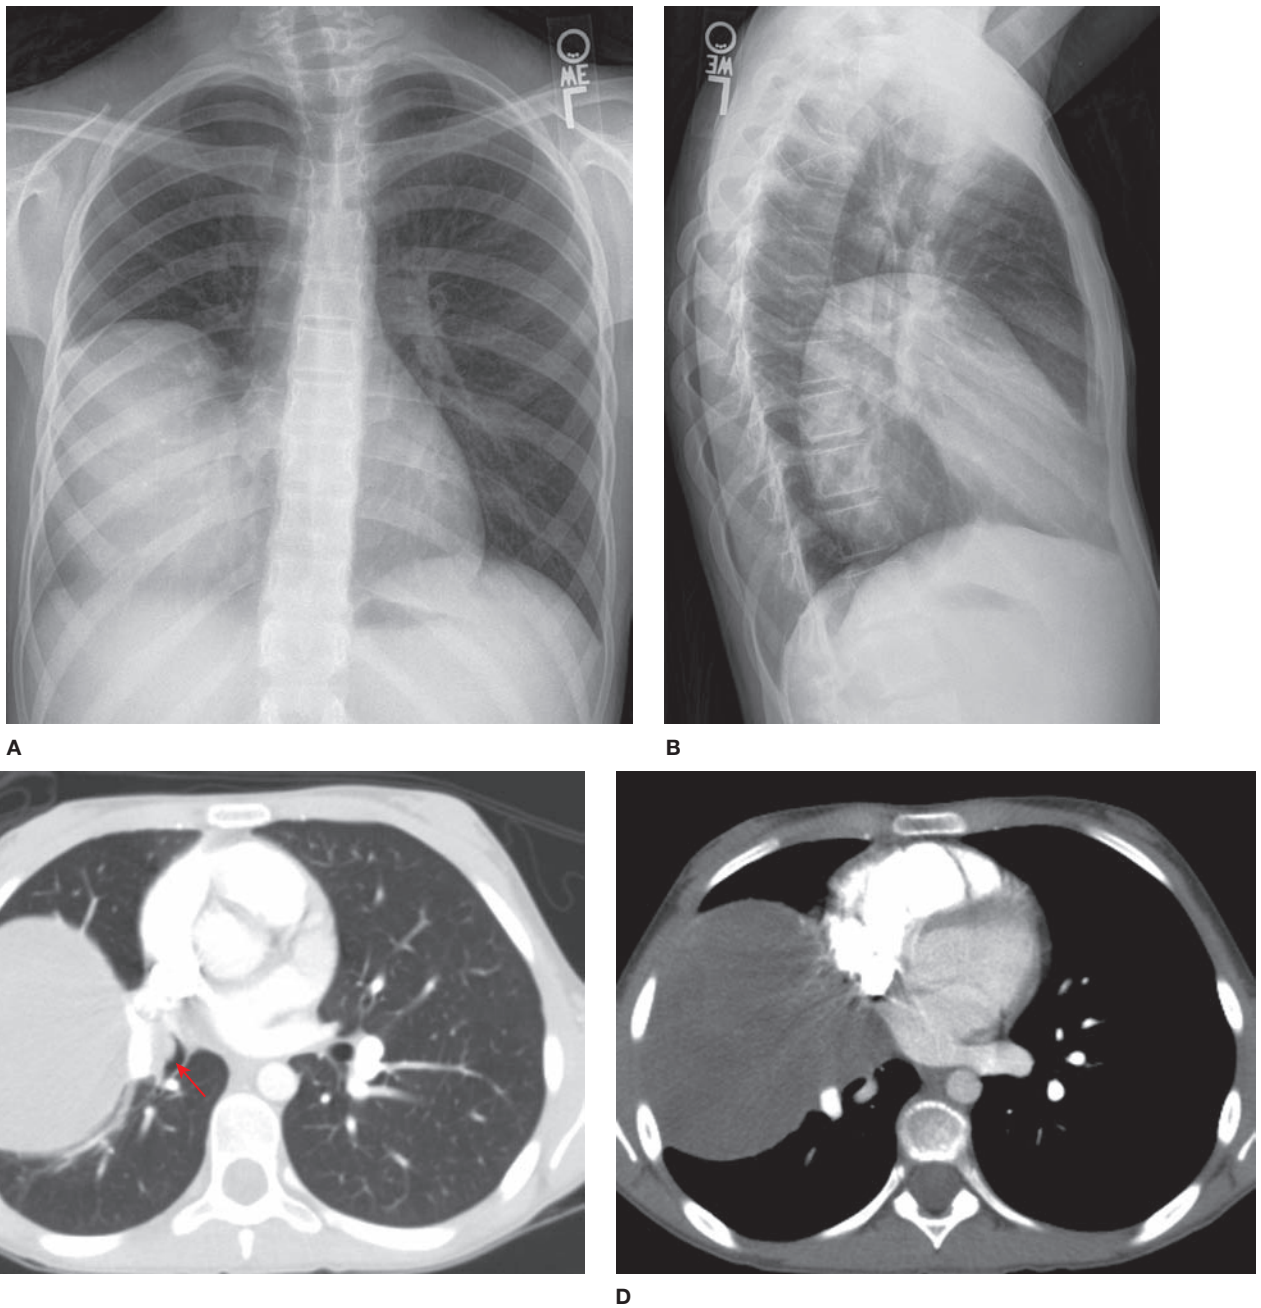

Figure 117-3 Frontal (**A**) and lateral chest (**B**) radiographs demonstrating a large mass in the right hemithorax and axial images (**C**, **D**) from a contrast-enhanced CT of the thorax demonstrating a well-defined mildly heterogeneous mass with an endobronchial component *(arrow)* of an 11-year-old girl with an inflammatory myofibroblastic tumor.

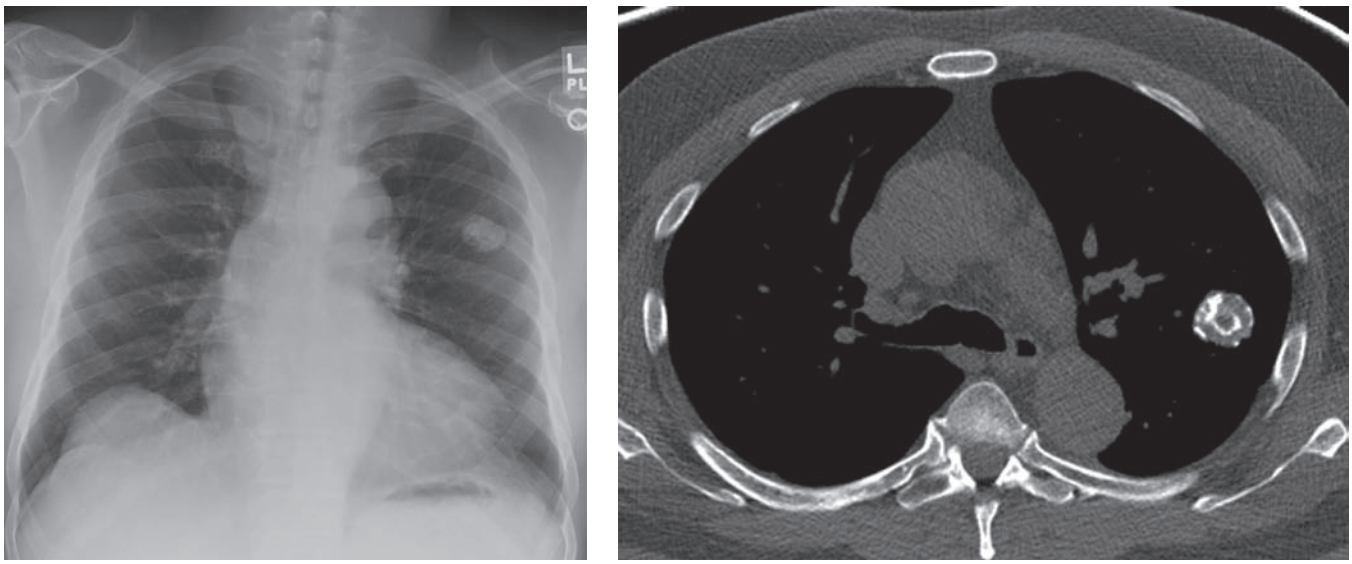
resection is necessary for establishing a diagnosis. Incomplete resection can result in recurrence, which can be treated with repeat resection. Symptoms, incomplete resection, as well as large size are predictors of mortality. Steroids, nonsteroidal antiinflammatory drugs, and laser therapy have been used with variable results in cases where complete resection cannot be achieved. Treatment with chemotherapy and radiation therapy remains controversial.[23]

GRANULAR CELL MYOBLASTOMA

Granular cell tumors are uncommon benign neoplasms that are thought to arise from Schwann cells.[24] Usually discovered incidentally on a chest radiograph, they are endobronchial in location and multicentric. Peribronchial extension is seen in half of the tumors. However, distant metastases have not been reported. They occur equally in men and women, with a median age of 42 years. Microscopically, sheets of granular cells with abundant lysosomes, which stain positive with periodic acid–Schiff stain, are present. Tumor cells also stain positive for S-100 and myelin basic proteins. Large tumor size, necrosis, increased mitosis, and p53 as well as Ki-67 immunoreactivity are consistent with malignant change. Treatment consists of local excision, either endoscopically (laser) or by sleeve resection. Larger resections are reserved for postobstructive bronchiectasis or abscess. Up to 13% of granular cell tumors coexist with other neoplasms such as esophageal, renal, and lung carcinomas.

HAMARTOMA

Hamartomas (mesenchymomas) are the most common benign tumors of the lung and are commonly seen in males in the sixth



A B

Figure 117-4 Radiographic appearance of a hamartoma. **A.** Frontal radiograph of the chest demonstrating a well-defined nodule with "popcorn" calcification in the left upper lobe. **B.** Axial image from a noncontrast CT demonstrating a well-defined nodule with course calcification and foci of fat.

decade.[25–28] They are slow growing and can be multiple. The majority are detected incidentally as peripheral round nodules on a chest radiograph. Only 20% are endobronchial (Fig. 117-4). The classic popcorn calcification is seen in 30% of hamartomas. Histologically, hamartomas consist of cartilage, fat, bone, connective tissue, and smooth muscle cells surrounding clefts lined with bronchial epithelium. Presence of fat and calcifications helps make the diagnosis on CT. Use of chemical shift MRI has been investigated as a tool to detect fat deposits in hamartomas with inconclusive CT findings.[29] Fine-needle aspiration has a high false-positive rate and low accuracy in diagnosing hamartomas. Malignant transformation is rare. Therefore, small peripheral hamartomas may be safely observed. Excision is indicated for obstructive symptoms or if the diagnosis is in doubt. Parenchyma-sparing resection should be performed. Recurrences are rare, although hamartomas may be associated with increased risk of developing primary lung cancers.[30]

■ LEIOMYOMA

Primary solitary leiomyoma accounts for 2% of all benign lung tumors and may present as endobronchial obstruction or as an asymptomatic peripheral radiographic nodule. Typically, primary solitary leiomyoma affects patients in their fourth decade. The tumor is slightly more common in women. Surgical resection is the treatment of choice, although laser resection of endobronchial tumors offers prolonged palliation.

Benign metastasizing leiomyoma consists of multiple pulmonary nodules of well-differentiated smooth muscle, resulting from hematogenous spread from a benign uterine leiomyoma (Fig. 117-5).[31–33] Tumors are strongly positive for Smooth Muscle Actin (SMA) and negative for CD117. Benign metastasizing leiomyoma is ER and PR positive and may respond to hormonal therapy.

MALIGNANT TUMORS

The diverse spectrum of malignant primary lung tumors, other than bronchogenic carcinoma, is discussed below.

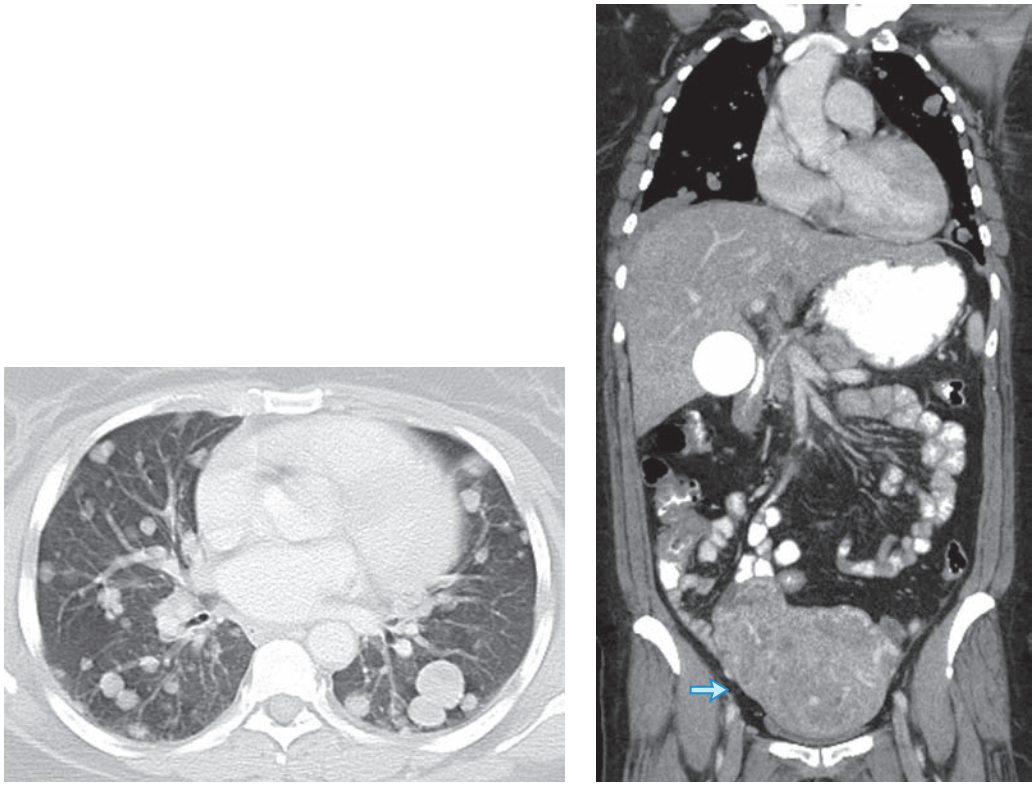
■ PULMONARY BLASTOMA

Pulmonary blastomas are divided into three subgroups: biphasic pulmonary blastoma (BPB), well-differentiated fetal adenocarcinoma (WDFA), and pleuropulmonary blastoma (PPB).[34–38] WDFA contains neoplastic epithelial glandular elements in an endometrioid pattern without mesenchymal malignancy. PPB is a dysontogenetic neoplasm having mesenchymal malignant elements (liposarcoma, rhabdomyosarcoma, or chondrosarcoma) without epithelial malignancy. BPB contains both epithelial and mesenchymal malignant elements, which mimic fetal lung. PPB is further subclassified as type I (purely cystic), type II (cystic and solid), and type III (purely solid). PPB occurs in infants and young children; WDFA and BPB occur in young adults, with a mean age of 35 years. Many patients with BPB and WDFA have a history of tobacco use. All three are fast-growing tumors that present in the periphery of the lung with a predilection for the lower lobes. Patients may be asymptomatic or may present with cough, hemoptysis, dyspnea, chest, or back pain. Radiographically, pulmonary blastomas appear as large solitary smooth masses. Fine-needle aspiration is usually nondiagnostic due to extensive necrosis and lack of cellular material. Neoadjuvant chemotherapy has been used to downstage the tumors before surgical resection. Adjuvant chemotherapy is combined with local radiation for control after resection. Poor prognostic factors are large tumor size, mediastinal or pleural involvement, and nodal metastasis. The central nervous system is the most common site of distant metastasis. Mutations of p53 gene are seen more frequently with BPB and PPB than with WDFA, suggesting a worse prognosis. Type II and III PPBs have an overall survival of 42% at 5 years, despite multimodality treatment.

■ CARCINOID

Carcinoid tumors are malignant neuroendocrine tumors arising from Kulchitsky (APUD system) cells and are classified by the World Health Organization into typical carcinoid (TC) and atypical carcinoid (AC) on the basis of presence of necrosis and mitotic activity.[39,40] Mean age at presentation is 55 years, but AC is seen in significantly older patients with a history of smoking. Seventy-five percent of carcinoids are central, endobronchial tumors and present commonly with postobstructive pneumonia, hemoptysis, or wheezing. Uncommonly, carcinoids may present with paraneoplastic syndromes such as Cushing syndrome due to ectopic adrenocorticotropic hormone production, or even acromegaly from ectopic growth hormone and insulin-like growth factor-1 production.

Radiologically, carcinoids present as solitary nodules (30%), infiltrates (60%), and calcified nodules (30%) (Fig. 117-6). CT scan



A B

Figure 117-5 Axial image (**A**) with lung algorithm from a contrast-enhanced CT of the thorax, abdomen, and pelvis demonstrating multiple bilateral well-defined pulmonary nodules and coronal reformatted image (**B**) with soft tissue window from the same study demonstrating enlarged heterogeneous uterus *(arrow)*, consistent with multiple leiomyomas, of a 55-year-old woman with a history of uterine leiomyomas and benign metastasizing pulmonary leiomyomas.

reveals a well-defined central tumor deforming an airway with punctate calcification and homogeneous contrast enhancement with or without hilar lymphadenopathy. Carcinoids demonstrate high signal intensity on T2-weighted MRI[41] and are hypometabolic on FDG-PET scans. Somatostatin receptor scintigraphy can be used in detecting occult primary tumors, staging, and localization of metastatic disease.

Figure 117-6 Atypical carcinoid in a 74-year-old woman. Axial image with lung algorithm from a noncontrast CT of the thorax demonstrating a well-defined mildly lobulated nodule in the lingula with extension into the lingular bronchus. Incidentally noted is diffuse mosaic attenuation of the pulmonary parenchyma, consistent with air trapping, a nonspecific sign of small airway disease.

Bronchoscopy frequently demonstrates a polypoid pinkish/yellow mass with intact overlying epithelium. Brushings and washings are usually nondiagnostic. Endobronchial biopsy is diagnostic in approximately 50% of patients, but rarely may precipitate a carcinoid crisis.

Carcinoids are characterized by an organoid growth pattern with uniform cells containing finely granular eosinophilic cytoplasm and nuclei with a fine chromatin pattern. Chromosome analysis shows evidence of 11q and 3p deletion in AC, with loss of 18q in metastatic carcinoid. Overexpression of p53 and loss of heterozygosity of 11q13 are seen in AC, which correlates with tumor aggressiveness. Five percent of patients with MEN I syndrome have associated sporadic carcinoids. Inactivation of the MEN I gene is seen in 67% of TC, and 25% of AC.

Treatment of choice for TC is surgical resection. Lobectomy and lymph node dissection are preferred because 20% of TC and 60% of AC are associated with nodal metastases. Bronchoplastic sleeve resection for central lesions of early-stage TC is preferable to pneumonectomy. *cis*-Platinum and etoposide-based chemotherapy is indicated for unresectable disease, as well as metastases. However, the response rate is only 22%, with a median survival of 20 months. Biotherapy with interferon alpha and octreotide is used for the treatment of carcinoid syndrome with symptomatic relief in 70% of patients. Liver embolization can be used to debulk liver metastases in symptomatic patients. Targeted radiotherapy with radiolabelled octreotide or metaiodobenzylguanidine remains investigational.

Recurrence-free survival is common in patients with TC. Tumor histology and nodal status are the main predictors of mortality. Completeness of resection, symptoms, and age are also significant

prognostic factors. Five-year survival rates following complete resection of TC and AC are 87% to 100% and 44% to 77%, respectively. Survival decreases to 25% to 69% in the presence of nodal metastases. There is no correlation between tumor size and presence of nodal involvement. Sixty-three percent of patients with nodal mediastinal metastases develop distant metastases, most commonly in the liver. Carcinoid syndrome occurs rarely (2%) and results from release of 5-HT. Urinary 5-HIAA is used to monitor disease activity in patients with carcinoid syndrome.

CARCINOSARCOMA

Carcinosarcoma is a biphasic tumor consisting of carcinomatous and sarcomatous elements containing differentiated cartilage, bone, or skeletal muscle.[42–44] This tumor is seven times more common in males than in females. The median age at presentation is 65 years. The upper lobes are affected in 60% of cases. Carcinosarcomas are divided into two groups: central endobronchial and peripheral solid parenchymal (Fig 117-4). Symptoms of airway obstruction or postobstructive pneumonia are common. However, one-third of all patients are asymptomatic. These tumors eventually invade the mediastinum and chest wall, causing pain.

Carcinosarcomas are firm, rubbery, or fleshy masses with areas of necrosis and cavitation. The carcinomatous elements are squamous cell carcinoma (46%), adenocarcinoma (31%), and adenosquamous carcinoma (19%). The sarcomatous elements are rhabdomyosarcoma (51%), chondrosarcoma, and osteosarcoma. The carcinomatous elements are often displaced to the periphery, suggesting rapid growth of the central sarcomatous elements, which form the bulk of the tumor. Immunohistochemical staining for keratin is positive for both the epithelial and mesenchymal components, suggesting that carcinosarcomas are of a monoclonal epithelial origin that has undergone sarcomatoid metaplasia. Metastases are found in lymph nodes, bone, kidney, liver, and lung and commonly contain only one of the components of the primary tumor. Complete surgical resection is usually possible and the 5-year survival rate ranges between 21% and 49%. Endobronchial location and tumor stage do not correlate with survival. However, tumor size greater than 6 cm is associated with poor survival.

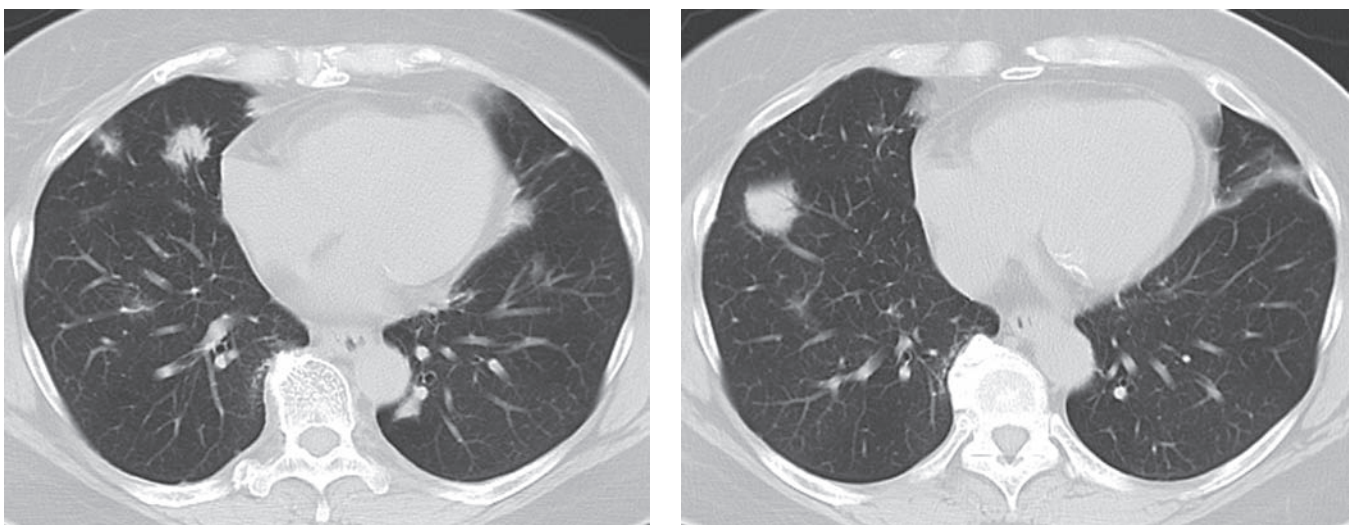
EPITHELIOID HEMANGIOENDOTHELIOMA

Originally named intravascular bronchoalveolar tumor (IVBAT), this neoplasm has since been demonstrated to be of endothelial origin on the basis of immunohistochemical staining for factor VIII-related antigen, CD31, CD34, and/or FLI-1.[45,46] Epithelioid hemangioendothelioma is best considered a low-grade sarcoma and is usually multicentric in origin. It is a disease of young women, with over 70% of cases seen in women with mean age of 40 years. Patients are usually asymptomatic, though they may present with respiratory symptoms. Multiple perivascular nodules less than 1 cm in diameter or diffuse thickening of interlobular septae are present on CT scan. Microscopically, epithelioid hemangioendothelioma consists of eosinophilic cells forming trabeculae or nests with characteristic central acellular sclerotic areas and lymphovascular and bronchiolar invasion. Pleural, intravascular, and endobronchial spread is associated with a poor prognosis, as are liver and lymph node metastases. Complete resection is the treatment for localized tumors.[47] Diffuse tumors have been treated with chemotherapy, interleukin-2, and interferonalpha-2b with mixed results. Radiation is ineffective and is used only for palliation of bone pain. Partial spontaneous regression has also occasionally been reported.

LYMPHOMAS

Primary pulmonary lymphomas account for less than 1% of all lung cancers. Criteria used for the diagnosis of primary pulmonary lymphoma include involvement of the lung with or without mediastinal involvement and absence of extra thoracic lymphoma at the time of diagnosis or for 3 months thereafter.[48]

Primary pulmonary B-cell non-Hodgkin lymphoma (NHL), also known as MALT (mucosa-associated lymphoid tissue) or BALT (bronchus-associated lymphoid tissue), accounts for up to 80% of primary pulmonary lymphomas. This small low-grade B-lymphocyte lymphoma is associated with a 5-year survival greater than 80%. The tumor is thought to arise due to chronic inflammation secondary to smoking, infection, or autoimmune disease (Sjogren syndrome, rheumatoid).[49] Age of onset is typically 50 to 60 years, with equal gender distribution. Respiratory symptoms include cough, dyspnea, and hemoptysis; half of the patients are asymptomatic. Extrapulmonary symptoms such as fever and weight loss occur in less than one quarter of patients. Radiographically, a localized alveolar opacity with blurred margins is seen, often associated with air bronchograms (Fig. 117-7). CT demonstrates bilateral multifocal disease in 70% of cases. CT-guided biopsy is diagnostic in 25%. Bronchoalveolar lavage is diagnostic if a lymphocytic alveolitis is present with B lymphocytes constituting greater than 10% of the total cells. Microscopically,



A B

Figure 117-7 Axial images with lung algorithm from a non-contrast CT of the thorax demonstrating irregularly marginated pulmonary opacities with air bronchograms in the right middle (**A**) and right lower lobes (**B**) of a 60-year-old woman with mucosa-associated lymphoid tissue.

MALT is defined as a lesion containing small lymphoid cells, lymphoepithelial lesions showing migration of lymphoid cells from the marginal zone to bronchiolar epithelium, reactive follicular hyperplasia, and rare blastic cells. Immunohistochemistry demonstrates B cell phenotype (CD19, CD20) and monoclonality. Bone marrow biopsy may show involvement in 25% of cases. Evaluation of other mucosal sites with upper endoscopy, ENT examination, and CT scan of salivary and lacrimal glands should be performed. Serum immunoelectrophoresis will reveal a monoclonal gammopathy (IgM) in 20% to 60% of patients. Elevated beta-2 microglobulin is associated with a poor prognosis. Solitary tumors should be removed. Long-term surveillance is necessary due to late local or systemic relapse after resection. Chemotherapy is recommended for residual, bilateral, progressive, or recurrent disease. Various regimens including CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) and rituximab have been used with success.

High-grade NHL-B, also known as large B-cell lymphoma, accounts for up to 15% of primary pulmonary lymphomas. Immunosuppression, HIV infection, and Sjogren syndrome are underlying disorders often associated with large B-cell lymphomas. These lymphomas are usually found in older patients and commonly present with either pulmonary or systemic symptoms. Radiologic presentation includes solitary or multiple nodules, masses, consolidations, adenopathy, pleural effusion, and, rarely, direct chest wall invasion (Fig. 117-8).[50] Bronchoscopy may reveal infiltrative bronchial stenosis. Transbronchial biopsy is often diagnostic. Microscopically, large blast-like lymphoid cells with frequent mitosis, necrosis, and bronchovascular invasion are seen. Survival is poorer than in small B-cell lymphomas, especially in those patients with underlying disorders. Resection is followed by combination chemotherapy. Progression of disease and recurrence occur earlier and more commonly than in small B-cell lymphoma.

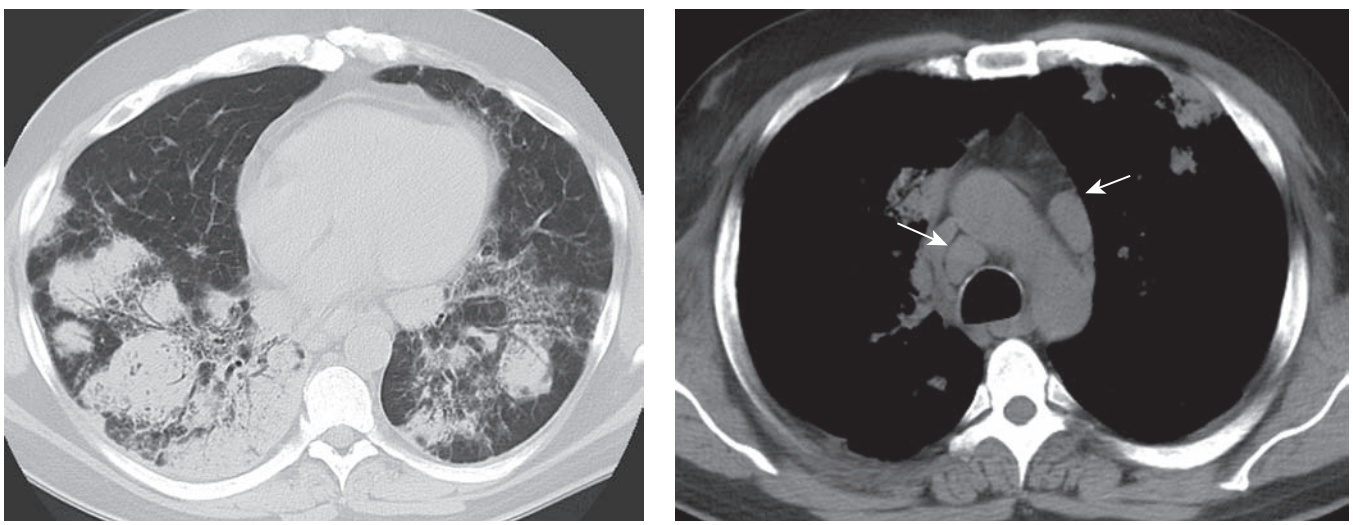
Lymphomatoid granulomatosis (LG), also known as an angiocentric immunoproliferative lesion (AIL), presents with either pulmonary or systemic symptoms and commonly affects patients in their sixth decade. Radiographically, multiple bilateral ill-defined nodular opacities, mainly affecting the lower lobes, are seen. These opacities can cavitate and disappear secondary to infarction of the granulomatosis lesions. Extrapulmonary involvement occurs in the CNS, skin, upper respiratory tract, or renal systems. Neurologic deficits can be central or peripheral. Skin lesions include erythema or nodules, with or without ulceration. Joint, ocular, and gastrointestinal manifestations have also been reported. Microscopically, an angiocentric lymphocytic infiltrate mixed with occasional large blastic cells compressing the lumen of arterioles and eroding into bronchioles is seen. Immunohistochemistry demonstrates the B cell origin of the lymphocytes, which also express Epstein–Barr virus latent membrane protein. Initial assessment should include brain MRI, CT scan of the abdomen for renal or lymphoid involvement, and a bone marrow biopsy. Localized LG should be removed. Combination chemotherapy is reserved for diffuse disease. Radiotherapy is useful for CNS involvement. Despite aggressive therapy, median survival approximates 4 years. Poor prognostic factors include early age of onset, CNS involvement, hepatosplenomegaly, leukopenia, fever, anergy, and predominant blast cells with necrosis.

There are only 13 cases reported of NK/T cell primary pulmonary lymphoma. Patients are elderly and females are affected twice as commonly as males. Radiographically, bilateral diffuse nodularities are seen. Diagnosis requires a surgical lung biopsy and immunohistochemistry, which reveals T cell markers. Microscopically, homogeneous cells with architectural effacement and dysplasia are seen. Monoclonality of the T cells is demonstrated by TCR gene rearrangement. Prognosis is very poor despite surgical resection and CHOP-based chemotherapy.

Primary pulmonary Hodgkin lymphoma peaks in the third and sixth decades. Most patients are females. Symptoms may be respiratory or systemic. Radiographically, multinodular and massive parenchymal involvement is seen with occasional cavitation. Bronchoscopy and Broncho-alveolar Lavage (BAL) are inconclusive and surgical lung biopsy is required to confirm the diagnosis. The most frequent histologic subtype is the nodular sclerosing variety. Combination chemotherapy, radiation, and surgery are the common modalities of treatment. Multilobar or bilateral disease is associated with a poor prognosis.

■ PLASMACYTOMA

Plasmacytomas arise from monoclonal plasma cells. The diagnostic criteria for extramedullary plasmacytoma are a biopsy-proven plasma cell proliferation and the absence of bone marrow infiltration, osteolytic lesions, renal failure, and hypercalcemia.[51–53] The average age at presentation is 54 years with equal distribution



A B

Figure 117-8 Representative axial CT images from a 49 year-old man with AIDS and diffuse large B-cell lymphoma. **A.** Lung window demonstrating ground glass and consolidative opacities with rounded configuration and air bronchograms in the lower lobes bilaterally. **B.** Soft tissue window demonstrating mediastinal lymphadenopathy *(arrows)*.

between males and females. Plasmacytomas commonly present as a hilar mass, but lobar consolidation or bilateral diffuse infiltrates with air bronchograms may also be seen. Serum electrophoresis reveals an M-protein spike, which usually consists of IgG kappa chains, and correlates with the tumor burden. Treatment is surgical resection, but chemotherapy with melphalan and prednisolone has been used with good results. The 5-year survival rate is 40%. These tumors need to be distinguished from marginal zone B-cell lymphomas of MALT origin. Forty percent of patients develop multiple myeloma and so surveillance with serum and urine electrophoresis, bone marrow biopsy, skeletal bone survey, and clinical monitoring is necessary.

MELANOMA

Primary pulmonary melanoma is an extremely rare lung tumor for which several theories have been suggested: aberrant migration of melanocytes from the primitive foregut, melanogenic metaplasia of bronchial epithelium, or melanocytic differentiation of neuroendocrine precursor Kulchitsky cells.[54–58] Jensen and Egedorf first suggested the clinical criteria for the diagnosis of primary pulmonary melanoma: (1) no previously removed skin or ocular melanomas, (2) solitary tumor, (3) morphology compatible with a primary tumor, (4) no melanoma in other organs at surgery, and (5) no evidence of primary elsewhere on autopsy.[54] Histopathologic criteria include junctional change with nesting of malignant cells beneath bronchial epithelium, and invasion of bronchial epithelium in an area without ulceration. Aggressive resection is the treatment of choice and offers the best chance for cure. Chemotherapy and immunotherapy are used for widespread disease.

MALIGNANT GERM CELL TUMORS

Malignant teratoma and choriocarcinoma are the two malignant germ cell tumors that arise in the lung.[59] Teratomas show elements from all three germ layers. Half of the primary pulmonary teratomas are malignant. Patients present with cough, hemoptysis, or chest pain. The most specific symptom—trichoptysis—is rarely present. Radiographically, the mass may show calcification with peripheral radiolucency. Resection is the treatment of choice. Adjuvant chemotherapy is usually a combination of *cis*-platinum, bleomycin, and etoposide.

Choriocarcinomas are usually seen in women or elderly men who present with symptoms of feminization. The most common symptom is hemoptysis. Various theories have been postulated to explain the origin of pulmonary choriocarcinomas: neoplastic transformation of misplaced primordial germ cells, spontaneous regression of an occult genital primary leaving behind pulmonary metastatic lesions, neoplastic transformation of placental emboli at the time of delivery or abortion, and neoplastic transformation of somatic neoplastic cells. The choriocarcinoma syndrome consists of bleeding from the primary lung lesion and elevation of beta-human chorionic gonadotropin (β-HCG). Choriocarcinoma can be distinguished from a large cell carcinoma producing ectopic β-HCG by immunohistochemistry, which will stain for thyroid transcription factor-1 (a marker of pulmonary origin) and not for β-HCG. Histologically, cytotrophoblastic cell nests are seen covered by syncytiotrophoblasts, with evidence of widespread necrosis and hemorrhage, as well as a lack of fibrovascular stroma. Surgical resection followed by adjuvant chemotherapy is recommended. Unlike their gestational counterparts, pulmonary choriocarcinomas are unresponsive to radiotherapy. Distant metastases can occur in the brain, kidneys, and contralateral lung.

SALIVARY GLAND-TYPE TUMORS

Adenoid cystic carcinoma (ACC) is the most common salivary-gland tumor found in the lung[60] and is thought to arise from ductal/myoepithelial cells of bronchial submucosal glands. Centrally located ACC arises in the trachea or mainstem bronchi and presents as an exophytic endobronchial mass causing obstructive symptoms. Overlying mucosa is often grossly normal. Peripheral ACC is uncommon. Males and females are equally affected. Histologically, there are three subtypes: cribriform, tubular, and solid. ACCs are slow-growing neoplasms that exhibit centripetal spread in the airways as well as perineural growth. Therefore, extensive resections are required. These tumors are extremely radiosensitive and local recurrences or residual disease may be treated with radiation. Following complete resection, 5- and 10-year survival of 91% and 76%, respectively, have been reported.

Mucoepidermoid carcinomas usually arise in mainstem bronchi or the proximal lobar bronchi. The right bronchial tree is more commonly affected in children. Patients present with symptoms of obstruction due to a polypoid endobronchial mass. Bronchoscopic biopsy is diagnostic. Three histologic grades have been defined (low, intermediate, and high) based upon the presence of cystic spaces, cell type (mucus cells, intermediate cells, and epidermoid cells), cellular pleomorphism, and mitosis. Complete resection with mediastinal lymph node dissection is the treatment of choice. High-grade tumors are more common in adults and may invade adjacent structures, lymph nodes, vascular, and perineural spaces. Incomplete resection is more likely in high-grade tumors and postoperative chemoradiation may be necessary. High-grade tumors are uniformly fatal in 11 to 28 months.

Acinic cell tumors (Fechner tumors) are usually found in the salivary glands and hence a diligent search for an extrathoracic primary is essential. Symptoms vary and are determined by whether the tumor is centrally located in the airway or peripheral in location. Histologically, these tumors demonstrate a pattern resembling a neuroendocrine tumor and may need to be differentiated from the more common carcinoid tumor. Acinic cell tumors are slow-growing and recurrence or metastases after complete excision has not been reported.

SARCOMAS

Primary pulmonary sarcomas account for less than 0.5% of all lung tumors.[61] Mean age at presentation is 53 years with a slight predominance in males. A history of smoking or previous radiation exposure may be present. Usual symptoms are chest pain and cough. Sarcomas appear as large (mean diameter 5 cm), solitary peripheral, or hilar nodular opacities usually located in the upper lobes. Bronchoscopy may show either extrinsic compression or a polypoid endobronchial mass. The variety of soft tissue pulmonary sarcomas reflects the range of mesenchymal tissue found in the lung (Table 117-3). The most common primary pulmonary

TABLE 117-3 Primary Soft Tissue Sarcomas of the Lung

Neurogenic sarcoma
Synovial sarcoma
Kaposi sarcoma
Liposarcoma

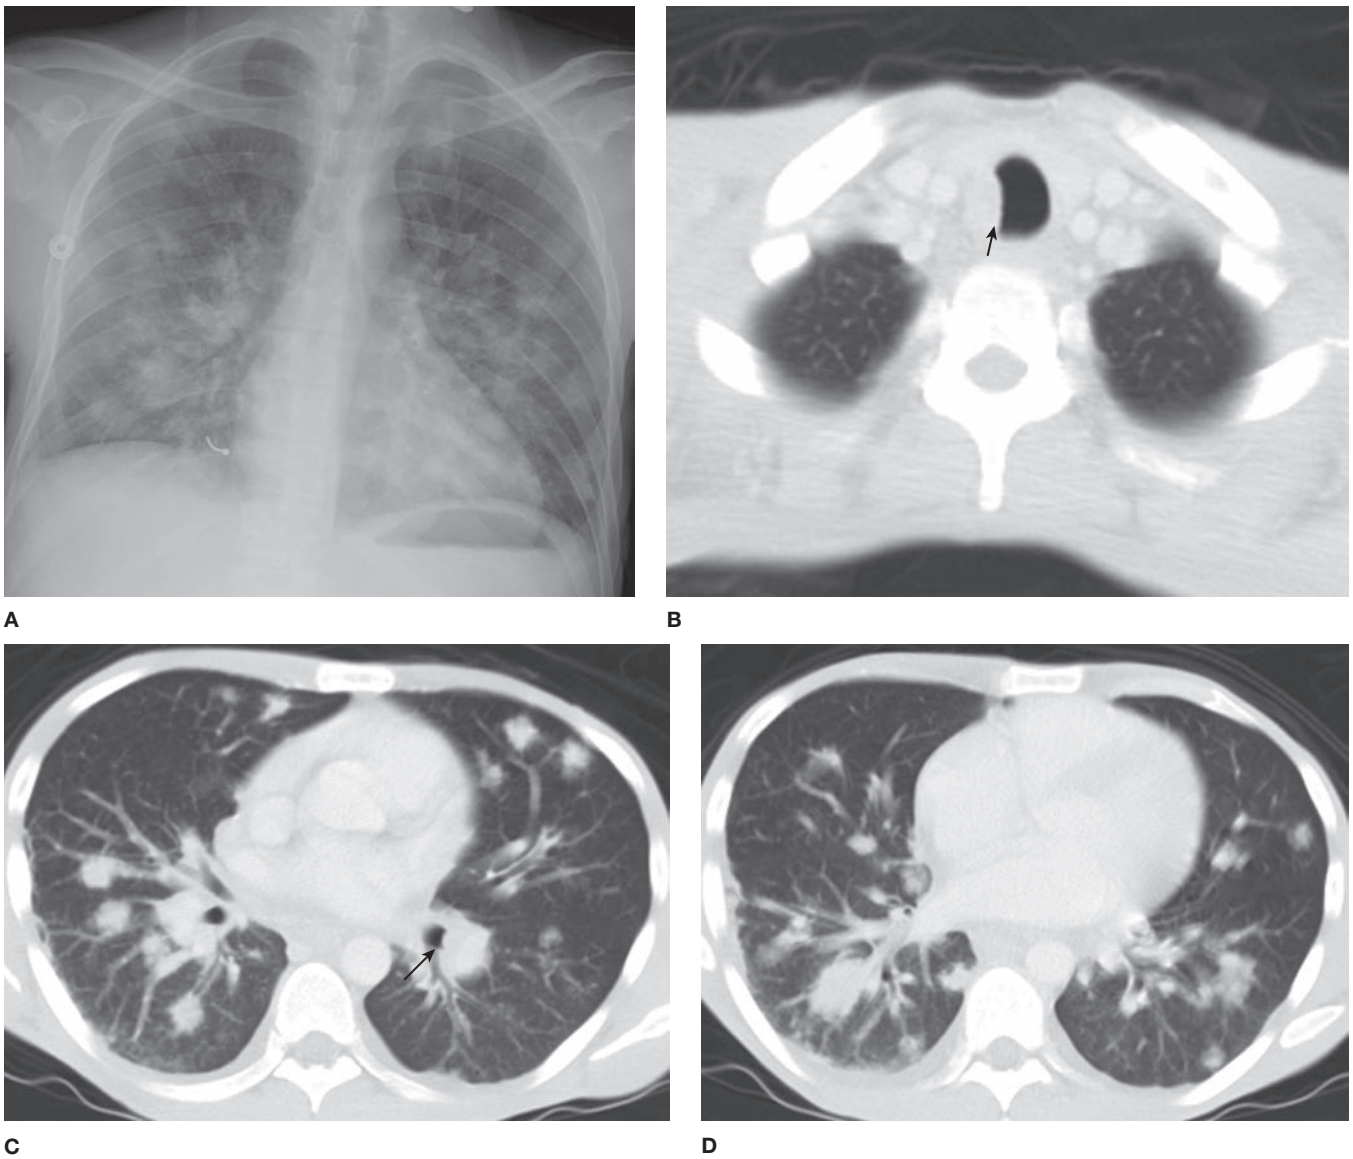

Figure 117-9 **A.** Frontal radiograph of the chest of a 35-year-old man with AIDS and Kaposi sarcoma demonstrating multiple bilateral "flame-shaped" pulmonary opacities with mid and lower lung zone predominance. Incidentally noted, is a linear metallic density at the right lung base, consistent with an aspirated earring. **B–D.** Axial images with lung algorithm from a noncontrast CT of the thorax of the same patient demonstrating endobronchial lesions *(arrows)* as well as multiple bilateral ill-defined pulmonary nodules in peribronchovascular distribution. Thoracic lymphadenopathy was also present in this patient (not shown).

sarcoma is leiomyosarcoma (30%), followed by malignant fibrous histiocytoma and synovial sarcoma. Histologic subtypes can be differentiated on the basis of immunohistochemical markers such as vimentin, desmin, actin, and epithelial membrane antigen. Treatment is wide resection with mediastinal lymph node dissection. Residual disease is treated with radiotherapy or re-resection. Recurrences can be resected with good results. Ifosfamide-based chemotherapy has also been used in the neoadjuvant and adjuvant setting for positive margins or positive lymph nodes. Median survival is 48 months and 5-year survival is 38% to 69%. Size and grade do not correlate with increased mortality. Incomplete resection is associated with poor survival.

Chondrosarcomas of the lung can occur either within central bronchi or peripherally in the lung parenchyma. Tumors consist of islands of chondroid and osteoid cells with foci of mineralization within sheets of small hyperchromatic mesenchymal cells. Chondrosarcomas are slow-growing and rarely metastasize. Complete resection is usually curative.

Osteosarcomas of the lung present with cough or hemoptysis and appear as large cavitating masses. Prognosis for patients with these rapidly growing tumors is poor and recurrence is seen in 50% of patients following resection. The majority of patients succumb within months from metastases to the lung, liver, lymph nodes, and bone. The role of adjuvant therapy remains unproven.

Pulmonary involvement with Kaposi sarcoma usually occurs in patients with AIDS and CD4 counts less than 100 cells/mm^3. A characteristic CT finding is the presence of bilateral symmetric ill-defined nodules in a peribronchovascular distribution.[62,63] The nodules have a mid and lower lung predominance. Peribronchovascular and interlobular septal thickening is another common finding. Endobronchial lesions, pleural effusions and nodularity, and lymphadenopathy within the thorax can also be present (Fig. 117-9). Prognosis is poor.

CHAPTER 118

Extrapulmonary Syndromes Associated with Lung Tumors

Nicholas J. Pastis
Nichole T. Tanner
Gerard A. Silvestri

A wide variety of extrapulmonary syndromes have been reported with lung cancer. This chapter will focus primarily on paraneoplastic syndromes, a heterogeneous group of disorders associated with cancer but not due to direct invasion, obstruction, or metastasis.[1,2] As many paraneoplastic syndromes share similar underlying mechanisms, they may be classified as endocrine, hematologic, and neurologic syndromes. More broadly speaking, they are either hormonally or immunologically based.

Paraneoplastic syndromes affect up to 8% of patients with cancer,[3] and of all malignancies, lung cancer is most commonly associated with these syndromes. The subtype of lung cancer most commonly associated with paraneoplastic syndromes is small-cell lung cancer (SCLC), but some such as hypertrophic pulmonary osteoarthropathy (HPO) and hypercalcemia are more common in non–small-cell lung cancer (NSCLC).[4]

Endocrine and hematologic syndromes associated with lung tumors are listed in Table 118-1. The endocrine syndromes are characterized by the ectopic production by tumor cells of biologically active peptide hormones that bind to receptors in adjacent or distant organs, giving rise to a clinical syndrome. Hematologic syndromes develop in patients with lung cancer through the production by tumor cells of cytokines that activate progenitor cells in the bone marrow. Neurologic syndromes, such as encephalomyelitis and subacute sensory neuropathy, are caused by the induction of

TABLE 118-1 Endocrine and Hematologic Syndromes Associated with Lung Tumors

Syndrome	Tumor	Proteins/Cytokines
Hypercalcemia of malignancy	Non–small-cell	Parathyroid hormone-related peptide
		Parathormone
Hyponatremia of malignancy	Small-cell	Arginine vasopressin
	Non–small-cell	Atrial natriuretic peptide
Ectopic ACTH syndrome	Small-cell	Adrenocorticotropic hormone
	Carcinoid tumors	Corticotropin-releasing hormone
Acromegaly	Carcinoid tumors	Growth hormone–releasing hormone
	Small-cell	Growth hormone
Carcinoid syndrome	Carcinoid tumors	Serotonin
	Large-cell	
	Small-cell	
Granulocytosis	Non–small-cell	G-CSF
		GM-CSF

Thrombocytosis	Non–small-cell	IL-6
	Small-cell	
Thromboembolism	Non–small-cell	Unknown
	Small-cell	

antibodies directed against proteins expressed by the lung cancer cells and directed against antigens present on cells in the nervous system. In clinical practice, an understanding of the extrapulmonary syndromes is important for several reasons: (1) recognition of a syndrome may serve as a harbinger of an occult malignancy or may signify disease recurrence; (2) the course of the endocrine and hematologic syndromes usually parallels the course of the lung cancer, although the neurologic syndromes frequently do not; and (3) appropriate treatment of the extrapulmonary syndrome often reduces the patient's morbidity and may allow definitive treatment of the cancer. In general, definitive treatment of the underlying tumor is the most effective form of therapy for the paraneoplastic syndromes, so their presence should not preclude treatment of lung cancer with curative intent as most syndromes are reversible once the patient receives treatment.

HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia is commonly seen in cancer patients[5,6] and lung cancer is the most common solid tumor associated with it, occurring in up to 20% of patients.[7,8] It is overall the most common of the paraneoplastic syndromes. It occurs most frequently in patients with squamous cell lung cancer, but is occasionally seen in patients with adenocarcinoma and very rarely in patients with SCLC.[9]

BIOLOGY

Etiologic mechanisms for hypercalcemia in patients with lung cancer include parathyroid hormone–related peptide (PTHrP) production, increased levels of the active metabolite of vitamin D (calcitriol, also called 1,25-dihydroxyvitamin D_3), and localized osteolytic hypercalcemia.[5,10] Most cases of hypercalcemia in patients with lung cancer are caused by the ectopic production of PTHrP by tumor cells (referred to as humoral hypercalcemia of malignancy).[11–13] The PTHrP gene expresses three messenger RNAs (mRNAs) that encode three distinct peptides, each differing at the COOH-terminal region (Fig. 118-1). Eight of the first 13 amino acids in PTHrP are homologous with PTH, so similar functional activity is shared between the two peptides. PTHrP mRNA and peptides have been demonstrated in cancer cells from patients with lung cancer and hypercalcemia. PTHrP has been shown to bind to PTH receptors in the bone and kidney, which causes increased osteoclastic bone resorption, decreased bone formation, and decreased calciuria, leading to hypercalcemia.[14,15] Levels of 1,25-dihydroxyvitamin D_3 are suppressed in patients with PTHrP-induced hypercalcemia, but are raised in patients with primary hyperparathyroidism. This difference occurs because renal α-hydroxylase activity is low in PTHrP-induced hypercalcemia, unlike primary hyperparathyroidism.[16] PTH production by lung cancer cells has also been described, but it is a very rare cause of hypercalcemia of malignancy.[17–19] Other factors that cause bone resorption have been identified in the plasma of patients with lung cancer, including transforming growth factor-α and a vitamin D metabolite. These are very rare, however, and their causative role in hypercalcemia has not been shown conclusively.

DIAGNOSIS

The early symptoms of hypercalcemia include thirst, malaise, fatigue, anorexia, polyuria, constipation, nausea, and vomiting. As hypercalcemia becomes increasingly severe (>14.0 mg/dL), confusion, lethargy, coma, and death can occur. The demonstration of a suppressed intact parathyroid hormone (iPTH) level and a low or normal calcitriol level along with an increased concentration (>10.5 mg/dL) of calcium in the serum of a patient with NSCLC should suggest this paraneoplastic syndrome. This is in contrast to the findings of elevated iPTH and calcitriol levels in primary hyperparathyroidism, which may occur in up to 10% of patients with cancer. A complete diagnostic evaluation includes measuring serum concentrations of iPTH, PTHrP,[20] 1,25-dihydroxyvitamin D, 25-hydroxyvitamin D, calcium, albumin, magnesium, and phosphorus. Other potential causes of elevated serum calcium should also be excluded. Thiazide diuretics, vitamin D or lithium administration, hyperthyroidism, and sarcoidosis are potential causes.[21] Bone scintiscan should be obtained to exclude bone metastases. An elevated PTHrP level in the absence of bone metastases establishes the diagnosis of humoral hypercalcemia of malignancy caused by ectopic PTHrP.[15,20]

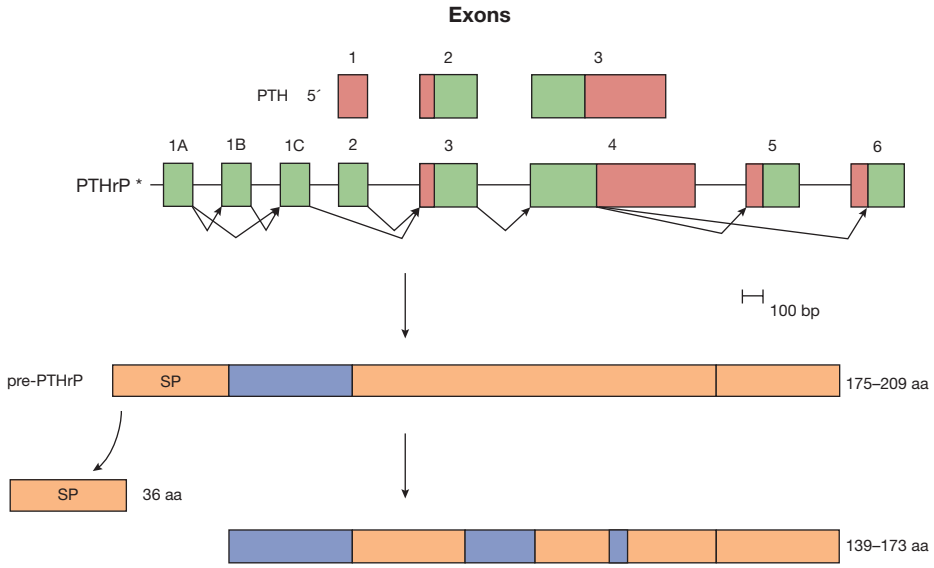

Figure 118-1 Parathyroid hormone and parathyroid hormone-related peptide. The human PTH gene has three exons, which constitute the protein-coding segments. The protein-coding segments are represented by the *black boxes*. The PTHrP gene is more complex, with eight exons. Through alternative splicing, three different isoforms of mRNA can be produced. These isoform mRNAs encode the pre-PTHrP proteins, which vary in size from 175 to 209 amino acids (aa). Thirty-six amino acids are removed from the amino terminal end as the signal peptide. Three different PTHrP molecules are produced, with 139 to 173 aa. The rectangular region at the carboxy terminal represents the different lengths of PTHrP. The N-terminal region (1–34 aa) mimics the classic PTH-like function (*hatched box*). The midregion (67–86 aa) of the peptide stimulates placental calcium transport (*shaded box*). The C-terminal region (107–111 aa) inhibits osteoclastic bone resorption (*double hatched box*).

■ TREATMENT

As with other paraneoplastic syndromes, treatment of the underlying cancer is the most effective method of treating the humoral hypercalcemia associated with lung cancer. Until this can occur, medical management of hypercalcemia must be considered. If asymptomatic or mildly symptomatic, hypercalcemic patients with calcium levels <12 mg/dL (3 mmol/L) do not require immediate treatment. Similarly, a serum calcium level of 12 to 14 mg/dL (3–3.5 mmol/L) may be well-tolerated chronically, and may not require immediate treatment. However, an acute rise to these concentrations may cause a marked change in sensorium, requiring intervention. In addition, patients with a serum calcium concentration >14 mg/dL (3.5 mmol/L) require treatment, regardless of symptoms.[22,23] Treatment includes intravenous saline, with the addition of furosemide diuresis only after correction of intravascular volume depletion. Subcutaneous calcitonin has a rapid onset of action and is most useful in severe cases. Mithramycin and long-acting bisphosphonates, such as pamidronate, are effective for long-term control of hypercalcemia.[24] Corticosteroids exert their effect through inhibition of dihydroxyvitamin D_3 synthesis and therefore have less effect in patients with elevated PTHrP.

Humoral hypercalcemia usually develops in patients with advanced progressive cancer and is associated with a median survival of about 1 month.[25,26] Nonetheless, in some cases, treatment of hypercalcemia serves an important palliative role by improving symptoms and allowing patients to be discharged from the hospital.

HYPONATREMIA OF MALIGNANCY

Hyponatremia is a frequent complication in patients with cancer. It occurs at presentation in approximately 15% of patients with SCLC and 1%of patients with NSCLC.[27] The ectopic production of arginine vasopressin (AVP) by cancer cells plays a causal role in the majority of cases.[27] This form of hyponatremia is recognized as the *syndrome of inappropriate antidiuretic hormone* (SIADH). Up to one-third of patients with lung cancer and hyponatremia do not demonstrate elevation of AVP in their tumors or plasma.[28–30] In these patients, the ectopic production of atrial natriuretic peptide (ANP) has been implicated, but the exact contribution of this hormone remains to be defined.[28]

■ BIOLOGY

AVP is a 9-amino acid peptide normally produced by the neurohypophysis. The peptide binds to receptors in the kidney to reduce the excretion of free water. When plasma osmolality exceeds 280 mOsm/kg, the release of AVP from the pituitary increases, causing the kidney to retain more free water and maintain fluid and osmolar balance. In patients with SCLC, ectopic production of AVP causes hyponatremia by inhibiting free-water excretion in the distal tubule of the kidney. AVP mRNA is expressed in SCLC cells and the peptide is translated and secreted (Fig. 118-2). Measured levels of AVP in plasma are often increased.[31]

There is a subgroup of patients with SCLC and hyponatremia, however, who have no detectable levels of plasma AVP.[32] Similar findings have been shown in SCLC cell lines.[33] The tumors from these patients express ANP mRNA, secrete the peptide, and have high levels of ANP in their plasma.[34] ANP is the leading candidate to be the natriuretic factor that Bartter and Schwartz proposed in their original description of SIADH. Further investigation into the precise role of ANP in patients with SCLC and hyponatremia of malignancy is ongoing.

■ DIAGNOSIS

In patients with lung cancer, hyponatremia is most frequently diagnosed as a laboratory abnormality in the absence of significant symptoms. The symptoms of acute hyponatremia do not typically occur because the syndrome develops over a prolonged period in concert with the growth of the lung cancer. When symptomatic, mild hyponatremia (serum sodium <135 mmol/L) can cause headache, difficulty concentrating, nausea, weakness, and fatigue. Severe hyponatremia (serum sodium <125 mmol/L), especially when it develops rapidly, can lead to serious symptoms including confusion, hallucinations, seizures, coma, respiratory arrest, decerebrate posturing, and death.[35]

The diagnosis of SIADH is based on the following criteria: (1) plasma hypo-osmolality (<280 mOsm/kg); (2) osmolality of urine greater than serum (usually >500 mOsm/kg); (3) persistent urinary excretion of sodium in the absence of diuretics (>20 mEq/L); (4) absent signs of volume depletion; and (5) normal renal, adrenal, and thyroid function.[36]

In patients with lung cancer, nonmalignant causes of hyponatremia should be considered in the initial evaluation. These include diuretic use, renal disease, cardiac dysfunction, hypoadrenalism, thyroid disease, and dilutional hyponatremia. Medications as a cause for hyponatremia should also be addressed. Patients with lung

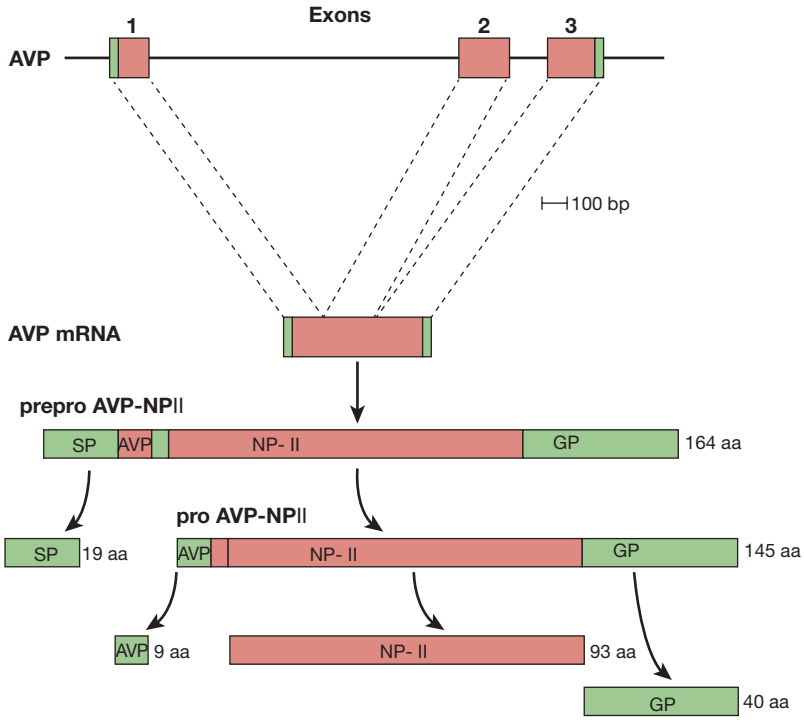

Figure 118-2 Arginine vasopressin. The three exons of the human AVP gene rise to a 700-base arginine vasopressin mRNA. The mRNA is translated into a 164-amino acid (aa) preprohormone with a 19-amino acid amino terminal signal peptide (SP). The SP is cleaved, giving rise to a 145-amino acid prohormone. This prohormone is processed into the nonapeptide AVP, a 93-amino acid neurophysin (NP), and a 40-amino acid glycoprotein (GP). The black portions of the boxes represent the protein-coding portion of the gene and mRNA.

cancer are commonly treated with cisplatin and narcotics, both of which can cause SIADH.

TREATMENT

The initial therapy for hyponatremia caused by lung cancer is treatment of the underlying malignancy. This often involves multimodality therapy with surgical excision, radiation, and/or chemotherapy. Even with tumor response to therapy, hyponatremia often persists or may recur following tumor progression. In SCLC, there are data to suggest that those patients who do not fully regain normal values of plasma sodium have a poorer survival than those patients who do.[37,38]

Asymptomatic patients with chronic hyponatremia are at low risk for serious neurologic sequelae, but are at risk of developing osmotic demyelination with rapid correction of the serum sodium concentration.[39] Treatment is therefore aimed at gradual correction. Fluid restriction, which can be estimated by urinary and plasma electrolytes, but is usually started at 500 mL per day, is a cornerstone of therapy.[40] Pharmacologic therapy may be indicated when fluid restriction is ineffective or poorly tolerated. Demeclocycline blocks the action of AVP on the renal tubule, thereby reducing urine osmolality and increasing serum sodium levels; however, its effects can be variable and it can cause nephrotoxicity.[35] Lithium and phenytoin also inhibit the effects of AVP on the renal tubule, but are no longer recommended for treatment. A more recent option for the treatment of hyponatremia is vasopressin receptor antagonists. Conivaptan is a nonselective vasopressin receptor antagonist indicated for patients with moderate-to-severe hyponatremia with nonsevere symptoms and is administered intravenously.[41] Tolvaptan is an orally active, selective AVP receptor 2 (V2) antagonist that has a similar indication. By blocking AVP effects in the renal collecting duct, aquaresis is promoted, leading to a controlled increase in serum sodium levels.[42]

For patients who present with severe, symptomatic hyponatremia characterized by seizure, delirium, or coma, rapid treatment is warranted.[43] The widely accepted goal of therapy is to correct the serum sodium by 1 to 2 mmol/L per hour through the infusion of 3% saline. The administration of concomitant furosemide is also recommended. The magnitude of correction within the first 24 hours is suggested to be no more than 8 to 10 mmol/L and no more than 18 to 25 mmol/L in the first 48 hours to avoid osmotic demyelination. An alternative approach is to treat until acute symptoms resolve and then adjust the correction rate.[44]

ECTOPIC ADRENOCORTICOTROPIC HORMONE (ACTH) SYNDROME

Lung cancers are the most common neoplasms that cause ectopic ACTH production and Cushing syndrome, accounting for 50% of all cases. SCLC accounts for 80% to 90% of cases associated with lung cancer. Carcinoid tumors (10%) and bronchial adenocarcinomas (5%) have also been reported to produce biologically active ACTH. While biochemical abnormalities suggestive of ectopic ACTH production are reported in 30% to 50% of SCLC, Cushing syndrome is clinically present in only 1% to 5% of SCLC.[45–50] Hypercortisolism is important to recognize as it increases the risk of therapy-induced complications[51,52] such as opportunistic infections and venous thromboembolism (VTE).[53–55]

BIOLOGY

Most cases of Cushing syndrome associated with lung cancers are caused by ectopic production of ACTH by the tumor.[56] The precursor gene, proopiomelanocortin (POMC), is expressed in the cancer cells, and a 241-amino acid prohormone is translated and then cleaved into ACTH (39 amino acids), melanocyte-stimulating hormone, and opiate-like hormones (Fig. 118-3). The ACTH binds to receptors in the adrenal gland, causing them to produce excessive glucocorticoid and mineralocorticoid hormones.[57]

Ectopic production of corticotropin-releasing hormone (CRH) has been reported as a cause of Cushing syndrome in a small number of patients with SCLC or bronchial carcinoids.[49] CRH is a 41-amino acid peptide normally produced in the paraventricular nuclei of the hypothalamus that stimulates the release of ACTH from the pituitary.

CLINICAL PRESENTATION AND DIAGNOSIS

Ectopic ACTH production occurs with equal frequency in males and females, but Cushing syndrome has an 8:1 female preponderance. Patients who have slow-growing carcinoid tumors often present with the clinical features of Cushing syndrome: truncal obesity, moon facies, striae, polyuria, and polydipsia. In contrast, patients with SCLC often present with other signs of mineralocorticoid and glucocorticoid excess due to the rapidity of tumor growth: edema, weakness, hypertension, and hypokalemic alkalosis.

The diagnostic evaluation of ectopic ACTH syndrome starts by excluding iatrogenic Cushing syndrome in order to avoid unnecessary chemical testing. Once iatrogenic disease has been excluded, initial testing should include the following: 24-hour urinary-free cortisol, late-night salivary cortisol, and the low-dose dexamethasone suppression test.[58–61] The diagnosis of Cushing syndrome is

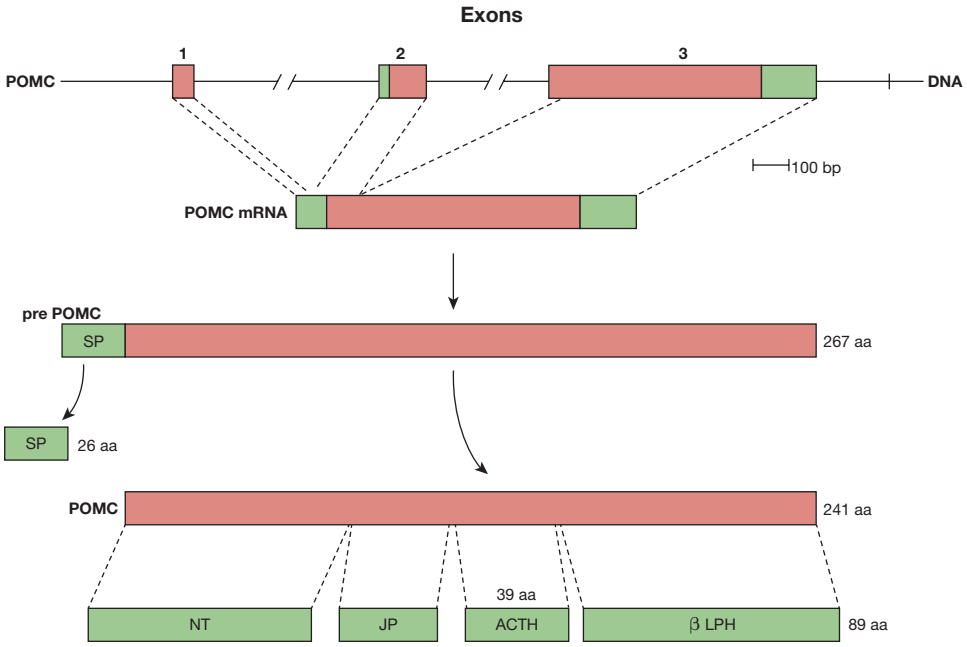

Figure 118-3 Proopiomelanocortin. The three exons of the POMC gene give rise to a 1072-base POMC mRNA. The mRNA is translated into a 267-amino acid pre-POMC with a 26-amino acid amino terminal signal peptide (SP). The SP is cleaved, creating the 241-amino acid POMC. The POMC peptide is cleaved into many products, including the N-terminal peptide (NT), the joining peptide (JP), a 39-amino acid mature ACTH, and β-lipotropin (β-LPH). The molecules can also undergo further processing. The black portions of the exons represent the protein-coding portion of the gene and mRNA.

established when at least two of these tests are unequivocally abnormal. Demonstration of an increased plasma ACTH level (>22 pg/mL) confirms that the hypercortisolism is ACTH-dependent. Finally, persistently elevated serum cortisol in response to a high-dose dexamethasone suppression test differentiates ectopic ACTH syndrome from a pituitary source.[58,62,63] Bronchial carcinoids are an exception, because in some tumors, ACTH and cortisol levels have been suppressed by dexamethasone.[64,65]

In patients with clinical features of Cushing syndrome in whom the dexamethasone suppression test is equivocal, a CRH stimulation test or bilateral inferior petrosal vein sampling will provide the definitive diagnosis. After CRH infusion, pituitary tumors release increased amounts of ACTH, whereas pituitary-independent lung tumors should not. Similarly, in pituitary-dependent Cushing syndrome, petrosal vein sampling will reveal a gradient between the level of ACTH in the petrosal vein and the peripheral concentration. In contrast, patients in whom ACTH is ectopically produced demonstrate no gradient between the petrosal vein and the peripheral blood.[66,67]

TREATMENT

Management of a patient with lung cancer and ectopic ACTH syndrome requires therapy directed at both the underlying tumor and the hypercortisolism. The treatment for a patient with ectopic ACTH production is to remove the source of the ACTH. This requires combination chemotherapy, with or without irradiation, for patients with SCLC and surgical resection and/or radiation for patients with carcinoid tumors. Chemotherapy for patients with SCLC and ectopic ACTH syndrome has been problematic. Patients often have a poor response to chemotherapy and are susceptible to early infection and death. Early control of a patient's glucocorticoid excess is beneficial and may reduce the morbidity of treatment.

When removal of the ectopic source of ACTH is not possible, pharmacologic agents directed at blocking adrenal cortisol production may be successful. These drugs include ketoconazole, mitotane, metyrapone, and aminoglutethimide. Ketoconazole is an imidazole derivative that inhibits steroidogenesis at both adrenal and gonadal sites; it may be the most effective and least toxic agent available.[68,69] Metapyrone and aminoglutethimide also have shown limited success by inhibiting adrenal steroid synthesis. Octreotide, a somatostatin analog, can suppress ectopic ACTH production and has been reported to be useful in some of these patients.[68] Bilateral adrenalectomy should be considered in patients who fail medical therapy.[62,70]

In some patients, the clinical signs and symptoms of ectopic ACTH production develop before the development of a clinically obvious lung cancer. In these cases, symptomatic management of hypercortisolism is undertaken and periodic imaging studies are performed because these patients may have a slow-growing carcinoid tumor that will be amenable to surgical resection.[64,71]

ACROMEGALY

Only 1% of acromegaly is caused by ectopic production of growth hormone–releasing hormone (GHRH) or growth hormone (GH) by tumors.[72] Of these, the majority are caused by carcinoid tumors of the lung and intestine.[73]

BIOLOGY

The ectopic production of GHRH or GH by lung cancers has been demonstrated to cause acromegaly. In most cases, the GHRH gene is expressed by the cancer cells, and a 40- or 44-amino acid peptide is produced.[74] Circulating GHRH peptide binds to receptors in the pituitary gland resulting in the production of excessive amounts of GH.[75] GH then mediates its effects through GH receptors in soft tissue and by stimulating the production of insulin-like growth factor-1 (IGF-1).

Although many carcinoid tumors express immunoreactive GHRH and result in abnormal GH secretion,[76–78] most patients with these tumors are not clinically acromegalic. It has been suggested that the observed high incidence of GHRH expression and low incidence of clinical acromegaly may be due to inadequate tumor production of GHRH or due to the impaired bioactivity of the circulating GHRH.[75]

DIAGNOSIS

The earliest features of GH excess are hypertrophy of the extremities and face (often manifest as increased glove, shoe, and ring size), thickened leathery skin, prominent skin folds, hyperpigmented skin, and hair growth. Bony changes, hypertension, and diabetes mellitus are later, less common findings.

The presentation of a patient with a lung mass and signs of acromegaly should raise suspicion of ectopic acromegaly especially if the mass is found to be carcinoid. The diagnosis of ectopic acromegaly is established by elevated serum levels of GHRH or GH, the absence of a pituitary tumor, complete recovery following lung tumor

resection, positive GHRH immunostaining, detection of GHRH mRNA, positive bioassay (cultured rat pituitary cells produce GH in response to tumor extract), or GHRH extraction from the tumor tissue.[79] Because coincidental pituitary tumors and solid tumors have been described, patients who have lung cancer in association with low GHRH levels and high GH and IGF-1 levels should undergo magnetic resonance imaging (MRI) to exclude a pituitary tumor.

TREATMENT

Management of ectopic acromegaly involves surgical resection of the tumor and is often curative in those with lung carcinoid. In those with unresectable or metastatic cancers, medical therapy with somatostatin analogs, such as octreotide and bromocriptine, have been shown to be effective.[80,81] Bromocriptine acts by inhibiting GH release by the pituitary; octreotide lowers both GH and IGF-1 levels in plasma and also appears to inhibit GHRH release by tumors. Clinical abatement of acromegalic features has been reported in patients treated with octreotide.

CARCINOID SYNDROME

Ectopic serotonin production is rare in lung neoplasms, occurring in 1% to 5% of patients with pulmonary neuroendocrine tumors (NETs).[82] Hallmarks of the syndrome include skin flushing of the upper thorax, secretory diarrhea, and bronchoconstriction. It is important to recognize an acute carcinoid crisis in patients with lung cancer as it can be precipitated by chemotherapy, biopsy, anesthesia, surgery, or the use of adrenergic drugs. It is a result of a massive serotonin release, and can lead to cardiopulmonary failure.[83]

The evaluation for carcinoid syndrome begins with a 24-hour urine collection for the main metabolite of serotonin, 5-hydroxyindoleacetic acid (5-HIAA). This test has a specificity of approximately 90%.[84] Detection of occult NETs in patients presenting with a carcinoid syndrome may be aided by testing for serum biomarkers of NETs such as neuron-specific enolase (NSE) and chromogranin A.[85] When these serum biomarkers are negative in a patient with high clinical suspicion of a NET, radionuclide-labeled octreotide scintigraphy is useful as up to 80% of pulmonary NETs express somatostatin receptors.

In patients who are surgical candidates, surgery is the optimal treatment of carcinoid syndrome. Otherwise, control of symptoms should be the goal via somatostatin analogs, serotonin receptor blockers, interferon, and antidiarrheal medications. In addition, carcinoid crisis can be prevented or treated with intravenous octreotide acetate.[83]

HEMATOLOGIC SYNDROMES

Most hematologic syndromes associated with lung tumors are not as well characterized as the endocrine syndromes, and an ectopic hormone responsible for the syndrome has not been identified in most tumor tissues. In many of the hematologic syndromes, such as granulocytosis and thrombocytosis, clinical sequelae are often absent. As with the endocrine paraneoplastic syndromes, the most appropriate therapy for the hematologic syndromes is the treatment of the underlying neoplasm.

GRANULOCYTOSIS

NSCLC is the most common cancer associated with granulocytosis. Fifteen to twenty percent of patients with NSCLC have granulocytosis, with absolute white blood counts ranging from 10,100 to 25,000 (normal range is 4000–10,000). Its presence is associated with a poorer prognosis compared to patients without granulocytosis.[86–88] Although granulocyte colony-stimulating activity can be demonstrated in serum and/or urine in 80% of affected patients, tumor production of granulocyte colony-stimulating factor, granulocyte monocyte colony-stimulating factor, or interleukin-6 (IL-6) has been shown in only a minority of patients.[89,90]

Virtually all patients with lung cancer who present with tumor-associated granulocytosis are asymptomatic. The diagnosis is suggested by the presence of an increased white blood count in which neutrophils predominate without immature forms, in the absence of non-neoplastic causes. An increased leukocyte alkaline phosphatase score and a normal bone marrow are consistent with this diagnosis.

THROMBOCYTOSIS

Thrombocytosis is common in patients with lung cancer, afflicting 16% to 32% of patients with both NSCLC and SCLC.[91,92] The pathogenesis of thrombocytosis in patients with lung cancer has not been definitively elucidated. IL-6, which is a cytokine for megakaryocytes, has been demonstrated in cell lines from patients with lung cancer and thrombocytosis, and increased levels of IL-6 have been demonstrated in the plasma of such patients. Thrombopoietin is increased in patients with lung cancer and thrombocytosis but is decreased in patients with essential thrombocytosis. The identification of the thrombopoietin gene may lead to a better understanding of the role of this protein in paraneoplastic thrombocytosis.

Patients with thrombocytosis are nearly always asymptomatic and do not have an increased incidence of thromboembolism. The diagnosis of cancer-associated thrombocytosis is suggested by an increased platelet count ($>500{,}000/mm^2$) in a patient with newly diagnosed lung cancer, and it is associated with advanced disease and worse clinical outcomes.[93,94] A primary myeloproliferative disorder can be excluded by a bone marrow biopsy.[95] In addition, the presence of the JAK2 V617F mutation may indicate essential thrombocytosis (present in 50% of cases) since it is not present in cases of reactive thrombocytosis.[96]

THROMBOEMBOLISM

Of all disease states, lung cancer is known to have one of the strongest associations with VTE.[97] The incidence of VTE in patients with lung cancer is approximately 40 to 100 cases per 1000 person-years compared to 1 to 2 cases per 1000 person-years in the general population. It is also notable that 20% of patients who present with recurrent idiopathic venous thrombosis are found to have an underlying diagnosis of cancer.[98] The spectrum of causes of thrombosis in patients with lung cancer is broad, including disseminated intravascular coagulation (DIC), Trousseau syndrome (recurrent migratory venous thrombophlebitis), nonbacterial thrombotic endocarditis, and obstruction of great vessels.[99,100] Surgical procedures and chemotherapy have also been demonstrated to increase cancer patients' risk of thrombotic complications.[101]

Cancer cells are able to directly activate the clotting cascade via two procoagulants: tissue factor (TF) and cancer procoagulant (CP). Increased expression of human TF has been shown in NSCLC tissue, and active TF-bearing microparticles, which may originate from tumor cells, have been demonstrated in the circulation of cancer patients.[102,103] Microparticle-associated TF activity has been proposed as a mechanism for the prothrombotic state in cancer patients.[104]

The treatment of VTE associated with active lung cancer differs from standard treatment of VTE. It was previously shown that for recurrent thromboses, long-term subcutaneous heparin is more efficacious than warfarin.[105] More recently, a meta-analysis of six randomized controlled trials in cancer patients being treated with long-term anticoagulation for VTE found no statistically significant survival benefit for low molecular weight heparin (LMWH) compared to warfarin, but a statistically significant reduction in VTE with LMWH, with no significant difference in bleeding. [106,107]

NEUROLOGIC SYNDROMES

There are a number of paraneoplastic neurologic syndromes associated with lung cancer. Encephalomyelitis, cerebellar degeneration, retinopathy, opsoclonus/myoclonus, and the Lambert–Eaton

TABLE 118-2 Neurologic Syndromes Associated with Lung Cancer

Syndrome	Tumor	Antibody	Antigen
Encephalomyelitis/subacute sensory neuropathy	Small-cell	Anti-Hu	Hu-D antigen: 35–40-kDa neuronal nuclear protein
Cancer-associated retinopathy	Small-cell	Antirecoverin	23-kDa protein specific to photoreceptor cells (recoverin)
Lambert–Eaton syndrome	Small-cell	Anti-P/Q channel	P/Q-type calcium channel

syndrome have all been described and are most commonly associated with SCLC. The majority of these syndromes are a result of an autoimmune response directed at shared antigens present in both cancer cells and normal neural tissue. The autoantibodies associated with each neurologic syndrome are listed in Table 118-2.

■ ENCEPHALOMYELITIS/SUBACUTE SENSORY NEUROPATHY

The paraneoplastic syndrome of encephalomyelitis/subacute sensory neuropathy was first described in a patient with SCLC. More than 70% of cases of paraneoplastic encephalomyelitis are diagnosed in patients with SCLC, with a wide range of clinical presentations. A specific antibody, anti-Hu, which reacts with the HuD antigen expressed by lung cancer cells and neuronal tissues, has been identified in many patients who develop this syndrome. Approximately 20% of patients with SCLC are seropositive for anti-Hu but only a few will develop a paraneoplastic neurologic disorder.[108]

Biology

Anti-Hu is an IgG antibody found in the sera and cerebrospinal fluid of patients with sensory neuropathy and encephalomyelitis. Patients with anti-Hu have an immune response targeting a family of proteins known as Hu, which are expressed in both neurons and SCLC cells. They are RNA-binding proteins involved in the post-transcriptional regulation of RNA in neurons.[109] The HuD gene has been mapped to the chromosome 1p region and appears to be a marker of neuroendocrine differentiation in these cells.

Diagnosis

The location and severity of neuronal loss predict the patient's clinical symptoms. Neuronal loss may be limited to one area of the nervous system, but more frequently involve multiple areas over time.[31] Onset of symptoms is subacute and precedes the diagnosis of SCLC in greater than 70% of cases, thus warranting a complete diagnostic evaluation for occult malignancy in those presenting with encephalomyelitis or subacute sensory neuropathy. One-half of patients undergo progressive sensory loss in the hands and feet. Others present with a limbic encephalopathy characterized by memory loss, behavioral changes, and seizures. Focal myelopathy with weakness, brain stem signs (nystagmus, dysarthria), and autonomic nervous system dysfunction also occur in patients with this syndrome. CT scans are typically normal in these patients, but MRI studies may show increased T2 signal in affected areas of the brain.

Pathologic examination demonstrates neuronal loss and inflammatory infiltrates in areas of the nervous system including the brain stem, hippocampus, spinal cord, and dorsal root ganglia.[110] Serum and cerebrospinal fluid from patients with paraneoplastic encephalitis will often reveal the anti-Hu antineuronal antibody.

Treatment

Early diagnosis and treatment of the underlying tumor offers the best chance for stabilizing the neurologic syndrome.[111] Alternative therapies with immunosuppressive agents and plasmapheresis, with the goal of clearing the responsible immunoglobulin, have been shown to be effective in only 10% to 20% of patients. Patients with anti-Hu positive neurologic paraneoplastic syndromes are more likely to die of neurologic causes including respiratory muscle failure, autonomic failure, and progressive diffuse encephalopathy rather than from metastatic cancer.[112,113]

■ PARANEOPLASTIC CEREBELLAR DEGENERATION

Paraneoplastic cerebellar degeneration is manifested by symptoms including ataxia, nystagmus, dysarthria, mental changes, muscular and sensory deficits, and diplopia. It has been recognized in 12% of patients with paraneoplastic neurologic syndromes secondary to lung cancer.[114] Pathologically, there is the diffuse loss of Purkinje cells accompanied by thinning of the molecular and granular layers, and degeneration of the long tracts of the spinal cord.[115] In patients with SCLC, paraneoplastic cerebellar degeneration can occur with or without the presence of Hu antineuronal antibodies, indicating that the syndrome can develop via different immunologic mechanisms.[112]

■ OPSOCLONUS AND MYOCLONUS

Opsoclonus is a disorder consisting of involuntary rapid conjugate eye movements in vertical and horizontal directions. It is often associated with myoclonus in patients with solid tumors. This syndrome of opsoclonus/myoclonus has been identified in both SCLC and NSCLC. Opsoclonus/myoclonus is the main presentation of paraneoplastic cerebellar degeneration associated with anti-Ri antibodies.[116] Anti-Ri binds to two proteins (55 and 80 kDa) expressed in the dentate nucleus.[117] Anti-Ri antibodies have also been identified in those presenting with a broad variety of neurologic symptoms.[118] The anti-Hu antibody has been identified in some patients with SCLC and opsoclonus/myoclonus. Patients with a known lung cancer presenting with any spectrum of neurologic symptoms should have serologic evaluation for these antibodies.

■ CANCER-ASSOCIATED RETINOPATHY

Cancer-associated retinopathy is a rare paraneoplastic syndrome that occurs predominantly in patients with SCLC. Autoantibodies have been identified in patients with this disorder that bind to a photoreceptor-specific protein called recoverin.[119,120]

Biology

Retinal ganglion cells and their processes are characteristically lost in this disorder because of the autoantibodies that bind to recoverin, a 23-kDa photoreceptor-specific protein found in rods and cones as well as in SCLC cells. The autoantibodies that cause the cancer-associated retinopathy specifically bind to the recoverin protein and do not recognize other retinal proteins.[86,87,121,122]

Diagnosis

The clinical triad of photosensitivity, ring-scotoma visual field loss, and attenuation of retinal arteriole caliber is considered highly suggestive of cancer-associated retinopathy. The typical patient presents with symptoms of rapid visual loss, night blindness, and color loss. On physical examination, most patients show visual field deficits, disk pallor, and cells in the vitreous body, along with arteriolar narrowing.

Demonstration of the antirecoverin antibody in a patient with signs of retinopathy establishes the diagnosis. As with paraneoplastic

cerebellar degeneration, cancer-associated retinopathy is often the first sign of an occult carcinoma. Therefore, an evaluation for lung cancer should be performed in all patients who present with this syndrome.[88,123,124]

Treatment

In contrast to those with the other paraneoplastic neurologic syndromes, more than half of patients with cancer-associated retinopathy have been reported to respond with visual improvement after systemic steroid therapy. Treatment of the primary tumor without immunosuppressive therapy has not been shown to result in visual improvement in patients with cancer-associated retinopathy, and most of these patients develop progressive visual loss and blindness within 18 months.[125]

LAMBERT–EATON SYNDROME

The Lambert–Eaton syndrome afflicts fewer than 2% of lung cancer patients but has been reported in up to 5% of patients with SCLC. Conversely, 50% to 60% of all patients with Lambert–Eaton syndrome will be diagnosed with SCLC.[126]

Biology

Lambert–Eaton syndrome is a consequence of the development of antibodies to P/Q-type voltage-gated calcium channels in motor and autonomic nerve terminals, leading to inhibition of acetylcholine release.[127] The resulting weakening of the neuromuscular signal results in neurologic dysfunction. This antibody also binds to the 58-kDa synaptic vesicle protein synaptotagmin, which is present in SCLC cells.[128] These antibodies have been detected in 85% to 90% of patients with Lambert–Eaton syndrome and some reports cite close to 100% detection in those with SCLC.[129]

Diagnosis

Lambert–Eaton syndrome is diagnosed based on clinical signs and symptoms, electrophysiologic studies, and antibody testing. The classic clinical triad is proximal muscle weakness (usually the first symptom noted), autonomic dysfunction, and areflexia.[130] Physical examination reveals decreased or absent tendon reflexes. Because there is a short-term return of reflexes following muscle contraction in 40% of patients, these should be tested after a period of rest.[131] Electrophysiologic studies with repetitive nerve stimulation are often diagnostic of Lambert–Eaton syndrome. A decrement in the amplitude of the muscle action potential of at least 10% is considered abnormal, a finding seen in the overwhelming majority of patients with Lambert–Eaton syndrome. Nerve stimulation post exercise demonstrates an amplitude increase, which has a high sensitivity and 100% specificity for Lambert–Eaton syndrome and distinguishes this entity from myasthenia gravis.[132,133]

Treatment

Treatment of the underlying SCLC with chemotherapy often can effectively treat Lambert–Eaton syndrome. Should symptoms persist, the first choice of treatment is 3,5-diaminopyridine which results in functional improvement the majority of the time. There are two proposed mechanisms of action. First, by blocking voltage-gated potassium channels, the action potential at the motor nerve terminals is prolonged and the opening time of the voltage-gated calcium channels is lengthened.[134] Second, neuromuscular transmission is potentiated by targeting a subunit on the voltage-gated calcium channel directly.[135] In those with severe weakness and impairment that develops gradually over time and fails to improve despite treatment of the underlying cancer and a trial of 3,5-diaminopyridine, combined therapy with prednisone and azathioprine has been shown to be effective.[136] For those with severe weakness and severe impairment that develops rapidly, treatment with intravenous immunoglobulin or plasmapheresis is indicated as it can provide marked improvement in strength although transient while treatment for SCLC is started.[137]

HYPERTROPHIC PULMONARY OSTEOARTHROPATHY

HPO is characterized by the abnormal proliferation of the cutaneous and osseous tissues at the distal parts of the extremities. While any intrathoracic malignancy may be associated with HPO, the disease is secondary to primary lung cancer in 80% of cases.[138] HPO is estimated to occur in 0.7% to 4.5% of patients with lung cancer.[138–141]

BIOLOGY

While the exact mechanisms of HPO have not been elucidated, there are a number of theories. One suggests that arteriovenous shunting within the tumor allows platelet clumps and megakaryocytes that are usually cleared by the pulmonary endothelium to enter the systemic circulation and deposit in the distal vasculature, causing the local release of growth factors including platelet-derived growth factor (PDGF) and vascular endothelial growth factor (VEGF).[142] PDGF causes proliferation of fibroblasts and an increase in vascularity and permeability resulting in connective tissue changes that are the hallmark of clubbing.[143] VEGF leads to vascular hyperplasia, osteoblastic differentiation with new bone formation, and edema; all are features of HPO.[144] Ectopic production of these growth factors by the lung cancer is an alternative hypothesis.[145] Finally, there is a neurogenic hypothesis that proposes a vagally-mediated alteration in limb perfusion. This is supported by experimental and clinical observation of resolution of HPO symptoms following unilateral vagotomy.[146]

DIAGNOSIS

HPO is diagnosed by clinical symptoms and radiographic findings. The classic triad consists of digital clubbing, arthritis, and bilateral, symmetrical periosteal formation of new bone. The latter finding is often present on plain films of the long bones but bone scintigraphy is the most sensitive method for the detection and evaluation of the extent of HPO-associated periostitis (Fig. 118-4). With its ability to delineate the subtleties of the disease, scintigraphy often reveals abnormalities that precede plain radiograph changes.[147] Scintigraphy findings range from symmetrical increased "bracelet-like" uptake to diffuse uptake in the juxta-articular regions and distal portions of the long bones.[148] Fluoro-18-deoxyglucose positron emission tomography (PET) is the preferred imaging modality for the clinical staging of lung cancer. There are case reports documenting the ability of PET to detect periosteal new bone formation of HPO and is more sensitive and specific than bone scintigraphy for detecting bone metastasis as an alternative cause of long bone pain.[149,150,151]

TREATMENT

With resection and/or treatment of the primary tumor, the symptoms of HPO will improve and often times resolve completely.[141,152,153] When the primary cause cannot be eliminated, there are a variety of symptomatic treatments for HPO, based largely on the theorized mechanisms of pathogenesis, that anecdotally have been demonstrated to have efficacy.[154] Performance of unilateral vagotomy on the ipsilateral tumor side has led to complete resolution of pain and radiographic regression of HPO.[155,156] There are a number of case reports to support the use of nonsteroidal anti-inflammatory drugs including ketorolac, indomethacin, and the COX-2 inhibitor rofecoxib.[142,157,158] Prostaglandin E is effectively reduced with these medications, thereby decreasing periostitis and HPO symptoms. The somatostatin analog octreotide has also been used with success in the treatment of HPO and is thought

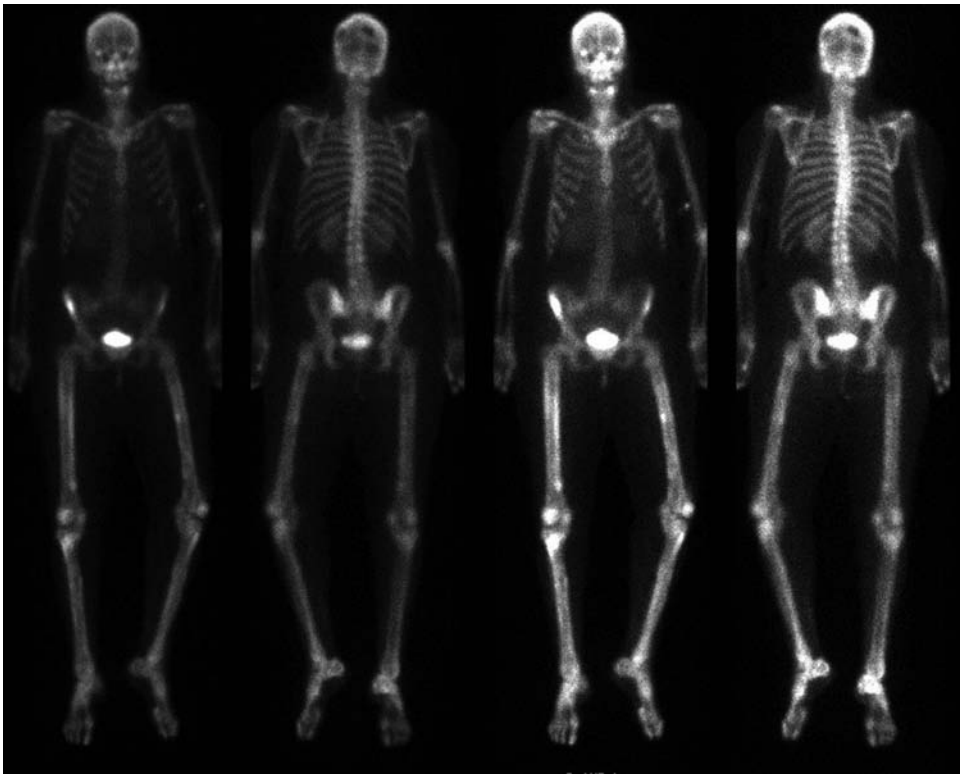

Figure 118-4 Tc99 bone scintigraphy reveals symmetric diffusely increased uptake mainly along the cortical margins of both femurs (seen best in the two delayed phase images on the right).

to be efficacious due to inhibition of VEGF and endothelial proliferation.[159,160] Bisphosphonates are potent inhibitors of bone metabolism and also decrease the levels of VEGF and symptomatic improvement has been demonstrated with both pamidronate and zoledronic acid.[161,162]

CHAPTER 119

Pulmonary Metastases: The Role of Surgical Resection

Loretta Erhunmwunsee
Thomas A. D'Amico

Pulmonary metastasectomy refers to the resection of secondary pulmonary malignancy. Most patients who develop pulmonary metastases are not curable, owing to presentation with extrathoracic metastases and lack of effective systemic therapy. Although there are no prospective, randomized trials comparing pulmonary metastasectomy to medical therapy or observation, metastasectomy has gained wide acceptance for patients who present only with metastases to the lungs. Several retrospective studies demonstrate an apparent survival advantage in patients with secondary pulmonary malignancy who undergo complete resection, comparing survival after resection to historical data for unresected patients, for whom survival is poor.

An important study that assessed the long-term results of pulmonary metastasectomy was based on an analysis of the International Registry of Lung Metastases.[1] This collaborative project retrospectively reviewed 5206 cases of lung metastasectomy performed in several institutions. Patients with a single metastasis had a survival of 43% at 5 years, compared with 34% in those with two or three metastases, and 27% in those with four or more metastases. The most important determinant of survival, however, was resectability: the ability to achieve complete resection of all recognizable pulmonary metastases. The overall 5-year survival for patients who underwent complete resection was 36%, with a median survival of 35 months. In those patients who had undergone incomplete resection, the 5-year survival was only 13%, and the median survival was 15 months.[1] These findings suggest that surgical resection offers a survival advantage for some patients.

A prognostic model was also created to select those who would benefit most, including the parameters of resectability, disease-free interval (DFI), and the number of metastases. Four distinct prognostic groups were identified: group 1 is the resectable group with no risk factors (DFI > 36 months and single metastasis); group 2 is the resectable group, with one risk factor (DFI < 36 months or multiple metastases); group 3 is the resectable group, with two risk factors (DFI < 36 months and multiple metastases); and group 4 is the unresectable group. Median survival was 61 months for group 1, 34 months for group 2, 24 months for group 3, and 14 months for group 4.[1] This prognostic model was presented as a reasonable guide to select patients for surgery.

In general, to be considered for pulmonary metastasectomy patients must fit the following criteria: the primary disease is controlled (or controllable); there is no other distant disease; complete resection of pulmonary involvement is achievable with adequate pulmonary reserve; and there are no effective medical therapies. For pulmonary metastasectomy to have survival value, the primary tumor itself must be controlled or controllable. If the pulmonary metastases are recognized metachronously, the site of the primary tumor is examined to exclude local recurrence. If the pulmonary disease has presented synchronously, the primary tumor is assessed and a decision is made regarding management. If no other metastatic disease is present, staged resection of the primary tumor and the pulmonary nodules is a reasonable approach if complete resection can be achieved. In some cases, management of a potentially resectable primary tumor is deferred until after attempted metastasectomy, with the understanding that inability to achieve complete resection would preclude surgical management of the primary tumor.

Assessment of the ability to achieve complete resection with adequate pulmonary reserve includes appraisal of the number of nodules, consideration of the location of nodules, and estimation of the postoperative pulmonary function. For patients with unilateral involvement of three or fewer nodules and preserved pulmonary function (forced expiratory volume in 1 second [FEV1] > 80%), the assessment is straightforward. For patients with bilateral involvement of five or more nodules, the calculation is more difficult, especially if any of the lesions are central and require anatomic resection (either segmentectomy or lobectomy). There is no consensus regarding the number of nodules and the ability to achieve complete resection, but increasing numbers of pulmonary nodules are associated with a higher risk of unresectability.

The ability to achieve complete resection is considered integral to achieving the potential survival benefit of metastasectomy. CT scan of the chest is regarded as the most important preoperative radiologic examination, but its ability to detect all metastatic nodules is uncertain. Thus, some surgeons also rely on manual palpation to locate nodules that may escape CT detection. McCormack et al.[2] prospectively studied the usefulness of video-assisted thoracoscopic surgery (VATS) versus thoracotomy for metastasectomy in 50 patients with nodules suspected to be pulmonary metastases on CT scan. They performed VATS resection of nodules identified on the CT scan and then proceeded with an open thoracotomy with bimanual palpation to find and resect undetected lesions. Of the first 18 patients, 10 were found to have malignant lesions that were missed by CT and VATS. The authors concluded that the CT scan would fail to detect all nodules and, therefore, that VATS for a metastasectomy would not result in complete resection.[2] Kidner et al.[3] came to the same conclusion after evaluating patients with melanoma metastases. Although single-detector row helical CT scans produce 3- to 5-mm-thick image reconstruction, thin-slice multidetector row CT scanners allowed the entire lung to be scanned with 1-mm sections in as little as 5 seconds. Kang et al.[4] used the thin-slice 16-detector row CT scan preoperatively in 27 patients and compared the findings to the pathology report after resection. In nonosteosarcoma patients, the CT found 67 of 69 metastatic nodules detected by bimanual palpation intraoperatively. Based on observations like this, thin-slice CT scanners are preferred for the evaluation of pulmonary metastases.

Staging for distant metastatic disease is performed prior to pulmonary resection, based on the primary tumor. In most patients, CT of the chest and abdomen is performed to exclude liver metastases. PET scan is also commonly used to assess metastatic disease in patients with epithelial tumors and melanoma, but the effectiveness of PET is questionable.[5] Mayerhogger et al. analyzed the utility of PET in a study of 181 patients with pulmonary metastases. The sensitivity of PET was 7.9% for lesions of 4 to 5 mm; 33.3% for lesions 6 to 7 mm; 56.8% for lesions 8 to 9 mm; 63.6% for 10 to 11 mm; 100% for 12 mm or higher ($p < 0.0010$);[6] thus, the larger the lesion, the more sensitive the PET results. Any patient with pulmonary metastases who presents with neurologic symptoms should undergo magnetic resonance imaging of the brain to exclude involvement of the central nervous system.

TABLE 119-1 Survival After Pulmonary Resection for Metastatic Colorectal Carcinoma

	No. of Patients	Median Survival (mo)	5-Year Overall Survival (%)	10-Year Overall Survival (%)

OUTCOMES ACCORDING TO HISTOLOGY

Pulmonary metastasectomy can be considered for a variety of primary tumors, as discussed in the following sections.

■ COLORECTAL CANCER

Colorectal cancer is the most common primary histology for patients with potentially resectable pulmonary metastases. Table 119-1 lists recent studies of patients with colorectal cancer who underwent resection for pulmonary metastases; 5-year survival ranged from 36% to 56%.[7–12] In spite of the improved outcomes from pulmonary metastasectomy in some patients with colorectal cancer, the survival of most patients with pulmonary colorectal metastases will not be improved by pulmonary resection. Thus, much focus has gone into determining which patients with colorectal metastases to the lungs should in fact undergo surgery and which patients should not be offered futile resection. In an analysis by Phannschmidt et al.,[13] none of the following factors were of prognostic value: unilateral versus bilateral disease, number of nodules, size of the dominant nodule, DFI, elevated preoperative serum level of carcinoembryonic antigen (CEA), use of chemotherapy, the type of surgical approach used, or repeat pulmonary resection for local recurrent disease. Recently, Iida retrospectively analyzed 1030 patients who underwent pulmonary metastasectomy for colorectal carcinoma, documenting a 5-year survival rate of 53.5% and median survival of 69.5 months. In this series, the number of nodules, tumor size, pre-op CEA, and lymph node involvement were all independent predictors of survival.[10] Onaitis et al.[14] found that the recurrence-free survival was 28% and overall survival was 78% at 3 years in 377 patients who underwent resection of pulmonary colorectal carcinoma metastases. DFI less than a year, female gender, and numerous metastases (>3) were independent significant predictors of recurrence.[14] Gonzalez et al. recently performed a meta-analysis of 25 studies encompassing 2925 patients, and analyzed factors that impacted survival after lung metastectomy for colorectal cancer. They found that a short DFI, multiple lung metastases, positive hilar or mediastinal lymphadenopathy, and elevated prethoracotomy CEA levels were associated with poor survival.[15] Review of these and other studies (see Table 119-2) demonstrates that there is not yet a consensus as to which factors have impact on survival.

In recent years, the selection criteria for pulmonary metastasectomy have expanded to include patients with limited hepatic metastases. There has been no reported difference in outcome in patients with and without history of previously resected hepatic metastases at the time of pulmonary resection, and thus many surgeons perform pulmonary metastasectomy even in patients who have undergone hepatic resection for colorectal metastases at an earlier stage.[13,14,17] Patients who undergo combination hepatic and pulmonary metastasectomy have a 30% 5-year survival rate.[17] Pfannschmidt et al.[13] found similar results with no significant difference in outcome observed between patients with and without history of previously resected hepatic metastases at the time of pulmonary resection with 5-year survival rates between 30% and 42%.[13]

■ SARCOMA

Dear et al. analyzed 114 patients who underwent resection of pulmonary metastases for bone and soft tissue sarcomas. They found that the 5-year survival was 43% and the relapse-free survival was 19%. An incomplete surgical resection was associated with an increased risk of death, but neither the diameter of the largest resected metastasis nor a DFI of <18 months was independent prognostic factors.[18] Treasure et al.[19] performed a systematic review of studies involving a total of 1357 patients with pulmonary sarcoma metastases. Among patients who underwent pulmonary metastasectomy, they found a 5-year survival of 34% for patients with metastatic osteogenic sarcoma and 25% for patients with soft tissue sarcomas, as compared to a 5-year survival of 20% to 25% for all osteogenic sarcoma patients and 13% to 15% for soft tissue sarcoma patients. In this review, patients with fewer metastases and longer DFI had longer survival. These authors suggest that pulmonary resection of osteogenic sarcoma, including repeat pulmonary metastasectomy, is a safe and viable option.

TABLE 119-2 Prognostic Factors Associated with Survival after Pulmonary Metastasectomy for Colorectal Cancer (by Multivariate Analysis)

	No. of Patients	No. of Mets	DFI	CEA Level	Nodal Disease	Incomplete Resection
Gonzalez et al.[15]	2925	SS	SS	SS	SS	~
Iida et al.[10]	1030	SS	~	SS	SS	SS
Onaitis et al.[14]	378	SS (>3)	SS (<1 y)	~	~	~

Pastorino et al.[1]	5206	SS (>1)	SS (<3 y)	~	~	~

ns, not significant; SS, statistically significant; ~, not reported; DFI, disease-free interval.

RENAL CELL CARCINOMA

Evidence suggests that patients with pulmonary metastases from renal cell carcinoma also derive a survival benefit from metastasectomy. Murthy et al.[20] studied 92 patients who underwent pulmonary metastasectomy secondary to renal cell cancer metastases. Complete resection was achieved in 68% of the patients, with an associated 5-year survival of 45%, compared with only 8% in those who were incompletely resected. Assouad et al.[21] found similar results in their evaluation of 65 patients with renal cell pulmonary metastases. The 5-year overall survival in those who underwent complete resection was 37.2%. They also found that mass size and lymph node involvement were important prognostic factors.[21]

MELANOMA

Chua et al. evaluated 292 patients who underwent pulmonary melanoma metastasectomy. The median overall survival was 23 months and the 5-year survival was 34%. Metastasis size greater than 2 cm and positive surgical margins were independently associated with poorer progression-free survival and overall survival. The presence of more than 1 metastasis was independently associated with poorer overall survival as well.[22] Petersen et al.[23] have also reported the survival benefits after the resection of lung metastases from melanoma. They analyzed 1720 patients with melanoma with pulmonary metastases and found that patients with complete resection had a median survival of 19 months and a 5-year survival of 21%; these outcomes were superior to those of patients who had incomplete resections, with a median survival of 11 months and a 5-year survival of only 13%.[23]

OTHER MALIGNANCIES

Pulmonary metastasectomy may be considered for patients with primary tumors of other histologic types, such as breast cancer,[24] uterine cancer,[25] and prostate cancer,[26] although patients with these malignancies are less likely to meet the criteria for operability.

PROGNOSTIC FACTORS

Important prognostic factors in considering resection of lung metastases include lymph node involvement and the extent of surgical resection, as discussed below.

LYMPH NODE INVOLVEMENT

The systematic review by Pfannschmidt et al.[13] revealed that mediastinal and pulmonary lymph node involvement were ominous prognostic factors only in studies in which nearly all the patients had undergone a systematic mediastinal and hilar lymph node dissection concurrent with pulmonary metastasectomy. The 5-year survival of the group with lymph node involvement was 0% to 33.5%, compared with 38.7% to 71% for patients with no thoracic lymph node metastases. In contrast, lymph node involvement did not predict survival in studies in which lymph node dissection was not routinely performed, or in studies in which lymph node dissection was carried out only in cases when node enlargement was detected by computed tomographic scan.[13] Many studies have evaluated the impact of positive nodes during mediastinal lymph node dissection in patients with metastatic disease.[11,16,27] All show worse survival in the presence of positive mediastinal lymph nodes. Recently, Hamaji et al.[12] concluded that mediastinal lymph node metastases are a significant negative prognostic factor for survival after pulmonary metastasectomy for metastatic colorectal cancer. Dominguez-Ventura and Nichols[28] went on to suggest that a complete mediastinal lymphadenectomy be performed for all patients undergoing pulmonary metastasectomy to better define a patient's prognosis and to guide adjuvant therapy. As these previously mentioned studies suggest, lymph node involvement is likely a negative prognostic factor, but debate still arises concerning which patients should be offered surgical exploration for resection in the setting of clinical nodal involvement. Based on the evidence of negative prognostic value, biopsy or resection of mediastinal or hilar lymph nodes would provide valuable information to guide further decision-making.

EXTENT OF SURGICAL RESECTION

Most pulmonary metastases are located peripherally and are frequently immediately subpleural, amenable to a wedge resection. When metastatic disease is more central, the anatomic resection should be performed with the goal of preserving as much pulmonary parenchyma as possible. Of the 5206 patients who were analyzed in the International Registry of Lung Metastases, 67% underwent a wedge resection, 9% a segmentectomy, 21% a lobectomy or bilobectomy, and 3% underwent a pneumonectomy.[1] It appears that wedge resection, if feasible, is as effective as anatomic resection. In their systematic review focused on the outcomes of pulmonary metastasectomy for colorectal cancer, Pfannschmidt et al.[13] suggested that the extent of resection was not an important prognostic factor for survival. These results support the practice of performing limited resection when possible to preserve lung parenchyma and function while achieving clear margins.

SURGICAL APPROACHES IN PULMONARY METASTASECTOMY

Potential surgical approaches to pulmonary metastasectomy include thoracotomy, thoracoscopy, thoracoscopy with subxiphoid manual palpation, median sternotomy, bilateral synchronous thoracotomies, and bilateral transsternal thoracotomy. In the International Registry, the surgical approach was unilateral thoracotomy in 58%, bilateral synchronous or staged thoracotomy in 11%, median sternotomy in 27%, and thoracoscopy in 2%.[1] Conventional open surgical approaches include thoracotomy, sternotomy, and bilateral transsternal thoracotomy (clamshell). The most frequently used approach is the posterolateral thoracotomy, which provides excellent exposure and the ability to palpate the lung for lesions not detected radiographically. The drawbacks of thoracotomy include postoperative pain and the inability to perform bilateral resection during a single operative session in most patients. Median sternotomy offers the advantage of assessing both lungs prior to resection and achieving bilateral resection, with less postoperative pain compared with bilateral thoracotomy (staged or simultaneous). However, a sternotomy provides suboptimal exposure of the posterior lung fields, and it is inadequate for sublobar anatomic resection of the lower lobes in most patients. Finally, a bilateral transsternal thoracotomy, also termed clamshell approach, can be used. This approach provides excellent bilateral exposure of all lung fields and adequate exposure for any anatomic resection. The disadvantages of this approach include acute and chronic postoperative pain, and the sacrifice of both internal mammary arteries. Most patients considered for resection for metastatic disease have bilateral involvement.[29] Roth et al.[29] studied outcomes in matched patients with unilateral metastases from extremity soft tissue sarcomas diagnosed on CT scan. They compared patients who underwent metastasectomy by a thoracotomy to those who underwent median sternotomy for their unilateral disease, and they found that there was no difference in survival. They concluded that neither the type of incision nor the use of bilateral bimanual palpation influenced outcomes.[29] Although the achievement of complete resection is the most important prognostic variable associated with survival, there is no evidence that the use of staged bilateral resection is inferior to a single bilateral approach.

Thoracoscopic resection is gaining favor. Potential advantages of the minimally invasive approach include smaller incisions, less postoperative pain, shorter length of stay, fewer adhesions at reoperation, and better compliance with adjuvant therapies if indicated.[30–35] The argument against the minimally invasive approach is that small (<5 mm) malignant nodules may be missed without the benefit of

bimanual palpation.[2,36,37] Recently, Eckardt performed thoracoscopic pulmonary metastasectomy on 37 patients followed by open thoracotomy. In this series, 92% of the lesions were found during VATS, but 29 lesions were resected by the thoracotomy approach that followed.[38] Of the 29 lesions missed by VATS, only 6 were metastases (21%), while 19 were benign (66%) and 3 were subpleural lymph nodes (10%). They concluded that a significant proportion of missed nodules proved to be malignant (~20%), although this is a small fraction of all nodules. The authors did not address the clinical significance, however, of missing 6 malignant nodules, nor the clinical significance of resecting a much larger number of benign nodules.

In spite of data that suggest that lesions might be missed via thoracoscopic means, the biology of pulmonary metastases may, in fact, support the use of thoracoscopic resection.[39] First, any resected metastatic disease was presumably present (at least microscopically) prior to the treatment of the primary lesion, and has been "missed" for a significant period of time. There is no evidence to suggest that the timing of resection of nodules that would be missed at thoracoscopic resection, which are usually <5 mm in diameter, is critical to the final outcome. Second, multiple resections do not adversely affect the overall outcome of patients with metachronously detected metastases. Third, patients who subsequently develop unresectable disease will not have benefited from thoracotomy. Fourth, resection may be less stressful for patients, and therefore result in less immunosuppression, resulting in a more favorable disease course.

Currently, there is no evidence that resection of pulmonary metastases at the time that they become radiographically apparent is any less efficacious than open procedures that remove all nodules, benign and malignant, before their radiologic identification. Gossot et al.[40] recently documented that patients with sarcomatous pulmonary metastases had favorable long-term survival after thoracoscopic resection. In this study, 31 patients who underwent thoracoscopic resection had similar 1-year, 3-year, and 5-year overall and disease-free survivals when compared with the 29 matched controls who underwent thoracotomy resection. Repeat procedures for further surgical resection were required in 36% and 41% of patients in the VATS and thoracotomy groups, respectively.

Several other recent studies also suggest that VATS resection of pulmonary metastases yields comparable survival to thoracotomy. Chao et al. performed a case-matched study of 53 patients with pulmonary metastases from colorectal carcinoma who underwent open resection compared to 90 who underwent a VATS approach. They studied 35 pairs of patients matched for tumor number, diameter, and surgical procedure. Both groups had similar recurrence and 5-year overall survival rates, suggesting that VATS is not inferior to that of open thoracotomy for pulmonary metastasectomy.[41] Nakajima et al.[42] studied 143 patients with pulmonary metastases secondary to colorectal cancer who were diagnosed by helical CT scan. In this study, 71 patients underwent open thoracotomy, whereas 72 patients underwent VATS; 22 patients in the open group and 21 patients in the VATS group had multiple lesions. The authors reported superior 5-year survival (49.3%) in the VATS group compared with 39.5% in the open group ($p = 0.047$). The 5-year disease-free survival was 34.4% for the VATS group and 21.1% for the open group ($p = 0.064$). The authors suggest that VATS metastasectomy is a safe and valuable alternative to the open thoracotomy in selected patients.[42]

Finally, in a study comparing VATS (79 patients) to open (43 patients) approach for pulmonary metastases from colorectal cancer, there was no difference between the groups in the number of additional nodules found at surgery and no difference in the development of ipsilateral recurrence at 2 years.[43]

Based on these findings, there is no evidence to suggest that the thoracoscopic approach is inferior to open approaches in selected patients. The role of thoracoscopic resection in patients with many nodules (>5–10) has not been tested.

The use of multiple sequential pulmonary resections for recurrent disease has also been studied in patients who develop pulmonary metastases in the absence of extrathoracic disease. Welter et al.[7] found that repeat resections of pulmonary metastases secondary to colorectal cancer was safe and provided long-term survival. The authors reported 5-year survival of 53.8% in those who had repeat resection of pulmonary metastases. This study suggests that a second metastasectomy can be performed when new lesions grow are detectable, with good outcomes. The outcome of patients who underwent a second metastasectomy in the International Registry was also excellent. The 5- and 10-year survival rates were 44% and 29%, respectively, compared with 34% and 25%for patients having had one operation.[1] The favorable long-term results suggest a curative benefit of repeated salvage operations, rather than a simple selection effect, with no apparent disadvantages. These results suggest that the biology of the tumor is more important than the strategy of resection. Some lesions that are not detected by CT scan may be removed once they are detected at a later date without negatively influencing survival, because their biology is less aggressive; whereas resection of every possible lesion in a patient with very aggressive tumor biology may still lead to poor survival.

OTHER TREATMENT OPTIONS

Alternatives to surgical resection of pulmonary metastases include isolated lung perfusion using chemotherapeutic agents and various ablation techniques.

■ ISOLATED LUNG PERFUSION

Although surgical resection is effective for some patients with metastatic disease involving the lung, the majority of patients with pulmonary metastases develop unresectable disease, either due to extensive pulmonary involvement or due to extrathoracic involvement. In addition, some patients present with disease not amenable to resection. The concept of isolated lung perfusion has been developed to treat unresectable disease. Isolated lung perfusion involves direct infusion of chemotherapeutic drugs into the affected lung, allowing higher doses of agents to be infused locally, without the systemic side effects that would accompany such doses.

Den Hengst et al. studied 23 patients in a phase I clinical trial who underwent isolated lung perfusion using melphalan for unresectable colorectal, renal, sarcoma, and salivary gland tumor metastases to the lung. They showed that the overall and disease-free 5-year survival rates were 54.8% and 27.5%, respectively, with an overall median survival time of 84 months and disease-free median survival time of 19 months. They noted no major long-term pulmonary toxicity.[44] A novel option for isolated lung perfusion is currently under investigation, thoracoscopic lung suffusion, which is less invasive than lung perfusion and limits the systemic absorption of chemotherapy.[45]

■ ABLATION TECHNIQUES

Several ablation techniques are being studied to treat patients who have a limited number of pulmonary metastases that are not operable based on medical issues, such as cardiac status. Stereotactic radiosurgery is one option for ablation, and this technique may be coupled with image-guided robotics (CyberKnife, Accuray, Sunnyvale, CA). Snider et al. used CyberKnife on 24 high-risk patients with biopsy-proven single-peripheral lung metastases. A mean dose of 52 Gy was delivered in three fractions. The 2-year Kaplan–Meier local control and overall survival rates were 87% and 50%, respectively. They concluded that CyberKnife is an effective treatment for high-risk surgical patients with single, small, peripheral lung metastases.[46]

SUMMARY

Metastases to the lungs are common in patients with malignancy, and isolated pulmonary metastases may be seen in patients with many types of cancer. Despite the absence of prospective, randomized

controlled trials, it seems highly likely that pulmonary metastasectomy does improve outcomes in appropriately selected patients. Selection criteria include established control of the primary tumor, an absence of extrathoracic involvement, and disease amenable to complete resection with adequate residual pulmonary reserve. Many studies have investigated prognostic factors related to pulmonary metastasectomy, including the number of nodules, size of the dominant nodule, ability to achieve complete resection, histology, and DFI. Although each of these factors may influence outcome, the most important determinant of long-term survival is achieving a complete resection.

To optimize postoperative pulmonary function, parenchymal-sparing techniques are used whenever possible. Wedge resection is the most common surgical procedure, but more central lesions may require segmentectomy, lobectomy, and (rarely) pneumonectomy. Although posterolateral thoracotomy with manual palpation is considered important to identify all nodules and achieve complete resection, many surgeons prefer thoracoscopic resection and there is no evidence that this approach is inferior, as measured either by survival or by ipsilateral intervention. In addition to advantages in quality-of-life outcomes, the thoracoscopic strategy also simplifies reoperation when necessary and may prevent futile thoracotomy. Although complete resection is essential to improve survival, it is possible that staged complete resection is equally effective.

Lymphoproliferative and Hematologic Diseases Involving the Lung and Pleura

Douglas B. Flieder

Lymphoproliferative disorders of the lung and pleura comprise a varied but rare group of localized and diffuse processes that span the morphologic gamut from reactive to neoplastic and include several peculiar lesions that do not fit conventional definitions of either hyperplasia or neoplasia. Although most diagnoses are based on light microscopy, immunohistochemical and molecular investigations have assumed a vital role. Nomenclature and classification schemes have undergone drastic changes over the past quarter century and current definitions appear reasonable. Malignant lesions are best classified according to the current World Health Organization (WHO) scheme.[1] This chapter presents the clinicopathologic features of primary and secondary pulmonary and pleural hematolymphoid lesions.

ANATOMY AND HISTOLOGY OF THE PULMONARY LYMPHOID SYSTEM

Pulmonary lymphatics are divided into two interconnecting channels that drain to peribronchial, hilar, and/or mediastinal lymph nodes and eventually into the thoracic duct, right lymphatic duct, and subclavian veins.[2] One system drains through the visceral pleura around the lung into mediastinal lymph nodes and the other drains from central lung parenchyma to peribronchial and hilar lymph nodes. The lymphatics communicate at lobar, lobular, and pleural boundaries and thus serve each other as potential collaterals.[3,4] Although not usually obvious in histologic sections of normal lung, lymphatics are prominent in disease states ranging from pulmonary edema to lymphangitic carcinoma. In the latter, lymphatic channels distended with malignant cells are apparent within the visceral pleura, interlobular septa, and adventitia of arteries, veins, and bronchioles. Of note, alveolar septa do not contain lymphatic channels. All lymphatics contain valves and flat endothelial cells line the discontinuous basal lamina. Larger lymphatics contain smooth muscle and collagen.

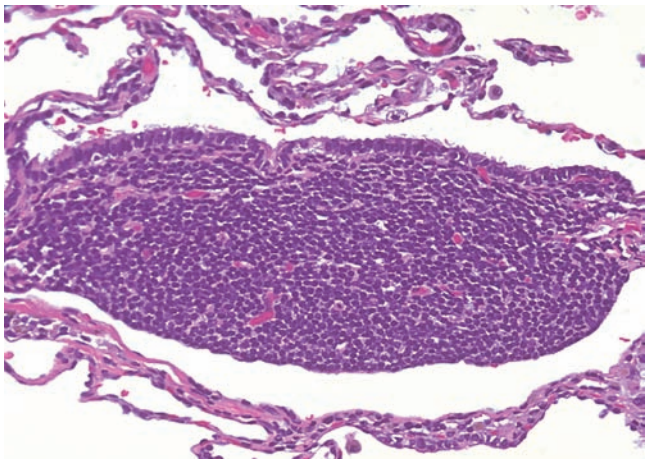

Figure 120-1 Bronchus-associated lymphoid tissue. The submucosal collection of lymphoid cells is intimately associated with overlying bronchiolar epithelium. Hematoxylin and eosin, 40× original magnification.

Small submucosal aggregates of lymphoid cells are often prominent at bronchial bifurcations and near distal respiratory bronchioles (pulmonary microtonsils) and represent bronchus-associated lymphoid tissue (BALT) (Fig. 120-1).[5–7] Whether humans are born with this specialized secondary lymphoid system, or whether the aggregates of B lymphocytes, T lymphocytes, HLA-DR+ interdigitating cells, follicular dendritic cells, and lymphoid follicles with overlying flattened and attenuated specialized epithelium develop in response to antigenic stimulation is controversial.[8,9] Viruses, connective tissue disorders, tobacco use, and obstructive pneumonia are just a few pathologic processes known to induce BALT (Table 120-1). Unlike typical lymph nodes that rely on

Hepatitis viruses
Human immunodeficiency virus
Drug-induced forms
Allogeneic bone marrow transplantation
Dilantin
Infections
Chlamydia
Mycoplasma
Tuberculosis
Familial

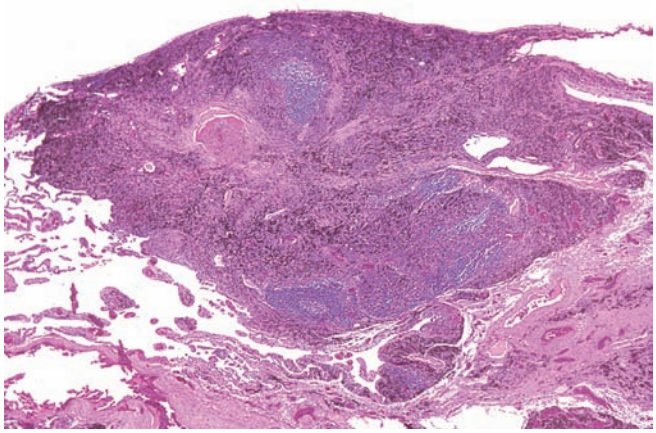

Figure 120-2 Intrapulmonary lymph node. Subpleural lymph nodes often accumulate carbon pigment and become fibrotic. The radiologic differential diagnosis includes carcinoma, while a fine-needle aspirate sample may mimic malignant lymphoma. Hematoxylin and eosin, 4× original magnification.

afferent lymphatics for antigen retrieval, BALT is integrated into lung tissue and antigen is sampled directly from the bronchial and bronchiolar lumens through specialized "lymphoepithelium." Immunoglobulins, most notably IgA, are synthesized and secreted by lymphocytes directly into airway lumens. Amazingly, this system appears capable of mounting a competent adaptive immune response. In addition, BALT B-lymphocytes circulate and "home" to other mucosal sites such as the conjunctiva, salivary glands, stomach, and intestines to create a common mucosal immune system, the mucosa-associated lymphoid system (MALT).[6] Thus, responses induced in one location can be replicated at other sites.[10] Malignant lymphoma arising in one MALT location can secondarily involve other MALT sites. BALT appears to be the origin of many primary pulmonary lymphoid lesions.[11]

Intrapulmonary lymph nodes (IPLs) may be part of the pulmonary immune system and may also be induced by antigenic stimuli rather than normal embryologic development.[12] Autopsy studies suggest a prevalence of 18%, and although many are related to bronchi of the first few orders, peripheral subpleural locations are not uncommon. In this age of high-resolution computed tomography (HRCT) and lung cancer screening programs, up to 80% of reported cases of IPLs occur in men with histories of tobacco use and almost 35% of cases are multiple.[13] They appear as round to angulated sharply circumscribed subpleural opacities up to 2 cm in diameter and are found along interlobular septa or within major and minor fissures. IPLs histologically resemble classic lymph nodes with well-developed cortical and medullary areas.[12,14] Sinus histiocytes frequently contain abundant anthracosilicotic pigment and silicotic nodules with calcifications may form (Fig. 120-2). In patients with chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), IPLs may be involved and, rarely, primary lung carcinoma or carcinoma from a nonpulmonary site can metastasize to IPLs. Most importantly, IPLs can be clinically, radiographically, and cytologically mistaken for malignancy.[15,16] Although fine-needle aspirates can exclude the possibility of carcinoma, an erroneous diagnosis of lymphoma might be considered.

GENERAL CONSIDERATIONS

Although internists, pulmonologists, and radiologists often diagnose pulmonary diseases on the basis of clinical and radiographic findings and rely on tissue samples merely for confirmation, lymphoid lesions of the lung are often unsuspected diagnoses rendered by pathologists. Yet clinical and radiologic studies are essential in the interpretation of all lesions. Often, light microscopic considerations can be excluded purely on the basis of radiographic findings. For example, whereas pulmonary lymphomas can be localized or diffuse, lymphoid interstitial pneumonia (LIP) is always bilateral and diffuse.

Although fine-needle aspirate biopsies and transbronchial biopsies supplemented with ancillary studies may suffice for a diagnosis of malignant lymphoma, architectural and cytologic variability necessitates generous sampling. Since cellular monotony is not the sole criterion for malignancy, pulmonary lymphoid lesions often require wedge biopsies for diagnosis. Whereas sheets of uniform cells may be diagnostic of lymphoma, many malignant processes such as Hodgkin lymphoma (HL) and T-cell lymphoma are polymorphous and admixed with inflammatory cells. Secondary changes and biopsy-related artifacts may also confound the interpretation of a small sample.

Larger samples also allow for low-magnification pattern recognition. A "lymphatic distribution" may be seen in nonlymphoid processes such as sarcoidosis, yet is most striking in lymphoproliferative lesions reflecting the homing of lymphoid cells to endogenous pulmonary lymphatic routes. Although malignant lymphoid processes usually obliterate underlying lung architecture, diffuse alveolar septal expansion with lymphoid cells without a beaded lymphangitic pattern tends to represent an inflammatory rather than neoplastic process.

In addition to histologic examination, immunophenotyping is routinely performed and has become indispensable in diagnosing and classifying lymphoid lesions of the lung. Immunohistochemical studies can be reliably performed on formalin-fixed, paraffin-embedded tissue, whereas flow cytometry is useful for demonstrating immunoglobulin light-chain restriction. Aberrant antigen expression by either method also allows for subclassification. Polymerase chain reaction (PCR) may be required in up to 20% of cases to prove clonality.[17] Either rearrangement of the immunoglobulin heavy-chain gene joining region (*JH*) or the T-cell receptor γ-chain gene (TCR-γ) can be investigated. Lastly, chromosomal abnormalities indicative of specific lymphomas such as t(14;18) translocation and bcl-2 gene rearrangement in follicular lymphoma or t(11;14) translocation and cyclin D1 (bcl-1) gene rearrangement in mantle cell lymphoma may be helpful.

Given the complex evaluation required of these lesions, it is incumbent upon the clinician to deliver the fresh tissue sample to the pathologist along with his or her concern for lymphoma. Although formalin-fixed or B5 fixed, paraffin-embedded samples may suffice for diagnosis and immunohistochemical evaluation, cell suspensions and fresh frozen tissue are required for flow cytometry, cytogenetics, and many molecular studies.

Lastly, although clonality indicates malignancy, clonality in pulmonary lymphoid lesions may not predict clinical outcome. Many pulmonary lymphomas have long indolent courses with 10-year survival rates of more than 80% yet LIP, a polyclonal process, is progressive with one-third of affected patients dying of end-stage pulmonary fibrosis.[18,19]

REACTIVE LYMPHOID PROCESSES

Although the terminology used to describe inflammatory processes of the lung has remained relatively static over the past 25 years, immunohistochemistry and molecular genetic analysis have redefined diagnostic criteria. Processes arising from BALT include nodular lymphoid hyperplasia (NLH), follicular bronchitis/bronchiolitis (FBB), diffuse lymphoid hyperplasia (DLH), and LIP. Pulmonary hyalinizing granuloma (PHG) is included in this section for historical reasons only. Although the lesions are best considered either localized or diffuse, clinicopathologic entities including Castleman disease (CD) can manifest with either distribution.

■ LOCALIZED REACTIVE LYMPHOID PROCESSES

Localized reactive lymphoid processes, including nodular lymphoid hyperplasia, pulmonary hyalinizing granuloma, amyloidosis, and light chain deposition disease are discussed below.

Nodular Lymphoid Hyperplasia

Known to previous generations of pulmonologists and hematopathologists as "pseudolymphoma," this reactive process was recognized as a form of BALT hyperplasia in the mid-1980s.[20] Although NLH was once considered to be quite common, ancillary studies have convincingly demonstrated that most cases were actually low-grade lymphomas.[21] Thus true NLH is now considered a legitimate but exceedingly rare polymorphous nodular lymphoid lesion of the lung.[22] Neutrophilic microabscesses and foreign body giant cells found in several reported cases indicate that the lesion may be the result of an inflammatory stimulus. Interestingly, immunohistochemical studies have documented B-cell lymphomas of BALT within pre-existing reactive masses of BALT, such that one could, in the most general sense, consider NLH a precursor lesion.[11,20]

Most affected individuals are middle aged with a nearly equal gender incidence.[22,23] Patients are usually asymptomatic, although a small percentage may have autoimmune diseases such as systemic lupus erythematosus or Sjögren syndrome, or polyclonal hypergammaglobulinemia. Lesions usually appear as solitary subpleural radiographic nodules with air bronchograms, but several nodules or localized infiltrates can be seen, the latter finding serving as a reminder that the distinction between nodular and diffuse processes is arbitrary.[24] Up to one-third of cases feature regional lymphadenopathy.

Excised tan-white rubbery to firm nodules measure from 0.6 to 6.0 cm. Histologically, the well-demarcated lesions may feature slight extension along alveolar septa and central scarring. Normal lung parenchyma is overrun by large reactive germinal centers with well-preserved mantle zones, and lymphoepithelial lesions are not seen (Fig. 120-3). Interfollicular areas are filled with plasma cells and mature lymphocytes. The follicles are clearly reactive with a variety of cell types, mitoses, and macrophages. Regional lymph nodes often feature reactive follicular hyperplasia.

Immunohistochemical studies demonstrate a mixture of B- and T-cells. The B-cells express both κ and λ light chains, that is, lack light chain restriction. Aberrant B-cell staining for CD5, CD23, or CD43 is not seen, and the germinal centers do not stain with bcl-2.[22,25] Immunoglobulin heavy chain gene rearrangement or evidence of t(14;18) breakpoints is not observed. These ancillary findings are of the utmost importance since light microscopy alone may not differentiate NLH from an extranodal marginal zone B-cell lymphoma of MALT. The latter usually features infiltrative growth, but may have reactive follicles and polytypic plasma cells with only a focal monotypic cell population.

Surgical excision is usually curative, although a small percentage of patients develop local recurrences at the original surgical site. Neither systemic spread nor death has been reported.[22,25]

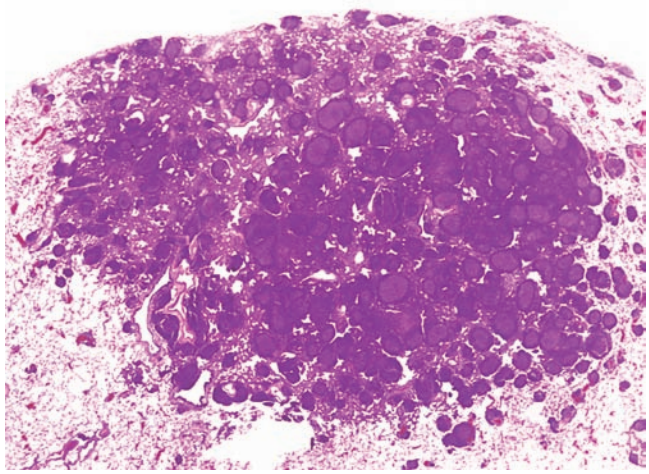

Figure 120-3 Nodular lymphoid hyperplasia. The lesion is composed of benign reactive germinal centers. Although radiographically nodular, germinal centers spill out into surrounding lung. Immunohistochemistry is required to exclude a diagnosis of malignant lymphoma. Hematoxylin and eosin, 1× original magnification.

Pulmonary Hyalinizing Granuloma

PHG is neither a lymphoid nor granulomatous lesion per se, but an ever-present lymphoid component allows for its discussion in a hematolymphoid chapter. This peculiar fibrosing process shares clinicopathologic and morphologic features with sclerosing mediastinitis, inflammatory pseudotumor of the orbit, Riedel thyroiditis, and idiopathic retroperitoneal fibrosis.[26] In fact, approximately one-fourth of cases feature concomitant mediastinal or retroperitoneal disease.[27,28] The etiology is unknown but it has been speculated to represent either an autoimmune phenomenon or exaggerated host response to mycobacteria or fungi.

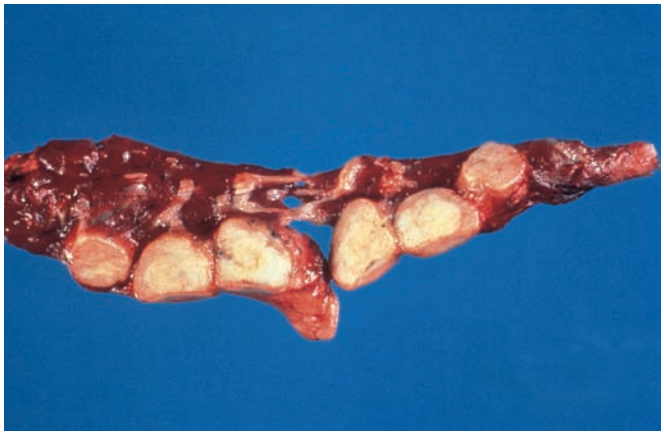
Age at presentation ranges from 24 to 77 years and women are affected twice as often as men. Most patients present with mild symptoms including cough, shortness of breath, fever, and fatigue but up to 25% of reported individuals are asymptomatic. Laboratory studies include positive antinuclear antibodies, rheumatoid factor, antineutrophil cytoplasmic antibodies, and Coombs-positive hemolytic anemia.[28] Elevated serum or tumor immunoglobulin G4 (IgG4) levels are rarely reported.[29,30] Skin testing often demonstrates exposure to *Mycobacterium tuberculosis* or *Histoplasma capsulatum,* but cultures and stains for microbes are negative. Radiographs reveal less than 4.0 cm bilateral and multilobar ill-defined homogeneous nodules that resemble metastases.[31] Unilateral and solitary cases measuring up to 15 cm have been reported. Although not common, focal central irregular calcification may suggest metastatic bone-forming neoplasms. Central cavitation is rare.

Lesions are sharply circumscribed white-tan rubbery masses composed of irregular concentric whorls of hyalinized collagen encasing vessels and airways (Fig. 120-4A).[27,28] The center of the lesion is paucicellular, whereas peripheral thick collagen bands are separated by mature T-lymphocytes, plasma cells, fibroblasts, and occasional giant cells (Fig. 120-4B). Blood vessels may feature transmural inflammation without necrosis. Microscopic calcifications can be seen, but granulomas are not present despite the designation PHG. The tumoral interface with lung parenchyma features reactive germinal centers, whereas adjacent lung may feature organizing pneumonia and hyperplasia of BALT. The morphologic differential diagnosis includes rheumatoid nodule, amyloidosis, granulomatosis with polyangiitis (Wegener granulomatosis), malignant lymphoma, inflammatory myofibroblastic tumor, and infections.[29] Clinicians should not be comfortable with a diagnosis of PHG rendered on anything less than a completely removed lesion.

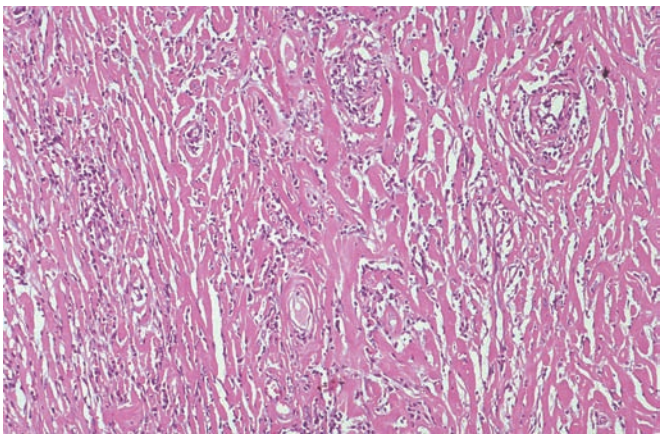
PHG tends to enlarge slowly and does not recur after surgical resection. However, growth of unresected or unresectable nodules can lead to respiratory compromise.[28]

Amyloidosis and Light Chain Deposition Disease

Immunoglobulin light chains can accumulate in many tissues in different forms, depending on the underlying condition and particular organ cytoskeleton. Clinically recognizable disease in the lung can manifest as tracheobronchial disease, solitary or multiple nodules, cystic lung disease, or in a diffuse interstitial parenchymal pattern.[32,33]



A



B

Figure 120-4 Pulmonary hyalinizing granulomas. **A.** Multiple well-circumscribed tan firm nodules can compromise respiratory function. **B.** Pink hyalinized collagen bands encircle vessels. Scant benign lymphoid infiltrates percolate between the collagen. Hematoxylin and eosin, 10× original magnification.

Most cases of diffuse light chain deposition in the lung are part of multiorgan involvement, are associated with plasma cell dyscrasia, have dismal clinical outcomes, and are not discussed further in this section.

Solitary and multiple amyloidoma are seen most often in older individuals, with a mean age of 67 years.[32] Central and solitary lesions are often incidental findings but airway or visceral pleural distortion may produce cough, hemoptysis, or pleuritic chest pain. A radiographic diagnosis can be suggested when calcification or ossification is noted (20%–50% of the time); otherwise, the clinical impression is that of a neoplasm.[34]

Serum or urine monoclonal proteins are found in 10% of patients, and this lung pathology may be associated with lymphoproliferative diseases such as benign monoclonal gammopathy of undetermined significance, Sjögren syndrome, Crohn disease, NLH, LIP, extranodal marginal zone B-cell lymphoma of MALT, or multiple myeloma.[32,35–37] Solitary amyloidoma without underlying blood dyscrasias probably represent a hyperimmune response to unknown antigens.

Waxy hard gritty and yellow-tan nodules measure up to 15 cm and are composed of amorphous eosinophilic hyaline material that obliterates lung parenchyma but spares many arterioles (Fig. 120-5). Lymphocytes, plasma cells, and multinucleated giant cells percolate through the amyloid, but the infiltrate is most dense at the periphery of the nodules. Calcification and ossification with secondary marrow space formation is common. Congo red staining examined by polarizing microscopy reveals lesional apple-green birefringence. Immunohistochemical studies usually demonstrate λ light-chain composition and negative immunoreactivity for amyloid A and transthyretin.[37,38] Plasma cells are most often polytypic; however, small foci of monoclonal plasma cells within foci of polytypic plasma cells have been identified.[39] Ultrastructurally, amyloid is composed of disorderly nonbranching hollow-core 8- to 10-nm fibrils. These extracellular deposits of chemically diverse proteins form a three-dimensional twisted β-pleated sheet. Resected lesions may not demonstrate malignancy, but patients should be screened for underlying monoclonal B-cell proliferations including multiple myeloma and overt B-cell malignancies.

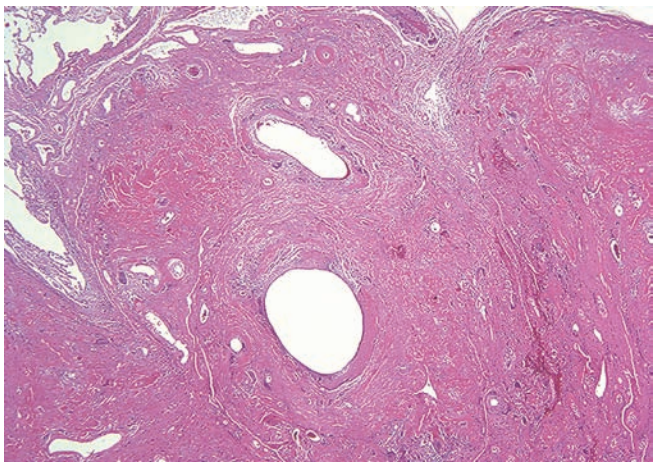


Figure 120-5 Nodular amyloidosis. Amorphous pink material replaces air spaces and overruns airways. In the absence of Congo red apple-green birefringence one should consider the possibility of nodular light chain deposition. Hematoxylin and eosin, 4× original magnification.

In stark contrast to nodular amyloidosis, pulmonary light chain deposition disease (LCDD) is associated with an underlying blood dyscrasia or renal failure in more than 50% of affected individuals.[40–42] Most patients have free κ monoclonal light chains (IgG, IgA, and IgM in decreasing order) in their urine or serum.[43] The clinical and light microscopic appearance of LCDD is similar to amyloid, and one might mistake a case lacking the characteristic Congo red staining as simply a poorly stained example of amyloid. These light chain deposits are composed of amorphous granular or globular electron dense material.[43] One should consider this entity when dealing with a nonamyloidotic deposit given its strong association with lymphoid malignancies including but not limited to multiple myeloma and renal failure.[43,44]

■ DIFFUSE REACTIVE LYMPHOID PROCESSES

Although NLH most likely represents a local response to an extrinsic stimulus and is clinically relevant owing to its radiographic appearance as a coin lesion and morphologic similarity with extranodal marginal zone B-cell lymphoma of MALT, the DLHs, FBB, and LIP represent a continuum of BALT hyperplasia often seen in patients with systemic diseases (Table 120-1).[20,25,45] The extent of lung involvement is due in large part to host immune factors.[46] Although thoracoscopic or open lung biopsies are required to establish these diagnoses and exclude other processes, including interstitial lung diseases and malignant lymphoma, morphology does not suggest etiology.

Follicular Bronchitis/Bronchiolitis

DLH *restricted* to the walls of airways and peribronchial tissue is referred to as FBB. FBB is often seen in individuals with

bronchiectasis, chronic infections, and chronic obstructive pulmonary diseases, including asthma.[45,47] The entity may also be seen in association with connective tissue diseases, congenital or acquired immunodeficiencies, or bone marrow transplantation; or as a manifestation of a hypersensitivity reaction.[48,49] When the process spreads along lymphatic routes of the pulmonary lobule some prefer the designation DLH instead of FBB.

Patients with FBB in association with connective tissue disease are usually in their forties and most often suffer from rheumatoid arthritis (RA) or Sjögren syndrome.[50,51] Patients with immunodeficiency syndromes such as acquired immunodeficiency syndrome (AIDS), common variable immunodeficiency, IgA deficiency, and Evans syndrome present in childhood, whereas those with hypersensitivity syndromes are usually in their sixth decade of life. Patients may also suffer with chronic low-grade infections such as mycoplasma, chlamydia, or Epstein–Barr virus (EBV).[45]

Individuals with FBB present with dyspnea, cough, and fever; some may have recurrent pneumonia or weight loss. Pulmonary function tests reveal restrictive, obstructive, or normal patterns.[47] Those with RA often have a very high rheumatoid factor on the order of 1:640 to 1:2560. Peripheral eosinophilia may be noted in those with hypersensitivity syndromes. Arterial blood gases show arterial hypoxia with a widened $AaPO_2$ gradient and hypocapnia. Chest radiographs feature bilateral diffuse reticular and nodular opacities, whereas HRCT show up to 12-mm centrilobular and peribronchial nodules with or without areas of ground-glass opacity.[24,52]

Gross pathology demonstrates numerous minute (1- to 2-mm) nodules adjacent to airways. Microscopically, nodular aggregates of B-cell rich lymphocytes and plasma cells with reactive germinal centers expand bronchial and/or bronchiolar submucosa and budge into and permeate overlying epithelium (Fig. 120-6). Rare T-cells wander beyond the follicles into adjacent alveolar septa.[25] Smaller airway lumens are distorted and narrowed predisposing to mucostasis and subsequent infections. Lymphoid follicles along interlobular septa and beneath the pleura represent a more diffuse form of lymphoid hyperplasia and warrant the descriptive diagnosis DLH.

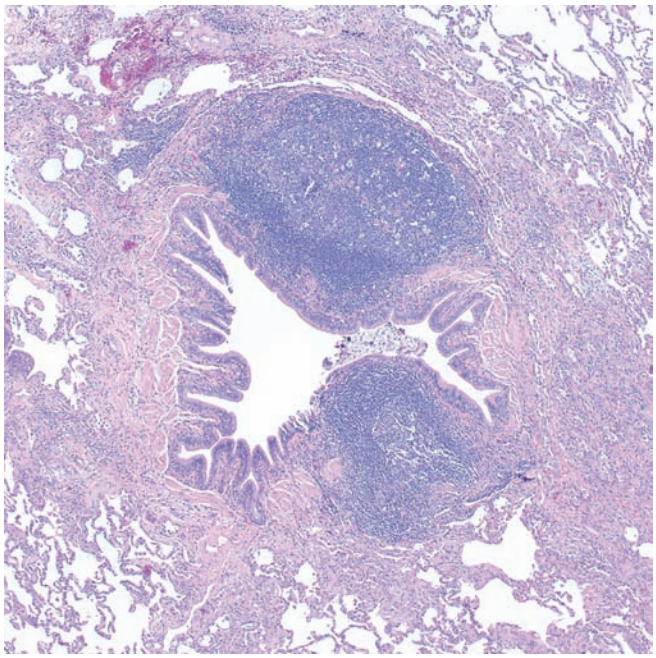

Figure 120-6 Follicular bronchitis/bronchiolitis. Reactive germinal centers expand airway submucosa and compress the lumen. Mucus accumulation often leads to infection and bronchiolectasis. Alveolar parenchyma is spared. Hematoxylin and eosin, 4× original magnification.

Treatment of FBB with corticosteroids has variable results.[47,48] Those with peripheral eosinophilia are reportedly steroid responsive.

Lymphocytic Interstitial Pneumonia

Although LIP is included in the American Thoracic Society/European Respiratory Society (ATS/ERS) classification of idiopathic interstitial pneumonias, this multifactorial but rarely idiopathic process represents the most florid form of BALT hyperplasia and may be difficult to differentiate from florid FBB and low-grade malignant lymphoma.[53] Almost all patients with LIP have immunologic disorders, dysproteinemias, or viral infections, including EBV and, especially in children, human immunodeficiency virus (HIV).[54–57] The age and sex distribution reflect these different populations. This clinicopathologic process is rare in the HIV-negative population, but represents a pulmonary manifestation of chronic graft-versus-host (GVH) disease in bone marrow transplant patients.[54] A strong association with Sjögren syndrome is also noted.[58] Most HIV-negative patients are middle-aged Caucasian women.

The clinical presentation includes cough and/or dyspnea in addition to symptoms and signs related to underlying diseases. More than 60% of patients have dysproteinemias, which can precede the onset of LIP or occur any time during the clinical course.[54,59,60] Most of these cases are associated with hypergammaglobulinemia; only 10% of cases are associated with hypogammaglobulinemia. A monoclonal spike on serum immunoelectrophoresis suggests a diagnosis of lymphoma rather than LIP. Pulmonary function tests reveal reduced lung volumes and diffusing capacity for carbon dioxide (D_{LCO}), and hypoxia is common.[54] Bronchoalveolar lavage (BAL) analysis shows an increased percentage of lymphocytes. Chest radiographs demonstrate bilateral reticular and nodular opacities, ground-glass opacities, and parenchymal consolidation with lower lung zone predilection. Computed tomography demonstrates diffuse ground-glass opacities, ill-defined centrilobular nodules, bronchovascular and interlobular thickening, and scattered less than 3.0-cm thin-walled cysts.[61–63]

The lungs are typically firm and tan-gray and end-stage cases feature honeycomb change with subpleural cysts. Although the radiographs and gross appearance suggest parenchymal consolidation, histologically LIP shows a diffuse prominently *interstitial* infiltrate of small lymphocytes, plasma cells, larger mononuclear cells, and histiocytes (Fig. 120-7A). Although these infiltrates are centered on airways, vessels, and interlobular septa, and include peribronchiolar lymphoid follicles, infiltration into alveolar septa is always present and distinguishes LIP from FBB (Fig. 120-7B). Small nonnecrotizing granulomas, reactive germinal centers, and infiltration into overlying respiratory epithelium are often seen, whereas lymphocytes frequently spill into alveolar spaces. In long-standing lesions, hyaline, collagen, or even amyloid widens the interstitium leading to honeycomb fibrosis. The lymphoid follicles largely consist of cytologically bland B-cells, whereas the interstitial lymphocytes are mostly T-cells. This pattern suggests that the lung can function like a giant lymph node.[25] Immunoglobulin heavy chain restriction or gene rearrangement is lacking. In addition to malignant lymphoma, nonspecific interstitial pneumonia (NSIP) and infections including *Pneumocystis* should be excluded.

Given the rarity of LIP, controlled treatment trials have not been undertaken. Corticosteroids are the primary therapy in addition to other immunosuppressive agents, such as cyclophosphamide and chlorambucil, with variable results. One-third of patients have resolution, one-third stabilize, and the remaining third progress.[18,54,60] Nonresponders often die of therapy-related infections, but occasional individuals die of end-stage pulmonary fibrosis. Lymphomatous transformation is very unusual; older reports

Hematoxylin and eosin, 60× original magnification.

of such most likely represented malignant lymphomas from the start.[64]

In patients with HIV infections or AIDS, LIP is part of a spectrum of lymphoid proliferations with virtually identical morphologies, but differing clinical presentations. Individuals with so-called *diffuse infiltrative lymphocytosis syndrome* (DILS) featuring sicca syndrome with increased numbers of circulating CD8+ T-cells in the blood, generalized lymphadenopathy, and enlarged parotid glands, are at high risk of developing LIP.[65]

LIP is most common is HIV-positive children and is a CDC category B indicator condition in children younger than age 13.[66,67] In fact, up to 17% of HIV-positive children have LIP.[68] Most present in their second or third year with lung infiltrates, failure to thrive, and increasing respiratory distress. The chest radiograph shows a diffuse micronodular or linear interstitial pattern with hilar and mediastinal widening.[69] Therapy is uncertain, response to steroids is unpredictable, and mean survival is 33 months.[70]

In HIV-positive adults, LIP is quite rare, and tissue sampling is required for diagnosis.[57] Most patients present with generalized lymphadenopathy and polyclonal hypergammaglobulinemia. BAL samples feature lymphocytes with CD8+ cells comprising up to 90% of the lymphoid cells.[71] Histologically, the lymphoid infiltrates are predominantly T-cells with few plasma cells. Germinal center formation is not a frequent finding. HIV-positive adults with LIP rarely die of the process, but rather of other AIDS-related diseases.

Castleman Disease

CD, the eponymous term for angiofollicular lymph node hyperplasia, encompasses two clinically and pathologically distinct entities. Solitary lesions usually feature hyaline-vascular (HV-CD) morphology, whereas multicentric disease almost always has a plasma cell pattern (PC-CD).[72]

Solitary CD is an uncommon form of lymphoid hyperplasia that usually presents as an incidental mediastinal mass in asymptomatic young to middle-aged individuals of either gender.[73] Pleural, chest wall, and extrathoracic involvement have been reported, but pulmonary parenchymal disease is a true rarity and most reported cases likely represent nodal rather than true pulmonary disease (Fig. 120-8A).[73–78] Solitary HV-CD lesions are usually asymptomatic or rarely cause compression-related symptoms.

Ninety percent of solitary CDs feature hyaline-vascular morphology, whereas the remainder are the plasma cell variant. HV-CD lymph nodes are enlarged and feature prominent lymphoid follicles with small atrophic germinal centers penetrated by hyalinized venules with plump endothelial cells originating in the interfollicular zone (Fig. 120-8B). Expanded mantle zones have concentric rings of lymphocytes imparting an onionskin appearance. TdT+ T-lymphoblastic populations are increased in this entity.[79] The solitary plasma cell variant only involves lymph nodes and has not been reported in the lung. Lymph nodes are hyperplastic with enlarged germinal centers and sheets of interfollicular plasma cells. Clinical suspicion of malignancy typically prompts surgical resection of solitary lesions. Excision results in the disappearance of any symptoms.[80] Neoadjuvant anti-CD20 monoclonal antibodies can shrink lesions prior to surgery.[81]

Multicentric Castleman disease (MCCD) is best considered a virus-driven polyclonal lymphoproliferative process that shares virtually no features with solitary CD.[72,82,83] In general, MCCD presents in the fourth and fifth decades of life but earlier in HIV-positive individuals.[82,84,85] An increased incidence is noted in the highly active antiretroviral therapy (HAART) era.[86] Signs and symptoms include fever, sweating, malaise, anemia, lymphadenopathy, hepatosplenomegaly, ascites, and pleural and pericardial effusions. MCCD appears to be a consequence of infection with human herpesvirus 8 (HHV-8), which in turn promotes production of interleukin-6 (IL-6).[72] Laboratory abnormalities include an elevated erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and bone marrow plasmacytosis that may lead to pancytopenia.[87] A chronic demyelinating polyneuropathy may present as part of POEMS syndrome (Crow–Fukase disease).[88] Patients may also develop non-HL. HIV-positive patients with MCCD have a greater likelihood of pulmonary involvement.[89]

Pulmonary histomorphology correlates with HRCT scan findings of peribronchovascular interstitial thickening and centrilobular nodules (Fig. 120-9A).[90,91] Polyclonal peribronchiolar lymphoplasmacytic infiltrates with focal extension into interlobular and alveolar septa may rarely be associated with honeycomb change (Fig. 120-9B). HHV-8 can almost always be demonstrated in lung samples, including BAL, by PCR and in situ hybridization with an HHV-8 probe.[92] Although MCCD shares many features with LIP, the plasma cell–rich nature of the infiltrate and presence of HHV-8 discriminate between the two.

Treatment is primarily nonsurgical but survival beyond 5 years is rare.[87] Although splenectomy may provide brief relief,

Figure 120-8 Solitary Castleman disease. **A.** Involved peribronchial lymph nodes are often mistaken for pulmonary parenchymal disease. Airway and vessel distortion may cause symptoms. **B.** Solitary lymph nodes and rare lung lesions feature hyaline-vascular morphology. Small germinal centers are penetrated by hyalinized venules. The follicle mantle zone rings the burnt-out center in an onionskin pattern. Hematoxylin and eosin, 20× original magnification.

chemotherapeutic regimens with or without immunotherapy, including anti–IL-6 and anti-CD20 monoclonal antibodies, appear to induce the longest remissions.[74,84,93] An 85% 1-year survival rate is now reported.[93]

Immunoglobulin G4–related Lung Disease

IgG4-related disease is a recently recognized fibroinflammatory condition with diverse organ manifestations linked by a unique histologic appearance.[94] As such, IgG4-related disease mirrors sarcoidosis. Despite a highly variable clinical presentation, the common histologic appearance, elevated serum, and tissue IgG4 levels along with a clinical response to immunosuppression warrant the creation of the broad yet poorly understood entity.[95] While most of the initial observations were made in individuals with autoimmune pancreatitis and/or lacrimal and salivary gland disease, the process is now recognized in almost every organ system.[96–98] General and organ-specific diagnostic criteria have been developed.[95,99] IgG4-related pulmonary disease likely accounts for many fibroinflammatory conditions of unknown etiology including but not limited to inflammatory pseudotumor, interstitial pneumonia, and fibrosing (sclerosing) mediastinitis.[26,100] Some patients with autoimmune idiopathic pancreatitis also have lung manifestations.[101]

Most patients with lung disease are males in their seventh decade of life.[102] One half of patients have respiratory symptoms

such as cough, exertional dyspnea, hemoptysis, and/or chest pain. Constitutional symptoms are uncommon.[103] No risk factors are recognized. Radiographic appearances vary and correlate with histomorphologic findings.[104] Solid nodules, bronchovascular, alveolar interstitial, pleural, and airway patterns may be seen, alone or in various combinations.[102] The three major histopathologic features are (1) dense lymphoplasmacytic infiltrate, (2) fibrosis, arranged at least focally in a storiform pattern, and (3) obliterative phlebitis (Fig. 120-10).[95] IgG4-related pulmonary disease may lack distinct storiform fibrosis while pulmonary arteries, in addition to veins, may be involved.[105] Furthermore, vascular changes without vessel lumen obliteration, concentric bronchiolar inflammatory infiltration with germinal centers, and/or prominent eosinophils may be seen.[106] Not surprisingly, histomorphologic findings can be considered highly suggestive, probable, or insufficient.[95] Unfortunately, the major findings are also seen in a myriad of entities, including but not limited to infections and organizing injuries related to, for example, granulomatosis with polyangiitis (Wegener granulomatosis).[107]

Tissue and serum IgG4 and IgG levels serve as supplemental data since a diagnosis is based on light microscopic findings. Immunohistochemical stain evaluation requires that one count the three 40x microscopic fields with the highest number of IgG4+ plasma cells and also count the number of IgG+ plasma cells in those same areas. According to the consensus statement, >50 IgG4+ cells per high-power field and >20 IgG4+ cells per high-power field are adequate cutoffs in surgical and nonsurgical lung biopsies, respectively.[95] The IgG4+/IgG+ plasma cell ratio should be >40%. However, other lung processes including idiopathic NSIP, usual interstitial pneumonia, connective tissue disease-associated interstitial pneumonias as well as inflammatory myofibroblastic tumor may have increased IgG4+ cell counts.[108] Elevated serum IgG4 levels are noted in most patients, although other respiratory, hepatobiliary tract, and connective tissue diseases may be associated with high serum levels.[103,109]

Standard therapy is not well delineated but most patients respond to glucocorticoids within weeks to months.[110,111] Resistant cases may improve with anti-CD20 monoclonal antibody therapy.[112] Relapses are common after therapy cessation. An increased risk for non-HL is postulated.[113]

MALIGNANT LYMPHOID LESIONS

Within the hematopathology field, past decades will probably be best remembered for the myriad of classification schemes and ever-changing nomenclature. Thankfully, the current WHO classification represents a consensus list of lymphoid neoplasms that appear to be distinct clinical entities.[1] Although complex, this scheme is reproducible among trained pathologists. Diagnoses are based on clinical, morphologic, immunophenotypic, and genetic features and not simply on morphologic, immunophenotypic, or even clinical subtleties. B-cell neoplasms, T- and NK-cell neoplasms, and HL are subgrouped according to lineage and stage of differentiation. Within this general context one can understand the practicality of a seemingly cumbersome diagnosis, such as pulmonary extranodal marginal zone B-cell lymphoma of MALT type, given the belief that these lymphomas arise from acquired BALT.

PRIMARY PULMONARY NON-HODGKIN LYMPHOMA

Although more than half of patients with nodal lymphoma have lung involvement, primary pulmonary lymphomas comprise less than 0.5% of primary lung neoplasms.[114,115] Furthermore, the most common primary lung lymphoma, marginal zone non-HL of MALT origin, represents less than 10% of extranodal lymphomas.[116] Non-HLs are considered lung primaries when the lung is the major site of disease at the time of diagnosis.[117,118] Thus, up to 20% of these lung lymphomas involve hilar and/or mediastinal lymph nodes. Pulmonary lymphomas have a range of morphologies and clinical aggressiveness such that separating the tumors into low- and high-grade categories is a dangerous oversimplification. Although most lung non-HLs differ from nodal lymphomas and are thought to have their origin in BALT, traditional nodal non-HLs, such as follicular lymphoma, mantle cell lymphoma, diffuse large B-cell lymphoma, peripheral T-cell lymphoma, and CD30+ anaplastic large cell lymphoma, also present as pulmonary primaries (Table 120-2).[19,119–122]

EXTRANODAL MARGINAL ZONE B-CELL LYMPHOMA OF MALT TYPE

Recent recognition that most primary pulmonary lymphomas arise from BALT revolutionized our thinking about extranodal lymphoid lesions. This hypothesis suggests that some degree of lymphoid hyperplasia is a necessary precondition for the development of these lymphomas and explains the association with inflammatory and autoimmune processes as well as the common finding of reactive germinal centers in lymphomas of BALT. These relatively indolent lymphomas must be discerned from both reactive processes, including NLH and LIP as well as more aggressive lymphomas.

Patients tend to be in their fifth through seventh decades of life with a slight male preponderance.[23,123] Those younger, including children, almost always have pre-existing immunosuppression such as HIV infection.[19] Most individuals are asymptomatic and are noted to have an abnormality on a routine chest radiograph. The presence of dyspnea, cough, hemoptysis, and shortness of breath reflect extensive disease causing airway constriction, poor compliance, and atelectasis. "B" symptoms are rare.[119] Mean lymphocyte counts are typically normal and peripheral blood does not show a leukemic phase, whereas a monoclonal gammopathy, usually IgM, is noted in up to 30% of patients.[124]

Chest radiographs and HRCT scans show either peripheral or perihilar solitary or multiple masses or alveolar opacities with air bronchograms.[125,126] Cavitation, calcification, and pleural effusions are very rare, and hilar adenopathy is present in less than 25% of

Nodular sclerosis classical Hodgkin lymphoma
Lymphocyte-rich classical Hodgkin lymphoma
Mixed cellularity classical Hodgkin lymphoma

cases.[24] The interval between the finding of a radiologic abnormality and definitive pathologic diagnosis averages over 5 years, reflecting the tendency of this tumor to remain localized for a long period.[23,123] Thus, it is not surprising that up to 80% of individuals present with stage I disease.[19,117,118,120]

Grossly, nodular areas vary from 2.0 to 20 cm and are tan and fleshy. Underlying lung architecture may be preserved (Fig. 120-11A). At low magnification these lymphomas appear as diffuse infiltrates surrounding reactive follicles with peripheral tracking along bronchovascular bundles and interlobular septa (Fig. 120-11B,C). Invasion of bronchial cartilage and visceral pleura are common. At high magnification, the small lymphoid cells may have round nuclei with little cytoplasm (centrocyte-like) or irregular nuclear contours and abundant clear cytoplasm (monocytoid differentiation) (Fig. 120-11D). Plasmacytic differentiation is also common. Scattered larger cells (immunoblasts) can also be seen. Malignant cells often infiltrate reactive germinal centers (follicular colonization) as well as bronchial, bronchiolar, and alveolar epithelium (lymphoepithelial lesions). This latter finding is seen in up to 90% of cases, but is not a useful diagnostic criterion.[122,124] Secondary features include fibrosis, sclerosis, and amyloid and sarcoidal granulomas.[37,38] Involved mediastinal lymph nodes feature typical morphology of nodal marginal zone B-cell non-HL.

When light microscopic features favor a diagnosis of this lymphoma, all available ancillary studies should be utilized to make a definitive diagnosis. The neoplastic cells are monoclonal B-cells, which may be identified with CD20 or CD79a stains.[122,123] Light chain restriction is present in all cases with equal κ and λ percentages; however, PCR amplification of the immunoglobulin heavy chain gene from paraffin sections detects monoclonality in only 60% of tumors.[127] Fifty percent to 60% of marginal zone B-cell lymphoma of MALT type demonstrate t(11;18), whereas t(1;14) or trisomy 3 may also occur.[128–130]

The differential diagnosis includes NLH, LIP as well as pulmonary involvement with a variety of different malignant lymphomas, such as lymphoplasmacytoid lymphoma/immunocytoma. These distinctions are of paramount importance and the surgical pathologist or hematopathologist has the necessary tools to make a correct diagnosis.

Pulmonary marginal zone B-cell lymphomas of MALT are indolent tumors with 85% to 95% 5- and 10-year survival rates.[23,117,118,123,131] In several studies, median survival was not reached at 10 years. Thus, patients with resectable disease are treated with resection, but those with diffuse lung involvement may be followed and treated with chemotherapy with or without anti-CD20 antibodies.[119,131] Patients with systemic symptoms at presentation may have a worse prognosis. Lymphoma recurs in the lungs or in other MALT sites such as salivary gland, orbital, or gastrointestinal tract in almost half of patients, and up to 15% of patients experience transformation of their lymphomas into more aggressive and usually deadly forms including diffuse large B-cell non-Hodgkin lymphoma (DLBCL).[23,124]

■ OTHER NON-HODGKIN LYMPHOMAS

Non-HLs other than extranodal marginal zone B-cell lymphomas originating in the lung are very rare and comprise less than one-fourth of primary lung lymphomas.[23,120,122,124,132] These tumors represent a heterogeneous group consisting primarily of DLBCL with fewer cases of follicular lymphoma, and rare examples of mantle cell lymphoma, lymphoplasmacytic lymphoma/immunocytoma, Burkitt lymphoma, anaplastic large cell lymphoma, and peripheral T-cell lymphomas.[132–136] Rare AIDS-related primary pulmonary B- and T-cell lymphomas containing EBV RNA are also described.[137,138] Of note, only primary pulmonary DLBCL appears to arise from BALT and is also weakly associated with both fibrosing interstitial lung diseases and connective tissue diseases.[120,123]

Although each lymphoma subtype has particular morphologic features, primary pulmonary DLBCL is best characterized clinically.[120,122–124] Patients are usually adults but younger individuals with immunodeficiency states may be affected.[114,119,124] Unlike those with extranodal marginal zone B-cell lymphomas of MALT, most patients present with shortness of breath, fever, chest pain, and hemoptysis and frequently develop extrapulmonary lesions and paraneoplastic syndromes shortly after diagnosis. Restrictive physiology is often observed. Imaging studies reveal solitary or multifocal nodules or infiltrates measuring at least 3.0 cm.[123] Cavitation and pleural effusions are frequently seen and regional lymph nodes are involved in up to 50% of cases.

Resected lesions are white-tan and fleshy with areas of necrosis. Histologically, largely necrotic nodules or striking lymphangitic growth with parenchymal destruction are accompanied by inflammatory infiltrates. Infarction is not uncommon. Sheets of malignant mitotically active B-cells are two to four times the size of normal lymphocytes (Fig. 120-12). Vascular infiltration and pleural involvement are common features and airway destruction leads to postobstructive pneumonia. Residual BALT hyperplasia and low-grade marginal zone lymphoma may be seen at the periphery of the mass. Neoplastic cells express pan-B antigens CD20 and CD79a. Monotypic immunoglobulin light chain expression can be demonstrated.[139] Although the cytologic atypia and necrosis in these lymphomas make it easy to distinguish them from benign lymphoid

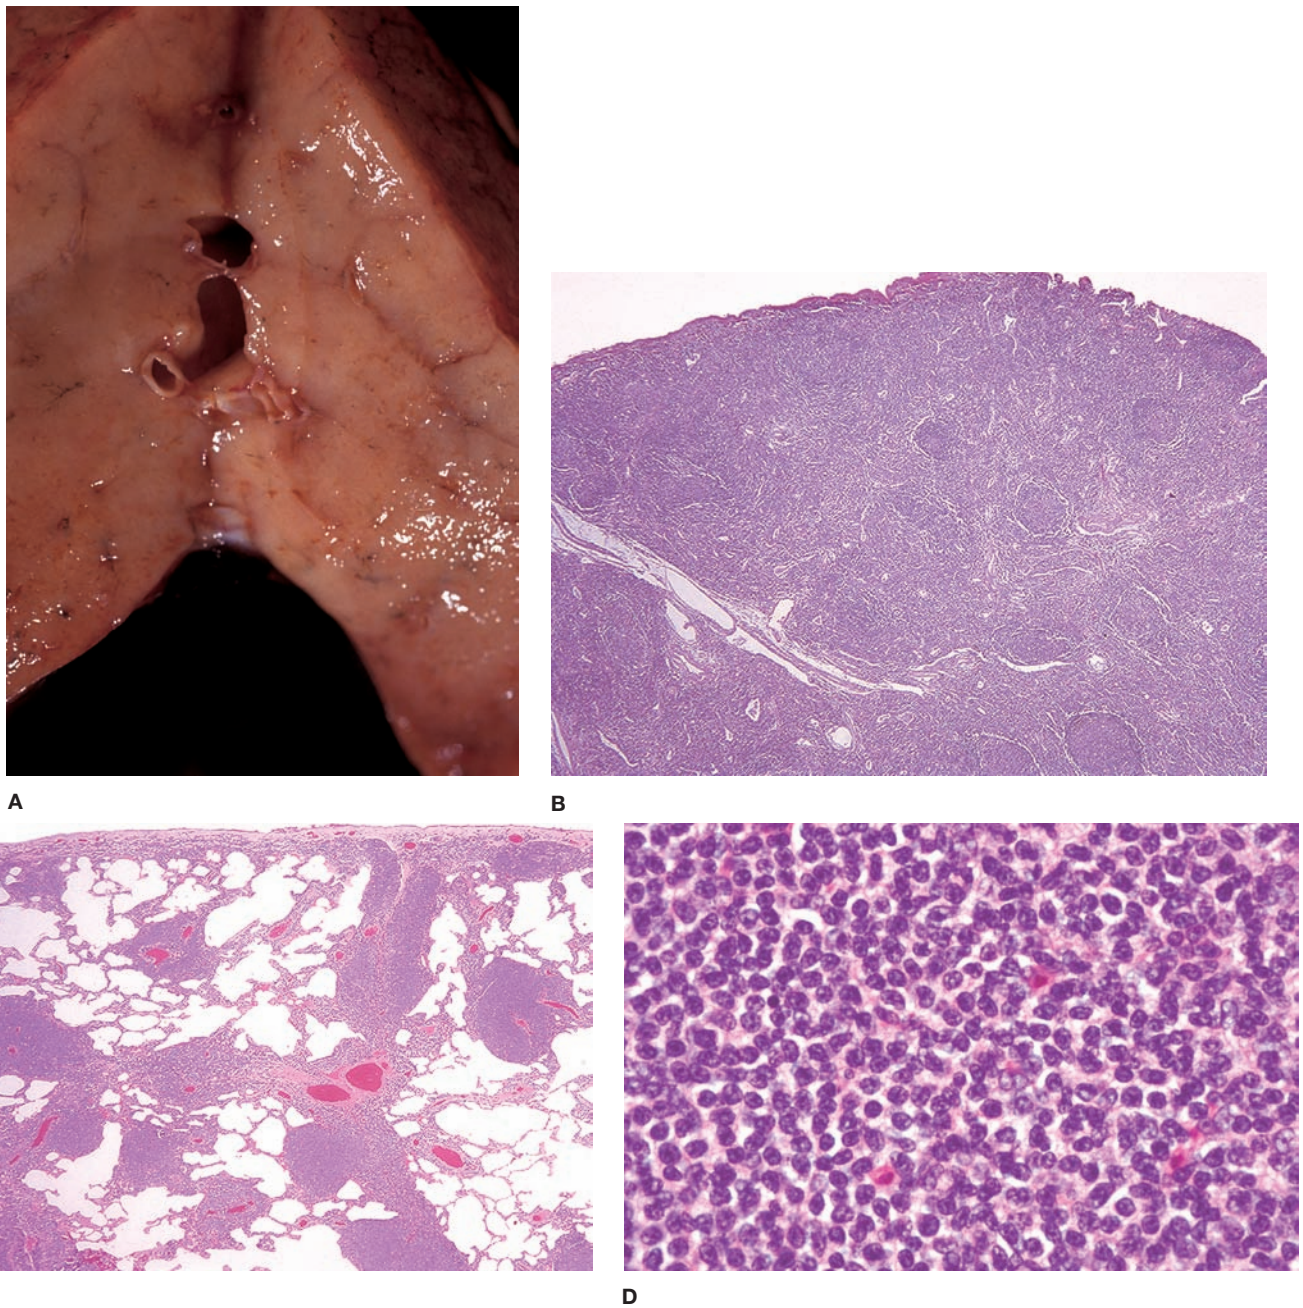

Figure 120-11 Extranodal marginal zone B-cell lymphoma of MALT type. **A**. Tan fleshy tumor fills alveolar spaces but preserves lobular architecture. **B.** Malignant lymphoid cells overrun lung tissue. Germinal centers are usually prominent. Hematoxylin and eosin, 4× original magnification. **C.** Malignant lymphoma often tracks along lymphatic pathways beyond the dominant mass lesion. If such a region was sampled the differential diagnosis would include diffuse lymphoid hyperplasia. Involvement of visceral pleura suggests the malignant nature of the process. Hematoxylin and eosin, 4× original magnification. **D.** Most pulmonary marginal zone B-cell lymphomas of MALT type are composed of small monotonous round (centrocyte-like) B-lymphocytes. Hematoxylin and eosin, 40× original magnification.

processes and extranodal marginal zone lymphomas, confusion with poorly differentiated carcinomas or HL can occur.

Localized DLBCL is potentially curable with surgery and adriamycin-based chemotherapy, but 5-year survival rates do not surpass 60% and the median survival is only 3 years.[19,114,119] Only half of HIV-positive patients achieve clinical remission and those remissions usually last only 6 months.

■ LYMPHOMATOID GRANULOMATOSIS

Lymphomatoid granulomatosis (LYG) is one of the most confusing lesions in all of human disease. The original investigators were not certain whether this lung-based process, which also involves the central nervous system, skin, and other organs, was a malignant lymphoma or a variant of granulomatosis with polyangiitis (Wegener granulomatosis).[140] Since that time erroneous ideas concerning its etiology and histogenesis have muddled the entity even further. We now recognize LYG as an EBV-driven B-cell lymphoproliferative disorder arising in individuals with either obvious or clinically undetected defects in cell-mediated and perhaps also humoral immunity.[1,141–144] In many ways, LYG is similar to post-transplant lymphoproliferative disorder (PTLD) with a spectrum of clinical behaviors.

Although quite rare, LYG has characteristic clinical features.[145,146] Patients usually present in the fifth or sixth decades of life but

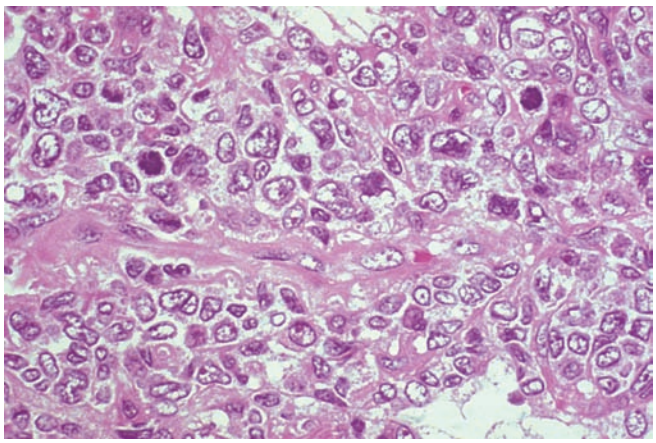

Figure 120-12 Diffuse large B-cell lymphoma. This lymphoma is composed of large cells with irregular nuclear features and significant mitotic activity. The B-cell phenotype is demonstrated by flow cytometry or immunohistochemistry. This lymphoma not only looks more aggressive than marginal zone B-cell lymphoma of MALT type, but also follows an aggressive clinical course. Hematoxylin and eosin, 40× original magnification.

children and the elderly can be stricken. Men are affected two to three times as often as women. Dyspnea, cough, chest pain along with fever, and malaise and weight loss are the most common presenting complaints and up to 40% of patients also have skin nodules, ulcers, rashes, peripheral neuropathies, or symptoms referable to central nervous system involvement. Gastrointestinal, musculoskeletal, or nodal involvement is uncommon. Presentation as an asymptomatic solitary lung nodule is very rare.

Laboratory findings can include either leukocytosis or leukopenia and elevated serum IgG or IgM.[145] Cerebrospinal fluid may have abnormal protein and glucose levels. Serologies for autoimmune diseases are negative but evidence of EBV infection has been reported.

Chest imaging in up to 70% of patients reveals bilateral middle and lower zone lung nodules as large as 10 cm.[140,145,147] Coalescence and cavitation are often seen. Nonspecific reticulonodular infiltrates as well as solitary infiltrates or masses are less common findings. Pleural effusion is present in up to one-third of patients.

Macroscopically the lungs and other affected organs contain yellow-white well-demarcated masses with either solid or granular textures (Fig. 120-13A). Microscopically LYG is composed of nodular lymphoid infiltrates centered on lymphatic routes including bronchovascular bundles. As the lesions increase in size, blood vessels are encircled, infiltrated, and perhaps occluded but not obliterated by the process (Fig. 120-13B). The infiltrate and nodules are composed of a heterogeneous population of small, intermediate, and large lymphocytes (Fig. 120-13C). The large cells are in the minority but can be very atypical or pleomorphic, stain as B-cells (CD20+ and CD79a+) and are EBV-infected according to PCR and in situ hybridization studies. CD30 positivity is also noted in infected monoclonal cells. The smaller and more numerous cells stain as T-cells (CD3+, CD4+, and/or CD8+). Secondary features include interstitial and consolidative pneumonia. Despite its designation, granulomas are not seen.

The grading system for LYG is based on the number of atypical large EBV-infected cells (Table 120-3). Grade 1 lesions probably include cases of so-called *benign lymphocytic angiitis* and *granulomatosis,* whereas grade 3 proliferations are alternatively considered a subtype of diffuse large cell lymphoma (DLCL). With greater relative numbers of EBV-infected cells, one observes more necrosis and a more aggressive clinical course.[1] Given the complex histologic features of LYG and need to identify scattered large cells in an inflammatory mass, diagnosis and accurate grading almost always requires a surgical lung biopsy.

Although similar to T-cell–rich B-cell lymphomas such as angiocentric nasal NK/T-cell lymphoma and PTLD, the former entity lacks EBV-infected monoclonal B-cells and the latter lacks the angiocentricity of LYG. Other diagnostic considerations include HL and necrotizing inflammatory conditions.

The natural history is variable and clinical behavior ranges from indolent to aggressive.[148] Spontaneous remissions and therapy-induced remissions occur but more than 60% of patients die, with a median survival of 14 months.[145] Although most organ systems can be involved, lymphoid tissue including the spleen is only involved in 25% of patients who develop grade 3 lesions. Hemophagocytic syndrome is related to systemic EBV infection rather than bone marrow involvement. Histologic grade correlates with outcome. Most patients have either grade 1 or 2 disease; one-third of those with grade 1 lesions progress to grade 3/malignant lymphoma, whereas two-third of those with grade 2 lesions develop grade 3/malignant lymphoma. Asymptomatic patients or those with minimal disease and grade 1 or 2 histology may be observed; those with symptomatic grade 1 or 2 histology require treatment with corticosteroids or single or multiagent chemotherapy. Clinically aggressive grade 1 and 2 and all grade 3 lesions are treated as DLCL with combination chemotherapy.[148] Therapies targeting EBV-bearing B-cells (interferon-α2β) or reactive T-cells (i.e., cyclosporine) as well as stem cell transplantation, have been reported.[148,149]

■ INTRAVASCULAR LARGE B-CELL LYMPHOMA

Intravascular large B-cell lymphoma (IVLBCL) is a rare non-HL characterized by lymphoma cells only in the lumina of small vessels, particularly capillaries.[1,150] A Western variant manifests with symptoms related to the involved organ, while an Asian variant presents with multiorgan failure, hepatosplenomegaly, pancytopenia, and hemophagocytic syndrome.[151,152] Although patients with the Western variant most often present with neurologic or dermatologic manifestations, older patients may complain of fever, dyspnea, cough, chest pain, or present with respiratory failure.[153–156] Hypoxia and decreased diffusion capacity are seen. Chest radiographs demonstrate reticulonodular infiltrates, whereas CT scans can show patchy ground-glass opacities.[153,154,157]

TABLE 120-3 Histologic and In Situ Hybridization Grading of Lymphomatoid Granulomatosis

Grade 1
Angiocentric polymorphous infiltrate without atypia or necrosis
Rare EBV-infected cells (<5 per high-power [40×] field)
Grade 2
Angiocentric, predominantly polymorphous, infiltrate with occasional large or atypical lymphoid cells and parenchymal necrosis
Scattered EBV-infected cells (5–20 per high-power [40×] field)
Grade 3
Angiocentric and destructive monomorphous infiltrate with widespread necrosis
Sheets of EBV-infected cells (>20 per high-power [40×] field)

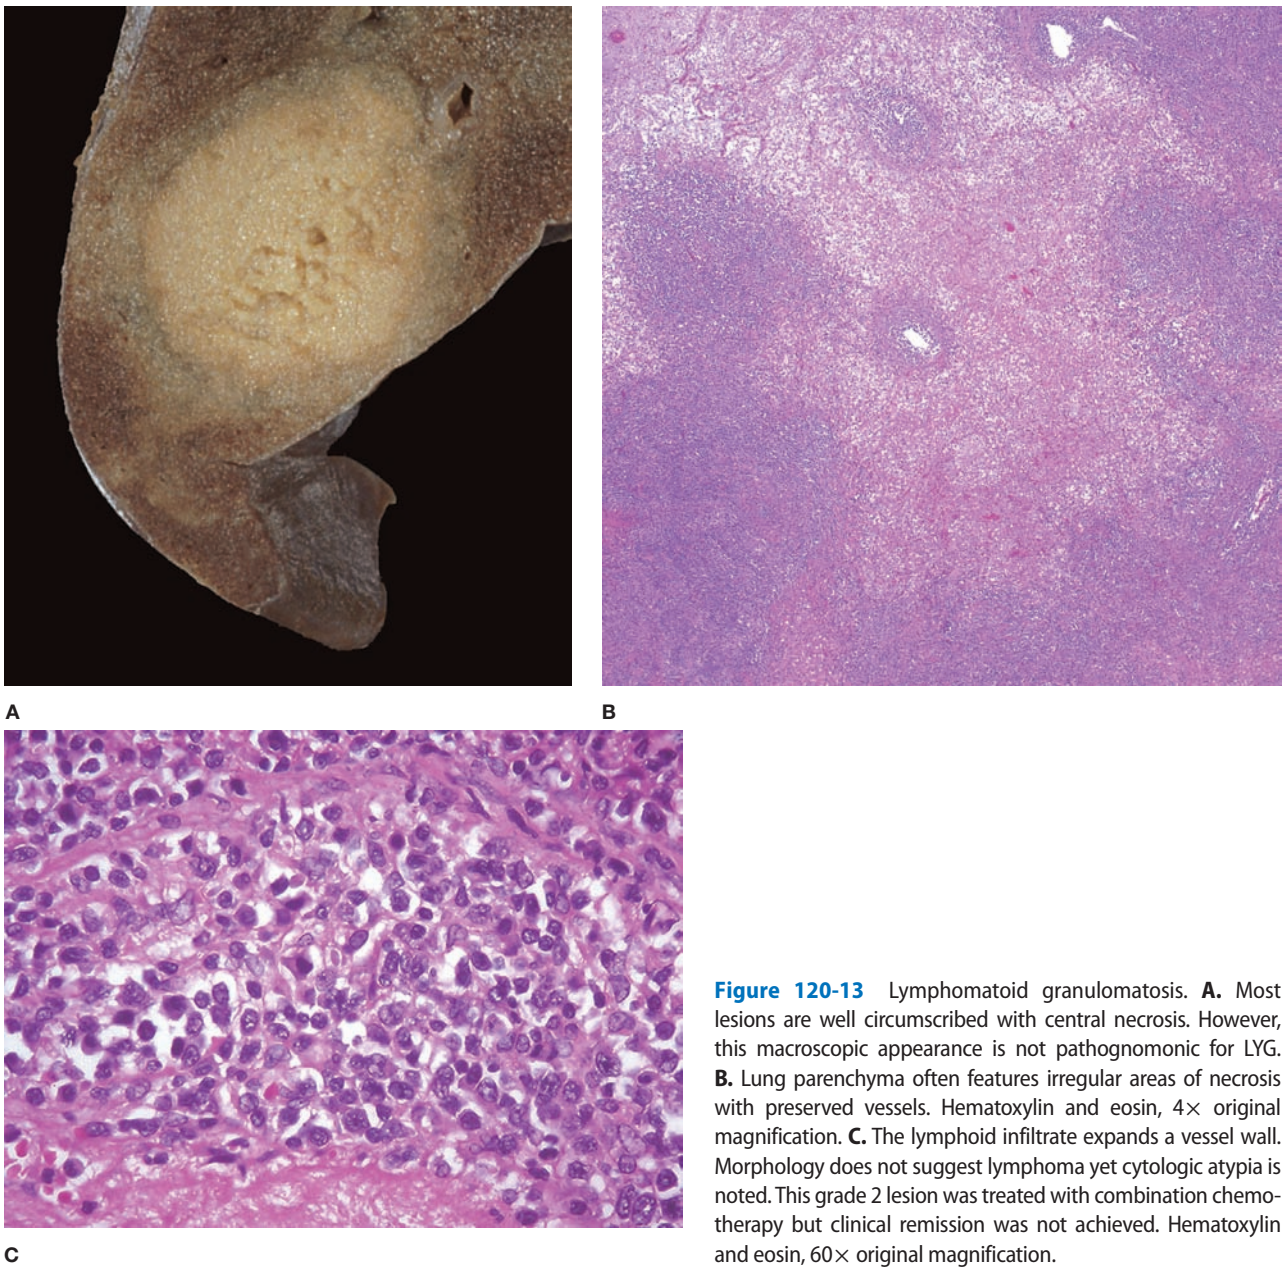

Figure 120-13 Lymphomatoid granulomatosis. **A.** Most lesions are well circumscribed with central necrosis. However, this macroscopic appearance is not pathognomonic for LYG. **B.** Lung parenchyma often features irregular areas of necrosis with preserved vessels. Hematoxylin and eosin, 4× original magnification. **C.** The lymphoid infiltrate expands a vessel wall. Morphology does not suggest lymphoma yet cytologic atypia is noted. This grade 2 lesion was treated with combination chemotherapy but clinical remission was not achieved. Hematoxylin and eosin, 60× original magnification.

Low magnification histology demonstrates a diffuse interstitial process resembling cellular interstitial pneumonia yet higher magnification reveals large cells with prominent nucleoli confined to arteries, veins, lymphatics, and especially capillaries (Fig. 120-14). Fibrin thrombi may be noted.

Although all cases of IVLBCL are B-cell lymphoma (CD19+, CD20+, CD79a+), a T-cell phenotype associated with EBV has been described and should be considered a different entity.[158–160] Although the intravascular nature of the lymphoma is not understood, absence of adhesion molecules CD54 (I-CAM-1) and CD29 (β_1 integrin) may prevent neoplastic cell–endothelial cell interactions and extravascular spread.[161]

Half of cases are diagnosed at autopsy yet a diagnosis is possible on thoracoscopic and even transbronchial biopsies.[155,162,163] Immunohistochemical stains are necessary to discern IVLBCL from metastatic carcinoma, malignant melanoma, and leukemia. Although prognosis is poor, complete remission and long-term survival can be

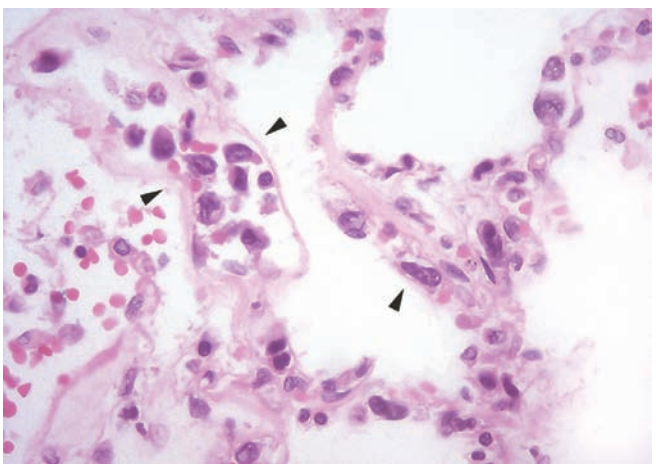

Figure 120-14 Intravascular large B-cell lymphoma. Malignant lymphoid cells remain confined to vascular channels *(arrowheads)*. Hematoxylin and eosin, 60× original magnification.

achieved with prompt diagnosis and aggressive combination chemotherapy and perhaps anti-CD20 monoclonal antibodies.[160,164]

HODGKIN LYMPHOMA

Primary pulmonary HL is very rare.[165] This is in part due to the requirement that, unlike non-HL, regional lymph nodes be free of disease to qualify as a lung primary.

Primary pulmonary HL shows the usual bimodal age distribution of systemic HL but patients are slightly older.[166–168] Women outnumber men by 1.5 to 1. Symptoms include cough, dyspnea, hemoptysis, and chest pain and one-third of patients experience B symptoms.[166] Radiographs demonstrate reticulonodular and linear infiltrates or multiple nodular lesions. Solitary lesions and consolidation are also seen. Upper lobe disease is most common, and atelectasis and cavitation are frequently observed.[169]

Tumors have a multinodular white firm macroscopic appearance and histologically grow along lymphatic routes in the lung. When small nodules coalesce, central necrosis is apparent. Visceral pleura is often infiltrated while bronchial involvement can result in plaque-like nodules, polypoid endobronchial masses, or airway collapse.[170,171] Within the WHO histologic classification of HL, one cannot be certain if nodular lymphocyte–predominant HL and the four subtypes of classical HL all involve the lung. Nodular sclerosis and mixed cellularity subtypes of HL are more commonly seen than lymphocyte rich, whereas lymphocyte depleted has not been reported in primary pulmonary HL.[166,167] Diagnosis requires the identification of Reed–Sternberg cells or variants (usually CD15+ or CD30+) within the appropriate inflammatory background. Central necrosis, granulomatous inflammation, and vascular permeation by the polymorphous infiltrate are commonly seen.

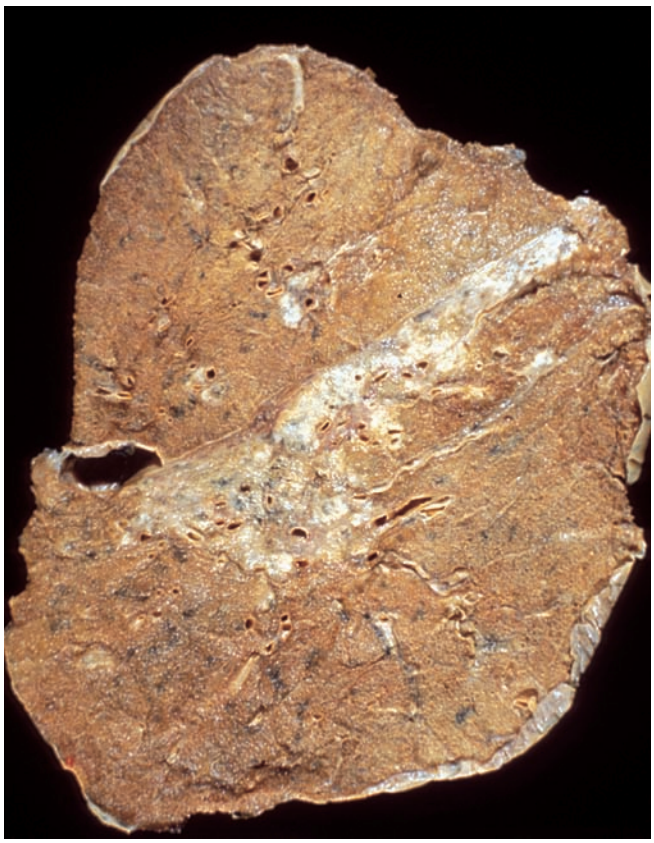
The morphologic differential diagnosis includes inflammatory and malignant processes. Infections, granulomatosis with polyangiitis (Wegener granulomatosis), and sarcoidosis as well as poorly differentiated carcinomas, LYG, and a variety of non-HLs must be considered. The nonneoplastic entities can be discerned histologically, whereas the neoplasms require at least immunohistochemical studies.

The prognosis for patients with primary pulmonary HL is variable.[168] Individuals with all types and stages of primary pulmonary HL have a 5-year survival of almost 75%.[166,167] Relapses occur in the lung and elsewhere and appear associated with multiple lobe involvement, pleural invasion, cavitation, and presence of B symptoms.

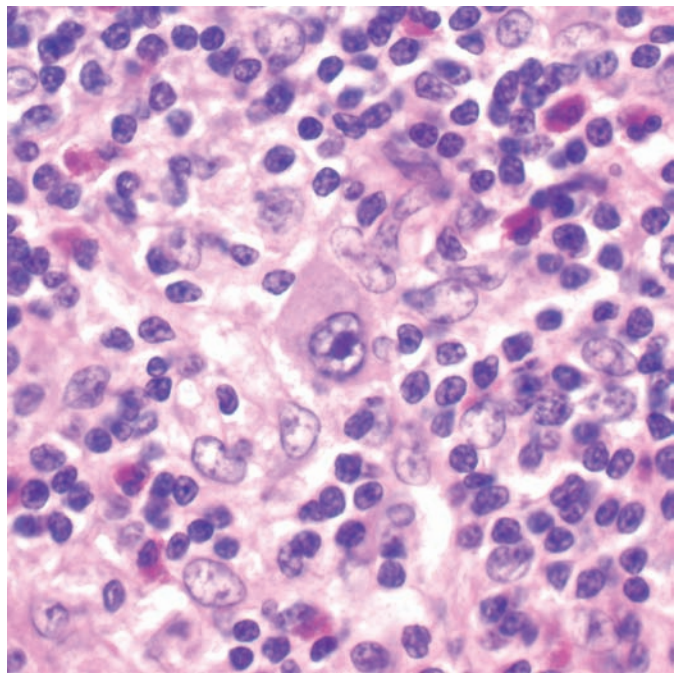
SECONDARY LYMPHOMA INVOLVING THE LUNG

Secondary lung involvement with nodal and extranodal lymphomas is significantly more common than primary pulmonary lymphoma. Lung involvement with common nodal and disseminated lymphomas surpasses 50% during life and at autopsy.[165,172–174] Clinical and radiologic features may suggest an infectious process, but tissue samples demonstrate a lymphangitic pattern of disease (Fig. 120-15A). Patchy infiltrates and endobronchial masses are, however, not uncommon.[175]

Morphology does not usually allow for distinction between primary and secondary lung disease. For example, pulmonary involvement with nodal marginal zone lymphoma is indistinguishable from primary pulmonary extranodal B-cell lymphoma of MALT. Thus, clinical history and review of previous diagnostic material are necessary for proper diagnosis. Secondary lymphomas involving the lung can also transform to more aggressive histology with increased numbers of large cells. This phenomenon is not infrequently seen in samples from patients with CLL/SLL.



A



B

Figure 120-15 Lung involvement with Hodgkin lymphoma. **A.** The striking lymphangitic distribution of this dense white tumor indicates secondary pulmonary involvement. **B.** A uninucleate Reed–Sternberg cell with typical prominent nucleolus *(center)* is surrounded by lymphocytes and eosinophils. Hematoxylin and eosin, 60× original magnification.

Several particular systemic lymphoproliferative disorders that may present with significant lung pathology warrant additional discussion. Mycosis fungoides may involve the lung after dissemination of cutaneous disease or as part of the Sézary syndrome. Indeed, the lung is the second most common extracutaneous site after lymph nodes.[176,177] Clinical and radiographic features often mimic pneumonia or even acute respiratory distress syndrome with nodular and diffuse disease.[178] Tissue samples demonstrate air space and interstitial infiltrates along lymphatic routes in addition to occasional granulomas, extensive vascular infiltration, and necrosis. Cells range from small with irregular twisted nuclei to large with prominent nucleoli.

The lungs are also frequently involved with angioimmunoblastic T-cell lymphoma.[179] Although originally described as a reactive process (angioimmunoblastic lymphadenopathy with dysproteinemia), this malignant disease in the lung can be mistaken for interstitial pneumonia.[180–182] However, the lymphatic distribution of atypical "clear" cells with indented nuclei admixed with immunoblasts, plasma cells, and histiocytes is neoplastic and must be distinguished from HL. Pulmonary involvement with HL is recognized at presentation in more than 10% of patients with mediastinal or extrathoracic disease. Fifty percent of patients with HL have relapses in the lung and almost 60% are noted to have pulmonary involvement at autopsy.[165,183] Unlike primary pulmonary HL, secondary involvement rarely manifests with large nodules, whereas infiltrates often surround blood vessels and may feature greater numbers of atypical cells and fewer inflammatory cells than in primary HL (Fig. 120-15B).[184]

■ PLASMACYTOMA/MULTIPLE MYELOMA

Extraosseous plasmacytomas most often affect the upper respiratory tract. Primary plasmacytomas of the lung are exceedingly rare; patients are usually in their fifth and sixth decades of life and asymptomatic.[44,185,186] Cough, dyspnea, and hemoptysis have been reported. Unlike multiple myeloma, individuals may lack a serum M-protein or Bence Jones light chains in the urine. Radiographs most commonly demonstrate a midlung or hilar solitary mass, but peripheral lesions amenable to transthoracic-needle aspiration biopsy occur.[187–189]

Tumors range from 2.5 to 8.0 cm and most often involve a major bronchus with occasional involvement of regional lymph nodes. Histologically, sheets of plasma cells including binucleate forms overrun lung parenchyma and bronchial cartilage (Fig. 120-16). Fibrous bands course through the tumor and amyloid or light chain may be associated with the neoplasm. κ and λ light chains as well as IgG, IgA, and IgD can be expressed immunohistochemically or produced as M-proteins by the tumor.[185,190,191] The pathologist must discriminate between plasmacytoma and marginal zone lymphoma with plasmacytoid features as well as inflammatory myofibroblastic tumor.

Although the natural history of this rare tumor is not well delineated, it appears that cases are either cured with either surgical excision or radiation therapy, or evolve into multiple myeloma.[185,192,193] The presence or absence and amount of M-protein may mirror tumor burden and clinical course while an increase or decrease in levels may be associated with recurrence or successful treatment, respectively. An overall 5-year survival of 40% has been reported.[185,194]

Pulmonary involvement with multiple myeloma is more common than pulmonary plasmacytoma.[40,195,196] Lung involvement may be nodular or have a diffuse lymphangitic pattern.[197] Nodular or diffuse amyloid deposition may accompany the neoplastic cells. Intracytoplasmic crystalline casts similar to those seen in the kidney are occasionally observed.[198]

POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDER

Posttransplant lymphoproliferative disorder (PTLD) is a lymphoid proliferation or lymphoma that develops as a consequence of immunosuppression in solid organ or bone marrow allograft recipients. Eighty percent of cases are associated with EBV infection in the setting of decreased T-cell immune surveillance; the etiology of EBV-negative PTLD is unknown.[1,184] Most cases are of host origin while approximately 10% of cases are of donor origin.[1] Those of donor origin are more common in lung and heart–lung transplantation patients due to the presence of donor BALT in the lungs.[199–203]

Allograft and extranodal MALT sites including Waldeyer ring, lung, and gastrointestinal tract, are usually involved and incidence varies based on type of allograft and immunosuppression regimen. One percent of renal transplant patients but up to 10% of lung transplant recipients are stricken.[202]

The majority of cases of PTLD in lung transplant recipients and approximately 10% of cases in other solid organ transplant recipients manifest with pulmonary lesions. Individuals may be asymptomatic or present with constitutional symptoms. In lung transplant patients, respiratory failure may occasionally occur. Radiographs demonstrate nodular or diffuse reticulonodular infiltrates, solitary nodules, or multiple mass lesions with or without regional lymphadenopathy.[204]

Morphologic categories of PTLD include early lesions, polymorphic PTLD, monomorphic PTLD, HL, and HL-like PTLD (Table 120-4).

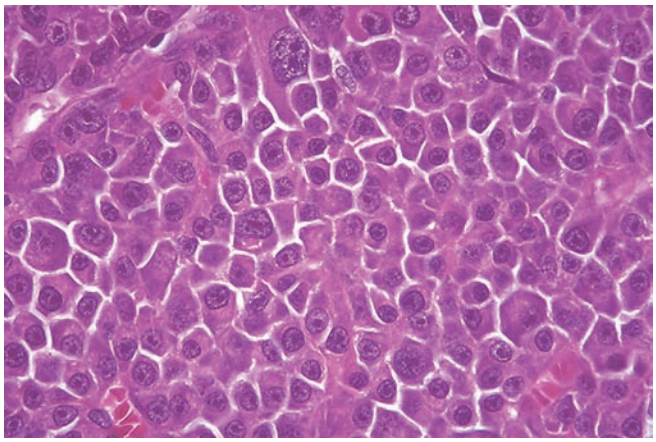


Figure 120-16 Plasmacytoma of lung. Sheets of plasma cells usually form a solitary nodule. Cytologic atypia is often seen. Since this lesion is less common than pulmonary involvement with multiple myeloma, clinical correlation is always required. Hematoxylin and eosin, 40× original magnification.

Figure 120-17 Posttransplant lymphoproliferative disorder. **A.** This polymorphic lesion features small and large lymphocytes admixed with plasma cells. Hematoxylin and eosin, 60× original magnification. **B.** Monomorphic lesions often comprise large atypical cells with numerous mitoses. According to the WHO scheme this lesion is classified as a diffuse large B-cell lymphoma. Hematoxylin and eosin, 60× original magnification.

Most proliferations are B-cell processes, although T-cell lesions are seen.[205] Early lesions usually involve lymph nodes and Waldeyer ring rather than lung; lymphoid tissue is hyperplastic with either sheets of plasma cells or paracortical expansion with immunoblasts that resemble infectious mononucleosis morphology. Polymorphic and polyclonal proliferations feature mixtures of small lymphocytes, plasma cells, and immunoblasts and may progress to monomorphic monoclonal proliferations with sheets of large transformed cells resembling aggressive lymphoma (Fig. 120-17A,B). In fact, the monomorphic monoclonal proliferations are subclassified according to lymphoma classification.[1] HL and HL-like PTLD are very rare and purportedly similar to methotrexate-related HL.[206] The morphologic findings may be difficult to differentiate from allograft rejection; immunophenotyping is essential, whereas molecular genetic testing for clonality and in situ hybridization studies for EBV may be necessary. For these reasons, tissue procurement rather than fine-needle aspiration biopsy is preferred for diagnosis.

Treatment often starts with reductions in immunosuppression, though this runs the risk of losing the allograft.[207] Early lesions usually regress while only a proportion of polymorphic and monomorphic PTLD respond.[208] Neither morphology nor molecular characterization of the PTLD can predict response to reduction in immunosuppression. Nonresponders, or those with bulky or multisystem disease are treated with anti-CD20 antibody therapy (rituximab).[209] Cytotoxic chemotherapy and perhaps radiation therapy are reserved for refractory cases and those who are CD20 negative. Early diagnosis with prompt reduction of immunosuppression and/or anti-CD20 antibody therapy has improved the prognosis of patients with PTLD.[210,211]

LEUKEMIC INFILTRATES INVOLVING THE LUNG

Secondary effects of leukemia or therapy including infections, alveolar proteinosis, leukemic cell lysis pneumopathy, hemorrhage, and chemotherapy toxicity afflict many leukemia patients but significant direct lung involvement with leukemia affects less than 10% of individuals.[212,213] Leukemic lung infiltration is often found at autopsy or as an "incidental" finding in a tissue sample demonstrating an infectious process, and only causes symptoms in those patients with high (40% or greater) blast counts.[214] Cough, dyspnea, and hemoptysis may precede the leukemia diagnosis for months or develop suddenly.[215] Bronchiolar involvement producing asthma-like symptoms has been reported. Radiographic findings run the gamut from localized to diffuse infiltrates.[216–218]

All leukemia subtypes can involve the lung but acute myeloid leukemia, acute lymphoblastic leukemia, and CLL/SLL are most often seen.[219] Infiltrates are predominantly restricted to the pulmonary lymphatic distribution and rarely form micronodules (Fig. 120-18). Bronchiolocentricity may be mistaken for bronchiolitis. Infiltrates can be subtle and chloroacetate esterase and myeloperoxidase stains may be useful in diagnosis and subtyping. Leukemic counts greater than 200,000/μm cause capillary leukostasis with resultant thrombosis. Pulmonary edema, infarct, and diffuse alveolar damage may result.

Patients with agnogenic myeloid metaplasia (myelofibrosis) occasionally have pulmonary manifestations.[220–223] Diffuse and nodular foci of extramedullary hematopoiesis usually follow lymphatic routes and associated fibrous tissue can form large nodules. Interstitial fibrosis often results and may be mistaken for a primary chronic fibrosing interstitial pneumonia.[224]

In addition to acute complications of leukemia, patients undergoing bone marrow transplantation for leukemia may experience a variety of pulmonary complications including pulmonary edema, diffuse alveolar damage/acute respiratory distress syndrome, bacterial, fungal, and viral infections and GVH disease.[214] Acute GVH rarely involves the lung but lymphocytic bronchiolitis, LIP, constrictive bronchiolitis, and pulmonary fibrosis are all considered within the spectrum of chronic pulmonary GVH. However, these manifestations may also represent cytotoxic chemotherapeutic effect.

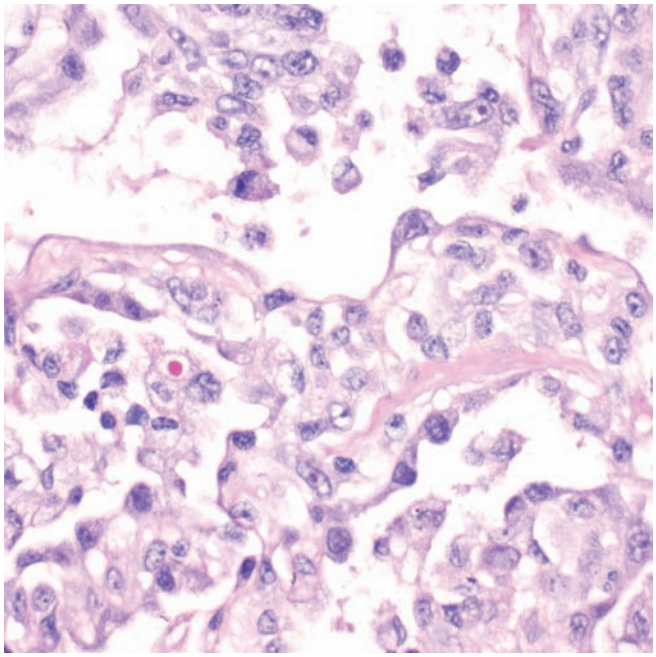

Figure 120-18 Leukemic infiltrate in the lung. Primitive mononuclear cells with clumped chromatin (blasts) expand alveolar septa and spill into air spaces. Although an infectious process was suspected clinically, acute myeloid leukemia represented the only lung pathology. Hematoxylin and eosin, 60× original magnification.

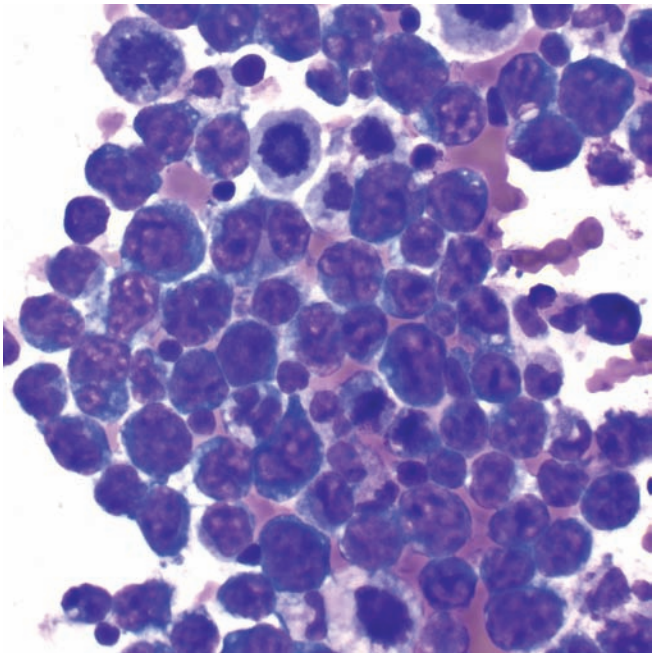

Figure 120-19 Primary effusion lymphoma. This pleural cytology demonstrates a large cluster of pleomorphic cells. This KSHV/HHV8-associated lymphoma is of B-cell origin despite the absence of immunohistochemical staining for B-cell markers. Modified Wright–Giemsa, 60× original magnification.

PLEURAL LYMPHOMAS

Disseminated lymphomas frequently affect the visceral pleura and pleural cavity. Non-HLs often invade the visceral pleura while HL often causes pleural effusions due to mediastinal lymph node involvement and secondary lymphatic obstruction. Leukemia and multiple myeloma infrequently manifest with pleural involvement.[225] Diagnosis often can be established with effusion cytology and flow cytometry; parietal pleural biopsies are rarely required.

Primary pleural lymphomas are much less common and only two types have been described: Primary effusion lymphoma (PEL) and pyothorax-associated lymphoma (PAL). Both are associated with EBV but similarities end there.

■ PRIMARY EFFUSION LYMPHOMA

Primary effusion lymphoma (PEL) is a rare large B-cell lymphoma that presents as either a pleural, pericardial, or peritoneal cavity effusion without a detectable tumor mass.[226] All cases are associated with Kaposi sarcoma–associated herpesvirus/Human herpes virus-8 (KSHV/HHV8) and most occur in young to middle-aged HIV-positive homosexual males.[227] Rare cases have been reported in supposedly immunocompetent elderly individuals and HIV-negative cardiac transplant patients.[228] A solid tissue-based variant is also recognized.[229] Some patients have pre-existing Kaposi sarcoma and rare cases are associated with MCCD.[230] In addition, most cases are coinfected with EBV but a pathogenetic role for this virus has not been elucidated.[231,232]

Effusion cytology specimens demonstrate large lymphoid cells with large round to irregular nuclei and frequent multinucleation as well as numerous mitotic figures (Fig. 120-19). Plasma cell features may be prominent and anaplastic cells can be seen. Pleural biopsies feature tumor cells admixed with fibrin. Chest wall or lung invasion are very rare findings. B-cell lineage is confirmed by immunoglobulin gene rearrangement studies but neoplastic cells rarely express B-cell markers. CD45, CD30, and plasma cell markers CD38 and CD138 are expressed. These findings suggest a postgerminal center B-cell origin. Rare cases with T-cell lineage have been reported.[233]

This lymphoma is extremely aggressive with survival measured in months. Combined antiviral therapy and chemotherapy are offered.[234,235]

■ PYOTHORAX-ASSOCIATED LYMPHOMA

Pyothorax-associated lymphoma (PAL) develops in the pleural cavities of immunocompetent patients with chronic suppurative pleuritis. Most cases arise decades after artificial pneumothorax for treatment of tuberculosis or pleuritis secondary to pulmonary asbestosis.[236] Approximately 2% of individuals with chronic pyothorax develop PAL. EBV is strongly associated but the pathogenesis is not clearly understood.[237] It is postulated that immunocompetent cells cannot enter the diseased pleural cavity resulting in local immunodepression facilitating proliferation of EBV-infected lymphocytes.

Patients, more often males, are usually in their sixth to eighth decades of life and usually present with chest pain, back pain, or shoulder pain and dyspnea.[236] Radiographic studies demonstrate an intense ^{18}F fluorodeoxyglucose positron emission tomography–positive visceral or parietal pleural mass invading chest wall, lung, pericardium, or diaphragm in the setting of pleural fibrosis and calcification.[238,239] In contrast to PEL, pleural effusion is not seen. Solid organ involvement is rare.[237]

Biopsy and resection specimens show masses composed of sheets of large atypical lymphoid cells with prominent nucleoli and basophilic cytoplasm (Fig. 120-20). Mitotic figures and apoptotic bodies as well as necrosis abound. Immunohistochemical studies discern this high-grade lymphoma from PEL. Typically lymphoma cells associated with PAL stain for B-cell antigens CD20 and CD79a, plasma cell markers CD38 and CD138, and on occasion a T-cell marker such as CD2, CD3, CD4, or CD7.[1,240] Immunohistochemistry is positive for EBV, whereas KSHV/HHV8 is absent.[241,242]

The prognosis for patients with PAL is dismal with most deaths occurring within 1 year. However, combination chemotherapy

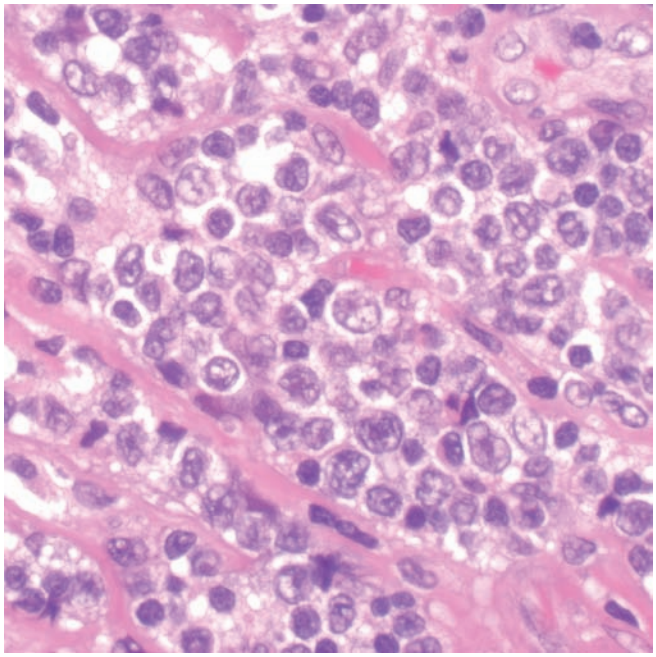

Figure 120-20 Pyothorax-associated lymphoma. Unlike primary effusion lymphoma, this aggressive large-cell B-cell lymphoma is pathogenetically linked to EBV and forms a mass lesion. Hematoxylin and eosin, 60× original magnification.

and radiotherapy may prolong survival with 5-year survival rates of 20%.[236]

CONCLUSIONS

Pulmonary and pleural lymphomas and reactive processes are uncommon entities with rich historical contexts. Current immunohistochemical and molecular methods allow for accurate reproducible classification. Since most lesions arise from BALT, using this construct to order most lung lymphoid proliferations is very appealing. The wide variety of diseases associated with underlying immunologic disorders is only surpassed by the complexities of the primary lymphoproliferative disorders themselves. Clinicopathologic correlation is required for interpretation of virtually all these lesions. Sound diagnoses combined with improved therapies will hopefully improve patient quality of life and survival.

INTRODUCTION

The primary function of the lungs is the exchange of gases at a rate required to support tissue metabolism. During gas exchange, the lung is continuously exposed to a varied burden of foreign substances, including infectious agents. In addition, the lung is repeatedly challenged with microbes via aspiration of secretions from the upper respiratory tract, particularly during sleep. The lung must defend itself against this potentially hostile environment while maintaining the alveolar architecture required for adequate gas exchange. This group of nonrespiratory functions has been collectively termed *pulmonary host defenses.*[1]

MECHANICAL DEFENSES

Mechanical defenses include those present in the nasopharynx and conducting airways of the lung.

■ NASOPHARYNGEAL AIRWAYS

Nasal hairs remove most particulates larger than 10 μm. Brisk airflow and rapid changes in direction of the airstream within the nose promote inertial deposition of large particulates, which are cleared primarily by swallowing, sneezing, or coughing. Mucociliary clearance participates in the removal of particulates from the nasopharynx. Ciliated mucosa is present on the nasal septum and turbinates; mucociliary action sweeps mucus toward the posterior pharynx, where secretions are either swallowed or cleared from the throat.[2–4]

■ CONDUCTING AIRWAYS

Defense mechanisms within the conducting airways include the so-called "mucociliary escalator" and a number of constituents of airway secretions.

Mucociliary Escalator

Most particulates larger than 2 μm in diameter affect the conducting airways. Mucociliary clearance and coughing are the principal means of mechanical defense.[3] The mucosa of the conducting airways is lined with mucus secreted by goblet cells, bronchial glands, and Clara cells. The mucus blanket is composed of two distinct layers: a watery sublayer, in which most ciliary movement takes place, and an upper viscous layer that is just penetrated by the ciliary tip.[2,4,5] Mucus is propelled cephalad within the respiratory tract by the pseudostratified ciliated epithelium that lines the conducting airways. Each ciliated cell has approximately 200 cilia, which are approximately 5 to 6 μm in length and have a beat frequency of 12 to 14 beats per second. Particulates can be cleared from the trachea and distal airways within minutes to hours.

Airway Secretions

Airway epithelial cells secrete a broad array of antimicrobial molecules.[6,7] Iron is essential for survival of many microbes.[8] Iron is sequestered in cells or firmly complexed to transport proteins. Microbes compete for this iron with their own transport proteins, known as siderophores. Lactoferrin, transferrin, and lipocalin-2 are host-derived molecules that effectively complex free iron in mucosal secretions, suppressing bacterial growth by limiting iron required for bacterial replication.[9]

Lysozyme is secreted in abundant quantities in human airways (10–20 mg per day). This enzyme catalyzes the hydrolysis of peptidoglycan constituents of the cell walls of most bacteria and some fungi. Airway secretions contain both serum-derived antiproteases (α_1-antitrypsin, α_2-chymotrypsin, and α_2-macroglobulin) and airway epithelial cell-derived antiproteases (secretory leukocyte protease inhibitor [SLPI] and elafin). Airway secretions and alveolar lining fluid also contain the small cationic antimicrobial peptides β-defensin and cathelicidin.[10–12] These proteins exert broad antimicrobial activity against bacteria, fungi, and viruses through hydrostatic interactions with cell membranes resulting in cell rupture.[10,13] Different classes of antimicrobial molecules can function in a synergistic fashion to markedly enhance microbial killing.[14] For instance, sub-MIC concentrations of lysozyme and lactoferrin can substantially enhance the bacterial killing activity of β-defensins and cathelicidins. The respiratory epithelium has the ability to generate reactive oxygen species at bactericidal concentrations. Hydrogen peroxide is produced in the airway via the dual NADH oxidase/peroxidase (Duox) system, which is induced during infection.[5,15] The bactericidal activity of H_2O_2 is greatly enhanced in the presence of lactoperoxidases produced in abundance by the airway epithelium.

INNATE IMMUNITY

Host defenses against invading microbial pathogens consist of two components: innate immunity and adaptive immunity. Innate immune recognition occurs via germ-line encoded receptors that recognize conserved molecular features common to multiple microorganisms (Fig. 121-1).

■ INNATE IMMUNE RECOGNITION

Microbial recognition is complex because microbes display molecular heterogeneity and have high mutation rates. The innate immune system recognizes a broad spectrum of pathogens using a repertoire of invariant extracellular and intracellular receptors that recognize highly conserved microbial molecules including combinations of sugars, proteins, lipids, and distinct nucleic acid motifs. The receptors that recognize these molecular patterns are termed pattern recognition receptors (PRRs). The ligands recognized by PRRs are pattern-associated molecular patterns (PAMPs). PAMPs share certain features. Specifically, PAMPs are invariant structures shared by classes of pathogens, are produced only by microbes, and are essential for microbial pathogenicity or microbial survival. PRRs can also recognize certain host-derived signals, referred to as danger-associated molecular patterns or DAMPs.[16,17]

PRRs can be divided into three general classes: secreted, endocytic, and signaling receptors. C-reactive protein (CRP), mannan-binding lectin (MBL), and serum amyloid protein (SAP) are secreted

*Deceased.

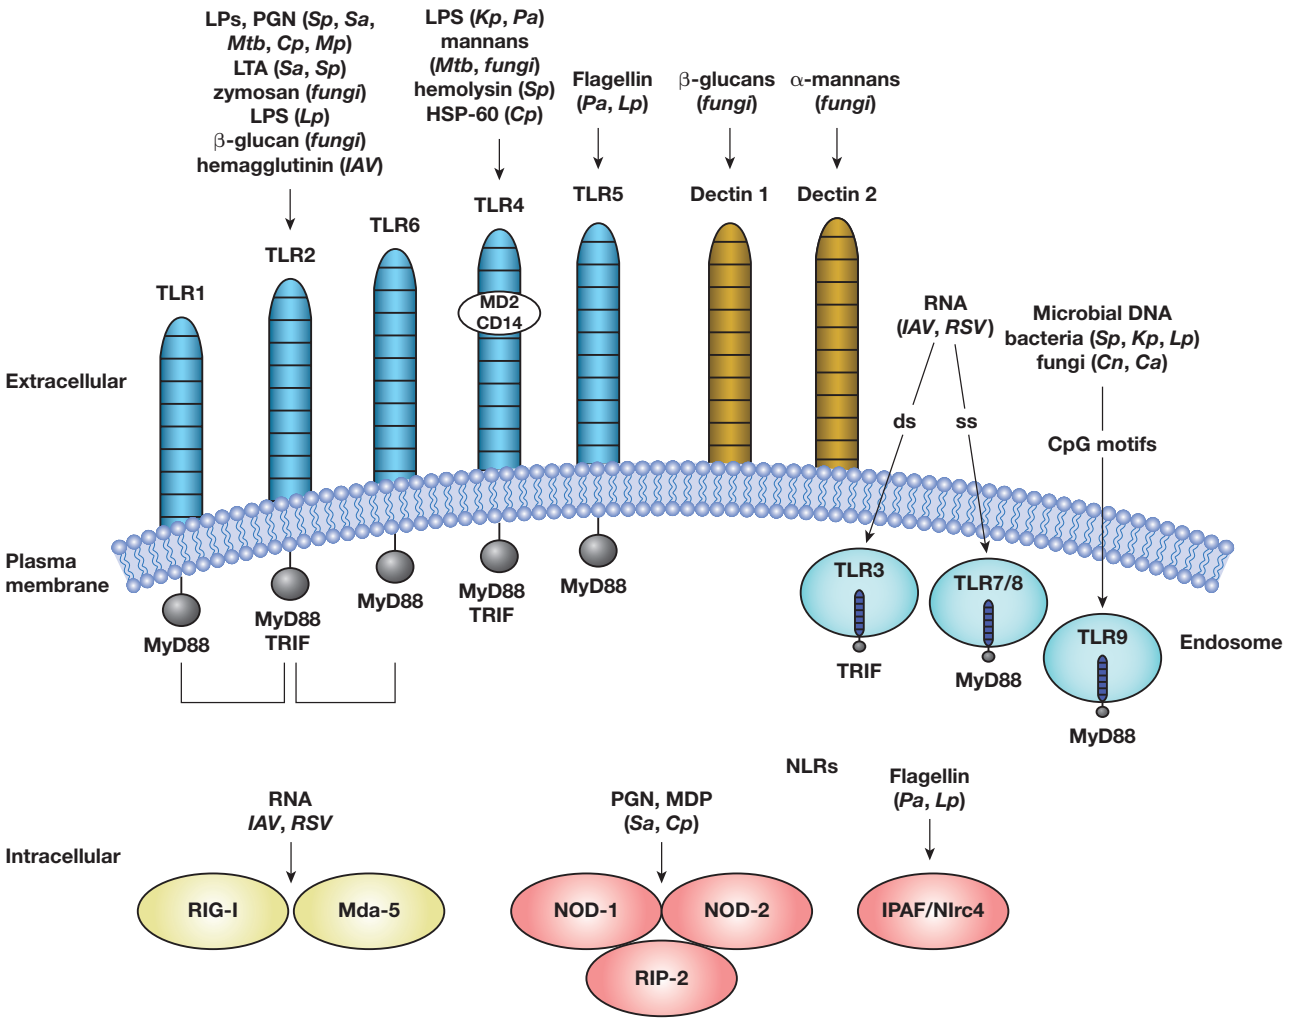

Figure 121-1 Pattern recognition receptors. TLRs, NLRs, dectin receptors, and RIG-I system for detection of extracellular and intracellular PAMPs. TLRs 1, 2, 4 to 6 and dectin receptors are extracellular; TLRs 3, 7/8, and 9 detect PAMPs within endosomes; NLRs and RIG-I detect PAMPs within the cytoplasm. All are signaling receptors. Pattern-associated molecular patterns, PAMPs; LPs, lipoproteins; LPS, lipopolysaccharide; LTA, lipoteichoic acid; PGN, peptidoglycan; MDP, muramyl dipeptide. Pathogens: *Sp*, *S. pneumoniae*; *Sa*, *Staphylococcus aureus*; *Kp*, *K. pneumoniae*; *Cp*, *Chlamydia pneumoniae*; *Mp*, *M. pneumoniae*; *Lp*, *L. pneumophila*; *Mtb*, *M. tuberculosis*; *Cn*, *Cryptococcus neoformans; Ca, C. albicans*; *IAV*, *Influenza virus; RSV, respiratory syncytial virus.*

pattern recognition molecules. CRP and SAP function as opsonins and bind to Clq to activate the classic complement pathway. MBL binds to mannose residues that are abundant on the surface of many microbes. Macrophage mannose receptor (MMR) interacts with Gram-positive and Gram-negative bacteria and fungal pathogens and mediates phagocytosis. Macrophage scavenger receptors (MSRs), including SR-AI/II and MARCO, have broad specificity for varied polyanionic molecules, including environmental particles, apoptotic cells, and microbial components.[18,19] Microbial ligands include double-stranded RNA (dsRNA), LPS, and lipoteichoic acid, and these scavenger receptors mediate binding and internalization of nonopsonized bacteria such as *Escherichia coli* and *Staphylococcus aureus*. While not considered classical signaling receptors, scavenger receptors can stimulate respiratory burst but not inflammatory cytokine production.[20] Signaling PRRs induce expression of inflammatory cytokines, chemokines, and other innate effector molecules following binding of PAMPs. Signaling PRRs include toll-like receptors (TLRs), nucleotide-binding oligomerization domain (NOD)-like receptors, the RNA helicase retinoic acid-inducible gene I (RIG-I) system, and dectin receptors.

TLRs are critical elements of innate immune recognition.[17,21–23] Thirteen TLRs have been described in mammals and are expressed by both traditional immune cells (macrophages, dendritic cells [DCs], mast cells, neutrophils, eosinophils, natural killer [NK] cells) and lung structural cells (epithelial cells, fibroblasts, and endothelial cells).[24–26] TLRs differ from one another in ligand specificity, expression patterns, and the genes they induce. TLR1, TLR2, TLR4, TLR5, and TLR6 are expressed on the surface of cells, whereas TLR3, TLR7, TLR8, and TLR9 are intracellular, primarily in the endosomal compartment. TLR2 recognizes a wide range of microbial constituents expressed primarily by Gram-positive bacteria, mycobacterium, fungi, and certain viruses.[27–34] These PAMPs include lipoproteins, peptidoglycan, lipoteichoic acid, lipoarabinomannan, hemagglutinin, and zymosan.[35] TLR2 also forms heterophilic dimers with other TLRs such as TLR1 and TLR6, substantially increasing the repertoire of ligands recognized by TLR2. TLR3 recognizes dsRNA produced by most viruses during replication.[36,37] TLR4 is the primary receptor for LPS recognition and is required for clearance of many Gram-negative bacteria, including *E. coli*, *Haemophilus influenzae*, and *Klebsiella pneumoniae*.[38,39] TLR4 also recognizes endogenous ligands such as heat shock proteins, matrix components, surfactant proteins, and β-defensins.[16] TLR5 is activated by flagellin, the principal component of bacterial flagella.[40] TLR7 and TLR8 recognize single-stranded RNA (ssRNA) from viruses such as human immunodeficiency

virus and influenza virus.[41] TLR9 recognizes unmethylated CpG motifs present in bacterial, mycobacterial, and fungal DNA but not in mammalian DNA.[42,43] This TLR mediates DC activation that is required for innate responses to bacteria (*Streptococcus pneumoniae*, *K. pneumoniae*, *Legionella pneumophila*) and fungi (*Candida albicans*, *Cryptococcus neoformans*).[43–45] Nearly all TLRs require the adaptor molecular MyD88 for downstream signaling, whereas TLR3 requires the adaptor TRIF. Several TLRs, including TLR2 and TLR4, can signal through both MyD88 and TRIF-dependent pathways, with the MyD88 pathway serving as the dominant pathway in innate antimicrobial responses to bacterial challenge.[46–48]

Another class of signaling PRRs is the NOD-like receptors (NLRs).[49] NLRs exist intracellularly and function to activate the inflammasome, an intracellular multimeric protein complex that regulates the maturation and release of proinflammatory cytokines of the IL-1 family (IL-1, IL-18). NLRs are activated by a diverse group of PAMPs, including the bacterial cell wall components peptidoglycan and muramyl dipeptide (MDP), bacterial flagellin, and several bacterial toxins.[50,51] NLRs and their adaptor molecules contribute to protective immunity against several respiratory pathogens, including *Staphylococcus aureus*, *L. pneumophila*, and *Chlamydia pneumoniae*.[52,53] NLRs can act cooperatively with TLRs to amplify innate responses. For instance, TLR5 and the NLR IPAF/Nlrc4 function cooperatively to optimally eradicate flagellated bacteria such as *Pseudomonas aeruginosa* and *L. pneumophila* from the alveolus.[54]

RIG-I is a complimentary system to sense and respond to intracellular dsRNA.[41,55,56] RIG-I is expressed most prominently by myeloid (conventional) DC and respiratory epithelial cells and is important for virus-induced type I interferon production. During influenza infection, both TLR7 and RIG-I are required for maximal antiviral IFN-α/β responses, with TLR7 mediating IFN production from plasmacytoid DC (pDC), and RIG-I necessary for myeloid DC (mDC) IFN responses.

Dectins are signal-transducing type II transmembrane proteins of the C-type lectin family that are expressed mainly in DC, macrophages, and neutrophils.[57–59] Dectin-1 recognizes β-glucans, whereas dectin-2 recognizes α-mannans. Both β-glucans and α-mannans are major cell wall components of fungi, including *Pneumocystis jiroveci* (formally *Pneumocystis carinii*), *Aspergillus fumigatus*, and *C. albicans*.[58–60] Activation of dectins can induce reactive oxygen species, production of cytokines and chemokines (CXCL1, CXCL8, IL-23, IL-17A, and IL-22), and influx on PMN. Collectively, dectins are crucial for recognition and host defense against fungal infection.

ALVEOLAR MACROPHAGES

Alveolar macrophages are a heterogeneous population of phagocytes that constitute the first line of defense against microbes that reach the alveolus.[34,61] These cells are derived from circulating monocytes and proliferating macrophage precursors in the interstitium of the lung. Alveolar macrophages have a life span of months to years. The signals and ligands that modulate monocyte traffic into the normal lung have not been defined. Other macrophage populations exist in the lung, including within the airway, interstitium, pleura, and intravascular space. These various macrophage populations are phenotypically distinct for one another and from macrophages that reside in the alveolar space.

The antimicrobial function of the alveolar macrophage is dependent on four essential attributes. Macrophages recognize signals, migrate in response to stimuli, secrete mediators, and ingest and kill microbes.[34] Macrophages recognize signals in their microenvironment via PRRs and surface receptors capable of binding specific ligands, including complement proteins, immunoglobulins, cytokines, PAMPs, and toxins (Fig. 121-2). Ligation of TLRs induces transcriptional activation of inflammatory cytokines (TNF-α, IL-1, IL-6, and the IL-1 family members IL-36 α/γ), chemokines, and signals that regulate the differentiation and activation of lymphocytes, such as IL-10, IL-12, transforming growth factor (TGF-β), and IFN-γ. Early response cytokines produced by alveolar macrophages network with structural cells within the alveolus (e.g., alveolar epithelial cell [AEC]).[62,63] As compared to monocytes and macrophages in other tissue compartments, alveolar macrophages preferentially produce 5-lipoxygenase rather than cyclooxygenase products, including LTB_4 and LTC_4, resulting in robust PMN recruitment and activation.[64] In the quiescent state, alveolar macrophages present antigen poorly. However, PRR ligation results in upregulation of costimulatory molecules (CD80, CD86) and transforms these cells into capable antigen-presenting cells (APCs).[34]

Alveolar macrophages migrate within the alveolar space in response to both endogenous signals and mechanical stimuli. The movement of these cells in response to bacteria is dependent upon chemotactic signals, including surfactant proteins (SP-A), and chemokines (CCL2/MCP-1), and adhesion molecule (ICAM-1)

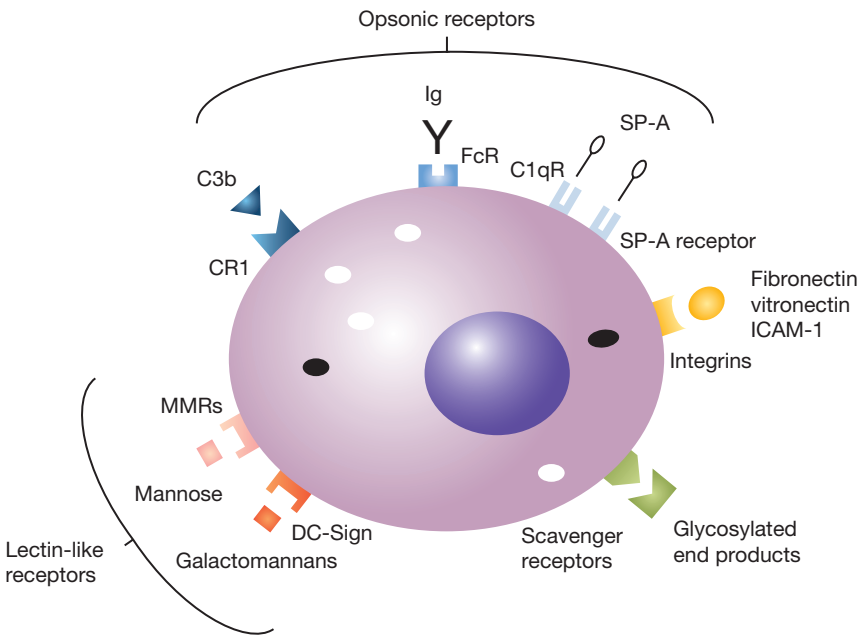

Figure 121-2 Cell-surface receptors expressed by alveolar macrophages that mediate adherence, movement, and pathogen internalization. Opsonic receptors mediate attachment and phagocytosis of pathogens opsonized with C3b, immunoglobulin, or SP-A. Lectin-like receptors and scavenger receptors mediate attachment and internalization of nonopsonized microbes expressing specific carbohydrate moieties. Integrins mediate alveolar macrophage binding to and migration along matrix components or alveolar epithelium.

expression by AECs.[65–67] Mechanical stretch can stimulate directed movement of alveolar macrophages, although the soluble signals involved in this response have not been defined.

Alveolar macrophages are highly phagocytic cells. The opsonization of microbes by the complement component C3b or immunoglobulin binding greatly facilitates phagocytosis. Macrophages express two distinct receptors for C3b. Complement receptor 1 (CR1) preferentially binds C3b, whereas the complement receptor 3 (CR3, Mo-1, MAC-1, CD11b/18) is a member of the β_2 integrin family required for cell–cell and cell–substrate adhesion. Three Fcγ receptors recognize the Fc domain of immunoglobulin G (IgG). All FcRs function as signal-transducing molecules. FcγRI, FcγRII, and FcγRIII trigger both phagocytosis and cytolytic responses, with FcγRII and FcγRIII the most indispensible.

The alveolar macrophage also expresses multiple cell-surface receptors that promote binding and internalization of nonopsonized particulates, including microbes. MMR binds mannose and mediates phagocytosis of yeasts, zymosan particles, and *P. jiroveci* (see Fig. 121-2). Scavenger receptors bind apoptotic cells and acellular debris and serve as a major mechanism to internalize nonopsonized Gram-positive and Gram-negative bacteria (*Staphylococcus aureus*, *S. pneumoniae*, *E. coli*).[18,19] SP-A-opsonized microorganisms bind to specific high affinity receptors and C1q receptors, triggering internalization and increased cell-surface expression of macrophage Fc receptors, mannose receptors, and scavenger receptors. DC-specific intracellular adhesion molecule 3-grabbing nonintegrin (DC-Sign) is a type II membrane C-type lectin expressed by DC and alveolar macrophages.[68] This PRR recognizes galactomannans of diverse pathogens, including bacteria, mycobacteria, fungi, and viruses.[69] Binding of microbes to DC-Sign can signal an IL-10 predominant anti-inflammatory response, thus subverting from a killer to a permissive phenotype in responding cells.

Phagocytosis requires sequential, circumferential interaction of phagocyte surface receptors with complementary ligands on the surface of the particle. The ingested microbe is initially contained within a phagosome that subsequently fuses with lysosomes to form phagolysosomes. TLR stimulation is linked to phagosomal maturation. The killing capacity of resting alveolar macrophages is low, and these cells require activation signals from the microenvironment for intracellular killing to occur. Activation stimuli include microbial products, inflammatory cytokines, and plasma proteins. Most notable is IFN-γ, the primary activator of macrophage antimicrobial effector responses. Other activating cytokines include TNF-α, IL-1, and GM-CSF, which provide a priming signal to augment macrophage differentiation and microbicidal activity.[70]

Both oxidative and nonoxidative processes are used to kill ingested microbes. Alveolar macrophages display less potent antimicrobial activity as compared to blood monocytes. Loss of granular peroxidase and a more modest respiratory burst account for reduced microbicidal activity. Resident alveolar macrophages contain minimal myeloperoxidase (MPO), and as a consequence the MPO-H_2O_2-halide system is less robust in resident macrophages than in recruited macrophages. Microbes are also killed by macrophage-dependent nonoxidative mechanisms, including proteases, lysozyme, nitric oxide products, defensins, and cathelicidins.

INNATE LYMPHOID CELLS

A population of lymphoid cells, referred to as innate lymphoid cells (ILCs), are present in the respiratory tract.[71] These cells produce large amounts of cytokines early in response to microbial invasion. Cytokines produced by ILC, including NK, natural killer T (NKT), and γδ T cells, drive protective innate and adaptive immune responses in the lung (Figs. 121-3 and 121-4).

NK cells are present in large quantities within the lung, making up approximately 10% of the entire lymphocyte population. NK cells are also rapidly recruited to the lung in response to infection, where they are activated by cytokines (IL-12, IL-15, IL-18, and TNF-α) produced by lung macrophages and DC.[72,73] Upon activation, NK cells produce robust quantities of TNF-α and IFN-γ, which are required for optimal pulmonary macrophage microbicidal activity during bacterial, mycobacterial, and fungal infection.[74] NK cells also mediate protective immunity during influenza infection via perforin-mediated lysis of virally infected cells and stimulate epithelial regeneration via release of IL-22.[75] Overzealous innate responses by NK cells can sometimes be detrimental to the host, as is the case in experimental respiratory syncytial virus (RSV) or influenza infection.[73,76,77] In addition to contributing to early innate responses, NK cells also substantially shape the development of adaptive immunity against the invading pathogen. Genetic deficiencies in NK cell function are associated with recurrent viral and bacterial infections, including those involving the respiratory tract.

NKT cells are a subset of lymphocytes that recognize glycolipid rather than protein antigens presented by CD1d, a nonpolymorphic major histocompatibility complex (MHC) class I-like antigen.[78,79] The majority of NKT cells express an invariant T-cell antigen receptor that is highly conserved among species. Activation of NKT cells by bacterial (*Streptococcus* spp.) or viral (influenza) glycolipids results in expression of TNF-α, chemokines, IFN-γ, and IL-17 required for microbial clearance.[80] Different subsets of NKT cells can either augment or suppress the development of innate and acquired immunity, suggesting an important regulatory role of these cells during lung infection.

Gamma–delta T cells are a unique innate T-cell subset that are small in number (approximately 1%–2% of the lung lymphocyte population) and localized to mucosal and epithelial surfaces. However, during respiratory infection the numbers of γδ T cells in the lung increase considerably (>30-fold), a process that is due primarily to local expansion rather than recruitment.[81,82] Upon activation by bacteria (*S. pneumoniae*, *K. pneumoniae*), γδ T cells function as a rich and early cellular source of TNF-α, chemokines, IFN-γ, IL-17, and IL-22. Like NKT cells, a heterogeneous population of γδ T cells exist, with specific subsets functioning to control the magnitude of DC and macrophage recruitment and activation during the resolution phase of pulmonary inflammation.[83] This nuanced response by γδ T cells is necessary to maintaining the immune and structural integrity of the lung during infection.

A novel population of lineage–negative ILCs have recently been described, including in the lung. Type I innate lymphoid cells (ILC1) produce primarily IFN-γ upon activation, where as type III ILC (ILC3) express large quantities of IL-17 and IL-22. The role of these cells in lung mucosal immunity is not yet known.

ALVEOLAR EPITHELIAL CELLS

The alveolar–capillary membrane is a dynamic assembly of innate immune cells that generate chemokines required to recruit and activate specific inflammatory cells during microbial insults. AECs are key participants in the innate response to microbial challenge.[8,84] These cells express an array of both extracellular and intracellular signaling PRRs that trigger the release of a variety of inflammatory cytokines (IL-1, IL-6, IL-36 α/γ, type I and III interferons, GM-CSF) and chemokines (CXCL1/KC, CXCL2/MIP-2, CXCL5/LIX, CXCL8/IL-8, CCL2/MCP-1, CCL20/MIP-3α) that regulate the engagement and activation of phagocytic cells.[7,24,70,84–87] AEC also secrete molecules that directly mediate antimicrobial killing, including large antimicrobial proteins (lysozyme, lactoferrin, calgranulins A and B, SLPI) and small antimicrobial peptides (β-defensins, cathelicidins).[12] Type II AEC produce surfactant proteins SP-A and SP-D, members of the collectin family of lectins. SP-A contains a carbohydrate recognition domain that binds to exposed carbohydrate residues on the surface of microbes, serving as an opsonin to promote internalization of diverse pathogens (Gram-positive and

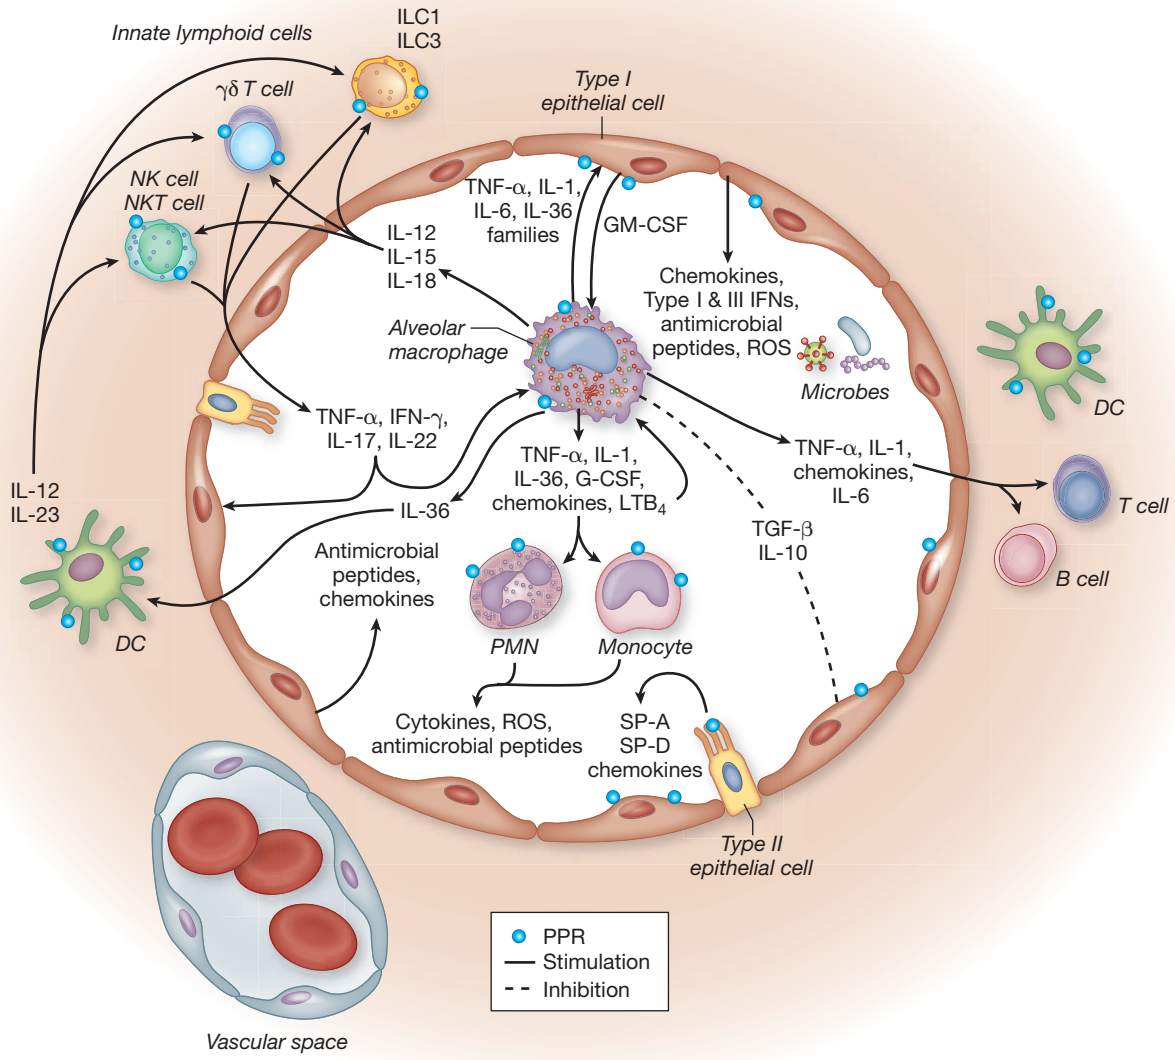

Figure 121-3 Initiation and regulation of inflammatory responses in the lower respiratory tract. Chemotaxins are generated sequentially following the entry of bacteria or bacterial products into the alveolus. PAMPs stimulate alveolar macrophages to produce proximal cytokines (TNF-α, IL-1β, IL-1, and IL-6 family members) and LTB_4. Proximal cytokines induce gene expression and production of chemokines and growth factors by epithelial cells and fibroblasts present in the alveolar–capillary wall and induce the expression of adherence molecules on inflammatory cells and endothelial cells. Microbes induce macrophages to produce IL-12, IL-15, and IL-18 to stimulate the expression of activating cytokines (e.g., IFN-γ, TNF-α) from ILC. ILC also produce IL-17 and IL-22 in response to IL-23 production from DC. IL-17 stimulates the paracrine induction of IL-1, IL-6, and CXC chemokines by parenchymal cells, whereas IL-17 and IL-22 drive antimicrobial peptide release from the alveolar epithelium.

Gram-negative bacteria, fungi, and viruses) by alveolar macrophage and type II AECs.[65] SP-A also increases secretion of GM-CSF, promotes directed migration of alveolar macrophages, and regulates macrophage oxidant production.[65,88] SP-D mediates agglutination of bacteria, fungi, and influenza, facilitating uptake by PMN and other phagocytic cells.[89]

INITIATION AND REGULATION OF THE INFLAMMATORY RESPONSE

A dual phagocytic system involving resident and recruited macrophages and recruited PMN is required for the clearance of bacteria from the lower respiratory tract (Fig. 121-3). Neutrophils ingest microbes by phagocytosis.[90] Effective killing requires products of granule constituents and molecular oxygen. Hydrogen peroxide and reactive oxygen intermediates are involved in neutrophil-mediated killing. The MPO-H_2O_2-halide system is a crucial participant in oxygen-dependent killing by neutrophils. Granule components are also crucial in PMN-mediated microbial killing. Microbicidal molecules found in azurophil granules include lactoferrin, lysozyme, cathepsin G, elastase, and cationic proteins such as α-defensins and cathelicidins. Neutrophil extracellular traps (NETs) are complex structures composed of nuclear chromatin, histones, and a variety of granular antimicrobial proteins.[91,92] NETs are released from azurophilic granules during infectious challenge and are capable of physically ensnaring bacteria. These structures facilitate the interactions between bacteria and antimicrobial effectors, ultimately leading to enhanced bacterial killing.[93]

Recruitment of PMNs from the blood into the alveolus is initiated by upregulation of selectins and β-integrins on the surface of leukocytes and endothelium, concurrent with the establishment

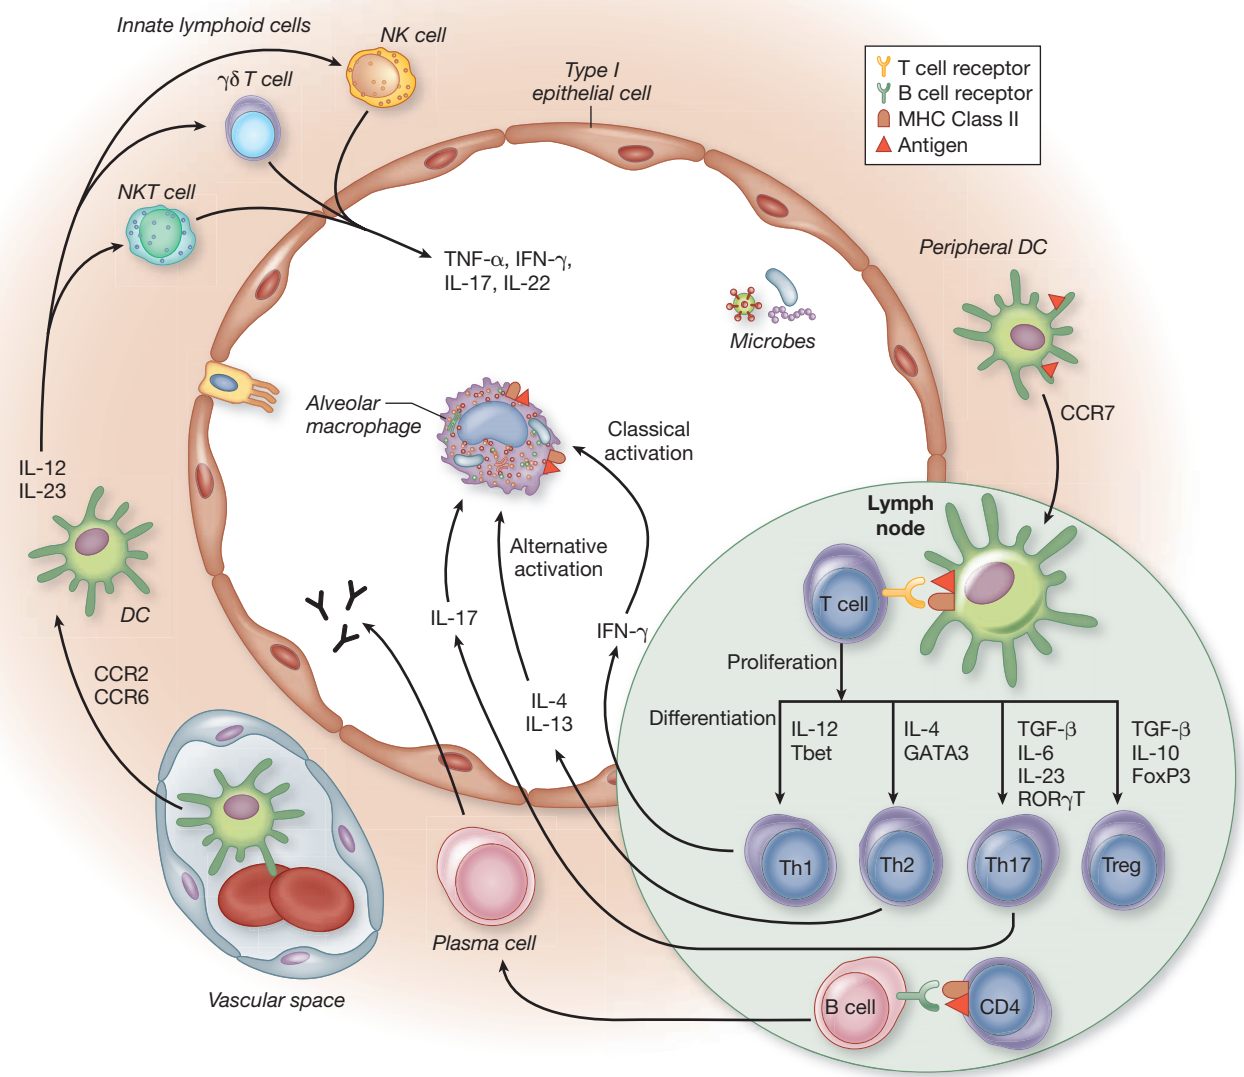

Figure 121-4 Initiation and regulation of specific immune responses in the lung. Dendritic cells located in the interstitium of the lung and in the airway epithelium function as sentinel antigen-presenting cells. Dendritic cells reside in close contact to airway epithelial cells, alveolar epithelial cells, and interstitial macrophages. Following exposure to microbial antigens, inflammatory DCs are recruited into the lung interstitium and alveolus in a CCR2- and CCR6-dependent fashion. DC differentiation occurs as a result of exposure to cytokines produced by cells of the innate immune system (macrophages) and cytokine produced as a result of injury to epithelial cells. Differentiated DC migrates to local nodes in a CCR7-dependent fashion where they present antigen to naive T lymphocytes. The control of CD4 T-lymphocyte subset differentiation occurs via complex, cross-regulatory interactions mediated by cytokines (e.g., IL-12, IL-4, IL-6, TGF-β, and IL-23) and transcription factors. Cytokines produced by Th1, Th2, and Th17 cells regulate macrophage activational state. Initial events in B-lymphocyte proliferation and differentiation occur in T lymphocyte-dependent areas of regional LNs. Proliferation, somatic hypermutation, and selection occur within the lymphoid follicle. B lymphocytes then migrate to bone marrow and to the lung, where they undergo differentiation to mature antibody-producing plasma cells.

of chemotactic gradients within the lung interstitium and alveolar space.[63] Chemotactic gradients are established in part by matrilysin-mediated shedding of syndecan–chemokine complexes into the alveolar space.[94] Early recruitment of PMN to the lung (<4 h) is directed by cytokines, chemokines, and leukotrienes secreted by pulmonary macrophages, whereas sustained neutrophil influx (24 h) appears to be driven by chemokines produced by lung structural cells, including AEC.[95] CXC chemokines that mediate PMN influx during lung infection include CXCL1/KC, CXCL2/MIP-2, and CXCL5/LIX in the mouse and CXCL8/IL-8 in humans.[63,95,96]

Recruited, or exudate, macrophages represent an essential arm of the innate response in lung bacterial and fungal infection. The recruitment of these cells to the lung requires specific chemokines and chemokine receptors. In particular, CCL2/MCP-1 with the receptor CCR2 mediates the influx of exudate macrophages in Gram-negative pneumonia.[97] MCP-1 also serves as an autocrine inducer of cytokine (G-CSF) and CXC chemokine (CXCL1, CXCL2) production from alveolar macrophages, further amplifying the neutrophilic response during pneumonia.[98] CCL3/MIP-1α is an additional CC chemokine that participates in both exudate macrophage and PMN recruitment during bacterial infection.[99]

Sentinel DC and macrophages produce IL-12, IL-15, IL-18, and IL-23 within minutes to hours after exposure to LPS and microbial products. Interleukin-12, IL-15, and IL-18 induce the release

of the activating cytokine IFN-γ from ILCs early in the innate response and antigen-specific T cells later in the adaptive response. Interleukin-23 triggers rapid (hours) production of IL-17 and IL-22 from tissue resident α/β, γδ, NKT cells, and ILC3.[100] IL-17 promotes production of IL-1, IL-6, TNF-α, CXC chemokines, IL-22, and antimicrobial peptides from both alveolar macrophages and cellular constituents of the alveolar–capillary membrane.[100–102] IL-22, like IL-17, stimulates effector responses, including mucus production and antimicrobial peptide expression from the respiratory epithelium.[103] Interleukin 1 family members, including IL-36 α and β, also serve as relevant proximal signals in the induction of cytokines and chemokines from DC and structural cells of the lung.

Robust innate responses are required for effective control of pathogens at mucosal sites of invasion. However, these responses need to be tempered to allow for protection and restoration of lung architecture. Certain cells and soluble factors present within the lung microenvironment contribute to the fine-tuning of innate responses. For instance, surfactant proteins A and D can antagonize binding of DAMPs and PAMPs to TLR4, hence reducing downstream inflammatory mediator release.[104–106] Inhibitors of TLR signaling, such as IRAK-M, suppress deleterious inflammation in influenza infection.[107] Anti-inflammatory molecules, including IL-10 and IL-1 receptor antagonist, produced by NKT, γδ T cells, and exudate macrophages, contribute to the resolution of inflammation.[108] Finally, the update of apoptotic neutrophils and other cells by lung macrophages signal an anti-inflammatory program that facilitates tissue repair.

ADAPTIVE IMMUNE RESPONSES

Microbial infections that elude the innate defense mechanisms and inflammatory responses generate a threshold dose of antigen, which is needed to trigger adaptive immune responses. Adaptive immune responses consist of two major effector systems, antibody- and cell-mediated immunity, which are generated by antigen-specific B and T lymphocytes, respectively. B and T lymphocytes rearrange their Ig and T-cell receptor (TCR) genes to maintain approximately 10^{11} different clones of B and T lymphocytes that express distinct antigen receptors. B lymphocytes recognize native antigens including carbohydrates, proteins, and simple chemical groups. T-lymphocyte receptors recognize only peptides derived from protein antigens bound to cell-surface proteins from the MHC.

Antigen-specific immune responses require at least 7 to 10 days for their development; this time is required for the proliferation and differentiation of antigen-specific T and B lymphocytes. During the development of specific immune responses, pathogens may continue to grow in the host or be held in check by innate and inflammatory mechanisms. The generation of specific immune responses to infectious antigens can be divided into three phases: the afferent phase, central control/processing phase, and efferent phase.

AFFERENT IMMUNE RESPONSE

APCs and ILCs provide an essential link between innate and adaptive immunity (Fig. 121-4).[109–117] DCs are the most potent APC for T cells. DCs are bone marrow-derived cells which take up residence in peripheral tissues at epithelial borders throughout the mammalian host where they become specialized for recognition of pathogens and microenvironmental tissue damage during antigen uptake and presentation. Following antigen uptake, they migrate to lymph nodes (LNs) or mucosa-associated lymphoid tissue.

Mucosa-associated lymphoid tissues are organized into unique inductive and effector sites. Inductive sites include specialized lymphoid follicles underlying the epithelium, such as nasopharynx-associated lymphoid tissue (NALT) and bronchial-associated lymphoid tissue (BALT) in the upper and lower airway, respectively, and Peyer's patches (PPs) and isolated lymph follicles (ILFs) in the gut, and downstream LNs, including cervical and mediastinal LNs draining the respiratory mucosa and mesenteric LNs draining the intestinal mucosa.[118,119] Clones of lymphocytes are triggered by APCs to proliferate and differentiate into effector cells. Antigen-specific lymphocytes remain expanded after elimination of an infection (memory lymphocytes). Memory lymphocytes provide a much more rapid response to a second exposure to antigen.

Two broad subsets of DC have been identified[109,120,121]: myeloid DC (mDC) and plasmacytoid DC (pDC). mDC express CD11c, CD11b, and varying levels of MHC class II and costimulatory molecules (CD40, CD80, and CD86). Human pDC express blood DC antigen (BDCA)2, whereas murine pDC express CD11c, GR-1, and B220. mDC contribute to a variety of T-cell responses or tolerance and pDC have been implicated in antiviral immunity and in murine models of asthma.

DCs exist in both immature and mature forms. Immature DCs are concerned mainly with antigen capture. DCs are mobilized from bone marrow precursors to peripheral blood in response to pulmonary inflammation. Monocytes contribute to the pool of newly recruited DC through transendothelial migration in which peripheral blood monocytes differentiate into tissue DC after crossing the vascular endothelium. CCR2 is a critical receptor in the recruitment of DC during inflammatory responses.[122,123] CCR6 mediates recruitment of DC specifically to the airways and alveolar space in response to CCL20 (macrophage inflammatory protein [MIP]-3α) secreted by respiratory epithelial cells.[124]

DC maturation is dependent on sensing of infection,[109,120,121] which may occur either directly by detection of pathogen products using PRRs, activation by inflammatory signals such as TNF-α, or indirectly through exposure to endogenous danger signals such as material released from damaged cells (e.g., DAMPs). Ingested antigens are rapidly processed for antigen presentation by one of two pathways.[125] The endocytic pathways process protein antigens obtained from the extracellular space in phagolysosomes converting them to small polypeptides. The polypeptides are loaded on to MHC class II molecules to prime DC for further presentation to MHC class II restricted CD4+ T helper lymphocytes. The endogenous pathway processes peptides from the intracellular environment and loads them onto MHC class I molecules for presentation to MHC class I restricted CD8+ T cells. Mature DCs upregulate MHC class II and costimulatory molecules allowing a phenotype focused on antigen presentation and the stimulation of naïve T cells.

DC maturation is accompanied by changes in the expression of chemokine receptors.[109,120,121] CCR1, CCR2, CCR5, and CCR6 are downregulated. CCR7 expression is enhanced allowing DC to respond to chemokine gradients of secondary lymphoid tissue chemokines (SLC/CCL21) and Epstein–Barr virus-induced molecule1 ligand chemokine (ELC/CCL19) emanating from local lymphatics and draining LNs. Mature DCs leave the local inflammatory environment carrying their antigenic load to draining LNs. DC–T-cell interactions within the draining LN are complex. T-cell stimulation, proliferation, and activation result if antigen recognition occurs. Induction of Th1, Th2, Th17, or T-regulatory responses may be the end result.[113,115,126]

The engagement of PRRs on DCs leads to increased expression of MHC-peptide complexes and costimulatory molecules as well as the production of immunomodulatory cytokines, all of which have a profound effect on T-cell priming and differentiation.[109,120,121] Triggering of the TCR occurs following an interaction with an antigen/MHC complex and provides "signal one" to the T cell. T-cell maturation results in upregulation of important costimulatory molecules. Specifically, DCs increase the expression of B7.1 (CD80) and B7.2 (CD86), which bind CD28 on T cells providing "signal two" to activate antigen-specific T cells.

Until recently, CD4 T helper cells were believed to be the most significant sources of regulatory cytokines during the development

of immune responses in the lung; however, it is now clear that ILC produce large amounts of cytokines early in a response that drive the development of Th1, Th2, and Th17 responses.[111,112] These cells produce many of the same cytokines as CD4 Th cells, but they do not express a TCR or cell-surface markers associated with other lineages. Thus, they are not antigen-specific. These ILCs include ILC1 (IFN-γ-expressing NK cells), ILC2 (IL-5 and IL-13-expressing nuocytes), and ILC3 (IL-17- and IL-22-expressing RORγ ILC and lymphoid tissue-inducer (LTi) cells). Activation of ILCs is an important step in the development of adaptive immunity and polarization of T-cell responses.

CD4+ T cells coordinate antigen-specific immune responses against inhaled antigens.[113–117,120] Separate, distinct subsets of CD4+ T helper (Th) cells mediate a variety of distinct adaptive immune response "programs." Antigen exposure can initiate the afferent phase of the adaptive immune response that includes all subsequent events that lead to the formation of a poised antigen-specific response. The priming of CD4+ Th cells from naïve precursor CD4+ T cells is a critical component of the afferent phase. CD4+ Th cells aid B cells in the production of antibodies that mediate components of the hypersensitivity reaction. Endowed with antigen-specific receptors, T cells and antibodies mediate the efferent phase of the adaptive immune response that encompasses all the immune activities directed at the antigen source. APC acquire antigen at the site of introduction and migrate to draining LNs to prime naïve CD4+ T cells. Naïve CD4+ T cells undergo multiple rounds of division and progress through multiple stages of differentiation along the pathway to becoming effector CD4+ Th cells.[127–129]

CD4+ Th cells differentiate into one of several distinct subsets that in turn mediate a distinct adaptive immune response "program."[113,115,126,130,131] Each program has a genetic foundation in CD4+ Th cells. Master regulation by a specific transcription factor promotes the acquisition of a particular Th phenotype at the expense of the other phenotypes. Tbet (Tbx21) promotes Th1 development, GATA3 promotes Th2 development, and RORγT promotes Th17 development. Likewise, CD4+ T-regulatory (Treg) cells that inhibit CD4+ Th activity to limit harmful inflammation are specified by the transcription factor Foxp3. During CD4+ Th cell activation, the cytokine milieu present (from DC and ILC early in the response and other inflammatory cells during chronic inflammation) guides cellular differentiation along one of the particular pathways. IL-12 along with IFN-γ promotes Th1 cell development, IL-4 promotes Th2 cell development, and the combination of TGF-β and IL-6 promotes Th17 development. IL-23 drives the expansion of the Th17 cell population. The presence of TGF-β alone supports the differentiation of Treg cells.

Cytokine production represents a key effector function by which CD4+ Th cells coordinate adaptive immune responses.[113,115,126,130,131] By producing a distinct set of cytokines, each CD4+ Th cell subset coordinates a distinctive adaptive immune response program that likely developed evolutionarily to counter a particular pathogenic threat. Th1 cells produce IFN-γ, along with IL-2 and TNF-α, and help protect against intracellular pathogens, but also mediate delayed-type hypersensitivity. Th2 cells produce IL-4, IL-5, and IL-13 and promote a response to parasite infection and responses where mucus shedding and expulsion are beneficial, as well as humoral immunity. Th17 cells produce IL-17 required for protection against several extracellular pathogens.

EFFERENT IMMUNE RESPONSES

Antigen-specific T cells must migrate via the blood stream to peripheral sites of ongoing infection (Fig. 121-4).[117,132] Chemokine–chemokine receptor and adhesion molecule–ligand interactions are involved. While DCs often migrate to local lymphoid tissue after activation, a subset of recruited DCs remains in the lung rather than migrating to draining LNs.[114,120,122] These recruited nonmigratory pulmonary DCs present antigen to newly recruited T cells to drive T-cell polarization and stimulate cytokine release. Cytokines produced by specific CD4 and CD8 lymphocytes play a central role in the ongoing recruitment of inflammatory mononuclear phagocytes and other effector lymphocytes. Monocytes and NK cells are recruited into the complex peripheral infectious environment.

Viruses including influenza, parainfluenza, RSV, Hantavirus, coronavirus (severe acute respiratory syndrome), herpesvirus, and CMV cause significant pulmonary disease. Viruses are intracellular pathogens; the killing of virally infected cells by MHC class I restricted CD8 cytotoxic T lymphocytes (CTLs) is required. CTLs kill target cells by two mechanisms (Fig. 121-5). Cytolytic mediators, including perforins and granzymes, are released from cytoplasmic granules. Perforins induce pore formation and osmotic cell lysis and granzymes are proteases that activate cell caspases, resulting in apoptosis. Killing of virally infected cells can also result from the direct induction of apoptosis by Fas/Fas ligand interactions and release of TNF-related apoptosis-inducing ligand (TRAIL) by CTL.[133] Viral infection of target cells results in reduced MHC class I expression, triggering perforin/granzyme-mediated killing by local and recruited NK cells.

The development of cell-mediated immunity to viral infections proceeds by mechanisms presented earlier, but may also proceed locally within the lung. Priming can occur in BALT, a submucosal lymphoid tissue found in the major bronchi.[118,119] Localized priming of the cell-mediated immune response may play a crucial role in viral host defense.

Memory T-cell responses are important in certain viral illnesses and following administration of antiviral vaccines.[116,117,129] Two subsets of memory T cells have been defined. Effector memory T cells are found within the lung, are short lived, retain markers of activation, and have effector functions; these cells lack expression of lymphoid trafficking molecules CCR7 or CD62L. Central memory T cells reside predominantly within lymphoid organs, persist for long periods of time, and express CCR7 and CD62L.

Numerous strains of bacteria and certain fungi have evolved the capacity to invade and survive within host leukocytes, primarily macrophages, to evade recognition and elimination by innate immune responses. Cell-mediated immunity is required to successfully eradicate these microbes. Cytokines produced by CD4 and CD8 T lymphocytes play a central role in the activation of microbicidal function in phagocytic cells (see Fig. 121-5). IFN-γ produced by both CD4 and CD8 T lymphocytes is the most important macrophage-activating factor. Macrophage activation is further enhanced by TLR stimulation and by inflammatory cytokines such as TNF-α and GM-CSF. Activated macrophages kill microbes. Intracellular microbes are exposed to toxic acid hydrolysis and cationic peptides in phagolysosomes. Expression of inducible nitric oxide synthase results in enhanced nitric oxide synthesis and the synthesis of reactive nitrogen intermediates that have antimicrobial properties. Induction of the respiratory burst results in generation of superoxide, hydrogen peroxide, and toxic reactive oxygen intermediates. The induction of macrophage apoptosis in response to intracellular infection has been shown to be of importance in blocking cell-to-cell spread of certain intracellular infections.

Granuloma formation is an important mechanism of host defense to intracellular microbes.[134,135] The recruitment of monocytes and lymphocyte populations to the site of infection is required for granuloma formation. Macrophages coalesce into large, epithelioid, and multinucleated giant cells. DC, CD4+ T lymphocytes, and CD8+ T lymphocytes form a loose meshwork that serves to contain

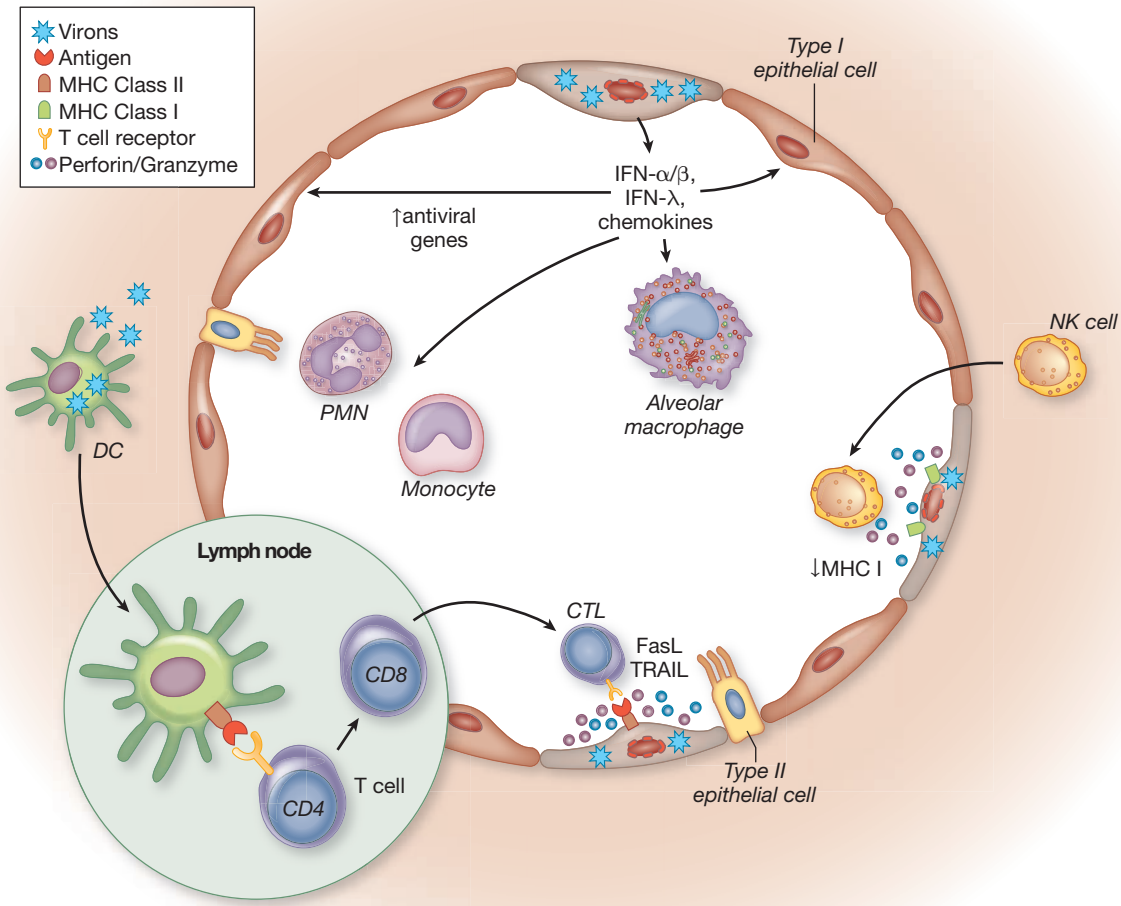

Figure 121-5 Initiation of antiviral immunity in the lung. Viral infection of respiratory epithelium results in induction of type I (α/β) and type III (λ) interferons, which stimulate the paracrine expression of antiviral genes by neighboring epithelial cells. Chemokines produced by epithelial cells promote inflammatory cell recruitment/activation. The development of CD8 effector T cells generally requires cognate interactions with CD4 T cells. Cytotoxic T cells (CTLs) recognize viral antigen presented in the context of MHC class I, resulting in apoptosis of virally infected target cells by perforin/granzyme, FasL, or TRAIL-dependent mechanisms. NK cells also kill virally infected cells by releasing pore-forming granules.

microorganisms. Granulomas are sites of ongoing production of inflammatory cytokines, including TNF-α, IFN-γ, and chemokines capable of recruiting additional effector cells.

CONTROLLING THE ADAPTIVE RESPONSE VIA REGULATORY T CELLS

The immune system possesses various mechanisms to control and regulate inflammation and adaptive responses to prevent and minimize reactivity to self-antigens or an over exuberant response to a pathogen. One of these mechanisms is through the generation of Treg cells.[130,136] CD4+CD25+ Treg cells are the best characterized subset. These cells represent 5% to 10% of the CD4+ T lymphocytes in healthy adult mice and humans. CD4+ Treg cells are recognized for the production of cytokines with anti-inflammatory activity, including IL-10 and TGF-β, and are able to limit CD4+ Th responses.

There are a number of subsets of Treg cells, with the major distinction being (1) Tregs that are induced in the periphery following antigen encounter (inducible Tregs, iTreg) and (2) Tregs that arise from normal T-cell thymic development (naturally occurring Tregs, nTreg). Both types of Treg cells have been shown to play a role in mucosal inflammation and infection. Activated Treg cells can suppress not only antigen-specific responses but also unrelated immune responses in a non–antigen-specific manner either through cell contact or through the regulatory cytokines they produce—a mechanism known as bystander suppression.

nTreg cells can prevent immunopathology in a variety of infections and the mechanisms by which nTreg regulate inflammation appear to vary between stimuli and include cell-contact and soluble mediators. Activated nTreg cells efficiently control self-reactive T cells and innate responses (thereby limiting tissue damage) in mouse models of chronic infection and inflammation. nTreg cells,

TABLE 121-1 Pulmonary Host Defense–Microbe Interactions

Host Mood	Defense Mechanism	Timing	Microbial Behavior
Content	Mechanical: epithelial barrier; mucociliary escalator	Continuous	Commensal
Irritated	Innate Immunity: macrophages, innate lymphoid cells	Hours to days	Replication in the airway and alveolar space
Interested	Inflammation: macrophages/PMN	Minutes to hours	Invasion
Angry	Antigen-specific immunity: DC; CD4, CD8 T lymphocytes; B lymphocytes	3–7 d	Tissue invasion/replication in phagocytes
Frustrated	Immunopathology: macrophages; CD4, CD8 T cells; NK cells, B cells	Weeks	Persistence of microbe

however, can also inhibit allergen-induced airway hyperreactivity through IL-10-dependent mechanisms or by inhibiting antigen presentation by DCs. The antigen specificity of iTreg cells is largely microbial or environmental antigens, whereas the nature of the antigens recognized by nTreg cells is not clear. nTreg cells are believed to recognize a wide array of self-antigens as a consequence of their development and selection in the thymus. During the onset of acute disease, nTreg cells have the potential to recognize self-antigens that are released by tissue damage; however, evidence from chronic infection suggests that nTreg cells can also recognize microbial antigens.

iTreg cells are generated in the periphery during an immune response and act in an antigen-specific manner. Several subsets of iTreg cells have been defined and iTreg cells do not constitutively express Foxp3 or CD25 but can express high levels upon activation. Foxp3 appears to act as a cell lineage differentiation factor because it correlates closely with suppressor activity, irrespective of CD25 expression. iTreg cells are often the most potent source of IL-10 in downregulating inflammatory responses to infections or allergens.

EFFERENT B LYMPHOCYTE-MEDIATED IMMUNE RESPONSES IN THE LUNG

Immunoglobulins are a major protein constituent of the fluid that lines the luminal surface of conducting airways and alveolar lining fluid. Effector functions for antibodies include opsonization, complement fixation, antibody-dependent cellular cytotoxicity (ADCC), agglutination, and neutralization (Fig. 121-4). Approximately 20% of the total protein present in bronchoalveolar lavage fluid consists of IgG, IgM, and IgA. IgA is the predominant immunoglobulin in secretions of the trachea and major bronchi while both IgG and IgE are present as well. IgG is the predominant immunoglobulin in alveolar lining fluid.

Humans produce more IgA than any other Ig class. The secretory IgA found in external secretions consists of two molecules of IgA that are held together by a joining chain and by a secretory component, a glycoprotein produced by epithelial cells. The role of IgA in pulmonary defenses remains enigmatic. The usual specificity of IgA antibodies is antiviral. Specific IgA antibodies against hemagglutinating antigen have been isolated from patients infected with influenza A. IgA may also be important in inhibiting bacterial adherence to the respiratory epithelium and may also serve as an antitoxin. Finally, IgA may also have a role as an opsonin, since human alveolar macrophages bear Fc receptors that bind either IgA1 or IgA2. Certain bacteria elaborate proteases that digest IgA; these proteases may provide a selective colonization advantage to the microbes.

Specific antibody is an important component in lower respiratory tract defenses against extracellular microbes. Many extracellular bacteria possess polysaccharide capsules that allow them to evade phagocytic cells. Antibodies function as: (a) opsonins that allow phagocytes to recognize and ingest microbes via the involvement of Fc receptors; (b) activators of complement, which enhances opsonization and leads to direct lysis of some bacteria; and (c) as neutralizing antibodies that neutralize pathogens or their toxins by binding to microbes or their products, thereby preventing injury to cells. Immunoglobulins are clearly present in the epithelial lining fluid of the lower respiratory tract. Serum IgG can gain access to the alveolar space in normal subjects and during inflammation when large changes in alveolar permeability occur. Systemic immunization enhances pulmonary clearance of many bacteria in animal models and enhanced clearance correlates with the appearance of antibodies in serum and bronchoalveolar lavage fluid that are directed against the organisms. Thus, it seems likely that alveolar antibodies are derived in large part from serum and, accordingly, it seems likely that direct airway immunization would not be required to obtain protective antibodies in the lung.

CONCLUSION

Infections are the evolutionary force for the development of a complex system of pulmonary host defenses. A coordinated response of many different cells is required for the lung to clear pulmonary pathogens. An increasingly complex and potentially injurious cascade of host responses is mobilized following pulmonary microbial challenges (Table 121-1). Although the interactions of microbes in the host are invariably complex, models of pulmonary infection have provided crucial information regarding the regulation of inflammatory and immune responses. These insights should eventually allow the development of rational strategies regarding vaccination and immunotherapy. The use of animal models offers the possibility of understanding the mechanisms that regulate immune responses sufficiently well so that the response to a specific antigen could be controlled. A more complete understanding of host defense would allow the stimulation of deficient responses and the suppression of harmful responses to microbial pathogens and other antigens that enter the lung.

CHAPTER 122

Approach to the Patient with Pulmonary Infection

Jay A. Fishman

OVERVIEW

Pneumonia is a common cause of infection-related mortality and is one of the most important challenges in clinical medicine. Inappropriate or delayed treatment of pulmonary infection contributes to poor clinical outcomes, avoidable drug exposures, and emergence of antimicrobial resistance. Pneumonia is defined as inflammation of the pulmonary parenchyma caused by an infectious agent. The clinical syndrome of pneumonia may include fever or hypothermia, sweats, rigors, or chills, pulmonary symptoms, such as cough, sputum production, dyspnea, pleurisy, or pulmonary lesions observed on radiographic examination. Nonspecific symptoms are common, including loss of appetite, fatigue, and confusion. The diagnosis and management of pneumonia has been complicated by the recognition of newer pathogens, expanded antimicrobial resistance, increased populations of immunocompromised patients, and by newer diagnostic tools and antimicrobial agents.

Pneumonitis reflects inflammation due to both infection and noninfectious causes. A variety of eponyms have been applied to various forms of pneumonia that *may* reflect the epidemiology of the process and the likely causative organisms: aspiration pneumonia, community-acquired pneumonia (CAP), nosocomial pneumonia, immunocompromised host, and atypical pneumonia (Table 122-1). These descriptions, coupled with the radiologic appearance and patient-specific epidemiologic factors, are useful in considering empiric therapy while awaiting microbiologic data. These categories may be misleading, emphasizing the importance of obtaining a definitive microbiologic diagnosis in optimizing clinical care (Table 122-2).

TABLE 122-1 Categorization of Pneumonia by Clinical Setting

Community-acquired pneumonia
Typical (i.e., classic) pneumonia
Atypical pneumonia
Aspiration pneumonia
Pneumonia in the elderly
Community acquired
Nursing home residents
Nosocomial pneumonia
Hospital-acquired pneumonia (HAP)
Ventilator-associated pneumonia (VAP)
Healthcare-associated pneumonia (HCAP)
Pneumonia in immunocompromised hosts
Immunoglobulin and complement deficiencies
Granulocyte dysfunction or deficiency (cyclic neutropenia, chronic granulomatous disease, leukocyte adhesion defects, myeloperoxidase, or G6PD deficiency)
Innate immune defects (NK deficiency, defects of interleukin/interferon-gamma pathways, pattern recognition receptor pathway defects)
Cellular and combined immune deficiencies
Neoplastic disease (notably hematopoietic malignancy and therapies)
Solid-organ and hematopoietic transplant recipients
Untreated HIV infection
Immune reconstitution syndromes (IRIS)
SCID and congenital deficiencies
Autoimmune and connective tissue disorders
Other immunocompromised patients
Cystic fibrosis and anatomic disorders (bronchopulmonary sequestration, tracheomalacia, or bronchomalacia)

TABLE 122-2 Routine Evaluation of Patients with Suspected Pneumonia

History
Age
Community (respiratory viruses, antimicrobial resistance) vs. hospital (ventilator)
Pace of onset, dyspnea
Recent infections (postviral pneumonia, endocarditis, aspiration)
Recent hospitalization or exposure to medical facilities (extended care)
Underlying conditions (mental status, immunity, cardiopulmonary, medications)
Exposures (illness, children, institutions, animals, gardens, travel)
Antimicrobial therapies, home infusion therapy, vaccinations
Duration of hospitalization or endotracheal intubation
Physical Examination
Laboratory
Complete blood count with differential counts
Electrolytes, liver function tests, BUN, creatinine
Radiology
PA and lateral chest radiograph (depending on host and severity of illness)
Consider: Chest CT with contrast, echocardiogram, thoracentesis
Microbiology *(adapted to clinical setting and severity of illness)*
Sputum Gram stain, culture, and sensitivity (susceptibility testing)
Nasal swab (direct immunofluorescence) for respiratory virus panel (influenza, RSV, parainfluenza, adenovirus, metapneumovirus)
Blood cultures two
Consider in appropriate setting:
• Pneumococcal urinary antigen
• Legionella urinary antigen
• Histoplasma urinary antigen
• Acid-fast smear (modified acid-fast smear) and culture
• Acute and convalescent sera (Mycoplasma, Chlamydophila, Q-fever [Coxiella burnetti], Histoplasma, Coccidioides, Tularemia, Anthrax)
• HIV status
• Molecular assays (Cytomegalovirus, Epstein–Barr virus, Adenovirus)

Consideration of any unique exposures and potential immune deficits in each host will define the urgency of empiric antimicrobial therapies. Physical findings may also be unreliable—particularly as reliance on radiologic techniques has displaced physical examination as an art form. Dual processes are common (e.g., superinfection of viral illness). Physical findings are often muted in the immunocompromised host. "Crackles" or "rales" are "appreciated" more often than the actual incidence of pulmonary consolidation. Commonly, radiographic appearances are "confused" with etiologic diagnoses: consolidation, bronchopneumonia, miliary patterns, nodules, abscesses, fluid collections, pleural effusions, interstitial pneumonitis, and lymphadenopathy. The goal of the clinician is to distinguish infectious from noninfectious processes, such as heart failure, malignancy, or pulmonary embolism; to initiate appropriate antimicrobial therapy quickly; and to define the microbiology of infectious pulmonary processes to facilitate management and reduce unnecessary exposures to antimicrobial agents.

THE ROLE OF HOST DEFENSES

The presence of pneumonia should be taken as evidence of an immune defect relative to the epidemiologic pressure of the microorganisms (see Chapter 121). Organisms of high native virulence (adhesion, invasive enzymes, motility, intracellular pathogens) may cause infection with a small inoculum size in an immunologically normal host (see Chapter 123). Organisms of low virulence should cause infection only if there is an immune or anatomic predisposition to infection or a high organism burden.[1] Microorganisms may reach the lungs via the airways, bloodstream, or lymphatics. Defects in specific components of the immune system (innate and acquired) predispose to specific types of infection (Table 122-3).

An important first step in many infections is colonization of the upper airway via adhesion of organisms to epithelial surfaces. These surfaces are normally protected by mechanical clearance of organisms via the nose or oropharynx, local production of complement and IgA, saliva, sloughing of epithelial cells, and bacterial interference by "normal flora." Changes in these surfaces (diminished IgA secretion, changes in production of adhesins, fibronectin, altered lectin binding) predispose to adhesion of microorganisms. Organisms carrying enzymes that can degrade IgA exotoxins, adhesion proteins or pili—are favored in colonizing the respiratory epithelium. Mucociliary clearance may be disrupted by cigarette

TABLE 122-3 Infections Associated with Specific Immune Defects

Defect	Common Causes	Associated Infections
Granulocytopenia	Leukemia, cytotoxic chemotherapy, AIDS, drug toxicity, Felty syndrome	Enteric gram-negative, Pseudomonas, S. aureus, S. epidermidis, streptococci, Aspergillus, Candida, and other fungi
Neutrophil chemotaxis	Diabetes, alcoholism, uremia, Hodgkin disease, trauma (burns), lazy leukocyte syndrome, CT disease	S. aureus, Candida, streptococci
Neutrophil killing	CGD, myeloperoxidase deficiency	S. aureus, E. coli, Candida, Aspergillus, Torulopsis
T-cell defects	AIDS, congenital, lymphoma, sarcoidosis, viral infection, CT disease, organ transplants, steroids	Intracellular bacteria (Legionella Listeria, mycobacteria sp.), HSV, VZV, CMV, EBV, parasites (Strongyloides, Toxoplasma), fungi (P. jiroveci, Candida, Cryptococcus)
B-cell defects	Congenital/acquired agammaglobulinemia, burns, enteropathies, splenic dysfunction, myeloma, ALL	S. pneumoniae, H. influenzae, Salmonella and Campylobacter spp., Giardia lamblia
Splenectomy	Surgery, sickle-cell, cirrhosis	S. pneumoniae, H. influenzae, Salmonella spp, Capnocytophaga
Complement	Congenital/acquired defects	S. aureus, Neisseria spp. H. influenzae, S. pneumoniae
Anatomic	IV/Foley catheters, incisions, anastomotic leaks, mucosal ulceration, vascular insufficiency	Colonizing organisms, resistant nosocomial organisms

ALL, acute lymphocytic leukemia; CGD, chronic granulomatous disease; CT, connective tissue disease; IV, intravenous.

smoking, or prior infections with viruses, *Haemophilus influenzae*, or *Mycoplasma pneumoniae*.

Aspiration may result from altered glottic closure (neurologic injury, sleep apnea, airway intubation, alcohol, anesthesia). Once past the glottis, most bacteria and viruses are small enough (up to 2 μ) to reach the alveoli unless impeded by alveolar lining fluid containing surfactant, IgG, complement, and other proteins. Surfactant includes a variety of components that serve to activate alveolar macrophage and neutrophil functions and may serve as an opsonin (SP-A and SP-D) for many organism types. Organisms surviving the upper airway defenses are left to the cellular components of the lower airways including T- and B-lymphocytes, macrophages, and dendritic cells.

Pulmonary defense mechanisms are also disrupted by systemic infections (sepsis), hyperglycemia and diabetes, acidosis, hypoxemia, pulmonary edema, malnutrition, uremia, age, and lung injury (ARDS). Endotoxin and lipopolysaccharide diminish clearance of bacteria from the lungs. Viral infections may diminish neutrophil and macrophage functions including phagocytosis, chemotaxis, and oxidative metabolism.

GENERAL GUIDELINES IN EVALUATING PATIENTS WITH PNEUMONIA OR OTHER RESPIRATORY INFECTIONS

The individual with pulmonary infection often presents in an ambulatory setting. Evaluation of the patient with possible pneumonia depends on a series of questions that provide clues to management, including the need for hospitalization and selection of antimicrobial agents. Subsequently, microbiologic data provide the basis for adjusting antimicrobial therapy. These initial questions include:

1. **Is the process life-threatening?** What is the rate of progression of the process? Is it rapidly progressive or gradual? Is there time to delay therapy or diagnostic procedures?
2. **Does the patient have immune deficits?** Could the process be underestimated based on the absence of normal inflammatory responses (see Chapters 20 and 121)?
3. **What are the most common infections in the community or hospital or institution where this "infection" was acquired?** In this appraisal, it is helpful to resort to the clinical groupings: community-acquired, nosocomial (hospital, ventilator, healthcare facility), and pneumonia in the immunocompromised patient. Such groupings provide a guide to empiric therapy while evaluation is underway. It is important to understand the incidence of tuberculosis, AIDS, respiratory viral infections, and antimicrobial-resistant organisms (e.g., Pneumococcus or Staphylococcus) in the community and of antimicrobial resistance in the institution. Dual infections are common (e.g., viral plus bacterial) and initial therapy must include both common bacterial and "atypical" pathogens (i.e., Mycoplasma, Chlamydophila, and Legionella species).
4. **What are the gross radiologic features of the pulmonary process?** Frank pneumonia with or without sputum production, focal infiltrates, lung abscess, chronic cavitary lesion, bronchiectasis, miliary lesions? As a corollary, since pulmonary infections are occasionally generated by the hematogenous rather than the bronchogenic route, consider possible extrapulmonary processes in the pathogenesis of pulmonary infection.
5. **For ambulatory patients, does the patient need to be admitted to the hospital for management?**[2–5] Does the patient have social supports in the community? Can he/she manage oral medications, other therapies, and follow-up visits from home? Does the patient need supplemental oxygen, assisted ventilation, surgery, blood products, monitoring, or isolation?

Initial antimicrobial therapies should be considered to be therapeutic trials—given adequate time to demonstrate effectiveness and subject to revision if ineffective.

■ CLINICAL EVALUATION

The clinical history often suggests the etiology of pulmonary infection. A history of prior infections or underlying clinical conditions (COPD, immune deficits, altered mental status, prior infections) often provides the basis for empiric therapy.

Consider the *epidemiologic history* (i.e., travel, contacts, exposures, vaccines, medications, prior infections, or hospitalizations): Has the patient traveled or have any hobbies (gardening, hiking, cooking) that might provide an epidemiologic clue (see Table 122-4)?

What are the patient's *symptoms:* What is the pace of the evolution of respiratory symptoms and of other systemic signs? Prior mild respiratory illness ("the flu") with improvement and then rapid deterioration is suggestive of bacterial superinfection of viral pneumonitis consistent with *Staphylococcus aureus* or other bacterial infection, especially in the patient known to have respiratory colonization. Pneumococcal pneumonia may be associated with a single severe rigor with fever and often with symptomatic herpes labialis. The abrupt onset of illness with recurrent (over several days) shaking chills, particularly if associated with mild diarrhea for 1 or 2 days, might suggest Legionnaires' disease. Gastrointestinal symptoms and confusion may be seen with any infection, but are notable

TABLE 122-4 Epidemiologic Exposures Associated with Pneumonia

Pathogen	Epidemiology
Anthrax	Bioterrorism; animals, hides, raw wool, goat hair
Brucella sp.	Domestic animals, dairy products, abattoir, veterinarian
Chlamydophila psittaci	Birds: parrots, budgerigars, cockatoos, pigeons, turkeys
Coccidioidomycosis	Southwest USA, Southern California, San Joaquin Valley
Coxiella burnetii (Q-fever)	Goats, sheep, cattle, domestic animals (feces, amnionic fluid, placenta, milk)
Cryptococcus neoformans and grubii	Birds (pigeons), caves, bats
Cryptococcus gattii	Eucalyptus trees
Hantavirus	Rodent droppings/urine (virtually all states)
Histoplasmosis	Bird/bat droppings, endemic regions
Legionella	Contaminated aerosols, pooled water
Leptospirosis	Rodents, animals, water contaminated by animal urine
Melioidosis	West Indies, Australia, Southeast Asia, South Central America
Pasturella multocida	Dogs, cats
Plague *(Yersinia pestis)*	Bioterrorism, Squirrels, chipmunks, rabbits, prairie dogs, rats
Paracoccidioides	South America (Brazil)
Rhodococcus	Horses, soil, farms
Middle eastern respiratory syndrome (MERS): Coronavirus	Endemic regions (Saudi Arabia)

in pneumococcal and Legionnaires' infections. The differential is broader in immunocompromised hosts with pulmonary-brain (*Nocardia* species, moulds) or GI-brain *(Strongyloides)* syndromes.

Skin lesions (e.g., furuncles, endocarditis, or gram-negative sepsis), lymph nodes (symmetrical or regional), retinal examination, ear examination (bullous myringitis with *Mycoplasma* infection), periodontal disease or absent gag reflexes (with aspiration pneumonia), chest splinting, neurologic disease (pulmonary-brain syndromes) are often ignored but provide valuable clues. The elderly patient with pneumonia will often present with globally depressed mental status while the immunocompromised host may have focal neurologic deficits consistent with embolic or invasive disease. Dullness to percussion, bronchial breath sounds, egophony ("E to A changes") are suggestive of pulmonary consolidation but may be absent. Patients infected with *Pneumocystis jiroveci*, *Mycoplasma*, or viruses (or severe immune compromise) may have a normal chest examination despite abnormal chest radiographs and marked hypoxemia.

Many systemic processes are reflected in abnormalities of blood counts, urinalysis, and routine blood chemistries. Most patients with bacterial pneumonia will have elevated white blood cell counts and increased neutrophils on differential. Viral pneumonia may depress the white cell count. Mixed pictures are common. Mild liver function abnormalities might suggest Q-fever, tularemia, miliary tuberculosis, or Legionnaires' disease, but are commonly seen with systemic infection. The presence of pigmented casts in the urine and markedly elevated serum levels of creatine phosphokinase might focus attention on the possibilities of influenza virus pneumonia, Legionnaires' disease, or a pulmonary infiltrate associated with intravenous drug abuse. Rapid screening tests (e.g., for respiratory viruses) are useful, but have limitations in terms of sensitivity.

Clinical measures detect pneumonia in about 79% of cases. Newer assays have been introduced, including measurements of serum procalcitonin (PCT) and C-reactive protein (hsCRP) levels.[6] In prospective trials, PCT appears to be sensitive both to the presence and severity of pneumonia and to concomitant bacteremia associated with pneumonia.[7] These assays may augment clinical judgment, but are not universally available.

Radiographs allow the practitioner to assess the severity of pneumonia and to distinguish this process form acute bronchitis, which, when infectious, is often viral in etiology (see Chapter 30). No radiographic findings are specific enough to define the microbial origin of a given pneumonia or pulmonary infiltrate. The only definitive way to obtain a specific etiologic diagnosis is through demonstration of the infecting organism—that is, by examination of stained smears of sputum and pleural fluid or other biologic materials, by culture of respiratory secretions and blood, or by demonstration of nucleic acids or proteins from an infecting microorganism, or by demonstrating an increase in antibody titer against the infecting microorganism. Nonetheless, the radiographic picture, taken along with other clinical information, may suggest one or several etiologic agents (see below). Multilobar involvement and the presence of pulmonary effusions are poor prognostic features.

In practice, initial therapy is empiric and based primarily on available clinical clues. The selection of drug(s) for empiric therapy depends on the clinical setting and on the gravity of the pulmonary process. The selection of specific antimicrobial agents is considered in detail in subsequent chapters.

In addition to the decision regarding empiric antibiotics, a key decision in management is whether the patient with suspected pneumonia merits hospitalization (see Chapter 128). In practice, this is often a function of a judgment as to whether appropriate therapy is available in the community with social supports adequate to caring for the patient's needs (medications, food, comfort) and to bring the patient back for further care if indicated. Multiple semiquantitative methods have been developed to assist in this process.[8]

The Pneumonia Severity Index (PSI) developed by Fine et al. stratifies patients according to 20 variables and has greater discriminatory power for mortality than the less complex CURB indices.[9,10] The "confusion of new onset, urea greater than 7 mmol/L (19 mg/dL), respiratory rate of 30 breaths per minute or greater, and blood pressure less than 90 mm Hg systolic or diastolic blood pressure 60 mm Hg or less with age 65 or older (CURB 65) rely on fewer variables to identify patients at high risk of mortality.[10] With one point per variable, risk of death at 30 days increases as the score increases (four points predicts 41.5% hospital mortality).[8] Hospital admission is generally advised for those with CURB 65 of two to three points, and ICU admission considered for four to five points.

The Infectious Disease Society of America/American Thoracic Society (IDSA/ATS) Guidelines for Severe Pneumonia and Intensive Care Unit Admission identify the sickest patients, who may ultimately require ventilatory support. The Guidelines can be found online at http://pda.ahrq.gov/clinic/psi/psi.htm and www.mdcalc.com/psi-port-score-pneumonia-severity-index-adult-cap.

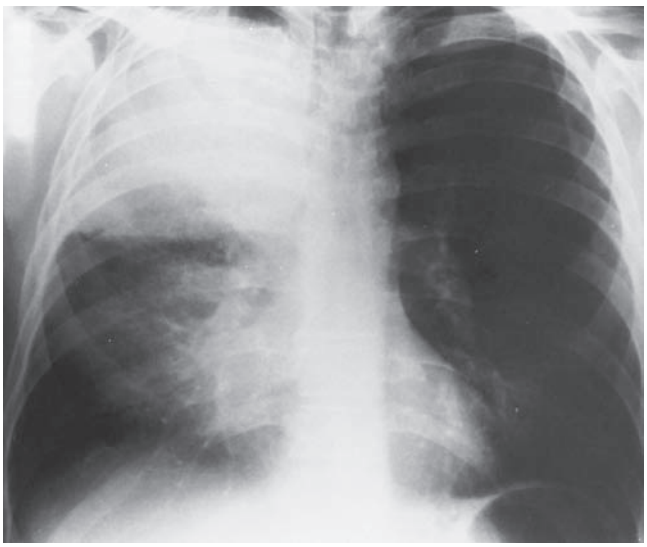
RADIOGRAPHIC FEATURES OF PNEUMONIA

No radiologic pattern provides a specific etiologic diagnosis (see also Chapter 30). However, the radiographic pattern, combined with clinical and epidemiologic information, may allow narrowing of the diagnostic considerations while microbiologic data are assembled. Several radiographic patterns may be helpful in categorizing infectious and noninfectious causes: (1) airspace or alveolar pneumonia, (2) broncho- or lobular pneumonia (Fig. 122-1), (3) interstitial pneumonia, and (4) nodular infiltrates. The chest radiographs of a particular patient may not fit neatly into one or another of these categories. Multiple patterns may suggest different etiologies or progression of a disease process. These patterns are generally best defined by CT scanning, which may also detect patterns within a pulmonary process, including lung necrosis; bronchial obstruction (e.g., due to hilar lymphadenopathy or endobronchial tumor); underlying parenchymal disease accounting for pleural effusion, empyema, or loculated fluid collections; bronchiectasis; or fungus balls within cavitary lesions. Subtle changes, including interstitial patterns or infections in immunocompromised hosts (e.g., *P. jiroveci*), are often better assessed using CT scanning. CT scanning can also assist in determining the best invasive diagnostic approach (needle, BAL, open biopsy) for diagnostic procedures.

PERIPHERAL AIRSPACE CONSOLIDATION: ALVEOLAR AND LOBAR PNEUMONIA

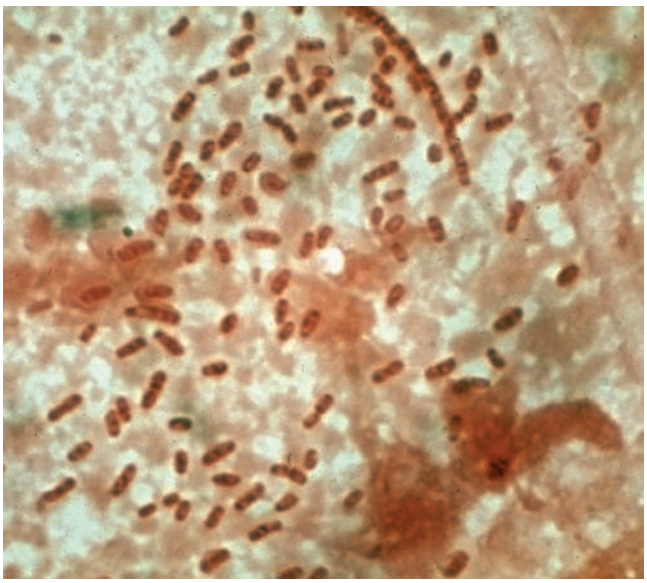
This form of infiltrate occurs when certain organisms, notably *Streptococcus pneumoniae*, induce inflammatory edema in peripheral alveoli. When the extent of the consolidation involves an entire lobe, this is the classic *lobar pneumonia*. Often the process is not that extensive, although the pathogenesis is the same. An air bronchogram is characteristic. Loss of volume is absent or minimal during the acute stage of consolidation, but some atelectasis may develop due to obstruction of bronchi by exudate.

Klebsiella pneumoniae is another common cause of CAP, which, like pneumococcal pneumonia, shows homogeneous parenchymal consolidation containing air bronchograms. Although *K. pneumoniae* pneumonia classically affects the right upper lobe and



A

B



C

Figure 122-1 **A.** Dense lobar consolidation involving right upper lobe and right middle lobe in an alcoholic patient with *Klebsiella pneumoniae* pneumonia. The minor fissure is bulging downward. **B.** Same patient 7 days later. Despite antibiotic therapy, *K. pneumoniae* pneumonia progressed to become a necrotic process with formation of multiple abscesses. **C.** Sputum Gram stain from patient with K. pneumoniae infection reveals gram-negative rod forms with trace of a surrounding capsule. *(Used with permission of Dr. R. Greene.)*

produces a dense, homogeneous lobar consolidation with bulging of the fissure, these features are not pathognomonic and cannot be relied on for diagnosis without supportive bacteriologic data (Fig. 122-1). The propensity for *K. pneumoniae* to produce tissue destruction and abscess formation may result in a shrunken, rather than an expanded, lobe. Pneumococcal pneumonia may also cause bulging of the fissure, albeit less commonly and less prominently. Extensive alveolar consolidation may occur with a variety of other bacterial causes of pneumonia, including mixed anaerobes of aspiration pneumonia and a variety of gram-negative bacilli implicated in nosocomial pneumonias. Occasionally, an unusual configuration of airspace consolidation, *spherical pneumonia*, occurs, particularly in children, with pneumococcal or *H. influenzae* pneumonia. It has also been reported with Q-fever (*Coxiella burnetti*).

In the immunocompromised host, alveolar consolidation on the plain chest radiograph may be delayed and appreciated only by chest CT scan. Among infectious etiologies, common pathogens, such as *S. pneumoniae,* cause infection in this group of patients and are often of greater severity than in the normal host, often despite less radiologic evidence for infection. Bacterial superinfection of viral processes (e.g., influenza, cytomegalovirus [CMV]) is also common. However, if the consolidation is lobar or multilobar, *Legionella pneumophila* and *M. pneumoniae* are common. Other, less likely, infectious agents are fungi (e.g., *Aspergillus*), *Nocardia*, and *Mycobacterium tuberculosis*. Less often, viruses alone (e.g., CMV) elicit a predominantly alveolar pattern. Bilateral diffuse involvement with an airspace pattern resembling pulmonary edema is uncommonly seen in *P. jiroveci* pneumonia, but may also reflect noninfectious etiologies.

CENTRILOBULAR AND PERIBRONCHIOLAR OPACITIES: BRONCHOPNEUMONIA

In bronchopneumonia, the focus of infection and the inflammatory response is in the walls of the bronchi and surrounding peribronchiolar alveoli, producing a segmental, patchy multifocal distribution. Segmental involvement may become confluent to produce a more homogeneous pattern. Bronchopneumonic patterns are commonly observed in pulmonary infections due to *S. aureus* or nonencapsulated *H. influenzae*. With *S. aureus* infections, macro- and microabscess formation may occur rapidly. Also, pneumatoceles occur during the first week of lung impairment in about half the children with *S. aureus* pneumonia. These cystic spaces are believed to be the consequence of a check valve opening between a peribronchial abscess and an adjacent bronchus.

A bronchopneumonic pattern of consolidation is commonly observed when CAP follows viral infection or pneumonia is engrafted on underlying bronchiectasis or chronic bronchitis. In such predisposing circumstances, *S. pneumoniae* infection may produce a bronchopneumonic pattern rather than a lobar consolidation (Fig. 122-2). In the presence of underlying emphysema, the radiographic pattern of pneumococcal pneumonia may also be altered from its usual homogeneous pattern to one that contains multiple radiolucencies (representing unconsolidated emphysematous areas) that may be misinterpreted for abscesses.

Segmental bronchopneumonia is the radiographic picture in pneumonia due to *Chlamydophila pneumoniae* (Taiwan acute respiratory agent or TWAR), *M. pneumoniae,* and in many viral pneumonias. Any of the bacterial species that cause nosocomial pneumonia may produce a radiographic pattern of bronchopneumonic consolidation.

C

Figure 122-2 **A.** Gram-stained smear of sputum from patient with pneumococcal lobar pneumonia ×1000. In this field there are numerous gram-positive lancet-shaped diplococci and polymorphonuclear leukocytes. **B.** Gram-stained smear of sputum from patient with bronchopneumonia superimposed on chronic bronchitis. This field (×1000) is teeming with gram-negative coccobacilli. Many polymorphonuclear leukocytes are present. *H. influenzae* was isolated from sputum as predominant organism. **C.** Gram-stained smear of sputum from patient with lobar pneumonia due to *K. pneumoniae*. In this field (×1000) there are moderate numbers of polymorphonuclear leukocytes and large, thick gram-negative bacilli. *(Used with permission of H. Provine.)*

Noninfectious etiologies of bronchopneumonia include aspiration of gastric contents, bronchioloalveolar cell carcinoma, granulomatous disease in pneumoconiosis, sarcoidosis, hypersensitivity pneumonitis, bronchiolitis obliterans organizing pneumonia (BOOP), autoimmune diseases, and bronchiolitis obliterans.

■ INTERSTITIAL PNEUMONIA (PERIBRONCHOVASCULAR INFILTRATE)

A reticular or reticulonodular pattern of infiltration is the radiographic representation of interstitial inflammation—that is, a peribronchovascular infiltrate. In otherwise healthy persons, *M. pneumoniae* is high on the list of community-acquired causes of a radiographic pattern of interstitial pneumonia. In some instances, interstitial infiltration progresses to produce patchy consolidation of airspaces, most often in the lower lobes. Pneumonias due to respiratory viruses sometimes have an interstitial pattern that progresses to patchy segmental consolidation or to diffuse airspace disease that resembles pulmonary edema. A variety of noninfectious causes of interstitial lung disease (e.g., hypersensitivity lung disease, collagen vascular disease, and sarcoidosis) may also produce a reticular pattern on the chest radiograph (Fig. 122-3).

D

Figure 122-3 Wegener granulomatosis. **A.** Onset with chills and fever in a previously healthy 64-year-old man. Lung biopsy was interpreted as Wegener granulomatosis. Partial clearing in response to combined chemotherapy (cyclophosphamide and prednisone). **B.** Onset with malaise, headaches, and fever in a previously healthy 62-year-old woman. Bilateral maxillary sinusitis. Widespread nodular pulmonary infiltrates are most marked on the right. **C.** Same patient as **B** after 3 years of intermittent combined chemotherapy. Bilateral large masses. **D.** Same patient as **C**, 2 months later. Necrosis within mass in left upper lobe has produced a fluid level.

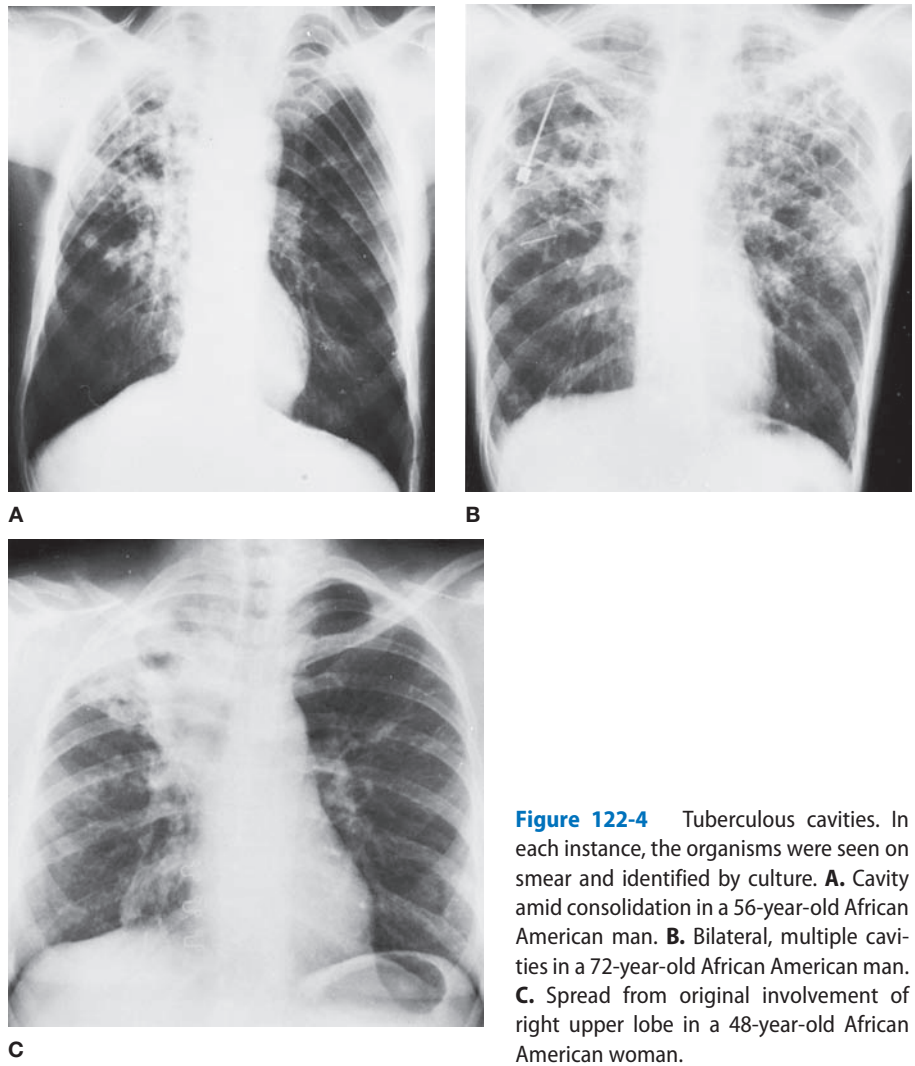

Figure 122-4 Tuberculous cavities. In each instance, the organisms were seen on smear and identified by culture. **A.** Cavity amid consolidation in a 56-year-old African American man. **B.** Bilateral, multiple cavities in a 72-year-old African American man. **C.** Spread from original involvement of right upper lobe in a 48-year-old African American woman.

In immunocompromised patients, particularly in those with AIDS in the absence of effective antiviral therapy, the infectious causes of interstitial pneumonia are broadened to include *P. jiroveci* pneumonia and opportunistic viral agents (e.g., CMV, varicella-zoster, herpes simplex). Noninfectious causes of a reticular pattern on chest radiography in an immunocompromised host include drug-induced (e.g., bleomycin, methotrexate, or sirolimus) pneumonitis, early radiation pneumonitis, and pulmonary edema.

NODULAR INFILTRATES: ROUND PNEUMONIA

Nodular infiltrates are considered here as well-defined large (greater than 1 cm on the chest radiograph) round focal lesions. Such a lesion may represent small aspirational abscesses (without air–fluid levels), a fungal or tuberculous granuloma, or a lesion of pulmonary nocardiosis. Multiple nodular infiltrates may also represent the necrotic lesions that develop in the lung secondary to the septic vasculitis produced by staphylococcal or pseudomonal bacteremia or the consequences of fungemic spread of candidal infection from an infected intravascular catheter. Infected nodular pulmonary lesions are sometimes caused by septic pulmonary infarcts produced by infected emboli that originate from right-sided bacterial endocarditis, septic thrombophlebitis of pelvic veins, or septic jugular vein phlebitis. On rare occasions, similar nodular lesions are produced by necrotic (but not infected) pulmonary infarctions; primary or metastatic neoplastic lesions may have a similar appearance. Nodular lesions that undergo rapid necrosis with cavity formation can be a feature of granulomatosis with polyangiitis (formerly known as Wegener granulomatosis) (Fig. 122-4).

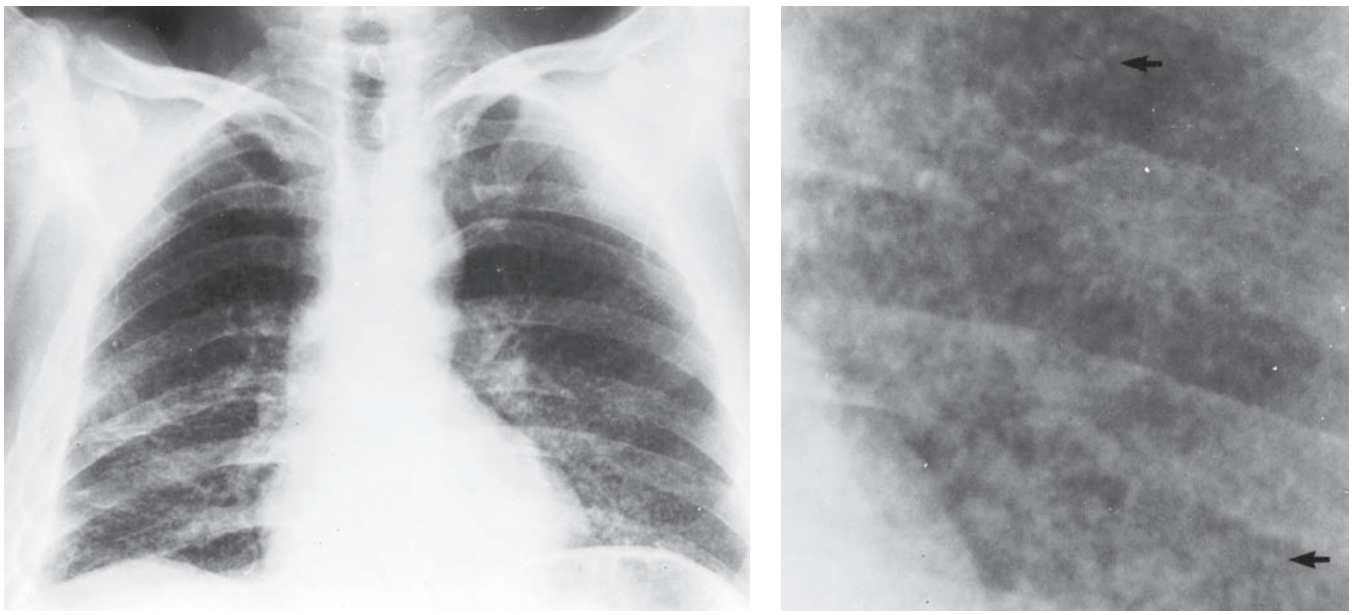
In the immunocompromised patient, nodular infiltrates may be due to bacteremic or fungemic spread of infection, most often as a result of nosocomial infection caused by an infected intravenous catheter. In this type of patient, nodular lesions should bring to mind the possibilities of pulmonary nocardial infection, aspergillosis, or other fungal infections. Tuberculous granulomas in the lungs may develop or enlarge in the immunosuppressed patient. Metastatic neoplasm or lymphoma sometimes presents a similar radiologic picture. Multiple small nodules, larger than miliary lesions but smaller than the gross nodular lesions described above, raise the possibility of varicella-zoster or CMV infection of the lung.

MILIARY AND MICRONODULAR PULMONARY DISEASE

Disseminated miliary lesions of infectious nature suggest tuberculosis, nontuberculous mycobacteria, and endemic fungi (histoplasmosis, or blastomycosis) in either the normal or immunosuppressed host. In the immunosuppressed patient, a miliary pattern may also be seen in disseminated cryptococcal infection or bacteremic spread of bacterial or candidal infection (Figs. 122-5 and 122-6).

APPLICATION OF RADIOGRAPHIC TECHNIQUES TO THE CLINICAL DIAGNOSIS OF PNEUMONIA

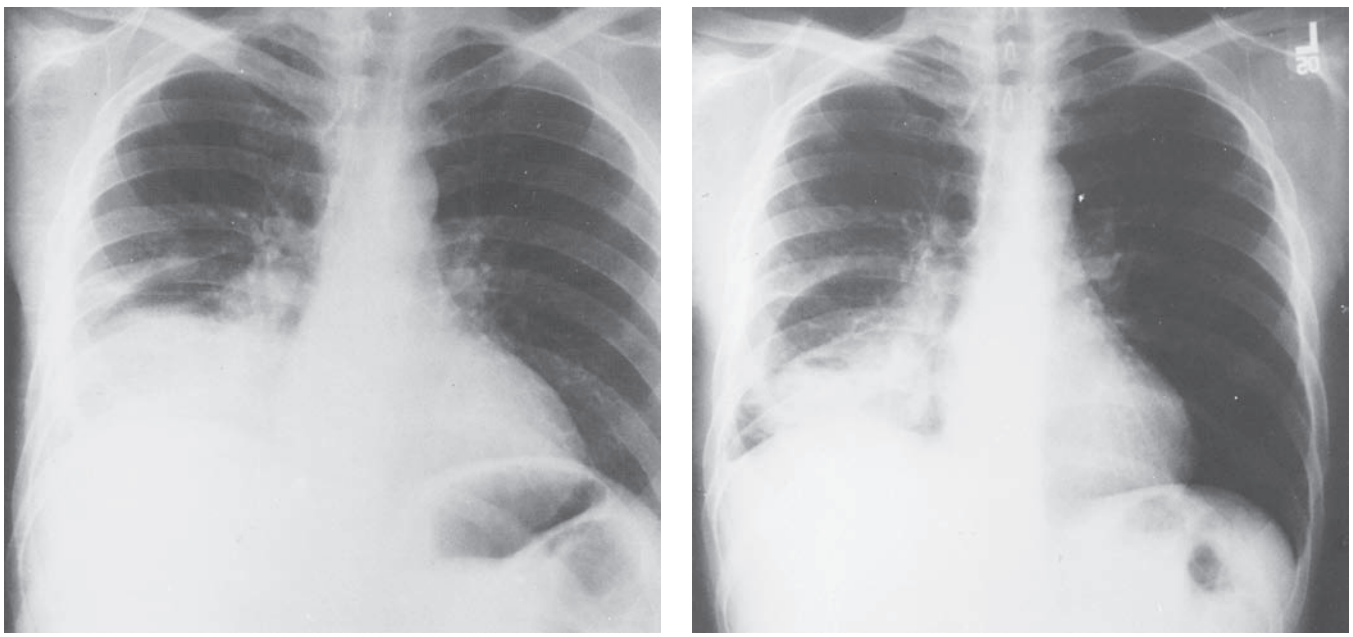
A consistent approach to the incorporation of radiographic imaging in evaluating a patient with suspected pneumonia is helpful.



A B

Figure 122-5 Miliary tuberculosis in a 45-year-old immigrant from Portugal with old calcified tuberculous empyema on the right. **A.** Fine nodularity present in both lungs. **B.** *Arrows* point to individual miliary lesions, which are more readily visible with added magnification. *(Used with permission of Dr. R. Greene.)*

One such approach incorporates the following four steps: (1) *Define the radiographic pattern* as lobar (Fig. 122-1) or segmental consolidation, patchy bronchopneumonia, nodules (large, small, or military) (Fig. 122-5), or an interstitial process (Table 122-5). Many large round pulmonary densities in a renal transplant recipient suggest *Nocardia* infection, rather than *Pneumocystis* pneumonia, whereas in a heroin addict with cough, fever, and pleuritic chest pain, such densities suggest acute right-sided endocarditis rather than pneumococcal pneumonia. (2) *Compare the radiograph with prior studies:* Is the process old or new? Are there multiple processes? Has the patient had surgery in the intervening period? Is the spleen enlarged or absent? (3) Consider *confounding*



A B

Figure 122-6 Necrotizing pneumonia, probably secondary to aspiration in a 39-year-old man, smoker and drinker, previously healthy. Onset with cough, shortness of breath, fever, and right-sided pleuritic pain. Despite antibiotics, signs and symptoms progressed to include high fevers, night sweats, greenish sputum, leukocytosis, and manifestations of hypertrophic osteoarthropathy. **A.** On admission, there was consolidation of right lower lobe, a right hilar mass (or adenopathy), and right pleural effusion. Mediastinoscopy and bronchoscopy revealed no tumor. **B.** Three months later, the process in the right lower lobe is more circumscribed. Right lower lobectomy revealed extensive necrotizing pneumonia, multiple abscesses, and "reactive" lymph nodes. Postoperatively, the patient was free of signs and symptoms, including hypertrophic osteoarthropathy.

TABLE 122-5 Radiographic Features and Differential Diagnosis of Pneumonia in the Immunocompetent Host

Consolidation/focal opacity	*Streptococcus pneumoniae*, *Mycoplasma pneumoniae*, *Haemophilus influenzae*, *Chlamydophila pneumoniae*, Legionella species, *Staphylococcus aureus*, *Mycobacterium tuberculosis* and "atypical" Mycobacteria (*M. avium* complex)
Cavitation	*S. aureus, anaerobic bacteria, M. tuberculosis, gram-negative aerobic bacteria, Aspergillus species, geographic/endemic fungi (Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis)*
Interstitial infiltrates	*Viruses, M. pneumoniae, M. tuberculosis, geographic/endemic fungi, Chlamydophila psittaci, drug*
Miliary	*Mycobacterium tuberculosis, geographic/endemic fungi, viruses, M. pneumoniae*
Lymphadenopathy	*M. tuberculosis, Viral (EBV, CMV, rubella), geographic/endemic fungi, Chlamydophila psittaci, cat-scratch*

variables: Is it too early in the process to detect radiologic changes (first 18–24 hours)? Is the patient neutropenic (early viral or fungal pneumonitis) or otherwise immunocompromised (*P. jiroveci* pneumonia with minimal or no findings on plain chest radiographs)? Dehydration is commonly cited as a cause of false-negative chest radiographs—but, in general, this concept is probably over-rated. (4) Consider *CT scanning:* CT scanning is sensitive to changes unrecognized in plain radiographs and may be useful in guiding invasive procedures.

EXAMINATION OF CLINICAL SPECIMENS AND ESTABLISHMENT OF A MICROBIOLOGIC DIAGNOSIS

The traditional approach to pneumonia places great emphasis on establishing a specific microbiologic diagnosis for pneumonia. An appropriately stained smear of sputum or pleural fluid, bronchoalveolar lavage (BAL) fluids, blood buffy coat, skin lesions, or throat swabs *may* provide a provisional diagnosis and allow deployment of more targeted antimicrobial therapy. This is discussed in detail below. Examination of sputum samples should not delay treatment.

Guidelines of the IDSA/ATS require administration of antimicrobials within 6 hours of presentation, notably for elderly, critically ill, and immunocompromised individuals.[11] However, in practice, the yield of most microbiologic evaluations is poor and the outcomes of therapy for pneumonia not requiring hospitalization quite good.[12]

Bartlett has observed that sequential clinical series appear to demonstrate a gradual reduction in the frequency with which the Pneumococcus is identified as the etiologic agent of CAP. The prevalence of *S. pneumoniae* in clinical studies from North America (20%–60%) and Great Britain (60%–75%) and in 4416 patients by Bullowa et al. in 1937 (81%) have gradually dropped to 5% to 12% in more recent studies. In more recent studies, the Pneumococcus has been replaced by viruses, aspiration, and a broad array of bacteria. This observation likely reflects the identification of organisms not identified in early studies by advanced techniques, a reduction in the detection of the Pneumococcus due to successful empiric therapy, shifts in "community flora" by antimicrobial therapies, as well as reduced efforts to obtain a microbiologic diagnosis.

In practice, most patients with pneumonia are treated empirically. In the United States, the performance and interpretation of Gram stain analyses is restricted to licensed laboratory technicians (CLIA88), which makes more difficult the rapid analysis of clinical specimens. The availability of rapid culture–independent microbiologic assays for viral respiratory infections and for some common pathogens (e.g., antigen detection for pneumococcal or *Legionella* infections, rapid viral screens) has, to some extent, reduced the need for other modalities of diagnosis.[13] Further, the availability of an etiologic diagnosis in CAP may not reduce mortality or the length of hospitalization in normal hosts, likely a reflection of improved antimicrobial therapies.[14,15] Thus, for community-acquired infection, etiologic diagnosis is often reserved for the sickest patients requiring hospitalization.

Multiple factors may mitigate an effort to obtain an etiologic diagnosis for pneumonia: increasing antimicrobial resistance in the community and in hospitals with the availability of in vitro susceptibility testing; a growing population of immunocompromised hosts in whom appropriate therapy is essential; for the adjustment of therapy when initial therapy fails; to establish the epidemiology of infection (public health); and to support antimicrobial stewardship programs.

SPECIMEN QUALITY

A microorganism isolated from deep coughed sputum cultures obtained before the initiation of antimicrobial therapy is considered relevant if detected in respiratory specimens, blood, or both, excluding normal skin or mucosal flora and the specimen is of good quality, that is, >25 leukocytes and <10 epithelial cells per high-power field. Specimens should be plated for cultures within 2 hours or stored at 4°C until plated. In practice, many patients with pneumonia (~30%) cannot produce good sputum samples, many have had prior therapies that alter the success of microbial cultures (15%–30%), and 40% to 60% of cultures are negative.[16–19] A specific etiology can be established in less than 50% of cases using routine studies (sputum and serologies). Sputum induction using inhaled nonbacteriostatic saline mist and chest percussion may increase the yield for Pneumocystis, mycobacteria, and malignancy on cytologic examination.

MICROBIOLOGIC TESTING

Noninvasive studies may provide information indicating the specific microbial cause of a pulmonary infection or may narrow the field of likely etiologic agents.

The Gram Stain and Point-of-Care Testing

Gram-stained smears provide information not only regarding the morphology and the tinctorial properties of bacteria (and some fungi) but also about the presence of polymorphonuclear leukocytes and squamous epithelial cells, the latter indicating that the specimen originated in the upper, rather than the lower, respiratory tract (Fig. 122-7). Other special staining methods provide additional data including Kinyoun and modified acid-fast stains for mycobacteria, *Actinomyces*, or *Nocardia* species, Wright–Giemsa or a variant such as Diff-Quik or direct fluorescent antibody staining of induced sputum samples for *P. jiroveci* or *Legionella species* may provide a diagnosis. Calcoflour white and silver stains are available to stain filamentous moulds.

Culture of sputum or blood or other bodily fluids may provide a specific etiologic diagnosis when evaluation of a sputum smear

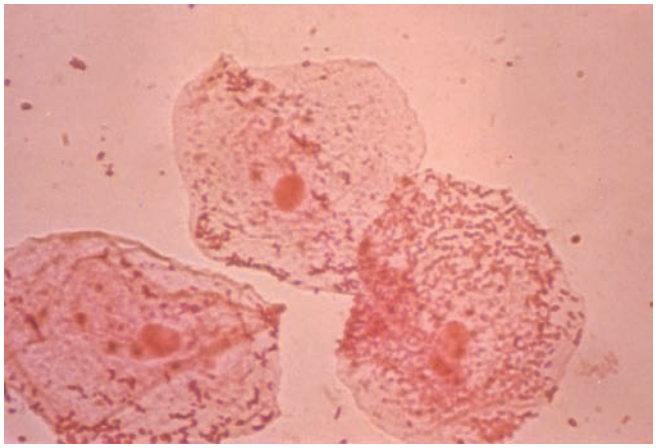


Figure 122-7 Three large oropharyngeal epithelial cells from a specimen of "sputum" that is inadequate for Gram stain analysis and culture because of its origin in the upper respiratory tract. Note the large number of organisms agglutinated on the surface of the squamous epithelial cells (×400).

have not supplied a provisional diagnosis, either because the infecting agent cannot be distinguished from components of the normal upper respiratory tract flora incorporated in the specimen or because the particular microorganism is not visible on Gram-stained smear (e.g., *Aspergillus, Mycobacterium, Mycoplasma,* or *Legionella* species).

Cytologic Examination

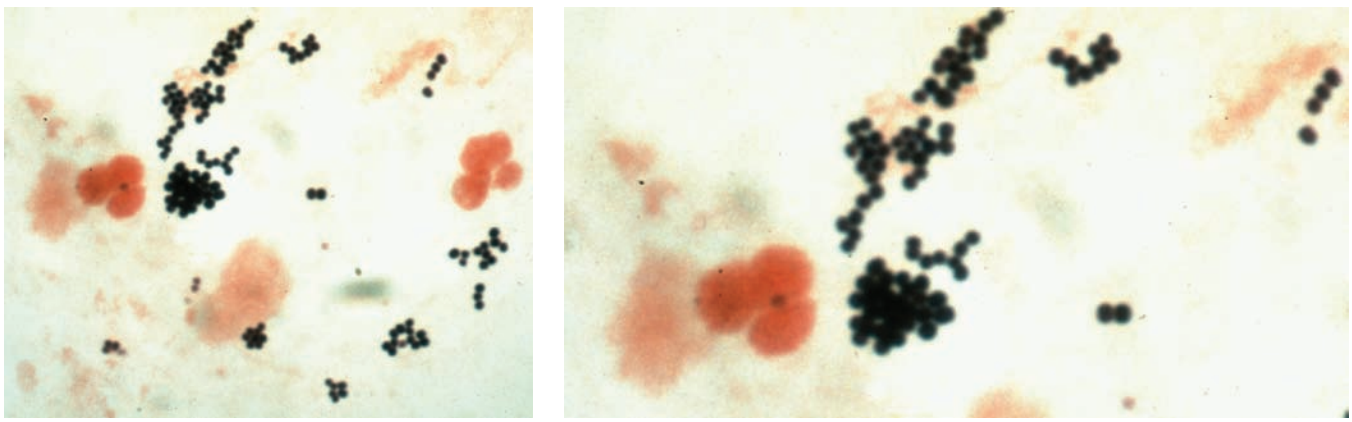
Examination of Gram-stained sputum smears can be of major value in pinpointing a bacterial cause of pneumonia and guiding initial and subsequent therapy. In practice, therapy is generally initiated prior to the availability of sputum examination. The quality of samples of expectorated or induced sputum for culture and interpretation stained smears can be determined by cytologic examination. Ten or more squamous epithelial cells (normally exfoliated from the oropharynx) per low-power (×100) magnification field indicate that the specimen is unsatisfactory; culture of such a specimen correlates poorly with results from culture of a transtracheal aspirate (Fig. 122-7). The presence of numerous polymorphonuclear neutrophils on Gram-stained smear (10–25 or more per low-power microscopic field) in the absence of an excessive number of squamous cells (see above) is indicative of a good specimen for bacteriologic evaluation.

Examination of Gram-Stained Smears for Bacteria

The oil immersion fields examined, and the immediately adjacent fields should not contain any squamous cells; each should also contain at least three or four neutrophils (in nonneutropenic hosts). The presence of squamous cells not only indicates that the specimen is derived from the upper respiratory tract but also may be confusing to the uninitiated because of the large number of bacteria, often gram-positive diplococci, which might be mistaken for *S. pneumoniae*, adherent to the surface of these cells.

Multiple bacterial respiratory tract pathogens have characteristic morphologies and strongly suggest an etiologic role when present in a suitable respiratory specimen containing inflammatory cells (in the absence of neutropenia). However, many common organisms are not visualized on stained smears. Such organisms include *S. pneumoniae* (gram-positive oval or lancet-shaped diplococci), *H. influenzae* (small, pleomorphic gram-negative bacilli), *M. catarrhalis* (gram-negative, biscuit-shaped diplococci), or the similar-appearing *Neisseria meningitis*, enteric gram-negative bacilli (not distinguishable from one another with respect to species except for large encapsulated rods that are suggestive of *Klebsiella*), and *S. aureus* (large gram-positive cocci in small groups or clusters) (Fig. 122-8). Since normal oral flora includes a variety of streptococcal species that are morphologically somewhat similar to *S. pneumoniae*, sputum smears may be misinterpreted. Thus, a predominance of gram-positive diplococci in multiple appropriate oil immersion fields needs to be observed to implicate *S. pneumoniae* (Fig. 122-9).[19] A quantitative aspect to the evaluation has been suggested: at least 10 gram-positive lancet-shaped diplococci per oil immersion field predicts the isolation of *S. pneumoniae* from sputum cultures with specificity of 85% and sensitivity of 62%.

Gram-stained smears may be helpful not only in the etiologic diagnosis of community-acquired bacterial pneumonia due to the usual respiratory pathogens, but also in supporting a diagnosis of atypical pneumonia when sputum examinations repeatedly show neither neutrophils nor bacteria. Uncommon bacterial species may be implicated in a pulmonary infection on the basis of unusual morphology on Gram-stained smear: irregularly staining, beaded, delicate gram-positive branching filaments suggest either *Nocardia*



A B

Figure 122-8 **A.** Left upper lobe pneumonia in a 17-year-old girl due to *S. aureus* that has progressed to formation of a huge lung abscess. Note air–fluid level. *(Used with permission of Dr. R. Greene.)* **B.** *S. aureus* on Gram-stained smear from a drug addict with right-sided bacterial endocarditis. In this field (×1000) there are polymorphonuclear leukocytes and clusters of gram-positive cocci. *(Used with permission of H. Provine.)*

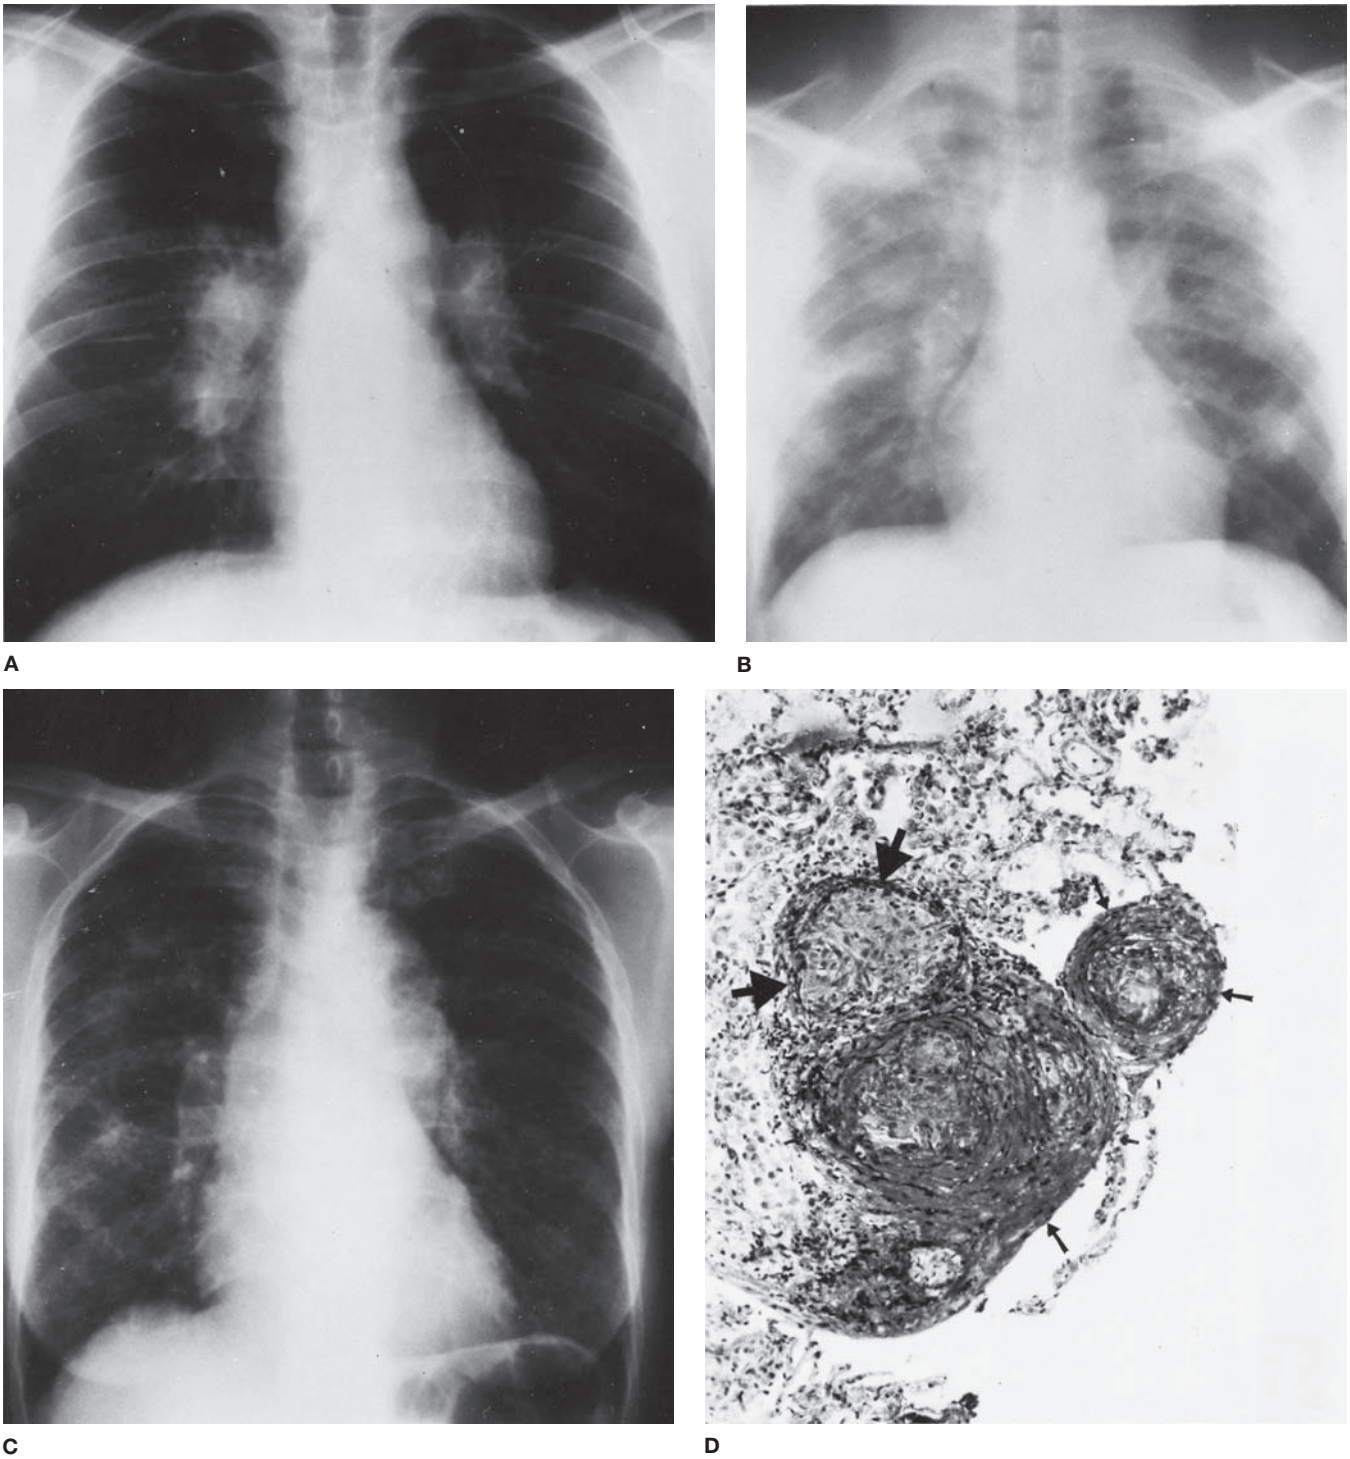


Figure 122-9 **A–C.** Chest radiographs illustrating the various stages of sarcoidosis. **A.** Stage I, bilateral hilar adenopathy. **B.** Stage II, bilateral hilar adenopathy with parenchymal infiltrates. **C.** Stage III, parenchymal infiltrates without hilar adenopathy. **D.** Transbronchial lung biopsy from a patient with sarcoidosis. *Small arrows* indicate granuloma with a surrounding rim of collagen (confirmed by positive trichrome staining). The *large arrows* indicate a granuloma without a surrounding rim of collagen. Original magnification ×10.

or *Actinomyces* (Fig. 122-10). Several organisms, uncommon causes of pulmonary infection, have morphologic characteristics that may mimic other, more common respiratory pathogens. *Pasteurella multocida* and *Acinetobacter* species, both small gram-negative coccobacilli, have each been mistaken in sputum of patients with pulmonary infections for either *H. influenzae* or *M. catarrhalis*.

Sputum or pleural fluid with foul odor provides evidence of activity of anaerobic organisms in infective processes such as lung abscess, aspiration pneumonia, empyema, and, occasionally, bronchiectasis. In these settings, the findings on Gram-stained smear may corroborate the preliminary diagnosis. Organisms of the *P. melaninogenicus–P. asaccharolyticus* group are small gram-negative coccobacilli. *Fusobacterium nucleatum* is a long, tapering, pale-staining gram-negative bacillus with irregularly staining gram-positive internal granules. Purulent secretions or pus from such anaerobic infections contains numerous neutrophils and usually a

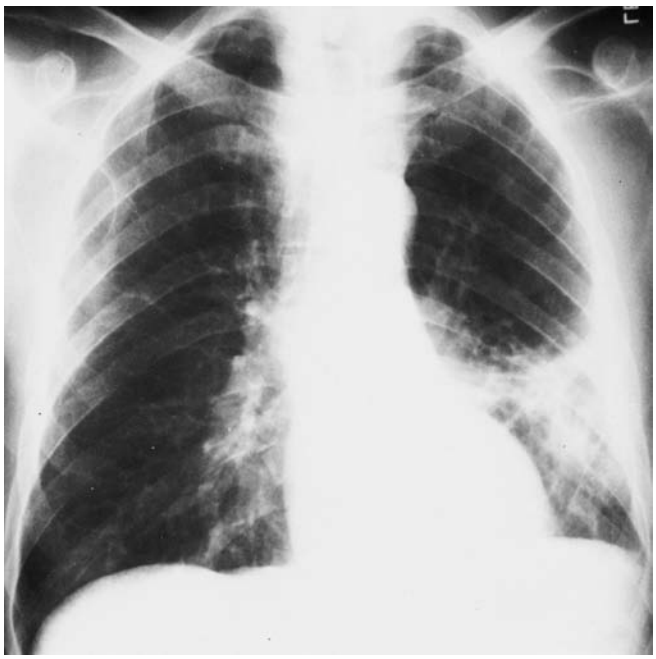

Figure 122-10 Actinomycosis in a 54-year-old chronic alcoholic man with pyorrheic gums who was admitted with signs of brain tumor. Chest radiograph shows mass in left lower lobe. Computed tomography is consistent with brain metastasis. Transthoracic needle aspirate revealed *Actinomyces israelii*.

mixture of bacterial species, including anaerobic and microaerophilic streptococci on stained smear.

Examination of Ziehl–Neelsen or Fluorochrome-Stained Smears for Mycobacteria

The number of new cases of tuberculosis in the United States steadily declined over past decades, reaching a nadir in 1995. During the period 1985 to 1991, the rate of development of new cases (increasingly due to multidrug-resistant [MDR] strains of *M. tuberculosis*) increased, primarily associated with microepidemics among the urban poor, racial and ethnic minorities, drug abusers, hospital and correctional facility populations, and patients with HIV infection. TB has decreased in AIDS due to the efficacy of highly active antiretroviral (HAART) therapies.

Pulmonary tuberculosis in the aforementioned settings may take the form of chronic cavitary tuberculosis or forms more likely to suggest pyogenic or atypical pneumonia—that is, progressive primary tuberculosis and tuberculous pneumonia (see Chapter 131). Acid-fast smears of sputum may provide the very first evidence of this disease. Mycobacteria are seen on smears of about 50% of specimens that subsequently prove to contain *M. tuberculosis*. Most laboratories currently employ a fluorochrome stain with auramine–rhodamine (mycobacteria fluoresce orange-yellow) for initial examination of sputum or other body fluids. Molecular diagnostics (PCR) for *M. tuberculosis* are also available for direct application to clinical specimens.

Atypical mycobacteria may be demonstrated on sputum smears of patients, usually older people with slowly progressive pulmonary disease or in immunocompromised hosts (see Chapter 132). Disseminated *M. avium complex* infection in patients with AIDS is usually diagnosed by isolation of the organism from blood culture or by histopathologic diagnosis on biopsy. However, the organism may be demonstrated on acid-fast smears and culture of respiratory secretions even though there may be little radiographic evidence of pulmonary infection directly attributable to its presence. Improved culture techniques are available to more rapidly isolate mycobacteria from clinical specimens. Modified Ziehl–Neelsen–stained smears are helpful in detecting Nocardia.

Fungal Wet Mounts (Potassium Hydroxide, KOH) Preparations

Fungal wet mounts, smears stained with Calcofluor white chemifluorescent agent or phase-contrast microscopy, are employed when epidemiologic considerations suggest community-acquired pulmonary mycoses (particularly coccidioidomycosis and blastomycosis). They should be a routine part of evaluation of respiratory secretions and lung biopsy materials from immunocompromised patients in whom additional fungal pathogens (e.g., *Aspergillus* and mucormycosis) may be active. In patients with allergic bronchopulmonary aspergillosis, or with the unexpected detection of *Aspergillus* in sputum, fungal hyphae must be considered in the clinical context of each patient.

Rapid Detection by Direct Immunofluorescent Microscopy

Direct immunofluorescent antibody (DFA) staining may be useful in rapid diagnosis of respiratory tract pathogens. DFA staining reagents for *L. pneumophila* are commercially available. Their use is not recommended in examination of sputum specimens because of the presence of cross-reacting species (*Bacteroides* species, *Pseudomonas* species, *Bordetella pertussis*) in the upper respiratory tract. However, biopsy specimens of lung (needle, bronchoscopic, or surgical), bronchoscopic aspirates, BAL washings, and pleural fluid samples are suitable for DFA staining for *L. pneumophila*.

Although a variety of stains (toluidine blue O, methenamine silver, Wright–Giemsa, Diff-Quik, Calcofluor) are useful in identifying *P. jiroveci* in induced sputa or BAL specimens, or on imprint smears of tissue specimens, the most widely used diagnostic technique utilizes immunofluorescence with monoclonal antibodies against *P. jiroveci*. Rapid viral diagnosis (RSV, influenza, parainfluenza, adenovirus) by DFA may be applied to specimens from bronchial lavage or brushings or from nasopharyngeal swabs or washings. Anti-*B. pertussis* DFA may be used on nasopharyngeal aspirate smears in the presumptive diagnosis of pertussis.

DFA may be used to detect viral antigens (adenovirus, influenza A and B, parainfluenza, and RSV, as well as CMV and HSV) in specimens of bronchial brushings, BAL, or nasopharyngeal washings. Enzyme immunoassay may also be used to detect viral antigens in respiratory secretions.

Giemsa and Other Special Stained Smears for the Diagnosis of Pneumocystis Infection

Since *P. jiroveci* pneumonia is an alveolar process, examination of routinely collected expectorated sputum samples for *P. jiroveci* is generally not regarded as rewarding in immunosuppressed patients with neoplastic disease or transplant recipients. In patients with AIDS and in others with advanced pneumonia, induced sputum examination for *P. jiroveci* may be helpful. Otherwise, fiberoptic bronchoscopy and transbronchial biopsy, combined with BAL, provide the highest diagnostic yield.

Sputum induction employing aerosolized, hypertonic saline provides a diagnosis in up to 80% of cases, particularly if coupled with microscopy of antibody-stained cytocentrifuged specimens. Immunofluorescent assays use monoclonal antibodies to *P. jiroveci* with induced sputum specimens and have a sensitivity of 69% to 92%, compared with that of 28% to 80% for tinctorial stains. Toluidine blue O and methenamine silver stains stain only the cyst (<10% of the organism burden) and not the trophozoite forms of *P. jiroveci*. Giemsa and Diff-Quik stain trophozoites and intracystic sporozoites. If results of examination of induced sputum are negative and clinical circumstances warrant further attempts at diagnosis, follow-up bronchoscopy with transbronchial biopsy or BAL is performed. The sensitivity of each of these procedures for the diagnosis of *P jiroveci* pneumonia is over 90%.

Special Microscopic Examinations

Occasionally, in the setting of apparent pulmonary inflammation with features atypical for infection, microscopic examinations using stains other than Gram stain may be indicated. For example, Wright-stained smears may show the presence of eosinophils in allergic pulmonary aspergillosis or other causes of pulmonary infiltrates that are accompanied by eosinophilia. Cytologic examination of exfoliated sputum using Papanicolaou stain may reveal a pulmonary neoplasm. Birefringent calcium oxalate crystals (needlelike in rosettes or arranged like sheaves of wheat) in sputum cytologic specimens have been reported as suggesting pulmonary infection with *Aspergillus* (aspergilloma and, occasionally, invasive aspergillosis).

In the intubated or tracheotomized patient, whose tracheobronchial secretions commonly contain neutrophils and often some bacteria on Gram-stained smears, it may be difficult to distinguish between colonization and nosocomial pneumonia.[20,21] The presence on light microscopy (×400) of characteristic elastin fibers with split ends (in a drop of tracheal aspirate to which a drop of 40% KOH has been added), in the appropriate clinical setting, is a strong indicator of a necrotizing pulmonary infection.

Intense bacteremia sometimes accompanies pulmonary infections, and the etiologic agent may be demonstrable on stained smears of the buffy coat of centrifuged blood: pneumococci have been identified in Gram-stained or Wright–Giemsa–stained smears of buffy coats from splenectomized patients; occasionally, *M. avium-intracellulare* has been found intracellularly in acid-fast stains of buffy coats from patients with AIDS.

Additional special microscopic examinations may be indicated for immunocompromised patients who have patchy pulmonary infiltrates on the chest radiograph. For example, the presence of the hyperinfection syndrome of strongyloidiasis (often accompanied by *Escherichia coli* bacteremia) can be established by the finding of filariform larvae in the sputum and in the stool after the latter is suitably prepared by concentration techniques. Although eosinophilia is often present in patients with strongyloidiasis, it may be absent in the hyperinfection syndrome.

■ SPUTUM CULTURES

In most patients with the common types of community-acquired and nosocomial bacterial pneumonia, the etiologic diagnosis can be made on the basis of the combined results of a Gram-stained smear of sputum and of proper culture of a suitable exudative portion of a freshly obtained sputum specimen. The criteria for a proper sample of sputum have been noted earlier. Culture generally entails streak dilution on blood agar and McConkey media. Expectorated sputum should not be cultured anaerobically, since contamination with oral anaerobes is inevitable. Blood agar best supports the growth of gram-positive cocci and most gram-negative rods and is especially useful for evaluation of the colony morphology and hemolysis of streptococci. McConkey agar is selective for gram-negative bacteria and is used to determine bacterial ability to ferment lactose (lactose-positive or -negative organisms). Chocolate agar is not used routinely, but allows recovery of *H. influenzae* and other fastidious organisms. Because patients with Legionnaires' disease often have little sputum production and growth requires special media, most attempts to isolate *Legionella* resort to specimens obtained either by induced sputum samples, fiberoptic bronchoscopy, or lung biopsy or at thoracentesis. Cultures of such materials are plated on buffered charcoal-yeast extract (BCYE) agar. Occasionally, *Legionella* species can be isolated from sputum with the use of a semiselective medium, either BCYE or BCYE-containing cefamandole, polymyxin B, and anisomycin. Culture is the most definitive method for diagnosis of *Legionella* infection. Unfortunately, it may take 5 or more days for colonies to appear.

Cultures for mycobacteria are undertaken when clinical circumstances raise the possibility of pulmonary infections due to *M. tuberculosis* or atypical mycobacteria. Similarly, cultures of sputum for primary invasive mycotic agents (e.g., *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*) are dictated by clinical and epidemiologic circumstances. In immunosuppressed patients, cultures of sputum are also directed toward a variety of opportunistic fungi, including *Cryptococcus neoformans*, *Aspergillus* species, and Mucoraceae.

Most hospitals do not have facilities for isolating viruses by tissue culture. This lack poses little problem in dealing with most community-acquired viral pneumonias, for which viral isolation is not necessary and the cost is prohibitive. However, viral isolation from throat washings is warranted in certain circumstances (e.g., to prove the presence of an outbreak of influenza) and to identify a specific viral agent, such as an adenovirus or SARS, as the cause of a serious pneumonia that is not responding to antibacterial therapy. Cultures may be grown in cell lines susceptible to the viral infections under consideration in either standard "tube cultures" or "shell vial" cultures (rapid culture achieved by centrifugation of specimens against the cultured cells). Viral replication in the tissue culture can be confirmed within 48 hours after inoculation with the use of fluorescent monoclonal antibodies. Because CMV and herpes simplex are frequently present in the oral secretions of immunosuppressed patients, isolation of these viruses is apt to be meaningful only if the materials used for the isolation procedure were obtained either by bronchoscopy with protected specimen brush (PSB) or with BAL, lung biopsy, or transtracheal aspiration. In practice, diagnostic cultures (e.g., for CMV, other herpesviruses, and adenovirus) have been replaced by quantitative molecular amplification assays (nucleic acid tests, NAT, polymerase chain reaction, PCR) or antigen detection systems (Table 122-6) that are more rapid and cost efficient than culture systems (see below).

■ BACTERIAL AND VIRAL ANTIGEN DETECTION

The quellung reaction was extensively used in the preantimicrobial agent era to identify *S. pneumoniae* in sputum.[22,23] It entails the use of light microscopy to detect capsular swelling after pneumococcal antiserum has been added to a loopful of sputum. The occurrence of the quellung reaction was shown to correlate closely with the presence of *S. pneumoniae* in sputum culture—in about 90% of the patients. Pneumococcal antigens may also be detected in the sputum of patients with pneumococcal pneumonia by ELISA, latex particle agglutination, or counterimmunoelectrophoresis; none of these techniques is commonly used at present. Antigen detection in sputum may have as high a sensitivity as 70% to 90%; but specificity is a problem, with about 20% false positives, probably due in part to the difficulty in distinguishing oropharyngeal contamination and colonization (e.g., in patients with chronic bronchitis without pneumonia).

In many patients, an etiologic diagnosis cannot be made on the basis of initial smears or cultures, antimicrobial therapy has been initiated before cultures were obtained or adequate sputum samples are not available. In the setting of likely CAP, urinary antigen tests for *Pneumococcus or Legionella (SG1)* or nasal swabs for direct immunofluorescence or culture for viral antigens (influenza, parainfluenza, metapneumovirus, adenovirus, respiratory syncytial virus [RSV]) are often helpful.[13,23–28] In adults hospitalized with CAP due to *S. pneumoniae*, generally without bacteremia (which increases sensitivity), the sensitivity of the pneumococcal urinary antigen assay was 71% and specificity was 96%.[29,30] The *L. pneumophila* antigenuria test is positive despite antimicrobial agent administration; antigenuria may persist for weeks or months after recovery from pneumonia.[31,32] The assay is available only for *L. pneumophila* serogroup 1, and this serogroup is responsible for only 80% of *L. pneumophila* infections.

Rapid, point-of-care tests for influenza viruses have good specificity but only 50% to 70% sensitivity; retesting using more sensitive

TABLE 122-6 Assays for Viral Agents of Adults

Virus (Type)	Season	Culture/Specimen	Culture Days to Positive	DFA/Serology	Molecular Amplification+
Influenza A/B (RNA)	Winter	Nasopharyngeal wash/BAL	3–5 (low yield)	+/+ (rapid antigen tests poor)	Qual (rapid, sensitive, specific)

[a]Testing of multiple specimens including lower and upper respiratory samples, serum, and stool samples.

assays may be required if clinical suspicion is high. Recently introduced multiplex molecular assays (PCR) for up to 16 respiratory viruses has been adopted by some clinical laboratories.[33] Molecular testing allows detection of *Legionella and Mycoplasma, and some Chlamydophila* species; quantitative PCR may assist in separating infection from colonization. Using this array of diagnostics, likely pathogens may be detected in up to 78% to 89% of cases of CAP. While the pneumococcus remains the most common pathogen at 38%, this pathogen was more often detected by molecular and urinary tests than sputum culture and examination.[28] Respiratory viruses are also common (29%).

For the immunocompromised host, the epidemiologic history may suggest other risk factors such as *Histoplasma* (urinary antigen), viral infections (serum antigenemia or nucleic acid testing) (see Tables 122-2 and 122-6), or the serum cryptococcal antigen assay. Retrospectively, serologic testing may reveal diagnoses such as psittacosis or Q-fever. The CMV antigenemia assay detects matrix protein pp65 and can be detected with the use of fluorescent or peroxidase-labeled antibody staining of peripheral blood neutrophils. This assay is semiquantitative. Quantitative and sensitive NAT assays are available for most clinically important viruses (Table 122-6 and see below). These are positive days in advance of antigenemia assays and are useful in management as well as diagnosis of acute infection. Strict criteria for CMV pneumonia include demonstration of the virus, typical cytologic changes, and absence of other evident pathogens. This is applicable in immunocompromised patients, in whom CMV is frequently isolated but in whom CMV rarely causes pneumonia. In contrast, isolation of CMV from BAL fluid in blood or bone marrow transplant recipients with pneumonia is sufficient evidence to make the diagnosis and institute treatment, in view of the high frequency and mortality of CMV pneumonia in these patients.

■ MOLECULAR DIAGNOSTIC TESTING

A variety of nucleic acid target amplification tests (NAT, often polymerase chain reactions or PCR) are available for the direct detection of pulmonary pathogens. PCR tests can detect *M. tuberculosis* (as distinct from nontuberculosis mycobacteria) directly from sputum and BAL specimens. These tests have shown a sensitivity of 90% to 100% in specimens that are acid-fast bacillus (AFB) smear–positive but a sensitivity of only 65% to 85% for specimens that are smear negative. Consequently, these PCR assays have been approved for use only on AFB smear–positive specimens. In some major medical centers, PCR assays for the detection of *C. pneumoniae* and *M. pneumoniae* on nasopharyngeal or throat swab specimens are available to markedly shorten (by 1–2 days) the time required to isolate these organisms by culture (up to 3 weeks).

Molecular detection of HSV, adenovirus, CMV, EBV, and other pathogens are used primarily with blood specimens but may also be used in BAL or CSF samples. In immunosuppressed patients with pneumonia, a broad array of opportunistic viral infections (CMV, RSV, varicella-zoster virus, herpes simplex) are diagnostic considerations. In vitro testing of CMV, including molecular antiviral resistance testing, may provide data regarding appropriate antiviral therapy. The interpretation of NAT assays with respiratory secretions is nonstandardized—and blood studies are preferred. Molecular amplification is under development for many common pulmonary pathogens including *P. jiroveci, L. pneumophila, and Candida and Aspergillus species.* PCR tests have been developed for agents of bioterrorism.

Blood Cultures

Blood cultures should always be performed in patients with suspected bacterial pneumonia.[34] Bacteremia occurs in approximately 30% of patients with pneumococcal pneumonia who represent up to two-thirds of those with positive blood cultures.[35–37] Blood cultures are more often positive in sicker patients: those with hypotension, renal and liver dysfunction, pleurisy and tachypnea, and embolic disease. Bacteremia in patients with pneumonia may indicate that the pulmonary infection is secondary to a focus of infection elsewhere (e.g., acute right–sided *S. aureus* endocarditis or *Pseudomonas aeruginosa* infection of thermal burns). In patients with AIDS and disseminated *M. avium-intracellulare* infection, mycobacterial blood cultures are almost always positive. The lysis centrifugation technique permits ready and rapid isolation of the mycobacterium and quantifies the intensity of the bacteremia. *L. pneumophila* has been isolated with some frequency from automated radiometric blood culture bottles, but blind subculture onto

BCYE agar is necessary because growth in the liquid medium does not achieve detectable levels.

Serologic Tests and Fungal Antigens

Serologic tests are sometimes of considerable help in establishing the causes of a number of pulmonary infections when the causative agents are difficult to isolate. However, this approach, requiring the demonstration of a fourfold or greater rise in titer between acute and convalescent samples, neither enables rapid diagnosis nor provides assistance in initial selection of antimicrobial therapy.

Microimmunofluorescence serologic tests are of value in the diagnosis of psittacosis (*Chlamydophila psittaci*). A fourfold rise in IgG or the presence of IgM antibody indicates recent infection.

The indirect immunofluorescent antibody test (fourfold titer rise to 1:128 or higher indicates recent infection) may provide a retrospective diagnosis of Legionnaires' disease, but the antibody rise occasionally may not be demonstrable for 4 to 6 weeks after the clinical onset. Antibodies may persist for months or up to a year or more. Thus, a single titer of 1:256 or higher may reflect a prior *Legionella* infection.

Cold agglutinins develop in about half the patients with *M. pneumoniae* pneumonia, but such antibodies occur in other conditions; complement fixation testing is the preferred diagnostic procedure.

The most sensitive and specific serologic test for infection with *C. pneumoniae* is the microimmunofluorescence test. A fourfold rise in IgG titer or an IgM titer of 1:16 or more reflects an acute infection.

The complement fixation test is usually used to confirm a diagnosis of Q fever pneumonia, but microimmunofluorescence, microagglutination, and enzyme-linked immunosorbent assays have been used to diagnose acute *Coxiella burnetii* pulmonary infection.

Tularemic pneumonia can be diagnosed serologically with an agglutination test for *Francisella tularensis*.

Serologic tests are also helpful in the diagnosis of invasive infection due to the primary pulmonary mycotic pathogens.

Serum IgM precipitins (latex agglutination, immunodiffusion) appear with primary coccidioidomycosis. Abnormally high complement fixation titers (at least 1:32) are present in most patients who have disseminated infection due to *C. immitis*.

A fourfold increase in complement fixation titer to yeast and to mycelial phases of *H. capsulatum* (or possibly a single titer of 1:64 or higher) and the presence of H and M precipitin bands strongly suggest histoplasmosis.

Complement fixation tests for blastomycosis lack sensitivity and specificity: titers of at least 1:8 suggest recent or active disease, particularly if precipitins to the A antigen are also present.

Cryptococcal antigenemia is detectable from latex particle agglutination in patients with cryptococcal pneumonia or disseminated cryptococcal infection.

Sporotrichosis can be diagnosed with a serologic agglutination test when the titer is 1:80 or greater.

Pulmonary toxoplasmosis is uncommon in seronegative individuals although acute toxoplasmosis is seen in endemic regions (Caribbean, France) and after organ transplantation.

Serologic tests (paired acute and convalescent sera) may be helpful for the retrospective diagnosis of infections due to influenza A and B, RSV, adenoviruses, and parainfluenza viruses.

Fungal pneumonia is generally a function of anatomic (fungus ball) or immune dysfunction (e.g., neutropenia). Screening assays have been developed to assist in the detection of fungal infection in high-risk patients. 1,3-β-D-glucan, a cell wall component of many fungal cell walls. Candida species, while frequently isolated in respiratory specimens, rarely cause pneumonia other than in infracted lung or as a function of embolic disease (e.g., endocarditis in injection drug users). Thus, a positive β-D-glucan assay in the immunocompromised host is likely a reflection of infection due to Pneumocystis, Cryptococcus, Aspergillus (or other moulds) species.[38,39] The sensitivity for proven or probable invasive fungal infection in various hosts is generally in the 50% to 77% range (often lower in practice) and specificity of 80% to 95%. The specificity is altered due to false-positive results from intravenous immunoglobulin and albumin, intravenous piperacillin–tazobactam and amoxicillin–clavulanic acid, cellulose hemodialysis membranes, gauze packing after surgery, and *Pseudomonas* bacteremias.

For *Aspergillus* species, galactomannan, a component of the cell wall, can be measured in serum by enzyme-linked immunoassay and has been shown to correlate with the burden of fungal disease (see also Chapter 133).[40–43] A meta-analysis of the performance characteristics of the assay in serum demonstrated a sensitivity of 0.71 (95% CI 0.68–0.74) and specificity of 0.89 (95% CI 0.88–0.90) using an index cutoff of 0.5 in immunocompromised patients with proven invasive aspergillosis.[42] Individual studies reveal variability in assay performance. In BAL fluids from stem cell transplant patients, the GM has a reported sensitivity of 0.61 (95% CI 0.46–0.75) and specificity of 0.98 (95% CI 0.89–1.0) using an index cutoff of 1.0.[44] Despite widespread use of the serum galactomannan assay for the early diagnosis of invasive disease, it is unclear that this assay results in the earlier initiation of appropriate antifungal therapy or is cost effective.

■ SKIN TESTS OF DELAYED HYPERSENSITIVITY

The tuberculin skin test (TST) is of great importance in the evaluation of a pulmonary infection of unknown origin. The intermediate (5 tuberculin units) purified protein derivative (IPPD) test should be used if no information is available about previous testing. A positive test does not distinguish between prior and current infection. A negative second-strength PPD skin test in a patient who is not anergic is evidence against a tuberculous origin of a pulmonary process in a normal host. Several caveats are noteworthy: since it may take 4 to 6 weeks for the skin test to become positive, the TST may be initially negative in progressive primary pulmonary tuberculosis, and in the patient who was infected long ago, cutaneous hypersensitivity may wane; in the elderly person, in whom waning has occurred, repeat testing several weeks later may show a positive result (booster effect) even if the original IPPD skin test was negative.

A PPD reaction of ≥5 mm is considered positive in HIV-infected and other immunosuppressed hosts, recent exposures and in some cases of x-ray positive, remote tuberculosis. PPD ≥10 mm is positive for individuals form an endemic region, intravenous drug users, TB laboratory personnel, and group housing residents. Positive PPD tests should be ≥15 mm induration in other hosts.

Interferon gamma release assays (IGRAs) carry a 70% to 90% concordance with PPD testing and are used in all circumstances in which TST is currently used.[45–47] The IGRA is more specific than TST but more expensive and requires whole blood testing.

Fungal skin tests do not distinguish between current and past infection; indeed, active disease is often accompanied by a negative skin test. The coccidioidin skin test is the best of the available tests, but the diagnosis of coccidioidomycosis is not excluded by a negative test. Blastomycin and histoplasmin skin tests are of little value because of frequent false-negative results and cross reactions. Also, the performance of the histoplasmin skin test may falsely elevate antibody levels to the *H. capsulatum* mycelial antigen.

A negative skin test response to a specific antigen must be interpreted in the light of possible anergy. A battery of control antigens (mumps, *Candida*, *Trichophyton*, streptokinase–streptodornase) serves to detect such anergy, but these reagents are increasingly unavailable and costly.

INVASIVE DIAGNOSTIC PROCEDURES

Some techniques developed to avoid potential contamination of sputum samples with upper airway flora have generally become less popular, including transtracheal aspiration, transthoracic aspiration, and even routine bronchoscopy.

Transtracheal aspiration involves placement of a 12-to 14-gauge intracath via the cricothyroid membrane with avoidance of air leakage and aspiration using a syringe.[48,49] This technique was very useful but occasionally complicated by bleeding, air leak, and lack of experience. Transthoracic needle aspiration similarly had a good yield but has also fallen into disfavor.[22,34]

Bronchoscopy also suffers from upper airway contamination and may be replaced by a variety of techniques: quantitative cultures of wedged terminal BAL specimens; double-lumen or PSB bronchoscopy; plugged telescoping catheter (PTC) sampling; fiberoptic bronchoscopy with transbronchial biopsy; CT-guided needle biopsy of the lung; and open lung biopsy via limited or video-assisted thoracoscopic surgery (VATS).[21,50–52] Important considerations include the type and location of the pulmonary lesion, the ability of the patient to cooperate with the required manipulations, the presence of coagulopathies, and experience at the particular hospital in performing each of the procedures. For patients who are critically ill or unlikely to tolerate invasive infections (immunocompromised hosts, recent major surgery, heart or liver or renal failure, COPD), it is reasonable to consider more invasive diagnostic procedures early in the clinical course, bearing in mind the risks inherent to invasive tests. In such patients, empiric antimicrobial therapies carry the risk of obscuring a specific microbiologic diagnosis as well as drug-associated toxicities. Such an approach may also be required if the patient's condition continues to deteriorate despite empiric antimicrobial therapy. The selection of such procedures should be based on the nature of the illness and the likelihood of success for each procedure at the institution.

Each procedure is best suited to lesions with selected location and radiographic appearance. Fiberoptic bronchoscopy using specialized devices to shield against oropharyngeal contamination (protected specimen brushing) can obtain tracheobronchial secretions for culture in acute bacterial pneumonias. A peripheral nodule or cavity (more than 1 cm in diameter) that is readily visualized on conventional (posteroanterior and lateral) radiographs and fluoroscopy and is in an accessible location may be aspirated and biopsied by needle percutaneously. A nodule that is inaccessible to needle aspiration, or a process placed peripherally, where the need for histopathology is not apt to be met by needle aspiration and biopsy, is best approached by open lung biopsy.

FLEXIBLE FIBEROPTIC BRONCHOSCOPY WITH LUNG BIOPSY

Fiberoptic bronchoscopy, in conjunction with transbronchial lung biopsy, provides an etiologic diagnosis in about 50% to 80% of immunosuppressed patients who do not have AIDS and in 60% to 90% of patients who do have AIDS, in whom *P. jiroveci*, CMV, and *M. avium-intracellulare* infections are common. Contraindications to transbronchial biopsy include inability of the patient to cooperate, marked hypoxemia, bleeding disorders (particularly those associated with hypoprothrombinemia, thrombocytopenia refractory to platelet transfusion, and uremia), and pulmonary hypertension. In such patients, correction of bleeding tendency and/or open procedures may be preferred. Fiberoptic bronchoscopy combined with transbronchial biopsy and segmental BAL is the usual initial invasive diagnostic procedure in the immunocompromised patient with an undefined diffuse pulmonary process. If this fails to provide a diagnosis, open lung biopsy is indicated.

Tissue specimens are processed for histopathologic examination (hematoxylin and eosin stain, tissue acid–fast stains, Gomori methenamine–silver stain, periodic acid–Schiff stain, tissue Gram stain, and Dieterle silver stain). Impression smears from tissues are made with sterile slides, which, after appropriate fixation, are stained with Giemsa, Gram, Ziehl–Neelsen, and methenamine silver (for *P. jiroveci*) stains, as previously described. As indicated, DFA staining for *Legionella* and monoclonal antibody staining for *P. jiroveci* are performed on separate impression smears. Appropriate cultures are made with tissue obtained either transbronchially or at open lung biopsy.

Bronchoalveolar Lavage

In patients with AIDS, fiberoptic bronchoscopy coupled with wedged, terminal, subsegmental BAL has proved particularly useful, providing a diagnosis in more than 95% of cases of *Pneumocystis* pneumonia. BAL alone, without transbronchial biopsy, is often substituted in patients who are thrombocytopenic, on mechanical ventilation, or severely hypoxemic. It should be noted that the yield in non-AIDS immunocompromised hosts is significantly less than in AIDS. Biopsies are often useful in these populations. The material obtained by BAL is processed for smear and culture. As indicated earlier, a variety of stains are available for demonstrating the presence of *Pneumocystis* in the cytocentrifuged material. Stained, cytocentrifuged BAL specimens can also be helpful in establishing other diagnoses: Papanicolaou stain is useful in detecting neoplastic cells and in identifying viral cytopathic effects in epithelial cells.

In at least two-thirds of immunosuppressed patients with CMV pneumonia, the diagnosis can be made from the finding of inclusion bodies in cytocentrifuged BAL specimens and with immunofluorescent monoclonal antibody staining. CMV is isolated more often on culture in these patients, but culture alone is not sufficient to establish the diagnosis, since viral isolation may represent only viral shedding in the presence of pulmonary disease due to other causes.

INVASIVE DIAGNOSTIC TESTING IN VENTILATOR-ASSOCIATED PNEUMONIA

PSB techniques with quantitative culture and protected-catheter BAL, also with quantitative culture, have been employed to obtain bacteriologic information while minimizing opportunity for contamination from colonization of the upper airway in patients with ventilator-associated pneumonia (VAP). The role of quantitative diagnostic techniques in the evaluation of patients with healthcare-associated pneumonia (HCAP) or VAP remains controversial (discussed below) because of questions of reproducibility and the optimal threshold concentration of bacteria. In at least one study, tracheal aspirate cultures correlated with PSB cultures in patients with VAP, suggesting no added value to use of such an invasive procedure to direct initial therapy. The routine use of such tests requires standardization of techniques at the institutional level.

PERCUTANEOUS TRANSTHORACIC NEEDLE LUNG BIOPSY

Percutaneous needle biopsy is often the invasive diagnostic procedure of choice for a sizable (greater than 1.0 cm) pulmonary nodule or cavity that is located peripherally. The use of smaller-gauge needles has reduced the frequency of pneumothorax as a complication. Diagnostic yields of 60% to 80% have been obtained in immunocompromised patients with pneumonia. This procedure has also provided the diagnosis in 70% of patients in whom the underlying lesion was granulomatous. The small core of tissue and aspirated fluid is examined by stained smear and culture for various infectious agents (see "Flexible Fiberoptic Bronchoscopy with Lung Biopsy"). Cytologic examination should be done for neoplastic cells. Because of the nature of the specimen, however, histopathologic examination is generally fruitless. In patients in whom respiratory status is tenuous, or in whom lymph node biopsy or sampling of pleural fluid may be desired, VATS or open biopsy may be preferred.

OPEN LUNG BIOPSY

Open lung biopsy and, more recently, VATS, constitute the most definitive procedures for histopathologic diagnosis in the immunocompromised host. They provide sufficient lung tissue for the diagnosis and also make it possible to sample several different

sites. Surgical lung biopsy is particularly suitable for evaluating processes that may not be infectious (e.g., neoplasm such as Kaposi sarcoma, antineoplastic drug toxicity, drug hypersensitivity, and lymphocytic interstitial pneumonia). Open lung biopsy has provided a specific diagnosis in 60% to 90% of non-AIDS immunocompromised patients. Major advantages include large specimen size and the ability to control bleeding, air leaks, and the airway. Its disadvantages relate to the thoracotomy: the need for general anesthesia, the inherent delay in preparing the patient for the surgical procedure, the need for intubation, the usual placement of a chest tube, and postoperative splinting due to incisional pain. Some of these complications are decreased in VATS. The mortality from the procedure is about 1%. Bleeding is a complication in about 1% of patients and delayed pneumothorax in about 9% of patients.

For the patient in whom the pace of the illness does not allow a sequential diagnostic approach, open lung biopsy may have to be procedure of first choice. It is also preferred in the patient who is unable to cooperate with fiberoptic bronchoscopy or in whom thrombocytopenia or hypoxemia present additional problems for transbronchial biopsy.

Processing of lung biopsy specimens should include special stained imprint smears for *P. jiroveci*, bacteria (including *Nocardia* and mycobacteria), fungi, and viral inclusion bodies; cultures for bacteria, viruses, fungi, and mycobacteria; and tissue sections stained for histology and for infectious agents.

CATEGORIZATION OF PULMONARY INFECTIONS ACCORDING TO PATHOLOGIC AND PATHOGENETIC FEATURES

Pulmonary infections can be categorized according to distinctive pathologic, anatomic, and radiologic features. Some general patterns are presented for their value in differential diagnosis and are discussed in detail in subsequent chapters.

BACTERIAL PNEUMONIA

Bacterial pneumonia commonly results from bronchogenic spread of infection following microaspiration of pharyngeal secretions. Such particles reach terminal airways and alveoli to initiate infection, which has the anatomic distribution and radiologic appearance of subsegmental, segmental, or lobar consolidation. Pneumonia may be patchy in distribution, with a peribronchial and multifocal distribution, in association with aspiration and bronchial plugging, superinfection of pre-existing chronic bronchitis, diffuse acute tracheobronchial inflammation (e.g., influenza, parainfluenza), and with specific infecting microorganisms (e.g., oral anaerobic bacteria). The progression of a pulmonary infiltrate or lobar consolidation to parenchymal destruction (necrotizing pneumonia or lung abscess) is usually the consequence of one or more of three factors: the intrinsic virulence of the infecting organism(s), the presence of bronchial obstruction or other anatomic abnormality, or immune compromise in the host (Fig. 122-1).

Pneumonia may develop via the bacteremic, rather than bronchogenic, route. The clinical setting and the radiographic pattern usually suggest this form of pathogenesis. The intravenous-drug abuser with *S. aureus* bacteremia and acute right–sided endocarditis presents with fever, cough, purulent sputum, a murmur of tricuspid insufficiency, numerous irregular infiltrates, and rounded densities on chest radiograph. Similarly, burn patients with *P. aeruginosa* bacteremia and multiple nodular pulmonary densities, are likely to have bacteremic *Pseudomonas* pneumonia with pulmonary bacterial arteritis. Septic pulmonary emboli, arising from septic thrombosis of the jugular vein may cause a clinical and radiographic picture suggestive of multifocal bronchopneumonia. On the chest radiograph, however, the lesions are nodular; histologically, they represent septic pulmonary infarcts (following emboli) upon which are engrafted pyogenic infection and abscess formation.

LUNG ABSCESS

A lung abscess is an area of pulmonary infection with parenchymal necrosis. Lung abscesses may be solitary or may occur as multiple discrete lesions. Most often it is secondary to aspiration of anaerobic or anaerobic and aerobic organisms that are colonizers of the upper respiratory tract and may be associated with periodontal disease (Fig. 122-6). Superinfection of damaged or infarcted lung tissue (e.g., as in aspirational pneumonia with chemical injury and anaerobic superinfection or primary anaerobic infection) may progress to necrosis with microscopic foci of abscess formation. Confluence of small necrotic foci can either create one or more lung abscesses or lead to a progressively fibrotic, shrunken, and destroyed lobe.

Pulmonary gangrene is an unusual consequence of severe pulmonary infection characterized by sloughing of a pulmonary segment or lobe. This process affects an entire segment or lobe secondary to thrombosis of both bronchial and pulmonary arteries with pulmonary infarction. The organism most commonly implicated has been *K. pneumoniae*, but others have been *S. pneumoniae*, *E. coli*, mixed anaerobes, *H. influenzae*, and *S. aureus*. If there is some degree of ball-valve bronchial obstruction, air may enter while contained pus may fail to drain, producing the radiographic picture of an air–fluid level.

Other causes of lung abscess are (1) progression of a bronchogenic pneumonia due to a pathogen with necrotizing potential (e.g., *K. pneumoniae*, Fig. 122-1), or *Nocardia asteroides* in an immunocompromised patient, (2) bacteremic spread of infection, and (3) septic pulmonary emboli. Lung abscesses complicating necrotizing pneumonia should be distinguished from pneumatoceles; the latter are thin-walled, air-filled structures that often develop early in the course of staphylococcal pneumonia, particularly in infants and young children, and usually disappear over the course of a few months. Lung abscesses should also be distinguished from acute or chronic cavitary pneumonia, which are often multiple and associated with specific pathogens (e.g., mycobacteria) or hosts (e.g., moulds in neutropenia).

BRONCHITIS AND BRONCHIECTASIS

Acute bronchitis is an inflammatory process, usually of viral origin, confined to the bronchi and bronchioles; it does not extend appreciably to surrounding pulmonary parenchyma and is not evident on radiographic examination. Purulent inflammatory secretions are common even though there may be no discernible bacterial infection. Such purulent secretions represent bacterial superinfection. The diagnosis of an acute exacerbation of chronic bronchitis is based solely on clinical grounds; the manifestations are increased cough, dyspnea, and enhanced production of purulent sputum, with or without fever, in a patient with chronic obstructive pulmonary disease. Bacteriologic examination in the absence of antimicrobial pressure generally reveals large numbers of pneumococci or nontypable *H. influenzae*, either as infecting organisms or as chronic colonizers of the bronchial tree. Patients with acute exacerbations of chronic bronchitis tend to improve with antimicrobial treatment while those with chronic bronchitis are less likely to improve with therapy.

Bronchiectasis is characterized by destruction of epithelial, elastic, and muscular elements of bronchi, resulting in their irreversible dilatation. The major proximate cause is repeated or chronic bacterial infection. Nontuberculous mycobacterial infections may contribute. However, predisposition to such infections may reflect a variety of factors, including certain types of prior infection (pertussis, adenovirus, or rubeola infections, necrotizing pneumonia), bronchial obstruction, immunodeficiencies, congenital anatomic lung disease (e.g., congenital tracheobronchomegaly), and other hereditable disorders, such as ciliary dysfunctional states and

α_1-antitrypsin deficiency. Cystic fibrosis is a common predisposing factor for bronchiectasis. As a result of repeated infections, stasis of secretions, and peribronchial fibrosis, bronchi are grossly distorted or completely destroyed. Although pneumonia or lung abscess may accompany recurrent acute infections, exacerbations are usually confined to bronchial and peribronchial tissues.

CHRONIC CAVITARY PULMONARY DISEASE

Chronic cavitary pulmonary disease is most often related to tuberculosis, but may be seen in a_1-antitrypsin deficiency, echinococcal disease, granulomatous polyangiitis, and other structural disorders. Tuberculosis commonly begins with a focus of pneumonitis, usually in the subapical posterior portion of an upper lobe. This patch of pneumonitis occurs at a latent site of earlier metastatic infection (Simon focus) produced by lymphohematogenous spread from primary pulmonary tuberculous lesions. Progressive caseation necrosis at this site, followed by drainage of caseous material through the bronchial tree, produces a cavity (Fig. 122-4). The cavity is encased in a rigid wall of fibrous tissue.

In addition to pyogenic lung abscess and pulmonary tuberculosis, other pulmonary infections may produce chronic cavities. These include *Nocardia* infections, *Rhodococcus equi* infections, actinomycosis, and chronic primary pulmonary mycoses (particularly histoplasmosis, occasionally coccidioidomycosis, uncommonly blastomycosis). Sporotrichosis may affect the lung and produce thin-walled cavities. Parasitic infestation of the lung (paragonimiasis, echinococcosis) may also form cavities.

Pulmonary cavities may also occur in noninfectious disorders (e.g., granulomatosis with polyangiitis, lymphoma or bronchogenic carcinoma, bland pulmonary infarcts, and intrapulmonary nodules of rheumatoid lung disease) (Fig. 122-3). Such cavitary lesions, as well as the cystic lesions that occur in chronic pulmonary sarcoidosis (Fig. 122-9) and in the markedly dilated bronchi of saccular bronchiectasis, may become superinfected with *fungus balls*. These represent tangled masses of fungal hyphae and debris lying freely within pulmonary cavities generally as noninvasive saprophytic growths in the immunologically normal host. The mycotic agents responsible are most commonly *Aspergillus* species (usually *A. fumigatus*), and the fungus ball are called aspergillomas. Invasion of the cavity wall may occur as with immune compromise; hemoptysis originating from the cavity wall is common and may be severe.

MILIARY LESIONS

Hematogenous dissemination of tuberculosis may follow initial infection in children or adults. It also can result from breakdown of formerly quiescent sites of pulmonary or extrapulmonary infection. Clinically unexplained fever may be accompanied by miliary lesions (like millet seeds, very small and uniform in shape) on the chest radiograph; histologically, these lesions are foci of granulomatous reaction (Fig. 122-5). Similar radiographic lesions also occur in the course of hematogenously disseminated bacterial and mycotic infections, including cryptococcosis and histoplasmosis.

THE CLINICAL SPECTRUM OF RESPIRATORY VIRAL INFECTIONS

Respiratory viral infections are a major cause of morbidity worldwide. Findings may predominate in either the upper or lower respiratory tract.

Viral Infections of the Upper Respiratory Tract

Patients present with cough, sore throat, bronchoconstriction, fever, rhinitis, and suffusion of mucus membranes. The majority of these infections are upper respiratory infections and of significance only as causes of discomfort and as predisposing conditions for lower respiratory infections. Spread is via aerosolized droplets and hand contamination. The most prominent viral pathogens include rhinovirus and coronavirus for which no specific antimicrobial therapies are available. Commonly, adenovirus, parainfluenza virus, RSV, and influenza virus may also cause this syndrome. Infections with respiratory viruses occur predominantly in the winter and early spring. Less commonly, reovirus, enteroviruses, metapneumoviruses, and picornaviruses may cause the same symptoms.[53,54]

Of nonviral etiologies, treatable infections with *M. pneumoniae* and *Chlamydophila* (formerly *Chlamydia*) *pneumoniae* also cause significant upper, as well as lower, respiratory tract infections. The main differential for these infections includes allergic, vasomotor, or atrophic rhinitis or nasal polyposis. These syndromes should be considered in patients with atopic history and recurrent upper respiratory infections. While these infections are generally self-limited, common complications include sinusitis, otitis, and bronchitis, exacerbations of chronic pulmonary disease (chronic bronchitis), asthma, and bacterial superinfection with pneumonia.

VIRAL INFECTIONS OF THE LOWER RESPIRATORY TRACT

Influenza virus is an agent of the family orthomyxoviridae that may be associated with sizable outbreaks or major epidemics of upper respiratory infections. Influenza is classified into three subtypes based on antigenic differences: influenza A, B, and C.

Primary influenza viral pneumonia usually occurs in the setting of an outbreak of influenza A infections. It impacts disproportionately patients with underlying heart disease (mitral stenosis), chronic pulmonary disease, pregnancy, and immunocompromised individuals. Unlike secondary bacterial pneumonia after influenza – a complication that occurs after a period (1–4 days) of improvement following typical upper respiratory illness – primary influenza pneumonia immediately follows typical influenza. Two classes of drugs are available to treat influenza A including M2 matrix protein inhibitors (amantadine and rimantadine) and neuraminidase inhibitors (zanamavir, oseltamavir, and peramavir). Resistance is emerging to both groups. Influenza A infects a wide range of hosts species including human, pigs, birds, horses, and marine animals, while influenza B and C are generally restricted to humans. As a result, influenza A may move between host species, risking recombination, mutation (drift) and geographic spread.

Recent outbreaks of pandemic influenza (e.g., avian influenza, 2004–2007, A/H5N1) were most likely to arise in birds as all of the hemagglutinin and neuraminidase variants are carried in that population with viral replication in the gastrointestinal tract and secretion in high titers in feces. The spread of mild variants of H5N1 influenza is common in Asian populations. Pandemic outbreaks of "swine flu" (1918 and 2009 pandemic A/H5N1) was the result of avian, human, and swine influenza viruses in Mexico, and was associated with significant mortality, notably in those with underlying diabetes, COPD, and obesity.

Rarely, viral pneumonia develops in an otherwise healthy person in the course of systemic infection with viruses whose principal impact is extrapulmonary. Pulmonary infiltrates occur in 16% of young adults with varicella, but only 2% to 4% have clinical manifestations suggestive of pneumonia. Some cases of mild pneumonitis have been observed in patients receiving live varicella vaccine. Pneumonia in children with varicella is more likely to represent bacterial superinfection than primary viral pneumonia. On rare occasions, pulmonary infiltrates develop in patients with clinical infectious mononucleosis; the infiltrates represent atypical pneumonia due to Epstein–Barr virus.

A novel Hantavirus, Sin Nombre virus, emerged acutely in 1993, in the Four Corners area of New Mexico, Arizona, Colorado, and Utah, USA. Cases had been reported worldwide but primarily in the west and southwestern United States.[55] The principal host for Sin Nombre virus is the deer mouse, and infection is acquired

through exposure to this rodent, rodent excreta, or contaminated dust. The Hantavirus pulmonary syndrome begins with a 3- to 6-day prodromal period consisting of myalgias and fever, sometimes accompanied by gastrointestinal symptoms. The prodrome is followed by progressive cough, dyspnea, tachycardia, and hypotension. Bleeding may occur. Laboratory findings include hemoconcentration, leukocytosis, thrombocytopenia. The chest radiograph demonstrates interstitial edema, peribronchial cuffing, and bilateral airspace (bibasilar and perihilar) disease. The patient develops pulmonary edema (interstitial and alveolar) consistent with a diffuse pulmonary capillary leak syndrome. The case fatality rate for the Hantavirus pulmonary syndrome is 50%.

Severe acute respiratory syndrome (SARS) is a viral respiratory illness that first appeared in Southern China in November 2002 before spreading globally. SARS is caused by a previously unrecognized coronavirus, called SARS-associated coronavirus (SARS-CoV). SARS-CoV is transmitted most readily by respiratory droplets. Illness begins with a high fever (measured temperature greater than 38.0°C) with chills and malaise. Diarrhea is seen in approximately 10% to 20% of patients. After 2 to 7 days, SARS patients may develop a dry, nonproductive cough that might be accompanied by or progress to a condition in which the oxygen levels in the blood are low (hypoxia). In 10% to 20% of cases, patients require mechanical ventilation. Most patients develop pneumonia. The incidence of pneumonia is greatest in immunocompromised individuals.

Between November 2002 and July 2003, a total of 8098 people worldwide developed SARS and 774 died. No new cases were reported after July 2004. However, a related infection emerged in 2012 in Saudi Arabia called the Middle Eastern Respiratory Syndrome (MERS) caused by a coronavirus called MERS-CoV. This is a severe acute respiratory illness presenting with fever, cough, and shortness of breath, after exposure in or near the Arabian Peninsula. Spread is achieved by close contact but sustained spread has not been identified. About half of known cases have died.

Human metapneumovirus (HMPV) is a ubiquitous virus (*Pneumovirinae* subfamily, *Paramyxoviridae* family) that is a major cause of acute respiratory infection, particularly in children and in immunocompromised individuals.[54] The virus has phenotypic and clinical characteristics similar to those of RSV, often presenting with bronchiolitis. This virus may coinfect individuals with other viral pathogens.

In the immunocompromised host, viral infection is most often due to CMV or community-acquired respiratory viruses, although varicella-zoster and herpes simplex viral pneumonias occur. In this population, the frequency, duration, and severity of viral illness exceed that of the general population. CMV pneumonia in the solid-organ transplant recipient occurs most often in seronegative (naive) recipients of donor organs from seropositive (latently infected) individuals. Conversely, in hematopoietic stem cell recipients, the seropositive recipient of cells from a seronegative donor is at greatest risk. The syndrome of hypoxia with diffuse interstitial infiltrates may predispose to or coexist with a similar syndrome due to *P. jiroveci*. This is most severe in the lung transplant recipient. By contrast, CMV pneumonitis in the hematopoietic stem cell transplant recipient (HSCT) occurs with the activation of CMV in the seropositive recipient of cells from a seronegative donor. With engraftment, the naive immune system reacts against CMV antigens expressed in the lungs. Superinfection is common; graft-versus-host disease may complicate the differential diagnosis.

FUNGAL PNEUMONIA

Fungal pneumonia occurs most often in immunocompromised hosts. However, in the normal host, infection due to the endemic or geographic fungi (*H. capsulatum, C. immitis*) or to *C. neoformans* may be asymptomatic or may present with systemic signs often confused with acute bronchitis, viral infection, mycobacterial infection, or aseptic meningitis. Otherwise, fungal infection of the lungs is most common with anatomic defects (aspergilloma) or aspiration (*Candida* species), but it is otherwise rare in individuals without immune defects. A few syndromes merit consideration.

P. jiroveci causes pneumonia with prominent hypoxia and often few physical or radiologic findings in immunocompromised individuals, particularly those on corticosteroids. As this infection is easily prevented, consideration should be given to prophylaxis in any individual receiving chronic immunosuppressive therapy or with HIV infection or AIDS unresponsive to antiretroviral therapy.

Aspergilloma was traditionally considered to be a noninvasive colonization of pulmonary cavities. However, gross hemoptysis may complicate management and dissemination may occur at the time of surgical resection. Immune suppression may convert benign disease into invasive infection.

Mucormycosis (due to the *Mucoraceae*) causes rapidly progressive sinus and lung infection that requires surgical resection for cure. This infection is most common in diabetics. Fusarium species typically disseminate via the bloodstream, producing diffuse infiltrates.

PARASITIC PNEUMONIA

Parasitic pneumonia is uncommon without endemic exposures. Pneumonia generally occurs when the normal lifecycle of the organism includes the lungs. Infection by *Entameba histolytica* causes pleuropulmonary disease as a result of (1) *sympathetic* reaction to an unruptured abscess within the liver; (2) empyema, after rupture of the liver abscess into the pleural space; or (3) parenchymal involvement with abscess, consolidation, or hepatobronchial fistula after the rupture of a liver abscess. Amebae that have broached the mucosal barrier are thought to gain entry to the liver via the portal vein. Subsequent liver abscesses can be either purely amebic or mixed bacterial and amebic. Other less common routes exist, including hematogenous spread that can lead to metastatic abscesses of brain, lung, and other organs. *Acanthamoeba* species cause subacute meningoencephalitis or keratitis secondary often after hematogenous spread of dermal or pulmonary disease.

Some form of pulmonary complication occurs in 3% to 10% of patients with falciparum malaria. Noncardiogenic pulmonary edema may develop suddenly, even after appropriate antimalarial therapy has been instituted and even after parasites are no longer detected on blood smears. Acute acquired infection due to *Toxoplasma gondii* in the immunocompetent host is generally asymptomatic, with cervical lymphadenopathy as the hallmark of disease. It may be confused with mononucleosis caused by Epstein–Barr virus or CMV. Fever, malaise, sore throat, and hepatosplenomegaly are also seen, and the peripheral blood may manifest atypical lymphocytosis. Rarely, acute acquired disease may present with severe dissemination, marked by pneumonitis, hepatitis, encephalitis, polymyositis, or myocarditis.

In the immunocompromised host, acute toxoplasmosis is most often associated with necrotizing encephalitis as a result of brain cyst reactivation, although myocarditis, hepatosplenomegaly, fever, and interstitial pneumonitis are also common. Pulmonary infections due to migrating worms include Loeffler-like syndrome with *Ascaris lumbricoides*, postobstructive pneumonitis and polymicrobial systemic sepsis and meningitis due to *Strongyloides stercoralis*, cysts and nodules due to *Echinococcus granulosus*, *Paragonimus westermani and Schistosoma species,* and pulmonary eosinophilia in filariasis.

OVERVIEW OF THE MAJOR PNEUMONIA SYNDROMES

The major clinical syndromes are considered elsewhere in this text. This section serves as an overview for the clinician.

TABLE 122-7 Underlying Conditions Contributing to Adverse Outcomes from Pneumonia

Alcohol consumption
Increasing age
Leukopenia
Congestive heart failure
Coronary artery disease
Diabetes mellitus
Immune compromise
Neurologic disease
Active malignancy
Clinical signs including: dyspnea/tachypnea, hypothermia, chills, hypotension, confusion or altered mental status
Laboratory tests: hyponatremia, hyperglycemia, azotemia, hypoalbuminemia, liver function test abnormalities
Radiographic infiltrates and pleural effusions, postobstructive pneumonia
Microbiology: gram-negative bacilli, *S. aureus*, mixed flora (aspiration), bacteremia

COMMUNITY-ACQUIRED PNEUMONIA

Over one million people are admitted to the hospital each year for pneumonia. Initial evaluations of pulmonary processes in the outpatient setting require a clinical assessment of whether the individual merits admission to the hospital for management (see Chapter 128).[14] This judgment is based on whether the patient can manage at home (needs oxygen or intravenous antimicrobials, weakness, cannot eat independently or take oral medications, other pre-existing medical or psychiatric conditions, substance abuse, home supports) and whether the patient is at risk for disease progression. Many factors have been implicated in risk for death due to pneumonia. These include both common (alcoholism) and less common (immune deficiency) underlying conditions (see Table 122-7). The Pneumonia Outcomes Research Team (PORT) Severity Index is a quantitative tool that assesses the severity of a patient's illness, prognosis, and the need for hospitalization.[3,5,56] This index provides the basis of North American practice guidelines for CAP and is discussed subsequently (see Chapter 128).

CAP is a major cause of infectious morbidity and mortality. Depending on the causative organisms, the mortality of CAP ranges from 10% to 15% for pneumococcal infection to 60% for *P. aeruginosa*.[57] Adverse clinical prognostic factors included comorbid conditions (neurologic or neoplastic disease, cirrhosis, congestive heart failure, respiratory compromise, diabetes, hepatic and renal dysfunction, immune deficiency), bacteremia, and multilobar involvement.

As was noted previously, microbiologic diagnosis is now uncommon. *S. pneumoniae* remains a common cause of bacterial CAP. *H. influenzae*, usually unencapsulated strains, may produce pneumonia in patients with chronic bronchitis or in the chronic alcoholic. During an outbreak of respiratory viral infections, bacterial superinfection often occurs, most often in the elderly or in patients with chronic cardiopulmonary disease or immune deficits. Patients with secondary bacterial pneumonia often have up to 4 days of clinical improvement after the initial illness before the onset of overt pulmonary infection. The superinfecting microorganisms are the pathogens that ordinarily colonize the upper airways and include *S. pneumoniae*, *H. influenzae*, *S. aureus*, *Streptococcus pyogenes*, *M. catarrhalis*, and *K. pneumoniae*.

The use of antimicrobial agents at the time of the initial respiratory infection may selectively promote the emergence of more resistant bacterial flora in the respiratory tract. *S. aureus* is increasingly common, notably with methicillin resistance, in the setting of an ambient influenza outbreak.[58]

ATYPICAL PNEUMONIA SYNDROMES AND ENDEMIC MYCOSES

In the evaluation of patients with CAP, it is often helpful to consider separately a group of patients whose illness is characterized by minimal sputum that does not reveal a predominant microbial etiology on routine smears (Gram stain, Ziehl–Neelsen) or cultures (including for mycobacteria or *Legionella* species). The clinical onset of illness is generally subacute with a radiologic picture consisting of patchy infiltrates or an interstitial pattern than a lobar consolidation. Fever and peripheral leukocytosis are less common or intense than in common bacterial pneumonias. For convenience, this grouping has been designated *atypical pneumonia*.

The entities in the category of atypical pneumonia are heterogeneous (Table 122-8). The syndrome may account for up to 60% of cases of CAP. *M. pneumoniae* is the causative agent in about 25% of the cases of atypical pneumonia. Respiratory viruses are responsible for about another 30% and should be considered in the initial evaluation.

C. pneumoniae (formerly known as *Chlamydia* strain TWAR) is an infectious agent, can be spread from person to person and appears to be responsible for 12% to 21% of cases of atypical pneumonia. This form of pneumonia typically occurs in young adults as a sporadic mild pneumonia, but may have enhanced severity when coinfecting individuals with pneumococcal infection. In adults, *M. pneumoniae* pneumonia, in contrast to bacterial pneumonia, often begins insidiously with malaise, fever, and prominent headache. Sore throat is common, but coryza is minimal or absent. Nonproductive cough develops over the next few days and is the hallmark of this disease. Skin rash (erythema multiforme) and bullous myringitis, usually appearing late in the course of illness, are uncommon findings but, when present, do suggest the diagnosis. Mini-outbreaks of *M. pneumoniae* infection in households, schools, and military camps may not be appreciated because of the long incubation period (3 weeks) and variation in clinical presentation.

TABLE 122-8 Causes of "Atypical Pneumonia"

Mycoplasma
M. pneumoniae
Chlamydophila
C. psittaci (psittacosis), *C. pneumoniae*
Bacteria
Legionella spp., *F. tularensis*, *Y. pestis*, *B. anthracis* (*Agents of bioterrorism*)
Fungi
Histoplasma, *Blastomyces*, *Coccidioides*, *Pneumocystis*
Aspiration pneumonitis
Sterile or mixed upper respiratory and oral flora
Viral agents
Respiratory tract viruses: Influenza, adenovirus, respiratory syncytial virus (RSV), parainfluenza virus, metapneumovirus
Varicella-zoster, measles, Epstein–Barr virus (EBV), cytomegalovirus (CMV), Hantavirus
Rickettsia
C. burnetii (Q-fever)

Q-fever, due to *C. burnetii*, is suspected on the basis of epidemiologic clues. Transmission of this disease to humans occurs as a result of inhalation of aerosols from surroundings contaminated by placental and birth fluids of infected livestock (cattle, sheep, goats), wild rabbits, and domestic animals (cats). Veterinarians, ranchers, taxidermists, and others that handle livestock are at particular risk. Since the incubation period of Q-fever is approximately 20 days, a source of exposure may be overlooked. Although the clinical picture resembles that of *M. pneumoniae* pneumonia, the onset may be more abrupt, with chills and high fever. Liver function abnormalities or clinical hepatitis in a patient with atypical pneumonia is suggestive of Q-fever. In some geographic areas (Australia, France), hepatitis has been the most frequent clinical presentation of *C. burnetii* infection; in others (Spain, Nova Scotia), pneumonia has been the major presenting sign.

Chlamydia trachomatis causes pneumonia in the newborn but has not been proved to be a cause of pneumonia in adults. *C. psittaci*, the causative agent of psittacosis, is spread to humans by avian species. Although psittacine birds (parakeets, parrots) are the major reservoir, human infection can be acquired from pigeons, sparrows, and turkeys. In a patient with atypical pneumonia, the clinical features that raise the possibility of this etiology are relative bradycardia, splenomegaly and hepatomegaly, and hepatic dysfunction. *C. pneumoniae* produces atypical pneumonia without the usual bird-to-human transmission of *C. psittaci* infection.

Legionella infections (due to *L. pneumophila* and other *Legionella* species) account for 2% to 4% of cases of atypical pneumonia. Although *Legionella* is an important nosocomial pathogen, it is also responsible for community-based sporadic cases and major outbreaks. The occurrence of summer outbreaks associated with the use of air conditioners, pooled water, and evaporative condensers should call attention to this possible cause of pneumonia. Various extrapulmonary manifestations are common with Legionnaires' disease including relative bradycardia, diarrhea for 24 hours at the onset of illness, confusion and obtundation, mild renal dysfunction (azotemia, microscopic hematuria, proteinuria), acute rhabdomyolysis, and mild hepatic dysfunction. Although many of these manifestations also occur with other pneumonias, the coincidence of several of these features should raise the possibility of *Legionella* infection. This is particularly important in view of the fact that the antimicrobial therapy (macrolides, fluoroquinolones) for Legionnaires' disease differs from that for the more common bacterial pneumonias. The mortality from Legionnaires' disease, if inadequately treated, can be as high as 15%. Recurrent chills, which occur over several days in Legionnaires' disease, are rare in pneumococcal pneumonia unless septic complications (e.g., endocarditis and pericarditis) develop. Although the initial radiographic picture of *Legionella* pneumonia is often that of an interstitial, segmental, or bronchopneumonic pneumonia, if the disease is untreated, it progresses to lobar or multilobar consolidation, a picture that mimics pneumococcal or *Klebsiella* pneumonia.

The other noteworthy bacterial types of atypical pneumonia are those due to *F. tularensis* (tularemic pneumonia), *Yersinia pestis* (plague pneumonia), and *Bacillus anthracis* (anthrax pneumonia). These are all singularly uncommon causes of pneumonia, and the principal clues to diagnosis again derive from epidemiologic considerations, including the risk of bioterrorism.

Exposure to *F. tularensis* comes through contact with tissues of an infected animal (rabbit), animal bites (coyote, cat), inhalation of infectious aerosols, tick or deerfly bites, or ingestion of contaminated water or poorly cooked meat from an infected animal. Ulceroglandular tularemia, or the typhoidal form of tularemia, may be complicated by patchy pulmonary infiltrates. Indeed, it is likely that typhoidal tularemia often represents infection initially acquired via the bronchogenic route. Plague is less common than tularemia in the United States and is strictly localized to southwestern states, including California. The diagnosis should be considered in a person from an endemic area who has a septic illness (septicemic plague) or painful localized lymphadenopathy with fever (bubonic plague) and a history of bites by rodent fleas or of handling tissues of infected animals, such as prairie dogs or coyotes. Pneumonia occurs as a complication in 10% to 15% of patients with bubonic or septicemic plague. Primary (inhalation) pneumonic plague is extremely rare and occurs only as a result of exposure to aerosolized particles from an infected animal or following close contact with cases of plague pneumonia.

Anthrax pneumonia (inhalation anthrax) is also extremely rare in Western regions; it is a consequence of the inhalation of anthrax spores during the processing, or use, of goat skin, hair or wool (usually imported from the Middle East, Asia, or Africa). The presence of influenza-like illness with chest radiographs demonstrating mediastinal widening and pleural effusions, less commonly with infiltrates, was observed with anthrax spread in 2001 via contaminated U.S. mail. After an initial phase with improvement over 3 to 5 days, the abrupt onset of high fever and severe respiratory distress (dyspnea, stridor, cyanosis) progresses to shock and respiratory failure over 24 to 36 hours.

The principal clues to the presence of pulmonary mycoses are epidemiologic (see Chapter 134). Thus, the principal endemic areas for histoplasmosis in this hemisphere are in the Midwestern United States and Central America. However, disease can be found in other locales (e.g., Northeastern US) and after travel. The organism is present in high concentrations in soil sites where avian, chicken, or bat excrement has accumulated. Movement of soil in such endemic areas by cleaning chicken coops or bird roosts, in old attics, or caves can expose people to high concentrations of airborne spores that, when inhaled, produce an acute pneumonia.

Blastomycosis occurs in most states in this country, but the endemic area is principally in the southeastern and south central areas. Rural exposure to soil contaminated with animal excrement appears to be a risk factor. Skin lesions, either verrucous or ulcerative, are the most common extrapulmonary manifestations of blastomycosis and afford a clinical clue to diagnosis.

Coccidioidomycosis is endemic in the southwestern United States (California, particularly the San Joaquin Valley, and Arizona) and in neighboring portions of Mexico. Infection is usually acquired in these areas by inhalation of highly infectious arthrospores. Occasionally, major dust storms carry the arthrospores considerable distances from their soil source and produce unexpected outbreaks of infection. Archeologic digs sometimes cause infection in those living elsewhere who receive an artifact uncovered in the explorations. Erythema nodosum may be associated with any of the primary pulmonary mycoses, but most often with coccidioidomycosis. The coincidence of this hypersensitivity skin lesion and an atypical pneumonia syndrome in a person from an endemic area suggests the possibility of one of these pulmonary mycoses.

Paracoccidioidomycosis (South American blastomycosis) is endemic to Brazil and in Colombia, Venezuela, and Argentina. This disease is caused by *Paracoccidioides brasiliensis*. In adults, the manifestations of this disease are mainly pulmonary; radiographs show patchy or confluent areas of consolidation, often bilateral. Cases have occurred in North America and Europe, but in those instances, the patients had previously resided in endemic areas where initial infection presumably had been acquired.

■ ASPIRATION PNEUMONIA

Aspiration pneumonia may occur after an overt episode of aspiration (e.g., of gastric contents) or of bronchial obstruction by a foreign body. More often the predisposing circumstances are clear-cut (e.g., alcoholism, nocturnal esophageal reflux, pyorrhea, a

prolonged session in the dental chair, epilepsy, or chronic sinusitis in a patient with absent gag reflex) (see Chapter 127). If untreated, aspiration pneumonia may progress rapidly to a necrotizing process that is usually due to anaerobic organisms. The process may involve a pulmonary segment, a lobe, or an entire lung, with ultimate extension to the pleura ("putrid empyema"); in some patients, the necrotizing pneumonia culminates in lung abscesses.[59] In others, aspiration produces an illness of several weeks' duration that is characterized by malaise, productive cough, and low-grade fever. If a chest radiograph is first taken after several weeks of untreated illness, it may show little, if any, evidence of pneumonia but will clearly identify a well-formed lung abscess.

In community-acquired aspiration pneumonia, bacteriologic studies provide a statistical basis for selecting initial antimicrobial therapy. Anaerobic bacteria are etiologically implicated in about 90% of community-acquired aspiration pneumonias and lung abscesses.[60] In 40% to 65% of these patients, anaerobic organisms are the sole infecting agents; in 40% to 45%, the cause is a mixture of anaerobes and aerobes. The most common anaerobes are *Prevotella melaninogenica*, *Bacteroides* species, *Porphyromonas* species, *Fusobacterium* species, peptostreptococci, peptococci, and microaerophilic streptococci. β-Lactamase–producing *Bacteroides* species, *P. melaninogenica*, and members of the *B. fragilis* group are present in about 15% of cases. *P. melaninogenica* may be the most important contributor in such mixed infections. The aerobic indigenous flora in mixed aerobic–anaerobic infections includes *Streptococci viridans*, *M. catarrhalis*, and *Eikenella corrodens*.

A rare form of anaerobic aspiration pneumonia (actinomycosis) that is community acquired is that due to *Actinomyces israelii*, part of the normal flora in the gingival crevice or may contribute to chronic sinus infection. The direct extension of such a necrotizing pneumonia to the pleura and chest wall is a characteristic finding that strongly suggests the diagnosis of actinomycosis.

Although anaerobic members of the oropharyngeal flora have a pre-eminent role in community-acquired aspiration pneumonia and lung abscess, occasionally colonizing gram-negative enteric bacilli such as *K. pneumoniae*, *E. coli*, and *Proteus* species may be the cause (notably in alcoholics).[59,60] Persistence of a necrotizing pneumonia or lung abscess despite antimicrobial therapy that would be expected a priori to be effective raises the possibility of an underlying obstruction, often in the form of bronchogenic carcinoma, particularly if the patient is edentulous.

Pneumonia in the Elderly

CAP in the elderly (over 60 years) primarily affects two populations: one that lives at home and another residing in nursing homes. The latter, from the point of view of oropharyngeal flora and the extent of exposure to antimicrobial agents, is generally considered as a part of HCAP, with a predisposition to nosocomial infection (see below) with an increased rate of antimicrobial resistance.[61] Pneumonia in the elderly has a more gradual onset, with less fever and cough, often with a decline in mental status or confusion and generalized weakness, often with less readily elicited signs of consolidation on examination. Among the bacterial causes of CAP in the elderly, *S. pneumoniae* is the most frequent, accounting for 30% to 60% of cases. *H. influenzae*, primarily nontypable strains, is the second most common cause (about 20%). *M. catarrhalis* is another cause of pneumonia in this age group, primarily in patients with chronic bronchitis. Aspiration pneumonia due to mixed aerobic–anaerobic flora occurs in this age group, particularly because of the presence of a diminished gag reflex or impaired pharyngeal motor function.

In nursing home residents or persons with recent hospitalizations, increased oropharyngeal colonization with gram-negative bacilli occurs, due to antimicrobial exposure, or exposure to the hospital environment or to other recent patients.[62] Microaspirational events predispose to pneumonia due to species such as *K. pneumoniae, E. coli* and other Enterobacteriaceae, and *P. aeruginosa*. Such gram-negative bacilli have been implicated as the cause in 25% to 40% of elderly nursing home residents with pneumonia. *S. aureus* is responsible for 2% to 10% of cases of CAP in the elderly overall, more commonly in nursing home residents and during community outbreaks of influenza. Common forms of CAP are also seen in the elderly.

HEALTHCARE-ASSOCIATED, HOSPITAL-ACQUIRED, VENTILATOR-ASSOCIATED, AND NONRESOLVING PNEUMONIAS

The hospitalized patient with pneumonia poses the dual challenge of infection with nosocomial pathogens and the presence of concomitant processes—the "sick" patient (Fig. 122-11) (see Chapter 129).[63]

Nosocomial pneumonia occurs at a rate of 5 to 10 cases per 1000 hospital admissions. The incidence increases 6- to 20-fold in patients receiving assisted ventilation. Hospital-acquired pneumonia (HAP) develops over 48 hours into hospitalization, while VAP occurs more than 48 to 72 hours after endotracheal intubation. HCAP includes patients with infection developing within 90 days of hospitalization, residents in a nursing home or long-term care facility, or had recent exposure to hemodialysis, intravenous antimicrobial therapy, chemotherapy, wound care, hospital-associated clinics. HAP accounts for up to a quarter of ICU infections. VAP occurs in up to a quarter of intubated patients in some series, generally in the first 4 days of intubation.[20,64,65]

Early-onset (first 3 days) nosocomial pneumonia is more often due to organisms without antimicrobial resistance including *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Community-acquired atypical pathogens (*Mycoplasma, Chlamydophila*) may also be seen early in hospitalization. Beyond 5 days of hospitalization, or in those with recent hospitalization or with prior antimicrobial therapy, infection is more often due to MDR organisms (*K. pneumoniae*, other *Enterobacteriaceae, Acinetobacter* species, and *P. aeruginosa*) and mortality is increased.[64,65] Attributable mortality for nosocomial pneumonia exceeds 50%.

In practice, pneumonia is defined as the presence of new or progressive radiologic infiltrate coupled with evidence that the infiltrate is of infectious origin—fever >38°C, leukocytosis or leucopenia, and/or purulent secretions. Two out of three criteria are generally considered adequate. Tracheal aspirates generally contain the offending organism(s) but may be contaminated by upper tract flora, notably with tracheobronchitis. Semiquantitative cultures are used to discriminate between pathogens and commensals. Gram staining of such specimens will provide added information about host response (neutrophils and macrophages) and predominant bacterial forms. In immunocompromised hosts, fungal smears and cultures, cultures and microscopy for Legionella, Nocardia, and mycobacteria should also be obtained. A good sputum specimen or aspirate lacking bacteria or inflammatory cells (in a nonneutropenic host) should suggest other diagnoses (nonbacterial or noninfectious). While the majority of HAPs are bacterial, nosocomial infection due to respiratory viruses and Legionella species are common. A negative Gram stain of a good tracheal aspirate has a strong negative predictive value (~94%) for VAP.

Use of appropriate antimicrobial agents initially has a major beneficial impact on patient survival.[66] Prior antimicrobial therapy and colonization patterns must be considered as risk factors for antimicrobial-resistant pathogens.[62] The major pathogens in "hospital-acquired" pneumonia vary between institutions and within hospitals. Thus, empiric therapies must be individualized by institution as well by patient. Initially broad-spectrum antimicrobial therapy directed at the likely pathogens (by clinical assessment) and to the major resistant flora of the given institution is likely to avoid inappropriate

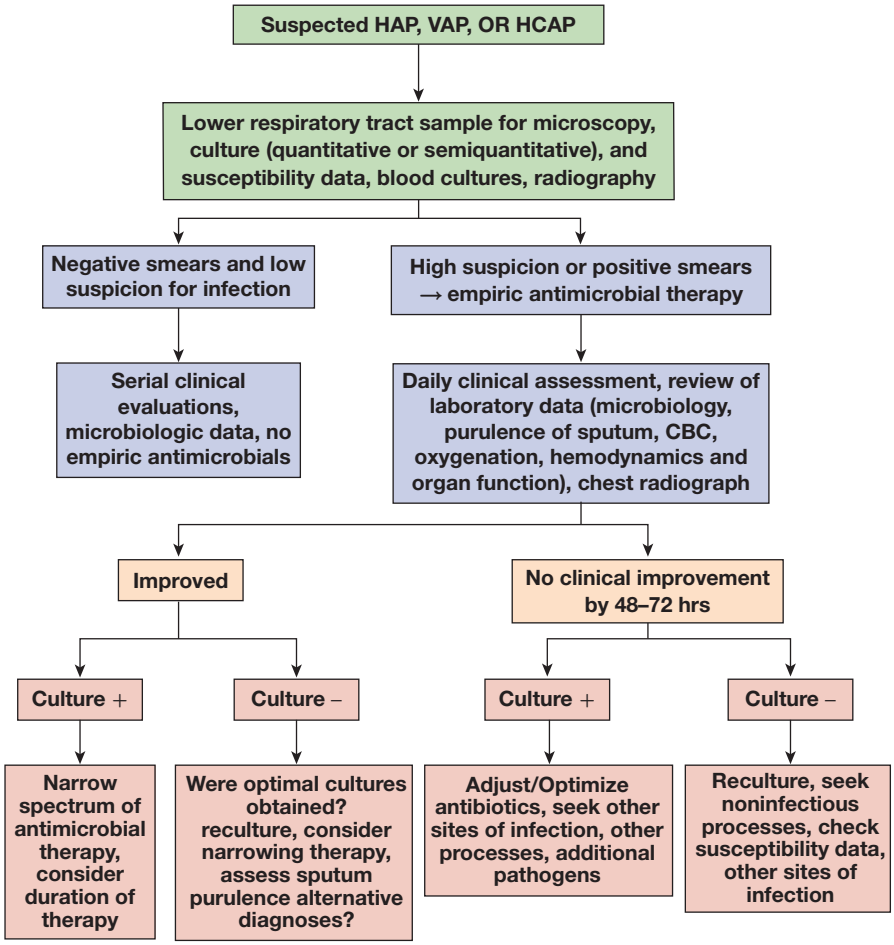

Figure 122-11 Algorithm for the evaluation of patients with nosocomially acquired pneumonia. Careful reassessment of patients on a daily basis is needed to assure an adequate response to therapy. Clinical judgment is the best guide to the use of empiric therapy.

selection of agents. This must be coupled with "de-escalation" of therapy based on culture data. Initial therapy should utilize appropriate doses of bactericidal therapies (including loading doses). If the patient has recently received antimicrobial therapy, drugs from a different class should be used in initial therapy. In normal hosts, sputum Gram stains are useful in gauging response to therapy (disappearance of neutrophils) while chest radiographs and oxygenation are helpful in evaluating response to therapy. Re-evaluation of antimicrobial selections must be made as microbiologic data become available and the clinical progress of the patient is observed.

MDR pathogens provide special challenges. Risk factors for MDR infection include recent hospitalization or antimicrobial therapy, exposure to clinical environment (dialysis, clinic, home intravenous therapy), and immune compromise (see Table 122-9). In intensive care units, *Burkholdaria* (formerly *Pseudomonas*) *cepacia*, *Stenotrophomonas* (formerly *Xanthomonas*) *maltophilia*, and *Acinetobacter baumannii* (formerly *Acinetobacter calcoaceticus* variant *anitratus*) have been implicated in localized outbreaks of nosocomial pneumonia. Combination therapy for gram-negative bacterial pneumonia is generally reserved for two situations: suspected *Pseudomonas* pneumonia or in the initial therapy of nosocomial pneumonia while susceptibility data are pending. Community- and hospital-acquired *S. aureus* is increasingly resistant to beta-lactam antimicrobial agents[58] (MRSA). Both Vancomycin and linezolid are reasonable alternatives for MRSA in this setting.

FAILURE OF THERAPY

Nonresolving pneumonia is observed as a result of inappropriate antimicrobial therapy, superinfection, inadequate host response, obstruction, empyema, noninfectious processes, or recurrent infection.[67] Inappropriate antimicrobial therapy includes inadequate dosing, agents that fail to penetrate infected lung tissue (e.g., aminoglycosides), or use of agents to which the organisms are resistant.[66] Empyema or loculated infection may occur during the course of appropriate therapy for pneumonia. Relapsed infection is common in intubated patients colonized with resistant microorganisms. Superinfection with resistant organisms (including

TABLE 122-9 Factors in the Emergence of Antimicrobial Resistance

Increase in "high-risk" (immunodeficient) population
Prolonged survival of persons with chronic diseases
Greater severity of illness of hospitalized patients
Newer devices and procedures in use
Increased introduction of resistant organisms from the community
Congregate facilities (e.g., jails, day care centers)
Increased use of antibiotics in animals and agriculture
Physician practices that contribute to inappropriate antibiotic use
Providing antibacterial drugs to treat viral illnesses
Using inadequate diagnostic criteria for infections that may have a bacterial etiology
Providing expensive, broad-spectrum agents that are unnecessary
Prescribing antibiotics at an improper dose or duration
Lack of rapid, accurate diagnostic tests to distinguish between viral and bacterial infections
Selection of antibiotic-resistance genes via abuse of antimicrobial agents
Ineffective infection control and isolation practices and compliance

TABLE 122-10 Noninfectious Causes of Febrile Pneumonitis Syndrome (Mimics of Pulmonary Infection)

Drug-induced pulmonary disease
Extrinsic allergic alveolitis
Injury due to inhaled toxic gases, dusts, chemicals
Acute eosinophilic pneumonia
Pulmonary infiltrate with eosinophilia (PIE syndrome)
Chronic eosinophilic pneumonia
Interstitial lung disease associated with autoimmune/connective tissue disorders
Systemic lupus erythematosus
Polymyositis–dermatomyositis
Mixed connective tissue disease
Interstitial lung disease associated with pulmonary vasculitis
Granulomatous polyangiitis (Wegener granulomatosis)
Lymphomatoid granulomatosis
Churg–Strauss syndrome (allergic angiitis and granulomatosis)
Polyangiitis overlap syndrome
Interstitial lung disease associated with airway disease
Allergic bronchopulmonary aspergillosis
Bronchocentric granulomatosis
Bronchiolitis obliterans (OB) and bronchiolitis obliterans with organizing pneumonia (BOOP)
Acute or subacute interstitial pulmonary fibrosis (AIP)
Chronic interstitial pneumonias of unknown origin
Usual interstitial pneumonia (UIP)
Lymphocytic interstitial pneumonia (LIP)
Desquamative interstitial pneumonia (DIP)
Giant cell interstitial pneumonia (GIP)
Pulmonary neoplasms
Sarcoidosis
Pulmonary infarction
Acute chest syndrome in sickle-cell crisis
Radiation pneumonitis
Lipoid pneumonia (exogenous or endogenous)
Acute respiratory distress syndrome (ARDS)
Extrapulmonary sepsis
Oxygen toxicity, chemical inhalation or aspiration, or aspiration of gastric contents
Pancreatitis
Fat embolization (surgery, trauma)
Shock of various etiologies
Drug overdose (aspiration)
Chest trauma
Pulmonary leukoagglutinin transfusion reactions
Pulmonary alveolar proteinosis
Plasma cell granuloma
Eosinophilic granuloma
Idiopathic pulmonary hemosiderosis
Goodpasture syndrome
Miscellaneous

fungi, *M. tuberculosis*) may occur in the hospital setting as well as viral coinfection with community-acquired respiratory viruses. Untreated bacteremia (endocarditis, abdominal abscess, catheter-associated infections) or septic pulmonary emboli may cause persistent lung infections.

In the compromised host, repletion of antibodies, neutrophils (colony-stimulating factor), treatment of concomitant viral infections (HIV, CMV), and repeat culturing may assist in management. Obstruction or empyema must resolve to allow resolution of infection. Recurrent infection may be observed if the patient is aspirating, has sinusitis, has a misplaced feeding tube, has airway compromise, or has pulmonary infarction. Additional cultures and radiologic studies (CT scans) may assist in defining lung processes failing to respond to therapy. Bronchoscopic evaluation and, in selected patients, lung biopsy may assist in management.

NONINFECTIOUS PROCESSES MIMICKING PULMONARY INFECTIONS

The list of noninfectious disorders that mimic pulmonary infections is extensive (Table 122-10). These should be considered in the course of taking the initial history.

The likelihood of noninfectious etiologies of pulmonary disease increases if the Gram-stained smear and culture of sputum are unrevealing, if the initial response to empiric antimicrobial therapy proves unsatisfactory, or if radiographic findings are atypical. Similar histologic appearances result from both infectious and noninfectious etiologies. The presence of a maculopapular skin rash, generalized lymphadenopathy, joint or rheumatologic symptoms, and/or peripheral eosinophilia should suggest hypersensitivity. However, as noninfectious and infectious processes often coexist, it is essential to exclude infectious causes of pulmonary dysfunction before treating (e.g. hypersensitivity reactions). Immunosuppressive agents, notably corticosteroids, will reduce inflammation due to both infectious and noninfectious causes.

CHAPTER 123

Pulmonary Infection in Immunocompromised Hosts

Jay A. Fishman

OVERVIEW

A growing group of individuals who have acquired immunodeficiency syndrome (AIDS), who are receiving immunosuppression for solid-organ transplantation, bone marrow transplantation (BMT), or for autoimmune ("connective tissue" diseases), who have primary immune deficiencies, or who have been treated with chemotherapeutic regimens for cancer, have increased susceptibility to infection as a result of acquired or intrinsic immune deficiencies. Prolonged survival of such immunocompromised individuals reflects the deployment of newer laboratory assays and newer antimicrobial agents, including antifungal, antibacterial, and antiviral agents (e.g., ganciclovir, foscarnet, oral agents) and highly active antiretroviral therapies (HAART) for HIV infection, hematopoietic growth factors, and clinical experience in caring for such patients. Wide use of immunosuppressive drugs, including "biologic agents," which are generally antibodies targeting specific cell types or pathways of inflammation, has further expanded susceptible populations.

Major challenges in providing care to these patients include systemic infections for which therapies or vaccines are limited or absent (e.g., management of respiratory viruses) and progressive antimicrobial resistance of common pulmonary pathogens, including *Staphylococcus aureus*, *Enterococcus*, *Pseudomonas*, *Acinetobacter*, *Stenotrophomonas* (formerly *Xanthomonas*), and *Burkholderia* species. In addition, selection of novel strains of bacteria, including nontuberculous mycobacteria and *Nocardia* species, has proved challenging. Resistance has increased to antimicrobial agents commonly used for prophylaxis (i.e., TMP-SMX and fluoroquinolones).

An essential difference exists in the management of pneumonia in immunocompromised individuals when compared with normal hosts. *Given the broad spectrum of potential pathogens and of noninfectious processes that may mimic infection, coupled with the inherent toxicities of many therapies, a specific microbiologic diagnosis should be considered essential to the management of pulmonary processes in the immunocompromised host.*

GENERAL PRINCIPLES OF MANAGEMENT OF OPPORTUNISTIC INFECTION

Important principles underlying the management of opportunistic infections in immunocompromised patients are discussed below.

Opportunistic infection is defined as infection occurring as a result of compromised immune function and that would not be expected to occur, or would otherwise cause disease of lesser intensity in the presence of normal immune function. Thus, immunocompromised individuals are subject to infections commonly present in the community; however, these infections are likely to be of greater frequency or severity than in the immunologically normal host. In addition, infection in these patients may be caused by organisms of low native virulence or that cause insignificant disease in the normal host, including such organisms as *Pneumocystis jiroveci (PCP)* or cytomegalovirus (CMV).

The risk of infection in any patient is determined by the interaction of two factors: the potential pathogens to which the individual is exposed (epidemiologic exposures), and a measure of the individual's susceptibility to infection, termed the "net state of immunosuppression" (Table 123-1).[1–3] The occurrence of infection in an individual at a time when the immune status of the patient is thought to be nearly normal is evidence that either an excessive environmental exposure has occurred or that the immune status of the individual is depressed. Conversely, even minimal environmental exposures may cause invasive infection in an individual who is maximally immunosuppressed.

EPIDEMIOLOGIC EXPOSURES

Epidemiologic exposures of importance to the immunocompromised patient may be divided into three general categories: those occurring within the community, those occurring within the hospital, and those associated with infection transmitted with donor cells or organs (transplantation). Exposures within the community vary, based on such factors as geography and socioeconomic status, and may be recent or remote in time. Thus, opportunistic pathogens acquired in the community include the geographically restricted systemic mycoses (blastomycosis, coccidioidomycosis, and histoplasmosis), *Mycobacterium tuberculosis, Strongyloides stercoralis, Leishmania donovani, P. jiroveci, Legionella* species, and community-acquired respiratory viral infections (e.g., influenza, adenovirus [AV], respiratory syncytial virus [RSV], parainfluenza virus [PIV], and metapneumovirus). Common viral agents may include herpes simplex virus (HSV), CMV, varicella-zoster virus [VZV], and hepatitis B and C viruses. Due to the limited effectiveness of many vaccines in immunocompromised individuals, infections due to influenza, *Streptococcus pneumoniae,* and *Haemophilus influenzae* are common.

Viral infection
Cytomegalovirus
Epstein–Barr virus
Hepatitis B and C
Human immunodeficiency virus
Respiratory viruses

Within the hospital, excessive environmental exposures may be divided into two general categories: domiciliary and nondomiciliary. Domiciliary exposures occur on the hospital unit where the patient is housed. When the air, food, equipment, or potable water supply is contaminated with pathogens such as *Aspergillus* species, *Legionella* species, or vancomycin-resistant enterococci (VRE), clustering of cases of infection in time and space will be observed. As a result, an increased incidence of nosocomial pneumonia or catheter and wound infections may be seen. Nondomiciliary exposures occur when the patient is transported to contaminated operating rooms, radiology suites, or catheterization laboratories for procedures. Nondomiciliary outbreaks, although possibly more common, are more difficult to detect because of the lack of clustering on a particular hospital unit. The leading clue to the presence of a nosocomial hazard is the occurrence of opportunistic infection in a patient whose net state of immunosuppression would not normally lead to such an event or nosocomial infection with organisms not known to be present on the clinical unit on which the patient is housed.

NET STATE OF IMMUNOSUPPRESSION

The "net state of immunosuppression" (Table 123-1) is a conceptual framework for the host factors that contribute to infectious risk.[1] These include: the dose, duration, and temporal sequence in which immunosuppressive drugs are deployed; injuries to the primary mucocutaneous barrier to infection (e.g., indwelling catheters and drains); leaks and fluid collections (hematoma, effusions, ascites); ischemic or underventilated tissues; surgical anastomoses; neutropenia or lymphopenia; underlying immune deficiency; pulmonary aspiration injury; metabolic problems including protein–calorie malnutrition, uremia, and hyperglycemia; and infection with immunomodulating viruses (CMV, Epstein–Barr virus or EBV, hepatitis B or HBV, and hepatitis C or HCV, influenza, and the human immunodeficiency viruses, HIV). These viruses predispose to other opportunistic infections and also to graft rejection and to graft-versus-host disease (GVHD). Foreign materials (e.g., vascular grafts, heart valves, sutures) provide a nidus for infection for an organism that would not be capable of causing infection under normal conditions. Thus, *Salmonella* infection in the organ transplant recipient "homes" to vascular anastomoses or grafts and may persist despite appropriate therapy, causing mycotic aneurysms.

The sum of the congenital, metabolic, operative, and surgery-related factors is the patient's "net state of immune suppression." Generally, more than one factor is present in each host; the identification of the relevant factors, and correction when possible, is central to the prevention and treatment of infection in these hosts. For example, in the lung transplant recipient with CMV infection and thoracic fluid collections, the net state of immune suppression includes the immunosuppression used to maintain graft function; diminished immunologic responsiveness due to CMV; the risk of empyema and bacteremia from fluid collections at surgical sites; exposure to, and colonization with, community-acquired and nosocomial organisms; and new infections (e.g., aspiration, *Clostridium difficile* colitis) that may occur during the prolonged waiting period for a compatible organ. When the organ for transplantation becomes available, it may carry latent infection (e.g., CMV, EBV) or organisms acquired by the donor during hospitalization (e.g., bacteremia) or procurement. The recipient is often critically ill and is subjected to a major surgical procedure. After surgery, the lungs are apt to be compromised, recovery of function in the allograft is often slow, immunosuppressive drugs are initiated, intravenous and urinary catheters and drains are placed, and major incisions need to heal. Drug toxicities are common and may result in renal dysfunction, confusion, or neutropenia. The sum of the underlying, operative, and transplant-related factors is the *net state of immune suppression*.

Pulmonary defense mechanisms are compromised to varying degrees in immunocompromised hosts (see Chapter 121). Structural defects (fibrosis, airway or lymphatic obstruction by tumor, emphysema) interfere with normal clearance mechanisms. Clearance mechanisms are further impaired by excess mucus and ciliary defects, as in cystic fibrosis, congenital defects, and postlung transplantation, including those due to recent viral or bacterial infections. For example, *Mycoplasma* shears off epithelial cilia, incapacitating the mucociliary elevator. Viral infections may immobilize pulmonary macrophages (CMV), produce local or systemic immunosuppression, and disrupt the local cytokine network. Alveolar macrophages are diminished in number and function in neutropenic hosts and in stem cell transplant (SCT) recipients. These effects are amplified in the lung transplant recipient in whom the impact of systemic immunosuppression is added to the possible effects of tracheal anastomotic narrowing and tissue ischemia, an impaired cough reflex, progressive bronchiolitis obliterans syndrome, decreased pulmonary T-cell and macrophage functions, hypogammaglobulinemia, and disrupted lymphatic drainage. Thus, in the solid-organ transplantation recipient, the immunosuppression used to prevent graft rejection, as well as technical factors, the diminished host immune responses in the major histocompatibility-mismatched organ, and the impact of immunosuppressive viral infections are the main mediators of susceptibility to infection.

In the stem cell recipient, the intensity of immunosuppression varies with the degree of histocompatibility mismatch between donor and recipient. Nonmyeloablative regimens have reduced the duration of the initial period of neutropenia. However, susceptibility to infection in both autologous and allogeneic HCT recipients persists despite immune reconstitution. Innate immune function is reduced early (first 6 months) as NK cells and alveolar macrophages suffer dysregulation of cytokine, eicosanoid (leukotrienes, prostanoids), and intracellular signaling, and alterations in scavenger receptors, resulting in reduced phagocytosis and bacterial and fungal killing. Over time, persistent reductions are observed in multiple T- and B-cell lineages and maintained in the setting of chronic GVHD. T-cell functions are suppressed by the immunosuppressive agents used to prevent or treat GVHD.

TIME LINES OF INFECTION

With standardized immunosuppressive and chemotherapeutic regimens, specific types of infections often occur in a predictable pattern ("time line") as a reflection of the specific risk factors (Figs. 123-1 and 123-2) present at each phase of the posttransplantation course. These time lines are altered by specific immunosuppressive regimens, use of antimicrobial prophylaxis, and individual factors (e.g., underlying immune deficits, microbial colonization, organ dysfunction, epidemiologic exposures), but they are useful in considering the "likely" etiology of infectious syndromes in immunocompromised hosts.

The time lines (Figs. 123-1 and 123-2) are used in a number of ways: (1) To develop a *differential diagnosis* for infectious syndromes by time posttransplant—what type of infections are most likely at various times after transplantation. (2) To develop prophylactic strategies for each patient population based on general considerations (e.g., duration of neutropenia or of T-cell defects) and patient- or institution-specific patterns (e.g., microbial resistance, drug allergies). (3) To identify *excess epidemiologic hazards*, including *nosocomial hazards*, for example, *Aspergillus*, MRSA, VRE, which may be clustered in time and space, by inpatient unit, by procedures, or surgical suite; *community exposures*, for example, respiratory viruses, *Legionella*, other outbreaks (SARS); and *individual risks*, including unique exposures (e.g., hobbies), travel, and occupational hazards. (4) *To assess excessive immunosuppression*—too many infections or unusual severity and/or at the wrong time on

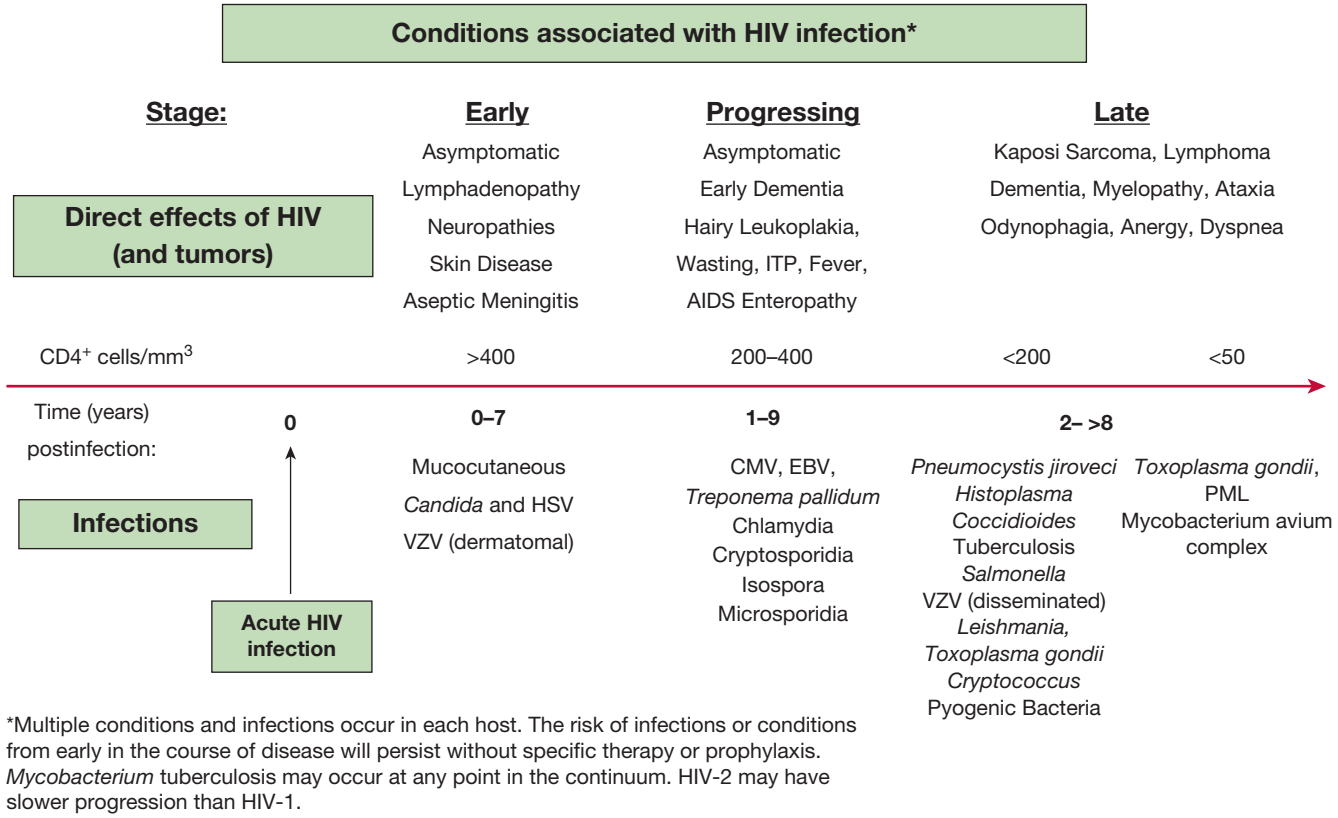

Figure 123-1 The progression of AIDS-associated conditions without effective antiretroviral therapy.

time line suggesting that a problem exists with routine immunosuppressive regimens.

The patterns are altered by antimicrobial prophylaxis, by antiviral therapies for HIV, CMV, and hepatitis B and C viruses, the broader range of immunosuppressive and chemotherapeutic agents, and the use of nonmyeloablative conditioning regimens for HCT. However, the general concepts and major determinants of infection remain the same—the epidemiology of the patient and the intensity of immunosuppression coupled with mucosal injuries and other individual risk factors. Superimposed viral infections will increase the risk of opportunistic infection at any point along the time line.

In immunocompromised hosts, the risks of infection may be *relatively stable* over time, as in the diabetic with vasculopathy and neuropathy who is prone to skin and soft tissue infections. The risks

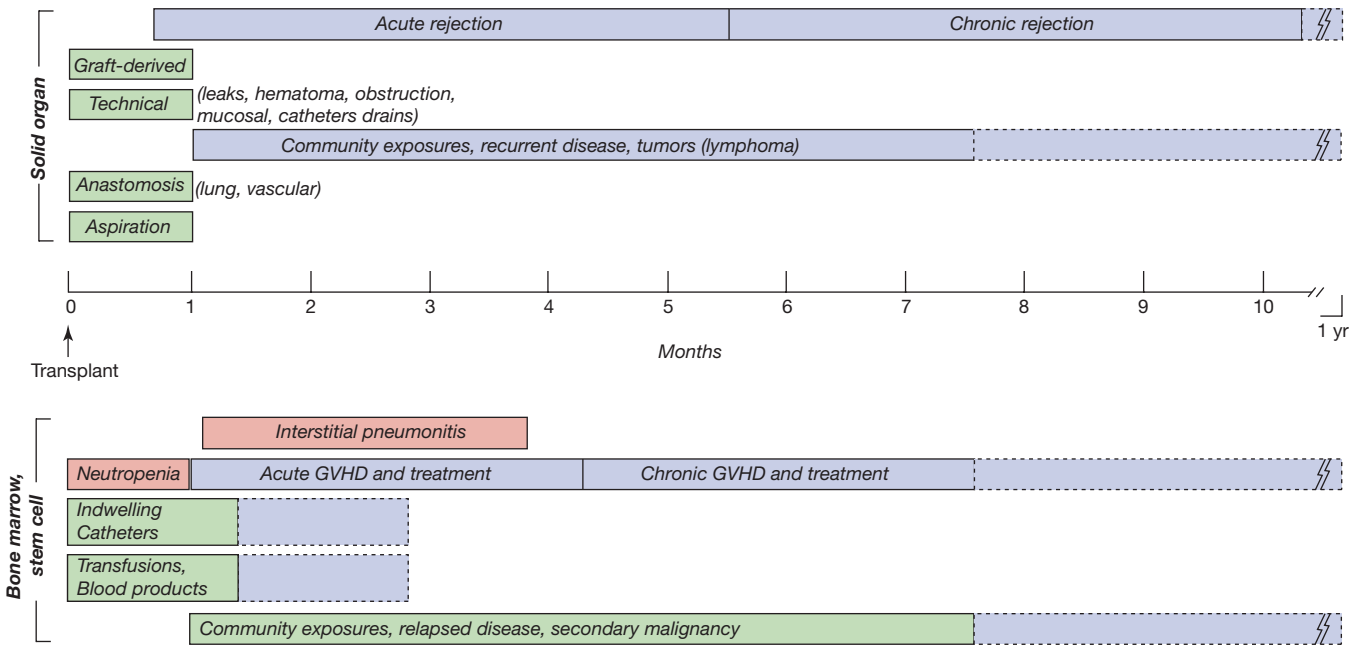

Figure 123-2 The time lines of conditions predisposing to infection in solid-organ transplantation (above the time line) and in bone marrow and stem cell transplantation (below the time line). Patients vary in individual susceptibility patterns and with regard to prophylactic therapies.

TABLE 123-2 Pretreatment Evaluations for Infectious Disease Risk in Immunocompromised Hosts

Anticipated Immune Deficit	Common Serologic and Other Assays	Routine Evaluations
Biologic agents (antibody therapies)	PPD/IGRA-TB, hepatitis A, hepatitis B, MMR, Histoplasma[a], Coccidioides[a]	Chest radiograph (and/or CT)
Solid-organ transplantation	CMV, EBV, HSV, VZV, HBV, HCV, HIV, MMR, PPD/IGRA-TB, Toxoplasma, VDRL, Strongyloides[a], T. cruzi[a], Coccidioides[a], Histoplasma[a]	Chest radiograph (and/or CT), urine cultures, sputum culture[a]
Hematopoietic cell transplant	CMV, EBV, HSV, VZV, HIV, HBV, HCV, T. cruzi[a], PPD/IGRA-TB, VDRL, HTLV, Strongyloides[a], T. cruzi[a], Coccidioides[a], Histoplasma[a], malaria[a]	Chest radiograph (and/or CT), *S. aureus* nasal culture, VRE rectal swab, *Aspergillus* nasal swab, serum galactomannan assay[a]; improved donor HLA matching
HIV/AIDS	HIV, PPD/IGRA-TB, toxoplasma	Chest radiograph (and/or CT), parasitic evaluation[a]

[a]*Where indicated by history.*

IGRA-TB, Interferon-gamma release assay for tuberculosis; CMV, cytomegalovirus; VZV, varicella-zoster virus; HSV, herpes simplex virus; EBV, Epstein–Barr virus; HTLV, human T lymphotrophic virus; VDRL, venereal disease research laboratory; TB, tuberculosis; HBV, Hepatitis B (hepatitis B surface antigen. antibodies to hepatitis B surface antigen antibodies to hepatitis B core antigen) ± viral load; HIV: HIV-1, -2 antibodies ± viral load; VRE, vancomycin-resistant Enterococcus.

of infection may be *time-limited,* as in the postsurgical patient without complications. The risk of infection may be *cumulative and progressive,* as in the untreated patient with AIDS, in whom infection is a function of declining immune function and immune memory, falling CD4– lymphocyte counts, rising viral loads, and the effects of persistent infections (CMV, *Cryptosporidium*) (Fig. 123-1). In these individuals, the occurrence of new types of infection suggests the progression of immune compromise.

The risks of infection may also *change predictably with time* as a function of relatively standardized immunosuppressive regimens and the evolving condition of the patient, as in allogeneic HCT or solid-organ transplantation. For example (Fig. 123-2), in the early phase after bone marrow or hematopoietic cell transplantation or the "pre-engraftment phase," the risk for infection is driven by neutropenia and mucositis and is generally related to nosocomial or endogenous exposures (gram-negative and gram-positive bacteria, *Candida* and *Aspergillus* species) during neutropenia. With nonmyeloablative preparative regimens, this period is generally 14 to 21 days, but it may be significantly longer. This reflects microbial colonization, pre-existing infections, and the impact of vascular access catheters, as well as defects in innate immune function and in mucosal barriers. Subsequently, following marrow engraftment ("early postengraftment phase" of 3 weeks to 3–6 months), but with continued immunosuppression and the absence of full cellular immune function, viral infections predominate, including pneumonitis or colitis (HSV, shingles, CMV, respiratory and enteric viruses), as well as encapsulated bacteria, *Pneumocystis,* and *Aspergillus*. In this period, unusual infections (toxoplasmosis) and endemic pathogens must also be considered. Thus, "common" pathogens might be dengue virus and tuberculosis in Southern Asia, or paracoccidioides and tuberculosis in Brazil. Full immune recovery is not achieved before 12 to 24 months, and gaps in immune function may persist for longer periods. During the development of, and treatment for, acute and chronic GVHD, susceptibility to infection is a function of the intensity of immunosuppression and mucosal injuries (from GVHD, chemotherapy, radiation, or infections such as *C. difficile* colitis). In patients with GVHD in particular, bronchiolitis obliterans, posttransplant lymphoproliferative disorders, and idiopathic pneumonitis syndrome may be observed. Nonmyeloablative conditioning has reduced the rate of diffuse alveolar hemorrhage (early), hepatic veno-occlusive disease (HVOD), and idiopathic pneumonitis syndrome.

In the solid-organ transplant recipient, immunosuppression is used for the life of the transplanted organ. Early (first month) nosocomial infections (surgical and nosocomial) and donor-derived infections are observed but opportunistic infections are not generally observed as the full impact of immunosuppression is not yet appreciated. After a month, as the effects of immunosuppression are maximized, viral infections (CMV, EBV, other herpesviruses, BK polyomavirus, respiratory viruses) predominate, and opportunistic pathogens (*Nocardia*, *Toxoplasma*, *Cryptococcus*, *Pneumocystis*, mycobacteria, and endemic species) are observed. The endemic species include community-acquired infections, such as geographically restricted fungi (*Histoplasma, Coccidioides, Blastomycosis, Paracoccidioides*) and parasites (Chagas', *Leishmania*).

Because each risk factor renders the patient susceptible to infection by new groups of pathogens, infections occurring with the "wrong" pathogen or at the wrong time suggest an undiscovered "immune deficit" (fluid collection, neutropenia) or an unusual epidemiologic exposure (Table 123-2). The occurrence of specific infections can be prevented by the use of antimicrobial prophylaxis, vaccines, and behavioral modifications (e.g., no raw vegetables or digging in gardens without masks). This will result in a "shift to the right" of the time line in that infections are delayed but incompletely prevented unless the intensity of immunosuppression is reduced.

MICROBIAL VIRULENCE

The risk of infection in any individual patient depends not only on the sum of the immune deficits and epidemiologic exposures, but also on the *virulence* of the organism relative to pulmonary defense mechanisms. Innate and adaptive immune responses will be blunted by immunosuppression, but also, when activated by infection, contribute to rejection of lung allografts or to GVHD. Such factors as the distribution of toll-like receptors (TLRs) and other pattern recognition receptors (PRRs), microbial production of biofilm, and antimicrobial resistance patterns will influence the pathogenesis of infection. Host cells may *enhance* the virulence of the invading organism by the *induction of genes in that organism* that contribute to bacterial persistence or invasion. Thus, resistance to phagocytosis is induced by target cells in *Yersinia* infections.

Another example of the host–pathogen interaction is the role of CMV in transplantation. CMV is the cause of common clinical syndromes in immunocompromised patients. Among these are fever and neutropenia, pneumonitis, hepatitis, glomerulonephritis, gastritis, colitis, retinitis, and mononucleosis-like syndromes. CMV also induces an array of host responses (i.e., immune suppression,

TABLE 123-3 Infections Associated with Specific Immune Defects

Defect	Common Causes	Associated Infections
Granulocytopenia	Leukemia, cytotoxic chemotherapy, AIDS, drug toxicity, Felty syndrome	Enteric gram-negative bacteria, Pseudomonas, S. aureus, Staphylococcus epidermidis, streptococci, Aspergillus, Candida, other fungi
Neutrophil chemotaxis	Diabetes, alcoholism, uremia, Hodgkin disease, trauma (burns), lazy leukocyte syndrome, CT disease	S. aureus, Candida, streptococci
Neutrophil killing	CGD, myeloperoxidase deficiency	S. aureus, E. coli, Candida, Aspergillus, Torulopsis
T-cell defects	AIDS, congenital, lymphoma, sarcoidosis, viral infection, HCT, solid-organ transplants, steroids, purine analogs (fludarabine)	Intracellular bacteria (Legionella, Listeria, mycobacteria), HSV, VZV, CMV, EBV, parasites (Strongyloides, Toxoplasma), fungi (P. jiroveci, Candida, Cryptococcus)
B-cell defects	Congenital/acquired agammaglobulinemia, burns, enteropathies, splenic dysfunction, myeloma, ALL	S. pneumoniae, H. influenzae, Salmonella, and Campylobacter spp., Giardia lamblia, gram negative (E. coli, skin)
Splenectomy	Surgery, sickle-cell anemia, cirrhosis	S. pneumoniae, H. influenzae, Salmonella spp., Capnocytophaga canimorsus
Complement	Congenital/acquired defects	S. aureus, Neisseria spp., H. influenzae, S. pneumoniae, Capnocytophaga
Anatomic	IV/Foley catheters, incisions, anastomotic leaks, mucosal ulceration, vascular insufficiency	Colonizing organisms, resistant nosocomial organisms

upregulation of histocompatibility antigens and other cell surface antigens, tumor necrosis factor alpha (TNFα) secretion, diminished antigen presentation, graft rejection) that contribute to the host's susceptibility to infection.[4] This is the result of "viral parasitism"—alterations in the target cell including decreased mobility, phagocytosis, and apoptosis, to assure the survival of the virus. Thus, the concept of "immune status" and "epidemiologic exposure" may require modification based on the virulence and immunoregulatory effects of some pathogens.

The incidence of antimicrobial resistance among bacteria, fungi, and viruses is amplified in the immunocompromised host due to repeated exposures to antimicrobial therapies (often for excessive periods at inadequate doses) and repeated hospitalizations. Increasingly, *Streptococcus* and other gram-positive species are detected with resistance to penicillins, fluoroquinolones, and macrolides. Enterococci are resistant to β-lactam antimicrobials, macrolides, vancomycin, teicoplanin, linezolid, quinupristin-dalfopristin, and aminoglycosides. *Pseudomonas, Stenotrophomonas,* and the enteric gram-negative bacteria are often resistant to fluoroquinolones and the broad-spectrum carbapenems. *Candida* and *Aspergillus* species may be resistant to the azole antifungals.

PRETREATMENT EVALUATION AND PROPHYLAXIS

Guidelines for the prevention of infection in common immunodeficiency states are available for HCT, solid-organ transplantation, and AIDS.[5–10] The clinical *evaluation of the patient prior to immunosuppression* may be very helpful in preventing disease (Table 123-3). This evaluation should include a careful epidemiologic history (travel, immigration, exposures including tuberculosis, HIV, endemic fungi and *S. stercoralis*), a vaccination history including *Pneumococcus* and *H.* influenza, varicella zoster, measles, mumps and rubella, diphtheria, pertussis and tetanus, and hepatitis B, exposure to Bacillus Calmette-Guerin (BCG), and chest radiography. Testing for tuberculosis (skin test or interferon-gamma release assay, IGRA) should be routine. Careful evaluation (baseline chest computed tomography [CT] scans) and pretreatment of PPD-positive patients and patients from areas endemic for tuberculosis are advised before HCT and common in solid-organ recipients. *Live virus vaccinations should be avoided in immunocompromised hosts and are best provided well in advance of immunosuppression.* Pretransplant cultures may guide prophylaxis and establish the presence of antimicrobial susceptibility patterns in advance of invasive infection. Serologic studies are often helpful in the stratification of risk for infection in the immunocompromised host (see Table 123-3). The use of CMV seronegative blood products in seronegative individuals may avoid acute infection during periods of intensive immunosuppression.[11]

Given the routine use of antimicrobial prophylaxis in the face of persistent immune defects, infection remains common due to organisms that are resistant to the agents employed. Prophylaxis falls into three categories: (1) Primary or universal prophylaxis in which all at-risk patients receive an agent to prevent common infections (TMP–SMX for *Pneumocystis*). (2) Secondary prophylaxis initiated after treatment to maintain remission or prevent recurrence. (3) Preemptive therapy in which a sensitive diagnostic assay is used for screening with treatment initiated based on the presence of a positive assay to avoid progression of disease. Oral agents including TMP-SMX, fluoroquinolones, acyclovir (and related agents), and azole antifungal drugs have widespread use in the management of immunosuppressed hosts. Oral decontamination regimens (i.e., nonabsorbable antimicrobials) have not been proven to prevent disease beyond limited periods of time, and are poorly tolerated because of taste, consistency, malabsorption of glucose and xylose bases, and cost.

INITIAL MANAGEMENT OF THE IMMUNOCOMPROMISED HOST WITH INFECTIOUS SYNDROMES

Infections in immunocompromised hosts often present without the expected signs and symptoms of infection. The presence of nonspecific clinical manifestations may delay identification of the critically ill patient. In the outpatient setting, the practitioner must have a low threshold for performing diagnostic tests (e.g., blood counts, cultures, radiographs) on patients with minimal symptoms. Appropriate cultures and invasive studies such as bronchoscopy or biopsy are best performed early in the course of possible infection and prior to the initiation of antimicrobial therapy.[12] The handling of clinical samples is outlined in Table 123-4 and in Figure 123-3. In practice, most febrile or possibly infected immunocompromised patients are treated empirically while awaiting data that identify specific pathogens. The selection of empiric therapy depends on the nature and intensity of the patient's immune deficit(s), risk for poor outcome (severe neutropenia, sepsis), the likely sites of infection, antimicrobial susceptibility patterns at the institution, and the toxicities and cost of the appropriate regimen. Synergistic

TABLE 123-4 Routine Laboratory Evaluation of Bronchoalveolar Lavage Specimens in Immunocompromised Hosts

Assays (molecular, ELISA, fluorescence, culture) for:
Cytomegalovirus (consider resistance testing)
Herpes simplex virus
Adenovirus
Respiratory syncytial virus
Influenza
Parainfluenza
Metapneumovirus
Endemic viruses (e.g., SARS, West Nile)

antimicrobial therapy for known or suspected pathogens must be used when available. *Agents or classes of agents used for prophylaxis should not be used for therapy of possible break-through infection*. Compromises are often made; loss of renal function will significantly hinder patient management. Thus, a balance is often made between optimal empiric therapy (e.g., empiric broad-spectrum antifungal therapy with lipid amphotericin vs. other agents) and other aspects of patient management. However, progression of infection while on static or inadequately dosed antimicrobial agents must be avoided.

Clinical signs predicting poor outcomes mitigate to broader initial therapy (e.g., including antifungal or antiviral agents) with adjustment based on microbiologic data at 24 to 72 hours and after the patient is stabilized. These worrisome signs include hypotension, newly altered mental status, meningitis, or encephalitis, diffuse or necrotic skin lesions, bleeding diathesis or new thrombocytopenia, vascular thrombosis, hypoxemia, typhlitis or acute abdomen, severe hyperglycemia, pancreatitis, or lactic acidosis, hypercalcemia, perirectal abscess, gas gangrene, or Fournier gangrene. The radiologic appearance of pneumonia is altered by immune suppression (Fig. 123-4). Radiographic patterns may also change during the care of the patient (e.g., cavitation of pulmonary nodules after the resolution of neutropenia).

Antimicrobials alone may not suffice in the treatment of infection in the immunocompromised host.[9] Infections may respond to a decrease in exogenous immune suppression, to correction of neutropenia by growth factors, or to treatment of simultaneous infections that predispose to superinfection (e.g., RSV, CMV). It should be noted that cessation of corticosteroids may provoke adrenal corticosteroid insufficiency with associated hypotension and metabolic complications. Similarly, cessation of immunosuppression may provoke GVHD or graft rejection or flares in other underlying diseases, and immune reconstitution syndromes will unnecessarily complicate the management of pneumonia and other processes.

Drainage of collections of infected fluid such as empyemas, hematomas, or lymphoceles, or removal of drains or catheters will enhance the clinical response. Identification of metastatic sites of infection (e.g., infections spreading from the lungs to the central nervous system due to *Nocardia, Aspergillus,* or *Cryptococcus* species) may facilitate diagnosis and management. The identification of *new* infectious disease syndromes has occurred in individuals with immune deficits. Thus, the cluster of cases of *P. jiroveci* pneumonia in homosexual males was the first indicator of a new viral pathogen (HIV-1), and the role of *Cryptosporidium* as a common cause of diarrhea in both normal and compromised individuals was elucidated as a result of diarrheal disease in AIDS patients in the 1980s. Similarly, many uncommon bacteria *(Bartonella species, Rhodococcus equi)*, viruses (Kaposi sarcoma-associated herpesvirus/human herpesvirus 8, polyomaviruses, SARS coronavirus), fungi *(Penicillium, Scedosporium)*, and parasites *(Microsporidia)* have been identified in immunocompromised patients. Thus, continuing consideration of new pathogens or novel presentations of known pathogens is essential for the care of the immunocompromised patient.[13]

RECOGNITION OF CONCOMITANT NONINFECTIOUS PROCESSES

The occurrence of multiple simultaneous infections or conditions often complicate and delay appropriate therapy (Fig. 123-4). For example, CMV infection may complicate the treatment of graft rejection or GVHD and contribute to the pathogenesis of *Pneumocystis* or *Toxoplasma* pneumonia. In the compromised host with fever and pneumonitis, chest radiographs may be difficult to interpret. Noninfectious causes of pulmonary infiltrates may coexist with infection, and atypical patterns predominate. Drug toxicities (bleomycin, cyclophosphamide, sulfa drugs), leukoagglutinin reactions, engraftment or immune reconstitution syndromes, radiation injury, pulmonary emboli, and lesions of metastatic cancer may coexist with opportunistic infection (Fig. 123-5). The "typical" evolution of pulmonary infection may be altered by the presence of underlying (e.g., interstitial) pulmonary disease, as well as by diminished inflammatory responses. It is commonly necessary to repeat tests, to utilize CT, or to use invasive diagnostic modalities (biopsy) in the evaluation of the patient who is unresponsive to therapy. Complications of therapy may contribute to the development of new infections: TMP-SMX can cause pneumonitis, hepatitis, or Stevens–Johnson syndrome; ganciclovir can cause neutropenia; transfusion reactions can cause pulmonary infiltrates and hemolysis; cyclosporine can cause hemolytic-uremic syndrome; and antimicrobials can contribute to thrush and *C. difficile* colitis.

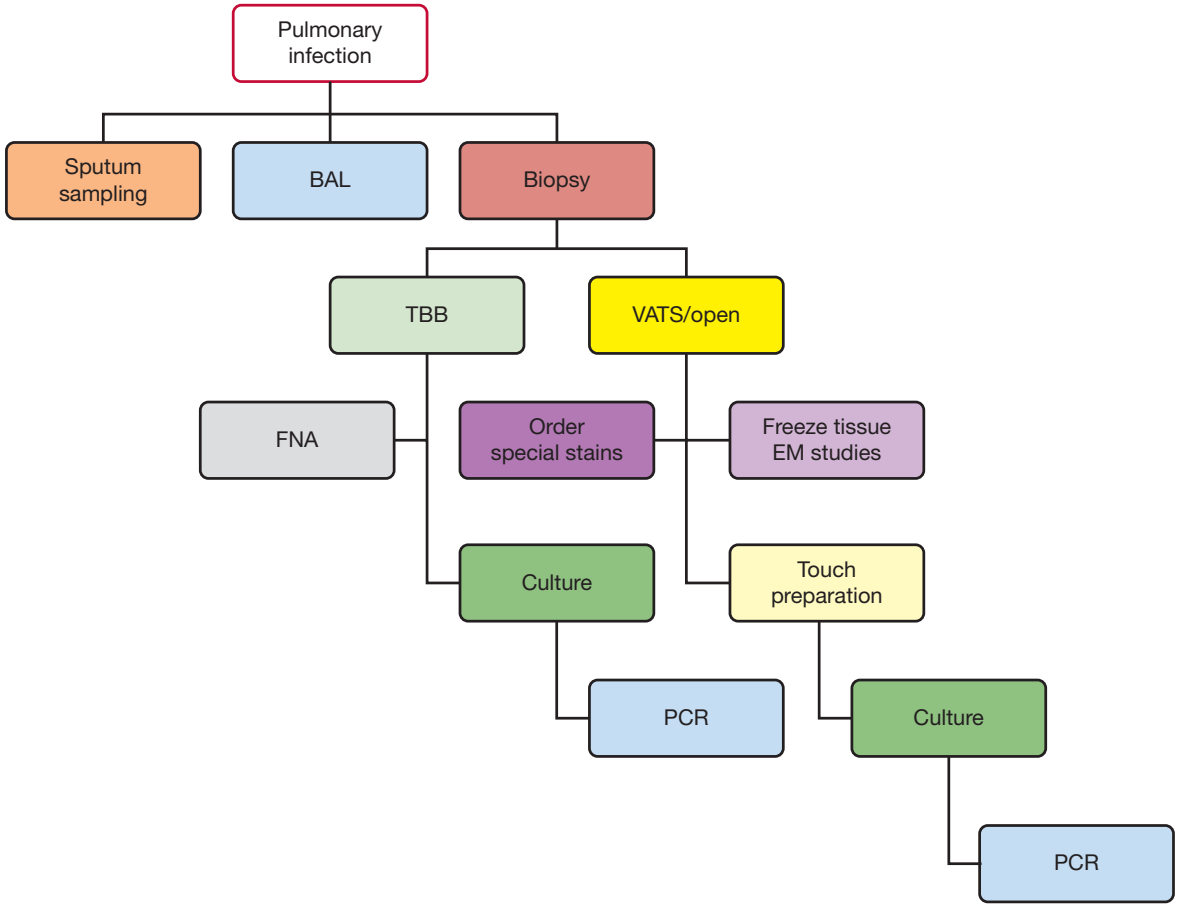

Figure 123-3 The diagnostic workup of pulmonary infection.

Figure 123-4 Chest radiograph of a 48-year-old heterosexual man with community-acquired pneumonia unresponsive to therapy. The patient was diagnosed as having AIDS on the basis of HIV seropositivity, CD4+ lymphocyte count of 113 per milliliter, and *P. jiroveci* and *Mycobacterium avium-intracellulare* complex pneumonia.

HIV INFECTION AND AIDS

The spectrum of common infections varies with specific immune defects in each type of host (Table 123-2), including HIV infection.

The management of HIV infection has been dramatically altered for those individuals with access to combinations of drugs in "highly active antiretroviral therapies" or HAART.[14,15] Prior to therapy, there is marked variability in the pattern of disease progression with viral load reaching a near steady state by approximately 6 months after infection. Rapid loss of CD4+ lymphocytes correlates with HIV viral load and precedes waning humoral immunity.[16–23] Of note, B cells demonstrate activation and proliferation with nonspecific polyclonal hypergammaglobulinemia. Thus, susceptibility to bacterial infections and recurrent pneumonia rises with deficiency in the production of specific antibodies. The degree of immunodeficiency correlates with loss of CD4+ cells with untreated progression to AIDS occurring within 8 to 10 years; levels of less than 50/mm^3 have a median survival of less than 2 years.

Underlying lung disease is common in HIV-infected patients even before the development of opportunistic infection. While FEV_1 and FVC are nearly normal, 11% to 13% of patients with CD4+ lymphocyte counts below 200/mm^3 or with a history of AIDS-associated extrapulmonary diseases (including thrush and varicella-zoster infections) and weight loss have decreased D_{LCO} measurements. Intravenous drug users have a higher incidence of abnormal FVC, FEV_1, and D_{LCO} measurements (33.3%), consistent with patterns of cigarette smoking and racial distribution. Thus, susceptibility to pulmonary infection is further exacerbated in this population.

One of the features of HAART is a syndrome of inflammatory responses referred to as the "immune reconstitution syndrome,"

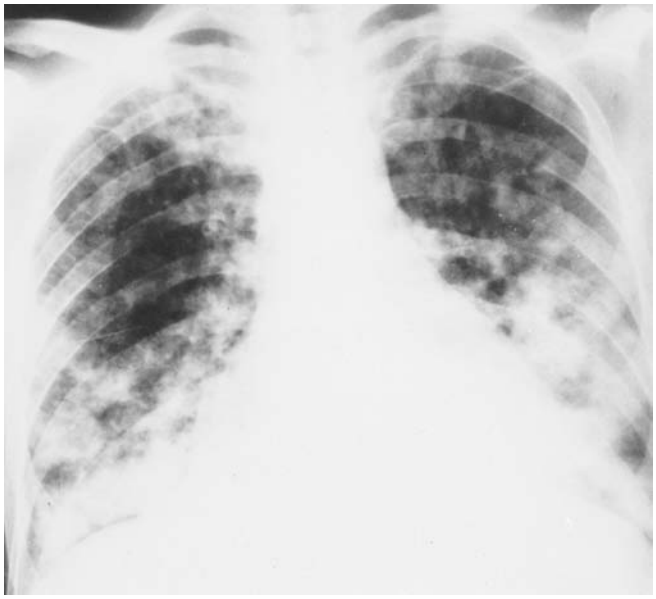

Figure 123-5 Chest radiograph of a 36-year-old homosexual man not known to be HIV-1 infected, with bilateral nodular infiltrates due to pulmonary Kaposi sarcoma.

which generally occurs within the first 3 months of starting effective antiretroviral therapy. This is thought to represent a hyperacute response to pathogens to which the HIV-infected individual has been exposed. It has been observed in *P. jiroveci* pneumonia, CMV retinitis and vitritis, disseminated *Mycobacterium avium* complex (MAC), tuberculosis, and histoplasmosis as pneumonitis and lymphadenitis, cryptococcosis with meningitis, hydrocephalus, and necrotizing lymphadenitis, and with acceleration of hepatitis C virus infection including cryoglobulinemia and renal failure. Thus, effective antiviral therapy may result in more intense symptoms and unusual manifestations of some opportunistic infections while the overall incidence of new infections has declined.

For adults and adolescents (i.e., persons aged ≥13 years), the surveillance case definitions for HIV infection and AIDS were revised into a single case definition for HIV infection in 2008 that includes AIDS and incorporates HIV infection staging classification system.[24] A confirmed case meets the laboratory criteria for diagnosis of HIV infection and one of the four HIV infection stages (stage 1, stage 2, stage 3, or stage unknown).

- **HIV infection, stage 1:** No AIDS-defining condition and either CD4+ T-lymphocyte count of ≥500 cells/μL or CD4+ T-lymphocyte percentage of total lymphocytes of ≥29.
- **HIV infection, stage 2:** No AIDS-defining condition and either CD4+ T-lymphocyte count of 200 to 499 cells/μL or CD4+ T-lymphocyte percentage of total lymphocytes of 14 to 28.
- **HIV infection, stage 3 (AIDS):** CD4+ T-lymphocyte count of <200 cells/μL or CD4+ T-lymphocyte percentage of total lymphocytes of <14, or documentation of an AIDS-defining condition. Documentation of an AIDS-defining condition supersedes a CD4+ T-lymphocyte count of ≥200 cells/μL and a CD4+ T-lymphocyte percentage of total lymphocytes of ≥14.
- **HIV infection, stage unknown:** No information available on CD4+ T-lymphocyte count or percentage and no information available on AIDS-defining conditions.

Anti-HIV therapy should be started before the immune system is irrevocably compromised. Most practitioners are treating all individuals with progressive HIV infection, and all HIV-infected individuals with CD4 counts below 200/mm^3. HAART has resulted in the recrudescence of immunity as manifested by rising CD4+ lymphocyte counts and diminished signs of opportunistic infection and cancer associated with severe T-cell deficits. In treated individuals, this has reduced the incidence of AIDS, AIDS-defining diagnoses, hospitalizations, and mortality by 60% to 80%. Treatment of HIV infection appears to virtually eliminate the risk of *Pneumocystis* pneumonia in AIDS patients with and without prior *Pneumocystis* pneumonia. The risk of MAC, tuberculosis, and CMV has also decreased. Thus, prophylactic (both primary and secondary) and therapeutic regimens must be considered in light of the individual's immune status. Not all patients respond to HAART or maintain viral suppression during therapy. The specifics of antiviral therapy will not be considered here.

HIV TESTING

HIV testing should be considered for all persons either in high-risk groups or with unusual infections (Table 123-5). High-risk groups include intravenous drug users, sexually active homosexual or bisexual men, hemophiliacs or individuals who have required blood or clotting factors, persons with sexually transmitted diseases (especially syphilis), people with heterosexual contacts with one of these increased risk groups, pregnant women or newborns with such contacts, healthcare workers with exposure to body fluids or needle stick injury, and all patients with conditions commonly associated with AIDS.

Testing for HIV infection is generally divided into viral culture assays (uncommon now that molecular resistance tests are available), antibody tests (Western blots), and specific, quantitative (molecular) viral tests including molecular antiviral susceptibility testing. Most patients produce antibodies to HIV within 6 to 8 weeks, and almost 100% will have detectable antibodies by 6 months after exposure. These tests are well standardized and easy to perform, but are troubled by false positives (cross-reacting antibodies) and false negatives (e.g., in the early or "window" period). Between 4% and 20% of Western blot tests are *indeterminate* because of seroconversion in progress, loss of antibody in advanced HIV disease, cross-reacting antibodies in pregnancy, blood transfusions, autoantibodies from collagen vascular disease, infection with HIV-2, recent influenza vaccination, or in recipients

TABLE 123-5 AIDS-Defining Diagnoses[a]

Diagnosis	Incidence (%)
Pneumocystis pneumonia	42.6
Thrush— esophageal candidiasis	15.0
Kaposi sarcoma	10.7
Wasting syndrome	10.7
Mycobacterium avium complex infection	4.8
Tuberculosis	4.5
Cytomegalovirus	3.7
Dementia	3.6
Recurrent bacterial pneumonia	3.0
Toxoplasmosis	2.6
Lymphoma—immunoblastic	1.9
Cryptosporidiosis	1.5
Burkitt lymphoma	1.5
Histoplasmosis	1.0
Cervical cancer—invasive	0.9
Herpes simplex infection	0.5

[a]*Local epidemiology is a major determinant of infectious risk.*

of trial HIV vaccines. These subjects should be retested and inconclusive assays resolved with specific viral (molecular, p24 antigen, or culture) testing. *Specific viral tests* include the p24 antigen detection, molecular amplification by PCR, and culture-based assays. These are positive earlier than the antibody tests and therefore may be useful in primary infection before the development of antibody; they have high sensitivity (95%–99%). Quantitative techniques are very useful in assessing the response to antiviral therapy and disease progression.

Measures of HIV viral RNA in plasma may not correlate with the CD4+ lymphocyte count. The CD4 count provides a surrogate marker for the response to antiviral therapy and the risk of opportunistic infection and death. At present, the best predictive value of testing is the combination of viral load with CD4+ lymphocyte enumeration. Viral RNA levels in long-term nonprogressors are consistently under 10,000 copies/mL, while progression and immunologic deterioration are often associated with loads over 50,000 to 100,000 copies. Patients with viral loads of 10,000 to 50,000 are considered at intermediate risk. Viral load changes generally precede CD4 count changes. Immune alterations due to infection (e.g., CMV) or immune modulation therapy (interferons) are not yet interpretable.

IMMUNIZATION

Immunization is a part of the routine management of AIDS. In general, HIV-infected persons are susceptible to the same community-acquired respiratory pathogens as the normal host but with a greater severity of disease. Thus, patients should be vaccinated early in the course of disease when they are clinically stable. Live vaccines are generally contraindicated, but measles vaccine is generally well tolerated in children, and MMR is recommended for unvaccinated adults born after 1957 or vaccinated between 1963 and 1967. The efficacy of vaccination in this population is not clear; HIV viral loads may temporarily increase after vaccination. However, general practice suggests that pneumococcal, influenza (inactivated whole virus and split virus vaccines), *H. influenzae,* hepatitis B recombinant vaccine, and MMR be given as indicated.

OPPORTUNISTIC INFECTIONS IN AIDS

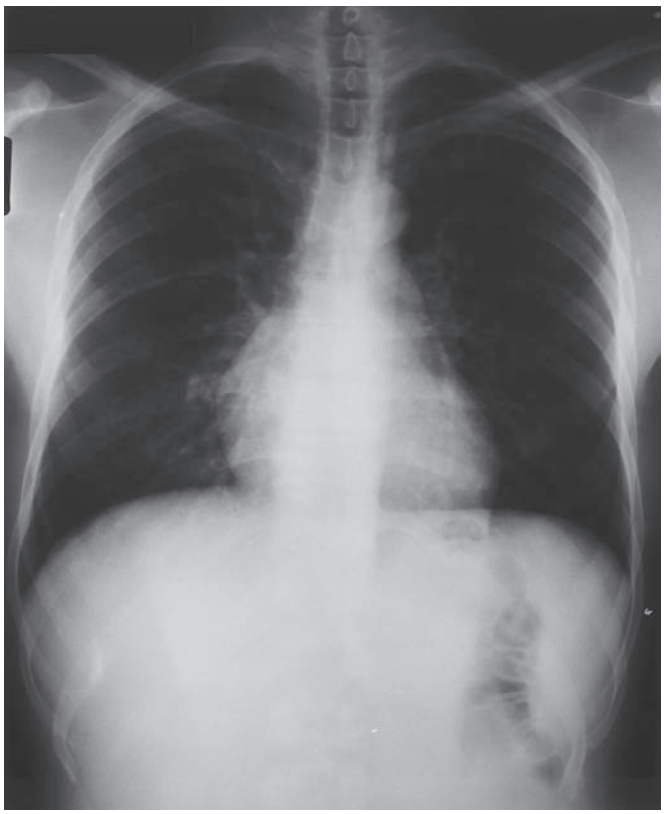
The problem of opportunistic infection in the untreated or newly diagnosed AIDS patient is unique because of the *progressive decline* in immune function when compared with the intermittent compromise seen after chemotherapy or the relatively stable immunosuppression utilized after solid-organ transplantation (Table 123-6). As a result of the progressive and cumulative risks, the incidence of opportunistic infections *increases* over time. A "time line" exists for the common infections and noninfectious manifestations seen in progressive AIDS, relating to the total CD4+ lymphocyte count as a measure of susceptibility (Fig. 123-1). In an individual, the time line is also related to the patient's viral load, but an exact correlation does not exist. The specific pattern of opportunistic syndromes will change for individual patients, but it reflects the overall progressive immunological deterioration of untreated AIDS.

Many opportunistic pulmonary infections in AIDS patients were initially assumed to be reactivation of latent infection. However, some of these processes – including *P. jiroveci, Toxoplasma gondii,* tuberculosis, and histoplasmosis – represent a mix of both new exposures and old disease. Similar observations have been made in terms of the drug susceptibility of mycobacterial isolates in recurrent disease (see Chapter 131) (Fig. 123-6). The clinical manifestations of opportunistic infections in AIDS are altered by prophylactic and therapeutic regimens, adverse drug reactions, and drug interactions. Toxicities of both prophylactic and therapeutic drug regimens (particularly rash, marrow suppression, and hepatic toxicities) are much more frequent in HIV-infected patients and are exacerbated by the simultaneous use of antiviral therapies.

TABLE 123-6 Infectious Agents and Syndromes Commonly Associated with AIDS

Viral (with HIV-1, HIV-2)
Cytomegalovirus (retinitis, colitis)
Herpes simplex (persistent mucocutaneous ulcer, bronchitis, pneumonia, esophagitis)
Varicella zoster
Epstein–Barr virus (lymphoma, CNS lymphoma)
Parvovirus B19
HHV-6
HHV-8 (Kaposi sarcoma)
HTLV-1, HTLV-2
HIV-associated wasting syndromes or dementia
JC virus (progressive multifocal leukoencephalopathy)
Parasitic
T. gondii
Cryptosporidium (persistent diarrhea >1 mo)
Isospora belli (persistent diarrhea >1 mo)
Microsporidium
Cyclospora
Strongyloides (extraintestinal)
Fungal
Candida species (thrush, vaginitis, tracheitis)
C. neoformans (extrapulmonary)
Histoplasma capsulatum (extrapulmonary, marrow, gastrointestinal)
Blastomyces dermatitidis
Aspergillus species
Petriellidium boydii
Coccidioides immitis (extrapulmonary)
Paracoccidioides species
Penicillium species
P. jiroveci
Sporothrix schenckii
Bacterial
Campylobacter species
Mycobacterium avium-intracellulare complex, *Mycobacterium kansasii* (disseminated, bacteremia, marrow)
M. tuberculosis (pulmonary or disseminated)
Legionella species
Nocardia species
Encapsulated gram-positive bacteria
Salmonella species (nontyphoid, recurrent bacteremia)
R. equi
Bartonella species
Other
Lymphoma (non-Hodgkin's or B cell or unknown phenotype, small, noncleaved lymphoma, immunoblastic sarcoma)
Pneumonia—recurrent bacterial
Cervical cancer, invasive

Primary prophylaxis in AIDS patients who maintain CD4+ lymphocyte counts above 200/mm^3 for over 3 to 6 months and with low or undetectable viral loads appears to be unnecessary, at least for *P. jiroveci* and mycobacterial infections.[25] For individuals with CD4+ lymphocytes below 100/mm^3 the incidence of PCP is



A

B

Figure 123-6 Chest radiographs of a 39-year-old man with AIDS on zidovudine, ritonavir, and TMP-SMX prophylaxis, and with a CD4+ lymphocyte count of 89 per milliliter. The patient presented to the outpatient clinic with low-grade fever, fatigue, and mild cough. **A.** Physical examination and chest radiograph were unremarkable. The patient was anergic on both PPD and control skin testing. Induced sputum examination was negative for bacteria, for *P. jiroveci,* and by mycobacterial stains. Blood cultures for mycobacteria were obtained. **B.** Ten days after initial presentation, the patient was admitted to the hospital with minimal dyspnea and cough; chest radiograph was remarkable for bilateral pulmonary reticulonodular infiltrates. Bronchoalveolar lavage samples were positive for mycobacteria. The organisms were subsequently identified from cultures of both blood and sputum as *M. tuberculosis,* resistant to both isoniazid and ethambutol. Induced sputum sample cultures remained negative for mycobacteria.

40% to 50% and toxoplasmosis 33% per year without prophylaxis. TMP–SMX prophylaxis (a single strength tablet daily) prevents most toxoplasmosis and nocardiosis, listeriosis, salmonellosis, and other common infections.[26–29] For MAC, prophylaxis should be considered for HIV-infected individuals with less than 50 to 100/mm^3 CD4+ lymphocytes with azithromycin (or clarithromycin).[30,31] For other infections and secondary prophylaxis, the data are less clear. Up to 15% to 20% of AIDS patients have more than one opportunistic infection at one time. The spectrum of clinical diagnoses in pulmonary disease in AIDS includes bacterial infection (45.5%), *P. jiroveci* pneumonia (27%), Kaposi sarcoma (7%), bronchitis (5%), *M. tuberculosis* (4.3%), other mycobacteria (4%), lymphoma (2.1%), and a variety of other processes. Common community-acquired upper respiratory infections, manageable on an ambulatory basis, constitute more than 50% of respiratory illnesses in HIV-infected persons. The incidence of fungal infections varies by geographic region, while the rate of demonstration of viral pulmonary infection is closely related to the diagnostic testing techniques used at each center and to seasonal variation.

APPROACH TO THE DIAGNOSIS OF OPPORTUNISTIC PULMONARY INFECTIONS IN AIDS

With the wide array of potential pathogens causing disease in HIV-infected patients, the frequency of atypical and multiple infections, and the urgency to diagnosis of infection in the immunocompromised host, a systematic approach to lung disease in these hosts is imperative. A few general rules are useful.

1. *Prophylaxis is generally effective.* When failure of prophylaxis occurs, it is usually due to noncompliance, malabsorption of drugs, emerging antimicrobial resistance, or coinfection or tumor that alters the local environment. For example, it is often impossible to eradicate *Candida* esophagitis unless erosive esophageal HSV infection is also treated. *Pneumocystis* is difficult to treat in the presence of CMV infection or bronchial obstruction.
2. Specific therapies for individual infections have a *high incidence of adverse reactions in the HIV-infected patient.* Thus, presumptive or empiric therapy without microbiologic confirmation, though often appropriate, has a greater risk in this population than in the normal host.
3. The *utilization of newer diagnostic tests* has improved the care of AIDS patients. The interpretation of some tests is unclear, and the availability of some tests (urinary *Histoplasma* antigen or immunoperoxidase stains for *T. gondii*) is not universal. The *induced sputum examination* has been useful in the early, noninvasive diagnosis of *Pneumocystis* infection, and for mycobacterial disease in the absence of spontaneous sputum production. The sensitivity of sputum induction for *Pneumocystis* infection approaches 90%, but the negative predictive value of the test is only 50%. The cost and sensitivity of this procedure cannot be justified for the routine diagnosis of bacterial infections,

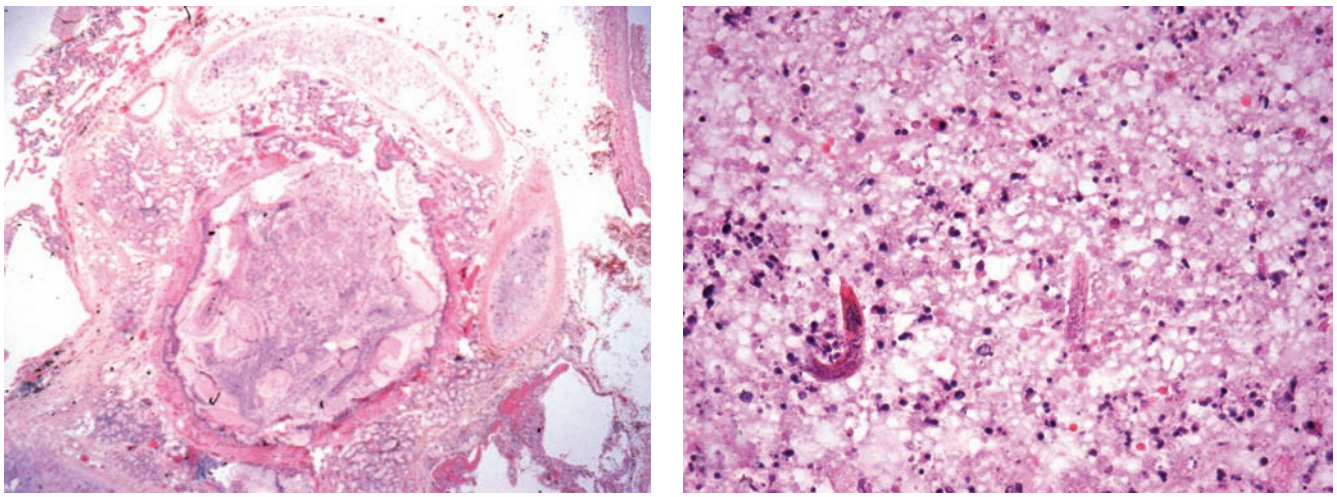
TABLE 123-7 Roentgenographic Findings in Opportunistic Pulmonary Diseases in AIDS

Diffuse Infiltrates	Cavitary Lesions	Hilar Adenopathy	Focal Infiltrates	Nodular Lesions	Pleural Effusions
P. jiroveci	Tuberculosis	Tuberculosis	Legionella sp.	C. neoformans	Tuberculosis
Tuberculosis	Pyogenic bacteria	Lymphoma	Tuberculosis	H. capsulatum	Fungal
T. gondii	Aspergillosis	Kaposi sarcoma	P. jiroveci	Tuberculosis	Pyogenic
H. capsulatum	C. neoformans	C. neoformans	S. pneumoniae	P. jiroveci	Lymphoma
				Kaposi sarcoma	Kaposi sarcoma
P. jiroveci and other agents	P. jiroveci	HIV acute	Kaposi sarcoma	Lymphoma	
	R. equi				
Lymphocytic interstitial pneumonitis	Septic emboli (addicts) C. neoformans	EBV acute	Nocardia asteroides	Septic emboli	

particularly in persons capable of producing sputum samples. The use of *more invasive tests,* such as bronchoscopy, with the obvious limitations of cost and risk to the patient, has the advantage of providing subglottic specimens and the potential for diagnosis of a broader range of pathogens. The interpretation of positive cultures for CMV or for MAC may be uncertain without tissue histopathology for confirmation. In patients with a rapidly deteriorating clinical condition or a failure to respond to initial therapy, bronchoscopy with biopsy or needle aspiration may be preferable to bronchoalveolar lavage (BAL) or sputum induction as an initial procedure. In general, noninvasive, nuclear isotope-based radiologic tests are rarely useful in the diagnostic evaluation of pulmonary disease in AIDS patients.

4. The *rate of progression of infection* is often a clue to the type of disease. Thus, community-acquired pneumonia develops rapidly (in 2–5 days), while the initial episode of *Pneumocystis* pneumonia generally evolves more slowly (over 7–12 days) in AIDS (as compared with other compromised hosts). Fungal infection and mycobacterial infection are generally preceded by systemic complaints. Pyogenic pulmonary infection is generally associated with sputum production, while the "atypical" infections may have little or no sputum despite cough and dyspnea.
5. The *radiographic pattern* is often suggestive of the diagnosis (Table 123-7). All "typical" patterns are altered by progressive immune deficits and coexisting or prior lung disease. *Diffuse infiltrates* (alveolar or interstitial) may be seen with a homogeneous distribution, as in *P. jiroveci, T. gondii,* CMV, mycobacterial species, *Histoplasma,* or *Coccidioides* (Fig. 123-7). Drug toxicity may also cause pulmonary infiltrates. Inhomogeneity with these pathogens reflects altered pulmonary parenchyma from previous disease, obstruction (e.g., with tumor, *S. stercoralis*), or upper zone disease or pneumothorax in *Pneumocystis* pneumonia (Fig. 123-8). Tumors may appear with interstitial radiographic patterns in HIV disease. Lymphoid interstitial pneumonitis is an interstitial process of unknown origin that is seen in AIDS patients. Diffuse interstitial infiltrates are often due to *P. jiroveci,* but not in patients receiving TMP–SMX prophylaxis and rarely without hypoxemia. Thus, the presence of a sepsis-like picture with a diffuse interstitial infiltrate in a patient receiving anti-*Pneumocystis* prophylaxis might suggest mycobacterial disease, *Legionella* infection, or *Cryptococcus neoformans. Focal airspace disease* is most often seen with bacterial infections (pyogenic, mycobacteria, *Legionella* species), *Mycoplasma pneumoniae* (viral influenza, AV, CMV), and mixed infections (e.g., CMV and *P. jiroveci*). Occasionally, primary cryptococcal pneumonia, *Aspergillus* infection, or obstructive disease will present with focal infiltrates. Each of these processes may evolve to frank *cavitation*, particularly infections due to pyogenic bacteria (*Staphylococcus, Klebsiella, S. pneumoniae*) or *M. tuberculosis*. Small cavities are seen with *P. jiroveci,* mycobacteria, and metastatic tumors. Large cavities are uncommon; *M. tuberculosis* or aspergilloma is most often present. *Nodular lesions* can be seen with any of the metastatic tumors or hematogenous infections. Endocarditis, KS, toxoplasmosis, tuberculosis, MAC, and *Cryptococcus* may all progress from nodules to small cavities (Fig. 123-9). In particular, unusual bacterial pathogens *(Bartonella, Rhodococcus, Candida, Salmonella)* have been observed as pulmonary nodules associated with right-sided endocarditis in AIDS patients (Fig. 123-10). *Intrathoracic adenopathy* is common in untreated AIDS patients, most often with infections earlier in the course of disease (CD4+ count greater than 400 per mL) and with tumors later in disease. Fungal infections *(Cryptococcus, Histoplasma, Coccidioides)*, CMV, and mycobacterial infections may also cause adenopathy. Adenopathy should prompt invasive diagnosis in the absence of a clear etiology in AIDS. *Pleural effusions* are common with tuberculosis, other pyogenic bacterial infections, and tumors.
6. The *CD4+ lymphocyte count* is a good indicator of susceptibility to specific infections, while the viral load is most closely associated with overall disease prognosis. Unresolving community-acquired pneumonia due to *S. pneumoniae,*

Figure 123-7 Diffuse ground-glass opacity of *P. jiroveci* pneumonia in AIDS at the time of initial presentation predominantly involved the subpleural lung and spared the central lung.



A B

Figure 123-8 **A.** A mucus plug in a small airway. **B.** Higher power view reveals the larval form of *Strongyloides stercoralis*.

H. influenzae, Mycoplasma, or *Legionella* species may be the sentinel infection of HIV disease. As host immunity declines, other opportunistic infections will occur. *M. tuberculosis,* an organism of high virulence, will cause infections at any CD4+ lymphocyte count but will occur increasingly as the CD4+ lymphocyte count falls below 500 per mL. In contrast, less virulent organisms will cause disease only with greater degrees of immune compromise.

7. *Chronic or recurrent sinus infection* may provide a source of *Pseudomonas* or *Aspergillus* for pulmonary infection.
8. The *spectrum of pulmonary disease varies by geographic region* and by HIV transmission category.
9. *Physical findings* are often useful in establishing a differential for pulmonary disease in contrast, often, with other types of immunocompromised hosts.

INFECTION IN PATIENTS WITH CANCER OR HCT

Patients with underlying malignancy who are treated with chemotherapy or HCT represent special challenges with respect to evaluation and management of known or suspected infectious diseases.

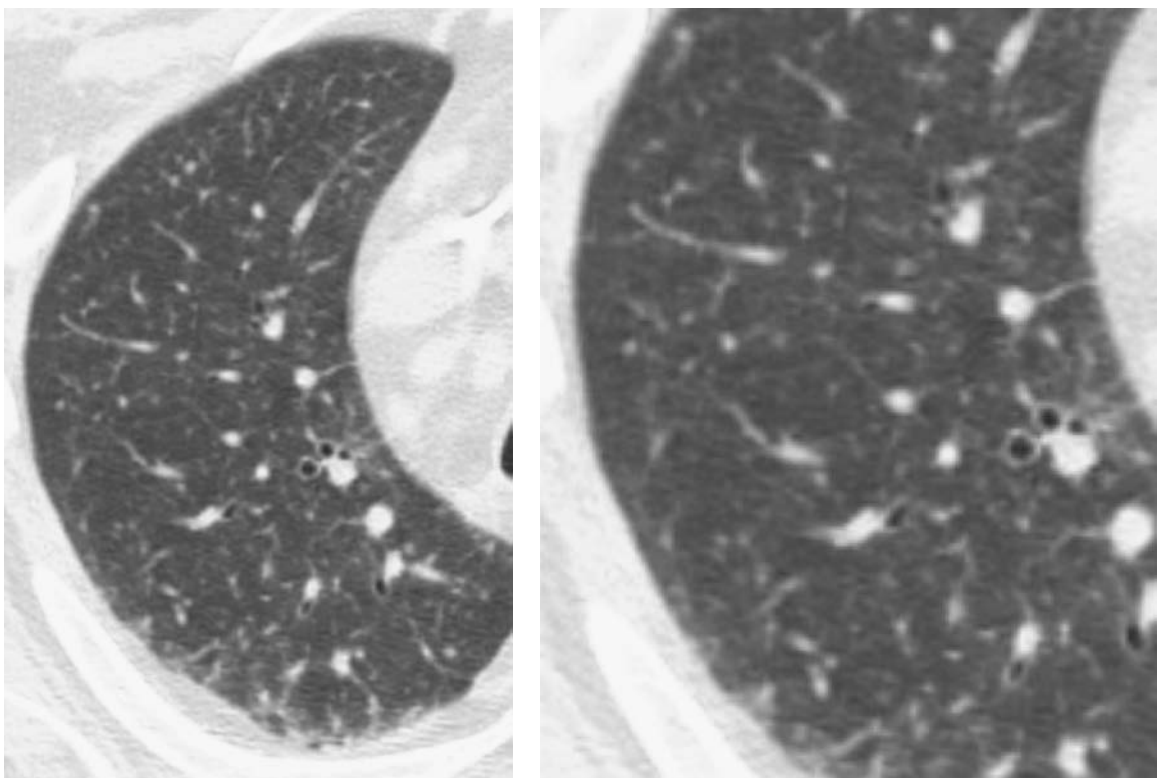


Figure 123-9 Miliary cryptococcal pneumonia in a 62-year-old man undergoing intensive chemotherapy for pancreatic cancer. *C. neoformans* was isolated from bronchoalveolar lavage specimens and cerebrospinal fluid (CSF). Cryptococcal antigen was positive in serum and CSF at titers greater than 1:1024. CT scan demonstrates diffuse 1- to 3-mm micronodules in both lung fields, often difficult to distinguish from small blood vessels on end. This requires review of serial CT cuts to distinguish nodules from tubular vessel structures.

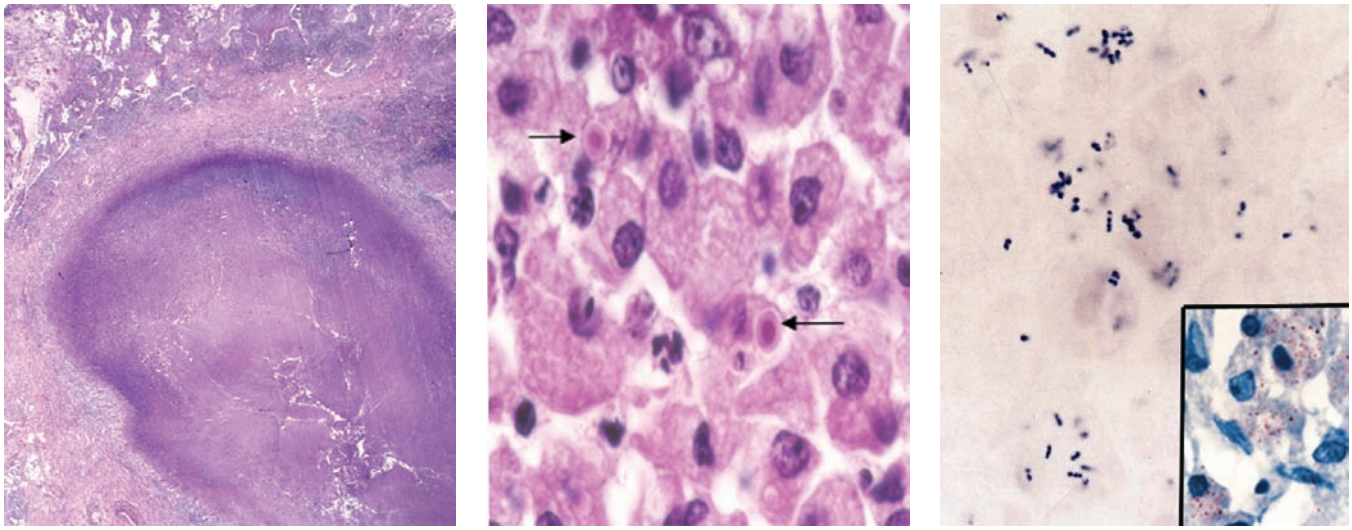

A B C

Figure 123-10 **A.** *Rhodococcus equi* pneumonia in AIDS produced a cavitary lung nodule in a lung biopsy specimen. **B.** The host response includes histiocytic inflammation and small calcified concretions termed Michaelis–Gutmann bodies *(arrows)*. **C.** The organism is a gram-positive coccobacillus that also stains with the modified Ziehl–Neelsen stain *(inset)*.

Important aspects of the underlying basis for their immunocompromised status are discussed below.

■ IMMUNE DEFECTS DUE TO TUMORS AND CHEMOTHERAPY

The incidence of infection in cancer patients is determined, in part, by the nature of the underlying neoplasm. Studies of pneumonia in cancer patients suggest the following approximate incidences of infection:

- Conventional bacteria—37%
- Fungi—14%
- Viruses—15%
- *P. jiroveci* (formerly *Pneumocystis carinii*)—8%
- *Nocardia asteroides*—7%
- *M. tuberculosis*—1%
- Mixed infections—20%

In the series by Bodey et al.,[32,33] fatal infections in acute leukemics were caused by bacteria in 66%, fungi in 33%, viruses in 0.2%, and protozoa (including *P. jiroveci*, now considered a fungus) in 0.1% (Fig. 123-11). In contrast, fatal infection in lymphoma patients (86%) and solid-tumor patients (94%) were more often bacterial in the preprophylaxis era. The rate of cryptococcal infection in chronic lymphocytic leukemia was more than double that in Hodgkin disease (24.3 vs. 10.9 per 1000), and the rate in breast cancer was only 0.159 per 1000.

Other tumors are associated with specific infections. For example, lung cancer is associated with tuberculosis at a rate of 92 per 1000, second only to the rate in patients with Hodgkin disease (96 per 1000) due to cellular immune deficits. Without therapy, the degree of depression in cellular immunity (delayed-type hypersensitivity) is more prominent in lymphoma, whereas humoral immunity is impaired to a greater degree in diseases affecting B-lymphocyte function, such as multiple myeloma and chronic lymphocytic lymphoma. Thus, the patient with lymphoma is particularly susceptible to intracellular organisms, including *Listeria monocytogenes*, *M. tuberculosis*, viruses, and fungi. The patient with myeloma is more apt to develop pneumonia or bacteremia due to *H. influenzae*, *S. pneumoniae*, and a variety of other acute bacterial infections. Acute leukemia is associated with a depression in the number and function of circulating granulocytes and is associated with severe pyogenic, bacterial infections. Patients with acute and relapsed leukemia have demonstrated impaired phagocytosis and killing of fungi and bacteria by these cells, which may appear morphologically normal. *These defects may persist well into periods of remission and may progress along with progression of the underlying disease.*

The impact of the various forms of chemotherapy on host defenses must be added to those caused by the underlying malignancy. Multiple immune functions are impaired by chemotherapy, including the phagocytosis and killing of bacteria by neutrophils (corticosteroids, carmustine, radiation); antibody production (methotrexate, cyclophosphamide, L-asparaginase, 6-mercaptopurine); uptake and processing of antigen by macrophages (corticosteroids,

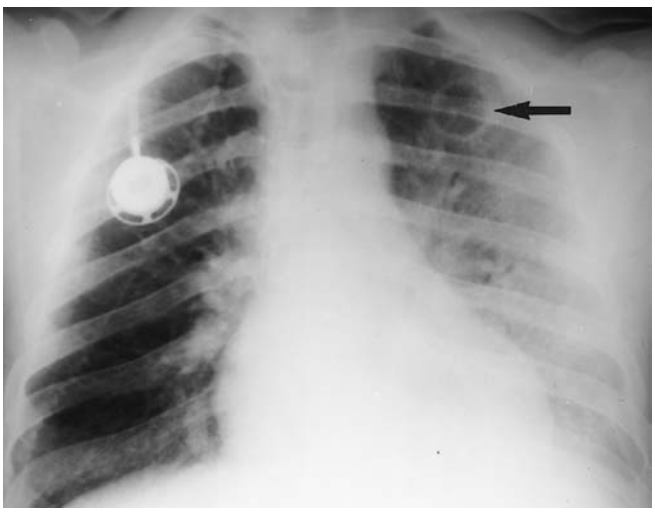

Figure 123-11 Lung abscess (*arrow*) in a febrile patient following intensive chemotherapy for relapsed acute myelogenous leukemia. Patient developed fever while granulocytopenic (<50 neutrophils/mm^3 for 8 days) without localizing symptoms and a clear chest radiograph. When the neutrophil count exceeded 200/mm^3, a lung abscess was detected in the left upper lobe. *Aspergillus fumigatus* was detected in fluid obtained from the abscess via CT-guided percutaneous needle aspiration. The infection responded well to amphotericin B.

cyclophosphamide, dactinomycin); recognition of antigens by T and B lymphocytes (corticosteroids, cyclophosphamide); and antigen-driven lymphocyte proliferation (methotrexate, 5-fluorouracil, fludarabine, cytarabine, L-asparaginase, dactinomycin, 6-mercaptopurine, hydroxyurea). Predisposition to infection induced by chemotherapy may mask more subtle defects due to underlying disease; for example, the effects of granulocytopenia due to intensive chemotherapy will generally predominate over the effects of underlying lymphoma or myeloma.

NEUTROPENIA

The most common predisposing condition for infection in the patient with cancer is granulocytopenia, often due to chemotherapy and occurring while awaiting engraftment of hematopoietic transplants. The *function* of inflammatory cells and of other immune (e.g., mucosal) barriers are also of great importance and are much more difficult to assess. The risk of infection increases as granulocyte counts decrease (Table 123-8). Thus, the risk of infection in the patient with neutropenia (under 1000 total granulocytes per mm^3) increases when granulocyte numbers fall further, to below 500/mm^3; the risk is greatest when counts are lower than 100/mm^3.[32,33]

The many causes of neutropenia differ qualitatively (Table 123-8). They include iatrogenic neutropenia (chemotherapy, drug toxicities), aplastic anemia and other immune neutropenia, hereditary and acquired cyclic neutropenia, and malignancy-associated (especially acute leukemias) and infection-induced neutropenia. The rate of decline in white blood cell numbers and the duration of neutropenia influence the risk of infection. Thus, the patient with acute leukemia and rapidly falling neutrophil counts is at greater risk than the person in whom counts are falling slowly or are stable.

TABLE 123-8 Causes of Neutropenia

Iatrogenic
Cancer chemotherapy
Drug toxicities (TMP–SMX, chloramphenicol, ganciclovir, AZT, allopurinol)
Infection
Viral (cytomegalovirus, HIV, Epstein–Barr virus, hepatitis B)
Parasitic *(Leishmania)*
Bacteria *(Clostridium)*
Acute neutropenia of sepsis/endotoxemia (gram-negative sepsis)
Bone marrow failure of neonatal sepsis
Immune
Drug-induced autoimmunity (haptenic: penicillins, sulfa drugs)
Aplastic anemia (includes idiosyncratic reactions: phenothiazines, chloramphenicol)
Alloimmune neonatal neutropenia (maternal–fetal incompatibility)
Congenital autoimmune neutropenia
Primary autoimmune (systemic lupus erythematosus, Felty syndrome, rheumatoid arthritis)
Transfusion-induced
Antineutrophil antibody-mediated
Cyclic neutropenia (CD57 lymphocyte expansion)
Hereditary
Infantile genetic agranulocytosis
Familial neutropenia
Cyclic neutropenia (autosomal dominant)
Old age

THE MICROBIOLOGY OF INFECTION IN NEUTROPENIA AND CANCER

Pulmonary infections in patients with functional or quantitative defects in neutrophils can reach the lungs via inhalation, microaspiration of colonizing organisms, and bacteremia after nonrespiratory penetration and bacteremia (e.g., from vascular catheters or disrupted mucosal surfaces). The classic presentations of pneumonia, transmural inflammation, and perforation of the cecum or "typhlitis" (often with *Pseudomonas*, anaerobic bacteria including *Clostridium septicum*) may be the first signs of life-threatening infection in a neutropenic patient. Decisions regarding management of these patients are made empirically because of the urgency of therapy in the immunocompromised host. Distinctions between pulmonary and extrapulmonary infections often become blurred in the attempt to treat most of the likely pathogens in a febrile neutropenic cancer patient. Often an unsuspected pulmonary pathogen is detected on routine blood or urine culture or from a biopsy of an extrapulmonary infected site.

Common infections in the neutropenic host and the patient with cancer are most often the result of colonization with, and infection by, pyogenic bacteria, including *S. pneumoniae*, *S. aureus*, the Enterobacteriaceae, *Pseudomonas aeruginosa*, *H. influenzae*, and *Stenotrophomonas* (formerly *Xanthomonas*) *maltophilia*. Common fungal pathogens include *Aspergillus* species, *Mucor*, *Absidia*, and *Rhizopus* species (Table 123-9). *Candida* species are often isolated from sputum samples but rarely cause pneumonia in the absence of pulmonary injury, hemorrhage, or fungal embolus. The emergence of bacteria and fungi with antimicrobial resistance takes on special importance in the neutropenic host because therapy is generally empiric and is started before microbiologic data become available. The common "resistant" organisms include vancomycin-resistant *Enterococcus faecium* and *faecalis* (now also resistant to linezolid,

TABLE 123-9 Factors in the Development of Fungal Infections in Patients with Cancer

Age/performance status
Prior chemotherapy or radiotherapy: dose and duration
Steroids
Purine analogs
Prior infections (specific isolates)
Recent antimicrobial use (resistance)
Broad-spectrum antimicrobials
Prophylactic agents
Functional immune status (cell number, activity)
Hematopoietic transplantation-related
Delayed engraftment or function of marrow
Graft-versus-host disease and treatment
Degree of donor–recipient histocompatibility mismatch
Insufficient dose of stem cells (CD34+)
Total T-cell number
Integrity of mucosal barriers (catheters, gastrointestinal)
Neutropenia (severity, duration >2 wk)
Hospital environment
Home environment—hobbies, travel
Nonhematopoietic organ failure (e.g., dialysis)
Other simultaneous infections (e.g., cytomegalovirus)

Figure 123-12 Postobstructive pneumonia and lung abscess (*arrow*) in a 45-year-old man with adenocarcinoma of the lung in the right hilum. The abscess was drained via a bronchoscopic approach. Cultures of the abscess fluid grew common oral bacterial flora, including *Prevotella melaninogenica* and *Bacteroides* species.

quinupristin-dalfopristin), methicillin-resistant *S. aureus*, inducible chromosomal and acquired plasmids encoding b-lactamases in gram-negative bacteria, and azole (i.e., fluconazole) resistance of *Candida* species.[34] In individual patients, the spectrum of colonizing organisms changes over time with antimicrobial use and chemotherapy. Seeding from blood-borne infection (e.g., due to vascular access catheters or localized infection) may occur. Patients with solid lung tumors may develop obstructive pneumonia or pulmonary hemorrhage, followed by superinfection with the flora of the upper respiratory tract and oropharynx (Fig. 123-12).

■ FUNGI AND LESS COMMON PATHOGENS

Combined cellular and granulocytic deficiencies occur with chemotherapy. As a result, pathogens normally controlled by cellular immune mechanisms (especially intracellular pathogens) can be detected; among these are *M. tuberculosis*, *Brucella* species, the geographic fungi, *C. neoformans*, *S. stercoralis*, *Salmonella*, and *P. jiroveci*. Fungal infections occur with increasing frequency, most often in acute leukemia and following stem cell transplantation with GVHD (see Table 123-9). Atypical presentations of infection may be from a portal of entry other than the gastrointestinal tract or the lungs. Thus, the first clinical signs of infection may be "spontaneous" or line-associated bacteremia or fungemia presenting as idiopathic hypotension, confusion, altered renal function, or skin lesions including black or necrotic skin lesions (e.g., ecthyma gangrenosum) seen most often with gram-negative bacteria, *Bacillus* species, *Fusarium* species, or dematiaceous molds. Pneumonia may accompany skin, sinus, or central nervous system infection with infection due to *Aspergillus* species, mucormycosis, *Nocardia asteroides*, *C. neoformans*, and the herpes viruses (herpes simplex or varicella zoster). The Mucoraceae *(Rhizopus, Mucor, Absidia)*, like the *Aspergillus* species, may present with invasive disease of the sinuses and periorbital and frontal cortex and rapidly progressive hemorrhagic pneumonia with infarction and fungemia (See also Chapter 133).[35] Invasive disease of the sinuses and periorbital and frontal cortex is especially prevalent in neutropenic

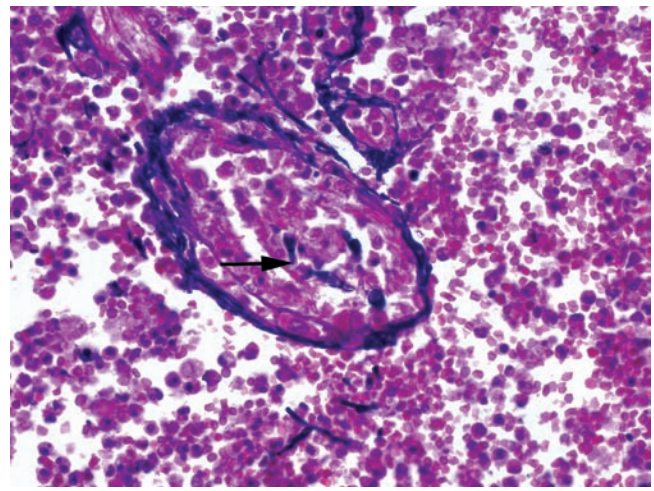

Figure 123-13 Disseminated *T. beigelii* infection in a patient undergoing chemotherapy for acute leukemia. GMS-H&E reveals hyphae (*arrow*) in a blood vessel with surrounding hemorrhage.

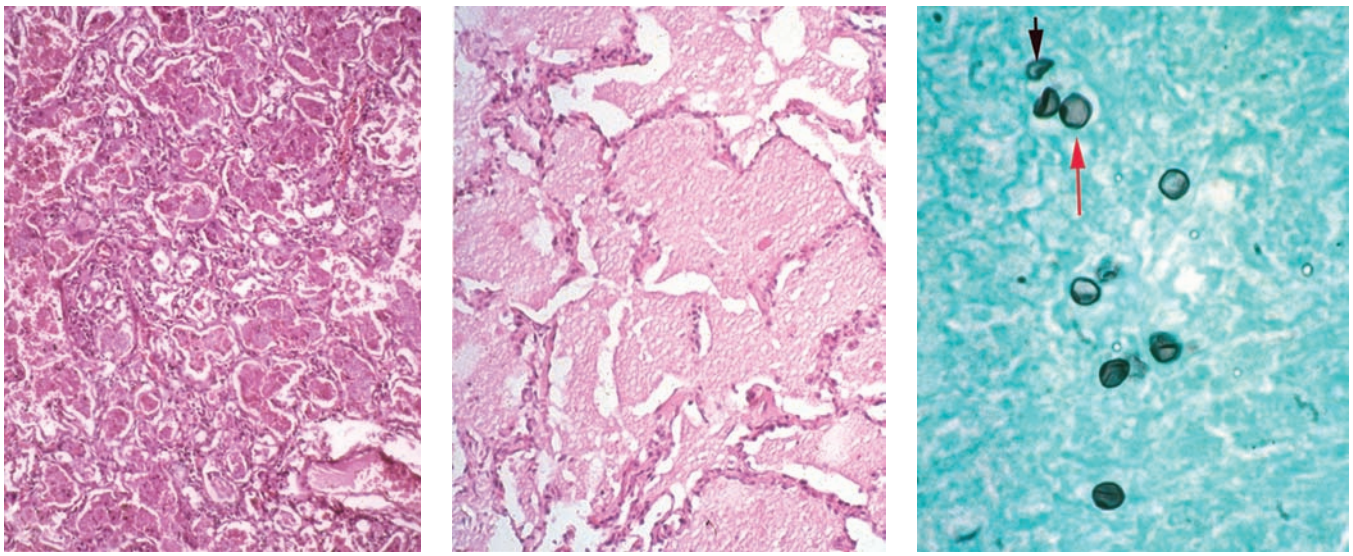
diabetics and in patients treated with deferoxamine, with prolonged corticosteroid therapy, or with broad-spectrum antimicrobials. The primary treatment of this invasive disease is surgical debridement in addition to antifungal therapy.

In patients with neutropenia or acute leukemia, a group of "benign" dermatophytes – including *Trichosporon beigelii*, *Aureobasidium*, *Alternaria*, *Curvularia*, *Phialophora*, *Wangiella*, and *Cladosporium*—have been associated both with disease of the skin and with invasive infection of the lungs, the sinuses, and the central nervous system (Fig. 123-13). Occasionally infections are caused by "atypical fungi" (e.g., *Saccharomyces cerevisiae*, *Scedosporium/Pseudallescheria species*, *Cunninghamella bertholletiae*, *Drechslera*, *Fusarium* species, *Geotrichum candidum*, and *Penicillium* species). *Fusarium* causes infection of the bloodstream and lungs that is indistinguishable from that due to *Aspergillus*, but with greater tendency to cutaneous involvement. The cardinal sign of *Pneumocystis* pneumonia is the presence of arterial hypoxemia out of proportion to physical or radiologic signs (Fig. 123-14).

■ VIRAL INFECTIONS

Viral infections are increasingly prevalent in patients with cancer. This is a reflection of prolonged T-cell defects, use of depleting antilymphocyte antibodies, and improved molecular diagnostic assays. HSV and VZV are frequently reactivated during periods of neutropenia or as a sign of the presence of new malignancies. Patients who are undergoing chemotherapy for Hodgkin disease or following HCT are at greater risk than other immunocompromised hosts (35%–50% in the first year). Specific antiviral prophylaxis is effective in reducing the incidence and severity of these relapses. Most often, these viruses cause painful, but relatively benign, skin or mucosal (especially esophageal, gastrointestinal, and perianal) lesions. These lesions may progress in neutropenic patients and the skin rash may become more diffuse, with hemorrhagic or nonhemorrhagic lesions extending beyond dermatomal limits.

Systemic dissemination to visceral organs occurs in 10% of patients with disseminated skin disease commonly involving the liver, lungs, brain, or gastrointestinal tract. Nasal, oropharyngeal, or esophageal HSV or VZV infections may spread directly to the lungs with the development of vesicular lesions in the trachea, or may cause viral pneumonitis in the parenchyma as a result of viremia secondary to cutaneous reactivation. Primary varicella pneumonia may accompany chickenpox in adults and in the compromised



A B C

Figure 123-14 **A.** The lung in a patient with *P. jiroveci* pneumonia demonstrates the filling of the alveolar space with eosinophilc frothy materials including trophozoites and macrophage debris. This appearance can be confused with alveolar proteinosis (seen in **B**) or fibrinous pulmonary edema (not shown). **C.** The cyst form of Pneumocystis is demonstrated using silver stain (GMS). Characteristic features include 4 to 6 micron size, the absence of "fungal" budding, and boat-shaped cysts, with pericapsular accentuation (*red arrow*)

host. Pulmonary invasion occurs within the first 7 days of illness, with mortality approaching 18%. Chest radiographs reveal nodular or interstitial infiltrates in up to 16% of adults with chickenpox, whereas only 10 to 25 of these have clinical symptoms. Pulmonary invasion by HSV and VZV in the neutropenic host should be considered a life-threatening emergency. In the granulocytopenic host, pulmonary CMV infection may be fatal. Therapy for CMV infection may include antiviral agents (ganciclovir, foscarnet, cidofovir) with some important toxicities as well as antibody repletion.

The community-acquired respiratory viruses are an important cause of pneumonia as well as predisposing to bacterial and fungal superinfection.[36–39] Nosocomial acquisition is common. AV, influenza, PIV, metapneumovirus, and RSV may be diagnosed with rapid molecular assays or using multiplexed screening panels (direct immunofluorescence).

■ PARASITIC INFECTION

The predominant parasitic infection enhanced by immune compromise is that due to *S. stercoralis*, a nematode that infects more than 100 million people worldwide, producing lifelong infection. *Strongyloides* is distinguished by its *ability to complete the replicative cycle within the human host* (Fig. 123-8). Malnutrition is a major cofactor; neutropenia and corticosteroids are common coinducers of parasitic replication. In the normal pattern of infection, the filariform larvae penetrate the skin, follow the veins to the lungs, and are then swallowed, entering the small intestine. The "hyperinfection syndrome" is the result of activation in the gastrointestinal tract by immune suppression, which causes penetration or transudation of worms across the wall, carrying gastrointestinal organisms with them. Peritonitis, bacteremia, and gram-negative, eosinophilic meningitis may result. Pneumonia may result from bacteremia or from obstruction of small airways and pneumonitis; the pulmonary infection fails to resolve without therapy directed at eliminating the nematode.

In endemic regions, activation of *T. gondii*, Chagas' disease (*Trypanosoma cruzi*), pulmonary or disseminated microsporidiosis or cryptosporidiosis (rare), leishmaniasis, and acute infection with *Acanthamoeba* and *Naegleria* species (primary amebic meningoencephalitis) must be considered in the differential of systemic and pulmonary infections.[40] Splenectomized hosts are at special risk for intense infection due to babesiosis, malaria, and ehrlichiosis/anaplasmosis.

■ CLINICAL APPROACH TO INFECTION IN THE PATIENT WITH CANCER

Clinical recognition of infection is often delayed in the neutropenic patient or patient with cancer because the inflammatory response is diminished (decreased numbers or mobilization of granulocytes) and the usual signs of infection are absent. Thus, in neutropenic patients, pneumonia may not be associated with sputum production and radiologic changes. In the febrile neutropenic patient with leukemia, the source of obscure infection is often the perineal and perirectal areas; less common are infections of the urinary tract, skin (including venous lines and wounds), and the lungs. In nonhematopoietic cancer patients, however, pulmonary infections predominate. A site of origin for a febrile episode is undetermined in 20% to 50% of patients. Many infections are detected only at autopsy, notably in patients with disseminated fungal or combined fungal and bacterial infections. Mortality in the febrile neutropenic population is 30% to 50%. Noninfectious causes of fever are common; among them are pulmonary thromboembolism, tumor, radiation pneumonitis, atelectasis with pulmonary edema, drug allergy or toxicity, and pulmonary hemorrhage. Often, the resolution of fever in response to a trial of antimicrobials is the only evidence of infection.

■ FEVER AND PULMONARY INFILTRATES

Pulmonary disease in the patient with cancer is clinically challenging, owing to the large array of processes that may cause radiologic infiltrates (Table 123-10). Noninfectious causes of pulmonary infiltrates and fever (edema, cancer, radiation injury, drug toxicity, leukoagglutinin transfusion reaction, pulmonary embolus, hemorrhage, alveolar proteinosis) are common (up to 25%) and may closely mimic infection (discussed also in Chapter 122). Conversely, the absence of inflammatory cells or mobilization may mask signs of significant infection. In the patient undergoing chemotherapy or in

TABLE 123-10 Common Causes of Pneumonia in Patients with Cancer Based on Radiographic Abnormalities and Disease Progression

Abnormality on Chest Radiograph	Common Cause by Rate of Disease Progression[a]	
	Acute (<24 h)	Subacute-Chronic
Consolidation	Bacteria (including *Legionella*) pulmonary embolus, hemorrhage, pulmonary edema	Fungi, Nocardia, tuberculosis (drug, virus [RSV], *P. jiroveci*, radiation)
Interstitial infiltrate	Pulmonary edema (including drug) Leukoagglutinin reaction (bacterial)	Viral, *Pneumocystis*, radiation, drug (fungi, Nocardia, tuberculosis, tumor)
Nodular infiltrate	Bacteria, edema (CMV, VZV)	Tumor, fungal, Nocardia, TB *Pneumocystis* (CMV)

[a]*Common causes (and less common in parentheses) in the absence of specific epidemiologic exposures or past history.*

the neutropenic host, cough, sputum, radiologic infiltrates or cavitation, and fever may all be absent. Infection may spread to the chest from contiguous structures (e.g., perforation of the esophagus due to *Aspergillus*) or may complicate anatomic changes (e.g., bronchial obstruction in lung cancer).

RADIOLOGIC CLUES TO DIAGNOSIS

A number of clues are available to assist in the differential diagnosis of pulmonary infiltrates in patients with cancer. For example, the clinical and radiographic appearance and progression of disease may suggest a diagnosis based on the time course and nature of the infiltrate (Table 123-10). In general, acute processes include both bacterial infections and noninfectious injuries, such as pulmonary embolus or edema. Subacute processes include *P. jiroveci*, viral, *Mycoplasma*, or *Nocardia* or *Aspergillus* infections. More chronic processes include drug-induced, radiation-induced, mycobacterial, nocardial, or malignant invasion of the lungs.

In particular, bronchial obstruction by tumor or enlarged lymph nodes may cause atelectasis or postobstructive pneumonia (Fig. 123-12). The underlying process may be suggested by pneumonia that fails to respond to antimicrobial therapy or recurs in the same location after successful treatment. Tumor masses, especially those due to lymphoma, may cavitate, giving the appearance of a lung abscess. Finally, it is important to bear in mind that a chronic process may be superinfected by an acute bacterial, viral, or drug-induced lung injury.

Clinical assessment, coupled with the radiologic pattern of lung disease, is usually the basis for forming a differential diagnosis for the patient with fever and pneumonitis. CT scanning has greatly improved differentiation of some processes. For example, in patients with simultaneous processes affecting the lung (e.g., aspiration and tumor), CT scans disclose distinctive patterns of parenchymal involvement (consolidation and infiltrative lesions with associated adenopathy) better than do conventional chest radiographs. Subtle interstitial infiltrates *(P. jiroveci)* or nodules *(Cryptococcus)* are better detected by CT scans than by conventional radiographs.

NONINFECTIOUS PNEUMONITIS

Following a dose of radiation to the lungs >2000 rads, radiation injury may be seen. The injury may become evident either acutely or more than 6 months after the initial exposure. The acute form of radiation pneumonitis may present as bronchitis or esophagitis, with dry cough, fever, fatigue, hypoxemia, and dyspnea that develop over 6 to 12 weeks. The histologic picture reveals vascular damage, mononuclear infiltrates, and edema. The severity of lung injury due to radiation appears to correlate with the rapidity of the withdrawal of steroid therapy, but it may also reflect the emergence of the underlying inflammatory response. Radiation fibrosis usually occurs in 6 to 9 months, and pulmonary function may take up to 2 years to plateau (see Chapter 59).

Acute, drug-induced lung disease may reflect hypersensitivity to chemotherapeutic agents (see Chapter 65) or to sulfonamide agents. Methotrexate, bleomycin, and procarbazine can cause a syndrome of nonproductive cough, fever, dyspnea, and pleurisy with skin rash and blood eosinophilia. Chest radiographs demonstrate diffuse reticular infiltrates. Cyclophosphamide may cause a syndrome of subacute pulmonary disease with interstitial inflammation and pulmonary fibrosis, with fever, dyspnea, fatigue, and cough. Drug toxicity for agents such as bleomycin, BCNU, and CCNU may be related to the cumulative dose (for bleomycin, over 450 mg) and patient age. Synergistic toxicity for the lung occurs between radiation and a variety of chemotherapeutic agents (e.g., bleomycin, mitomycin, busulfan) and supplemental oxygen use. A variety of noninfectious processes may mimic infection. Alveolar proteinosis may be associated with hematologic malignancies or accompany infection due to *Nocardia* or, less often, *Cryptococcus*, *Aspergillus*, *M. tuberculosis*, and *Histoplasma*.[41] Pulmonary infarction may mimic infections in association with hemoptysis, leukocytosis, pleuritic chest pain, and segmental pleural-based infiltrates on the chest radiograph.

INITIAL MANAGEMENT OF THE PATIENT WITH CANCER AND FEVER: STRATIFICATION OF RISK

Each patient presenting with signs of infection must be evaluated in terms of the perceived risks of infection and noninfectious causes of fever and for the presence of neutropenia or other immune dysfunctions. Attempts to manage patients with greater efficiency and to shorten hospital stays have led to the development of *critical pathways*, which include standard patterns of evaluation and treatment for many patients, including those with cancer. Such uniform approaches are useful in establishing a *minimal standard* of care, but they do not address concerns about the pitfalls of failing to individualize therapy.

The safe application of critical pathways for the outpatient management of neutropenic patients necessitates careful stratification of these compromised patients by experienced clinicians in terms of their risk for infectious complications. *Any sign of infection* requires at least a brief hospitalization (1–3 days), with careful evaluation. Experienced oncologists manage some febrile neutropenic patients as outpatients. Any febrile neutropenic patient – or patient in whom absolute neutrophil count (ANC) is expected to fall below 1000/mm^3 – with localizing signs (headache, altered mental status, rash, dyspnea, chest pain, pain over an indwelling catheter site, pulmonary infiltrates) should be considered for emergency admission. In particular, patients with leukemia or lymphoma, uncontrolled metastatic cancer, recent need for antimicrobials, or ANC under 100 (or expected to fall below 100) are generally considered "higher-risk"

patients and are best managed as inpatients until clinically stable. Patients with a history of frank rigors, hypoxia, or hypotension merit admission. Any febrile patient with cancer needs an assessment of vital signs; oxygen saturation; complete blood count with differential; electrolytes, blood urea nitrogen, and creatinine (to assess for urinary obstruction by tumor or acute drug toxicity); blood cultures (at least one from a peripheral site and one from any indwelling catheter); urine sediment examination and culture; sputum Gram stain examination and culture; and chest radiograph. After a careful physical examination, the threshold should be low for lumbar puncture and determination of serum or spinal cryptococcal antigen. The patient's history and medical record should be reviewed, with attention to current drugs, recent chemotherapy (especially corticosteroids), recent microbiologic data and antimicrobial use, allergies, and exposures.

EMPIRIC USE OF ANTIMICROBIALS IN FEVER AND NEUTROPENIA

After appropriate smears and cultures have been obtained, empiric antimicrobial therapy in the febrile neutropenic patient is required. The specific antimicrobials selected for "routine use" in the febrile neutropenic patient remain controversial. Ultimately, this is because many combinations appear to work equally well, and because there are few studies of various combinations in identical patient populations using the same entry and end-point criteria. The antimicrobials selected must "cover" previously documented infections or surveillance culture data, physical findings, known hospital flora, and potential community exposures.

Initial therapy should assume that the organisms causing infection are likely to be resistant to current prophylactic or therapeutic antimicrobials. Many infections are loculated and require drainage (e.g., sinusitis, postobstructive pneumonitis) (Fig. 123-12). Patients thought to be at *low risk* for infection or other complications (nonleukemic, underlying cancer not progressing, no serious coexisting illness, no recent infections or courses of antimicrobials, expected ANC to remain above 100) may be *considered* for home management after 24 hours (to await blood culture data), based on the clinical assessment. In these patients, empiric antimicrobials should target gram-negative organisms and be based on the known resistance patterns in the institution and in the patient. Monotherapies include antipseudomonal beta-lactams (ticarcillin-clavulanate, piperacillin-tazobactam, third or fourth generation cephalosporins) or carbapenems. Optimal antimicrobial therapy should include synergistic therapy for *Pseudomonas* infection in medical centers where this organism is prevalent or if the patient is colonized and/or profoundly neutropenic. Aminoglycosides remain useful for synergy but have limited activity in pneumonia and have been supplanted by fluoroquinolones if these agents have not been used recently for prophylaxis or therapy.

A decision regarding coverage for gram-positive organisms including MRSA (e.g., vancomycin) or VRE is based on the possibility of catheter-associated infection and clinical judgment. Such patients might include those with skin wounds, decubitus ulcers, hypotension, or indwelling vascular access catheters. Gram-positive bacterial infections generally progress more slowly than do the gram-negative infections; the *routine use* of vancomycin in these patients does not appear to be justified, because of the increased risk of VRE. Routine surveillance for VRE may be of assistance in adjusting the regimen if fever persists. Routine use of antifungal agents is complicated by the common use of fluconazole in prophylaxis. High-risk patients, especially if colonized with yeasts (thrush, skin, and/or urinary), may merit empiric coverage with echinocandin agents until blood culture data are available.

If an abdominal or anaerobic bacterial source is suspected, clindamycin or metronidazole can be added. Anaerobic infections other than those due to *Bacteroides fragilis* are uncommon as a source of major morbidity in these patients. Restrictions on the use of clindamycin have been instituted at many centers because of outbreaks of *C. difficile* colitis. Topical oral antifungal therapy (clotrimazole, nystatin) is commonly administered with broad-spectrum parenteral antimicrobials. Antimicrobials may be adjusted on the basis of microbiologic data or if the patient is afebrile for 7 to 10 days with the ANC over 500 and increasing.

Empiric therapy must be individualized. In a patient receiving empiric therapy who becomes afebrile on antimicrobials by 72 hours and with a neutrophil count above 500/mm^3, the antimicrobials may be stopped after 7 days and the patient reevaluated if no localizing source is found or untreated pathogens detected. Patients who are clinically well and who become afebrile with neutrophil counts of 100 to 500 per mm^3 should be afebrile for 5 to 7 days before antimicrobials are stopped to reevaluate sources of infection. If the patient is not clinically well (e.g., has mucositis, fewer than 100 neutrophils per mm^3, or unstable vital signs), the antimicrobials should be continued until the patient is stable and afebrile for 48 to 72 hours.

Unless a specific source of infection is located and the pathogen(s) identified, patients with persistent fever and neutropenia should have antimicrobials broadened 48 to 72 hours after the start of therapy. The options include (1) addition of vancomycin (or other gram-positive agent if colonized with resistant organisms such as VRE); (2) addition of antianaerobic therapy for oral mucositis or gingivitis, abdominal pain, or perirectal tenderness; (3) expansion of gram-negative bacterial coverage (generally adding a second agent from a different class of antimicrobials); (4) consideration of antiviral therapy in patients with esophagitis or a history of HSV or VZV or at risk for CMV infection; and (5) addition of antifungal therapy. The toxicities of antifungal agents must be considered carefully in these patients, notably those with decreased renal function or systemic fungal infection. The use of amphotericin B products (generally lipid associated) must be in full dose and patient must be well hydrated and volume expanded (using blood or saline) with attention paid to magnesium and potassium maintenance. Slowly advancing doses of this drug have been advocated without supporting data and entail the disadvantage of delay in achieving adequate therapy. Voriconazole (and other azoles) have significant interactions via the hepatic P450 metabolic system and the intravenous incipient has been associated with cardiac arrhythmias in renal dysfunction. The echinocandins have fewer drug interactions but are rarely the drug of choice for initial therapy of filamentous fungal infection. The *Mucoraceae* lack susceptibility to both voriconazole and echinocandins. *Cryptococcus* lacks susceptibility to echinocandins.

Special attention must be paid to any symptoms of pulmonary disease, the presence of new pulmonary infiltrates on chest radiographs, or the presence of sinus or CNS symptoms in patients with persistent fevers. New infiltrates should prompt examinations of sputum and procurement of specimens (open biopsy, thoracoscopic biopsy, or bronchoscopy, preferably with biopsies, or needle aspirates under tomographic guidance) for histologic and microbiologic evaluation.

BONE MARROW AND STEM CELL TRANSPLANTATION

Pulmonary manifestations of bone marrow and stem cell transplantation include a broad spectrum of infectious and noninfectious etiologies. Important pulmonary disorders complicating these procedures are discussed in detail below.

TEMPORAL SEQUENCE OF PULMONARY DISEASE SYNDROMES

The patterns of infection in hematopoietic transplantation have shifted due to early engraftment with hematopoietic stem cell

transplantation (HCT) compared with BMT and the use of nonmyeloablative transplantation (Fig. 123-2).[42] The impact is apparent in the shorter duration of neutropenia in the initial phase, early engraftment—but has not decreased the incidence of GVHD or the infections associated with immunosuppressive treatment of GVHD (Table 123-11).[43] Specific pulmonary complications can be grouped according to the status of the individual patient: preengraftment neutropenia (1–4 weeks), engraftment (fever and cytokine release, renal dysfunction), early and late postengraftment (up to approximately 26 weeks and 1 year), and late infections (based on the status of host immunity and epidemiology). Although this division is clinically useful, overlap occurs in the timing of specific complications, and the categorization of pulmonary complications is often arbitrary, since the cause of many respiratory abnormalities is uncertain. As a result, the microbiologic evaluation often accompanies empiric therapy including antimicrobial agents and diuresis (Fig. 123-15).

Inadequate tools are available to accurately assess the individual's immune function. Mucociliary clearance and macrophage function are decreased, often for years after transplantation.[44,45] T-cell depleted grafts and patients treated with T-cell depleting antibodies have less GVHD but more viral and fungal infections. Treatments including B-cell depletion have more bacterial infections due to encapsulated organisms. Prophylaxis served only to delay infection and to select resistant organisms unless immune function is restored. Killed organism vaccination is appropriate by 1 year post transplant with use of live vaccines reserved until immune function has normalized, generally by 2 years post transplantation.

In the early phase, neutropenia predominates with mucositis (and aspiration) being common, herpes simplex (in seropositive recipients), idiopathic pneumonia (respiratory viruses, CMV, pulmonary edema), *Aspergillus* infection, and line-associated infections (*Candida* species, gram-positive and gram-negative bacteria).[42,46] Viral pathogens predominate after engraftment but before T-cell function normalizes—CMV, VZV, AV (and other respiratory viruses), but also *P. jiroveci* (PCP), *T. gondii,* and molds (see Figs. 123-16 and 123-17).[47–50] Routine prophylaxis (TMP-SMX, antivirals) is generally effective in preventing such infections but may be limited by toxicity. Late and uncommon infections may occur at any time in the post-HCT course notably in those with persistent immune deficits.[51,52] Such individuals are at persistent risk for infections due to *Legionella, Nocardia, Mycoplasma*, mycobacteria, *S. stercoralis*, *Cryptosporidium* species, Epstein–Barr virus (EBV), posttransplant lymphoproliferative disorder or PTLD, and in those with hypogammaglobulinemia-encapsulated organisms including *S. pneumoniae, Neisseria meningitidis, and H. influenzae*.[53–55]

The most important characteristic that separates patients receiving ablative or nonmyeloablative conditioning for allografts from those receiving syngeneic or autologous marrow or stem cells is the occurrence of GVHD in the former group. Syngeneic and autologous graft recipients share early risk factors, such as neutropenia, with patients receiving allogeneic transplants and are at risk for early pulmonary complications, such as bacterial or fungal pneumonia and noninfectious treatment-related pulmonary injury.[56,57] Transplant recipients who have delayed engraftment or subsequent marrow failure are at continued risk for bacterial or fungal infection.[58,59] Allogeneic marrow recipients with GVHD, including those undergoing nonmyeloablative transplants, have continued abnormalities in immune function that increase the risk of opportunistic infections.[60] Among patients with chronic GVHD, infection and pneumonia due to encapsulated organisms (e.g., *S. pneumoniae, H. influenzae,* and *S. aureus*) appear related to deficiencies in specific antibody production, use of anti-CD20 antibodies, recurrent viral infections, resistance to common antimicrobials used for prophylaxis, and possibly continued defects in macrophage and NK cell functions.[61,62]

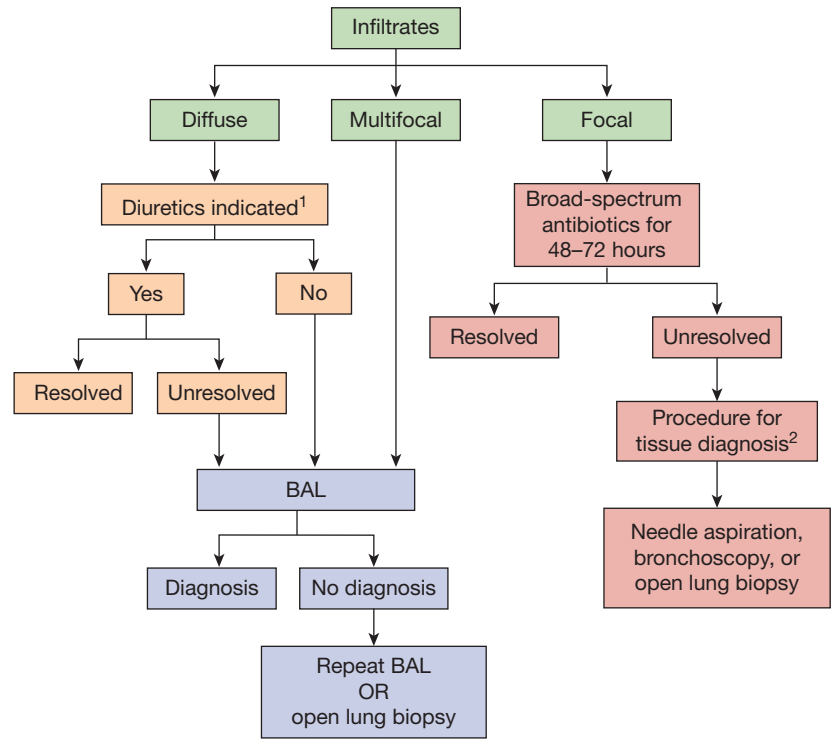

Figure 123-15 Diagnostic approach to pulmonary infiltrates after hematopoietic stem cell transplantation. [1]Diuretics often indicated in the first 30 days after transplantation. [2]Choice of procedure often influenced by results of CT scan of thorax.

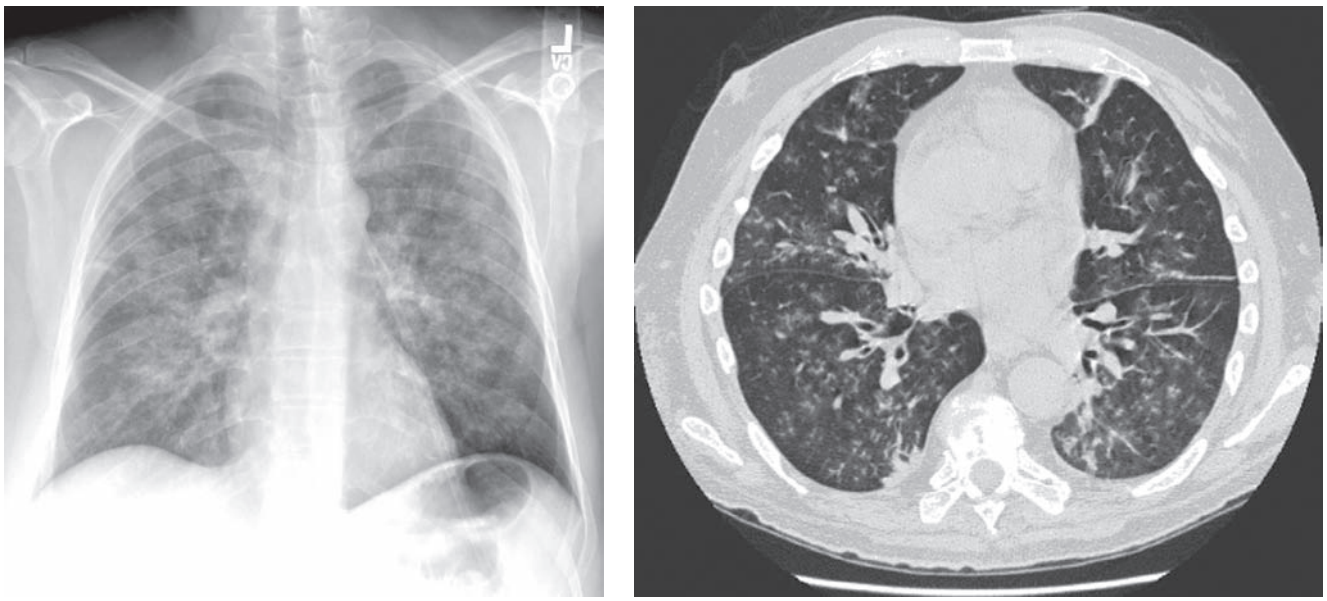


A B

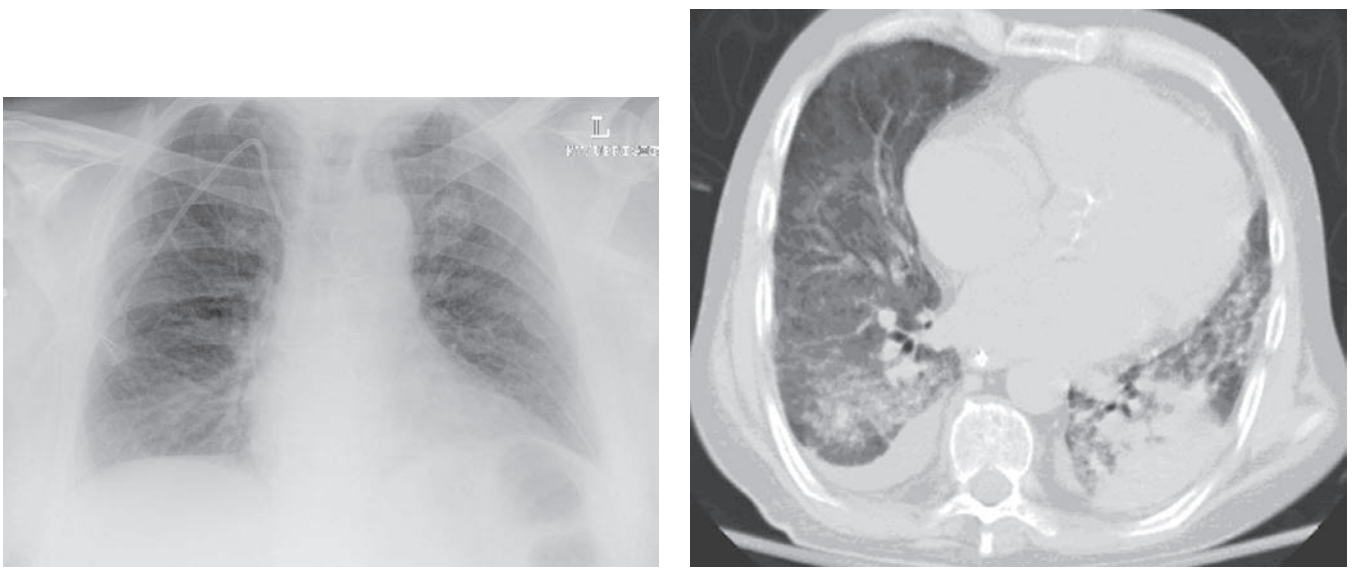
Figure 123-16 Adenovirus pneumonia during week after marrow engraftment following allogeneic hematopoietic stem cell transplantation for acute myelogenous leukemia. Routine chest radiograph (**A**) reveals diffuse pneumonia while CT scan (**B**) demonstrates bronchiolitis. The patient failed to respond to cidofovir therapy but cleared infection after infusion of autologous stem cells.

■ COMMON CLINICAL PRESENTATIONS

Signs and symptoms of pulmonary disorders related to marrow and hematopoietic stem cell transplantation are often nonspecific (Fig. 123-15). Tachypnea is common, as are fever, cough, and crackles. However, any or all of these may be absent at the time of presentation of pulmonary complications. Routine chest radiographs are obtained frequently during the first weeks of neutropenia and often provide the first indication of pulmonary impairment.

■ DIFFUSE INFILTRATES

Diffuse infiltrates are common radiographic abnormalities noted in marrow recipients.[63] However, these infiltrates are most often nonspecific. Infectious causes for diffuse infiltrates have been documented in fewer than 20% of marrow recipients undergoing open lung biopsy within 30 days after marrow transplantation. Within this early period, pulmonary edema syndromes predominate. The edema may be associated with cardiac decompensation or intravascular volume excess, or with acute respiratory distress syndrome (ARDS) and pulmonary capillary leak due to treatment-related toxicities or sepsis syndrome. Infections presenting with diffuse infiltrates within the first weeks after transplantation include respiratory viral causes, such as RSV or AV, while CMV is uncommon (Fig. 123-16). Alveolar hemorrhage may contribute to the radiographic infiltrates in



A B

Figure 123-17 Diffuse process on plain radiograph (**A**) of *Pneumocystis* pneumonia 8 weeks following hematopoietic stem cell transplantation for T-cell lymphoma. CT scan (**B**) revealed pattern most consistent with aspiration pneumonia. Bronchoalveolar lavage revealed *Pneumocystis* and antimicrobial-resistant *K. pneumoniae*. Treatment of both processes resulted in resolution of infection.

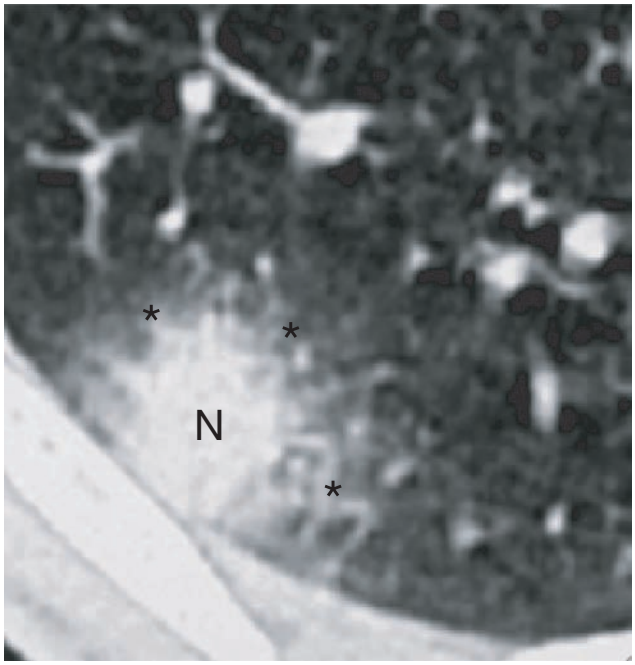


Figure 123-18 "Halo" sign in angioinvasive aspergillosis. CT scan of patient with fever and prolonged neutropenia during therapy for hematopoietic malignancy demonstrates a macronodule (N) surrounded by a halo of ground-glass opacity (*).

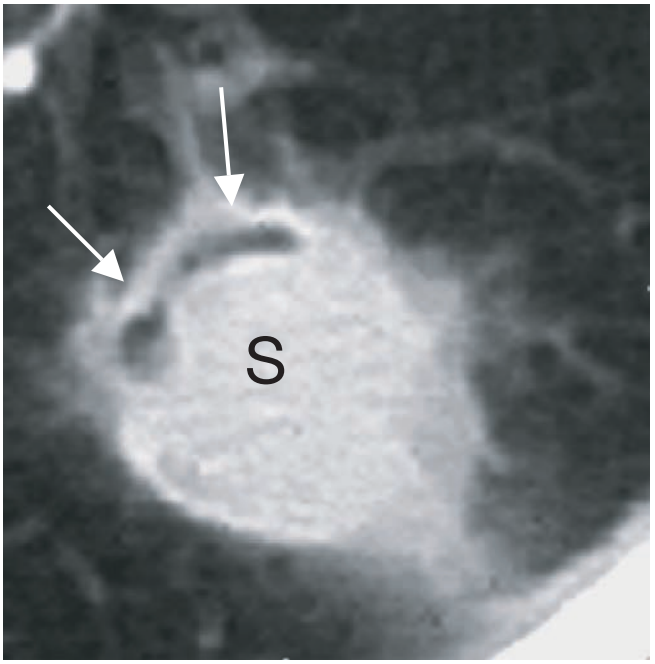

Figure 123-19 Air-crescent sign in late angioinvasive aspergillosis. CT scan of a patient with hematologic malignancy after recovery from profound neutropenia demonstrates a cavitary macronodule with an air crescent *(arrows)* at 10 to 1 o'clock outlining a central necrotic sequestrum (S).

the presence of thrombocytopenia, regardless of the cause of the lung injury.

After marrow engraftment, infections are a major reason for diffuse radiographic abnormalities. CMV was most common in the past, but is now less common in patients receiving appropriate prophylaxis or monitoring. Diffuse pneumonia due to bacterial infections (occasionally disseminated nontuberculous mycobacterial disease, *Mycoplasma* or *Chlamydophila*) also is unusual; however, diffuse involvement with fungus may occur in as many as 20% of diffuse infiltrates and may be extremely difficult to detect.

■ FOCAL LESIONS

Focal parenchymal infiltrates are frequent due to infection regardless of the time of presentation after transplant. Focal consolidations or masses are related to local fungal infection in 80% of marrow transplant recipients receiving broad-spectrum antimicrobials.[64] Classic signs of *Aspergillus* infection include pleural-based nodules with surrounding "halo" of ground-glass opacity (Fig. 123-18), occasionally with cavitation or development of the "air-crescent sign" (Fig. 123-19). Other causes are *Legionella* species, *Nocardia,* relapse of lymphoma in patients transplanted for that disorder, bronchiolitis obliterans with organizing pneumonia (BOOP), and, rarely, infarct due to thromboembolic disease.[65]

■ ASPIRATION

Desquamation of the oropharyngeal mucosa is a frequent complication after intensive chemotherapy, and the stomatitis is often referred to as "mucositis." It develops within the first week after radiotherapy and reaches its greatest severity after 10 to 14 days, and impaired mucociliary clearance is common. Recurrent aspiration of oropharyngeal contents is common among transplant recipients with oral mucositis due to sedation, poor cough reflex, and dysphagia.[66] These patients may present with basilar infiltrates or consolidation. Infection by HSV-1 of the oropharynx or esophagus may be confused with mucositis and may progress to pneumonia.

■ PLEURAL EFFUSIONS

Pleural effusions are common in the first weeks after marrow transplantation and are rarely related to an identifiable infectious source. Pleural effusions may be associated with fluid retention of any cause, especially with ascites secondary to HVOD. HVOD may occur in as many as 60% of patients after total-body irradiation or in association with GVHD. Characteristics include weight gain within the first weeks after transplantation and elevation of the serum bilirubin, which usually precede the development of pleural effusions. The effusions are frequently bilateral. Bilateral pleural effusions in the presence of weight gain can be approached conservatively without diagnostic thoracentesis. Cautious diuresis coupled with treatment of GVHD often produces satisfactory results. Small effusions are common and may be associated with treatment-related pleuropericarditis or thromboembolic events, but a specific cause is seldom determined. A large unilateral or rapidly accumulating effusion in the presence of fever or ipsilateral chest pain may represent hemorrhage or infection and should be evaluated promptly by thoracentesis.

■ NONINFECTIOUS ETIOLOGIES

Noninfectious causes of lung injury after marrow and hematopoietic stem cell transplantation include a spectrum of syndromes: idiopathic pneumonia, alveolar hemorrhage, pulmonary edema, obliterative bronchiolitis or BOOP.[56,57,67–70] Idiopathic pneumonia is characterized as a syndrome of hypoxemia and radiographic nonlobar infiltrates in the absence of congestive heart failure and without evidence of an infectious origin.[71,72] It is included as a form of "interstitial" pneumonia.[57,73,74] The term *interstitial pneumonia* in marrow transplant recipients refers to the syndrome of diffuse inflammatory pulmonary disease presenting with fever and tachypnea. This term includes noninfectious causes, as well as infectious pneumonia due to viruses (CMV). To avoid the ambiguity of the term *interstitial* in relation to inflammatory and other disorders of the lung, it is preferable to classify the clinical conditions as *diffuse*

pneumonia on the basis of the radiographic presentation. Most noninfectious causes of lung injury are attributed to treatment-related toxicities. Alkylating chemotherapy agents and ionizing irradiation are likely contributors; however, ARDS secondary to sepsis syndrome also may occur. While pneumonia is associated with the presence of GVHD, whether GVHD causes a direct lung injury is unproved. The role of unrecognized infections remains a concern.

IDIOPATHIC PNEUMONIA SYNDROME

The largest studies of idiopathic pneumonia after allogeneic marrow transplantation estimate the incidence at 12% to 17%. The spectrum of idiopathic lung injury is referred to as a "syndrome" (idiopathic pneumonia syndrome, or IPS) in recognition of the multiple causes and varied clinical presentation of this process.[57,71–74] The diagnosis of IPS is defined by a BAL that does not reveal an infection in the presence of nonlobar radiographic infiltrates and physiologic changes consistent with pneumonia. A common series of laboratory evaluations is presented in Table 123-4. Many clinicians use IPS to describe noninfectious lung injury occurring within the first 3 to 4 months after transplantation.

The causes of diffuse idiopathic pneumonia are often multiple and include treatment-related toxicities due to radiation or chemotherapeutic agents.[71,72,75] However, sepsis-related pulmonary toxicity may account for a proportion of cases of diffuse idiopathic pneumonia with histology consistent with ARDS. While GVHD is associated with an increased incidence of idiopathic lung injury, it is unclear whether this is a cell-mediated immune response to the lung or related to an increased incidence of sepsis in these immunosuppressed patients. Also, administration of large volumes of blood products during the transplantation procedure may lead to pulmonary vascular injury through leukoagglutination reactions. Other unusual causes of noninfectious diffuse pneumonia after marrow transplantation are leukemic infiltration due to relapse of primary malignancy, injection of malignant cells with reinfused autologous marrow, and fat embolization due to marrow infusion. Several cases of fat embolization have been associated with pulmonary hemorrhage and steroid administration.

The clinical presentation of IPS is nonspecific. Most patients develop a syndrome of fever, nonproductive cough, and tachypnea. Hypoxemia with hyperventilation is common. The onset is most often rapid, occurring over a few days. Occasionally, insidious onset similar to that of idiopathic pulmonary fibrosis is seen. The median onset is within the first 3 weeks of transplantation, but it may occur months later. The chest radiograph shows diffuse intra-alveolar and/or interstitial infiltrates. The presentation is not sufficiently distinct to be readily differentiated from that of pulmonary edema syndromes or diffuse infectious pneumonia. Marked tachypnea in the absence of radiographic infiltrates should raise the suspicion of obstructive airway disease or pulmonary veno-occlusive disease (PVOD), rather than idiopathic pneumonia.[76]

IPS after marrow transplantation represents a histologic spectrum ranging from a primarily interstitial reaction with diffuse or focal widening of the alveolar septa and interstitial spaces with mononuclear inflammatory cells and edema to diffuse alveolar damage (DAD) with alveolar epithelial necrosis, intra-alveolar hyaline membranes, edema and hemorrhage, and type 2-cell hyperplasia. The predominantly interstitial presentation has been referred to as *idiopathic interstitial pneumonia,* whereas the pathology of DAD is identical to that of ARDS. Variable degrees of alveolar hemorrhage may be seen with either of these presentations. By definition, all microbiologic and histologic evaluations for infectious agents (viral, protozoal, fungal, and bacterial) are negative in idiopathic pneumonia. The importance of a thorough microbiologic examination lies in the fact that these histologic presentations are similar to those of infectious pneumonia, especially CMV pneumonia.

Mortality from idiopathic lung injury after marrow transplantation remains over 70%. The diagnosis of idiopathic lung injury rests largely on the results of BAL. Lung biopsy (transbronchial or open) appears to add little to the diagnostic sensitivity of BAL for infection in the presence of diffuse parenchymal infiltrates. At present, histopathology does not help to direct therapy in idiopathic lung injury after hematopoietic stem cell transplantation. Lung biopsy should be considered in cases with patchy or multifocal infiltrates because of the higher incidence of infection and concern for false-negative results from BAL. There are no randomized studies of treatment of idiopathic lung injury after marrow transplantation. High-dose corticosteroids (ranging from 1 to 16 mg/kg per day of methylprednisolone) and other forms of intensive immune suppression are commonly used.

PULMONARY HEMORRHAGE

Robbins et al. described a potentially specific form of idiopathic pneumonia: diffuse alveolar hemorrhage (DAH).[77,78] The syndrome consisted of progressive dyspnea, hypoxemia, cough, and a progressively bloodier return from BAL in autologous marrow recipients, usually within 2 weeks of transplant. The incidence of DAH was 20.5% and was associated with age over 40 years, high fever, transplantation for a solid tumor, severe mucositis, white blood cell recovery, and renal insufficiency. Thrombocytopenia was a common finding, and patients with DAH received more platelet transfusions than patients without DAH. It is unclear whether this hemorrhagic pneumonia represents a unique syndrome or represents severe lung injury in the presence of a bleeding diathesis (see Chapter 68).

PULMONARY EDEMA SYNDROMES

Biventricular failure after transplantation is often iatrogenic and associated with excessive fluid administration and an increase in total body weight. Radiographic evidence of pulmonary edema after marrow transplantation has been reported in up to 50% of patients, most occurring in the second week. Close attention to the total amount of sodium and fluids administered can lead to dramatic reduction in the incidence of pulmonary edema. Also, pulmonary edema may be associated with left ventricular decompensation related to cardiotoxic cytoreductive regimens, including anthracyclines in excess of 500 mg/m^2 and high-dose cyclophosphamide. Posttransplantation cardiac and pericardial toxicity occur in 4% to 10% of cases, usually associated with total-body irradiation and cyclophosphamide, often in the setting of prior anthracycline administration. The utility of cardiac imaging studies before transplantation to predict heart failure is limited.

The most frequent noncardiac association with pulmonary edema is HVOD. The syndrome is often associated with interstitial pulmonary edema, the formation of pleural effusions, and renal failure. Noncardiac pulmonary edema also develops in association with acute GVHD and may be due, in part, to DAD and capillary leak. The presentation of pulmonary edema is nonspecific and usually occurs within 30 days after marrow infusion. Marrow recipients are often febrile and tachypneic at this time in the transplant course, and recipients of allogeneic marrow may display evidence suggestive of acute GVHD. Thus, the distinction between pulmonary edema and idiopathic pneumonia often cannot be made with certainty without pulmonary artery catheterization. However, recent increase in total body weight appears to correlate well with total-body fluid accumulation and should prompt a trial of diuretic therapy and a search for other signs of GVHD (GI, liver, skin) before consideration of invasive diagnostic procedures. Noninvasive assessment of cardiac function with

ultrasonographic or radionuclide techniques is often warranted to guide treatment.

NEW-ONSET AIRFLOW OBSTRUCTION AND OBLITERATIVE BRONCHIOLITIS

About 10% of allogeneic marrow recipients with chronic GVHD are likely to develop airflow obstruction consistent with obliterative bronchiolitis.[79,80] However, the reported incidence of obliterative bronchiolitis varies, in part, with the method used to identify the presence of the disease. Factors associated with the increased risk of GVHD, such as increasing age and HLA-nonidentical marrow grafts, are not independent risk factors for the development of obliterative bronchiolitis.[67–69,81,82] The cause of obliterative bronchiolitis after marrow transplantation is unknown (see Chapter 106).

The main manifestation of new-onset airflow obstruction is the insidious onset of tachypnea, dyspnea on exertion, and dry, nonproductive cough. Fever is uncommon. Although the chest radiograph is commonly interpreted as normal, high-resolution chest CT often reveals parenchymal hypoattenuation and segmental bronchial dilatation.[76] Auscultation of the chest may reveal scattered expiratory wheezing and occasionally diffuse inspiratory crackles, but results are sometimes normal. Arterial blood-gas analysis reveals moderate hypoxemia and, in the later stages, hypercarbia. Systemic evidence of GVHD is usually present. The major differential diagnoses of the gradual onset of nonspecific respiratory symptoms in the presence of a normal chest radiograph include PVOD and pulmonary embolism. Obliterative bronchiolitis is characterized by reduction in expiratory airflow on spirometry and increases in residual lung volumes not found in the other two diseases. Obstruction may be recognized incidentally as a result of coinfection due to respiratory viruses or *Pneumocystis*.

Patients with early onset of airflow obstruction after marrow transplantation tend to have a rapid decline in pulmonary function and a fatal outcome. These patients may not survive long enough to develop manifestations of chronic GVHD but usually display acute GVHD after BMT or HCT. It is possible that infection plays a role in the development of the airflow obstruction in some of these patients. Marrow and stem cell recipients with later onset of airflow obstruction tend to have a more gradual decline in lung function. Airflow may stabilize in 50% of these patients.

There are no prospective trials of treatment for new-onset airflow obstruction. At present, the accepted approach to these patients is to aggressively control with immunomodulating agents the chronic GVHD that most often accompanies the airflow obstruction. Treatment usually consists of increased immunosuppression. Reversal of the airflow obstruction is uncommon. The usual goal of management is stabilization of the obstruction. For this reason, prompt recognition and treatment for this progressive process are critical. Supportive measures include prophylaxis against *P. jiroveci* pneumonia and *S. pneumoniae* infection, inhaled bronchodilators, supplemental immunoglobulin administration to maintain normal serum levels, and prompt treatment of intercurrent infections.

PULMONARY VENO-OCCLUSIVE DISEASE

PVOD is a rare complication of treatment with chemotherapeutic regimens, and as a solitary pulmonary complication, PVOD is an uncommon but potentially catastrophic complication after transplantation. The primary histologic lesion of PVOD – obstruction of the pulmonary veins and venules by loose intimal fibrosis proliferation – may be difficult to detect with hematoxylin and eosin stains alone, and specific stains for elastic tissues, such as Verhoeff–van Gieson stain, are required to demonstrate the fibrotic reaction in the veins. The typical presentation of PVOD is that of insidious dyspnea on exertion and resting tachypnea within 3 to 4 months after transplantation. Significant hypoxemia may occur along with hyperventilation. The chest radiograph is often unrevealing. On cardiac examination, there is evidence of pulmonary hypertension. Auscultation of the lungs is often normal, although scattered inspiratory crackles may be heard. Noninvasive examinations, echocardiography, perfusion ventilation nucleotide scans, and electrocardiograms are nondiagnostic. Pulmonary function testing (PFT) may be consistent with mild restrictive defect, but airflow obstruction, suggesting obliterative bronchiolitis, is absent. BAL has failed to demonstrate pathogens or inflammatory cells. The diagnostic procedure of choice is a pulmonary angiogram. Right heart catheterization reveals elevated pulmonary artery pressure, with normal pulmonary artery wedge pressures. Angiography excludes the presence of thrombi as a cause of the pulmonary hypertension. In most cases presenting after treatment for malignancy, the disease follows an insidious course, with progressive hypoxemia and dyspnea on exertion due to pulmonary hypertension. Some patients recover with high-dose corticosteroid therapy or other immunosuppressive therapy.

INFECTIOUS ETIOLOGIES

The spectrum of infectious agents complicating stem cell and BMT is broad. Major categories of pathogens are discussed below.

Cytomegalovirus and Viral Pneumonias

In hematopoietic stem cell and BMT recipients, CMV pneumonitis occurs in the CMV-seropositive recipient of CMV-seronegative grafts. Because much of the lung injury is due to immune responses to CMV antigens, the full pneumonitis develops not during lymphopenia but rather with the engraftment of the marrow and with the reemergence of immune function. Viral replication is not needed for CMV pneumonitis to occur. The incidence of CMV pneumonia has declined significantly in recent years with routine prophylaxis and monitoring. Most CMV infection occurring in seropositive patients is due to reactivation of latent infection. The risk of infection in seronegative patients with seronegative marrow or stem cell donors is attributable to blood product exposure, and this risk can be virtually eliminated by use of screened seronegative or filtered blood products.

The clinical presentation of CMV pneumonia is not distinct from that of other entities associated with diffuse pneumonia. Patients with CMV pneumonia may have nonproductive cough, dyspnea, hypoxemia, or fever, with a median onset of 60 days after marrow transplant. Onset within the first 2 weeks is unusual. The period of risk of CMV pneumonia generally ends by approximately the fourth or fifth month after transplant, although later cases occur among patients with chronic GVHD or after autologous transplant. The chest radiograph generally shows bilateral infiltrates; in later stages, diffuse consolidation occurs. Unilateral, focal, and even nodular infiltrates have been seen in the early stages.

Treatment of proven CMV pneumonia remains disappointing, despite the availability of effective antiviral agents, including ganciclovir, cidofovir, and foscarnet and CMV-specific immunoglobulins.[83] Early therapy (any effect takes at least 5 days) should allow survival of up to 80%, but poor outcomes are common, notably in patients with respiratory failure at time of initial treatment. CMV pneumonia can be prevented in most cases with the prophylactic administration of ganciclovir or oral valganciclovir to seropositive recipients. Most seropositive patients who are at the highest risk of developing CMV pneumonia can be prospectively identified by CMV antigenemia or molecular assays on blood or sputum. Prospective use of these techniques after allogeneic transplantation permits preemptive treatment with ganciclovir, which appears to eliminate the incidence of CMV pneumonia. The side effects of the antiviral agents (neutropenia, thrombocytopenia, renal toxicity, neurotoxicity, magnesium wasting) may be limiting.

Other Viral Infections: RSV, Parainfluenza Virus, Adenovirus, Metapneumovirus, HSV, HHV-6

The respiratory viruses, particularly RSV, influenza, picornaviruses, and human metapnuemovirus (hMPV), are increasingly recognized as significant pathogens in these populations (see also Chapters 128 and 130).[84] Nosocomial transmission from infected healthcare workers has been documented. RSV is the most common respiratory viral pathogen in transplant recipients, but little progress has been made in managing RSV infections. Influenza annually causes increased morbidity and mortality in transplant recipients. M2 and neuraminidase inhibitors, alone or in combination, result in shorter duration of viral replication, decreased progression to lower tract disease, and reduced mortality. PIV continues to be recognized as a significant pathogen that is a risk factor for the development of acute and chronic rejection. Therapeutic options remain limited for PIV infections. AV has recently been shown to cause asymptomatic viremia in association with respiratory infection that resolves without therapy. Approximately 20% of marrow transplant patients with AV infection develop pneumonia (Fig. 123-16). Cidofovir appears to be the drug of choice in managing disseminated or life-threatening adenoviral infections, but not all strains are susceptible. Rhinoviruses have recently been recognized to cause significant lower tract disease and increased mortality. hMPV and coronaviruses, including severe acute respiratory syndrome (SARS)-associated coronavirus, have been recently discovered and are increasingly recognized as significant pathogens in immunocompromised hosts. Therapeutic options for both viruses are not yet clearly defined.

Pneumonia due to HSV or VZV occurs uncommonly. HSV pneumonia is generally due to contiguous spread of virus to the trachea or aspiration from the oropharynx, although it may be due to generalized infection with viremia. Pneumonia due to VZV occurs among patients with disseminated infection and viremia. Both situations have become exceedingly uncommon with the advent of acyclovir treatment and, in the case of HSV, acyclovir prophylaxis. Human herpesvirus 6, the cause of childhood roseola (exanthema subitum), has been detected in the lungs of some patients with idiopathic pneumonia. It is unclear whether this virus is a cause of pneumonia or merely latently reactivated, since virtually all adults are seropositive for the virus.

Fungal Infections

Fungal infections are reviewed in detail elsewhere (Chapter 133). Major risk factors for invasive fungal infections are the level and duration of neutropenia, age of the patient, the presence of GVHD, total number of other infections, and immunosuppressive administration after BMT or HCT. The frequency of *Aspergillus* infections is similar in recipients of allogeneic and autologous transplants, but they occur during periods of neutropenia before engraftment among autologous marrow recipients and after engraftment and during GVHD among allogeneic recipients.

Pneumocystis pneumonia occurs in as many as 10% to 15% of HCT recipients without the use of TMP-SMX prophylaxis, although regional and center-to-center variations exist. Except for patients being treated for chronic GVHD (who remain at risk and who should continue to receive prophylaxis), the risk period for *Pneumocystis* pneumonia ends approximately 120 days after transplantation. Because it is highly effective, TMP-SMX is the prophylactic regimen of choice. Other regimens have been discussed elsewhere. Patients with allergies to sulfa may undergo desensitization so that prophylaxis with TMP-SMX can be administered.

Other Nonbacterial Infections

Most infections with *T. gondii* infection have had only central nervous system disease diagnosed and treated during life, while involvement of heart and lungs may be documented at postmortem. Chest radiographs show diffuse, patchy involvement. These patients have also had concomitant bacterial or viral infections. Most infections have been fatal.

PULMONARY FUNCTION TESTING IN HEMATOPOIETIC STEM CELL TRANSPLANTATION

Pulmonary function testing (PFT) (see Chapter 33) is a standard part of the pretransplant evaluation at many centers. The results form baseline data for comparison with later testing, and have been used as an indication to exclude a candidate for transplantation. Abnormalities in the measures of airflow, lung volume, and diffusing capacity have been associated with increased risk of pulmonary complications after transplantation. After accounting for other clinical characteristics associated with death after transplantation (age, relapsed malignancy, HLA-mismatched graft), restrictive lung defect (decreased total lung capacity), hypoxemia, and reduced diffusing capacity are associated with statistically increased risk of death, especially within the first few months after transplant. The risks associated with these PFT results are applicable to autologous as well as allogeneic marrow recipients, suggesting that they predict mortality due to treatment-related toxicities. Hypoxemia and reduced diffusing capacity were independently associated with death, each carrying risk.

PFT performed after marrow transplantation has consistently revealed reductions in lung volumes and diffusing capacities associated with total-body irradiation and intensive chemotherapy. PFT abnormalities have been reported to include declines in lung volume, gas diffusion, and airflow. Losses of lung volume are more pronounced among patients who survive pneumonia after transplant. The declines in lung volume may be at least partly reversible within 2 years after transplantation, while the low diffusing capacity reportedly persists for several years. Development of airflow obstruction has been seen in approximately 10% of allogeneic marrow recipients in the presence of chronic GVHD and most often is related to obliterative bronchiolitis. Such PFT results strongly suggest that lung parenchymal and vascular injury is common features of marrow transplant, even in the absence of recognized infection or idiopathic pneumonia.

SOLID-ORGAN TRANSPLANTATION

In solid-organ transplant recipients, the time of onset of pulmonary manifestations of disease, coupled with the radiographic appearance, provide helpful clues regarding etiology.

■ TIMETABLE OF INFECTION

As immunosuppressive regimens have become standardized in recent years, it has become apparent that different infectious processes occur at different points in the posttransplant course.[1,60] That is, although pneumonia may occur at any point in the posttransplant course, its etiology varies according to time elapsed since transplantation (Fig. 123-2).

■ INFECTIONS IN THE FIRST MONTH FOLLOWING TRANSPLANTATION

In the first month after transplant, two major causes of pulmonary infection apply to all forms of organ transplantation. The first is the recurrence of pneumonia that was present prior to transplantation (in the lung allograft donor or in the recipient) but was incompletely treated, and which may be exacerbated after transplant due to superinfection with nosocomially acquired gram-negative bacilli and fungal species. This is most commonly seen in patients with end-stage liver or cardiac disease who require critical care support prior to transplant. Second, infection due to aspiration of nosocomial flora is often the result of postoperative vomiting (because of gastric distention or metabolic dysfunction) or due to a technical problem with the endotracheal tube in the perioperative period. The risk of antimicrobial-resistant

pneumonia increases with the duration of the pretransplant hospitalization, as well as with the duration of posttransplant intubation or ventilatory restriction (following the transplant surgery).

Donor-derived infection has been recognized in many recipients of lung transplants (mycobacteria, *Aspergillus*, colonizing gram-negative bacteria), occasionally with rapid progression after transplantation. It is essential to distinguish early lung allograft dysfunction from diffuse infection due to donor-derived viruses (HSV, VZV, CMV, respiratory viruses) or other pathogens (e.g., *Mycoplasma*). Extensive pulmonary injury before transplant places the patient at high risk for postoperative pneumonia that is poorly responsive to therapy. In the special case of the lung transplant patient who may require prolonged intubation, bacterial pneumonia and infection that threatens the bronchial anastomosis, particularly with *Aspergillus*, are special concerns (Figs. 123-20 and 123-21). These patients require exquisite attention to the technical aspects of the transplant procedure, to the management of the endotracheal tube, and the maintenance of pulmonary toilet (including, on occasion, repeated therapeutic bronchoscopy).

Notable by their absence in the first posttransplant month are the opportunistic infections, despite the fact that the highest daily doses of immunosuppression are administered during this first month. This emphasizes that it is the *sustained exposure to immunosuppressive therapy,* "the area under the curve," that is the major determinant of the net state of immunosuppression.

■ INFECTIONS ONE TO SIX MONTHS FOLLOWING TRANSPLANTATION

In the period 1 to 6 months after transplant, the nature of pulmonary infections changes markedly. During this time period the immunomodulating viruses, particularly CMV, are of importance in terms of direct effects (invasive disease) and immunologic or indirect effects (rejection, opportunistic infections). CMV may directly cause pneumonia; CMV may contribute to the incidence of graft rejection necessitating increased exogenous immune suppression and increasing the risk of opportunistic infection; or CMV (and the other immunomodulating viruses) are globally immunosuppressive and can enhance the likelihood of pulmonary infections due to *P. jiroveci, Aspergillus* species, and *Nocardia asteroides* in the *absence* of an unusual epidemiologic exposure (Fig. 123-20).

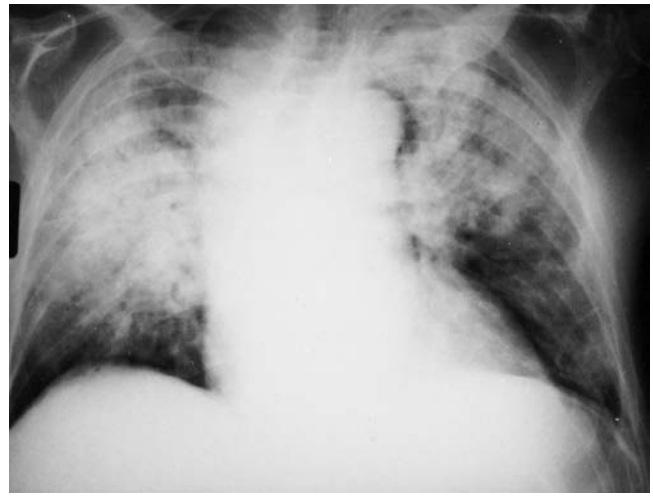

Figure 123-20 Invasive pulmonary aspergillosis after liver transplantation. A diffuse *Klebsiella* pneumonia was treated with a good clinical response to therapy. After 2 days without fever, the patient became febrile with increasing shortness of breath although the chest radiograph remained unchanged. One day after this radiograph was taken, the patient died. Autopsy revealed two processes in the lungs: a diffuse gram-negative pneumonia and focal areas of invasive aspergillosis restricted to the right lower and middle lobes. This figure illustrates the difficulty in differentiating the focal areas of *Aspergillus* superinfection from the primary bacterial process.

Unlike the bone marrow transplant recipient, the risk of active CMV *disease* (as compared with viral secretion) in the solid-organ transplant recipient is greatest in the CMV-seronegative recipient of an organ from a seropositive donor. Thus, CMV prevention and the utilization of diagnostic techniques for CMV viremia (e.g., quantitative nucleic acid testing, antigenemia assays, less often shell vial cultures with early antigen detection) are important parts of the therapeutic program.[85,86]

During this period, *in the absence of specific prophylaxis,* significant nonviral pulmonary infections are also common, including those

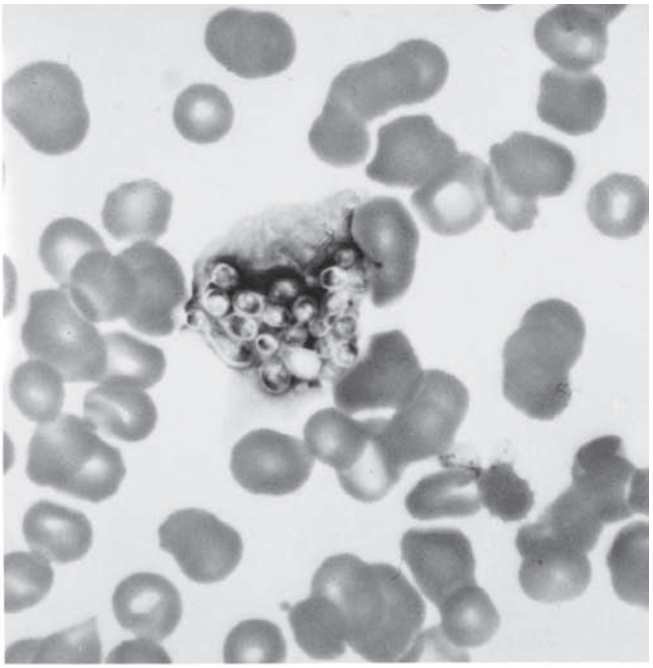
Figure 123-21 **A.** *Scedosporium (Pseudoallescheria boydii)* at the dehisced anastomotic site of a recent lung transplant. The organism is septate and branching and can be confused with *Aspergillus* species but may not respond to routine anti-*Aspergillus* therapy. Prominent terminal chlamydospores *(arrow)*, evoking the image of a tadpole, are a distinguishing feature. **B.** *Fusarium* sp. is septate with nonparallel walls, and branches predominantly at right angles, and n*arrows* at the branch points *(white arrow)*. Blastoconidia can be seen in many cases *(red arrow)*.

A



B

Figure 123-22 *H. capsulatum.* A 56-year-old man, lifelong resident of Kansas, presented 2½ years after a renal transplant with fever, nonproductive cough, and 3-month weight loss. The chest radiograph was diffusely abnormal. **A.** Close-up reveals extensive micronodular disease. **B.** Peripheral blood smear shows a macrophage laden with *H. capsulatum.* Treatment with liposomal amphotericin B resulted in clearing of the radiograph and cure of the infection.

due to *P. jiroveci, Aspergillus* species, endemic fungi (*Histoplasma, Coccidioides*) and *Nocardia asteroides* (Fig. 123-22).[87–89] There is important regional variation in the occurrence of each of these pathogens. At centers with high endemicity of these infections, low dose TMP-SMX prophylaxis (which effectively eliminates *Pneumocystis* and nocardial infection) and epidemiologic protection against *Aspergillus* (as with a HEPA-filtered air supply within the hospital) are effective, particularly in the context of effective CMV prevention.

■ INFECTIONS BEYOND SIX MONTHS FOLLOWING TRANSPLANTATION

In the period more than 6 months after transplant, patients can be divided into two groups in terms of the forms of pulmonary infection that can develop. Most patients will have had a good result from their transplant and will have good allograft function and receive relatively modest levels of maintenance immunosuppression. These patients are subject to community-acquired respiratory virus infection, particularly influenza and RSV, and pneumococcal pneumonia. The remaining patients have had a less positive outcome from their transplant; these individuals have less satisfactory graft function and require far more intensive acute and chronic immunosuppressive therapies to manage rejection. These patients, often termed "chronic ne'er do wells," are the subgroup of transplant patients at highest risk for pulmonary infection with such organisms as *P. jiroveci, C. neoformans, Nocardia asteroides,* and *Aspergillus* species (Fig. 123-23). Fungal infections are increasingly recognized in this population.[90–97] For this subgroup of patients, prolonged TMP-SMX prophylaxis and a consideration of antifungal prophylaxis in individuals from regions with high rates of endemic fungal infections are indicated (Fig. 123-22). Notable among the ne'er do well group is the liver transplant recipient with recurrent hepatitis C infection, the lung transplant with cystic fibrosis and resistant *Pseudomonas, Burkholderia*, or *Stenotrophomonas* infections, and the kidney transplant with chronic allograft dysfunction.[98,99] Mucociliary clearance is diminished in the lung recipient, often for the duration of graft survival.[100]

■ RADIOLOGIC CLUES TO THE DIAGNOSIS OF PNEUMONIA IN THE ORGAN TRANSPLANT PATIENT

The presentation and evolution of the chest radiograph provide important clues to both the differential diagnosis of pulmonary infection in the transplant patient and the appropriate diagnostic workup that should be undertaken (Table 123-12). The following radiologic parameters are useful in developing clinical-radiologic-pathologic correlations: (1) Time of appearance, rate of progression, and time to resolution of pulmonary roentgenographic abnormalities in relation to clinical events. (2) Distribution of radiologic abnormalities. An abnormality confined to one anatomic area is considered *focal,* whereas widespread lesions are considered *diffuse.* Abnormalities that are present in more than one area, but are countable, are termed *multifocal.* As visualized particularly on CT scanning, abnormalities may be located *centrally* or *peripherally* or both. (3) Which of three types of pulmonary infiltrate is present? The first type is a *consolidation,* in which there is substantial replacement of alveolar air by material of tissue density, typically with air bronchograms and a peripheral location of the abnormality. The second type is *peribronchovascular* (or *interstitial*), in which the infiltrate is predominantly oriented along the peribronchial or perivascular bundles. Finally, *nodular* lesions are space-occupying, nonanatomic lesions with well-defined, more or less rounded edges surrounded by aerated lung.

By combining this classification with information concerning the rate of progression of the illness (Table 123-12), a useful differential diagnosis is then generated.[101,102] Thus, focal or multifocal consolidation of acute onset will quite likely be caused by bacterial infection. Similar multifocal lesions with subacute to chronic progression are more likely secondary to fungal, tuberculous, or nocardial infections. Large nodules are usually a sign of fungal or nocardial infection in this patient population, particularly if they are subacute to chronic in onset.

C

Figure 123-23 *C. neoformans* in an asymptomatic renal transplant patient. The patient presented with minimal complaint of nonproductive cough of a few weeks duration. **A.** The chest radiograph was essentially clear other than a shadow in the right midlung field *(arrow)*. **B.** Chest tomography revealed a nodular lesion in the right midlung field *(arrow)*. Percutaneous needle aspiration of this lesion yielded *C. neoformans* on fungal culture. **C.** Nonhealing ulcer at site of previous intravenous catheter in the same patient subsequently grew *C. neoformans*.

TABLE 123-12 Differential Diagnosis of Fever and Pulmonary Infiltrates in the Organ Transplant Recipient According to Roentgenographic Abnormality and the Rate of Progression of the Symptoms

	Etiology According to the Rate of Progression of the Illness	
Chest Radiographic Abnormality	Acute[a]	Subacute–Chronic[a]
Consolidation	Bacterial (including Legionnaires' disease) Thromboembolic Hemorrhage (pulmonary edema)	Fungal Nocardia Tuberculosis Viral (Drug-induced, radiation, *Pneumocystis* tumor)
Peribronchovascular	Pulmonary edema (Leukoagglutinin reaction bacterial)	Viral *Pneumocystis* (Fungal, nocardial, tuberculous, tumor)
Nodular infiltrate[b]	(Bacterial, pulmonary edema)	Fungal Nocardial Tuberculous *(Pneumocystis)*

[a]*An acute illness develops and requires medical attention in a matter of relatively few hours. A subacute–chronic process develops over several days to weeks. Note that unusual causes of a process are in parentheses.*

[b]*A nodular infiltrate is defined as one or more large (>1 cm^2 on chest radiography) focal defects with well-defined, more or less rounded edges, surrounded by aerated lung. Multiple tiny nodules of smaller size, as sometimes caused by such an agent as CMV or varicella-zoster virus, are not included here.*

Subacute disease with diffuse abnormalities, either of the peribronchovascular type or miliary micronodules, are usually caused by viruses (especially CMV) or *P. jiroveci* (or, in the lung transplant patient, rejection).[103] Additional clues can be found by examining the pulmonary lesion for the development of cavitation, with cavitation suggesting such necrotizing infections as those caused by fungi, *Nocardia,* and certain gram-negative bacilli (most commonly with *Klebsiella pneumoniae* and *P. aeruginosa*). The depressed inflammatory response of the immunocompromised transplant patient may greatly modify or delay the appearance of a pulmonary lesion on radiograph, particularly if neutropenia is complicating the effects of the antirejection therapy. CT of the chest has revolutionized the evaluation of these immunocompromised patients, and CT is particularly useful when the chest radiograph is negative or when the radiologic findings are subtle or nonspecific. An additional important application of CT in this patient population is defining the extent of the disease process. Particularly with opportunistic fungal and noncardial infection, precise knowledge of the extent of the infection at diagnosis, and the response of all sites to therapy, will lead to the best therapeutic outcome, as therapy should be continued until all evidence of infection is eliminated, not just the primary site. CT findings are also quite useful in defining which invasive diagnostic procedure should be utilized to obtain diagnostic samples and in identifying the anatomic site at which sampling should be directed to optimize the diagnostic yield.

PRIMARY IMMUNE DEFECTS

Primary immune deficiencies are defined as alterations in the immune system that are congenital, as opposed to those related to chemotherapy, autoimmune disease, organ transplant, or chronic systemic disease. Clinical problems that require evaluation of the immune system include chronic or recurrent bacterial or fungal infections of the skin, sinuses, and respiratory and digestive tracts and repeated infections with unusual viruses. Other suggestive signs and symptoms are persistent atypical rashes, chronic diarrhea, failure to thrive, paucity of lymphoid tissue, lymphadenopathy, chronic conjunctivitis, and unusual reactions to live virus vaccines. Patients are often unresponsive to common vaccines.[104] About two-thirds of such disorders affect the production of immunoglobulins, while the remainder include cellular immune deficits, defects in phagocytosis, complement, innate immune function, or combined deficits.[105]

The initial evaluation begins with a physical examination, identification of any ongoing infectious process, and routine laboratory studies including a complete blood count and differential, chemistries and urinalysis. Lymphopenia is defined as an absolute lymphocyte count <1500 cells/μL in adults. Leukopenia is found in many primary disorders of the monocyte, macrophage and neutrophil lines. By contrast, leukocytosis may suggest chronic infections. Common metabolic disorders (diabetes, renal dysfunction, malnutrition) should be identified as well as protein losing enteropathy or renal wasting. The evaluation of recurrent infections will ultimately analyze all compartments of the host defense system, including anatomic structures, mucociliary function, B- and T-cell activity, phagocytic cell function, and complement activity.[106,107] Definitive diagnosis often requires specialized laboratory techniques including genetic analyses available only at referral centers. Table 123-13 outlines some of the initial and confirmatory screening tests available to most clinicians. As genetic studies have progressed, defective pathways have been identified to account for some of the more

TABLE 123-13 Immunologic Evaluation of Primary Immune Deficiencies

Suspected Abnormality	Screening Tests	Confirmatory Tests
Antibody	Serum IgM, IgG, IgA levels IgG antibody response to protein (diphtheria, tetanus, influenza) and polysaccharide (pneumococcus, *Haemophilus influenzae*) antigens Isohemagglutinin titers for IgM antibody response Serum IgG subclass levels	B-cell enumeration (total B [CD20] and surface IgM-, IgG-, IgA-, IgD-bearing B cells) In vitro immunoglobulin synthesis
Cell-mediated immunity	Total lymphocyte count Delayed hypersensitivity skin tests (diphtheria, tetanus, *Candida,* PPD, SK/SD for T-cell function) Tests for HIV antibodies	Enumerate total T cells and T-cell subsets (CD3, CD4, CD8) Measure T-cell function with mitogenic, antigenic, and allogeneic (mixed lymphocyte reaction) responses, lymphokine production, cytotoxic assay Assays for Th and Ts activity Enzyme assay (ADA, PNP) for ADA or PNP deficiency
Complement	CH_{50} or CH_{100} for classical pathway activity APH_{50} for alternative pathway activity Serum C2, C3, C4, C5, and factor B levels	Other specific component levels C1 esterase inhibition levels C1 esterase functional component
Phagocytic	NBT test for respiratory burst activity (defect in CGD) Serum IgE levels for HIE	Leukocyte adhesive protein analysis: (CD11 a/CD18, CD11 b/CD18, and CD11 c/CD18) Adherence and aggregation Chemotaxis and random motility Phagocytosis Assays for respiratory burst activity (chemiluminescence, oxygen radical production) Bacterial killing test Enzyme assay (MPO, glucose-6-phosphate dehydrogenase) for phagocyte enzyme defects Cytochrome *b* or cytosolic protein measurement for CGD

common immune deficiencies and some have been corrected by stem cell transplantation.

■ ANTIBODY (B-CELL) DEFICIENCY

Antibody deficiency states are among the most common of the primary immunodeficiency diseases.[105] Although the defect in immunoglobulin production can occur at any point in B-cell maturation/activation or secretion of antibody, or even in T- and B-cell interaction, the end result is a decrease in serum antibody levels or the inability to respond to antigens with specific antibody. Patients typically present with recurrent sinopulmonary infections caused by encapsulated bacteria such as *S. pneumoniae, H. influenzae* (both type b and nontypable), and *S. aureus*. Diseases caused by *Mycoplasma*, enteroviruses, and intestinal parasites are also occasionally seen. The incidence of autoimmune abnormalities and hematologic malignancies is also significant in patients with these defects. Treatment for most of these defects relies on the administration of gammaglobulin. Annual chest radiographs and pulmonary function tests are especially helpful, given that the lung disease in patients with hypogammaglobulinemia may be insidious in onset and progression.

■ X-LINKED AGAMMAGLOBULINEMIA

X-linked agammaglobulinemia (XLA or Bruton agammaglobulinemia) is a relatively common inborn error of immunity, occurring in 1 per 50,000 live births. A block in the normal maturation of immunoglobulin-producing B cells (block in V_HDJ_H recombination) results in the absence or severe reduction of serum immunoglobulin, absence of circulating mature B cells, and absence of plasma cells in all lymphoid tissue. T-cell number and function are intact. Inheritance is sex-linked recessive, although a clinically indistinguishable syndrome with autosomal recessive inheritance has been observed in some patients. Recent studies have localized the defect to a protein tyrosine kinase gene (Bruton tyrosine kinase, *btk*) on the proximal region (q21.3–q22) of the X chromosome. After maternal antibody is consumed (usually after the first 4–6 months of life), patients develop sinopulmonary infections, bacteremia, and meningitis with encapsulated gram-positive and gram-negative bacteria, such as *H. influenzae, S. pneumoniae, S. aureus, P. aeruginosa,* and *Mycoplasma pneumoniae.* Respiratory disease due to *P. jiroveci* or gastrointestinal infection with *Giardia lamblia* is also commonly observed. Although viral infections are not typical, enterovirus (polio and echo) and hepatitis viruses may cause severe or fatal disease. Autoimmune diseases, such as rheumatoid arthritis, occur in up to 20% of patients, while lymphomas and other lymphoreticular malignancies occur in approximately 5% of cases. IgG levels are very low (less than 100 mg/dL), and IgA and IgM are often undetectable.

■ COMMON VARIABLE IMMUNODEFICIENCY

Common variable immunodeficiency (CVI) is a not uncommon defect due, in general, to B-cell activation or differentiation defects, resulting in low serum levels of IgG and depressed levels of IgA or IgM. B cells may be normal, high, or low, and T-cell number and function, although usually normal at diagnosis, deteriorate with time. Although the disease is familial, it is not strictly X-linked or autosomally inherited. In some patients, the genomic defects of both CVI and isolated IgA deficiency appear to be localized to the major histocompatibility complex region of chromosome 6. The disease is characterized by the development of recurrent sinopulmonary infections or chronic bronchiectasis in childhood or adulthood. Chest radiograph findings consistent with atelectasis, bronchiectasis, and/or interstitial markings, along with pulmonary function tests revealing mild to severe obstruction and restrictive disease, are seen in 60% to 80% of CVI patients (Fig. 123-24). A few patients with CVI present with infections with unusual organisms, such as

B

Figure 123-24 **A.** PA chest radiograph of an adolescent boy with common variable immunodeficiency demonstrating marked bibasilar opacification, atelectasis, and infiltrative changes. Sputum culture grew only *H. influenzae* (nontypable). **B.** Pulmonary function tests from the same patient demonstrate significant restrictive disease; concurrent obstructive disease was supported by RV/TLC measurements. Marked improvement in radiographs and pulmonary function tests occurred with the use of continuous, rotating ciprofloxacin, cefaclor, and clarithromycin, in conjunction with aggressive chest percussion via a percussor vest and inhaled DNase.

P. jiroveci, mycobacteria, or fungi. Recurrent attacks of both herpes simplex and zoster are not uncommon.

■ SELECTIVE IGG SUBCLASS DEFICIENCIES

Patients with selective IgG subclass deficiencies have recurrent sinopulmonary infections associated with normal or decreased total concentrations of serum IgG, but with selective deficiencies of IgG subclass 1, 2, 3, or 4. Patients with IgG2 subclass deficiency can make antibody, but the spectrum of the response is decreased, resulting in recurrent infection. Recent studies suggest a critical role for IL-6 and IFN-γ in enhancing IgG subclass production. Titers to bacterial polysaccharide antigens are low even after immunization, since antibody responses to polysaccharides reside predominantly in the IgG2 subclass. Titers to protein antigens such as tetanus or diphtheria toxoids may be normal. IgG2 subclass deficiency

may be associated with IgG4 subclass deficiency, IgA deficiency, Wiskott–Aldrich syndrome (WAS), and ataxia-telangiectasia (AT). Persons with low or absent IgG2 or IgG4 appear to be particularly predisposed to recurrent or severe pneumonias and middle ear infections. Selective IgG3 deficiency is also associated with recurrent sinopulmonary infections, but the mechanism is not clear. These IgG3-deficient patients have normal responses to both common protein (Dt) and polysaccharide antigens; however, responses to influenza or rubella vaccine may be abnormal. Treatment is based on clinical findings of recurrent infections, rather than isolated laboratory abnormalities. It is important to document not only a low concentration of a subclass but also failure to make specific antibody when immunized, before immunoglobulin therapy is contemplated.

■ SELECTIVE IGA DEFICIENCY

This most common of all the inborn defects of humoral immunity, occurring in 1 per 700 persons, accounts for more than 1% of recurrent infections in children. The defect is assumed to be a differentiation block affecting IgA-committed B cells. Typically, peripheral counts of patients with IgA deficiency show normal numbers of mature B lymphocytes, as well as normal numbers and proportions of CD4 and CD8 cells. Selective IgA deficiency has been defined as serum IgA less than 5 mg/dL in severe deficiency and greater than 5 mg/dL but less than 2 SD below the age normal mean in partial IgA deficiency. The diagnosis and treatment of IgA deficiency depend not only on the serum level of IgA but also on the history and results of related diagnostic studies, particularly the immune workup. In general, treatment relies on the administration of appropriate antimicrobials for acute infection or chronic suppressive therapy for chronic infection. When IgA deficiency is associated with IgG2 deficiency, IVIG depleted of IgA may be indicated.

■ HYPER-IGM IMMUNODEFICIENCY

These patients have absent or markedly reduced IgA, IgE, and IgG levels, elevated levels of IgM, circulating mature B lymphocytes bearing IgM or IgD and plasma cells, as well as hyperplastic lymphoid tissue. Recurrent neutropenia, probably secondary to autoimmune phenomena, may coexist with the humoral defect. Because antibody protection for the gastrointestinal and respiratory tracts is normally provided by IgA and IgG isotypes, patients with this syndrome are especially prone to respiratory and GI infections with pyogenic organisms. They are also predisposed to *P. jiroveci* pneumonia. As with other immunoglobulin deficiencies, patients with the hyper-IgM syndrome have very high rates of autoimmune (involving the formed elements of the blood) and lymphoproliferative disorders.

■ COMPLEMENT DISORDERS

Disorders due to primary deficiencies of complement components are rare causes of pulmonary infections. Disorders fall into two general categories, including deficiencies in components of the complement activating cascades and deficiencies in complement regulatory proteins.[108,109] The former includes inherited disorders of complement components and presents with recurrent infections and/or autoimmune disorders such as systemic lupus. Deficiency of C1 inhibitor causes hereditary angioedema, a disorder of unregulated systemic swelling, while incomplete deficiencies of other complement inhibitors predispose to atypical hemolytic-uremic syndrome (aHUS). Eculizumab is a humanized monoclonal antibody and terminal complement inhibitor used in aHUS to inhibit thrombotic microangiopathy and to protect renal function. Complement function can be assessed by determining the total hemolytic activity in serum (CH50), which measures the ability of serum to lyse antibody-coated sheep cells. A low-to-absent CH50 suggests a deficiency in a classic pathway complement component. Levels of specific complement components can then be determined.[110]

Congenital absence of C3 or consumption of C3 due to deficiency of factor I (C3b inactivator) results in a clinical picture like that seen in deficiency of the critical antibody opsonins, including infections due to pyogenic bacteria including severe and recurrent pneumonias due to *S. pneumoniae, H. influenzae,* and Enterobacteriaceae.

The terminal complement components, C5–9, form the cytolytic membrane attack complex (MAC), and deficiency of any one of these will block MAC formation. C5–9 deficiencies predispose to disseminated infection with *N. meningococci* and *N. gonococci.*

C1 esterase inhibitor deficiency results in persistent consumption of C2 and C4 by the C1 esterases, resulting in release of vasoactive kinins and the development of nonpruritic angioedema. Although angioedema can occur in any tissue, including the GI tract, edema of the upper airway can be life-threatening. Diagnosis is suggested by family history (autosomal dominant state), edema without pruritus, and chronically decreased C4 and C2 levels, especially during the 24 to 72 hours of the episode. Patients with the familial form of the disease will have low-to-absent C1 esterase inhibitor concentrations. Angioedema with later onset, without a familial pattern, may be due to the absence of the functional component of the inhibitor, which may be associated with malignancy. Treatment is with danazol or purified C1 inhibitor for acute attacks.

■ DISORDERS OF CELL-MEDIATED IMMUNITY

Although the most characteristic infections in patients with cellular immune deficiency are those caused by opportunistic intracellular pathogens, including protozoa (*P. carini* and *T. gondii*), fungi (*Candida* and *Aspergillus* species), viruses (particularly those of the herpesvirus family), and some intracellular bacteria (including *Listeria* and *Mycobacteria species*), defects in humoral or phagocyte defense mechanisms may also be seen.

DiGeorge Syndrome

DiGeorge syndrome (DGS) is a constellation of abnormalities resulting from dysmorphogenesis of the third and fourth pharyngeal pouches.[111,112] Patients have hypoplasia or aplasia of the thymus and the parathyroid glands, complex cardiac malformations, esophageal atresia, bifid uvulas, cleft palate, short philtrums, mandibular hypoplasia, hypertelorism, and low-set notched ears. The severity of immunologic manifestations varies from severe forms with complete thymic aplasia, resembling severe combined immunodeficiency disease (SCID) (see below), to only latent hypoparathyroidism, which may also be seen in relatives of patients with DGS. Most patients have partial T-cell function, which may improve with age, presumably due to the adaptation of functional extrathymic sites for T-lymphocyte maturation. T-cell numbers are typically reduced, with reduced percentages of CD3 and CD4 cells, but CD8 cells may be normal or even elevated. Patients with more significant CD4 T-cell deficiency seem to have more frequent and severe infections requiring hospitalization. B-lymphocyte counts are usually normal; antibody production is also usually normal, but of poor biologic quality. Some patients may have low IgA or elevated serum IgE levels. Surviving infants often have the tendency to acquire parathyroid function, cell-mediated immunity, and functional T cells. Patients are prone to severe viral pneumonias, particularly those of the herpes and measles family. Pneumonias due to fungal and gram-negative bacilli and *P. jiroveci* also occur.

Severe Combined Immunodeficiency Disease

SCID is a syndrome of heterogeneous lymphocyte stem cell defects that affect both T- and B-cell function, resulting in profound hypogammaglobulinemia and absence of T-cell function. An array of genetically encoded SCID disorders appear to be linked by failure of immune cell signaling mechanisms.[113] Laboratory analysis may reveal lymphopenia (10%–20%) and normal or increased numbers

of circulating B cells, but severely reduced IgG levels. In general, patients with SCID syndrome present with a triad of mucocutaneous candidiasis, intractable diarrhea, and *P. jiroveci* pneumonia, evident shortly after birth or within 6 to 9 months of life and progressing to severe failure to thrive.[114,115] Within a few days after birth, patients may also develop a morbilliform rash that is probably a manifestation of GVHD from passively transferred maternal lymphocytes. Infections with a wide range of microbes occur in all forms of SCID, including viral pathogens, particularly herpesviruses (herpes, CMV, varicella), adenovirus, measles, influenza, and *Legionella.* Fatal giant-cell pneumonia has resulted from measles infection and live measles vaccination, and progressive vaccinia has occurred after smallpox vaccination.

Purine Nucleoside Phosphorylase

Absence of the enzyme purine nucleoside phosphorylase (PNP) is associated with marked cell-mediated immunodeficiency but intact humoral immunity. The gene encoding the enzyme is localized to chromosome 14q13.1. Patients are prone to disseminated viral infections, *P. jiroveci* infection, mucocutaneous candidiasis, and chronic diarrhea. Neurologic disorders afflict more than 50% of patients, and more than a third of patients with PNP develop autoimmune diseases.

Wiskott–Aldrich Syndrome

WAS is caused by a defect localized to the short arm of the X chromosome (Xp11.22–11.3), resulting in severely impaired production of antibodies to polysaccharide antigens, as well as variable reductions of T-cell numbers and impaired mitogen responses that tend to worsen with age. Both T-cell numbers and function progressively decrease, and profound lymphopenia becomes apparent at approximately 6 years of age. Most patients have abnormalities of serum immunoglobulin levels, with low IgM and isohemagglutinin concentrations, a tendency toward elevated IgA and IgE levels, and normal or slightly depressed IgG levels. Males afflicted with this syndrome suffer from a triad of recurrent infections, thrombocytopenia, and a skin disease indistinguishable from atopic dermatitis. Typical infections include pyoderma or cellulitis associated with eczematous eruptions, chronic otitis media with persistent otorrhea and/or mastoiditis, and chronic pneumonitis. Encapsulated pyogenic bacteria, such as *S. pneumoniae, H. influenzae,* herpesvirus, and *P. jiroveci,* are the most frequently identified pathogens.

Ataxia-Telangiectasia

AT syndrome is characterized by profound deficiencies of cellular immunity, (including lymphopenia, defects in cutaneous anergy, decreases in Th:Ts ratios, decreases in cytotoxic T cells, and an increase in immature T cells with increased gamma/delta TCR expression), impaired humoral responses (thymic hypoplasia associated with IgA deficiency, IgE deficiency, and IgG2 and IgG4 subclass deficiency), and a constellation of progressive cerebellar ataxia with degeneration of Purkinje cells. The defective genes of the two most common AT variants map to chromosome 11q22.3, which may result in a recombination defect that interferes with the rearrangement of T-cell and B-cell genes, an inability to repair damaged DNA, and a failure of normal organ maturation. Telangiectasias, particularly ocular and cutaneous, and a high incidence of malignancies, particularly non-Hodgkin lymphoma, and breast cancer (in heterozygous female carries of the AT allele) are seen. AT is also associated with insulin-resistant diabetes mellitus, gonadal agenesis, premature aging, elevated levels of serum a_1-fetoprotein and carcinoembryonic antigen, and hypersensitivity of fibroblasts and lymphocytes to ionizing radiation, reflecting an inability to repair damaged DNA. Patients suffer from an increased incidence of bacterial and viral sinopulmonary infections, and many eventually develop chronic bronchiectasis. The most frequent pulmonary pathogens are *S. aureus* and other encapsulated bacteria. Concurrent IgG2 (50%), IgG4, and IgA deficiencies (70%) may be associated with the tendency toward recurrent infections of the respiratory tract. Approximately 80% of patients have depressed IgE levels.

■ PHAGOCYTIC DEFECTS

Compromised immunity may be related to inadequate phagocyte numbers or to deficient phagocyte function. Disorders representing each of these categories are discussed below.

Disorders of Phagocyte Numbers

These disorders include cyclic neutropenia, Felty syndrome, Kostmann syndrome, Shwachman–Diamond syndrome, and autoimmune neutropenia. They are characterized by absolute PMN counts as low as 50 to 200/mm but typically lower than 1000/mm.[116] Owing to the presence of a compensatory monocytosis, these disorders are associated with a low incidence of severe respiratory infections, although pneumonia is seen – as are furunculosis, subcutaneous abscess, and otitis media. Typical pathogens include *S. aureus, P. aeruginosa,* and enteric bacteria.

Defects of Phagocyte Function

A variety of syndromes characterized by alterations in phagocytic function have been described. The most commonly observed are noted briefly in subsequent sections.

Chronic Granulomatous Disease Chronic granulomatous disease (CGD) is caused by a defect in a membrane-associated nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in phagocytic cells, resulting in the failure of phagocytic cells to produce superoxide, hydrogen peroxide, and other reduction products of oxygen that are necessary for killing certain microbial species.[117] Diagnosis is made by the inability of neutrophils to reduce nitroblue tetrazolium (NBT) from yellow to blue-black formazan and by the inability of neutrophils to kill staphylococci or other catalase-positive microorganisms. Additional laboratory findings suggestive of CGD include leukocytosis, elevation of erythrocyte sedimentation rate, abnormal chest radiographs, and hypergammaglobulinemia.

Onset is typically in infancy, childhood or, less commonly, early adolescence, with a male-to-female ratio of 6:1. All forms of CGD are characterized by abscess formation at sites of bacterial tissue invasion and in lymph nodes, liver, and lung. Patients present with severe recurrent lymphadenitis and infections of the skin, sinopulmonary and GI tracts. Severe and recurrent pulmonary infections occur in almost all patients with CGD, including bronchopneumonia, empyema, lung abscess, and hilar adenopathy syndromes. Most young adult patients demonstrate chronic bilateral infiltrates, pulmonary fibrosis, or pulmonary calcifications associated with restrictive/obstructive disease. Aggregates of granulomas, leading to mechanical obstruction, may form as a response of activated macrophages to microbial persistence and chronic antigenic stimulation. *S. aureus* represents by far the most common cause of infections in CGD. Other catalase-positive and non–H_2O_2-producing organisms include *Escherichia coli, Klebsiella,* and *Enterobacter* species, *Serratia marcescens, Salmonella* and *Pseudomonas* species. Pneumonias in CGD patients may be caused by *M. tuberculosis,* atypical mycobacteria, and *P. jiroveci.* In specific geographic locations, such as the southeastern United States, *Chromobacterium violaceum* has been recognized as the cause of infection in several CGD patients. *Nocardia* infection, particularly of the respiratory system, is also relatively common, as are fungal infections (Figs. 123-25 and 123-26). Antimicrobials and interferon-gamma have been useful in therapy.[118]

B

Figure 123-25 **A.** PA chest radiograph of a child with CGD who originally presented as an infant with recurrent pneumonia in the right upper lobe diagnosed radiographically as cystic adenomatoid malformation. Subsequent histologic examination and culture revealed this to be nocardial pneumonia. This radiograph reveals recurrent diffuse nocardial pneumonia. **B.** Pulmonary function tests from the same patient showing mild restrictive disease, probably secondary to right upper lobectomy and recurrent airspace disease.

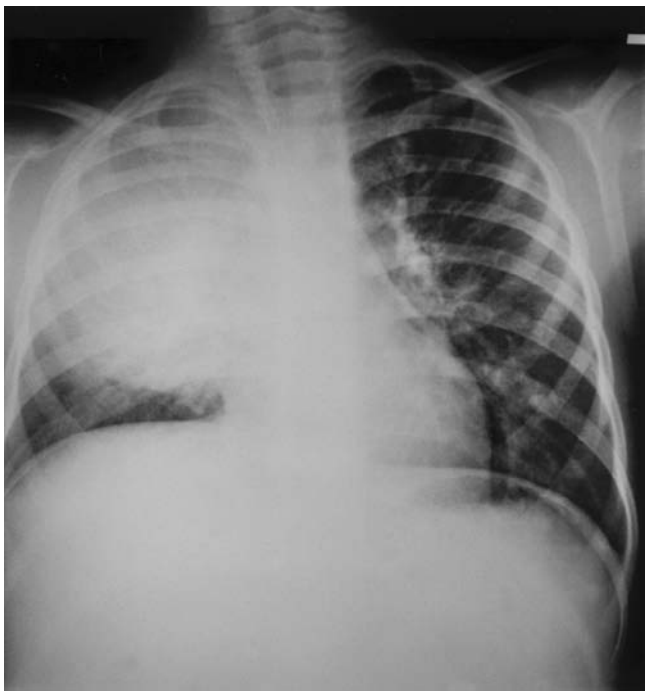

Figure 123-26 PA chest radiograph in a patient with CGD demonstrating nocardial abscess of right upper lobe, extending into the anterior chest wall.

Glucose-6-Phosphate Dehydrogenase Deficiency This is a variant of CGD, in which glucose-6-phosphate dehydrogenase (G6PD) levels are less than 1%, resulting in an inability to generate oxygen by-products and a slightly milder form of disease than that in patients with CGD.

Chediak–Higashi Syndrome Chediak–Higashi syndrome (CHS) is a rare autosomal recessive defect characterized by abnormal fusion of azurophilic lysosomes of neutrophils and cytoplasmic granules of monocytes and lymphocytes. This defect results in impaired microbicidal activity of phagocytes due to the presence of giant lysosomal granules, which have abnormal postphagocytic phagolysosomal fusion and degranulation. In addition, neutrophil counts tend to be low, secondary to their rapid turnover. Chemotactic defects and impaired natural killer cell activity have also been noted. Patients present with recurrent skin and upper and lower respiratory tract infections, including recurrent or chronic otitis media, sinusitis, and pharyngitis, in addition to lower respiratory tract infections, including bronchopneumonia. Segmental or lobar lung involvement may account for up to 30% of documented infections. Most infections are due to *S. aureus, H. influenzae,* group A streptococcus, and gram-negative enteric organisms (*Klebsiella, Proteus, Shigella, Pseudomonas*). *Aspergillus* and *Candida* represent less common etiologic agents. Respiratory failure can occur with extensive histiocytic infiltration of the lungs during an accelerated lymphoma-like proliferative phase marked by widespread tissue infiltrates of lymphoid and histiocytic cells, usually without malignant histologic characteristics. Anemia, hypersplenism, and platelet dysfunction, associated with the accelerated phase, and albinism or hypopigmentation, due to abnormal fusion of melanocyte pigment organelles, are also seen.

Leukocyte Adhesion Deficiency Patients with this autosomal recessive disease lack or have markedly reduced α_2 integrins, essential glycoprotein constituents of the CD11/CD18 receptor complex that mediates leukocyte adhesion. Recurrent necrotic and indolent infections of soft tissues, primarily in skin, mucus membranes, and the intestinal tract, are the clinical hallmarks of this disease. The recurrent infections reflect a profound impairment of leukocyte mobilization into extravascular inflammatory sites, despite peripheral blood granulocyte counts of 15,000 to 161,000/mm. A wide spectrum of gram-positive or gram-negative bacteria (*S. aureus* and gram-negative enteric bacteria) and fungal microorganisms (*Candida* and *Aspergillus*) infect LAD patients, similar to those with neutropenia syndromes (Fig. 123-27).

■ HYPERIMMUNOGLOBULIN E SYNDROME

Also known as the hyper-IgE (HIE) recurrent infection or Job syndrome, this unusual disorder appears to be autosomal dominant with incomplete penetrance or sporadic and is related in many cases to defects in the signal transducer and activator of transcription 3 gene (STAT3).[119–121] This syndrome presents in adults with elevated serum levels of polyclonal IgE and are susceptible to disseminated nontuberculous mycobacterial infections, viral infections, and fungal infections including histoplasmosis and molds. Some patients develop alveolar proteinosis. Patients demonstrate circulating monocytopenia, B lymphocytopenia, and NK cytopenia. Many patients develop malignancy involving the hematopoietic system or of the female genital tract.

Figure 123-27 PA chest radiograph in a child with CD18 neutrophil receptor deficiency demonstrating extensive airspace disease due to probable candidal and pyogenic bacterial pneumonia.

B

Figure 123-28 **A.** PA chest radiograph in a patient with Job syndrome, after left upper lobectomy for bronchiectasis due to *Aspergillus fumigatus,* resulting in recurrent, severe hemoptysis. Chest radiograph shows residual bronchopleural fistula with loculated air collection in the left upper lobe, extensive airspace disease in the left lower lobe, and pleural thickening. **B.** Pulmonary function tests from the same patient showing mild restrictive disease despite his extensive left-sided pulmonary disease.

Most patients have mild to moderate eosinophilia, despite lacking a significant history of classic allergic diseases. All patients have chronically elevated erythrocyte sedimentation rates. Diagnosis of HIE can be established in patients (usually during infancy) with a history of staphylococcal infections of the skin and sinopulmonary tract, and IgE levels at least 10 times normal. Coarse facies, chronic eczematous eruptions, cold cutaneous or subcutaneous abscesses, eosinophilia, and mucocutaneous candidiasis are also seen, as are recurrent bone fractures and osteopenia. "Cold abscesses" are not seen in all HIE patients, but are rare in other immunodeficiency states. They can present in any part of the body as fluctuant masses, with little evidence of inflammation and often without fever. Drainage of these abscesses usually reveals large volumes of purulent material, which almost always grow *S. aureus*. Otitis externa and chronic otitis media, occasionally complicated by mastoiditis, are common in HIE patients. Recurrent bronchitis represents the most common pulmonary manifestation of HIE. Patients often suffer several days a month of productive cough, rarely associated with fever. Less commonly, pneumonia, with or without associated complications – including bronchiectasis, lung abscess, empyema, pneumatocele formation, and bronchopleural fistula formation – may represent serious and potentially devastating features in HIE patients. *S. aureus* and *H. influenzae* are the most frequent causes of pneumonias in HIE, but fungal infections may complicate management (Fig. 123-28). Management relies on the use of narrow-spectrum antistaphylococcal prophylaxis, such as cloxacillin or dicloxacillin. TMP-SMX may also be employed as a prophylactic agent.

■ DEFECTS IN INNATE IMMUNITY AND PATTERN RECOGNITION RECEPTORS

The innate immune system responds to microbial products via a system of germ-line encoded PRRs. In addition to physical barriers (skin, mucosa), phagocytes and antimicrobial peptides (AMPs) (e.g., defensins), epithelial enzymes (lysozyme), cytokines and inflammatory mediators (including the complement system), the PRRs play a central role in the recognition and response to microbial invasion. The microbial components recognized by PRRs are called pathogen-associated molecular patterns (PAMPs). PRRs sit at the interface of the innate and adaptive immune systems to accelerate development of focused, specific immune responses. Defects in innate immune mechanisms are being recognized in individuals with recurrent infections.

Secreted and circulating PRRs participate in direct microbial killing and opsonization and include AMPs, defensins, lectins, cathelicidin, collectins, and pentraxins. The AMPs disrupt the cell membranes of many organism types including bacteria, fungi, parasites, and enveloped viruses. The collectins bind to microbial cell wall carbohydrate or lipid moieties to enhance microbial killing or phagocytosis. The pulmonary surfactant proteins SP-A and SP-D are collectins that bind oligosaccharides on many bacteria, fungi and viruses. The lectins are proteins that bind microbial carbohydrates and include mannose binding lectin (MBL), the ficolins and galectins. MBL is an acute-phase reactant produced by the liver that binds terminal mannose residues of carbohydrates to opsonize many organisms for phagocytosis via the C1q receptor with activation of the complement pathway. MBL deficiency is associated with frequent infections of various types. The pentraxins are acute phase reactants secreted in response to inflammatory cytokines and/or binding of TLRs. C-reactive protein (CRP) is a pentraxin that opsonizes pneumococci via the C-polysaccharide with fixation of C1q and activation of the complement system.

Defects are likely to be detected in many of the transmembrane PRRs expressed on neutrophils, monocytes, macrophages, epithelial cells, and on antigen-presenting cells including monocytes, macrophages, dendritic cells, and B lymphocytes. In this group, the TLRs are a series of transmembrane and intracellular PRRs that recognize a variety of PAMPS, including microbial cell wall components, proteins, and nucleic acids. Binding of the TLR results in changes in the transcriptional regulation controlling inflammatory processes. The first identified was TLR4 which binds bacterial endotoxin (LPS) and via the MyD88-dependent signaling pathway, activates proinflammatory cytokines, including TNF, interleukin (IL)-6, and proIL-1. TLRs 3, 4, 7, 8, and 9 can activate antiviral type-1 interferons. Families with deficiencies in TLR-3, -4, -7, -8, or -9 signaling suffer severe HSV infections including encephalitis. TLR4 mutations may also predispose to pulmonary complications after stem cell transplantation.[122] The transmembrane C-type lectin receptors (Dectins 1 and 2 and MINCLE) bind sugars (glucans and glycans) notably on fungi. Defects in Dectin 1 or its signaling pathways are associated with recurrent mucocutaneous fungal infections while phagocytosis and killing of fungi by leukocytes is normal. Thus, in individuals with a history of unusual infections, genetic defects in the innate immune system might be considered.

CHAPTER 124

Microbial Virulence Factors in Pulmonary Infections

Gregory P. Priebe
Gerald B. Pier

OVERVIEW: MICROBIAL PATHOGENESIS

Beginning at birth, microbial organisms enter and leave the body, primarily on external or mucosal surfaces. Some of these predominantly commensal organisms become resident; others are transient; and still others establish latent foci in otherwise sterile spaces. Over a lifetime, a person is the reservoir for hundreds of strains of viruses, thousands of bacterial species, and a scattering of fungi and parasites. When these organisms violate their niche, invade, or produce toxic products, and at the same time overcome innate and adaptive host defenses, virulent interactions take place and occasionally lead to disease. Organisms can cause disease without entering or adhering to tissues by releasing toxic products. However, all infections caused by obligate intracellular parasites such as viruses require attachment of microbes onto cells and subsequent intracellular invasion as typified by the viral hemagglutinin molecule on the surface of the influenza virus, which determines species and tissue tropism, transmissibility, and replication.[1,2]

Binding to cells does not always occur with bacterial pathogens, particularly in the lung. In contrast to the GI tract where most bacterial pathogens must attach to surfaces and some, such as *Shigella dysenteriae*, do enter into cells, many studies with common respiratory bacterial pathogens such as *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Streptococcus pyogenes*, and others have found that avoidance of binding to respiratory epithelial cells promotes progression of infection and development of disease. Thus, the statement that one often encounters that bacterial binding to epithelial cells initiates infection in

the respiratory tract is not correct for some prominent lung pathogens. This is likely due, in large part, to the role of bacterial cell binding to the respiratory epithelium in promoting clearance of most organisms entering the lung (see Chapter 121). This occurs by a variety of nonspecific innate immune mechanisms that are potently activated by microbial binding to epithelial surface or, following binding and internalization, binding to intracellular toll-like receptors (TLRs) and other conserved pattern-recognition molecules. Along with induction of cytokine synthesis and release there is a rapid activation of beneficial inflammation and clearance. In some situations, however, organisms are able to avoid such clearance and propagate and produce clinical symptoms. For example, in neutropenic mice, the infectious dose of *P. aeruginosa* applied to the nose of an anesthetized animal that produces a lethal pneumonia and sepsis can be in the range of 10 to 50 bacterial cells, whereas in a neutrophil-sufficient setting usually 10^7 to 10^8 bacterial cells are needed to initiate infection. Clearly, avoiding polymorphonuclear leukocyte (PMN)-mediated clearance initiated by innate immunity is essential for serious disease due to *P. aeruginosa*. This finding highlights how pathologic conditions in the host can predispose to entry and survival of microbes, ranging from breaks in mucosal surfaces to defects in the immune system (see Chapter 121). Organisms become parasites when they express the requisite *virulence determinants* to gain entry and overcome or evade host defenses.

An important step in establishing infection occurs when the potential pathogen encounters the immune system. There are numerous mechanisms whereby the immune system detects and tries to limit the extent of microbial challenge, including inflammation (acute and chronic), phagocytosis (neutrophils and macrophages), complement activation, and humoral and cellular immune responses. The immune system also maintains surveillance for organisms that invade phagocytes, propagate, and resist killing, and also for organisms that invade nonphagocytic cells. Means by which microbes can be controlled range from physical clearance mechanisms to phagocytosis (followed by oxidative or nonoxidative killing) to nutritional depletion (e.g., sequestration of iron, which is an essential nutrient for bacterial growth).

Microbes have evolved a variety of strategies to overcome host defenses, evade the immune system, scavenge for nutrients, eradicate competing bacteria, and survive to spread to other hosts. These processes can lead to tissue damage and even death of the host. However, ultimate survival of the microbe requires eventual spread to a new host. A new "generation" of microbes is established (by clonal division) approximately once an hour, whereas a new generation of humans occurs about once every 20 years. Thus, the microbes have a clear genetic advantage in selecting properties that enhance virulence and survival. In response, the human immune system has developed a variety of defenses against a broad range of pathogenic mechanisms. Infections can occur at specific sites on surfaces or within the body or involve local, distal (metastatic), or systemic spread. Infection can occur without damaging cells, through direct cellular damage by microorganisms or their toxins, or as a consequence of the immune response. When physiologic disruption or cellular damage occurs, the host needs to recover and repair the damage. In addition, the immune system attempts to recognize the pathogen and develop an effective adaptive immune response involving T cells and antibody to prevent reinfection. Pathogens have also evolved a series of mechanisms to avoid immune detection, including local interference with immune processes, antigenic variation, avoidance of inducing immune responses, or inducing ineffective immune responses.

Organisms are constantly evolving to meet the demands and opportunities of modern society. Just as the cities of the Middle Ages brought together humans and rats and caused outbreaks of bubonic plague, the use of antibiotics, chemotherapy, and various medical devices has led to a number of new pathogenic interactions between microbes and humans. A key to understanding the pathophysiology of infectious diseases and appreciating the complexity of both the immune system and the microbial world is knowledge of the facts and processes of each; this knowledge base is necessary for an appreciation of the ideas presented above and the conceptual basis of immunity and infection as related to respiratory tract infections.

GENERAL MECHANISMS OF INFECTIOUS PROCESSES IN THE RESPIRATORY TRACT

The pathogenesis of acute and chronic microbial infections of the lung entails complex interactions between the microorganisms and a variety of host defense mechanisms. The general steps and molecular factors involved in the pathogenesis of microbes causing lung infections are summarized in Table 124-1. Although the alveolar spaces are generally sterile, low levels of microorganisms are continually inhaled into the lungs. Inoculation of the lungs can occur from a variety of sources, including aspirated oropharyngeal secretions or bacteria in small aqueous droplets inhaled directly via the nose or mouth. Most commonly, inhaled organisms, either alone or in association with particles of mucus, gain access to the lower airways. They are generally either cleared by mucociliary flow or scavenged by phagocytes (see Chapter 121). Particulates greater than 10 μm in diameter are deposited in the larger airways. Particles of less than 5 μm that are not cleared in the larger airways can be deposited in the alveoli. Most particulate matter is not infectious, and only spores or organisms that remain viable can cause infection. Thus, the pathogenesis of microbial infection will initially depend on a microbe's ability to enter the respiratory system and avoid clearance by mechanical and innate immune mechanisms.

As noted earlier, microorganisms can reach the lower airways from various sources. Organisms in ambient air can be inhaled as droplet nuclei—particularly in closed environments, where density is great and infected individuals can deposit organisms into the air. Perhaps the most important source of organisms causing pneumonia

TABLE 124-1 Steps and Molecular Factors for Infectious Microorganisms to Cause Lung Disease

Step	Molecular Factors	Result
Attachment to or entry into the body	Pili, flagella, surface proteins, LPS, specific ligands for receptors on host cells, or mucins	Establish organisms in a host
Multiplication	Iron-binding factors; quorum-sensing signals, biofilm matrix	Increase microbial numbers; activate other virulence systems; initiate clinical symptoms
Local spread in the lungs	Capsular polysaccharides, antiphagocytic factors, motility (pili and flagella), toxins	Evade defenses and the natural barriers to spread
Damage to lung tissue, dissemination to bloodstream	Exotoxins (including type III secretion system), LPS, cytotoxins, immunosuppressive factors	Inflict pathology due to the infectious agent, cause systemic evidence of infection (sepsis, septic shock)
Shedding (exit) from the body	None identified	Leave body at site and on a scale that ensures spread to a new host

is the flora of the upper respiratory tract. A large ecosystem of microorganisms that includes both pathogenic and nonpathogenic bacteria and fungi normally resides in the upper airways (see Chapters 127 and 133). The quantity and species diversity of many of these organisms can be stable over long periods, but transient colonization with a variety of microbes also occurs with some frequency, and these changes are often correlated seasonally and/or with concomitant infections with respiratory viruses. For example, *Streptococcus pneumoniae* (pneumococcus) and *Neisseria meningitidis* are more frequently isolated from the nasopharynx or throat during the winter months. Bacteria colonizing the nasopharynx of healthy children are often associated with the concurrent presence of certain viruses and bacteria, for example, *Staphylococcus aureus* with influenza but not rhinoviruses or pneumococcus; pneumococcus with rhinoviruses, *Haemophilus influenzae*, and *Moraxella catarrhalis*.[3] In addition, organisms that make up the normal microbial flora in other parts of the body can be transferred to the lung, where they can cause infection. In early-onset group B streptococcal pneumonia and sepsis in neonates, the organisms are transferred during birth from the vaginal canal of the mother to the respiratory tract of the infant.

Organisms causing infections at other body sites can spread to the lungs. Although not common, hematogenous spread from the bloodstream to the lungs can occur, perhaps most notably in Lemierre disease related to septic thrombophlebitis due to the anaerobe *Fusobacterium necrophorum*. The existence of heavy colonization or infection in the upper airways also increases the potential for infection in the lungs by a variety of mechanisms, mostly by a simple dose effect, whereby a large burden of potentially pathogenic organisms overwhelms the clearance mechanism of the lungs. Another mechanism for pneumonic infection can result from conditions that perturb the specific and nonspecific defenses, leading to respiratory infection as a sequela of another pathogenic process. A common example of this process is bacterial infections secondary to influenza virus. The neuraminidase of influenza virus has been shown to play a synergistic role in pneumococcal pneumonia models by cleaving the sialic acid residues on host glycoconjugates, thereby leading to increased adherence of the bacterium.[4] Activation of the innate immune response to viral RNA, modeled by polyI:C-mediated stimulation of the TLR3 and RIG-I pathways, which induce Type I interferons, can also increase susceptibility of mice to pneumococcal and *S. aureus* pneumonia.[5] During the adaptive immune response to influenza in mice, interferon-gamma can interfere with alveolar macrophage phagocytic function and heighten susceptibility to *S. pneumoniae* pneumonia.[6] Finally, any process that disrupts the physiologic and physical barriers between the upper and lower airways can lead to infection—for example, the placement of an endotracheal tube or changes in normal clearance mechanisms associated with cystic fibrosis.

Once a microorganism gains access to the lower respiratory tract, it must be able to resist clearance from this space, remain viable, and multiply. Usually organisms will either multiply locally, resisting local defenses, or spread to other body sites by traversing epithelial barriers that normally inhibit microbial spread. In order for extracellular organisms to multiply, they must scavenge for nutrients. Of particular note is the universal requirement for iron, which must be extracted from iron-binding molecules such as transferrin. Many bacteria produce iron-binding substances known as siderophores that have an affinity for iron of greater than 10^{18} M and bind to high-affinity receptors on the bacterial surface. Organisms must also resist opsonophagocytosis or be able to survive and multiply within phagocytes. Subsequent to microbial growth and resistance of host defenses, damage to the host tissues occurs. This process is aided by a variety of pathogenic factors and results in invasion of tissues often with destruction of cells. Secreted toxins can act locally and/or systemically spread to cause clinical symptoms. Many Gram-negative bacilli possess a type III secretion system that can function like a hypodermic needle to inject toxins directly into host cells. The potential for inflammation to cause tissue destruction can be a devastating consequence of microbial growth in normally sterile lung sites. Finally, although not necessary for the pathologic process to take place, most organisms that successfully multiply will have mechanisms with which to leave the body and transmit disease, thereby propagating their species.

MOLECULAR FACTORS AND PROCESSES IN RESPIRATORY INFECTIONS

The study of pathogenic microorganisms has benefited greatly from the ability to identify microbial factors that are at work to elicit a particular pathologic process. Often these factors by themselves are responsible for a particular aspect of the infectious process, whereas at other times these factors act in consort to promote microbial colonization, growth, infection, and ultimately host responses and disease.

The success of the microorganism in establishing infection (the presence of a microorganism in a tissue where it is not normally found) and causing disease (the signs and symptoms of clinical illness) is predicated on the organism's ability to elaborate specific molecular factors that allow it to progress from the colonization to the disease state. Factors that inhibit or neutralize the host's response to eliminate the organism are also critical for pathogenesis. The ability of specific microorganisms to produce virulence or pathogenic factors, even among bacterial strains of the same species, is highly variable and is doubtless a major reason for the differences in pathogenicity among closely related strains of bacteria. Initially, most microbes that establish themselves in the respiratory tract will bind to host tissues including mucins and other factors in mucus, often in a specific manner. For example, *P. aeruginosa* places at the tip of the flagella that provide mobility to the organism, a protein called FliD that mediates adherence to respiratory mucin[7] and *H. influenzae* similarly uses its pilus to bind to mucins[8] and anchor the cells within the respiratory tract. Pathogens will produce specific molecules to promote this process. Some potentially pathogenic microorganisms, such as *S. pneumoniae*, *S. aureus*, and *N. meningitidis*, can establish colonization in the nasopharynx or throat without causing harmful effects. Almost everyone is colonized by these potential pathogens many times during life. Viruses and obligate intracellular parasites, such as *Chlamydia*, usually must find their way to the lower respiratory tract and invade a specific cell in order to start growing. Some bacterial pathogens, such as *Legionella pneumophila* and *Mycobacterium tuberculosis*, need to encounter alveolar macrophages where they are ingested but resist destruction within these cells.

In some cases, as long as a potential pathogen confines itself to a local site, no disease will ensue. At other times, growth at the local site and/or elaboration of toxins can cause frank disease; this is the mechanism of group A streptococcal pharyngitis and whooping cough caused by *Bordetella pertussis*. In general, the nasopharynx and throat readily tolerate the presence of a dynamic bacterial population, comprising mostly nonpathogenic strains along with potential pathogens that often come and go quietly, not spreading to other tissues or causing disease except when other factors intersect, such as a respiratory viral infection or other types of host stressors.

Most of the initial host response to pathogens in normally sterile sites, indicative of infection, involves the basic inflammatory responses of innate immunity. The microbes generally initiate this response by activating complement, binding quasi-specific host molecules such as mannose-binding lectin, and generating other tissue signals via cell-associated pattern-recognition molecules such as the TLRs[9,10] that lead to an influx of inflammatory cells and serum factors into the site of infection (see Chapter 121). Inflammation leads to clinical symptoms in the form of a sore throat, sneezing, coughing, feeling of malaise, and so on. Some particularly virulent microbes can rapidly produce much more serious disease as the organisms

spread and cause inflammation diffusely throughout the respiratory tract. Failure to control microbial growth and sustained inflammation leads to pathologic tissue destruction. The balance between the host inflammatory response and microbial growth is the key factor in the disease process. As is often the case with microbial infection, inflammation is a double-edged sword, critically important for resolution of infection but also responsible for tissue damage.

SPECIFIC VIRULENCE MECHANISMS OF MICROBIAL PATHOGENS

Much of our knowledge in the area of molecular mechanisms that microbial pathogens use to establish and cause respiratory infections is derived from studies of bacteria. In the case of viruses, clear factors, such as the neuraminidase and hemagglutinin proteins on the coat of the influenza virus, are needed to promote viral shedding from infected cells followed by binding to uninfected cells, which leads to subsequent cellular invasion, viral replication, inflammation, and disease. All viruses causing respiratory infections must enter cells in some manner that includes binding of a specific viral factor to a specific host cellular receptor. Intracellular nonviral microbes such as *Chlamydia* are probably taken into cells nonspecifically by phagocytosis or endocytosis.

A fairly good understanding of the molecular basis for the pathogenesis of *B. pertussis* infection has been established. *Bordetella pertussis* binds exclusively to the cilia on ciliated respiratory epithelium, using at least two bacterial cell-surface factors, designated pertactin and filamentous hemagglutinin (FHA). A fraction of the organism's cell wall, the muramyl dipeptide, is then extensively produced and secreted, and this factor is toxic to the ciliated tracheal cells. These cells are extruded from the epithelial surface, perhaps in an attempt to clear the bacteria from the respiratory tract. Secretion of pertussis toxin also contributes to the pathology. Pertussis toxin is composed of two subunits, designated A and B; the B subunit binds to receptors on host cells, allowing the A subunit to enter the cell. The A subunit transfers the ADP-ribosyl part of NAD to a membrane-bound, GTP-binding protein that normally inhibits the enzyme adenyl cyclase. This leads to increased synthesis of cAMP. Pertussis toxin can also inhibit neutrophil recruitment, thereby delaying antibody-dependent clearance of the bacterium even in immune hosts.[11]

Other extracellular pathogens that cause lung infections establish themselves in tissues by binding to either cellular receptors or factors in the mucus, notably mucin. Several bacterial pathogens that frequently cause pneumonia—including *P. aeruginosa*, *H. influenzae*, *S. aureus*, *S. pneumoniae*, *K. pneumoniae*, and some *Escherichia coli*—bind specifically to terminal or internal GalNAc-β(1–4)-Gal sequences lacking sialic acid residues commonly found on cellular glycolipids in the respiratory tract. *Pseudomonas aeruginosa* itself has been prominently studied in regard to binding to respiratory mucins as a mechanism to establish and maintain infection in the lung. Nontypeable *H. influenzae* also appears to utilize pilus-mediated adherence to human respiratory mucins to establish chronic infections in the lung.

Intracellular respiratory bacterial pathogens usually are ingested by alveolar macrophages and must resist phagocytic killing in order to establish infection and cause disease. *Mycobacterium tuberculosis* enters these cells in the lower and middle airways with high airflow, as it is an obligate aerobic organism (see Chapter 131). Bacterial ligands and cellular receptors involved in this process are not fully characterized, although dendritic cell-specific intercellular adhesion molecule-3 grabbing nonintegrin (DC-SIGN) on dendritic cells and macrophages appears to play a role.[12] Following inhalation, most individuals will effectively clear or contain the tubercle bacilli, while in a minority the bacteria escape from the macrophage phagolysosome, or prevent its formation in the first place, leading to bacterial growth and host inflammation and resulting in lesions typical of tuberculosis. On the opposite side of the time spectrum from *M. tuberculosis*, inhaled spores of *Bacillus anthracis* are phagocytosed by alveolar macrophages but within 6 hours can germinate, escape from phagosomes, replicate within the cytoplasm, and escape from the macrophage to enter the lymphatics or bloodstream.[13]

Respiratory pathogens elaborate additional virulence factors beyond those needed to establish infection in normally sterile tissues. Many respiratory bacterial pathogens are encapsulated—a critical factor in promoting bacterial resistance to phagocytic killing. Neutralization of this antiphagocytic property by specific antibody results in high-level host immunity. Successful vaccines against *S. pneumoniae*, *H. influenzae* type b, and certain serogroups of *N. meningitidis* have been developed by engendering capsule-specific immunity via immunization, and comparable vaccines against *P. aeruginosa*, *K. pneumoniae*, group B streptococcus, and *S. aureus* are in various stages of development and testing in humans. Many studies support a role for the M protein capsule-like antigen of group A streptococcus in preventing phagocytosis of this organism along with the nonimmunogenic hyaluronic acid capsule, both playing prominent roles as antiphagocytic factors for group A streptococci.[14]

Regulation of the expression of virulence factors is tightly controlled by the pathogen via complex networks of two-component regulatory systems and other systems. In *P. aeruginosa*, quorum sensing (cell-density-dependent gene expression) via small organic molecules called acyl homoserine lactones has been shown to be important for virulence in pneumonia models both by regulating expression of secreted toxins and by inducing inflammation.[15] *Staphylococcus aureus* strains control virulence through regulatory peptides involved in activating and suppressing the accessory gene regulator *(agr)* network, with similar systems found in other Gram-positive pathogens as well.[16] Interfering with these systems with appropriate inhibitors holds promise for future therapeutic interventions in bacterial pneumonia.

Many respiratory pathogens, particularly *P. aeruginosa* and *S. aureus*, elaborate some very potent toxins. *Pseudomonas aeruginosa* secretes elastase, an enzyme that can interfere with innate immunity in the lung by cleaving surfactant protein D, thereby abrogating its role in bacterial clearance.[17] In addition to toxins secreted extracellularly, protein effectors of the type III secretion system of *P. aeruginosa* can be directly injected into host cells, injuring the alveolar epithelium and subsequently allowing the release of proinflammatory cytokines such as TNF-α into the circulation, resulting in septic shock. *Pseudomonas aeruginosa* also possesses a type VI secretion system that lyses nearby bacteria, allowing it to dominate its local environment.[18] The emergence of strains of community-acquired methicillin-resistant *S. aureus* (MRSA) associated with severe cases of necrotizing pneumonia appears to be related to elaboration of the alpha-hemolysin toxin (also called α-toxin), which injures epithelial cells after binding to a specific receptor, the zinc-dependent metalloprotease ADAM10.[19] The increased virulence of these MRSA strains was initially attributed to the Panton–Valentine leukocidin (PVL),[20] a pore-forming toxin specific for white blood cells, but subsequent work has shown that the PVL-producing strains are relatively rare causes of systemic infection[21] and these genes are mostly a marker for strains causing skin and soft-tissue infections with no real role in pneumonia.[22,23] The Gram-negative endotoxin, also called lipopolysaccharide (LPS), can cause serious damage to lung tissues, although the lung seems relatively resistant to the effects of inhaled endotoxin when compared with the systemic response to circulating LPS.

EXAMPLES OF THE MOLECULAR PATHOGENESIS OF ACUTE AND CHRONIC BACTERIAL RESPIRATORY INFECTIONS

Pneumococcal pneumonia is the prototypic acute bacterial respiratory infection. As important a pathogen as *S. pneumoniae* is in the respiratory tract, the understanding of how it causes pneumonia and sepsis is not extensive. The capsular polysaccharide is a critical

virulence factor, but beyond this, the role of other bacterial products in pathogenesis is mostly unknown. The cell-wall bacterial phosphorylcholine of virulent *S. pneumoniae* has been shown to bind to the G protein–coupled platelet-activating factor (PAF) receptor following inflammatory activation of human cells.[24] This leads to invasion of epithelial and endothelial cells, indicating a mechanism whereby *S. pneumoniae* could escape through the lung epithelium via the vascular endothelium into the circulation to cause sepsis. The fact that lung inflammation increases PAF receptor levels is likely another reason for the hypersusceptibility of people with viral upper respiratory infections to secondary infection with *S. pneumoniae.*

Chronic lung infections can be caused by a variety of bacterial pathogens, many of which occur in persons with underlying lung disease. Patients with chronic obstructive pulmonary disease are particularly susceptible to chronic infection with nontypeable *H. influenzae*, although beyond the propensity of the organism to bind to respiratory mucins,[8] the molecular bases for infection and disease are mostly unclear. Interestingly, co-colonization experiments with *H. influenzae* and *S. pneumoniae* in mice have found that *H. influenzae* predominates due to *H. influenzae*-induced complement-dependent phagocytic killing of *S. pneumoniae*.[25]

Among patients with cystic fibrosis (CF), 80% to 90% will become chronically infected with *P. aeruginosa* (see Chapter 50). This infection is currently the major factor limiting their life expectancy. Of note, while use of newer technologies that identify the complex mixtures of microbial DNA in samples of human tissues and secretions has greatly expanded our insights and understandings into the microbial communities or microbiomes present in the GI and vaginal tracts, skin, and oropharynx, the role they play in chronic respiratory infections is still under assessment. In CF, increasing concurrence with the concept of a community of microbes being associated with disease has to be placed in the context of findings that, when examining tissues from autopsies or lung transplants, only traditional CF pathogens such as *P. aeruginosa* are found by either culture or DNA analysis. In contrast, the microbiome community DNA is found in oropharyngeal swabs and expectorated sputum that must come through the oropharynx in order to be collected,[26] likely confounding the conclusion that these organisms are truly present in the lung and contributing to disease pathogenesis.

Thus, *P. aeruginosa* remains the major infectious entity associated with pulmonary decline in CF and a large research effort has focused on understanding how this pathogen infects the vast majority of patients with a genetic defect that does not appear related to chronic bacterial lung infection. In patients with CF, mutations are found in the CF transmembrane conductance regulator (CFTR) gene, which codes for a large protein that regulates chloride ion secretions directly and also appears to affect the flow of glutathione and bicarbonate. Seventy percent of people carry at least one mutant CFTR allele that lacks the codon for the phenylalanine at position 508 (ΔF508 mutation), making one-half of affected persons (~49%) homozygous for this mutation. The lack of phenylalanine at position 508 leads to an inability of the mature protein to get into the cell membrane.

The relationship of mutant CFTR and hypersusceptibility to chronic *P. aeruginosa* infection is undergoing intensive study. Pier et al. have proposed that clearance of *P. aeruginosa* from the lung following inhalation of bacteria is critically dependent on CFTR-controlled internalization of the bacterium by lung epithelial cells followed by rapid activation of innate immunity involving NF-κB nuclear translocation and production of inflammatory cytokines such as IL-6, IL-8, and CXCL1.[27,28] The combined effects of epithelial cell internalization and shedding along with rapid activation of innate immunity that most likely brings in neutrophils to phagocytose and eliminate any other extracellular bacteria can lead to efficient microbial clearance. Resolution of this response via apoptosis has also been shown to be important in the CFTR-dependent response of the lung to *P. aeruginosa*. The CFTR protein has been identified as the actual cellular receptor for clearance of *P. aeruginosa* from the lung. In a neonatal mouse model of clearance of *P. aeruginosa* from the lungs after nasal inoculation of bacteria, it was found that blocking of CFTR-mediated epithelial cell ingestion of *P. aeruginosa* led to higher bacterial burdens in the lung. Similarly in transgenic CF mice there is reduced epithelial cell uptake of *P. aeruginosa* and increased overall bacterial burdens in the lung. Of note, there appeared to be little to no binding of bacteria to tracheal epithelial cells in the infected CF mice, whereas extensive binding, ingestion, and shedding of *P. aeruginosa* by epithelial cells could be seen in tracheas of infected wild-type mice. Thus, *in vivo*, *P. aeruginosa* binding to CF epithelial cells is not observed, a situation completely consistent with results from histopathologic examination of lungs taken at transplant or autopsy from CF patients, where *P. aeruginosa* also is not seen binding to the epithelium but rather encased in mucus plugs within the airways. Overall, the initial establishment of *P. aeruginosa* infections in the lungs of CF patients can be directly attributable to the lack of functional CFTR in cell membranes to bind to this microbe and initiate appropriate innate immune responses, which overall prevents efficient bacterial clearance from the lung. Reduced airway surface pH, as noted in the recently developed CF pig model,[29] may also play a role in impaired innate defenses against *P. aeruginosa* and other bacteria in the CF lung.

The pathogenesis of chronic *P. aeruginosa* lung infections in CF patients is more extensive. After avoiding initial clearance, the bacteria adhere to mucins and become embedded in mucus plugs within the airways[30] and eventually undergo a phenotypic conversion wherein they lose both their ability to produce the long *O*-polysaccharide side chains that are usually on the LPS and acquire the ability to elaborate copious quantities of a bacterial exopolysaccharide called alginate. The hypermutable phenotype seen in *P. aeruginosa* strains from CF patients likely speeds this adaptation.[31] Alginate is unable to provoke a protective antibody response in the host[32] and encases the bacteria in microcolonies within a hypoxic microenvironment in the lung.[33] Within this protective coating, phagocytes such as neutrophils are unable to ingest and kill the microorganisms. This leads to a vicious cycle of additional but ineffective inflammation and bacterial growth, the result of which is tissue destruction subsequent to the chronic inflammatory process. Alterations in the lipid A structure of the *P. aeruginosa* LPS in strains isolated from CF patients appear to confer resistance to antimicrobial peptides and a hyperinflammatory response.[34] For most of the patient's life, *P. aeruginosa* infection appears to remain confined to endobronchial surfaces, which become plugged with mucus while the airway tissues are being destroyed, although recently reported histopathologic results from lungs of CF patients who died in the 1970s prior to more modern medical management with aggressive antibiotic therapy used in some countries also showed extensive alveolar involvement.[35] The finding of quorum-sensing signals in the CF lung suggests that the *P. aeruginosa* may exist as a biofilm (defined as a structured community of bacteria encased in a self-produced matrix), which likely contributes to the recalcitrance of this infection to antibiotics,[36] as does the recently described ability of *P. aeruginosa* to produce the gases hydrogen sulfide and nitric oxide in order to resist the oxidative stress induced by antibiotics.[37,38] Thus, the pathogenesis of chronic *P. aeruginosa* infection in CF involves at least two components: an initial phase of hypersusceptibility to infection that is predicated on an inability of CF patients to kill or clear inhaled *P. aeruginosa* cells and a subsequent phase directly related to the bacterium's ability to elaborate alginate, which allows the organism to resist host defenses while continuing to provoke inflammation that damages lung tissues.

From these two examples we garner some important insights into mechanisms whereby bacterial pathogens cause lung infections.

Many of the principles apply to other types of pathogenic microbes that follow the basic scenario of entry, attachment, multiplication and survival, elicitation of inflammation, and ultimately tissue damage and compromise of respiratory function. Although each of these steps can often be characterized at a highly specific molecular level, usually using isolated factors such as toxins to elicit clinical symptoms of disease, the overall pathogenesis of disease requires that elaboration of molecular factors of pathogenesis be coordinated and that each step in the process occur under the proper circumstances and at the right time. Research in identifying and understanding the microbe's genetic and molecular factors that control and coordinate pathogenesis is in its infancy. Presumably, greater understanding of particular factors and the interactions among both the factors and host tissues will lead to development of better vaccines and other therapies that will minimize the occurrence of microbial infections in the lung.

CHAPTER 125

Principles of Antibiotic Use and the Selection of Empiric Therapy for Pneumonia

Bala Prakash
Michael S. Niederman

Antibiotics are the foundation of therapy for respiratory tract infections. This approach varies with the type of pneumonia, age of the affected patient, presence of various comorbid illnesses and risk factors for infection by specific pathogens, and the severity of the acute illness. For most of the patients, initial therapy is empiric, aimed at a broad spectrum of potential pathogens (see Chapter 122). Once culture data become available, therapy can be pathogen-specific making it possible to de-escalate to fewer drugs with a narrower antimicrobial spectrum.[1,2] In some cases, initial empiric therapy must be continued because no etiologic pathogen is identified (see Chapter 123).

When a pathogen is defined, the term "appropriate" refers to the use of at least one antimicrobial agent that is active in vitro against the etiologic pathogen.[1] The term "adequate" includes not only appropriate therapy, but also the use of that agent in the correct dose, via the right route, given in a timely fashion, and with penetration to the site of infection. Timely and appropriate antibiotic therapy can improve survival in patients with community-acquired pneumonia (CAP) and nosocomial pneumonia or hospital-acquired pneumonia (HAP) and the benefits are most evident in patients who are not otherwise terminally ill.[1,3–5] In general, with severe illness, those receiving antibiotics earlier in their course have a lower mortality than those receiving delayed therapy, with the risk of death rising 7% to 8% for each hour of delay of therapy during the first 6 hours of septic shock and hypotension.[6]

The term HAP encompasses pneumonia in nonventilated patients, ventilated patients, and those with healthcare-associated pneumonia (HCAP) (see Chapter 129). Ventilator-associated pneumonia (VAP) is nosocomial pneumonia that develops after at least 48 hours of preceding mechanical ventilation, and thus some ventilated HAP patients may not have VAP, since they do not satisfy this definition of prolonged preceding mechanical ventilation. HCAP includes those coming from nursing homes, those in the hospital for more than 2 days in the past 90 days, those with a history of regular visits to places like dialysis or infusion centers, or those getting home wound care. Because of their exposure to the healthcare environment, some patients with HCAP are at risk for infection with multidrug-resistant (MDR) pathogens, although not all of these patients are at the same risk. Presence of this entity has blurred the distinction between CAP and HAP, since HCAP patients may reside in the "community," but be infected with organisms very similar to those present in patients with HAP.

In the setting of CAP, effective initial antibiotic therapy is associated with a marked improvement in survival, compared to ineffective therapy, particularly in patients with severe illness.[3,7] In several studies, identification of the pathogens causing severe CAP did not lead to an improved survival rate, while the use of a broad-spectrum, empiric regimen directed at likely pathogens reduced mortality (see Chapter 128). Further, patients with CAP have reduced mortality if initial antibiotic therapy is provided within 4 hours of arrival to the hospital. In the treatment of VAP, data show that appropriate therapy should be given as soon as the infection is clinically identified and lower respiratory tract samples have been collected for culture. Delay of even 24 hours in starting therapy is an important mortality risk factor in VAP.[1,5]

Even with the use of correct agents, not all patients recover. The fact that some HAP patients die in spite of microbiologically appropriate therapy is a reflection of the degree of antibiotic efficacy, as well as a reflection of host response capability (which may in part have a genetic determination). In some HAP patients, death is the result of the serious underlying illness; the percentage of deaths that occur because of infection, termed "attributable mortality" of HAP, has been estimated to be as high as 50% to 60%.[8] However, the timely use of appropriate antimicrobial therapy can reduce this attributable mortality to as low as 20%, and recent studies suggest that excess mortality in VAP may be even lower.[8,9]

In recent years, a number of guidelines for empiric therapy for both CAP and HAP have been developed, but several caveats should be remembered. First, although current guidelines are evidence-based, outcome studies are required to demonstrate their utility in clinical practice. Second, guidelines must be re-evaluated relative to local patterns of antibiotic susceptibility. In the case of CAP, the emergence of penicillin-resistant pneumococcus, community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA), and epidemic viral illness (influenza, SARS) may affect the selection of initial therapy. In the setting of HAP, each hospital has a unique flora and antimicrobial susceptibility patterns; knowledge of such patterns is essential for selection of the optimal agents.

The majority of data establishing "standard" antibiotic doses are derived from studies in healthy volunteers or ward patients, which

have been extrapolated into a wide range of patients, including the elderly, the obese, and the critically ill, with differing clearances of these agents. Critically ill patients may manifest significantly altered end-organ function whereas those with sepsis may have a hyperdynamic circulation and augmented renal clearance (ARC), necessitating higher than normal doses of antibiotics to achieve effective serum and intrapulmonary concentrations. In these patients, as well as in obese individuals who have an altered volume of distribution (Vd) of some drugs, subtherapeutic concentrations may result in treatment failure or in selection of antimicrobial-resistant organisms.[10]

In this chapter, the principles underlying antibiotic use are examined, followed by a discussion of the commonly used antibiotics for respiratory tract infections, and the principles of empiric therapy of both CAP and HAP. Further, pharmacokinetics and pharmacodynamics (PK/PD) considerations are a theoretical way to optimize the delivery of antibiotics; recent data indicate that the use of such "optimized therapy" may have clinical benefits.[11] To preserve antibiotics for future use, it is necessary to understand mechanisms of antibiotic resistance and to practice antimicrobial stewardship by focusing on proper antibiotic dosing, de-escalation therapy, the development of local protocols for antibiotic choice, but not necessarily by restricting access to potentially effective broad-spectrum agents for seriously ill patients.

PRINCIPLES OF ANTIBIOTIC USE

Antibiotics interfere with the growth of bacteria using various mechanisms including undermining the integrity of their cell wall, interfering with bacterial protein synthesis, or common metabolic pathways.[12] The mechanism of activity can be used to define whether an agent is bacteriostatic or bactericidal, terms discussed in the section "Mechanism of Action."

MECHANISM OF ACTION

Bactericidal antibiotics kill bacteria, generally by inhibiting cell-wall synthesis or by interrupting a key metabolic function of the organism. Agents of this type include the penicillins, cephalosporins, aminoglycosides, fluoroquinolones, vancomycin, daptomycin, colistin/polymyxin, rifampin, and metronidazole. **Bacteriostatic agents** are antibiotics that inhibit bacterial growth but generally do not interfere with cell-wall synthesis, and rely on host defenses to eliminate microbes. Agents of this type include the macrolides, tetracyclines, sulfa drugs, chloramphenicol, linezolid, and clindamycin.

The terms bactericidal and bacteriostatic are broad categorizations, and may not apply for a given agent relative to all organisms, with certain antimicrobials being bactericidal for one bacterial pathogen but bacteriostatic to another.[15] The use of a specific agent is dictated by the susceptibility of the causative organism(s) in a given anatomic location to individual antibiotics. When neutropenia or immune compromise are present or if there is accompanying endocarditis or meningitis the use of bactericidal agents is preferred (see Chapter 123). Thus, for most patients with pneumonia, it is not essential to choose a bactericidal agent. One additional consideration is that certain organisms such as *S. aureus* can produce toxins, and the optimal agent must be able to kill the bacteria and also to inhibit the production of disease-mediating toxins. Agents that inhibit bacterial toxin production include clindamycin, rifampin, and linezolid.

The **Minimum Inhibitory Concentration (MIC)** is the minimum antibiotic concentration necessary to inhibit the growth of 90% of a standard sized inoculum, leading to no visible growth in a broth culture. The MIC is used to define the sensitivity of a pathogen to a specific antibiotic, under the assumption that the concentration required for killing (the MIC) can be reached in the serum in vivo. This term must be interpreted cautiously in the treatment of pneumonia, because the clinician must consider the MIC data in light of the penetration of an agent into lung tissues, with some agents achieving higher than serum levels at respiratory sites of infection and others reaching lower levels.[13,14]

The **Minimum Bactericidal Concentration (MBC)** is the minimum concentration needed to cause a 3-logarithmic decrease (99.9% killing) in the size of the standard inoculum, and generally all pathogenic bacteria are killed at this concentration.

The **Mutation Prevention Concentration (MPC)** is the lowest concentration of an antimicrobial agent that prevents bacterial colony formation from a culture containing greater than 10^{10} bacteria.[13] At lower than MPC concentrations, spontaneous mutants can persist and be enriched among the organisms that remain during therapy. The concept has been most carefully studied with the pneumococcus and fluoroquinolones. In general the MPC is higher than the MIC, implying that it is possible to use an antimicrobial to successfully treat a clinical infection but with inadequate levels to eradicate the bacteria. These remaining organisms may provide a basis for the emergence of antimicrobial-resistant bacteria.

IMPORTANT PHARMACOKINETIC–PHARMACODYNAMIC VARIABLES

Pharmacokinetics refers to the absorption, distribution, and elimination of a drug in the body, which can be used to describe the concentration of a drug in the serum. **Pharmacodynamics** refers to the physiological and biochemical effects of a drug on the body or any organisms within the body, the mechanisms of action and the relationship between a drug's concentration and effect. Bacterial killing is affected by the way in which an antibiotic reaches the site of infection considering the frequency of administration and dose administered, thus defining a close relationship between PK/PD. There are three types of bactericidal antibiotics.[13]

First, are those that kill in relation to the duration in which the nonprotein-bound free concentration of the agent stays above the MIC of the target organism, $fT > MIC$ **(Time-dependent killing)**.[16] Examples include the β-lactams, carbapenems, aztreonam, macrolides, and linezolid. For maximal efficacy, β-lactam concentrations should be maintained at four times the MIC, for approximately 40% to 70% of the dosing interval, depending on the agent being employed.[14] Second, are agents that kill in relation to how high the peak concentration is, relative to the MIC, defined by the C_{max}:MIC ratio **(Concentration-dependent killing)**.[17] Examples include the aminoglycosides and fluoroquinolones, as well as the ketolides and daptomycin. Finally, agents like the glycopeptides and fluoroquinolones also have efficacy defined by the area under the concentration–time curve divided by the MIC (AUC: MIC ratio, or AUIC) to define the optimal PK/PD index.[18,19]

To optimize time-dependent killing, dosing should be chosen to achieve the maximal time above the MIC of the target organism; this can be done with continuous or prolonged (over 3–4 hours) infusions. The rate of killing is saturated once the antibiotic concentration exceeds four times the MIC of the target organism. In spite of these considerations, for many organisms, the concentration of the antibiotic only needs to be above the MIC for 40% to 50% of the dosing interval, and possibly for as little as 20% to 30% of the interval as for the carbapenems.[13] For the time-dependent killing drugs listed above, the pharmacodynamic parameter that best predicts clinical efficacy is the time above the MIC.

The target AUIC for gram-negative bacteria is 125 or greater, whereas for most antibiotics that treat the pneumococcus, the target value is at least 30. Some studies have shown that aiming for C_{max}/MIC target of 12 for fluoroquinolones against pneumococcus is optimal. Appropriate use of these agents would entail infrequent administration but with high doses, which is the underlying principle behind the once-daily administration of aminoglycosides.

The **Post-Antibiotic Effect (PAE)** maintains the efficacy of the antibiotic after the serum (or lung) concentrations have fallen below

the MIC of the target organism. Thus, with once-daily aminoglycoside dosing regimens, the patient achieves a high peak concentration (maximal killing), and a low trough concentration (minimal nephrotoxicity) with the PAE achieving continued antimicrobial effects. While most agents exhibit a PAE against gram-positive organisms, prolonged PAEs against gram-negative bacilli are achieved by the aminoglycosides and fluoroquinolones.[13] For pneumococcus, a PAE exists for the macrolides/azalides, clindamycin, vancomycin, quinupristin/dalfopristin, tetracyclines, and the oxazolidinones (such as linezolid). Most of the agents that kill in a concentration-dependent fashion have a prolonged PAE. Agents with little or no PAE against gram-negatives are generally also agents that kill in a time-dependent fashion and are administered several times daily. The β-lactams (including the penicillins, cephalosporins, and monobactams) generally have little or no PAE against gram-negatives; one notable exception is imipenem, which has a modest PAE against *Pseudomonas aeruginosa*. In clinical practice, the use of once-daily aminoglycoside dosing has had variable benefits in both efficacy and toxicity, but the advent of this type of dosing regimen follows from an understanding of pharmacodynamic principles. **Postantibiotic Leukocyte Enhancement (PALE)** refers to the ability of functioning leukocytes to kill organisms in the postantibiotic phase of growth. Thus, when the patient has functioning neutrophils, the PAE of some agents is extended by their PALE.

Inflammatory effects. Recently, some investigators have suggested that antibiotics should be selected based on whether they stimulate inflammation and cytokine production in response to the presence of the bacterial cell-wall lysis products.[15] Certain antibiotics liberate bacterial cell-wall products that interact with cytokine-producing cells, stimulating the production of high levels of cytokines such as tumor necrosis factor. In theory, this could lead to the development or the worsening of sepsis syndrome. This may be a consideration in patients with *Pneumocystis jiroveci* pneumonia or pneumococcal meningitis who may benefit from the use of corticosteroids with antimicrobial therapy in these infections. In general, the clinical role of cytokine release is uncertain, but bactericidal antibiotics tend to produce a greater host inflammatory response than bacteriostatic agents. Antibiotics that are cell-wall active, and that kill slowly, have been associated with the greatest cytokine release.

As was noted previously, the use of antibiotics that inhibit protein synthesis (linezolid, clindamycin) may have an advantage in toxin-mediated illnesses, such as those caused by certain strains of *S. aureus*, when compared with cell-wall active bactericidal antibiotics.[20]

FACTORS AFFECTING ANTIBIOTIC CONCENTRATIONS

Alterations in lung penetration, protein binding, and changes in drug Vd and clearance (Cl), can significantly influence antibiotic concentrations achieved at a site of infection and, therefore, the probability of microbiological success.[10] The pharmacokinetic profile of piperacillin was explored in a small cohort of septic and critically ill patients, demonstrating a wide distribution of values (up to 14-fold variation) for drug clearance, Vd, and half-life[21] despite "normal" biochemical renal indices in all patients. Similar data are available for other antibiotics in this setting,[22] confirming that in a significant fraction of critically ill patients, drug elimination is likely to be markedly different from healthy volunteers, and thus it is challenging to define optimal dosing in these patients.

Beyond the immediate threat of treatment failure, subtherapeutic antibiotic concentrations are a risk factor for the selection of drug-resistant organisms.[23] Tigecycline resistance was identified within months of the commercial release of this antibiotic, and this may have been related to suboptimal concentrations at the site of infection.[24] In this respect, accurately identifying patients at risk of suboptimal drug exposure for a given causative pathogen remains a difficult clinical problem. While therapeutic drug monitoring (TDM) provides the most robust means of identifying subtherapeutic concentrations, its availability for all classes of antibiotic is largely limited to specialized centers.[25–27] In addition, changing organ function during the course of critical illness will affect antibiotic PK parameters, necessitating a regular review of dosing requirements.

PENETRATION INTO THE LUNG

A key requirement for the successful treatment of pneumonia is the achievement of therapeutic drug concentrations at the site of infection; in pneumonia, the targets are the lung parenchyma and alveoli (Table 125-1).[28] The drug concentration within the epithelial lining fluid (ELF) has been the most commonly used surrogate in pneumonia therapy. Research over a number of years has established that there is wide variability both within and between antibiotic classes in terms of ELF penetration.[29] The physiochemical properties that govern drug movement across biological membranes include the degree of ionization, fat solubility, molecular weight, and protein binding. Despite accounting for such characteristics, many of the differences between antibiotics in ELF to plasma concentration ratios (C_{ELF}:C_{Plasma}) remain poorly understood.[29] Sputum and bronchial concentrations may be the most relevant measurements for bronchial infections, whereas the concentrations in lung parenchyma, ELF, and cells such as macrophages and neutrophils may be more important for pneumonia. The localization of the pathogen may also be important; intracellular organisms such as *Legionella pneumophila* and *Chlamydophila pneumoniae* may be best eradicated by agents that achieve high intracellular concentrations in macrophages.

Macrolides have good penetration into ELF (e.g., C_{ELF}:C_{Plasma} >10 for azithromycin),[29] whereas β-lactams have varying penetration ratios,[30] without a predictable pattern. Vancomycin demonstrates limited lung penetration (C_{ELF}:C_{Plasma} <1),[31] while both linezolid and fluoroquinolones are reported to have ELF concentrations equivalent to or greater than those in plasma (C_{ELF}:C_{Plasma} ≥1).[32–34] Specific data from critically ill subgroups are generally limited, and in those where results have been reported, significant interpatient variability has been noted.[35]

TABLE 125-1 Penetration of Antibiotics into Respiratory Secretions

Good Penetration: Lipid Soluble, Concentration of the Antibiotic is Not Inflammation-Dependent
Fluoroquinolones
Macrolides (newer azalides: azithromycin, clarithromycin)
Tetracyclines
Tigecycline
Clindamycin
Trimethoprim/sulfamethoxazole
Linezolid
Poor Penetration: Relatively Lipid Insoluble, Concentration of the Antibiotic is Inflammation-Dependent
Aminoglycosides
Vancomycin
Polymyxins (colistin)
β-lactams
Penicillins
Cephalosporins
Monobactams
Carbapenems

The local concentration of an antibiotic must be considered in light of the activity of the agent at the site of infection. For example, antibiotics can be inactivated by certain local conditions. Aminoglycosides have reduced activity in acidic pH, which may be present in infected lung tissues. In addition, some bacteria develop resistance by producing destructive enzymes (such as β-lactamases), by altering the permeability of the outer cell wall, by changing the target site of antimicrobial action, or by pumping (efflux) of the antimicrobial from the interior of the cell. In these conditions a high local concentration of antimicrobial may help to offset bacterial resistance mechanisms.

The concentration of an antibiotic in lung parenchyma depends on the penetration through the walls of the bronchial capillaries, which have a fenestrated endothelium. Antibiotics penetrate in proportion to their molecular size and protein binding with small molecules that are not highly protein bound passing readily into the lung parenchyma. When inflammation is present, penetration is increased. Antibiotics reaching the ELF must pass through the pulmonary vascular bed with a nonfenestrated endothelium. This presents an advantage for lipophilic agents generally not inflammation-dependent.

Lipophilic agents include chloramphenicol, the macrolides (including the azalides and ketolides), linezolid, clindamycin, the tetracyclines, the quinolones, and trimethoprim–sulfamethoxazole (TMP-SMX). Agents that are poorly lipid soluble are inflammation-dependent for entry into the ELF; these include the penicillins, cephalosporins, aminoglycosides, vancomycin, carbapenems, and monobactams.

Active transport can facilitate antibiotic entry into lung tissue and phagocytes. Agents that are concentrated in phagocytes in this manner include the macrolides, clindamycin, and the fluoroquinolones. Antibiotics, such as the β-lactams, that are not concentrated in phagocytes by active transport remain in the extracellular space, which constitutes 40% of the weight of bronchial tissue; thus, penicillins achieve only about 40% of the serum level in lung tissue.

Drugs that penetrate well into the sputum or bronchial tissue include the quinolones, the newer macrolides and azalides (azithromycin and clarithromycin), the ketolides (telithromycin), the tetracyclines, clindamycin, and TMP-SMX. On the other hand, the aminoglycosides, vancomycin, and to some extent the β-lactams, penetrate less well into these sites. With the use of once-daily aminoglycoside dosing, high peak serum concentrations can be achieved, but the alveolar lining fluid concentration in patients with pneumonia is only 32% of the serum level over the first 2 hours; the two sites have more similar concentrations later in the dosing interval.[36] Since aminoglycosides require high peak concentrations for optimal killing, their poor penetration with systemic administration often impacts efficacy suggesting a potential role for delivery by the aerosol route.

VOLUME OF DISTRIBUTION

The Vd defines the relationship between the drug concentration observed in plasma and the dose administered. Values exceeding 3 L imply a distribution outside the plasma. Hydrophilic drugs that are poorly lipid soluble diffuse freely into interstitial fluid but do not penetrate cells. Thus only the free, nonprotein-bound drug can be distributed outside the plasma. Aminoglycosides and β-lactams are hydrophilic and will distribute into the extracellular space (~0.6 L/Kg).[37] Lipophilic agents such as the macrolides and quinolones are extensively distributed in body tissues, and serum levels underestimate the effect at the site of infection. This observation explains the efficacy of azithromycin, which achieves relatively low serum levels with high intracellular concentrations in phagocytes and can treat pneumonia.

Vd is also affected by obesity. Dosing based on ideal body weight may lead to underdosing in general, while for hydrophilic antibiotics, dosing based on total body weight may result in excessive drug levels. In critical illness, the Vd of many agents can differ from that in healthy subjects, primarily as a reflection of changes in microvascular function. Also volume resuscitation, an ubiquitous intervention in critical illness, may increase Vd for hydrophilic agents in the face of increased capillary permeability and interstitial edema.[38] Sánchez et al.[39] described the hemodynamic changes observed after fluid resuscitation for septic shock, showing that antibiotics such as the β-lactams, aminoglycosides, and glycopeptides "go where the water goes," meaning that in critical illness, these drugs will be preferentially "dragged" into the interstitial space by extravascular movement of free fluid. The Vd of such drugs is much higher than in the absence of "leaky" capillaries. This effect is associated with decreased serum concentrations for any given dose with thus a larger dose required to compensate for the increased Vd. As patients improve, fluid redistribution from tissues into the vascular space occurs, resulting in a significant decrease in the Vd.[40] Thus for drugs that distribute into extravascular interstitial fluid, an initial loading dose[41] is required to adequately "fill" these compartments and the Vd will change in parallel with the patients' physiology. This may explain why higher doses of vancomycin were needed to reach target serum concentrations in ICU patients in whom standard "ward" doses are likely to be inadequate. A larger Vd is also well described for β-lactams.[42]

PROTEIN BINDING

Many antibiotics demonstrate plasma protein binding, to either albumin or alpha-1-acid glycoprotein (AAG)[37] which can be disturbed in critical illness with many patients manifesting hypoalbuminemia.[43] The free fraction of the drug is eliminated with low plasma protein concentrations resulting in an increase in Vd and CL for highly protein-bound agents such as flucloxacillin, ertapenem, ceftriaxone, and teicoplanin.[43,44] Measuring the free drug concentration can be technically difficult, thus most published research has focused on total serum levels without correction for protein binding based on data from healthy volunteers.

DRUG CLEARANCE

Drug Cl represents the volume of plasma cleared of a specific pharmaceutical per unit time, and can involve organ independent enzymatic degradation, hepatic metabolism, or renal elimination of the parent compound or metabolites. During critical illness many aspects of these elimination pathways are disturbed. There are changes in major organ blood flow, saturation of enzyme systems, or complex drug–drug interactions.[37] Few data are available that describe the impact of changes in hepatic function on antibiotic PK–PD.

For many antibiotics (such as the aminoglycosides, β-lactams, and glycopeptides), renal drug clearance is directly proportional to Creatinine clearance (CrCl).[37] With the administration of large volumes of fluid and the use of vasoactive agents in critically ill patients with sepsis, trauma, burns, and in neurosurgery patients, there is often an increased cardiac output and organ perfusion with enhanced delivery of solute to drug eliminating organs leading to the phenomenon of ARC. With ARC, serum creatinine concentrations are almost always within the "normal range," while measured creatinine clearance is elevated, even as high as 200% of normal.[44] In such patients the use of an isolated serum creatinine concentration to extrapolate GFR is not possible; dosing derived from noncritically ill patient populations may fail to account for ARC.[45] In this setting, a timed urinary CrCl provides a simple, cheap, and repeatable estimate of renal drug elimination,[46] and affords an alternate means of identifying such patients. Recent research has confirmed an association between ARC and suboptimal trough β-lactam concentrations in critical illness,[47] thereby impacting the likelihood of achieving the necessary $fT > MIC$ targets. From an antibacterial prescribing perspective, ARC will lead to an increased rate of drug elimination, and

may necessitate more frequent intermittent doses or administration by continuous or extended infusion.[22]

A paucity of data to guide dose selection is also present when patients receive extracorporeal renal replacement therapy (RRT). In such instances, native renal drug elimination is limited (although not completely absent), whereas nonrenal mechanisms may assume a greater role in total body clearance. As a consequence, highly variable antibiotic concentrations have been observed in patients receiving RRT.[48] The variety of RRT modalities available further complicates such determinations due to variations in the parameters employed (including blood flow rates, effluent flow rates, and membrane pore size) and the unique physiochemical characteristics of each drug.[49] Not surprisingly, optimal dosing strategies in RRT remain largely uncertain.[50]

ANTIMICROBIALS USED IN THE THERAPY OF RESPIRATORY TRACT INFECTIONS

A variety of classes of antibiotics are used in treatment of respiratory tract infections. Each is discussed below.

MACROLIDES (INCLUDING AZALIDES)

Macrolides are bacteriostatic agents that bind to the 50 S ribosomal subunit of the target bacteria and inhibit RNA-dependent protein synthesis. They have good activity against pneumococci as well as "atypical" pathogens (*C. pneumoniae, Mycoplasma pneumoniae, Legionella*). Older macrolides including erythromycin are not active against *Haemophilus influenzae* and have poor intestinal tolerance so that prolonged therapy is difficult. The newer agents in this class include azithromycin (also referred to as an azalide) and clarithromycin. These agents have enhanced activity against *H. influenzae* (including β-lactamase producing strains), although on an MIC basis, azithromycin is more active. Erythromycin is active against *Moraxella catarrhalis* although the new agents have enhanced activity against this pathogen. Among the new macrolides, azithromycin is more active than clarithromycin against not only *H. influenzae* and *M. catarrhalis*, but also *M. pneumoniae*. On the other hand, clarithromycin is more active than azithromycin against *Streptococcus pneumoniae, Legionella,* and *C. pneumoniae.*

Both of the newer agents have better intestinal tolerance than erythromycin and penetrate well into sputum, lung tissue, and phagocytes. Clarithromycin, which has an active 14-hydroxy metabolite that is antibacterial, is administered twice a day orally at a 500-mg dose for 7 to 10 days in the treatment of CAP and acute exacerbations of chronic bronchitis (AECB). A new preparation of extended-release clarithromycin is administered as a 1000-mg dose once daily and has been effective as a 7-day course of therapy for AECB. Azithromycin has a longer half -life than clarithromycin, and concentrates in tissues, achieving very low serum levels when administered orally. The dosing regimen for CAP is usually 500 mg daily for 3 days in outpatients, but an extended release preparation allows the administration of 2000 mg as a one-time dose for CAP. For the hospitalized patient, an intravenous preparation of azithromycin is available and is dosed as 500 mg daily, with the duration defined by the clinical course of the patient, but usually for 7 to 10 days.[3] Because of its intravenous administration, the serum levels achieved have been adequate for the therapy of bacteremic pneumococcal pneumonia.[51]

Clinical studies of CAP have consistently shown a benefit of using macrolide therapy, usually in conjunction with a β-lactam, but the mechanism for this favorable effect is not known.[52,53] Speculation has included the possibility of atypical pathogen coinfection, a possibility supported by studies that have found the benefit of the addition of a macrolides to vary over the course of time. Another explanation is the anti-inflammatory effects possessed by macrolides, which may explain their benefit in improving quality of life in patients with cystic fibrosis. Macrolides have a myriad of other effects, including interference with "quorum sensing" between bacteria, which could inhibit the in vivo proliferation of *P. aeruginosa* after colonization has occurred. A recent study has shown that azithromycin may prevent progression of pseudomonal colonization to VAP.[54]

Although macrolides remain an important therapeutic option for community respiratory tract infections, pneumococcal resistance is becoming increasingly common, resistance may have plateaued at ≈30% in the United States[55,56] especially in patients who have received an agent of this class in the past 3 months.[57] In addition, macrolide resistance can also coexist with penicillin resistance with up to 30% to 40% of penicillin-resistant pneumococci also erythromycin-resistant. The clinical relevance of these in vitro findings remains to be defined. However, there are two forms of pneumococcal macrolide resistance, one involving efflux of the antibiotic from the bacterial cell and the other involving altered ribosomal binding of the antibiotic. The former mechanism is associated with much lower levels of resistance than the latter and is present in two-thirds of the macrolide-resistant pneumococci in the United States. The latter form of resistance is less common and, when present, makes macrolide therapy for pneumococcal infection ineffective.

TETRACYCLINES

The tetracyclines are bacteriostatic agents that act by binding the 30S ribosomal subunit and interfering with protein synthesis. These agents can be used in CAP because they are active against *H. influenzae* and atypical pathogens, but in the United States, pneumococcal resistance to tetracyclines may be approaching 20%, and may exceed 50% among organisms with high-level penicillin resistance. Photosensitivity is the major side effect, limiting the use of these agents in sun-exposed patients. This drug still remains as a good alternative to treat patients with suspected atypical pneumonia infection in those with electrocardiographic QT prolongation.

TIGECYCLINE

Tigecycline is the first clinically available drug from a new class of antibiotics, the glycylcyclines. It is structurally similar to the tetracyclines, and contains a central four-ring carbocyclic skeleton, but is a derivative of minocycline. Tigecycline is bacteriostatic and is a protein synthesis inhibitor that acts by binding to the 30 S ribosomal subunit of bacteria, thereby blocking entry of aminoacyl-tRNA into the ribosome during prokaryotic translation.

This drug is approved to treat complicated skin and skin-structure infections and complicated intra-abdominal infections, but can also be used in CAP caused by *S. pneumoniae, H. influenzae,* and *L. pneumophila.* With the exception of gastrointestinal adverse events, tigecycline was generally well tolerated. It is not approved for the therapy of MRSA pneumonia or HAP. In a study by Freire et al.[58] tigecycline was compared with imipenem/cilastatin in a multicenter, randomized, double-blind study of HAP in 945 patients. Tigecycline at a dose of 100 mg per day was found to be noninferior to imipenem/cilastatin in a modified intent-to-treat analysis but not in the clinically evaluable population and not in VAP. Some data suggest that efficacy may have been limited by the relatively low dose studied. Guner et al.[59] compared tigecycline alone or in combination therapy in the treatment of carbapenem-resistant *Acinetobacter baumannii*, a major MDR VAP pathogen. This retrospective study of 33 patients showed a 30-day overall mortality rate and attributable mortality rates of 57.6% and 24.2%, respectively. Tigecycline should not be used as monotherapy of VAP, but could be part of a combination when treating resistant *Acinetobacter* strains.

TRIMETHOPRIM–SULFAMETHOXAZOLE

This combination antibiotic is the mainstay of therapy against *Pneumocystis* pneumonia. In the past, given its antimicrobial spectrum, ease of use and low cost, it was an effective agent for CAP

and AECB. It has bactericidal activity against the pneumococcus, *H. influenzae* and *M. catarrhalis*, but not against atypical pathogens. Recently, it has become less popular because of the emergence of pneumococcal resistance at rates of at least 30%, since 80% to 90% of organisms that are penicillin resistant are also resistant to TMP-SMX. The sulfa component of the drug inhibits the bacterial enzyme responsible for forming the immediate precursor of folic acid, dihydropteroic acid. Trimethoprim is synergistic with the sulfa component and inhibits the activity of bacterial dihydrofolate reductase. TMP-SMX is available in a fixed combination of 1:5 (TMP:SMX), and is dosed as either 80/400 mg or 160/800 mg orally twice a day for 10 days, but the dosage should be adjusted in renal failure. An intravenous preparation is also available. Side effects generally result from the sulfa component and include rash, GI upset, and occasional renal failure (especially in elderly patients).

BETA-LACTAM ANTIBIOTICS

β-Lactam antibiotics are bactericidal agents that interfere with the synthesis of bacterial cell–wall peptidoglycans by binding to bacterial penicillin–binding proteins. They share a β-lactam ring with structural modifications determining classification: (a) penicillins with the β-lactam ring is bound to a five-membered thiazolidine ring; (b) cephalosporins with the β-lactam ring bound to a six-membered dihydrothiazine ring; (c) carbapenems with modifications in the thiazolidine ring (imipenem, ertapenem, and meropenem); (d) monobactams with absence of a second ring structure found in the carbapenems (aztreonam).These agents can also be combined with β-lactamase inhibitors such as sulbactam, tazobactam, or clavulanic acid, to create the β-lactam/β-lactamase inhibitor drugs, which may overcome the bacterial resistance mechanism of β-lactamase production.

The penicillins used for respiratory tract infections include the natural penicillins (penicillin G and V), the aminopenicillins (ampicillin, amoxicillin), the anti-staphylococcal agents (nafcillin, oxacillin), the anti-pseudomonal agents (piperacillin, ticarcillin), and the β-lactam/β-lactamase inhibitor combinations (ampicillin/sulbactam, amoxicillin/clavulanate, piperacillin/tazobactam, and ticarcillin/clavulanate). Among the anti-pseudomonal penicillins, piperacillin is the most active agent.

The cephalosporins span four generations. The earlier agents were generally active against gram-positive bacteria without activity against the more complex gram-negatives or anaerobes, and were susceptible to destruction by bacterial β-lactamases. The newer generation agents are generally more specialized, with broader-spectrum activity and with resistance to breakdown by bacterial enzymes. The second generation and newer agents are resistant to bacterial β-lactamases, but recent data suggest that cefuroxime may not be an optimal pneumococcal agent if resistance is present.[60] The third-generation agents such as ceftriaxone and cefotaxime are active against penicillin-resistant pneumococci, while ceftazidime is not reliable against the pneumococcus but is active against *P. aeruginosa*. The third-generation agents may induce β-lactamases among certain gram-negatives (especially the *Enterobacteriaceae* spp.) and thus may promote the emergence of resistance during monotherapy. The fourth-generation agent, cefepime, is active against pneumococci and *P. aeruginosa* but is also less likely to induce resistance among the *Enterobacteraceae* than the third-generation agents. Ceftaroline is a new, advanced-generation cephalsosporin that has been approved for the therapy of CAP; although it has in vitro activity against MRSA, it has not been studied in a randomized controlled trial for pneumonia due to this pathogen and its efficacy in this setting is unknown.

Imipenem, doripenem, and meropenem are the carbapneems, the broadest-spectrum agents in this class, being active against gram-positives, anaerobes, and gram-negatives including *P. aeruginosa*. They have shown efficacy for patients with severe pneumonia, both community-acquired and nosocomial. A nonpseudomonal carbapenem, ertapenem is also available and has been used effectively in the therapy of CAP and HCAP. Aztreonam is a monobactam that is antigenically distinct from the β-lactams and can be used in penicillin allergic patients. It is only active against gram-negative organisms, having a spectrum very similar to the aminoglycosides.

The role of continuous or extended infusions for time-dependent antibiotics has been extensively studied as a means to optimize *f*T > MIC, with numerous studies suggesting an improved ability to achieve the required PK-PD targets,[61,62] particularly with more virulent bacteria. The clinical benefit is uncertain, with only a limited number of studies demonstrating improved outcomes. Chytra et al.[63] performed a randomized, open-label controlled trial, comparing continuous versus intermittent application of meropenem in critically ill patients with severe infection with approximately 50% requiring treatment for a respiratory tract infection. Continuous infusion resulted in higher microbiological success with a shorter duration and lower dose of meropenem although no differences in clinical cure rates or outcomes were observed.[63] Similar data have been reported by Dulhunty et al.[64] using three commonly prescribed β-lactams and showing that continuous infusion was associated with a significantly improved ability to achieve optimal PK-PD targets along with higher clinical cure rates; however, no difference was identified in ICU-free days or hospital survival. Recently, Arnold et al.[65] found that 3-hour infusions of β-lactams for gram-negative infection were not more effective than 30-minute infusions based on endpoints of mortality, duration of therapy, and use of de-escalation.

The unique challenges to effective antibiotic dosing for pneumonia in critical illness have been highlighted in studies of new or emerging antibiotics. A recent clinical study of prolonged infusion and short duration (7 days) therapy of doripenem was compared to 10 days of imipenem/cilastatin for the treatment of VAP, and showed greater mortality and lower clinical cure rates in those receiving shorter durations of therapy even though the PK/PD targets might have been achieved by the extended infusion in patients with ARC.[66,67] These data are consistent with an earlier trial (ClinicalTrials.gov Identifier: NCT00229008) examining the use of ceftobiprole versus ceftazidime/linezolid for the treatment of nosocomial pneumonia in which subgroup analyses, showed a trend favoring ceftazidime/linezolid in VAP patients, particularly those <45 years of age, and with a CrCl ≥150 mL/min.[68] These findings illustrate the impact of ARC on drug dosing and reinforce the need to further investigate optimal dosing strategies in those with critical illness.

FLUOROQUINOLONES

Fluoroquinolones are bactericidal agents that act by interfering with bacterial DNA gyrase and/or topoisomerase IV, leading to impaired DNA synthesis repair, transcription, and other cellular processes and resulting in bacterial cell lysis. Quinolones inhibit many forms of bacterial topoisomerase enzymes including DNA gyrase. The earlier quinolones (such as ciprofloxacin and ofloxacin) are active primarily against DNA gyrase, which accounts for efficacy against gram-negative bacteria. The newer agents (levofloxacin and moxifloxacin) bind both DNA gyrase and topoisomerase IV, accounting for efficacy against even drug-resistant gram-positive organisms, including drug-resistant *S. pneumoniae* (DRSP). Resistance to fluoroquinolones can occur via a variety of mechanisms including mutations in the topoisomerase enzymes, by altered permeability of the bacterial cell wall or efflux of the antibiotic from inside of the bacteria.[69]

The quinolones kill in a concentration-dependent fashion allowing optimal antibacterial activity with infrequent dosing and high peak concentrations and high ratios of AUC/MIC or C_{max}/MIC. In addition, because quinolones have a PAE against both gram-positive and gram-negative organisms, killing is maintained after local concentrations fall below the MIC of the target organism. These properties allow the fluoroquinolones to be infrequently dosed

often at once daily, particularly given the relatively long half-life of the newer compounds. The factor limiting once-daily dosing for all quinolones is the toxicity associated with higher doses of some agents such as ciprofloxacin, given concerns related to neurotoxicity and possible seizures.

Two features of quinolones that make them well suited to respiratory infections are good oral bioavailability and excellent penetration into respiratory secretions and inflammatory cells within the lung, achieving local concentrations that often exceed serum levels; similar serum and tissue levels can be reached with oral or intravenous administration. Given good lung penetration, the quinolones may be clinically more effective than predicted by MIC values and may be better than other agents in prolonging the "disease-free" interval between exacerbations of COPD, a finding that has been demonstrated for moxifloxacin.[70] High bioavailability allows some "borderline" patients (such as nursing home patients) with pneumonia to be managed with outpatient oral therapy and maintain high therapeutic levels in the serum. In addition, these agents permit an easy transition from intravenous to oral therapy of inpatients with pneumonia, facilitating early discharge when the patient is clinically improving.

The fluoroquinolones are active against β-lactamase producing organisms like *H. influenzae* and *M. catarrhalis* making them very useful for patients with AECB. However, the newer agents (levofloxacin and moxifloxacin) extend the activity of the quinolones with enhanced gram-positive activity as well as by being more active against *C. pneumoniae* and *M. pneumoniae* when compared to the older agents. The new agents are also highly effective against *L. pneumophila* and may be the drug of choice for this organism. For *P. aeruginosa*, as in certain patients with CAP, AECB, and HAP, only ciprofloxacin (750 mg twice daily orally or 400 mg every 8 hours intravenously) or levofloxacin (750 mg orally or intravenously daily) are active enough for clinical use.[1] Since the older agents (ciprofloxacin and ofloxacin) have borderline activity against the pneumococcus, if they are used for AECB or CAP, the dose should probably be optimized to either 750 mg twice daily of ciprofloxacin for AECB or 750 mg once daily of levofloxacin for CAP or AECB.

In clinical trials, all of the newer agents have been effective in treating AECB with 5 days of therapy. In CAP, therapy is usually for 7 to 14 days, but levofloxacin at 750 mg daily can be used for 5 days. Levofloxacin, but not moxifloxacin, is renally excreted, and thus requires dosage adjustment in patients with renal insufficiency. There are no good studies of severe CAP demonstrating efficacy of any of the quinolones as monotherapy, although monotherapy has been shown to be effective in both nosocomial pneumonia and AECB. These agents also differ in the degree of protein binding. The relevance of this feature to clinical outcome is uncertain, but agents like levofloxacin and moxifloxacin are not highly protein bound and have higher free serum concentrations. Although the newer agents are highly active against both penicillin sensitive and resistant pneumococci, there is concern that widespread use may increase pneumococcal resistance to these agents. Recent data show that many pneumococci (up to 20%) have quinolone-resistance determinant genes present but have not developed full resistance.[69] Risk factors for quinolone resistance among pneumococci are recent hospitalization, recent quinolone therapy, and residence in a nursing home.

One major distinction among the new quinolones is their profile of toxic side effects. A number of agents have been removed from clinical use because of toxicities including QT prolongation (grepafloxacin), hypoglycemia (gatifloxacin), phototoxicity (sparfloxacin), and liver necrosis (trovafloxacin). The side effect profiles of other new agents have generally been acceptable, but the risks of use should be weighed against the benefits. A study comparing moxifloxacin to levofloxacin in elderly hospitalized patients with CAP and a high incidence of heart disease, showed comparable safety, with low-frequency cardiac arrhythmias and *Clostridium difficile* diarrhea among both groups.[71]

AMINOGLYCOSIDES

The aminoglycosides are bactericidal agents that act by binding to the 30 S ribosomal subunit of bacteria, thus interfering with protein synthesis. Aminoglycosides have primarily a gram-negative spectrum of activity and are usually used in combination with other agents targeting difficult organisms such as *P. aeruginosa* or other resistant gram-negative bacteria. When combined with certain β-lactam agents they can achieve antibacterial synergy against *P. aeruginosa*. Amikacin is least susceptible to enzymatic inactivation by bacteria whereas tobramycin is more active than gentamicin against *P. aeruginosa*. Aminoglycosides penetrate poorly into lung tissue, and can be inactivated by the acidic environment of pneumonic lung tissue. Because of poor penetration, some investigators have used nebulized aminoglycosides for the therapy and/or prevention of gram-negative pneumonia, but clinical data are limited for this application. Clinical trials conducted for nosocomial pneumonia therapy revealed that the use of an aminoglycoside with a β-lactam antibiotic compared to a β-lactam monotherapy alone was not more effective and the combination did not prevent the emergence of *Pseudomonal* resistance. In the treatment of bacteremic *Pseudomonal* pneumonia, aminoglycoside combination therapy may be more effective than monotherapy.[1,72]

As discussed above, aminoglycosides kill in a concentration-dependent fashion, and can be dosed once daily to optimize killing while minimizing toxicity (primarily in renal insufficiency). In clinical practice, this has not been proven to occur, and once-daily dosing is comparable in efficacy and nephrotoxicity to multiple dose regimens.[73] When aminoglycosides are used, it is necessary to monitor serum levels to minimize the occurrence of acute renal failure. Peak concentrations correlate with efficacy, but only have meaning with multiple daily doses, and their utility in once-daily regimens has not been established. Trough concentrations are monitored to minimize toxicity and probably should be followed regardless of dosing regimen.

METHICILLIN-RESISTANT *S. AUREUS* INFECTIONS

MRSA has emerged as an important pathogen in patients with nosocomial pneumonia, particularly VAP and in association with necrotizing post-influenza pneumonia. In the past, vancomycin was the agent used most commonly against this pathogen. However, there have been concerns about the limited efficacy of vancomycin, primarily because of poor penetration into respiratory secretions. In addition, vancomycin is dosed intermittently with the goal of maintaining trough concentrations between 15 and 20 μg/mL; in critically ill patients this level may be associated with nephrotoxicity and may not be effective for organisms with MIC values >1 μg/mL. Vancomycin is often underdosed in critically ill patients with pneumonia and ARC.[74] Higher doses may be required in those receiving RRT. Use of a weight-based loading dose (approximately 35 mg/kg, using actual body weight) followed by continuous infusions (adjusted according to the CrCl) has been advocated by some investigators to rapidly achieve therapeutic vancomycin concentrations in critical illness, but without proven benefit.

Quinupristin/dalfopristin has been tested in patients with VAP and was not as effective against MRSA as vancomycin in spite of good in vitro activity. There are several other agents in various stages of development that have activity against MRSA that have not been proven to be useful for the therapy of respiratory tract infections. This includes daptomycin, which is inactivated by pulmonary surfactant, thus explaining a lack of efficacy in pneumonia therapy trials. Tigecycline and ceftaroline are available for nonrespiratory tract infections caused by MRSA, but efficacy of these agents in the therapy of MRSA pneumonia is not known.

LINEZOLID

Linezolid is the first agent in a new antibiotic class, the oxazolidinones, which act by inhibiting bacterial protein synthesis, and has activity against MRSA. Oxazolidinones bind to the 50 S ribosomal subunit preventing binding to transfer RNA and blocking formation of the 70 S initiation complex. Oxazolidinones inhibit production of antibacterial toxins such as the Panton-Valentine leukocidin, which can be produced by community-acquired MRSA strains. Linezolid is active against MRSA as well as against DRSP, and vancomycin-resistant enterococci (VRE) (both *Enterococcus faecium* and *Enterococcus faecalis*). This agent has a high bioavailability with serum levels the same with oral or iv therapy. Renal and nonrenal clearance occurs, and dosing adjustments are not needed for patients with renal failure.

Given the increased recognition of the unique PK-PD changes in critical illness, empiric use of linezolid instead of high-dose vancomycin has a theoretical advantage for the treatment of MRSA pneumonia. One prospective double-blind controlled trial involving patients with confirmed MRSA pneumonia, randomized to receive either linezolid (600 mg 12 hourly) or vancomycin (15 mg/kg every 12 hours with dose adjustment on the basis of trough levels) for 7 to 14 days, showed higher clinical success with linezolid with similar 60-day mortality rates between groups.[75]

Linezolid is a reasonable alternative for patients with treatment failure while receiving vancomycin, for isolates with vancomycin MIC values >2 μg/mL, with allergic reactions, or vancomycin-induced nephrotoxicity.[76] Side effects are not common and include nausea, diarrhea, anemia, and thrombocytopenia (especially with prolonged use). It is a weak monoamine oxidase inhibitor.

TELAVANCIN

Telavancin is a semi-synthetic derivative of vancomycin and a bactericidal agent that inhibits bacterial cell-wall synthesis and has been used to treat MRSA pneumonia, and is now approved for this use in the United States. In a prospective randomized double-blinded trial, telavancin was compared against vancomycin in the treatment of MRSA HAP in 1503 patients.[77] Higher cure with monomicrobial *S. aureus* were seen with telavancin and it was more effective than vancomycin for MRSA with vancomycin MIC values >1 μg/mL.[78]

POLYMYXINS

Polymyxins are bactericidal antibiotics that work in a concentration-dependent fashion, and include polymyxin B and E, the latter known as colistin. After binding to lipopolysaccharide (LPS) in the outer membrane of gram-negative bacteria, polymyxins disrupt both the outer and inner membranes, causing increased permeability of the bacterial cell wall to other antibiotics. Gram-negative bacteria can develop resistance to polymyxins through various modifications of the LPS structure that inhibit the binding of polymyxins to LPS. Colistin is used in the treatment of gram-negative bacterial infections.

Polymyxins can be used for pneumonia caused by strains of MDR *P. aeruginosa, Acinetobacter* resistant to carbapenems, or carbapenemase-producing *Enterobacteriaceae*. Polymyxins are not absorbed from the gastrointestinal tract and therefore they are administered intravenously or by inhalation. Elimination is primarily renal, and they are 50% protein bound. Major side effects include nephrotoxicity and neurotoxicity (neuromuscular block, confusion, ataxia, visual disturbances, and dizziness).[79]

A retrospective matched case-control study comparing intravenous (IV) colistin or aerosolized (AS) plus IV colistin in the treatment of VAP by MDR pathogens, in which *A. baumannii* was the most common pathogen, followed by *Klebsiella pneumonia* and *P. aeruginosa* showed no significant differences between the groups for eradication of pathogens, clinical cure, and mortality.[80] Optimal pneumonia dosing is not fully established. Dosing is from 3 million (240 mg) units to 5 million (400 mg) units every 8 hours.

AEROSOLIZED ANTIBIOTICS FOR RESPIRATORY TRACT INFECTIONS

Lung penetration of many intravenous antibiotics, including aminoglycosides and colistin, is limited despite appropriate antibiotic administration. Increased dosages and prolonged duration of therapy used to treat resistant organisms can be associated with greater systemic toxicity with an increased risk of development of antimicrobial resistance.[81,82] Aerosolized antibiotics might address these concerns by direct delivery to the site of respiratory infection, particularly for agents that penetrate poorly into the lung with systemic administration. Direct delivery of antibiotics is usually achieved by nebulization, which achieves high intrapulmonary concentrations with generally low systemic absorption, reducing the risk of systemic toxicity. The majority of studies of inhaled antibiotics have been done in nonventilated patients with cystic fibrosis, and chronic bronchial infection with *P. aeruginosa*, including patients with bronchiectasis. Nebulized tobramycin has been shown to improve pulmonary function, as well as decrease the density of *P. aeruginosa* in sputum and thus reduce the risk of hospital admission[83] in cystic fibrosis.

The use of this approach in mechanically ventilated patients has been reported for patients with either infectious tracheobronchitis or VAP, particularly when the infections involve highly resistant gram-negative bacteria (*P. aerogenosa, Klebsiella,* and *Acinetobacter*) and in whom topical delivery of antibiotics might allow effective therapy of pathogens that cannot be eradicated by systemic therapy. The appropriate dose of aerosolized antibiotics is uncertain, but can be calculated using the intravenous dose for that particular medication and adding to it the amount of drug with extrapulmonary deposition. When concentration-dependent killing antibiotics are administrated, higher peak tissue concentration is associated with greater bactericidal activity, while time-dependent antibiotics are required to maintain lung tissue concentrations above the MIC of the target organism for a prolonged period.[84–89]

Factors that influence lung deposition of nebulized antibiotics during mechanical ventilation include aerosol particle size, type of the nebulizer, physical characteristics of the carrying gas, respirator settings, pneumonia severity, and degree of lung aeration (bronchopneumonia differs from consolidation).[90–92] Ultrasonic or vibrating plate nebulizers are preferred to jet nebulizers.[93–95] Aerosolized particles with median mass aerodynamic diameter of 1 to 5 μm can reach the distal bronchioles and alveolar space.[96] A volume control mode of mechanical ventilation has been used with a constant inspiratory flow, but may require sedation during aerosol administration.[95,97] Nebulization should be synchronized to the inspiratory cycle, while the inspiratory to expiratory ratio is maintained at 1:1, and the nebulizer can be placed in the inspiratory tubing or in line between the endotracheal tube and the Y connector.[95,98,84] Conventional humidifiers need to be used in the ventilator, but humidification is discontinued during nebulization.[91] While the optimal method of administration of aerosol therapy is unknown, most studies have shown that nebulization can be effective and achieve more uniform distribution than direct instillation and, with modern delivery methods, more than 50% of the nebulized dose is retained in the lung.

In experimental studies, it has been shown that the alveolar capillary membrane permeability is markedly increased during lung parenchymal infection.[85,88] Thus, inhaled antibiotics like aminoglycosides and cephalosporins, but not colistin, could be absorbed into the systemic circulation, with some potential for toxicity. The BAY41–6551 (NCT01004445) drug-device investigational combination using amikacin has demonstrated high-level local drug delivery with low corresponding systemic levels.[99]

Several recent studies have shown that inhaled antibiotics can be used as either sole therapy or adjunctive (to intravenous) therapy for MDR gram-negative VAP. Cure rates above 60% have been reported, especially with the use of the vibrating mesh plate, small particle

nebulizer. Aerosolized antibiotics have shown efficiency in studies to treat the lung infection as well as the bacterial reservoir within the biofilm of the endotracheal tube. One randomized trial compared nebulized amikacin and ceftazidime (without systemic therapy) in the treatment of *Pseudomonal* VAP to intravenous treatment with the same medications. The study showed that nebulized medications were able to treat VAP but prevented treatment-related acquisition of antibiotic resistance that was seen in patients receiving intravenous antibiotics.[100]

Another prospective randomized trial examined the impact of adjunctive inhaled amikacin, using a vibrating mesh plate nebulizer in patients with VAP, many of whom had MDR gram-negative infection, and showed that inhaled therapy led to less systemic antibiotic use and more de-escalation than adjunctive inhaled saline.[99] In an older study, the addition of endotracheal tobramycin did not improve clinical outcome compared to placebo in VAP, although microbiologic eradication was significantly greater in the patients receiving aerosolized antibiotics.[101] In this trial, the lack of benefit may have been related to the use of suboptimal nebulization devices; recent studies using older nebulization devices have not been successful. In general, sporadic small and uncontrolled series have shown that when patients have VAP due to MDR *P. aeruginosa* or *Acinetobacter* spp., aerosolized aminoglycosides or colistin may be helpful as adjunctive therapy to systemic antibiotics.[95,102]

In mechanically ventilated patients, even though local antibiotic administration has been successful, there has been concern about the emergence of MDR gram-negatives with nebulized antibiotic therapy. Most current studies of VAP using either aminoglycosides or polymyxin B have not shown resistance to emerge. One side effect of aerosolized antibiotics has been bronchospasm, which can be induced by the antibiotic or the associated diluents present in certain preparations. A specially formulated preparation of tobramycin for aerosol administration has been designed to avoid this complication.

PRINCIPLES OF THERAPY FOR RESPIRATORY TRACT INFECTIONS

Principles of therapy underlying treatment of community-acquired, healthcare-associated, and hospital-acquired pneumonia are considered below.

■ COMMUNITY-ACQUIRED PNEUMONIA

Empiric therapy for CAP is selected by categorizing patients on the basis of the presence or absence of cardiopulmonary disease or other specific "modifying" factors that make certain pathogens more likely, severity of illness, and place of therapy (outpatient, inpatient, ICU). Table 125-2 describes the common pathogens causing CAP in specific patient populations. Figure 125-1 describes

TABLE 125-2 Common Pathogens Causing CAP in Specific Patient Populations (In Order of Decreasing Frequency)

Outpatient, no cardiopulmonary disease or modifying factors	*S. pneumoniae, M. pneumoniae, C. pneumoniae* (alone or as mixed infection), *H. influenzae*, respiratory viruses, others (*Legionella* sp, *M. tuberculosis*, endemic fungi)
Outpatient, with cardiopulmonary disease and/or modifying factors[a]	All the above plus: DRSP, enteric gram-negatives, and possibly anaerobes (with aspiration)
Inpatient, with cardiopulmonary disease and/or modifying factors[a]	*S. pneumoniae* (including DRSP), *H. influenzae, M. pneumoniae, C. pneumoniae*, mixed infection (bacteria plus atypical pathogen), enteric gram-negatives (which can include *P. aeruginosa*), anaerobes (aspiration), viruses, *Legionella* sp., others (*M. tuberculosis*, endemic fungi, *Pneumocystis jiroveci*)
Inpatient, with no cardiopulmonary disease or modifying factors	All of the above, but DRSP and enteric gram-negatives are not likely. These patients are rarely admitted to the hospital
Severe CAP, with no risks for *P. aeruginosa*	*S. pneumoniae* (including DRSP), *Legionella* sp., *H. influenzae*, Enteric gram-negative bacilli, *S. aureus*, *M. pneumoniae*, respiratory viruses, others (*C. pneumoniae, M. tuberculosis* endemic fungi)
Severe CAP, with risks for *P. aeruginosa*[a]	All of the pathogens above plus *P. aeruginosa*

[a]*Some patients in this category are now classified as having HCAP if they have risk factors such as hospitalization in an acute care hospital for 2 or more days within 90 d of the infection; those residing a nursing home or long-term care facility; those who have received recent intravenous antibiotic therapy, chemotherapy, or wound care within the past 30 ds of the current infection; or individuals who have attended a hospital or hemodialysis clinic.*

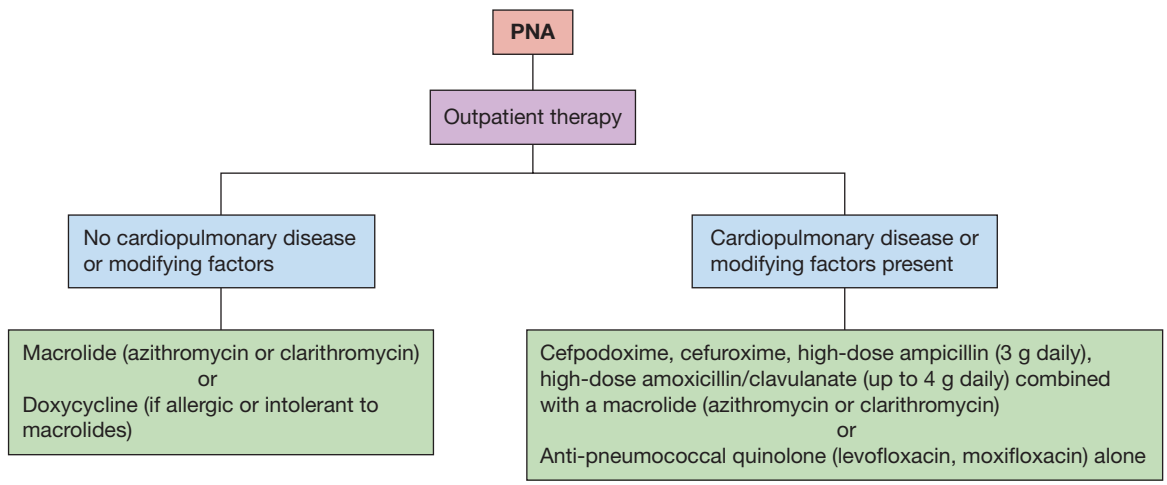

Figure 125-1 Antibiotic preferences for outpatient CAP management based on patient risk factors.

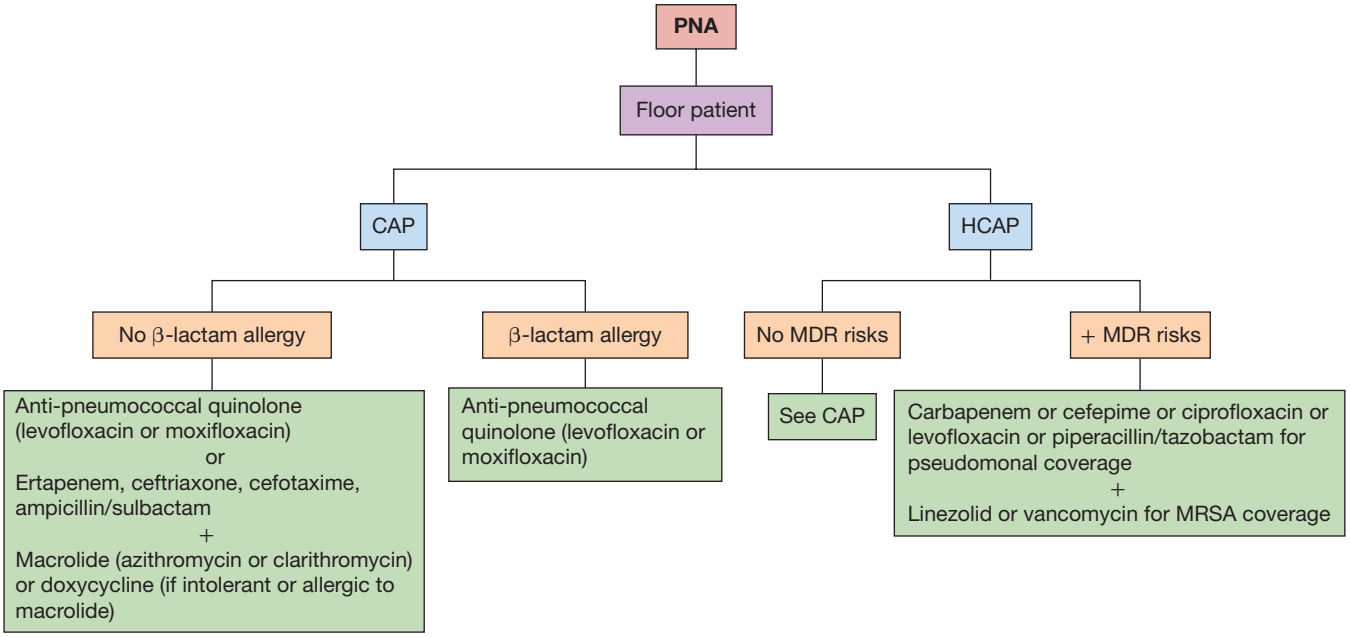

Figure 125-2 Antibiotic preferences for hospitalized CAP management (non-ICU) based on patient risk factors and allergies.

antibiotic preferences for the treatment of CAP in an outpatient setting, based on patient characteristics and risk factors. Figure 125-2 describes the antibiotic preferences for the treatment of pneumonia for non-ICU hospitalized patients (hemodynamically stable) based on risk factors and allergy status.

Modifying factors that increase the risk for infections with specific pathogens include[3]:

MDR: Hospitalization for 2 or more days in the past 90 days, broad-spectrum antibiotics within the past 3 months, immune suppression, poor functional status, admission to an ICU with a high rate of MDR organisms, residence in a nursing home or long-term care facility, or regular visits to a hospital clinic or hemodialysis center. These last two risk factors would actually classify the patient as having HCAP and not CAP.

DRSP: Age >65 years, β-lactam therapy within the past 3 months, alcoholism, immune suppressive illness (including therapy with corticosteroids), multiple medical comorbidities, and exposure to a child in a day care.

Enteric gram-negative bacteria: Residence in a nursing home (which is actually an HCAP risk), underlying cardiopulmonary disease, multiple medical comorbidities, and recent antibiotic therapy. Specific risks for *P. aeruginosa include* structural lung disease (bronchiectasis), corticosteroid therapy (>10 mg prednisone/d), broad-spectrum antibiotic therapy for more than 7 days in the past month, and malnutrition.

Post-influenza pneumonia can be caused by *S. aureus* (including community-acquired MRSA), *H. influenzae, or* pneumococcus. Oral anaerobes occur in the presence of poor dental hygiene.

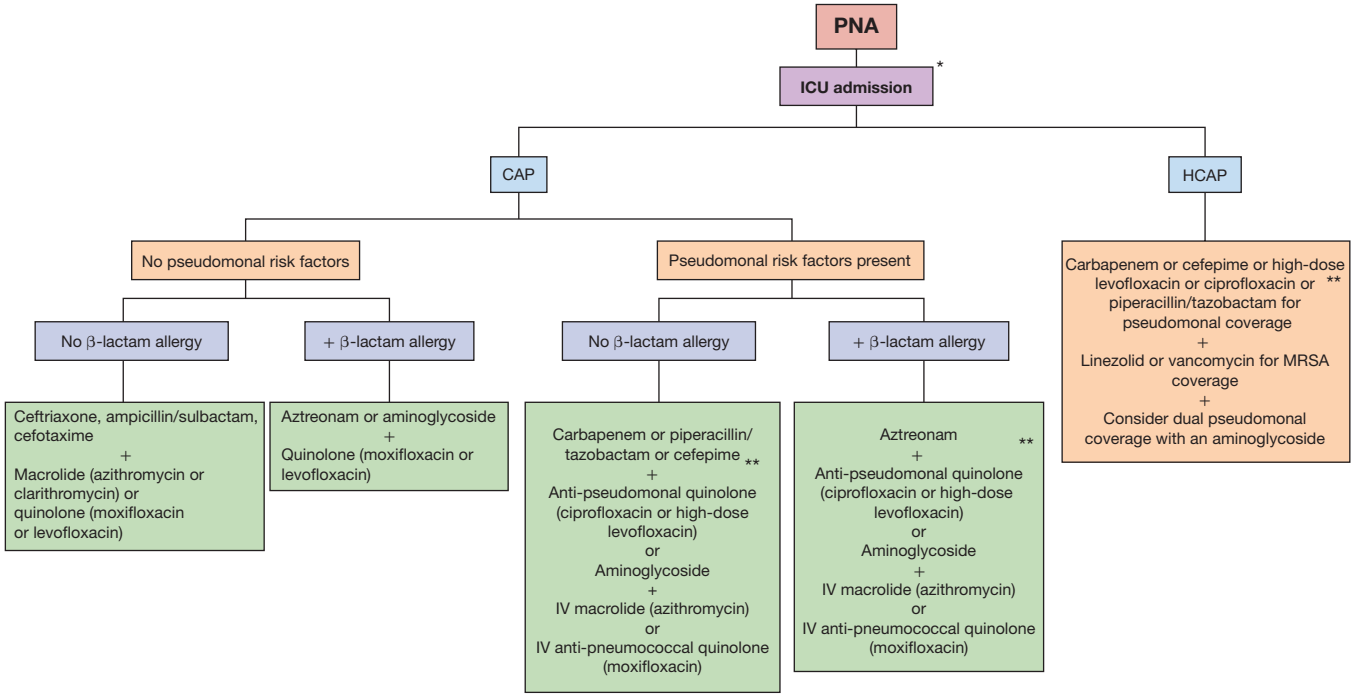
From the available data, either a fluoroquinolone or a β-lactam/macrolide combination regimen is therapeutically equivalent in nonsevere CAP. Although not proven, it may be useful to use these two types of regimens interchangeably, striving for "antibiotic heterogeneity" being sure to select an agent in a different class from those the patient received in the past 3 to 6 months. Recent data have shown that if patients have received a macrolide, fluoroquinolone or penicillin in the past 3 months, then a subsequent infection with pneumococcus is more likely to be resistant to the agent received in the past than to other agents.[58] Although oral quinolones may be as effective as intravenous quinolones for admitted patients with moderately severe illness, most admitted patients should receive initial therapy intravenously to be sure that the medication has been absorbed. Once the patient shows a clinical response, oral therapy can be initiated. Selected inpatients with mild to moderate disease can initially be treated with the combination of an intravenous β-lactam and an oral macrolide, switching to exclusively oral therapy once the patient shows a good clinical response.

Figure 125-3 shows antibiotic preferences to treat CAP in ICU patients based on risk factors and allergy status. In the ICU population, all individuals should receive combination therapy directed at DRSP and atypical pathogens; only those with appropriate risk factors should have coverage for *P. aeruginosa*. Monotherapy should not be used in any ICU admitted CAP patient. In the therapy of *P. aeruginosa*, combination therapy is often needed, but a quinolone may not always be a good choice for use given antimicrobial resistance patterns at many hospitals.

In the empiric therapy of CAP, there is a limited need for routine therapy against MRSA; however, a strain of this organism (community-acquired [CA] MRSA) has been described to cause a severe, necrotizing form of CAP after influenza.[20] Although the frequency of this organism is currently low, vigilance is needed for determining the role of this organism in the future. Optimal therapy for CA-MRSA is uncertain, but the organism produces exotoxins and may be best treated by using both an antibiotic and a toxin production inhibitor. This can done using linezolid alone or vancomycin with clindamycin. These algorithms suggest that all patients should receive empiric therapy that provides coverage for atypical pathogens, based on outcome studies showing improved survival with this approach, and may reflect a high frequency of coinfection by atypical pathogens. In fact, even with bacteremic pneumococcal pneumonia, particularly in the ICU, mortality is reduced when a β-lactam is used with a macrolide, compared to β-lactam monotherapy.[53,54,103]

HEALTHCARE-ASSOCIATED PNEUMONIA

When the patient has HCAP, therapy is dictated by risk factors for MDR pathogens, which include severe pneumonia, recent hospitalization, recent antibiotic therapy, poor functional status, and immune suppression. Not all HCAP patients require empiric therapy directed at MDR pathogens; those without severe CAP and 0 to 1 risk factors can be treated with the same regimen as those with CAP admitted to the hospital (a β-lactam/macrolide combination or fluoroquinolone



*Consider linezolid or vancomycin against MRSA in selected patients.
**Anti-pseudomonal quinolones may not be effective in hospitals with high rates of pseudomonal resistance to these agents.

Figure 125-3 Antibiotic preferences for inpatient-ICU-admitted CAP management based on patient risk factors and allergies.

monotherapy). Those with severe HCAP and no other risk factors should be treated as if for severe CAP, with a β-lactam and either a quinolone or a macrolide. If the HCAP patient has nonsevere pneumonia and at least two MDR risk factors, or severe pneumonia and at least one risk factor, they are treated like HAP, generally with dual pseudomonal therapy plus therapy for MRSA.[104]

■ HOSPITAL-ACQUIRED PNEUMONIA

Prompt empiric therapy should be initiated as soon as there is clinical suspicion of hospital-acquired infection, since mortality is increased if incorrect antibiotics are used or if a delay in antibiotic initiation occurs.[1,5,105] A lower respiratory tract culture (sputum, tracheal aspirate, protected brush, BAL) should be collected prior to initiation of antibiotic therapy, and samples can be cultured quantitatively or semiquantitatively, depending on local expertise.

A narrow-spectrum regimen can be used for patients at risk for infection with the "core pathogens" (nonresistant enteric gram-negatives, pneumococcus, *H. influenzae*, and methicillin-sensitive *S. aureus*) and with no risk factors for MDR pathogens, although very few patients fall into this category. Antimicrobial options include ceftriaxone, ampicillin/sulbactam, ertapenem, levofloxacin, or moxifloxacin. For penicillin allergy, a quinolone or the combination of clindamycin and aztreonam can be selected.

Combination therapy with a broad-spectrum regimen containing at least two anti-pseudomonal agents should be used for patients with risk factors for MDR pathogens. Specific choices should be guided by knowledge of local microbiology patterns and should include an aminoglycoside or an anti-pneumococcal quinolone (ciprofloxacin or high-dose levofloxacin) and an anti-pseudomonal β-lactam such as cefepime, ceftazidime, imipenem, meropenem, or piperacillin/tazobactam. If there is concern about MRSA, a third agent can be added using either linezolid or vancomycin. Linezolid may be the preferred in patients with proven MRSA VAP and renal insufficiency or in those receiving other nephrotoxic medications (such as an aminoglycoside).

Initial therapy should be given in full recommended doses adjusted as needed for renal function: cefepime 1 to 2 g every 8 to 12 hours; imipenem 500 mg every 6 hours or 1 g every 8 hours; meropenem 1 g every 8 hours, piperacillin/tazobactam 4.5 g every 6 hours; levofloxacin 750 mg daily or ciprofloxacin 400 mg every 8 hours; vancomycin 15 mg/kg every 12 hours leading to a trough level of 15 to 20 mg/L; linezolid 600 mg every 12 hours; and aminoglycosides of 7 mg/kg per day of gentamicin or tobramycin and 20 mg/kg of amikacin.[1]

When choosing empiric therapy, it is important to select agents from a different class of antibiotics than the patient has received in the past 2 weeks, with a plan to de-escalate to monotherapy once culture and clinical response data are available. If *P. aeruginosa* is present, consider stopping the aminoglycoside after 3 to 5 days and finish with a single agent to which the organism is sensitive. If it is a non-pseudomonal infection, it is best to switch to a single agent that the organism is sensitive to, using either imipenem, meropenem, cefepime, piperacillin/tazobactam, ciprofloxacin, or high-dose levofloxacin.

The drug of choice for *Acinetobacter* spp. is a carbapenem, but colistin should be considered with carbapenem resistance. Tigecycline monotherapy is not recommended, but this agent can be combined with a carbapenem, colistin, or sulbactam. Aerosolized aminoglycosides or colistin can be added as adjunctive therapy in patients with highly resistant gram-negative pathogens.

The use of empiric combination therapy in VAP is controversial, and there few data to suggest that use of an aminoglycoside with a β-lactam is more effective than β-lactam monotherapy. Dual therapy may have value if the patient is neutropenic or if pseudomonal bacteremia is present, but both situations are uncommon. Thus, the most compelling reason for using empiric combination therapy in patients with suspected MDR pathogens, is to provide a broad enough spectrum of agents to increase the likelihood that the initial therapy is appropriate. Once the organism is identified, it is possible to de-escalate therapy. New data suggest that with pneumonia and sepsis, dual adequate therapy is more effective than single effective therapy, possibly because of more rapid bacterial eradication.[106]

DE-ESCALATION OF ANTIBIOTIC THERAPY

Antibiotic overuse causes resistance, which can in turn lead to inappropriate empiric therapy. To minimize this risk, it is necessary to de-escalate after an initial broad-spectrum therapy, which can involve using fewer drugs, drugs of a narrower spectrum, and short durations of therapy.[2] It is possible to effectively treat VAP with 6 to 8 days of therapy, provided that the initial therapy is appropriate.[1] The optimal duration of therapy for infections caused by *P. aeruginosa* and MRSA is still uncertain, but prolonged therapy may be no better than short duration therapy, in the absence of bacteremia.

In clinical studies of VAP, the rate of de-escalation has varied from 22% to 74%, with the highest rates being in those who are treated with a protocol for de-escalation, when initial therapy is appropriate, when initial cultures are positive (although it can be done with negative cultures), when the therapy involves broad-spectrum agents and multiple agents, and if the frequency of MDR pathogens is not high.[2] De-escalation does not appear to be dangerous and may be associated with reduced mortality, compared to no change in antibiotics. The decision to change antibiotics is made by assessing clinical features such as fever, leukocytosis, and purulence of secretions, radiographic patterns, and oxygenation. In general, the best clinical predictor of response is improvement in oxygenation, which usually occurs by day 3 in survivors of VAP, but not in nonsurvivors. If the patient is improving, then cultures should be checked, and efforts made to de-escalate and shorten duration of therapy. In some instances, all signs of pneumonia are gone by day 2 to 3, respiratory cultures are negative and in retrospect, the diagnosis was heart failure or atelectasis, and antibiotics can be completely stopped.

ANTIMICROBIAL STEWARDSHIP

Antimicrobial control or stewardship programs involve a number of interventions, but require a committed champion and a good knowledge of local antibiotic usage patterns. The principles of antimicrobial stewardship have been compiled into a guideline, where the focus is on prospective audit and feedback of antibiotic use, de-escalation of broad-spectrum therapy, proper dosing, and the development of local guidelines for antibiotic use, based on knowledge of local microbiology.[107] Antibiotic restriction was not a highly recommended strategy, nor was restricting access to specific antibiotics.

CHAPTER 126

Infections of the Upper Respiratory Tract

Thomas M. File Jr.

Upper respiratory tract infections are the most common infections and the most frequent reasons for office visits in the United States. Most upper respiratory infections are minor and self-limiting and do require specific antimicrobial therapy, but some (e.g., peritonsillar abscess [PTA], epiglottitis, invasive fungal sinusitis) may be life-threatening.[1]

THE COMMON COLD

The common cold is a mild, self-limiting infection and is the most frequent acute illness in the United States.[2] Approximately 500 million noninfluenza viral respiratory infections occur yearly, resulting in estimated direct costs of $17 billion and indirect costs of $22.5 billion annually.[3] Six major viral families are responsible: rhinovirus (30%–40% of cases); influenza virus (25%–30%); coronavirus (10%–15%); adenovirus (5%–10%); parainfluenza virus (5%); and respiratory syncytial virus (RSV) (5%). Each virus has several serotypes; rhinovirus has 100. More recently recognized viruses, such as human metapneumovirus and bocavirus can also cause the common cold.[4] Adults have an average of two to four colds and children six to eight colds per year.

In the United States, the incidence of colds is seasonal, with most occurring fall through spring. Young children are the main reservoir of respiratory viruses, and adults with children have more colds than those without. Transmission probably occurs either by inhalation of infectious droplets or by hand-to-nose "self-inoculation" after touching infectious secretions. The pathogenesis of rhinovirus infections is thought to include viral entry into the nose followed by infection of the epithelial cells of the upper airway. Frequent use of alcohol-based hand sanitizers or virucidal impregnated nasal tissues may reduce transmission.[5] Symptoms (sneezing, nasal discharge and congestion, and a "scratchy" throat) develop 16 to 72 hours after inoculation, and last for 1 to 2 weeks. Fever is uncommon in adults but may occur in children. Acute viral bronchitis is commonly associated with the common cold in adults. The peak of rhinoviral excretion in nasal secretions coincides with the peak of clinical illness. Complications of the common cold include bacterial superinfections of the upper respiratory tract, such as acute otitis media (AOM) and acute sinusitis, and exacerbations of asthma.[6]

Treatment of the common cold is symptomatic. Symptoms of rhinorrhea and sneezing may be improved by the use of intranasal ipratropium.[7] Antihistamine use alone in patients with the common cold is of minimal benefit and frequently results in troublesome side effects.[8] Guidelines from the American College of Chest Physicians do not recommend use of cough suppressants (codeine or dextromethorphan) for cough associated with upper respiratory infections.[9] Treatment with antibiotics for uncomplicated upper respiratory tract infections causes more harm than benefit and should not be used.[10,11] The value of zinc, vitamin C, Echinacea, and other herbal products has not been definitely proven.[12–14] Careful hand washing and use of hand disinfectants may be the most effective preventive measures.[15]

PHARYNGITIS

Acute pharyngitis is one of the most frequent illnesses for which physicians are consulted, with an estimated 12 million visits per year in the United States.[16] The great majority of cases are caused by viruses and often occur as part of the common cold for which antimicrobial therapy is not warranted. These cases are mild, nonexudative, and self-limiting.

The major causes of pharyngitis are listed in Table 126-1. Bacterial agents other than Group A streptococcus (GAS) that may cause pharyngitis include *Mycoplasma pneumoniae*, *Chlamydia pneumoniae, Neisseria gonorrhoeae*, groups C and G streptococci, *Arcanobacterium haemolyticum, Fusobacterium necrophorum, and Corynebacterium diphtheriae*.

Patients with pharyngitis typically complain of sore throat, particularly when swallowing. Fever is lacking for most viral infections but often present with GAS. Patients may note "swollen glands"

TABLE 126-1 Microbial Etiology of Acute Pharyngitis

Organisms	Clinical Syndrome(s)
Bacterial	
Group A streptococcus	Pharyngotonsillitis, scarlet fever
Group C and group G streptococcus	Pharyngotonsillitis
Arcanobacterium haemolyticum	Scarlatiniform rash, pharyngitis
Neisseria gonorrhoeae	Tonsillopharyngitis
Corynebacterium diphtheriae	Diphtheria
Mixed anaerobes	Vincent angina
Fusobacterium necrophorum	Lemmiere syndrome, peritonsillar abscess
Francisella tularensis	Tularemia (oropharyngeal)
Yersinia pestis	Plague
Yersinia enterocolitica	Enterocolitis, pharyngitis
Viral	
Adenovirus	Pharyngoconjunctival fever
Herpes simplex virus 1 and 2	Gingivostomatitis
Coxsackievirus	Herpangina
Rhinovirus	Common cold
Coronavirus	Common cold
Influenza A and B	Influenza
Parainfluenza	Cold, croup
EBV	Infectious mononucleosis
Cytomegalovirus	CMV mononucleosis
HIV	Primary acute HIV Infection
Mycoplasma	
Mycoplasma pneumoniae	Pneumonitis, bronchitis
Chlamydia	
Chlamydophla pneumoniae	Bronchitis, pneumonia
Chlamydophla psittaci	Psittacosis

CMV, cytomegalovirus; EBV, Epstein–Barr virus; HIV, human immunodeficiency virus.

TABLE 126-2 Antibiotic Regimens Recommended for Group A Streptococcal Pharyngitis

Drug, Route	Dose or Dosage	Duration or Quantity
For individuals without penicillin allergy		
Penicillin V, oral	Children: 250 mg twice daily or 3 times daily; adolescents and adults: 250 mg 4 times daily or 500 mg twice daily	10 d
Amoxicillin, oral	50 mg/kg once daily (max = 1000 mg); alternate: 25 mg/kg (max = 500 mg) twice daily	10 d
Benzathine penicillin G, intramuscular	<27 kg: 600,000 U; ≥27 kg: 1,200,000 U	1 dose
For individuals with penicillin allergy		
Cephalexin,[a] oral	20 mg/kg/dose twice daily (max = 500 mg/dose)	10 d
Cefadroxil,[a] oral	30 mg/kg once daily (max = 1 g)	10 d
Clindamycin, oral	7 mg/kg/dose 3 times daily (max = 300 mg/dose)	10 d
Azithromycin,[b] oral	12 mg/kg once daily (max = 500 mg)	5 d
Clarithromycin,[b] oral	7.5 mg/kg/dose twice daily (max = 250 mg/dose)	10 d

Max, maximum.
[a]Avoid in individuals with immediate type hypersensitivity to penicillin.
[b]Resistance of GAS to these agents is well-known and varies geographically and temporally.

or anterior neck pain related to lymphadenopathy. When throat symptoms are due to a viral upper respiratory, symptoms such as nasal congestion, coryza, hoarseness, sinus discomfort, ear pain, or cough are common. A severe, usually exudative pharyngitis occurs in about half of the patients with either adenovirus infection or Epstein–Barr virus mononucleosis. The pharyngitis seen in herpangina, due to group A coxsackievirus, is characterized by a vesicular enanthem. Lesions (usually only two to six) begin as papules on the soft palate between the uvula and tonsils. These vesiculate and then ulcerate. Primary herpes simplex virus may cause a severe vesicular or ulcerative pharyngitis; when there is an overlying exudate, it may mimic streptococcal pharyngitis.

GAS is the most important bacterial cause of pharyngitis because of its suppurative (e.g., PTA) and nonsuppurative complications (e.g., rheumatic fever, acute post streptococcal glomerulonephritis).[17] Patients with GAS may have a severe exudative pharyngitis accompanied by fever, leukocytosis, and cervical lymphadenopathy, or they may have a mild pharyngitis that mimics that of the common cold. Manifestations independently associated with group A streptococcal pharyngitis include tonsillar exudates, cervical lymphadenitis, lack of cough, and history of fever. However the signs and symptoms of GAS and nonstreptococcal pharyngitis overlap so broadly that diagnosis on this basis of clinical grounds alone lacks acceptable accuracy.

Diagnosis of streptococcal pharyngitis is made by culture or by rapid antigen detection test.[17] The latter is 95% specific but not as sensitive as culture. Therefore, a negative test requires culture confirmation in children and adolescents, whereas a positive test is sufficient for the diagnosis. In adults, practice guidelines suggest that it is not necessary in usual circumstances to require culture backup because of the low incidence of GAS pharyngitis in adults and because the risk of subsequent acute rheumatic fever is generally exceptionally low in adults with acute pharyngitis. The use of a clinical algorithm without microbiological confirmation has been suggested as an acceptable alternative basis for the diagnosis of infection in adults (based on the presence of fever, adenopathy, and exudates, and lack of cough).[18] However, use of this diagnostic strategy would result in treatment of an unacceptably large number of adults with nonstreptococcal pharyngitis; that is an undesirable result in this age group, which has a low prevalence of GAS pharyngitis and a very low risk of rheumatic fever or rheumatic carditis.

Penicillin or amoxicillin is the recommended drug of choice for GAS. Treatment in penicillin-allergic individuals may include a first-generation cephalosporin (for those not anaphylactically sensitive) for 10 days, clindamycin or clarithromycin for 10 days, or azithromycin for 5 days (Table 126-2). A PTA (quinsy) may follow untreated streptococcal pharyngitis—see Deep Neck Infections.

Other bacteria may also cause pharyngitis. Group C and G streptococci may cause an exudative pharyngitis and may be endemic or related to foodborne outbreaks. *A. haemolyticum* may cause an exudative pharyngitis along with a maculopapular rash, and typically occurs in children and young adults. Diphtheria, caused by *C. diphtheriae,* is rare in the United States. Sore throat is a common symptom (in 90%), and findings include mild pharyngeal injection and an overlying adherent gray membrane (especially over the tonsillar pillars) that bleeds if removal is attempted. *N. gonorrhoeae* may cause a mild pharyngitis, although most cases are asymptomatic. *Neisseria meningitidis* has rarely been noted as a cause of pharyngitis, but it is often isolated from throat cultures because the meningococcal carrier state is common. Carriers are not treated except in epidemic situations or if they have had close contact with a case of invasive meningococcal disease. *C. pneumoniae* and *M. pneumoniae* may cause a mild pharyngitis.

The anaerobe *F. necrophorum* is the causative agent of most cases of Lemmiere syndrome, septic thrombophlebitis of the internal jugular vein, which often results in metastatic pulmonary infections.[19] Lemmiere syndrome should be suspected in patients with pharyngitis (usually severe), unilateral neck pain with swelling, septic pulmonary emboli, and persistent fever despite antimicrobial therapy. Patients typically present acutely with high fever (>39°C) and rigors, often accompanied by respiratory distress. Since *F. necrophorum* is often β-lactamase producing, empiric therapy should include a β-lactamase resistant β-lactam antibiotic, such as ampicillin–sulbactam (3 g every 6 hours), piperacillin–tazobactam (4.5 g every 6 hours), ticarcillin–clavulanate (3.1 g every 6 hours), or monotherapy with a carbapenem. Surgical ligation or excision of the internal jugular vein may be necessary. The role of anticoagulation for jugular vein suppurative thrombophlebitis is controversial and generally not recommended.

ORAL CAVITY INFECTIONS

The oral cavity extends from the lips to the circumvallate papillae of the tongue. Various streptococci (e.g., *Streptococcus mutans,*

Streptococcus mitis, Streptococcus salivarius) and anaerobes (e.g., *Peptostreptococcus, Veillonella, Lactobacillus, Bacteroides, Prevotella*) heavily colonize this area, and are the main pathogens in dental and oral cavity infections. *S. mutans* is a major pathogen in dental cavities. Gingivitis and periodontitis are associated with anaerobic gram-negative rods such as *Prevotella intermedia* and *Porphyromonas gingivalis*. Mouth anaerobes are the major cause of Vincent angina (acute necrotizing ulcerative gingivitis, or trench mouth). Patients have gingival pain, halitosis, cervical adenopathy, and ulcerations of the interdental papillae. Treatment is with oral clindamycin or penicillin plus metronidazole.[20]

DEEP NECK INFECTIONS

Deep neck infections include PTA (quinsy), retropharyngeal abscess, parapharyngeal space abscess, and infections of the sublingual or submandibular spaces.[21,22] Pharyngeal space infection most often arises via contiguous spread of infection from a peritonsillar or retropharyngeal abscess. PTA is located between the tonsil and pharyngeal muscles. Most PTAs present as a severe sore throat (usually unilateral), fever, subdued voice; drooling and trismus are often present. Examination of the oral pharynx includes an extremely swollen and fluctuant tonsil with deviation of the uvula to the opposite side. If drooling is present care must be taken not to be aggressive during the examination of the oral cavity in case if epiglottis is present. Computed tomography (CT) with IV contrast distinguishes PTA from cellulitis and also demonstrates the spread of infection to contiguous deep neck spaces. PTAs are often polymicrobial. The predominant bacterial species are *Streptococcus pyogenes, Staphylococcus aureus*, and respiratory anaerobes. Management consists of drainage (needle aspiration or incision and drainage) and antimicrobial therapy (e.g., ampicillin–sulbactam or clindamycin).[23]

Ludwig angina is a rapidly spreading cellulitis of the sublingual and submandibular spaces. It usually begins from the floor of the mouth from an infected mandibular molar tooth. The sublingual area becomes edematous, pushing the tongue to the roof of the mouth. The infection is bilateral and can cause acute airway obstruction. Patients present with fever, difficulty swallowing, drooling, and prominent submandibular and sublingual swelling. They may lean forward to maximize the airway diameter and may have a muffled voice. CT is the imaging modality of choice for the diagnosis of Ludwig angina and other deep neck space infections. They should be admitted for airway monitoring, as intubation or tracheostomy may be necessary. Intravenous antibiotics active against streptococci and anaerobes should be given (e.g., ampicillin/sulbactam, clindamycin, penicillin G plus metronidazole). Surgical incision of the infected soft tissue compartment may be necessary. Mediastinitis is a rare complication resulting from spread into the parapharyngeal space and from there to the retropharyngeal space and the superior mediastinum.

LARYNGITIS

Laryngitis, or inflammation of the larynx, is characterized by hoarseness. Acute laryngitis is usually caused by the same viruses that cause the common cold, usually resolves within 3 weeks, and treatment is symptomatic.[24] Hoarseness may accompany infections with human metapneumovirus and primarily associated with bronchiolitis in young children. Herpes simplex virus may cause acute laryngitis; ulcerations or vesicles are typically seen. Streptococcal pharyngitis may be associated with laryngitis and should be treated with penicillin. Patients with chronic hoarseness often have gastroesophageal reflux disease, but must be examined for laryngeal malignancies. In rare instances, fungi or mycobacteria may cause chronic laryngitis. In chronic progressive disseminated histoplasmosis, ulcers may occur on the larynx, as well as on the tongue, buccal mucosa, and gingiva (see Chapter 134). Blastomycosis may also produce laryngeal ulcers. Tuberculosis (TB) may cause laryngeal lesions that mimic a laryngeal neoplasm. Patients typically present with hoarseness but often lack systemic symptoms to suggest TB (see Chapter 131).[25] They may have negative sputum smears for acid-fast bacilli and a clear chest radiograph. In a retrospective study of 22 patients with laryngeal TB, had clear lungs and only 7 had active pulmonary TB.[26] The patients with concurrent pulmonary TB characteristically had multiple ulcerative lesions on their vocal cords, whereas those with clear lungs had nonspecific, polypoid, single laryngeal lesions.

CROUP

Croup, or acute laryngotracheitis, is characterized by inflammation of the larynx and trachea, associated with subglottic edema and occurs most often in children ages 3 months to 3 years old, with peak incidence in the second year of life.[27] It is more common in boys. Most cases occur in fall, winter, and spring; the most common cause, parainfluenza virus (usually type 1), has caused biennial epidemics in the fall in the United States. Croup is characterized by fever, inspiratory stridor, and a "seal's bark" cough. In severe cases, there is both inspiratory and expiratory stridor. There is typically a fluctuating course, and there can be alternating clinical improvement and worsening within an hour. Croup usually follows the onset of upper respiratory tract infection symptoms by 1 to 2 days. Other viruses that can also cause croup include RSV, adenovirus, human coronaviruses; influenza and *M. pneumoniae* are uncommon causes.

The diagnosis of croup is based primarily on clinical grounds. A diagnosis of the viral etiology may be made by one of the rapid viral antigen detection techniques (e.g., PCR) on nasopharyngeal swabs. The most important differential diagnosis in the acute clinical setting is epiglottitis (see below). Children with epiglottitis usually lack the characteristic seal's bark cough of croup, appear more toxic, and their illness worsens more rapidly.

Appropriate management of croup depends upon an assessment of severity of illness. A commonly used scoring system for evaluating the severity of croup is the Westley croup score, the elements (and score) are as follows[28]:

- Level of consciousness: Normal, including sleep = 0; disoriented = 5
- Cyanosis: None = 0; with agitation = 4; at rest = 5
- Stridor: None = 0; with agitation = 1; at rest = 2
- Air entry: Normal = 0; decreased = 1; markedly decreased = 2
- Retractions: None = 0; mild = 1; moderate = 2; severe = 3

Children with mild symptoms, defined by a Westley croup score of ≤ 2, can be treated as outpatients and be treated symptomatically with humidity, fever reduction, and oral fluids. Close follow-up of response is recommended. Patients with moderate to severe croup (score ≥ 3) should be evaluated in a facility equipped to handle airway obstruction.

Treatment of croup consists of nebulized epinephrine, corticosteroids, and humidified air, although the value of humidified air has been questioned.[29,30] Nebulized epinephrine is associated with clinically and statistically significant transient reduction of symptoms of croup 30 minutes posttreatment. Children should be monitored for rebound edema for several hours after initiation of therapy. Corticosteroids are also beneficial.[31–33] Dexamethasone and budesonide are effective in relieving the symptoms of croup as early as 6 hours after the treatment. Fewer return visits and/or (re)admissions are required and the length of time spent in hospital is decreased. Oral or intramuscular dexamethasone has shown benefit for moderate to severe croup, and a single dose of oral dexamethasone is beneficial for mild croup.

EPIGLOTTITIS

Acute epiglottitis (supraglottitis) is a medical emergency, as it can rapidly lead to airway obstruction. It begins as a cellulitis between the base of the tongue and the epiglottis, pushing the epiglottis posteriorly. It then involves the epiglottis itself, with rapid swelling

and airway compromise. Epiglottitis has become a rare disease in children since the advent of vaccination against *Haemophilus influenzae* type b (Hib) in 1985, which decreased the incidence of all types of invasive Hib disease by over 99%.[34] In the prevaccine era, the incidence of epiglottitis was highest in children ages 2 to 4. Disease in children is due to rare cases of Hib vaccine failure or to other organisms, including nontypable *H. influenzae*. In one study, the incidence of acute epiglottitis in children was 0.02 cases/100,000 population/y.[35] The incidence in adults was a mean of 1.9 cases/100,000 population/y. Two uniquely recognized vulnerable populations for epiglottitis are infants and the elderly. Blood cultures are usually negative in adults and cultures of the epiglottis difficult or dangerous to obtain, so the etiology is often unknown. Pathogens isolated from throat cultures in adults with supraglottitis include *H. influenzae*, *H. parainfluenzae, Streptococcus pneumoniae,* GAS, and *S. aureus*. Viral epiglottitis is very rare and poorly substantiated. In children, the onset of symptoms occurs rapidly, usually within 6 to 12 hours, and patients appear toxic. Patients are febrile, irritable, complain of sore throat and dysphagia, prefer to sit leaning forward, and may be drooling. Inspiratory stridor may occur, but the barking cough seen in croup is absent. Adolescents and adults usually have a less fulminant presentation, often with 2 to 3 days of symptoms.[36] Severe sore throat, odynophagia, and fever are the main presenting symptoms, each occurring in 90% of adults in a recent study; muffled voice was present in 70%. In adults, diagnosis is made by direct flexible fiberoptic nasolaryngoscopy, a procedure that takes just minutes to perform in the emergency room by an otolaryngologist. A swollen, erythematous epiglottis is seen. Examination of a child in whom epiglottitis is a consideration should occur in a setting where the airway can be secured immediately if necessary.[37,38] Children suspected of having epiglottitis should be transported, sitting up, to the operating room for direct endoscopic visualization of the epiglottis. An uncuffed endotracheal (or nasotracheal) tube should be immediately inserted (or, if necessary, a tracheostomy performed) if a "cherry red" edematous epiglottis is seen. Lateral neck radiographs, used in the past to demonstrate the "thumb sign" of an edematous epiglottis, are rarely used now as they may be falsely negative and may cause a critical delay in securing the airway.

All patients with epiglottitis should be monitored in an intensive care unit. Children with epiglottitis should be intubated for airway protection, whereas adults whose endoscopic examination reveals no impending airway compromise may be managed with close observation. The empiric regimen generally should provide coverage against the following pathogens: *H. influenzae*; Penicillin-resistant *S. pneumoniae*; β-hemolytic streptococci; *S. aureus*, including community-acquired methicillin-resistant *S. aureus* (MRSA) strain (e.g., combination therapy with a third-generation cephalosporin—ceftriaxone or cefotaxime – and an antistaphylococcal agent active against MRSA—clindamycin or vancomycin). If the patient with epiglottitis due to *H. influenzae* has household contacts that include an unvaccinated child younger than 4 years, the patient and all members of the household should receive rifampin prophylaxis to eradicate carriage of the organism.

BACTERIAL TRACHEITIS

This rare disorder, sometimes called membranous croup, presents acutely like epiglottitis but primarily involves the subglottic region like croup.[39,40] Bacterial tracheitis almost always occurs in the setting of prior airway mucosal damage, as occurs with antecedent viral infection. It may represent bacterial superinfection of a viral tracheitis. The majority of cases occur in the fall and winter, coinciding with the typical seasonal epidemics of parainfluenza, RSV, and seasonal influenza. It usually affects children between 3 weeks and 13 years of age, and is uncommon in adults. Patients present with the acute onset of high fever, stridor, and dyspnea after a viral prodrome. Drooling is uncommon. They usually have leukocytosis. They do not respond to racemic epinephrine or corticosteroids. Lateral neck or anteroposterior radiographs typically show narrowing of the subglottic trachea that may be indistinguishable from that in viral croup. On endoscopy, patients have a normal epiglottis but the subglottic trachea is covered with a thick exudate. Inspissated secretions may produce a pseudomembrane. Cultures of tracheal secretions yield *S. aureus* in approximately half of the cases; other organisms include GAS, *S. pneumoniae*, and *H. influenzae*. Gram-negative bacilli have been rarely described. Treatment consists of maintenance of the airway, fluid resuscitation (if needed), and administration of appropriate antimicrobial agents. Many patients require immediate intubation; some require tracheostomy. Up to 60% will have concurrent pneumonia. Management consists of broad-spectrum intravenous antibiotics active against *S. aureus* and *H. influenzae* (e.g., ceftriaxone plus vancomycin), along with airway humidification and aggressive pulmonary toilet.

SINUSITIS (RHINOSINUSITIS)

Sinusitis is defined as an inflammation of the mucosal lining of the paranasal sinuses and can be caused by various factors including allergy, environmental irritants, and infection by viruses, bacteria, or fungi.[41–44] It is more appropriately referred to as rhinosinusitis because there is almost always coexisting inflammation in the nasal mucosa. Rhinosinusitis can be classified on the basis of duration of symptoms into acute, subacute, and chronic. Acute rhinosinusitis lasts up to 4 weeks and is usually caused by a viral or bacterial infection. Chronic sinusitis lasts more than 12 weeks and may result from a wide range of allergic and nonallergic causes. Rhinosinusitis is an extremely common condition. In a national health survey conducted during 2008, nearly one in seven (13.4%) of all noninstitutionalized adults were diagnosed with rhinosinusitis within the previous 12 months.[41] Incidence rates among adults are higher for women than men (by 1.9-fold), and adults between 45 and 74 years are most commonly affected. Recent estimates suggest that the direct annual costs of sinusitis are approximately $5.8 billion in the United States.[41] Rhinosinusitis ranks among the top five reasons for antibiotic prescriptions for adults. Ninety percent to 98% of patients presenting with symptoms of sinusitis have viral causes and will not benefit from antibiotics. The overuse of antibiotics among this population has contributed largely to the emergence of antimicrobial resistance.

The paranasal sinuses develop as outpouches of the nasal cavity. The maxillary and ethmoid sinuses are present at birth, the frontal sinus develops after age 2, and the sphenoid sinus develops after age 7. The sinuses are lined with respiratory epithelium that includes ciliated cells and mucus-producing goblet cells. The cilia normally move the mucus blanket toward the sinus ostia (and then to the nasopharynx) at a speed of up to 1 cm/min. Inflammation causes a marked decrease in the beat frequency of the cilia, as well as narrowing or obstruction of the sinus ostia due to mucosal edema. The resulting disruption of mucociliary transport results in sinusitis. The frontal, anterior ethmoid, and maxillary sinuses open into the middle meatus, whereas the posterior ethmoid and sphenoid sinuses open into the superior meatus. The osteomeatal complex, an area between the middle and inferior nasal turbinates representing the confluence of drainage from the paranasal sinuses, is a particularly important anatomic site because of its potential for mucosal thickening and impaired drainage from viral infection leading to sinus infection. A viral etiology associated with a URI or the common cold is the most frequent cause of acute rhinosinusitis. Secondary bacterial infection of the paranasal sinuses following an antecedent viral URI is relatively uncommon, estimated to be 0.5% to 2% of adult.[41] Viral infections increase the amount of mucus produced and

may damage ciliated cells. Another predisposing factor for sinusitis is allergic rhinitis, which may cause ostial obstruction by mucosal edema or polyps. Dental infections, especially of the upper teeth that abut the maxillary sinus (second bicuspid, first and second molars), may cause some cases of maxillary sinusitis. Anatomic obstruction of the sinus ostia due to a deviated septum, tumor, granulomatous disease (e.g., granulomatous polyangiitis, formerly known as Wegener granulomatosis), or nasotracheal or nasogastric tubes may also lead to sinusitis. Barotrauma from deep-sea diving or airplane travel, chemical irritants, and mucus abnormalities (e.g., cystic fibrosis) are other risk factors for sinusitis.

■ ACUTE BACTERIAL RHINOSINUSITIS

Symptoms of acute bacterial rhinosinusitis (ABRS) include purulent nasal or postnasal drainage, nasal congestion, and sinus pain or pressure. Nasal discharge and cough (which may be worse at night) are both common, whereas the presence of fever headache, or facial pain is more variable. The location of this pain depends on the sinus affected. Patients usually complain of pain in their cheek or upper teeth in maxillary sinusitis, the sides of the bridge of the nose in ethmoid sinusitis, supraorbital or frontal pain in frontal sinusitis, and retroorbital, frontal, occipital, or vertex pain in sphenoid sinusitis. Fever occurs in about half of the adults with ABRS. The gold standard for the diagnosis of ABRS is the recovery of bacteria from the cavity of a paranasal sinus.[45] However, sinus aspiration is an invasive, time-consuming, and potentially painful procedure that does not have utility in the daily practice of primary care physicians. Endoscopically guided cultures of the middle meatus may be used as a surrogate for sinus aspirates in patients with ABRS. Performance of such cultures is beyond the scope of most primary care physicians, and its validity in children has not been established. Thus, the diagnosis of ABRS in most randomized controlled trials (RCTs) of antimicrobial is based on suggestive clinical manifestations.

Appropriate therapy is based on the presence of compatible symptoms and signs of acute rhinosinusitis with radiographic confirmation of sinus involvement. Unfortunately, these diagnostic criteria do not adequately distinguish bacterial from viral infection. Imaging studies such as plain radiographs or CT are frequently used by clinicians for the diagnosis of ABRS. Unfortunately, these studies are nonspecific and also do not distinguish bacterial from viral rhinosinusitis[46] With no simple test to quickly determine whether an infection is viral or bacterial, many physicians prescribe antibiotics to play it safe. Such practices can lead to increased antibiotic resistance, exposure to drug side effects, and higher costs without resolution of their symptoms. Recent guidelines suggest antimicrobial therapy is appropriate in the following scenarios[41]:

- Symptoms of sinusitis lasting for more than 10 days without improving.
- Severe symptoms of sinusitis associated with fever of 102° F (38.9°C) or higher, nasal discharge, and facial pain for 3 to 4 days.
- Symptoms of viral sinusitis that continue to gradually worsen more than 5 or 6 days and are accompanied by new fever, headache, or increased nasal discharge, typically following a viral upper respiratory infection of 5 or 6 days.

The bacteriology of sinusitis has been well defined only for acute, community-acquired maxillary sinusitis.[45,47] Sinus puncture studies of adults with this infection have revealed that over 50% of cases are due to *S. pneumoniae* or nontypable *H. influenzae* (Table 126-3. Other pathogens include other streptococci, anaerobes, *Moraxella catarrhalis*, and rarely *S. aureus*. Studies of sinuses other than the maxillary sinus are hindered by the difficulty of obtaining culture material that is not contaminated by nasal flora.

The approach to therapy of ABRS is represented in Figure 126-1. Treatment should be empiric and target the bacterial pathogens noted above.[41,48] Oral therapy (e.g., amoxicillin–clavulanate, cefuroxime, levofloxacin) is sufficient except in severe disease or in patients who also have a complication of sinusitis (e.g., orbital sinusitis) (see Table 126-4). The recommendation of amoxicillin/clavulanate rather than amoxicillin for first-line therapy is a major change from prior consensus recommendations.[41] This recommendation for adults is primarily based on in vitro data and awareness of trends indicating an increasing rate of *H. influenzae* etiology as a result of use of the conjugate pneumococcal vaccine in pediatrics that has significantly reduced transmission of *S. pneumoniae* to adults. The recommended duration of therapy for uncomplicated ABRS in adults is 5 to 7 days.[41,49] In children with ABRS, a longer treatment duration of 10 to 14 days is recommended. Intranasal saline irrigation with either physiological or hypertonic saline is recommended as an adjunctive treatment in adults with ABRS.[41,50] Neither topical nor oral decongestants and/or antihistamines are recommended as adjunctive treatment in patients with ABRS.[41,51] Despite the common use of decongestants and antihistamines in patients with ABRS, there is scant evidence to support that they hasten recovery. Although patients may subjectively feel improvement in nasal airway patency, objective rhinometric findings do not support this impression.

TABLE 126-3 Pathogens Isolated from Sinus Aspirates in Patients with Acute Bacterial Rhinosinusitis

Microbial Agent	Publications before 2000		Publications in 2010	
	Adults (%)	Children (%)	Adults (%)	Children (%)
S. pneumonia	30–43	44	38	21–33
H. influenza	31–45	30	36	31–32
M. catarrhalis	2–10	30	16	8–11
S. pyogenes	2–1	—	13	—
S. aureus	2–3	—	13	1
Gram-negative bacilli[a]	0–24	2	—	—
Anaerobes[b]	0–12	2	—	—

■ NOSOCOMIAL BACTERIAL SINUSITIS

Nosocomial bacterial sinusitis is usually seen in patients in the intensive care unit, and often considered in those with fever of unknown origin.[52] The incidence is higher in patients with nasotracheal tubes. It is also higher in patients with nasogastric tubes versus those without, 20 versus 12 cases per 1000 patient-days in one study. A sinus CT scan showing sinus opacification or an air–fluid level suggests the diagnosis. Bedside nasal endoscopy performed by an otolaryngologist may be helpful in obtaining cultures, either by endoscopically directed cultures of purulent meatal secretions or by maxillary sinus (antral) puncture. Antral puncture may not be indicated in all intensive care unit patients suspected of having sinusitis, however. One study found that only 8% of antral punctures yielded positive cultures in patients with normal endoscopic examinations.[53] The pathogens in nosocomial sinusitis are usually *S. aureus* and gram-negative bacilli, and often include antibiotic-resistant organisms. Empiric treatment should be directed against these organisms

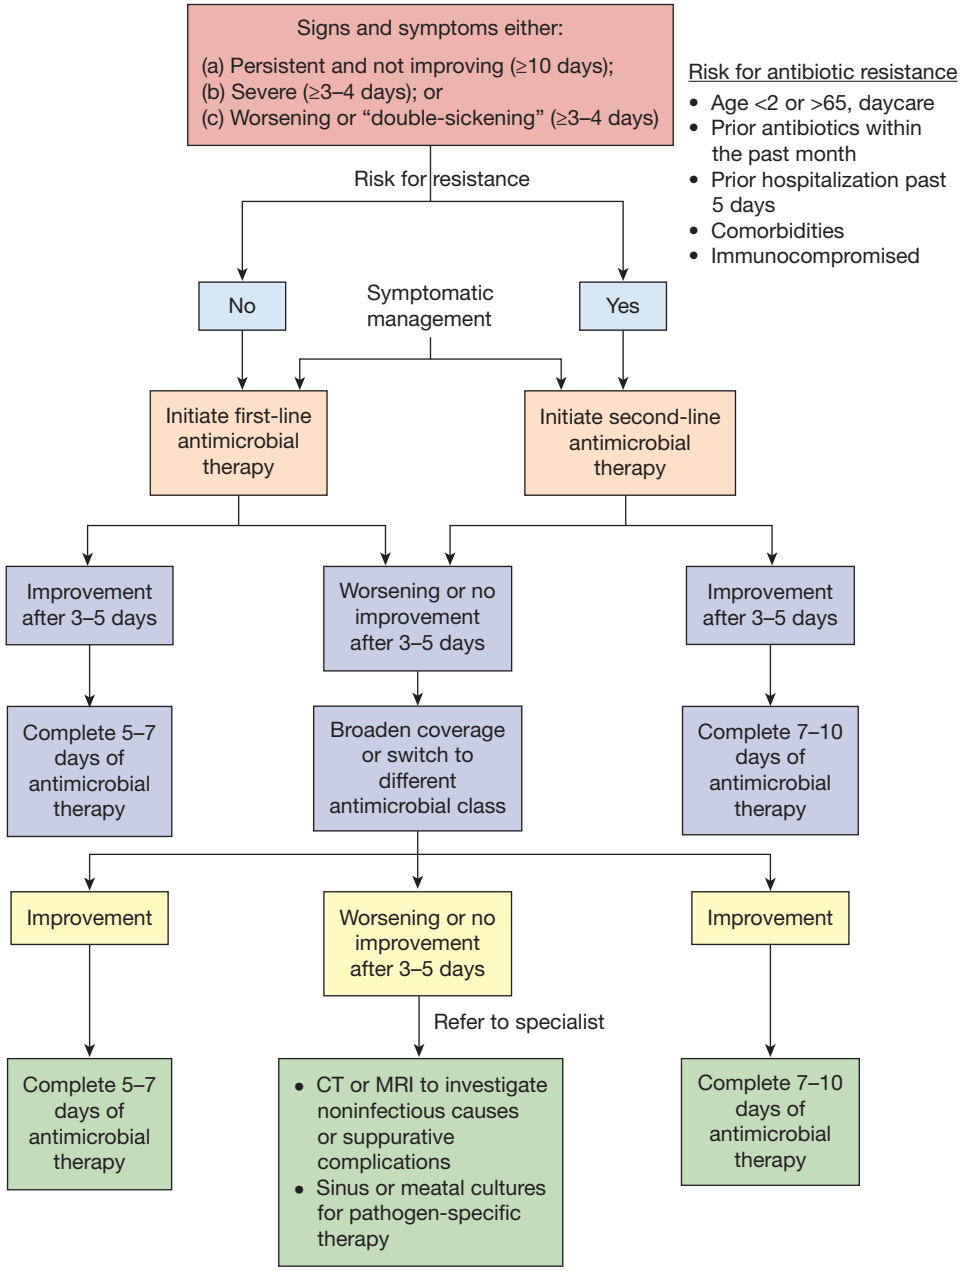

Figure 126-1 The approach to therapy of acute bacterial rhinosinusitis (ABRS). *(Reproduced with permission from Chow AW, Benninger MS, Brook I, et al. IDSA clinical practice guideline for acute bacterial rhinosinusitis in children and adults. Clin Infect Dis. 2012;54(8):e1–e41.)*

(e.g., intravenous vancomycin plus cefepime) until culture results are known. In immunocompromised patients or poorly controlled diabetics, invasive fungal etiology (e.g., *Aspergillus*, Mucor) should be considered; diagnosis is most often established by biopsy and if suspected an otolaryngologist should be consulted.

■ CHRONIC BACTERIAL SINUSITIS

Chronic sinusitis is an ill-defined term but usually is characterized by symptoms that last for 12 weeks or longer.[54] The cardinal symptoms are persistent dull pain, postnasal mucopurulent drainage, nasal obstruction, foul odor and taste, and fatigue. True fever is rare, although many patients complain of having temperatures around 99°F (37.2°C). Most patients have stable, low-grade symptoms punctuated by episodes of acute sinusitis. These episodes may be signaled by a change to purulent secretions and increased sinus pressure. Factors that may contribute to the development of chronic bacterial sinusitis (CRS) include exposure to allergens and irritants, defects in mucociliary function, immunodeficiency, and infections with bacteria, viruses, and fungi. The common endpoint is local inflammation and swelling of the sinonasal mucosa and impairment of normal sinus drainage.

CRS can be classified into three distinct syndromes: Chronic rhinosinusitis with polyposis (20%–33% of cases); allergic fungal rhinosinusitis (8%–12%); and chronic rhinosinusitis without nasal polyposis (the majority of cases). CRS with polyposis affects immunocompetent patients and is associated with asthma and adverse reactions to aspirin and other nonsteroidal anti-inflammatory drugs. In such cases large polyps are often visible with anterior rhinos copy, whereas smaller polyps require nasal endoscopy or imaging such as CT. A sinus CT scan is indicated in patients with chronic sinusitis, both to define the extent of disease and to exclude other causes of their symptoms. Patients should be evaluated by an otolaryngologist to exclude conditions that may be causing obstruction, such as a deviated septum, nasal polyps, granulomatous polyangiitis (Wegener disease), or cancers such as adenocystic carcinoma.

TABLE 126-4 Antimicrobial Regimens for Adults with Acute Bacterial Rhinosinusitis

Indication	First-Line (Daily Dose)	Second-Line (Daily Dose)
Initial empirical therapy	Amoxicillin–clavulanate (500 mg/125 mg PO tid or 875 mg/125 mg PO bid)	Amoxicillin–clavulanate (2000 mg/125 mg PO bid) Doxycycline (100 mg PO bid or 200 mg PO qd)
β-lactam allergy		Doxycycline (100 mg PO bid or 200 mg PO qd) Levofloxacin (500 mg PO qd) Moxifloxacin (400 mg PO qd)
Risk for antibiotic resistance or failed initial therapy		Amoxicillin–clavulanate (2000 mg/125 mg PO bid) Levofloxacin (500 mg PO qd) Moxifloxacin (400 mg PO qd)
Severe infection requiring hospitalization		Ampicillin-sulbactam (1.5–3 g IV every 6 h) Levofloxacin (500 mg PO or IV qd) Moxifloxacin (400 mg PO or IV qd) Ceftriaxone (1–2 g IV every 12–24 h) Cefotaxime (2 g IV every 4–6 h)

bid, twice daily; IV, intravenously; PO, orally, qd, daily; tid, 3 times a day.

Medical therapy often requires a combination of topical or oral glucocorticoids, antibiotics, and nasal irrigation. When these measures fail, the patient should be referred to an otolaryngologist for consideration of sinus surgery. Numerous studies of the bacteriology of chronic sinusitis have reported the recovery of mixed polymicrobial flora of gram-positive and gram-negative aerobic and anaerobic bacteria.[55] An appropriate empirical antimicrobial agent for these pathogens is amoxicillin–clavulanate. Clindamycin can be used in penicillin-allergic patients. A culture (preferably through sinus puncture) should be obtained in patients who fail to have significant improvement such that pathogen-directed antimicrobial therapy can be selected.

■ COMPLICATIONS OF BACTERIAL SINUSITIS

Orbital infections are caused by penetration of the orbit as a result of spread from an infected sinus. The spectrum of orbital infections can be classified into five groups[56]:

- Periorbital cellulitis
- Orbital cellulitis
- Subperiosteal abscess
- Orbital abscess
- Cavernous sinus thrombosis

The most common complication of bacterial sinusitis is preseptal cellulitis or deeper orbital infection, conditions usually grouped under the heading "orbital cellulitis" (Fig. 126-2). Most cases are secondary to ethmoid sinusitis, since the ethmoid is separated from the orbit by only a very thin plate of bone, the lamina papyracea. Preseptal cellulitis only involves the eyelids and surrounding skin anterior to the orbital septum, but not the structures of the orbit. The lids appear red and edematous, but vision is normal and there are no orbital findings. In patients with orbital cellulitis, subperiosteal abscess, or orbital abscess, the eyelids are also red and swollen, but examination of the eye reveals one or more orbital findings as well. These include proptosis, limitation of extraocular movements, and decrease in vision. In subperiosteal and orbital abscess, the abscess is almost always located medially or superomedially in the orbit (reflecting the involvement of the adjacent ethmoid sinus), and the eye looks "down and out." A CT scan should be performed on any patient with orbital findings. An orbital or subperiosteal abscess usually requires emergency surgical drainage. Some authors also advocate a CT scan for children with apparent preseptal cellulitis, as some have a subclinical abscess.

Most patients with uncomplicated orbital cellulitis can be treated with antibiotics alone; but specialists of both ophthalmology and otolaryngology should be consulted since surgery is required for

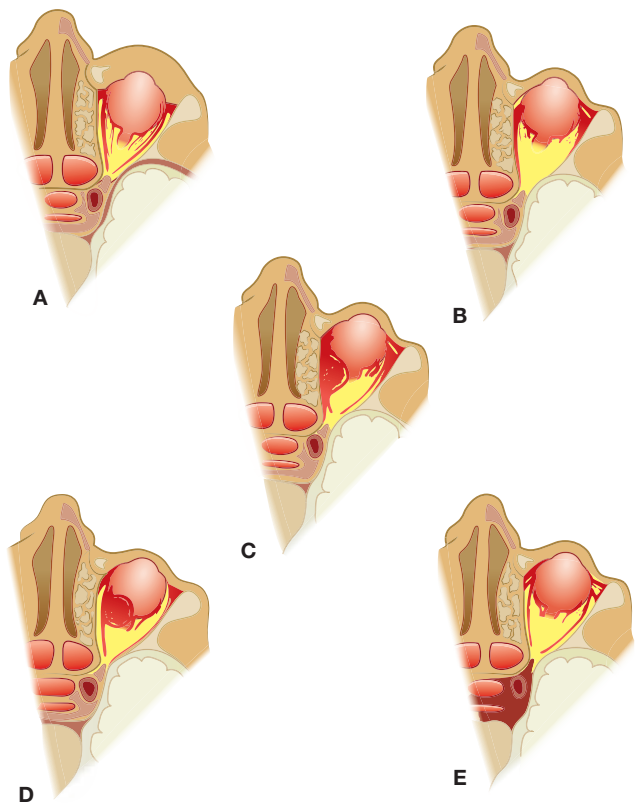

Figure 126-2 Orbital complications of sinusitis. **A.** Preseptal cellulitis. **B.** Orbital cellulitis. **C.** Subperiosteal abscess. **D.** Orbital abscess. **E.** Cavernous sinus thrombosis. *(Reproduced with permission from Chandler JR, Langenbrunner DJ, Stevens FR. The pathogenesis of orbital complications in acute sinusitis. Laryngoscope. 1970;80(9):1414–1428.)*

many patients with abscess.[57] Antimicrobials should be directed at *S. aureus, S. pneumoniae*, other streptococcal species, and gram-negative bacilli (e.g., vancomycin plus ceftriaxone or ampicillin/sulbactam). The main indications for surgery are a poor response to antibiotic treatment, worsening visual acuity or pupillary changes, or evidence of an abscess, especially a large abscess (>10 mm in diameter) or one that fails to respond promptly to antibiotic treatment. "Pott's puffy tumor," or subperiosteal abscess of the frontal bone, is a complication of frontal sinusitis. Patients present with frontal pain and a tender, doughy swelling over the forehead. Treatment consists of 6 weeks of intravenous antibiotic therapy, and surgical drainage of the frontal sinus and subperiosteal abscess may be necessary.

Intracranial complications of sinusitis usually result from frontal or sphenoid sinusitis. These include epidural abscess, subdural empyema, meningitis, cerebral abscess, and dural vein thrombophlebitis. Because of the proximity of the sphenoid sinus to the cavernous sinus, sphenoid sinusitis also may cause cavernous sinus thrombophlebitis. Cavernous sinus thrombosis may occur as a complication of orbital infection (in which case ocular signs dominate the clinical picture with orbital pain, chemosis, proptosis, and oculomotor palsies) or sphenoid sinusitis. Symptoms and signs can be grouped in three major syndromes[58]

- Isolated intracranial hypertension syndrome (headache with or without vomiting, papilledema, and visual problems)
- Focal syndrome (focal deficits, seizures, or both)
- Encephalopathy (multifocal signs, mental status changes, stupor, or coma)

Magnetic resonance imaging (MRI) using gradient echo T2 susceptibility–weighted sequences in combination with MR venography is the most sensitive imaging method for demonstrating the thrombus. Although not definitive evidence, there is a general consensus that anticoagulation is the appropriate treatment. Broad-spectrum antimicrobials should be administered when there is evidence of active infection from the sinuses or the orbits.

FUNGAL SINUSITIS

Fungal sinusitis (see also Chapter 133) can be associated with four major forms[59]:

- Acute invasive sinusitis—risk factors include immunocompromised state, corticosteroids, diabetes with ketoacidosis and the most common pathogens are Aspergillus and the Zygomyces (e.g., Mucor spp.).
- Chronic invasive sinusitis—characterized by chronic symptoms and often invasion into bony structures and the orbit and possibly the brain; Aspergillus is seen most commonly.
- Mycetoma—fungus balls that do not invade the mucosa usually due to Aspergillus or dematiaceous fungus (e.g., Curvilaria, Alternaria, Cladosporium).
- Allergic fungal sinusitis (AFS)—allergic response to colonization of certain molds, mostly aspergillus; often associated with nasal polyps.

Patients with acute invasive disease are usually seriously ill. The diagnosis of acute invasive fungal sinusitis in an immunocompromised patient or diabetes is extremely urgent since it carries a significant risk of mortality (see also Chapter 123). Rhinocerebral mucormycosis is a life-threatening infection due to molds of the order Mucorales *(Rhizopus, Mucor, Absidia).* Approximately 70% of patients with mucormycosis have diabetes, whereas other risk factors include corticosteroid therapy or other immunosuppressant therapy, or hematological malignancies. Patients usually present with signs mimicking bacterial orbital cellulitis involving one eye, with swollen eyelids, proptosis, decreased extraocular movements, and decreased vision in that eye. If there are bilateral eye findings, involvement of the cavernous sinus should be suspected. Significant facial pain, headache, purulent or bloody rhinorrhea, and fever are commonly present. Progressive symptoms related to ophthalmic or CNS invasion may occur. CT and MRI scans are very useful in differentiating invasive from noninvasive infection and defining the extent of disease. Patients in whom the diagnosis is suspected should undergo immediate endoscopy by an otolaryngologist to look for a characteristic black eschar signifying infarcted intranasal or sinus mucosa. The eschar and adjacent tissue should be biopsied and examined for fungus on frozen section by a pathologist. Treatment of mucormycosis requires a combination of aggressive surgical debridement and intravenous amphotericin or liposomal amphotericin therapy. Voriconazole is not active against mucormycosis. Posaconazole is a new agent that may be effective in patients who fail debridement and amphotericin therapy.

Aspergillus and other fungi (e.g., *Bipolaris, Curvularia, Exserohilum*) may also cause invasive fungal sinusitis. Immunocompromised patients, such as those who have received organ transplants, usually present acutely. Treatment is aggressive surgical debridement and systemic antifungal therapy. Normal hosts, in contrast, usually present subacutely, with weeks to months of symptoms. Fungi in the ethmoid and sphenoid sinuses may invade the orbital apex and cavernous sinus, affecting cranial nerves III to VI. Symptoms include headache, unilateral retroorbital pain, proptosis, ptosis, limitation of eye movement, decreased vision, and hypesthesia in the distribution of cranial nerve VI on the affected side. Symptoms of sinusitis are often absent. Diagnosis is suggested by the clinical findings and CT and MRI scans showing inflammation in the orbital apex or cavernous sinus. The diagnosis is made by demonstrating tissue-invasive fungi on pathology. Treatment is with appropriate systemic antifungal therapy (e.g., voriconazole for *Aspergillus*). Unlike immunocompromised patients with invasive fungal disease or patients with rapidly progressive mucormycosis, nonimmunocompromised patients may not require extensive surgical debridement as the disease is slowly progressive, allowing time for assessment of antifungal therapy. A patient with chronic fungal infection usually present with facial pain and swelling, but the acuity of infection is much less than for acute invasive disease. Patients are usually afebrile. There is a high recurrence rate and it is not unusual that all infected tissue cannot be removed by surgical debridement. Thus, long-term antifungal therapy (e.g., an azole) is often required.

Sinus aspergilloma is a noninvasive fungal disease that may cause symptoms of obstruction and chronic sinusitis. Usually only one sinus (most often maxillary) is affected, and symptoms are therefore unilateral. Surgical removal of the fungus ball is usually curative. Careful review of the pathological slides is required to verify that there is no tissue invasion.

AFS is characterized by the presence of "allergic mucin" in the involved sinuses and is thought to be due to a local hypersensitivity reaction to fungi.[60,61] Mold spores are ubiquitous in the environment and in the nasal mucus, where they are trapped after being inhaled. Diagnostic criteria include: no underlying immunosuppression; presence of atopy, nasal polyps; allergic mucin found at surgery or endoscopy; and no invasion of mucosa or bone. Patients with AFS present with chronic sinusitis symptoms, and most have a history of nasal polyposis, aspirin allergy, and asthma. The CT typically shows inhomogeneous opacification of one or more sinuses, and there may be evidence of bony erosion of the sinus. Erosion is due to pressure necrosis, not fungal invasion. On MRI, the affected sinus often appears black on T2 ("T2-weighted signal void"), a finding also seen in other types of fungal sinusitis. The diagnosis of AFS may be suspected at surgery because allergic mucin is tenacious, with the consistency of anchovy paste. It has histological features similar to that of mucin found in allergic bronchopulmonary aspergillosis, with many eosinophils and Charcot–Leyden crystals. Fungal hyphae are found in the mucus of half of the cases, but there is no evidence of tissue invasion. Surgical removal of the inspissated mucus, along

with intranasal steroids or short courses of oral steroids, seems to be effective. There is no proven role for antifungal agents.

EAR AND MASTOID INFECTIONS

The spectrum of acute and chronic infections of the ear and mastoid is considered below.

OTITIS EXTERNA

The external auditory canal is about 2.5 cm long. It is lined by a thin layer of skin, which covers cartilage in the lateral half of the canal and bone in the medial half. In the bony portion, the skin lacks a subcutaneous layer and is attached directly to the periosteum; therefore, minimal inflammation of the bony canal causes significant pain and/or injury. Glands secrete cerumen, which acidifies the canal and suppresses bacterial growth. Desquamated skin and retained moisture make the canal especially susceptible to *Pseudomonas aeruginosa,* a hydrophilic organism.

Acute otitis externa, or swimmer's ear, occurs mostly in summer months and is often a result of exposure to water.[62,63] It may be due to a decrease in canal acidity and the resulting bacterial overgrowth. Any trauma such as from excessive probing of the ear canal with a cotton swab can also create abrasions along the thin layer of skin in the ear canal predisposing to infection. The ear is pruritic and often extremely painful; the canal appears swollen and red. Tenderness when the auricle is manipulated or pulled is an indicative finding of external otitis. The usual pathogens are *P. aeruginosa, S. aureus,* and streptococci; anaerobes have been implicated in some cases.[64] Treatment consists of cleaning the ear (aural toilet) and topical antibiotic drops. Topical antibiotics are highly effective for treating external otitis (e.g., a quinolone otic solution). One systematic review found that topical antibiotics increased absolute clinical cure rate compared to placebo by 46% (95% CI 29%–63%).[65] A meta-analysis of randomized trials, which included three studies comparing antimicrobial/glucocorticoid versus antimicrobial alone, found comparable clinical and bacteriological cure rates at 7 days for regimens with and without glucocorticoids.[66] The addition of a hydrocortisone to either acetic acid or ciprofloxacin, however, did decrease time to symptom resolution by 1 day. Acidifying the ear canal inhibits bacterial growth. Commonly used acidifying solutions are acetic acid, boric acid, hydrochloric acid, and sulfuric acid. Acidifying solutions are generally safe, but may be associated with local irritation manifested by burning or stinging. In the presence of tympanic membrane perforation, acidifying solutions can be particularly irritating to the mucosa of the middle ear. The ear should be protected from water during recovery from external otitis. This can be accomplished by placing a cotton ball coated with petroleum jelly in the ear canal while bathing.

Invasive ("malignant") otitis externa (MOE) is a potentially life-threatening osteomyelitis of the temporal bone and skull base. It occurs primarily in elderly diabetics but also found in immunocompromised patients (e.g., in HIV) and is nearly always caused by *P. aeruginosa.*[67] The infection begins in the external canal, then invades the adjacent soft tissues, petrous apex of the temporal bone, and eventually the skull base. The typical patient is an older diabetic whose diabetes is in good control, who presents with unilateral hearing loss, usually severe ear pain, and drainage progressive over the previous weeks to months. In one case-control study patients with MOE were more likely to have antecedent history of ear irrigation (generally for the purposes of removing cerumen) compared with matched controls.[68] The symptoms may have been misdiagnosed as chronic otitis media, a condition not characterized by otalgia. There is often a history of irrigation of the ear canal for wax removal a few days before the onset of ear pain. On examination, the ear canal is edematous, and there is granulation tissue in the inferior wall about halfway down the canal (the area overlying the bony-cartilaginous junction). As the infection advances, osteomyelitis of the base of the skull and temporomandibular joint osteomyelitis can develop. Progression of the osteomyelitis can be associated with cranial nerve palsies. Some patients also present with unilateral facial paralysis from involvement of cranial nerve VII; other cranial nerves (VI, IX, and X) may also be involved. Fever occurs in less than half of the patients and the white blood cell count is usually normal. The sedimentation rate is almost always very elevated, however, typically in the 80 to 100 range. A CT and an MRI scan are essential for defining the extent of involvement. Bony involvement is best seen on CT, while soft tissue changes are best seen on MRI. Cultures should be obtained of ear canal drainage or of superficial biopsies of canal granulation tissue; more extensive surgery is not usually indicated. Nearly all cases are due to *P. aeruginosa*, but cultures are important in determining antibiotic sensitivity and in excluding rare causes of invasive otitis (e.g., *S. aureus, Proteus, Aspergillus*). As soon as cultures are obtained, empiric treatment directed at *Pseudomonas* should be started (e.g., anti-pseudomonal β-lactam; or anti-pseudomonal quinolone) and therapy is continued for at least 6 weeks. Aminoglycosides should be avoided due to the toxicities associated with therapy, especially in the elderly diabetics with hearing loss who typify the patient with MOE.

■ ACUTE OTITIS MEDIA

AOM is the most common bacterial infection seen in pediatric patients, and treatment of AOM is the most common reason children receive antibiotics.[69] AOM follows eustachian tube dysfunction, which is most often seen with a viral upper respiratory infection. The middle ear is connected to the nasopharynx by the eustachian tube. AOM (Fig. 126-3), or infection of the middle ear, is thought to result from bacterial entry into the middle ear via the eustachian tube. It is often initiated by a viral upper respiratory infection, and is most common in fall through spring. The incidence of AOM decreases with age. More than two-thirds of children under age 3 have had at least one episode of otitis media, while the incidence in adults is only 0.25%. There are several risk factors for AOM (Table 126-5). The most common symptoms are ear pain and decreased hearing. Children often have fever, but this is less common in adults. There are two parts to establishing the diagnosis of AOM: evidence of middle-ear effusion and abnormalities of the tympanic membrane that indicate inflammation. Both must be present for diagnosis to be confirmed. The tympanic membrane is usually red, opaque, and bulging. Spontaneous perforation of the tympanic membrane may occur, resulting in otorrhea and, frequently, decreased pain. *S. pneumoniae*, nontypable *H. influenzae*, and *M. catarrhalis* are the leading pathogens. Whereas viruses play a pivotal role in predisposing the host, middle-ear taps of children with AOM rarely yield a viral pathogen alone.

Of all the features associated with AOM, establishing appropriate therapy has recently undergone the greatest change and yet is associated with the most significant controversy. Most notably, many experts have advocated that selected patients might appropriately be observed and not treated with antibiotics. However, randomized trials suggest that signs and symptoms of AOM resolved more quickly in children and the risk of perforation with otorrhea is reduced in those initially treated with antibiotics compared with placebo.[70,71] The decision to withhold antibiotic therapy should be reserved for patients otherwise healthy, >2 years of age, with mild illness. Treatment of AOM is usually empiric and should be directed against *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Approximately 50% of *H. influenzae* strains and 100% of *M. catarrhalis* strains produce β-lactamase, and approximately 30% of *S. pneumoniae* are not susceptible to penicillin (15% are highly resistant) due to altered penicillin-binding protein. Amoxicillin should not be effective for any of these resistant organisms, yet approximately 20% of children with *S. pneumoniae*, 50% with *H. influenzae*, and 75% with *M. catarrhalis* will clear their AOM despite no or ineffective antibiotic therapy.

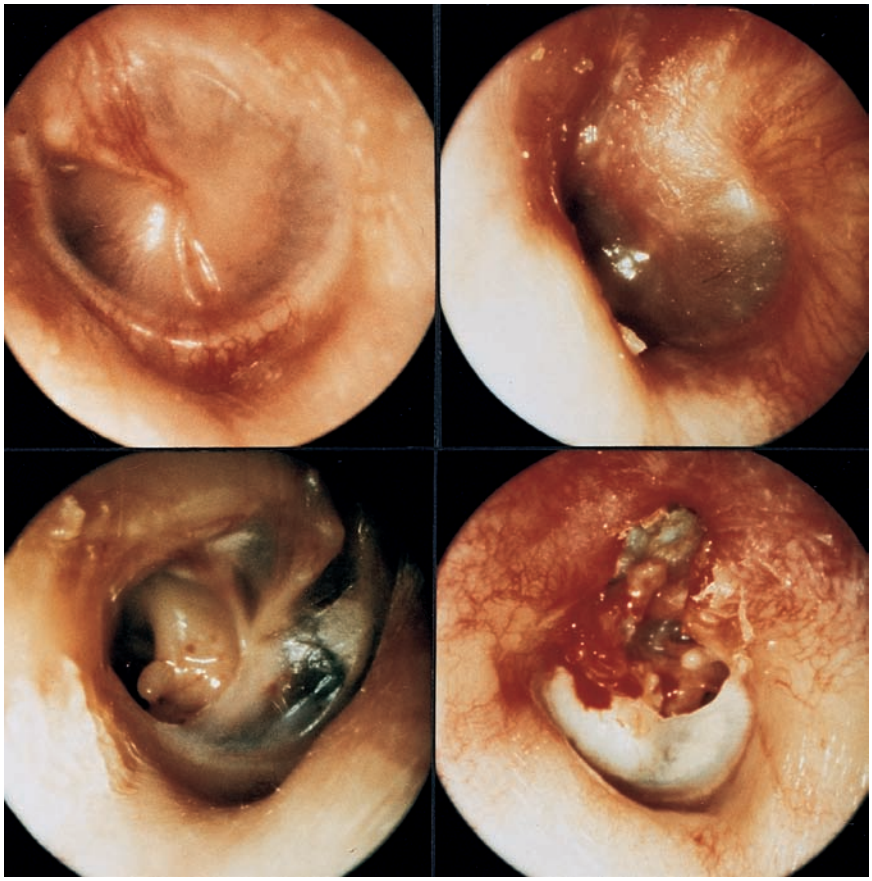

Figure 126-3 Clockwise, from top left, tympanic membranes: normal ear, resolving acute otitis media, chronic suppurative otitis media (CSOM) with cholesteatoma, CSOM without cholesteatoma. *(Used with permission of Steven D. Rauch, MD.)*

Therefore, recent practice guidelines by the American Academy of Pediatrics recommend amoxicillin as first-line therapy for most children with AOM at doses of 80 to 90 mg/kg per day. Amoxicillin–clavulanate is recommended for children who present with severe disease, defined as fever of 39°C (102.2°F) or higher and/or severe otalgia, or for amoxicillin-treatment failures as determined at 48 to 72 hours. For most children with non-type I allergy to penicillin, cephalosporins (cefdinir, cefpodoxime, cefuroxime) are recommended, and azithromycin or clarithromycin is recommended for those with type I allergy. Ceftriaxone is recommended for children with severe disease and who are either penicillin-allergic with a non-type I penicillin allergy or who have failed initial antibiotic therapy with amoxicillin–clavulanate. Clindamycin is recommended in patients who have failed therapy and have a type I allergy to penicillin.

TABLE 126-5 Major Risk Factors for Acute and Recurrent Otitis Media

Onset of otitis media in infancy
Male gender
Sibling with recurrent acute otitis media
Bottle feeding only
Parents who smoke at home
Daycare attendance
Craniofacial anomalies

OTITIS MEDIA WITH EFFUSION

Otitis media with effusion (OME), also called serous otitis, refers to the persistence of middle-ear fluid without symptoms or other signs of infection.[72] This condition may occur spontaneously as a result of eustachian tube dysfunction, or may occur as a result of AOM. Approximately 50% of children will have OME in the first year of life, and 90% before school age. Diagnosis is made by otoscopy. The majority of episodes resolve spontaneously, but 30% to 40% have recurrent OME and 5% to 10% have OME episodes that last at least 1 year. The American Academy of Pediatrics published practice guidelines in 2004 that state that antihistamines and decongestants are ineffective, and that antibiotics and corticosteroids have no long-term efficacy and thus are not recommended routinely for treating OME. These guidelines recommend hearing tests for children with persistent OME at 3 months; decisions regarding the need for tympanostomy tube placement may be determined by these test results. Children with OME at special risk for developmental delays (e.g., who also have blindness, autism, Down syndrome) should have earlier hearing, speech, and language assessments.

CHRONIC SUPPURATIVE OTITIS MEDIA

Chronic suppurative otitis media (CSOM) is an inflammatory disease of the middle ear and mastoid characterized by tympanic membrane perforation, hearing loss, and persistent or recurrent otorrhea.[73] It is associated with irreversible pathological changes of the mucosa of the middle ear and mastoid. There are two major subtypes of CSOM: CSOM with cholesteatoma and CSOM without cholesteatoma.

In CSOM with cholesteatoma, there is a perforation of the tympanic membrane, usually at the margin, which leads into a sac within the middle ear lined by skin. This sac constitutes a cholesteatoma, which contains desquamated keratin and may be superinfected with bacteria. Bacterial overgrowth results in purulent drainage via the perforation. An important feature of a cholesteatoma is its ability to enlarge by erosion of surrounding bone, which can result in serious intratemporal and intracranial complications. In CSOM without cholesteatoma, there is a chronic central perforation of the tympanic membrane. Bacterial infection of the middle ear or mastoid can occur and leads to purulent drainage through the perforation ("active" chronic otitis media). Such drainage may be constant or episodic. The latter may be incited by an upper respiratory infection or by exposure of the ear canal to water.

The classic symptoms of both types of CSOM are painless otorrhea and hearing loss. Diagnosis is made with otoscopy, which reveals otorrhea in the presence of a perforated tympanic membrane. The appearance of the tympanic membrane varies with the type of CSOM (Fig. 126-3). Audiological assessment usually reveals a conductive type of hearing loss. Cultures of ears with CSOM in both adults and children often yield *S. aureus, Pseudomonas* and other gram-negative bacilli, and anaerobes. Most cases of CSOM with cholesteatoma require a mastoidectomy and tympanoplasty to remove the cholesteatoma and reconstruct the middle-ear sound transmission mechanism. Cases of "active" CSOM without cholesteatoma are treated with

ear cleaning and topical antibiotic otic drops (e.g., a quinolone otic agent). Oral antibiotics are also sometimes used. The choice of antibiotics should be guided by culture results from the purulent middle-ear drainage, but most cases are treated empirically with a topical quinolone (e.g., ofloxacin 0.3% otic solution). Topical quinolones have proven to be nonototoxic and effective. Topical aminoglycoside therapy, commonly used in the past, is used infrequently now due to concern for ototoxicity.[74] Surgery is indicated for patients who develop complications of chronic otitis, to remove infected tissue in the middle ear or mastoid, and to repair ear damage that results in hearing loss. Cholesteatoma removal is typically performed in conjunction with tympanoplasty and, if the lesion extends superiorly or posteriorly, mastoidectomy.[63] Surgery may be indicated in some cases of CSOM without cholesteatoma if medical therapy fails to control otorrhea or if surgery will improve hearing.

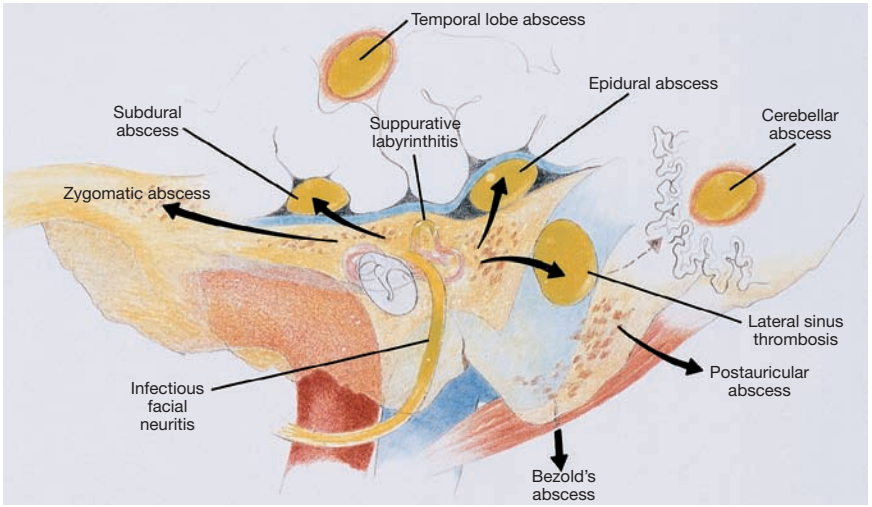

Figure 126-4 Complications of chronic otitis media. *(Reproduced with permission from Nadol JB, Schnuknecht HF. Surgery of the Ear and Temporal Bone. New York, Raven Press, 1993.)*

■ ACUTE MASTOIDITIS

The mastoid is the portion of the temporal bone posterior to the middle ear that contains a honeycomb of air cells lined by low, cuboidal epithelium. These air cells connect with the middle ear. Some degree of mastoid mucosal inflammation invariably accompanies episodes of AOM and is also present in many cases of CSOM. A CT scan of a patient with a middle-ear effusion or infection will often also show opacification of the mastoid air cells without destruction of the cells, and this usually represents a sterile effusion in the mastoid rather than acute mastoiditis. In contrast, acute mastoiditis is an acute bacterial infection of the mastoid. Untreated, this infection often results in breakdown of the bony partitions between the mastoid air cells and can extend beyond the mastoid compartment. Acute mastoiditis has become rare in the antibiotic era, and occurs primarily in children.[75] Studies evaluating the incidence subsequent to utilization of the strategy of a nonantimicrobial, observational approach in selected patients with AOM has been conflicting.[76–78] It occurs with the first episode of AOM in 10% to 50% of children, but may also occur with an episode of recurrent AOM. Patients present with pain, tenderness, and swelling over the mastoid. Fever is common. The pinna is pushed out and forward when there is a subperiosteal abscess or cellulitis. A CT scan may demonstrate bony destruction or a mastoid abscess. Major pathogens include *S. pneumoniae*, GAS, *H. influenzae, and S. aureus. Pseudomonas aeruginosa* and enteric gram-negative bacilli are also and should be considered especially if a history of recurrent AOM and recent antibiotic use. Antimicrobial therapy directed at the likely organisms (e.g., vancomycin plus cefepime or piperacillin/tazobactam if risks for gram-negative bacilli) and drainage of the middle ear and mastoid are the cornerstones of therapy for acute mastoiditis.

■ COMPLICATIONS OF ACUTE AND CHRONIC OTITIS MEDIA

Otogenic complications are more likely to occur from chronic otitis media than from AOM (Fig. 126-4). Extracranial complications include sensorineural hearing loss, labyrinthitis and the resulting vertigo, facial nerve palsy, and osteomyelitis of the petrous portion of the temporal bone. In mastoiditis, infection may track under the periosteum of the temporal bone and cause a subperiosteal abscess, or may break through the mastoid tip and cause an abscess in the neck deep to the sternocleidomastoid muscle (Bezold abscess). Intracranial complications include epidural abscess, thrombophlebitis of the dural veins, meningitis, and temporal lobe abscess.

CHAPTER 127

Aspiration, Empyema, Lung Abscesses, and Anaerobic Infections

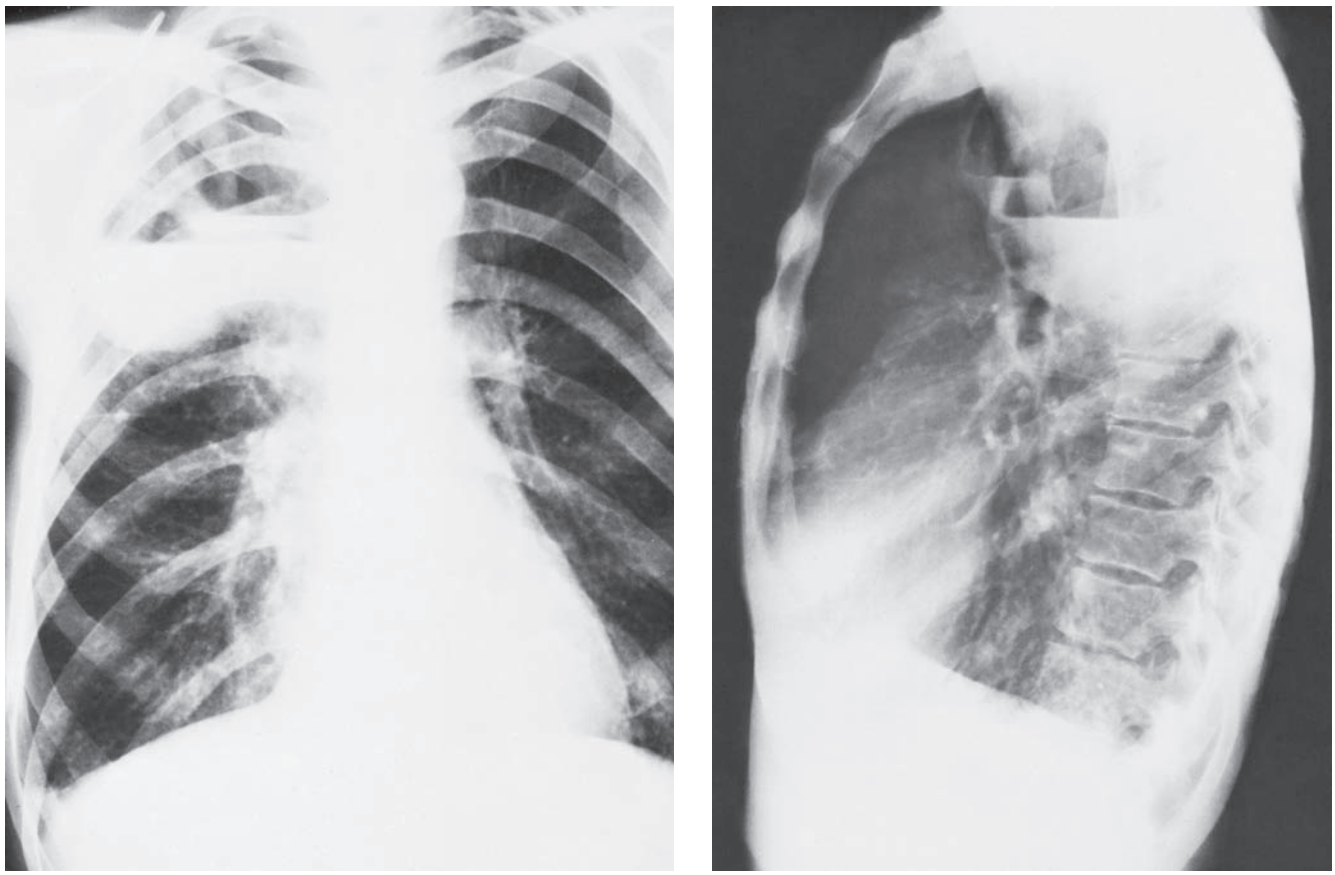
Kyle B. Enfield
Costi D. Sifri

OVERVIEW

Aspiration pneumonia, lung abscess, and necrotic lung are parenchymal lung diseases. Aspiration pneumonia refers to the pulmonary consequences that follow abnormal entry of fluid, particulate substances, or endogenous secretions from the upper airways or gastric contents into the lower airways (see also Chapter 69). To develop aspiration pneumonia, a series of formidable host defense mechanisms that normally protect the lower airways must be overcome, including glottic closure via the cricopharyngeus muscle, the cough reflex, ciliary clearance, and other defense mechanisms. The material aspirated must generate an inflammatory response or cause obstruction. The nature of the pneumonia that develops depends on the inoculum and the host response. Anaerobic bacteria are the most common pathogens in this setting, reflecting both pathogenic potential and importance in the normal flora of the upper airways. Risk factors for aspiration may be transient (anesthesia, intoxication) or persistent (e.g., neuromuscular disorders, achalasia) with the risk for recurrence depending on recognition and resolution of the inciting defect.[1,2]

Lung abscesses reflect infection with an unusual microbial burden (e.g., acute aspiration), a failure in microbial clearance mechanisms (e.g., bronchial obstruction), or both, leading to necrosis of pulmonary tissue and formation of cavities containing necrotic debris or fluid (Fig. 127-1). The formation of multiple smaller (less than 2 cm) abscesses in pulmonary tissue is occasionally referred to as necrotizing pneumonia or lung gangrene. Both lung abscess and necrotizing pneumonia are manifestations of the same pathologic processes, and the distinction is, therefore, arbitrary.[3]

Empyema refers to a purulent collection in any body site but is commonly used to indicate infection of the pleural space.[4] Empyema is typically associated with underlying pulmonary parenchymal



A B

Figure 127-1 **A.** Anaerobic pneumonia with abscess formation in a 48-year-old alcoholic man. The abscesses are located in the posterior segment of right upper lobe, a dependent segment that is seen best on lateral view (**B**).

infection but may also be associated with blood-borne infection, thoracic surgery, trauma, abdominal infection, or neoplasm.[3] Failure to recognize and treat either empyema or lung abscess is associated with a poor clinical outcome.[5,6] In the preantibiotic era, lung abscess was associated with a mortality approaching 40%.[7] However, controversy exists over the best approaches to both processes in terms of antimicrobial selection and physical drainage.[5,6]

HISTORY

In 1893, Veillon[8] published a review of "fetid infections," first marking the published record of infections due to anaerobic pathogens. However, anaerobes are now largely forgotten potential pathogens in pulmonary infection, including in both community- and healthcare-associated pneumonia.[1] The clinical and bacteriologic features of anaerobic infections of the lung have been documented by extensive studies during two periods of investigation.[1] The first was at the turn of the century, when anaerobic bacteria were initially reported as important causes of empyema. This early work continued through the late 1920s, when David Smith conducted classic studies on the pathogenesis of lung abscess. At that time, approximately one-third of patients with lung abscess died. Smith noted that the bacteria in the walls of the abscess at autopsy resembled the bacteria found in the gingival crevice, leading him to conclude that aspiration was the major mechanism in pathogenesis. He subsequently supported this hypothesis by inoculating the trachea of experimental animals with gingival crevice material to reproduce the sequence of events of pneumonitis, followed by lung abscess formation in 7 to 10 days.[9] Bacteriologic studies of the inoculum showed that four bacterial species were critical, and all were anaerobic bacteria: a fusiform bacterium now recognized as *Fusobacterium nucleatum*, *Prevotella melaninogenica* (formerly *Bacteroides melaninogenicus*), *Peptostreptococcus*, and an anaerobic spirochete. This study is one of the first demonstrations of bacterial synergy, defined as the demonstration that two or more bacterial species are required to produce a pathologic process that could not be reproduced by any single component of the inoculum.[9]

In the first two or three decades of the antibiotic era, the role of anaerobic bacteria in this and other pathologic processes was largely ignored. Patients with lung abscesses often had putrid sputum and no identifiable pathogen; these infections were frequently referred to as nonspecific lung abscess. Although the microbial cause was unknown, it was well established that these patients almost invariably responded to penicillin treatment. The role of anaerobes in empyema was also largely ignored. Much of this neglect is ascribed to the paucity of laboratories capable of cultivating oxygen-sensitive bacteria. Studies of anaerobic bacteria were spawned by the ability to culture anaerobes in clinical laboratories with the introduction of anaerobic gas–generating culture jars, the description of the taxonomy of these organisms, and the availability of new antimicrobial agents (clindamycin, metronidazole, cefoxitin) for the therapy. The introduction and widespread use of transtracheal aspiration (TTA) in the late 1960s made it realistic to collect uncontaminated specimens from the lower airways that could be used for anaerobic cultures. TTAs are seldom performed today, so anaerobic bacteria are rarely established as pulmonary pathogens. These organisms are often suspected on the basis of the etiologic route of infection (e.g., oropharyngeal flora) and their importance in patients with aspiration pneumonia, necrotizing pneumonia, lung abscess, and empyema.[1]

PATHOPHYSIOLOGY OF ASPIRATION, EMPYEMA, AND LUNG ABSCESS

The bacteria implicated in anaerobic lung infections represent the normal flora of the oral cavity—primarily the gingival crevice, where anaerobic bacteria are found in concentrations that approach the geometric limits with which bacteria occupy space: 10^{12}/g.[10] Compromised consciousness or dysphagia is the most frequently predisposing risk factor for clinically significant aspiration. Common conditions associated with clinically significant aspiration include alcoholism, general anesthesia, seizure disorder, drug abuse, esophageal lesions, hepatic failure with decreased level of consciousness, and neurologic deficits associated with dysphagia.[11]

Additional conditions that appear to predispose to anaerobic infections include pulmonary infarction, obstruction due to carcinoma or a foreign body, and bronchiectasis. These conditions are associated with stasis or necrosis of tissue, which presumably accounts for the association with anaerobic infections. The use of acid suppressing medication has also been associated with community-acquired, hospital-acquired, and ventilator-associated pneumonia, presumably due to loss of the gastric acid barrier to bacterial growth.[12–14]

A somewhat unique feature of anaerobic lung infections is the proclivity for necrosis of tissue, resulting in abscess formation or a bronchopleural fistula associated with empyema.[15] Virulence factors of anaerobic bacteria presumed to account for this association include the capsular polysaccharide of anaerobic gram-negative bacilli. The most extensively studied is the polysaccharide of *Bacteroides fragilis*, but the same observations may apply to *P. melaninogenica* and other anaerobic gram-negative bacilli.[16,17] The capsule of *B. fragilis* consists of a family of polysaccharides composed of oligosaccharide repeating units with sugars containing positively charged free amino groups and negatively charged carboxyl, phosphate, and amino groups.[18–20] These positive and negative charges mediate the capacity to induce abscess formation in experimental animals.[21,22] Another virulence factor possessed by most anaerobic bacteria is the production of short-chain fatty acids that inhibit phagocytic killing at low pH levels.[23,24] Short-chain volatile fatty acids are metabolic products of anaerobic bacteria that are used to classify these organisms taxonomically, and they appear to be responsible for the putrid odor that is often a characteristic feature of infections by these organisms.[25,26]

MICROBIOLOGY

Bacteriologic findings of anaerobic lung infections from two large series are summarized in Table 127-1. Most of these infections involve multiple bacterial species, and approximately half of the patients have anaerobic bacteria combined with potentially pathogenic aerobic or facultative anaerobes. Analysis of community-acquired infections involving only anaerobes versus those that are mixtures of aerobic and anaerobic bacteria shows common clinical features with no difference in terms of the frequency of suspected aspiration, indolent presentation, or the frequency of putrid discharge. The implication is that a putrid lung abscess with *Escherichia coli* in expectorated sputum or anaerobic bacteria plus *E. coli* in a TTA should usually be considered an anaerobic infection. Caution is advised in applying these conclusions to nosocomial pulmonary infections, since this is a setting in which the aerobic component of the infection is probably more important.

The establishment of anaerobic bacteria in pulmonary infections requires specimens of respiratory secretions that are devoid of contamination from the upper airways. The usual procedures satisfying this criterion are TTA, transthoracic aspiration, open lung biopsy, thoracentesis, and more recently, bronchoscopy with quantitative cultures. In addition, there must be appropriate laboratory expertise for the cultivation of anaerobic bacteria. The incidence of anaerobic lung infections reported in published studies from the antibiotic era that satisfy both requirements is summarized in Table 127-2.

TABLE 127-1 Bacteriology of Anaerobic Lung Infections

	Bartlett	Marina et al.
Period reviewed	1968–1975	1976–1991
Patients	193	110
Total anaerobic isolates	461	404
Major isolates		
Gram-negative bacilli

Peptostreptococcus/peptococcus[c]	126	39
Gram-positive bacilli		
Clostridium spp.	18	12
Eubacterium spp.	18	22
Actinomyces	5	1
Lactobacillus	8	22
Propionibacteria	10	9

[a] *Numbers indicate the total number of isolates. Some of the differences are due to taxonomic changes.*
[b] *Pigmented Prevotella refers to organisms previously classified as B. melaninogenicus.*
[c] *Most peptococci have been reclassified as Peptostreptococcus.*

Most published reports deal with the role of anaerobic bacteria in aspiration pneumonia or lung abscess, and these show recovery rates ranging from 62% to 100%. The usual specimens in these studies are TTA and transthoracic aspiration. One of the best studies is by Beerens and Tahon-Castel,[27] who used transthoracic needle aspiration to characterize the flora in lung abscesses; this series showed recovery of anaerobic bacteria, usually in pure culture, in 22 (85%) of 26 cases.

The major bacterial isolates in patients with anaerobic lung infections are *Peptostreptococcus*, *F. nucleatum*, and *P. melaninogenica*. Aerobic and microaerophilic streptococci are commonly present and may contribute to the pathogenic events. At least 15% to 25% of anaerobic bacteria responsible for lung infections are resistant to penicillin, generally due to penicillinase production. These susceptibility data are rarely available in individual cases unless specifically requested.

There have been few studies to identify the frequency of anaerobic bacteria in unselected cases of community-acquired pneumonia. One was by Ries et al.,[28] who performed TTAs in patients hospitalized with a diagnosis of pneumonia and recovered anaerobic bacteria in 29 (33%) of 89 cases. A more recent study by Pollock et al.,[29] using fiberoptic bronchoscopy with a protected catheter and quantitative cultures, showed recovery of anaerobes in 16 (22%) of 74 patients. These two reports suggest that anaerobic bacteria are relatively common pathogens among patients with community-acquired pneumonia and presumably account for a substantial proportion of cases that are now considered enigmatic. In nosocomial pneumonia, a study by Bartlett et al.[30] utilized TTA in 159 consecutive patients and showed anaerobes in 56 (35%). Nevertheless, most of these patients also showed the concurrent presence of aerobic gram-negative bacilli or *Staphylococcus aureus*, and their clinical course was determined largely by the aerobic pathogens.

TABLE 127-2 Incidence of Anaerobic Infection of the Lung

CLINICAL FEATURES

Nearly all patients with anaerobic lung infections have the usual constitutional findings for patients with infection (Table 127-3). A review of 193 bacteriologically confirmed cases showed that the mean peak temperature for hospitalized patients was 39.1°C and all but five patients were febrile. The average peripheral leukocyte count was 15,000/mL^3. Patients who presented with the suppurative complications had a longer duration of symptoms before presentation; this was commonly associated with other evidence of chronic disease, including weight loss and anemia. Another common feature of patients with suppurative complications was putrid sputum or empyema fluid, which was noted in 40% to 60%. It should be emphasized that the putrid discharge in these cases is considered diagnostic of anaerobic infection, since aerobic bacteria are not capable of producing this characteristic odor either *in vitro* or *in vivo*. Thus, anaerobic bacteria may cause a diverse range of pulmonary infections, which may be acute, subacute, or chronic. The anaerobic etiology is rarely established or even suspected in patients with acute pneumonitis. This compares with aspiration pneumonia, where anaerobes are presumed pathogens in most community-acquired infections and may contribute to many nosocomial cases. By contrast, anaerobic bacteria are readily recognized as probable pathogens in patients who have the late suppurative complications, such as lung abscess or empyema.

One review of 46 patients with anaerobic bacterial pneumonitis showed clinical features that were similar to those of pneumococcal pneumonia.[31] The diagnosis was established by TTA, and the results in this group were compared with those in a second group of patients in whom TTAs yielded *Streptococcus pneumoniae*. The two groups were similar in terms of age, changes on the chest radiograph, peak temperature, and peripheral leukocyte count. Significant differences in the group with anaerobic infections were the lack of rigors, a somewhat longer duration of symptoms before presentation, and a more frequent association with predisposing conditions for aspiration.[31] An important point to emphasize is that patients seen in this early stage of infection rarely have the features that are commonly associated with anaerobic lung infections, such as putrid sputum, tissue necrosis with abscess formation, or a chronic course. These infections presumably account for some and possibly many of the cases of community-acquired pneumonia in which no etiologic diagnosis is established despite extensive study; such cases account for 40% to 50% of cases in most series. Features of anaerobic infections that are nearly unique are the association with conditions that predispose to aspiration and infection in the gingival crevice, putrid discharge, and a high frequency of suppurative complications in late-stage disease.

ASPIRATION SYNDROMES

Aspiration is a relatively common event that is typically well tolerated. Numerous studies indicate that virtually all healthy persons aspirate, but that this is usually inconsequential. In one study, airway protective mechanisms were challenged by placing contrast material in the mouths of sleeping patients. The following morning, most patients had radiographic evidence of aspiration, defined as contrast material seen on imaging of the lungs, but no evidence of a disease process.[32] Similarly, dye markers placed in the stomach of postoperative patients has later been aspirated from the tracheobronchial tree, indicating aspiration of gastric contents during general anesthesia in 7% to 16%.[33,34] Scintigraphic methods have also been used to demonstrate frequent aspiration in patients with intubation of the airways or gastrointestinal tract.[35,36] None of these studies, however, have demonstrated any clinical consequences from occult aspiration. The conclusion is that aspiration is relatively common but

TABLE 127-3 Clinical Features of Anaerobic Pulmonary Infections[a]

	Lung Abscess (83 pts)	Empyema (51 pts)	Pneumonitis (only) (79 pts)	Total (193 (pts)
Age (median)	52 y	49 y	60 y	51 y
Peak temperature (mean, °F)	102.1	102.4	102.6	102.4
Peripheral leukocyte count (median/mm)	15,000	21,600	13,700	15,000
History of weight loss	36 (43%)	28 (55%)	3 (4%)	57 (30%)

TABLE 127-4 Classification of Aspiration Pneumonia

Inoculum	Pulmonary Sequelae	Clinical Features	Therapy
Acid breathing	Chemical pneumonitis	Acute dyspnea, tachypnea; tachycardia; cyanosis, bronchospasm, fever Sputum: pink, frothy Radiographic infiltrates in one or both lower lobes Hypoxemia	Supplemental oxygen, bronchodilators, mechanical ventilation as needed
Oropharyngeal bacteria	Bacterial infection	Usually insidious onset Cough, fever, purulent sputum Radiographic infiltrate in dependent pulmonary segment or lobe ± cavitation	Antibiotics
Inert fluids	Mechanical obstruction Reflex airway closure	Acute dyspnea, cyanosis ± apnea Pulmonary edema	Tracheal suctioning, supplemental oxygen, mechanical ventilation as needed
Particulates	Mechanical obstruction	Dependent on level of obstruction, ranging from acute apnea and rapid death to irritating chronic cough ± recurrent superimposed infections	Extraction of matter Antibiotics for infection

usually resolves spontaneously. The decisive factor for the development of lung complications depends on the frequency, volume, and character of the material in the inoculum. The aspiration of large volume or frequent aspirations lead to three distinct syndromes according to the nature of inoculum: chemical pneumonitis, bacterial infection, and airway obstruction. The nature of inoculum also dictates the pathogenesis of pulmonary complications, clinical presentation, and management strategies (Table 127-4).

CHEMICAL PNEUMONITIS

Chemical pneumonitis refers to aspiration of an inoculum that is inherently toxic to the lungs. Examples include acid, animal fats such as milk and mineral oil, and volatile hydrocarbons. These substances are toxic to the lower airways and initiate an inflammatory reaction. The effect of acid on the lungs was initially described in animal studies in World War I and subsequently confirmed in humans by Mendelson. His work was the first to describe gastric acid pneumonitis leading to chemical pneumonitis in humans, which came to be referred to as Mendelson's syndrome.[37] This is a severe pneumonitis with fever, hypoxia and respiratory alkalosis, which typically clears rapidly in healthy hosts within 4 to 7 days but may progress following lung injury and superinfection to pneumonia, lung abscess, or acute respiratory distress syndrome (ARDS) (see Chapters 140 and 141). Factors that contribute to hypoxemia are pulmonary edema, reduced surfactant activity, reflex airway closure, hyaline membrane formation, and alveolar hemorrhage. Pulmonary function tests show decreased compliance, abnormal ventilation–perfusion, and reduced diffusing capacity.[2] The pathophysiology of gastric acid pneumonitis has been studied in experimental animals with intratracheal instillation of graded acid inocula. This work shows that the pH must be 2.5 or less, and a relatively large inoculum, usually a minimum of 0.3 to 0.6 mL/kg, is required for the inflammatory process to be initiated.[38–41] It is possible that smaller volumes initiate a less dramatic presentation or may go undetected.[39,41] Support for this hypothesis is the observation of frequent bouts of pneumonitis and otherwise unexplained pulmonary fibrosis in patients with gastric reflux or esophageal disease.[42–44]

Pathologic changes in acid pneumonia occur rapidly. Atelectasis occurs within seconds and is extensive within minutes. There is also peribronchial hemorrhage, pulmonary edema, and bronchial epithelial cell degeneration. The alveolar spaces fill with neutrophils within hours and hyaline membranes are seen within 48 hours. Resolution begins by the third day and may be complete or may result in residual scarring of the pulmonary parenchyma.[45,46] Long-term follow-up studies in patients who have gastric acid pneumonia show either complete recovery or radiographic evidence of pulmonary fibrosis with abnormal gas exchange.[47,48] Pulmonary fibrosis may also be associated with repeated, small, "silent" aspirations of gastric secretions without clinically overt pneumonitis (see Chapters 56 and 57). [42,49]

The diagnosis of acid pneumonia is usually presumed on the basis of clinical observations such as the abrupt onset of dyspnea in a patient who is aspiration prone and has radiographic evidence of infiltrates, usually in the lower lobes. Other characteristic clinical features are the rapid clearing of the infiltrates and progression to ARDS.[46,50] Bronchoscopy demonstrates erythema of the bronchi, suggesting a "chemical burn."[51] Confirmation of the acid inoculum is not possible because of rapid neutralization by pulmonary edema fluid and bronchial secretions within minutes after aspiration.

The treatment of gastric acid aspiration includes tracheal suction to clear fluids and particulate matter that may have been concurrently aspirated. Supportive care consists primarily of ventilatory support with positive pressure ventilation and resuscitation with intravenous fluids.[46,52] While use of corticosteroids dates back to the 1950s, clinical trials have not shown them to be beneficial.[53–55] Antimicrobial agents are reserved for superinfection.

ASPIRATION PNEUMONIA

While not as fulminant as chemical pneumonitis,[56] bacterial infection following aspiration is associated with an increased risk of prolonged hospitalization and death.[57,58] In the preantibiotic era, the natural history of these infections could be followed. The initial presentation was similar to chemical pneumonitis, usually combined with purulent sputum. After 8 to 14 days, progression to tissue necrosis with abscess formation or extension into the pleural space may occur. This stage is marked by putrid discharge and cavitation.[59–61] The distinction between aspiration pneumonia and other forms of pneumonia is largely based on the clinical characteristics, but clear overlaps exist. For example, healthy elderly patients with community-acquired pneumonia have a markedly higher incidence of silent aspiration than matched control patients.[62] While no gold standard for the diagnosis of aspiration exists, studies suggest that 5% to 15% of community-acquired pneumonia may be due to aspiration.[11,63,64] The incidence of aspiration pneumonia in elderly patients with community-acquired pneumonia may be much

higher.[65,66] The diagnosis of aspiration pneumonia is often inferred from patient characteristics. Antimicrobials with specific anaerobic activity may only be indicated in patients with periodontal disease, patients expectorating putrid sputum, and patients with necrotizing pneumonia or lung abscess on chest radiograph.[46,67–69]

MECHANICAL OBSTRUCTION

Aspiration may involve fluid or particulate material. In this form of aspiration pneumonia, the inoculum is not toxic to the lung but may cause obstruction or reflux airway closure. In most cases there is only transient, self-limited hypoxemia due to rapid clearance.[45] Some patients develop pulmonary edema, with hypoxemia and reduced compliance apparently due to an intrinsic pulmonary reflex closure.[45] Other patients suffer sequelae due to failure to clear relatively large volumes of the aspirate, such as near-drowning victims and patients with profound neurologic deficits or in coma. The obvious critical intervention is tracheal suction.

Aspiration with mechanical obstruction may also be associated with solid particles. Foreign-body aspiration is most frequent in children 1 to 3 years of age.[70–72] The most common objects in the lower airways are vegetable particles, inorganic materials, and teeth.[70–72] The severity of the obstruction depends on the relative size of the material aspirated and the caliber of the lower airways. Large objects may cause obstruction at the level of the larynx or trachea, leading to sudden respiratory distress, cyanosis, stridor, and in some cases, aphonia.[73,74] This is referred to as café coronary syndrome because it often involves meat aspiration during restaurant dining and may simulate an acute myocardial infarction.[75] Aspiration of smaller particles may result in complete obstruction of more distant components of the tracheobronchial tree or partial obstruction. Chest radiographs often show atelectasis or obstructive emphysema.[76] Common symptoms include chronic cough, fever, hemoptysis, and dyspnea.[77,78] An important clue in some cases is unilateral wheezing.[79] Bacterial infection is not important in the early stages of obstruction but is a common feature when obstruction has been present for more than 1 week.[80] The most common pathogens are anaerobic bacteria from the upper airways. These patients may respond well to antibiotics, but often have recurrent infections in the same pulmonary segment.[70] The most important therapeutic intervention is removal of the foreign body, usually with bronchoscopy.[71]

RADIOLOGIC DIAGNOSIS

Chest radiographs in patients with anaerobic lung infections typically demonstrate infiltrates (with or without cavitation) involving dependent pulmonary segments.[1,46] The favored locations are the superior segment of the lower lobes or posterior segments of the upper lobes; these are dependent in the recumbent position. The basilar segments of the lower lobes are favored in patients who aspirate in the upright position. The right lung is more frequently affected, owing to the more direct takeoff of the right mainstem bronchus.

LABORATORY DIAGNOSIS

Aspiration pneumonitis is a clinical diagnosis. It is generally assumed that there is an anaerobic component to pneumonia in patients with altered consciousness or after surgical procedures. It is important to emphasize the utility of the Gram stain in making the diagnosis of anaerobic lung infection. Often culture data are not available to confirm the presence of these organisms. However, most anaerobic gram-negative bacteria have unique morphologic features that make them relatively easy to identify or suspect on direct Gram stain. For example, peptostreptococci appear like their aerobic counterparts. Aspiration pneumonia is usually a mixed infection involving multiple bacteria; about half of the cases demonstrate mixtures of aerobic and anaerobic bacteria.[1,81,82] Thus, the detection of polymicrobial flora or bacteria with the unique morphology of anaerobes on any specimen that is devoid of contamination by normal flora represents an important clue to the probable presence of anaerobic infection.

Determination of the microbiology of anaerobic infections of the lower airways requires a specimen devoid of contamination by the flora of the upper airways or quantitative cultures that distinguish pathogens from normal flora. Uncontaminated specimens that are considered valid for anaerobic culture include pleural fluid, TTAs, transthoracic aspirates, and specimens obtained at thoracotomy or thoracoscopy. Quantitative cultures of specimens obtained at fiberoptic bronchoscopy, either by BAL or with the protected brush, may also be used for this purpose.[1] Anaerobic bacteriology should not be obtained from standard bronchoscopic aspirates. Quantitative culture of lower airway secretions improves diagnostic accuracy with virtually any specimen that is subject to contamination, including expectorated sputum and tracheostomy aspirates. Most studies employing these techniques have used them to detect aerobic bacteria; relatively few studies evaluated anaerobic cultures. Whether treatment decisions based on quantitative cultures of anaerobic pathogens improve treatment outcomes has not determined.

When possible, respiratory samples should be obtained before the inception of antibiotic treatment. In clinical practice, specimens are often not obtained for anaerobic culture until the patient has developed complications of persistent infection, which greatly reduces their yield. Thus, the anaerobic pathogens should be considered in the appropriate clinical context, even when only aerobic organisms are isolated.

It is essential that material obtained for culture be placed under anaerobic conditions promptly before transport to the laboratory. A sealed syringe provides the best container, with delivery of the specimen to the laboratory within 20 to 30 minutes for immediate plating. It is imperative that air bubbles be eliminated from the syringe and needle. Special anaerobic transport tubes are also available for brush or liquid specimens. It is important to obtain additional pulmonary specimens for culture and antibiotic susceptibility measurements from patients failing to respond to initial therapy (Fig. 127-2). Such data may demonstrate the presence of unrecognized or antibiotic-resistant organisms. Most of these infections are polymicrobial and many of the organisms grow slowly *in vitro*. Thus, it often takes several days to separate, identify, and report results of anaerobic cultures. There is great variation in the availability and quality of *in vitro* susceptibility tests. These factors illustrate the need for empiric decisions regarding antibiotic selection.

PREVENTION

The reversibility of underlying conditions predisposing to aspiration must be considered. It has recently been recognized, for example, that aspiration in lung transplant recipients is a major predisposing factor to graft injury and obliterative bronchiolitis.[83] In the general patient population, nasogastric-feeding tubes, sedation, lying flat in bed while sleeping, reflux, and frequent choking are associated with aspiration and should suggest strategies for remediation.[46] Gastric surgery for obesity has also been associated with a high incidence of aspiration disease.[84]

Positioning, dietary changes, medications, oral hygiene, and tube feeding, among other interventions, have been proposed to prevent aspiration both in hospitalized and nonhospitalized patients, particularly in the elderly. However, studies have failed to support a specific intervention in the outpatient setting.[85] While using nectar or honey-thickened liquids decreases aspiration among patients with dementia or Parkinson disease,[86] the incidence of pneumonia is not changed.[87]

Methods to prevent aspiration have been studied most extensively in hospitalized patients, especially in those who are aspiration prone. Most important is use of semirecumbent or upright positioning.[88] Additional measures to prevent aspiration with variable efficacy include tracheostomy, reducing gastric contents by suction or metoclopramide, feeding via gastrostomy tube, and neutralization of gastric acid. Many of these procedures may alter colonization

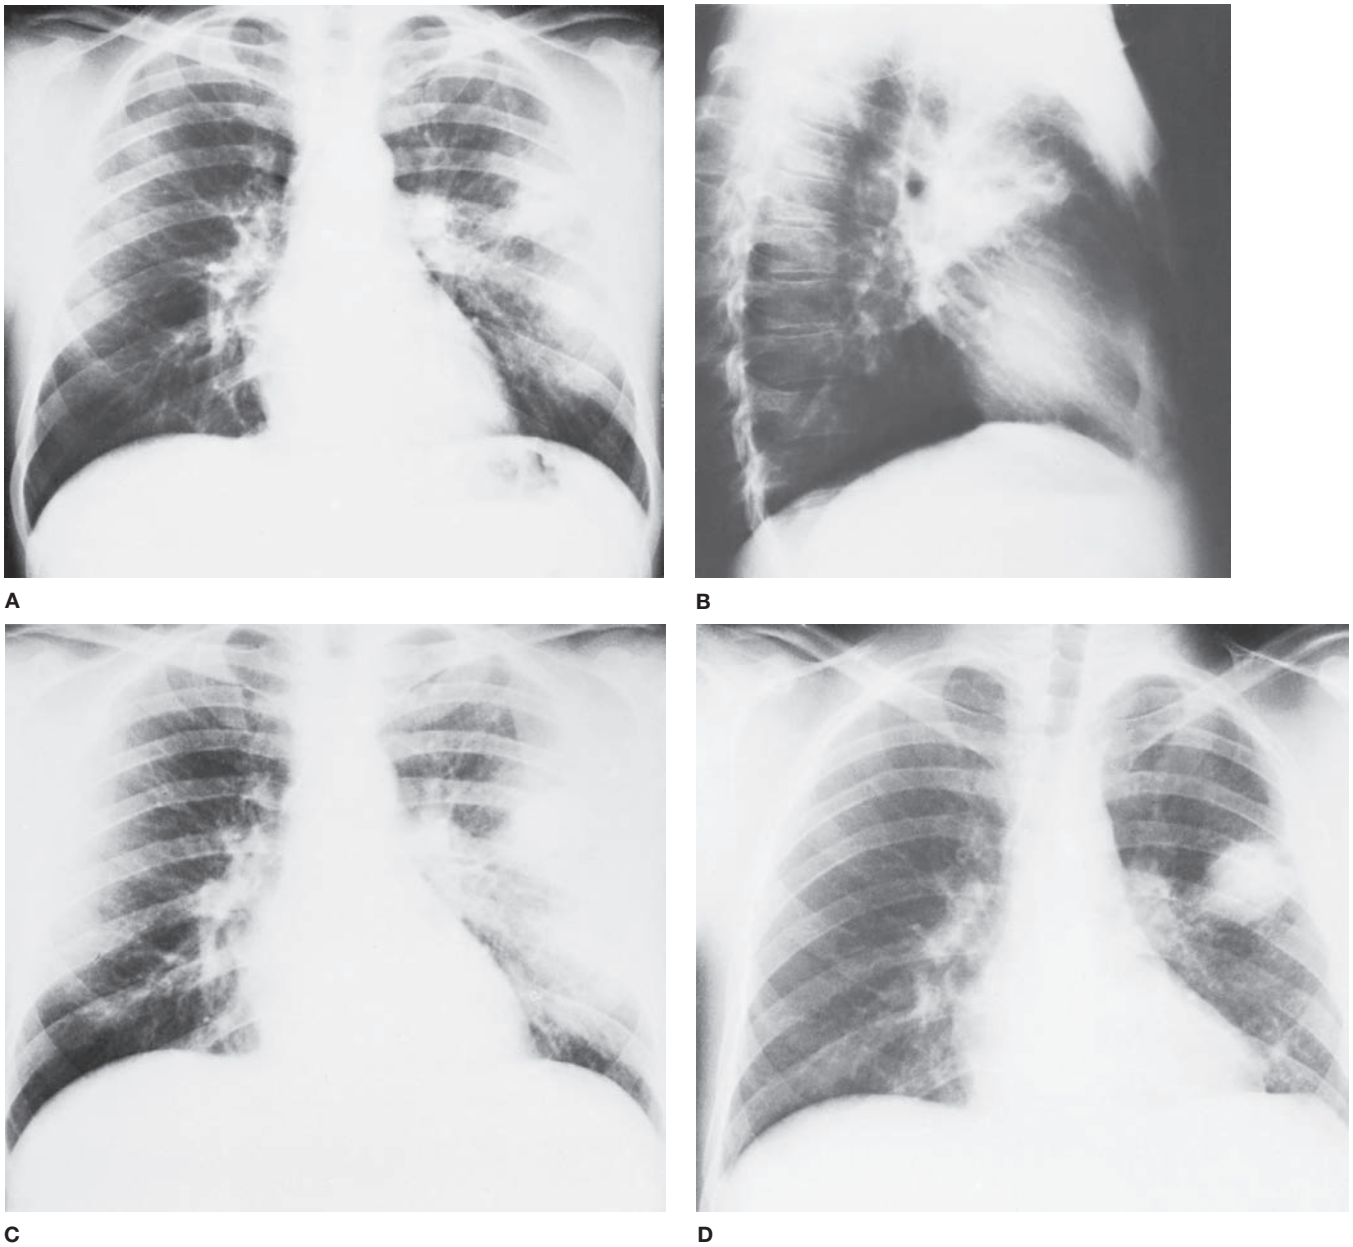

Figure 127-2 Failure of penicillin therapy for anaerobic lung abscess in a 29-year-old alcoholic man. **A.** Admission chest radiograph reveals a radiolucent area within a zone of consolidation in the left upper lung field. **B.** Lateral view demonstrates multiple cavities. The patient was treated for 5 days with penicillin (6 million units per day intravenously), followed by the same dosage orally for 10 days. **C.** Radiographic infiltrate persists but no cavity is visible. **D.** Six weeks after the cessation of penicillin therapy, the abscess has recurred in the same area. Marked pleural reaction is noted in the vicinity of the recurrent disease.

patterns and potentially may predispose to more significant infections. Neutralization of gastric acid may increase colonization of the oropharynx and thereby increase the risk of bacterial infection following aspiration of gastric contents. Tracheostomy is useful in some patients with repeated aspiration, but inflation of the balloon may occlude the esophagus and promote aspiration of upper airway contents. Patients who require nasogastric feedings are aspiration prone; percutaneous endoscopic gastroscopy (PEG) may be alternative method to address this issue, but study results are quite variable. A recent meta-analysis of nine studies found that while PEG feeding was superior to nasogastric tube feeding in providing consistent nutritional support, the incidence of pneumonia was no different between the two groups.[89] Alternative procedures sometimes considered to prevent or limit aspiration include is postpyloric feeding jejunostomy and Nissen fundoplication.

■ ANTIMICROBIAL THERAPY

It is essential, whenever possible, to obtain microbiologic samples from the lungs and blood in advance of antimicrobial therapy. As for all pneumonias, inappropriate initial therapy has an adverse impact on outcome. The initial choice of antimicrobial agents should be guided by the Gram stain and the likely bacteriology of the infection and then adjusted as culture data become available. The history and a review of previous culture results may be useful in the selection of specific antibiotics. The standard drug historically for aspiration pneumonia and lung abscess involving anaerobic bacteria has been penicillin, usually given intravenously or with high-dose oral treatment. However, in the face of increasing penicillin resistance among *S. pneumoniae* and in 40% to 60% of strains of fusobacteria and *P. melaninogenica* as well as anaerobic gram-negative bacilli, alternatives should be considered for empiric

TABLE 127-5 Antibiotic Treatment of Anaerobic Lung Infections: Results of Two Randomized Trials

Source	Treatment	# Pts	Number of Patients with		Mean Days to Symptom Resolution	
			Failure	Relapse	Fever	Putrid Sputum
Levinson (1983)	Penicillin (6 million units/d)	21	5 (29%)	3 (19%)	7.7	7.8
	Clindamycin (1.8 g/d)	17	0[a]	0	4.7[a]	4.1[a]
Gudiol (1990)	Penicillin (12 million units/d)	18	7 (39%)	2 (11%)	7.2	7.3
	Clindamycin (2.4 g/d)	19	1 (5%)	0	6.4	3.9[a]

[a]*Difference for treatment favoring clindamycin is statistically significant.*

therapy. In early therapeutic trials in patients with lung abscess involving anaerobic bacteria (Table 127-5), clindamycin proved superior to penicillin in terms of response rates and time to defervescence. Alternative regimens that have been used successfully based on anecdotal experience include amoxicillin–clavulanate and penicillin combined with metronidazole. Metronidazole should not be used as a single agent in patients with anaerobic lung infections, since there is a poor response in about 50%.[90,91] The presumed explanation is the contributing role of aerobic and microaerophilic streptococci, which are resistant to this drug.

Many other antimicrobial agents are likely to be useful in anaerobic or mixed aerobic–anaerobic infections: combinations of a β-lactam and β-lactamase inhibitor (ticarcillin–clavulanate, ampicillin–sulbactam, amoxicillin–clavulanate, piperacillin–tazobactam), imipenem or meropenem, and second-generation cephalosporins such as cefoxitin or cefotetan. Macrolides (erythromycin, clarithromycin, and azithromycin) offer good *in vitro* activity against most species except fusobacteria. Tetracyclines show limited activity against many anaerobic bacteria *in vitro*; vancomycin is active only against gram-positive anaerobes. Oxacillin and nafcillin are much less active. Drugs that have virtually no activity against anaerobes include aminoglycosides, first-generation fluoroquinolones, aztreonam, and trimethoprim-sulfamethoxazole (TMP-SMX). Moxifloxacin has broad coverage that includes anaerobes[92] however, increasing resistance in *Bacteroides* spp. raises concerns for the suitability of moxifloxacin monotherapy.[93]

The appropriate duration of therapy is unclear. No clinical trials have been performed to determine optimal treatment term. Typically the duration is dependent on the clinical and radiographic response of the patient. Patients should be treated at least until fever, putrid sputum, abscess fluid has resolved, and any fluid collections have resolved or stabilize, typically over 2 to 3 weeks. In the absence of abscess formation, a course of 7 to 10 days of antibiotics is recommended, but longer courses are often necessary. Relapse is common and may involve organisms resistant to initial antibiotic agents (Fig. 127-2).

LUNG ABSCESS

Because the most important predisposing condition for lung abscess is aspiration, lung abscesses are most often located in the posterior segment of the right upper lobe, less often in the left upper lobe, and the apical segments of the lower lobes (Fig. 127-1). Periodontal disease is highly associated with lung abscess formation; in edentulous people, lung abscesses are uncommon and may suggest the presence of an obstructing lesion of the bronchus, pulmonary embolus, septic embolus, or unsuspected pathogen. Nosocomial aspiration often involves gram-negative bacteria, particularly organisms with hospital-acquired antibiotic resistance patterns. Many of these infections progress to suppurative complications, with presentation as lung abscess or empyema. Usually 1 to 2 weeks are required for cavity formation.

Lung abscesses generally develop after inflammation produces tissue necrosis with cavitation. In the presence of pre-existing cavitary disease, for example, due to emphysema or old tuberculous lesions, infection may proceed without frank necrosis. The abscess cavity may become lined with regenerated epithelium. Local obstruction may produce bronchiectasis or emphysema in the surrounding lung.

The classification of lung abscesses is based on the duration and likely cause of the process. Acute abscesses are less than 4 to 6 weeks old, whereas chronic abscesses are of greater duration. Primary abscesses are infections due to aspiration or to pneumonia in the normal host; secondary abscesses are due to pre-existing conditions (obstruction, spread from an extrapulmonary site, bronchiectasis, immune compromise). Abscesses with foul odors associated with anaerobic organisms are often called putrid abscesses.

MICROBIOLOGY

In lung abscesses, anaerobes are recoverable from up to 93% of patients.[15] In some patients, anaerobic organisms of presumably greater virulence (e.g., *Fusobacterium* or *Peptostreptococcus*) may be found as the sole infecting organism. In studies by Bartlett and Finegold,[3] 46% of patients with lung abscesses had only anaerobes isolated in cultures, while an additional 43% had a mixture of anaerobes and aerobic bacteria. In addition to anaerobes, among the organisms often implicated in lung abscess formation or in necrotizing pneumonia included are *S. aureus*, *Streptococcus pyogenes*, *Klebsiella pneumoniae,* and *Pseudomonas aeruginosa*. Infrequently, other gram-negative bacilli, such as *E. coli* and *Haemophilus influenzae* type B, may cause pulmonary necrosis. Uncommon but important causes of cavitating pneumonia are *Nocardia* spp., *Paragonimus westermani*, *Legionella* species, *Burkholderia pseudomallei*, *Burkholderia mallei* (glanders), and tuberculosis. Certain fungal infections may cause cavitation in diabetic and immunocompromised hosts (e.g., the *Mucoraceae*, *Aspergillus* species). *Entamoeba histolytica* is an important but uncommon cause of lung abscess, almost always in the basilar portion of the right lower lobe.

CLINICAL FEATURES

The clinical presentation of lung abscess may be coincident with the initial presentation of pneumonia or other underlying condition or may occur later in the clinical course. Suspicion may be heightened by the presence of conditions predisposing to aspiration or anaerobic pneumonia: alcoholism or other causes of altered consciousness, anesthesia, dysphagia or pharyngeal dysfunction, gingivitis or pyorrhea (purulent inflammation of the gums), blunt or penetrating chest trauma or lung surgery, obstruction due to neoplasm, bronchiectasis, or pulmonary embolism. Bad breath or putrid sputum may be noted. However, the absence of a foul odor does not exclude the possibility of anaerobic infection, since certain anaerobes do not generate the end products of metabolism responsible for this type of odor, and communication may be lacking between the lesion and tracheobronchial tree. A change in sputum production, either increased or decreased, may be noted in patients with chronic bronchitis or bronchiectasis.

The patient with primary lung abscess gradually develops fever, cough, pleurisy, chest heaviness, shoulder pain, and malaise.

Pneumonia may be present or suspected from history for a period of 1 to 3 weeks before the recognition of the lung abscess. By contrast, secondary lung abscesses – due, for example, to septic pulmonary emboli with infarction – can evolve over 48 to 72 hours (Fig. 127-3). Clinically, the distinction between primary and secondary abscesses may be unapparent at the time of presentation but is important in the proper management of the patient. Thus, the patient with staphylococcal or streptococcal endocarditis may present with pneumonia, lung abscess, and empyema. The main clue to the presence of underlying endocarditis may be the development of new lung abscesses during the course of therapy. The patient with lung abscesses complicating subdiaphragmatic infection, for example, due to amebic abscess of the liver or pancreatic phlegmon, may have abdominal signs in addition to acute pulmonary disease. Seizures due to brain abscesses are occasionally the presenting clinical manifestation of bacteremia due to lung abscesses.

■ RADIOLOGIC DIAGNOSIS

The classic radiographic appearance of a lung abscess is an irregularly shaped cavity with an air–fluid level. Because the presentation is often indolent, numerous chest radiographs may be needed to follow the evolution of pneumonia into necrotizing pneumonia and then a pulmonary cavity (Figs. 127-4 and 127-5). Anaerobic infection is suggested by rapid pulmonary cavitation within a dense segmental consolidation; there may be rapidly enlarging nodular lesions, with or without cavitation. Although anaerobic pulmonary infections may be acute and fulminating, almost two-thirds have a subacute or chronic presentation. Natural progression of virulent

infection, delays in appropriate therapy, or tissue infarction may allow the underlying infection to progress into pulmonary gangrene (Fig. 127-5). Seeding of infection or rupture of a lung abscess into the pleural space may cause empyema (Fig. 127-3). Up to one-third of lung abscesses may be accompanied by empyema. Solitary cavities are generally observed with primary lung infections, whereas many smaller collections may be found in metastatic infection. Chest tomography will define the size and location of abscesses, and may distinguish between related processes (empyema, infarction) better than conventional radiographs. The common organisms and conditions associated with lung abscesses are listed in Table 127-6.

■ LABORATORY DIAGNOSIS

Microbiologic specimens from patients with lung abscesses should be obtained, if possible, without contamination by oral flora, especially after nosocomial colonization. Thus, invasive procedures are preferred to routine sputum samples. In particular, the diagnosis of anaerobic infection is complicated by the prevalence of large numbers of anaerobes as normal flora in the mouth and upper respiratory tract (Figs. 127-6 and 127-7). However, there may also be significant colonization with nosocomially acquired pathogens in hospitalized patients.

Blood and sputum cultures should be obtained as adjunctive guides to therapy. When empyema or bacteremia complicates lung abscess, adequate specimens for microbiologic evaluation may be obtained from the pleura or blood. However, to obtain adequate specimens from the abscess, bronchoalveolar lavage, use of a protected double-lumen catheter or percutaneous transthoracic aspiration under radiographic guidance is recommended. The specific procedure selected depends on the location of the infection and the expertise of the institution. Specimens collected through a fiberoptic bronchoscope, using bronchoalveolar lavage or a plugged double-lumen sampling catheter with a protected sampling brush, are generally preferred; these require the use of quantitative cultures. Growth at a dilution of 10 from a protected brush represents approximately 1×10^{10} organisms per milliliter in the lower respiratory tract. Recovery of nonbacterial and anaerobic bacteria from these specimens has not been well standardized. Specimens obtained from blind, deep suctioning via an endotracheal tube may also be useful if cultured quantitatively and examined microscopically.

■ TREATMENT

The treatment of lung abscess must be guided by the microbiology and knowledge of any underlying or associated conditions that may predispose to the development of severe pulmonary infection. A small abscess in an otherwise healthy person may respond to conservative management with antimicrobial therapy and chest

TABLE 127-6 Organisms and Conditions Associated with the Radiographic Appearance of Lung Abscess

Infectious
Bacteria Anaerobes, *Staphylococcus aureus,* Enterobacteriaceae (e.g. *Klebsiella pneumoniae*), *Pseudomonas aeruginosa*, *Burkholdaria pseudomallei*, streptococci, *Legionella* spp., *Nocardia asteroids*, *Rhodococcus equi*, *Actinomyces* spp.
Mycobacteria (often multifocal) *M. tuberculosis, M. avium* complex, *M. kansasii*, *M. malmoense*, other nontuberculous mycobacteria
Fungi *Aspergillus* spp., zygomycetes, *Histoplasma capsulatum*, *Blastocystis hominis, Coccidioides immitis, Cryptococcus neoformans*, *Pneumocystis jiroveci*, *Penicillium marneffei*
Parasites *Entamoeba histolytica, Paragonimus westermani, Strongyloides stercoralis* (post-obstructive)
Miscellaneous Empyema (with air-fluid level), septic embolism (endocarditis)
Noninfectious and Predisposing Conditions
Anatomic, fluid-filled cysts, bland infarction, bronchiectasis, vasculitis, Goodpasture's syndrome, granulomatosis with polyangiitis (formerly, Wegener granulomatosis), periarteritis, obstruction (neoplasm, foreign body), pulmonary sequestration, pulmonary contusion, carcinoma

physical therapy. A rapidly expanding pulmonary abscess in an immunocompromised host (e.g., due to one of the *Mucoraceae*) requires urgent lung resection in addition to antimicrobials. Intermediate to these approaches is the use of bronchoscopic-guided or radiographically guided catheter drainage of any fluid and necrotic debris. In the absence of antibiotics, the mortality of lung abscess is approximately 33%.[94] However, up to half of patients surviving a lung abscess acutely in the preantibiotic era had significant pulmonary complications, including recurrent infections and abscesses, pleural empyema and adhesions, chronic bronchitis, and bronchiectasis. The introduction of penicillin, orally or parenterally administered, resulted in resolution or collapse of the abscess in up

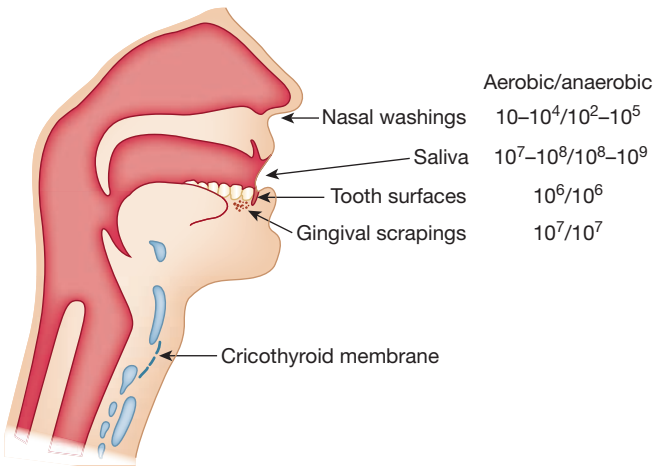

Figure 127-7 Sagittal section illustrating presence of large numbers of organisms, including anaerobes, as indigenous flora in upper respiratory tract. (Values given as number of aerobic/anaerobic organisms per milliliter.) *(Used with permission of PD Hoeprich.)*

to 90% of patients (although long courses of treatment were often needed). Therefore, these patients could avoid surgical resection.

The role of drainage or surgery is based on serial clinical assessments of the patient. Bronchoscopic drainage may be most useful in the relief of abscesses without air–fluid levels, which indicate the possibility of persistent connection with the bronchi.[95] However, experience dictates caution with the bronchoscopic drainage of closed cavities; spillage of cavity contents into other lung segments may produce catastrophic pulmonary dysfunction. Further, there are few data to suggest that bronchoscopic drainage offers a significant advantage in terms of rapidity of recovery in the immunologically normal host. In patients with coexistent empyema and lung abscess, it is often useful to address drainage of the empyema first, stabilizing the patient, and then considering further procedures for the lung abscess. In critically ill patients or those with bronchial obstruction related to the abscess cavity, bronchoscopic drainage should be considered.

Bronchoscopy and chest CT have major roles in the evaluation of the patient failing therapy. Persistence of bacteremia or high-grade fevers after 72 hours, or the absence of change in sputum production or character or in the radiographic images over 7 to 10 days suggests unappreciated anatomic or microbiologic problems. Obstruction or resistant organisms (including fungi, parasites, or mycobacteria) may be present. Multiple loculations may be present, or empyema, including drainage of the abscess into the pleural space, may develop. New sites of infection, including extrathoracic sites, may have developed in the bacteremic patient. Progression of pulmonary infiltrates may occur after the initiation of appropriate antibiotic therapy, reflecting the relatively poor activity of many antibiotics at the low pH levels of poorly ventilated and underperfused, infected lung tissues, as well as the delayed radiographic response to treatment.

Surgical resection of necrotic segments of lung is helpful if the response to antibiotics is poor, for large abscesses, or when ventilation–perfusion scans suggest little residual lung function in a limited necrotic region. Infarcted lung or rapidly progressive infection may force surgical resection of the affected tissue. Surgery is also indicated if airway obstruction limits drainage. Such presentations are seen in the presence of tumor or a foreign body. In patients thought to be poor surgical risks, percutaneous drainage via catheters may be a useful temporizing measure. However, leakage of the abscess contents into the pleural space in such patients may be disastrous and must be avoided.

Mortality in patients with lung abscesses reflects the quality of the host's inflammatory response and overall condition. Patients with large abscesses (over 5–6 cm), progressive pulmonary necrosis, obstructing lesions, aerobic bacteria (especially *K. pneumoniae*, *S. aureus*, or *P. aeruginosa*), immune compromise, old age, malnutrition, or systemic debility, and those with major delays in seeking medical attention have a significantly increased mortality.[96]

EMPYEMA

The microbiology, diagnosis, clinical features, and management of empyema are considered below.

MICROBIOLOGY

Pleural infections are associated with a significant degree of morbidity and mortality, with death or surgical intervention in more than 30% of patients.[97,98] In the preantibiotic era, up to 11% of cases of pneumococcal pneumonia were associated with empyema, and 64% of all cases of empyema were associated with *S. pneumoniae*. β-Hemolytic streptococci (15%) and staphylococci (8%) were the other organisms most commonly isolated from empyema fluid. In the 1960s and 1970s, with new culture techniques, one study found only anaerobic bacteria in pleural empyema fluid in 35% of cases, and a mixture of aerobic and anaerobic bacteria in 41% in a series of 83 medical patients who had not received antibiotics or surgical intervention (Tables 127-7 and 127-8; Figs. 127-6, 127-8 and 127-9). With the introduction of

Figure 127-8 Large anaerobic empyema accompanying right middle-lobe pneumonia.

the sulfa drugs and penicillins, the expansion of thoracic surgery, and the emergence of antibiotic resistance in the staphylococci, the isolation of *S. pneumoniae* from empyema fluids decreased and that of *S. aureus* and other nosocomial pathogens increased. In more recent studies of empyema, the pneumococcus accounts for only 5% to 10% of cases, whereas anaerobes are found in 25% to 40%. The highest yield reported in recent years is a collaborative study at Cook County Hospital in Chicago and two VA hospitals in Los Angeles. Anaerobes were recovered in 63 (76%) of 83 cases.[4]

Anaerobic Bacteria in Empyema

The frequency of anaerobic infection of the lung and pleural space is a function of the colonization pattern of the individual patient, including the presence of hospital-acquired pathogens, and the role of aspiration in many of these infections (Tables 127-7 and 127-8). The most frequent isolates are the anaerobes *Prevotella*, *F. nucleatum*, and *Peptostreptococcus* and the streptococci (Figs. 127-4 and 127-5).

TABLE 127-7 Bacteriology of Anaerobic Empyema: Predominant Flora

Organism	Number of Isolates
Anaerobic isolates	
Fusobacterium nucleatum	19

A B

Figure 127-9 *Prevotella melaninogenica*. **A.** Distinctive black colonies (on blood-containing medium); pigment is hematin. **B.** Microscopically, the organism is a coccobacillus.

In early studies, the *B. fragilis* group was isolated from 15% to 20% of patients with anaerobic pleuropulmonary infections. However, later studies employing newer techniques and utilizing newer taxonomic criteria found *B. fragilis* group in only 6.8% of 46 patients with pleural empyema specimens. The *B. fragilis* group is important because of resistance to penicillin (a property shared by a number of common anaerobes) and other antimicrobial agents. Subdiaphragmatic infection may extend to the lung or pleural space by way of lymphatics, directly through the diaphragm or defects in it, or by way of the bloodstream. Anaerobic pulmonary and pleural processes rarely extend to the chest wall unless associated with actinomycosis, tuberculosis, or tumor.

Nonanaerobic infections

In immunologically normal adults, the aerobic organisms currently most often associated with empyema and lung abscesses are *S. aureus*, β-hemolytic streptococci, and various gram-negative aerobic or facultatively anaerobic bacilli, particularly *P. aeruginosa*, *E. coli*, *Klebsiella* species, and other nosocomial enteric gram-negative organisms—reflecting infections associated with pneumonia treated with antimicrobial agents to which the causative organism is resistant, with thoracic surgery or high-grade bacteremias. Mixed aerobic–anaerobic infections are often related to subdiaphragmatic processes. Increasingly, *Mycobacterium tuberculosis*, *Nocardia asteroides*, and fungi have been identified. In the immunocompromised host, the infecting organisms will more often be gram-negative bacteria (especially *Pseudomonas* and *Enterobacter)*, less virulent streptococci, *Aspergillus*, *Candida* species, or will be due to reactivation of latent or subclinical infections due to *M. tuberculosis*. In all hosts, the colonization pattern of the individual will often predict the causative organisms, even if these are not easily isolated.

■ CLINICAL FEATURES

The pathogenesis and presentation of both pleural empyema and lung abscesses are often indistinguishable. Shared presentations of empyema and lung abscess include the indolent development of symptoms, most often fever, sweats, cough, dyspnea, weight loss, and pleurisy; an association with conditions predisposing to aspiration events (altered consciousness, dysphagia, and gingivitis); and foul odors of sputum or breath associated with anaerobic bacteriology. Lung abscesses and empyemas often coexist. Both are generally associated with primary pneumonias.

The clinical presentation of empyema is determined by the underlying cause of infection. Empyema associated with aspiration pneumonia may develop over 1 to 3 weeks, usually with associated symptoms of pneumonia. The patient may have high fever and leukocytosis. Physical examination reveals dullness to percussion and decreased breath sounds on auscultation. These changes may be quite localized in the setting of loculated fluid. The empyema fluid is generally purulent by the time of detection, but pleural infection may be noted only after treatment for pneumonitis has failed to resolve fever or pleurisy. Empyema associated with thoracic surgery may be radiologically "hidden" in areas of the chest not drained by chest tubes or behind relatively benign pleural effusions. The patient may appear minimally toxic or severely ill, depending on the extent of the infection and organisms present. The presentation is modified by routine prophylactic antibiotic use, sedation, intubation, and antipyretics. Acute empyema may be seen in staphylococcal and streptococcal infections and following rupture of hepatic abscesses, especially those due to *E. histolytica*.

■ RADIOLOGIC DIAGNOSIS

With empyema, chest radiographs generally reveal fluid, most often in the costophrenic angles; free-flowing effusions layer on lateral decubitus radiographs. Loculations and pleural disease are often best defined by computed tomography of the chest, which should include the neck and diaphragms to rule out extrathoracic sites of infection. Spinal disease is better detected with magnetic resonance imaging (MRI). Before invasive diagnostic procedures, a careful history and physical examination may suggest a reason for the accumulation of pleural fluid. Noninfectious causes include bland pulmonary embolus, malignant effusion, benign postsurgical changes, pericardiotomy syndrome, collagen vascular diseases (systemic lupus, rheumatoid arthritis), congestive heart disease, sympathetic effusion related to subdiaphragmatic disease (pancreatitis), leakage of ascites or peritoneal dialysis fluids, and hemorrhage (from venous access catheters or aortic tears). Infectious causes include extension of all classes of pulmonary infections from the lungs (parapneumonic), esophageal rupture, parapharyngeal space drainage, drainage or sympathetic effusion due to hepatic or subdiaphragmatic abscesses, septic metastasis, and direct infection via thoracic defects or chest tubes used for pleural drainage. Pyopneumothorax, in the absence of bronchopleural fistula, prior surgery, or prior

thoracentesis, suggests the possibility of gas formation by bacteria implicated in the infection. Although nonspecific, pyopneumothorax suggests a component of anaerobic infection.

LABORATORY DIAGNOSIS

The diagnosis of empyema is based on the characteristics of thoracic fluid. The urgency to diagnosis is due to the development of pleural scar and of loculated effusions in the presence of undrained pus. Thus, diagnostic thoracentesis should be attempted unless the nature of the pleural fluid is clear or the clinical risk to the patient is too great. Pleural fluid analysis should include Gram stain and cultures (routine, anaerobic, mycobacterial, and fungal), parasitologic examination when appropriate, fluid cell count and differential, cytology, pH, lactic dehydrogenase, total protein, and glucose measurements at a minimum. (see Chapter 76) Purulent fluid requires drainage. Empyema is diagnosed on the basis of the neutrophilic predominance in fluids with more than 25,000 white blood cells per milliliter. Parapneumonic effusions will generally have lower white blood counts, negative Gram stains and cultures, a pH over 7.3, and glucose over 50% of serum glucose levels. Parapneumonic fluids may become infected over time. Blood cultures and sputum cultures should be obtained as adjunctive guides to therapy.

TREATMENT

The management of empyema includes antimicrobial treatment, identification and treatment of any anatomic processes, and drainage of the infected fluid. The approach to a specific patient is based on the clinical status of the patient as well as the microbiology of the infection. For example, patients with empyema following thoracic surgery and other hospitalized patients may have useful culture data available from chest tube drainage samples or sputum cultures to assist in the selection of antibiotics. The Gram stain may indicate the predominant organism type. Mixed aerobic and anaerobic organisms may be the first suggestion of esophageal tear or parapharyngeal infection. Fastidious organisms (*S. pneumoniae*, anaerobes) may be seen on Gram stain but not isolated in culture. Antibiotic susceptibility data should be used to guide therapy, especially in nosocomially acquired infection. Local administration of antibiotics (e.g., inhaled, instilled) is unnecessary and may be irritating; intrapleural injection of antibiotics should be reserved for pleural ablation (pleurodesis), as may be achieved with erythromycin.

The decision to drain a pleural fluid collection is based on the characteristics of the fluid. In the presence of pleural fluid and unexplained fever, leukocytosis, or bacteremia, or in the postoperative patient, thoracentesis should be performed routinely. Noninfected parapneumonic pleural effusions resolve with appropriate treatment of the underlying infections. Drainage is required if infection or frank pus is present. Highly viscous or purulent fluids and fluids with acid pH also require the insertion of a chest tube via thoracostomy or the thoracoscopic drainage of the fluid. In approximately one-third of patients, however, drainage through a chest tube along with antibiotic treatment fails to cure an empyema, necessitating surgical intervention.[99] This may be improved through use of DNase plus tissue-plasminogen activator (t-PA) instilled through the chest tube. The use of these two agents in combination has been shown to decrease the number of patients who require surgical intervention.[100]

In the early or exudative phase of parapneumonic effusion, the fluid is thin and serous or serosanguineous. This may resolve during appropriate antibiotic therapy either without drainage or with multiple needle aspirations. If the pH is over 7.3, this method may be preferred. If the pH is less than 7.0, however, complete drainage should be performed, often requiring closed chest tube insertion. If the pH is between 7.0 and 7.3, failure to demonstrate improvement of infection or inflammation on multiple thoracenteses over 3 to 4 days should lead to consideration of formal drainage, especially if the primary process is adequately treated. Loculation of pleural fluid or failure to respond to antimicrobial therapy may require either multiple thoracenteses guided by ultrasound or chest tomographic evaluation (CT scans) or surgical intervention. Bloody fluid or persistent parapneumonic fluid should prompt cytologic evaluation and CT scans for lung masses or undrained mediastinal or retrocardiac collections.

Empyema diagnosed later in the course, persistently infected pleural fluid, viscous fluid, or fluids with acid pH may require large-bore tube drainage. This heavily proteinaceous fluid is characteristic of the fibropurulent phase of the evolving empyema. Indications for closed chest tube placement include bronchopleural fistula with empyema, loculated fluid unresponsive to thoracentesis and antibiotics, the presence of blood clots, and rapidly accumulating empyema not otherwise manageable. Under suction, and with removal of the gel-like material, pus, and clots, the lung expands and obliterates the empyema space. Failure to expand the underlying lung, persistence of drainage beyond 7 days, inability to achieve drainage assessed radiologically, fever without change in 2 to 3 days, or pus formation with persistent infection (as opposed to colonization of the chest tubes) necessitates a search for undrained foci of infection, failure to close a bronchopleural fistula or esophageal tear, undetected rupture of a lung abscess, or antibiotic failure. As the infection enters the chronic phase, open drainage with rib resection or pleurocutaneous fistula formation may be needed, with or without decortication, to achieve lung expansion and healing. Open drainage is obtained by making the pleura adherent to the chest wall during the insertion of chest tubes directly into the empyema cavities. Drainage achieved too late in the course of infection may result in the development of pleural scar and fibrous peel with restrictive pulmonary physiology. Decortication may be needed to achieve sterilization of the pleural space and restore lung expansion. Thoracoscopic drainage of empyema has been used with excellent results at a number of institutions, particularly in children. Often, thoracoscopic drainage of empyema is used as a temporizing maneuver (e.g., following acute rupture of a lung abscess into the pleural space). Patients achieving rapid re-expansion of the lungs may avoid open drainage procedures while achieving limited decortication and disruption of loculations. Alternatively, once a patient is stabilized and can better tolerate open drainage, or has demonstrated an inability to resolve the empyema without further drainage, surgical intervention may be needed. Early, aggressive treatment of empyema may reduce the duration of hospitalization and the risk of nosocomial superinfection.

CHAPTER 128

Acute Bronchitis and Community-Acquired Pneumonia

Thomas J. Marrie

ACUTE BRONCHITIS

Acute bronchitis is an inflammation of the tracheobronchial tree, usually in association with a generalized respiratory infection affecting 40/1000 adults each year in the United Kingdom.[1] It is the fifth most common diagnosis in patients presenting with cough.[2] It occurs most commonly during the winter months and is associated with respiratory viruses, including rhinovirus, coronavirus, influenza viruses, and adenovirus. *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Bordetella pertussis* may also cause bronchitis. Secondary invasion with bacteria such as *Haemophilus influenzae* and *Streptococcus pneumoniae* may also play a role in acute bronchitis. However in only 50% of persons with acute bronchitis have a pathogen identified.[1]

Cough is the most prominent manifestation of acute bronchitis. Initially, the cough is nonproductive, but later mucoid sputum is produced. Still later in the course of the illness, purulent sputum is present. Many patients with acute bronchitis also have tracheitis. Symptoms of tracheal involvement include burning substernal pain associated with respiration and a very painful substernal sensation with coughing. Rhonchi and coarse crackles may be heard on examination of the chest; however, there are no signs of consolidation and the chest radiograph shows no opacity. Cough persists on average 11.4 days.[1,2]

Most cases of acute bronchitis require measures directed only at relieving cough. There are very few good clinical trials comparing various symptomatic relief measures to placebo so we do not know whether or not they are better than placebo.[1] Such measures include analgesics, antihistamines, antitussives, inhaled or oral beta$_2$-agonists, expectorants and mucolytics. For patients with fever or a predominant tracheitis component and purulent sputum, the sputum should be gram stained and cultured. If there is a predominant microorganism seen in the presence of more than 25 polymorphonuclear neutrophils and fewer than 10 squamous epithelial cells per low-power field, antibiotic therapy directed against *S. pneumoniae* and *H. influenzae* should be instituted. Most patients, however, do not require antibiotic therapy for acute bronchitis; it is a self-limited disease. Indeed, overuse of antibiotics in this setting is a driver of antimicrobial resistance.

COMMUNITY-ACQUIRED PNEUMONIA: EPIDEMIOLOGY, CLINICAL ASSESSMENT, AND DIAGNOSTIC WORK-UP

Pneumonia is defined as inflammation and consolidation of lung tissue due to an infectious agent (see also Chapter 122). Pneumonia that develops outside the hospital is considered community-acquired pneumonia (CAP). A clinical definition of pneumonia is two or more of the following symptoms/physical findings: productive cough, purulent sputum, dyspnea or tachypnea (respiratory rate >20 breaths per minute), rigors or chills, pleuritic chest pain in conjunction with a new opacity on chest radiograph.[3] Pneumonia developing 72 hours or more after admission to hospital is nosocomial, or hospital acquired. There is still some debate as to whether nursing home–acquired pneumonia (NHAP) should be considered community-acquired or nosocomial pneumonia. In recent years, the concept of healthcare-associated pneumonia (HCAP) has arisen. This term was introduced in 2005 to

recognize that as a result of the shift of many inpatient hospital services to home, ambulatory care facilities and extended care facilities patients were at risk for infections that resembled hospital-acquired infections.[4] HCAP was defined as pneumonia in patients who have been hospitalized in an acute-care hospital for 2 or more days in the past 90 days, have been residents in a nursing home or long-term care facility (nursing home–acquired pneumonia, or NHAP), received intravenous antibiotic therapy, chemotherapy, or wound care within the past 30 days, or attended a hospital or hemodialysis clinic.[5]

This chapter focuses on CAP.

EPIDEMIOLOGY

CAP is both a common and serious illness. In combination with influenza, it is the most frequent cause of infection-related death and the eighth leading cause of death overall in the United States.[6,7] CAP occurs in approximately 4 million adults in the United States—accounting for 10 million physician visits, 1.1 million hospitalizations, and 50,000 deaths per year.[8–10] It accounts for ~3.5 million deaths each year globally and is the highest cause of mortality among infectious diseases.[11] Changes in the epidemiology (both emergence of new pathogens and changing antimicrobial susceptibility of old ones) of the various pathogens, difficulty in making an etiologic diagnosis and complex guidelines for management make this illness a challenge for both patients and their physicians.

The overall attack rate is about 12 cases per 1000 persons per year. In adults, the rate of admission to hospital for the treatment of pneumonia is low from age 17 to 55 years, at which point it begins to increase. The attack rates are highest at the extremes of age.

The epidemiology of pneumonia has changed in recent years. This is due in part to changes in the population at risk and in part to the discovery of new microbial agents that cause pneumonia and changes in antimicrobial susceptibility of old microbial agents, such as *S. pneumoniae, H. influenzae,* and *Staphylococcus aureus.* Population changes include continued increase in the number and proportion of patients who are 65 years of age or older.

There has been a steady increase in the number of organ transplant recipients in the general population and in the number of patients with HIV infection. This has created a subset of patients with CAP who may be infected not only with the traditional pathogens that cause pneumonia but also with opportunistic pathogens; furthermore, these patients may have severe or atypical presentations of this infection. Newer pathogens recognized as causing pneumonia include Hantavirus, SARS CoV, human metapneumovirus, *S. aureus* isolates carrying the Panton-Valentine leukocidin (PVL) genes, and methicillin-resistant *S. aureus* (MRSA). *Pneumocystis jiroveci,* previously a rare cause of pneumonia in intentionally immunocompromised patients, is a common cause of pneumonia in HIV-infected patients with CD4 counts of less than 200/μL.

In a study carried out in a Swedish town in which all persons 60 years of age and older were studied, independent risk factors for CAP were alcoholism, relative risk (RR) 9; asthma, RR 4.2; immunosuppression, RR 1.9; age greater than 70 years versus age 60 to 69 years, RR 1.5.

Risk factors for specific etiologies of pneumonia may differ from those for pneumonia as a whole. Thus, dementia, seizures, congestive heart failure, cerebrovascular disease, and chronic obstructive lung disease were risk factors for pneumococcal pneumonia in one study. In other studies, cigarette smoking and asthma have been found to be independent risk factors for invasive pneumococcal disease. Among HIV-infected patients, the rate of pneumococcal pneumonia is 41.8 times higher than those in the same age group who are not HIV infected. However, with the advent of highly active antiretroviral therapy, the incidence of pneumococcal bacteremia among HIV-infected persons has dropped from 24.1 episodes per 1000 patient-years to 8.2 per 1000 patient-years. Up until a recent study from the Centers for Disease Control and Prevention, the effect of chronic illness on the incidence of invasive pneumococcal disease in adults was underappreciated. In this study, the overall incidence rates of invasive pneumococcal disease was 8.8/100,000 adults. For those with diabetes it was 51.4; 62.9 for adults with chronic lung disease; 93.7 for those with chronic heart disease; and 100.4 among those who abused alcohol. The rate was highest in adults with solid cancer, 300.4, and HIV/AIDS, 422.9.

Risk factors for Legionnaires' disease include male gender, tobacco smoking, diabetes, hematologic malignancy, cancer, end-stage renal disease, and HIV infection. Risk factors for severe respiratory syncytial virus infection in elderly persons include the presence of underlying chronic pulmonary disease (odds ratio [OR] 3.97), functional disability (OR 1.67), and low serum neutralizing antibody titer (OR 5.89). The usual risk factors for aspiration pneumonia are altered level of consciousness and various neurologic diseases that interfere with the swallowing mechanism. Recently, there has been an association between the use of gastric acid suppressive drugs and aspiration pneumonia. The incidence rates of pneumonia in non–acid-suppressive drug users and those who used these agents was 0.6 and 2.45 per 100 person-years, respectively. The risk seemed to be highest among those using proton pump inhibitors.

There is seasonal variation in the rate of pneumonia. Both attack rates and mortality rates are highest in the winter months. This is likely due to many factors, including more time spent indoors (crowding) and hence more opportunity for person-to-person spread of infectious agents. In a study carried out in Tennessee, the weekly frequency of invasive pneumococcal disease correlated with the weekly frequency of isolation of respiratory syncytial virus and influenza virus.

Antimicrobial resistance of the common bacterial pathogens is also a key component of the epidemiology of CAP. Penicillin-resistant *Staphylococcal pneumoniae* (PRSP) is now a fact of life in most North American communities. Many of the PRSP isolates are resistant to three or more antibiotic classes (multidrug resistance). In one study, 14% of bacteremic *S. pneumoniae* isolates were resistant to penicillin, 12% to ceftazidime, and 24% to trimethoprim–sulfamethoxazole. In a recent study, the investigators examined 1817 *S. pneumoniae* isolates collected from patients with community-acquired respiratory tract infections at 44 US medical centers during the winter of 2002 to 2003. The overall rates of resistance were as follows: penicillin 34.2%; ceftriaxone 6.9%; erythromycin 29.5%; clindamycin 9.4%; tetracycline 16.2%; and trimethoprim–sulfamethoxazole 31.9%. There was no resistance to the following agents: vancomycin, linezolid, and telithromycin. Multidrug resistance was present in 22.2% of the isolates and 2.3% of the isolates had ciprofloxacin MICs of greater than or equal to 4 μg/mL. Currently in the United States about 26% of *S. pneumoniae* are resistant to penicillin and 25% are resistant to erythromycin.[12] However within serotype nonsusceptibility varies widely across the various states.[12] Serotypes 6C, 15A, 19A, 23A account for most of the penicillin nonsusecptibility and 6C, 15A, 19A, and 22F account for most of the isolates that are both penicillin and erythromycin nonsusceptible.[12] Fortunately, it is possible to predict who is likely to have pneumonia due to PRSP. Previous use of beta-lactam antibiotics, alcoholism, noninvasive pneumococcal disease, age less than 5 or greater than 65 years, and immunosuppression are risk factors for PRSP pneumonia. In Canada, *S. pneumoniae* resistance to levofloxacin remains very low, peaking at 1.5% in 2008, while no isolates tested in 2011 were resistant.[13] However in Spain 3.3% of *S. pneumoniae* isolates are resistant to levofloxacin and there is evidence of clonal spread.[14]

CLINICAL MANIFESTATIONS

Symptoms that are suggestive of pneumonia include fever, chills, pleuritic chest pain, and cough. The cough may be nonproductive (dry) or productive of mucoid or purulent sputum. It may be rusty in color and frankly bloody; in patients with a lung abscess (anaerobic infection), it may have a foul odor. The latter is suggestive of anaerobic infection.

TABLE 128-1 Clues to the Etiology of Pneumonia from the History and Physical Examination

Feature	Organism
Environmental	
Exposure to contaminated air-conditioning cooling towers, recent travel associated with a stay in a hotel, exposure to a grocery store mist machine, visit or recent stay in a hospital with contaminated (by *L. pneumophila*) potable water	*Legionella pneumophila*
Pneumonia after windstorm in an endemic area	*Coccidioides immitis*
Outbreak of pneumonia in shelters for homeless men, jails, military training camps	*Streptococcus pneumoniae; Mycobacterium tuberculosis*
Exposure to contaminated bat caves, excavation in endemic areas	*Histoplasma capsulatum*
Animal contact	
Exposure to infected parturient cats, dog, cattle, sheep, or goats	*Coxiella burnetii*
Exposure to turkeys, chickens, ducks, or psittacine birds	*C. psittaci*
Exposure to mouse droppings	Hantavirus
Travel history	
Travel to Thailand or other countries in Southeast Asia	*Burkholderia (Pseudomonas) pseudomallei (melioidosis)*
Pneumonia in immigrants from Asia, India, Africa	*M. tuberculosis*
Travel almost anywhere	*Legionella species*
Occupational history	
Pneumonia in a healthcare worker who works in a large city hospital with patients infected with HIV	*M. tuberculosis*
Welding	*S. pneumoniae*
Host factors	
Diabetic ketoacidosis	*S. pneumoniae* *Staphylococcus aureus*
Alcoholism	*S. pneumoniae* *Klebsiella pneumoniae* *S. aureus*
Chronic obstructive lung disease	*S. pneumoniae* *Haemophilus influenzae* *Moraxella catarrhalis* *Pseudomonas aeruginosa* (in the subset of patients with advanced COPD)
Solid-organ transplant recipient (pneumonia occurring >3 mo after transplant)	*S. pneumoniae* *H. influenza* *Legionella* spp. *Pneumocystis jiroveci* *Cytomegalovirus* *Strongyloides stercoralis*
Sickle cell disease	*S. pneumonia*
HIV infection with	*P. jiroveci*
CD4 cell count <200/μL	*S. pneumonia* *H. influenza* *Cryptococcus neoformans* *M. tuberculosis* *Rhodococcus equi*
Physical findings	
Periodontal disease and foul-smelling sputum	Anaerobes, may be mixed aerobic-anaerobic infection
Bullous myringitis	*Mycoplasma pneumoniae*
Absent gag reflex, altered level of consciousness, or a recent seizure	Polymicrobial (oral aerobic and anaerobic bacteria) can be macro- or microaspiration
Encephalitis	*M. pneumonia* *C. burnetii* *L. pneumophila*
Cerebellar ataxia	*M. pneumonia* *L. pneumophila*
Erythema multiforme	*M. pneumonia*
Erythema nodosum	*C. pneumonia* *M. tuberculosis*
Ecthyma gangrenosum	*P. aeruginosa* *Serratia marcescens*
Cutaneous nodules (abscesses) and CNS findings	*Nocardia* spp.

Source: Reproduced with permission from Marrie TJ. Community acquired Pneumonia. Clin Infect Dis. 1994;18(4):501–513.

Elderly patients complain of fewer symptoms than do younger patients. Indeed, those greater than 75 years of age with pneumonia had 3.3 fewer total symptoms than did patients aged 18 to 44 years with pneumonia.

For some time it was held that typical pneumonia (due to pyogenic organisms such as pneumococcus, staphylococcus, or *H. influenzae)* could be distinguished from that due to *M. pneumoniae*, *Legionella* spp., and *C. pneumonia* – so-called atypical pneumonia agents – on the basis of a distinct clinical presentation. Atypical pneumonia is said to be characterized by a more indolent illness than that of typical pneumonia, with a cough that is nonproductive or productive of mucoid sputum only. Careful studies have shown that one cannot reliably distinguish between typical versus atypical pneumonia on clinical grounds. However, this is not to say that a careful history and physical examination are not helpful in suggesting a cause of the pneumonia. Table 128-1 gives a partial list of clues to the cause of pneumonia that may be obtained from the history and physical examination.

Nonrespiratory symptoms such as headache, nausea, vomiting, abdominal pain, diarrhea, myalgia, and arthralgia are also common symptoms in patients with pneumonia. It is wise to remember that the elderly complain of fewer symptoms with pneumonia than do younger patients.

In some instances extrapulmonary signs and symptoms may dominate the clinical picture. Thus, *M. pneumoniae* may be complicated by a variety of neurologic manifestations including encephalitis, meningitis, and cranial nerve palsies. In addition a maculopapular skin rash is not uncommon. Occasionally, Stevens–Johnson syndrome develops. Patients with *Legionella* pneumonia may have glomerulonephritis or cerebellar ataxia. One should also remember that pyogenic bacteria that cause pneumonia *(S. aureus, S. pneumoniae)* can cause metastatic infections such as endocarditis, brain abscess, and meningitis. Indeed, all patients with pneumonia and *S. aureus* bacteremia should have a careful evaluation for endocarditis.

■ PHYSICAL EXAMINATION

Fever is usually present, but some patients may be hypothermic (a poor prognostic sign), and some (20%) are afebrile at the time of presentation with pneumonia. Crackles are heard on auscultation over the affected area of lung, and physical findings of consolidation (dullness to percussion, increased tactile, vocal fremitus, whispering pectoriloquy, and bronchial breath sounds) are present in about 20% of patients with pneumonia. A pleural friction rub is heard in about 10% of cases. Early in the course of the illness physical examination of the chest may be normal. It is most important to count the respiratory rate for at least 1 minute in patients suspected of having pneumonia. A respiratory rate of ≥28 breaths per minute in an adult is indicative of severe pneumonia and an alert that such patients are at high risk for respiratory failure.

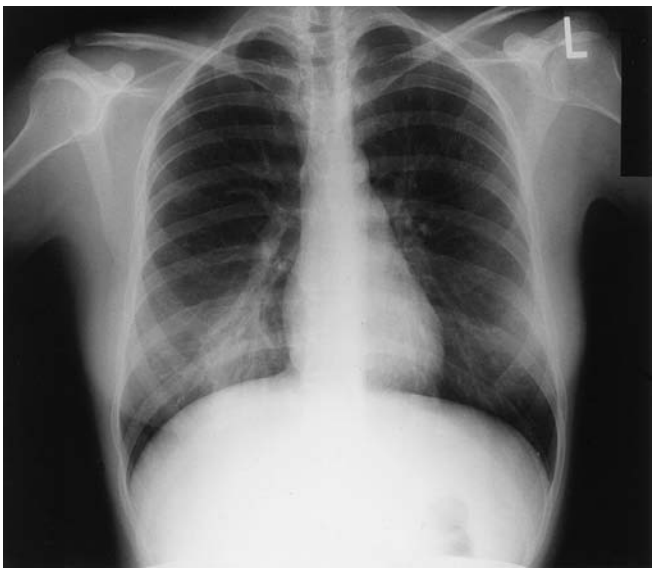

Figure 128-1 Right lower lobe pneumonia due to *Coxiella burnetii* (Q fever). This young woman developed pneumonia after exposure to the products of conception of her infected pet cat.

■ RADIOGRAPHIC DIAGNOSIS

A clinical suspicion of pneumonia usually prompts a chest radiograph. An opacity on the chest radiograph is considered the gold standard for the diagnosis of pneumonia. However, this opacity may be due to infection, infarction, hemorrhage, edema fluid, malignancy, or inflammation caused by a variety of processes, such as vasculitis or adverse drug reactions. Several studies have shown that radiologists cannot differentiate bacterial from nonbacterial pneumonia on the basis of the radiograph. Representative chest radiographs of patients with pneumonia are shown in Figures 128-1 to 128-4. For patients with pneumonia treated on an ambulatory basis, there is considerable disagreement (in up to 50% of cases)

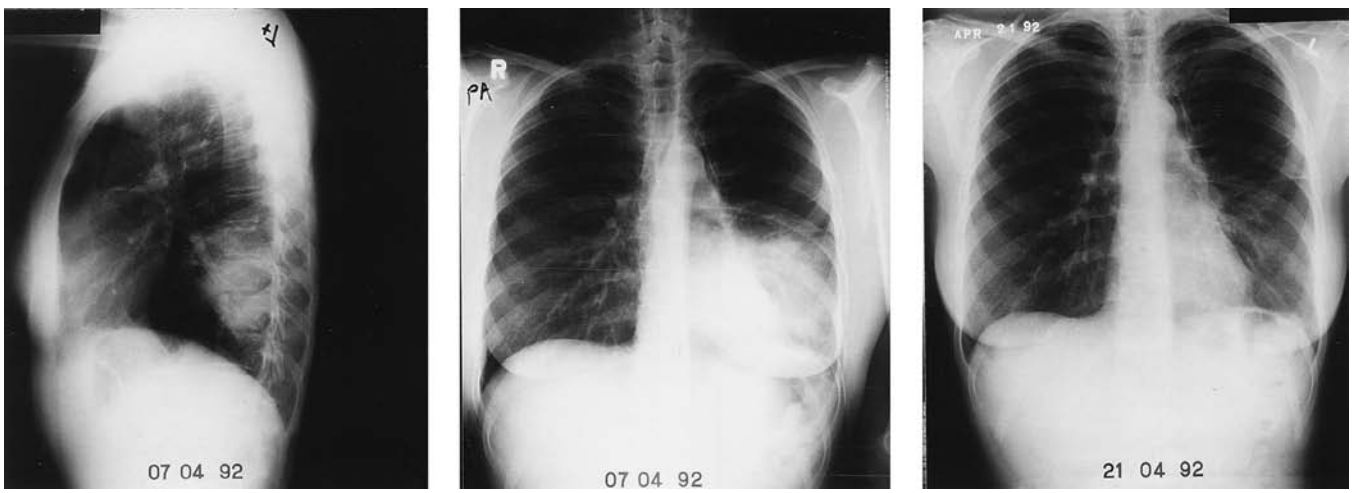

Figure 128-2 Serial chest radiographs of a 32-year-old nurse with *Chlamydia psittaci* pneumonia. She was severely ill with fever, chills, and headaches. She had severe fatigue for 8 months after this episode of pneumonia.

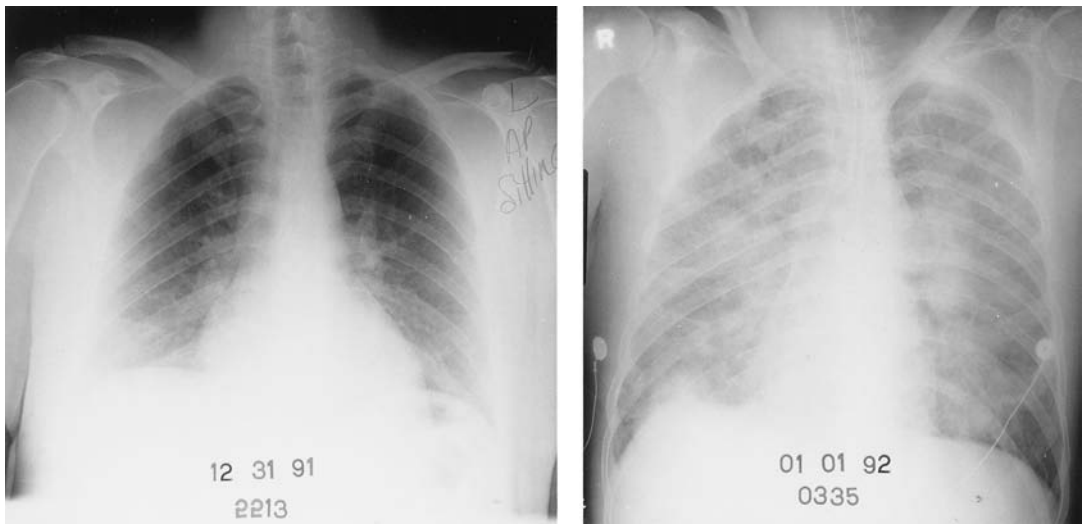

Figure 128-3 Chest radiographs showing rapidly progressive diffuse pulmonary opacities in a 22-year-old man with bacteremic *Streptococcus pneumoniae* pneumonia. This patient had had his spleen removed 6 years earlier. He rapidly developed septic shock and died about 8 hours after admission.

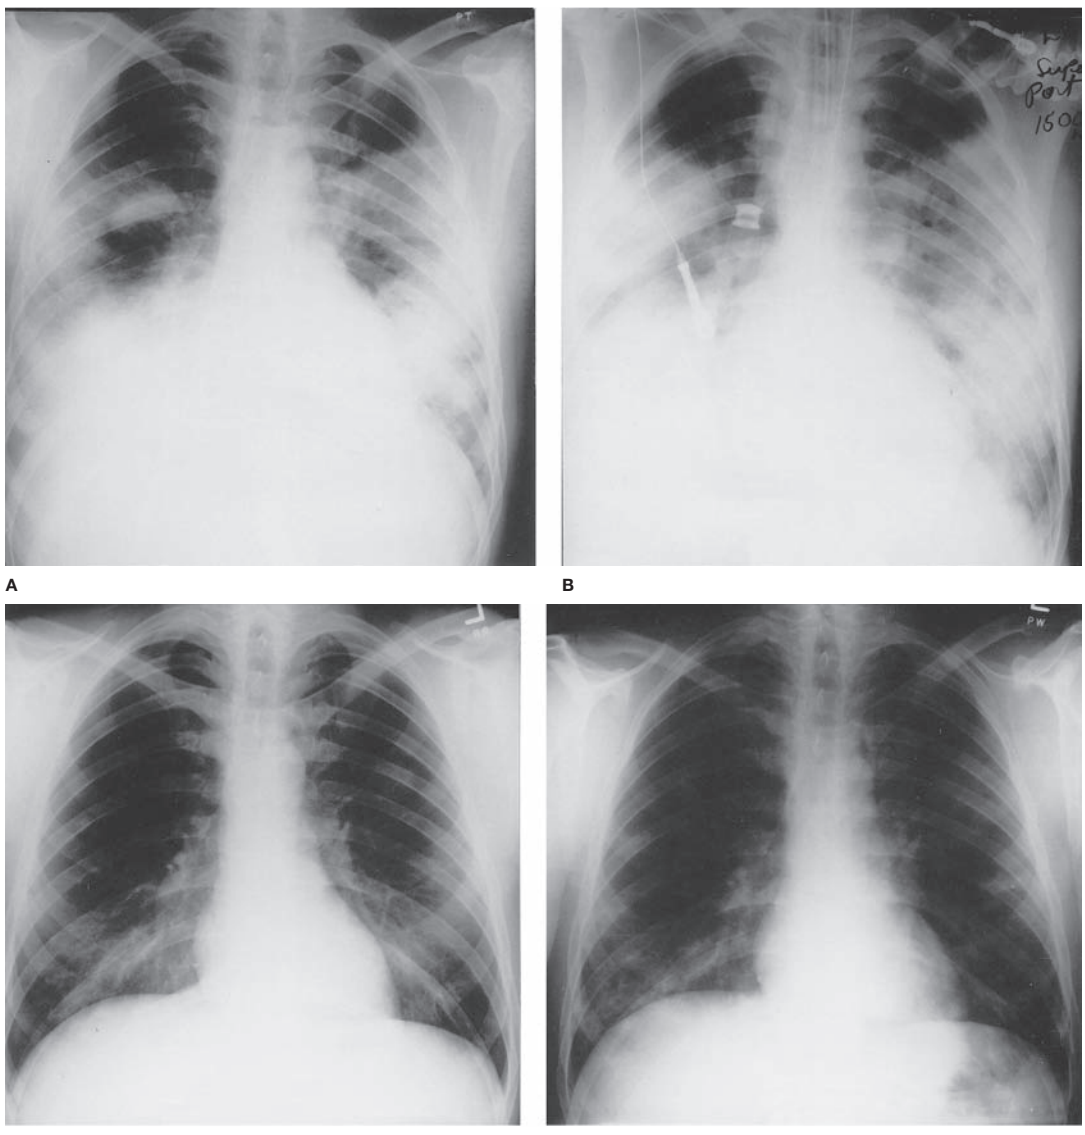

Figure 128-4 Serial chest radiographs (temporal sequence: A., B., C., D.) of a 40-year-old man with pneumonia due to *Legionella pneumophila* serogroup 6.

between the radiologist's reading of the chest radiograph regarding the presence of pneumonia compared with that of the attending physician. In about 20% of patients with symptoms compatible with pneumonia and a plain chest radiograph read as normal or no pneumonia by the radiologist, computed tomography of the chest will be compatible with pneumonia. It is noteworthy that when patients who are admitted to hospital with a clinical diagnosis of pneumonia (radiologist says no pneumonia) are compared with those with radiologist-confirmed pneumonia, there is no difference in mortality between the two groups. While the percentage of patients with positive blood cultures does not differ between the groups, the microorganisms isolated do; about 60% of the isolates for those with definite pneumonia are *S. pneumoniae* compared with 31% for those with clinical pneumonia.

■ ETIOLOGIC DIAGNOSIS

Pneumonia represents a difficult challenge for the clinician, since the etiology cannot be determined from the clinical presentation and data from microbiologic studies are not available for at least 48 hours. Even then, in the case of microorganisms isolated from the sputum, one cannot be sure that this is the organism causing the pneumonia, and not just a microorganism that had colonized the upper airway through which the sputum passed on its way to the specimen jar. For this reason, it is useful to categorize the etiology of pneumonia as definite or probable (Table 128-2).

Newer tests that can be used to help make an etiologic diagnosis of pneumonia include testing urine for antigens of *S. pneumoniae* or *Legionella*. However, only tests for *Legionella pneumophila* serogroup 1 are readily available. Nasopharyngeal swabs can be test for a variety of pathogens using multiplex polymerase chain reaction.

The etiology of CAP as determined in prospective studies is given in Tables 128-3 to 128-5. Table 128-4 shows data for patients with severe pneumonia requiring admission to intensive care units. Table 128-5 gives the etiologic data for bacterial pneumonia in patients with HIV infection. Early in the course of the HIV epidemic, *P. jiroveci* accounted for most cases of pneumonia. Now, with widespread use of prophylaxis to prevent *Pneumocystis* pneumonia, bacterial pneumonia is more common in HIV disease than previously seen (see Chapter 123). Indeed, the rates of pneumococcal pneumonia and *H. influenzae* pneumonia are 20 times higher among HIV-infected persons than in those of an age- and sex-matched population without HIV infection. In any young person with pneumococcal bacteremia, consider underlying HIV infection. However, one should not forget about *P. jiroveci* pneumonia, since many persons do not know they have HIV and this form of pneumonia is the presenting manifestation of HIV disease in these individuals. Likewise, one should never forget *Mycobacterium tuberculosis* as a cause of pneumonia, especially in the elderly.

While the data given in the tables are old, these studies remain some of the best that have been done to determine the etiology of pneumonia. In a study carried out at a Veterans Administration Hospital in Houston, Texas during 2011 and 2012, using the most up to date methods, no etiology was found in 45.9%; 23% bacterial cause; 16% viral (about 20% of these had a coinfection with a bacterial pathogen); 26% had a syndrome indistinguishable from bacterial pneumonia and 17% were clearly uninfected.[15]

Given the difficulty in making an etiologic diagnosis investigators have sought a biomarker that would distinguish bacterial infection from viral infection or noninfectious causes. Procalcitonin is the biomarker that has been most intensively studied. Procalcitonin is the hormone precursor of calcitonin expressed by C cells of the thyroid gland. The rationale for measuring procalcitonin is that its conversion to calcitonin is inhibited by a number of cytokine and bacterial endotoxins, hence in bacterial infections procalcitonin levels will be high. Indeed a number of studies have shown that serum procalcitonin levels rise and fall rapidly in bacterial infections. A level of 0.25 ng/mL or higher in the setting of pneumonia is felt to be predictive of a bacterial infection as the cause.[16] While a number of studies to date have validated the usefulness of procalcitonin as an aid to starting or stopping antimicrobial therapy, it is only that an aid.

■ ADMISSION DECISION

Once a diagnosis of pneumonia has been made, the next decision is whether or not to admit the patient to the hospital. Now, more than ever, there is considerable pressure to treat as many patients as possible at home. In order to do this, it is important to know the factors that are predictive of complicated course in pneumonia, some of which are given in Table 128-6. Several clinical rules that predict mortality have been developed that are often used to guide the admission decision. Two of these are the pneumonia severity index, often known as the patient outcomes research team (PORT) score (Tables 116-7 and 116-8) and the CURB-65 (confusion; urea; respiratory rate; blood pressure; age >65 years) rule (Table 116-9).[17,18] The former, developed by Fine et al.,[17] assigns points to each of 20 different items that had been shown to be associated with mortality (see Table 128-7). This system allows categorization of patients with pneumonia into five strata, with increasing risk for mortality from risk classes I to V. Mortality is less than 1% for patients in risk classes I to III, but increases to 9% in class IV, and

TABLE 128-2 Guidelines for Determining the Degree of Certainty of the Etiology of CAP

Definite
Blood cultures positive for a pathogen
Pleural fluid positive for a pathogen
Presence of *Pneumocystis jiroveci* in induced sputum or in bronchoalveolar lavage fluid
A fourfold or greater rise in antibody titer to *Mycoplasma pneumoniae, Chlamydia pneumoniae, Coxiella burnetii*, or other pathogens for which serologic testing is available
Isolation of *Legionella pneumophila* or a fourfold rise in antibody titer or positive urinary antigen test for *Legionella*
Positive direct fluorescence antibody test for *Legionella* plus an antibody titer of ≥1:256 for *Legionella*
Serum or urine positive for *Streptococcus pneumoniae* antigen
Isolation of Mycobacterium *tuberculosis* from sputum
Amplification of nucleic acid of *Legionella* species from a nasopharyngeal swab specimen
Probable
Heavy or moderate growth of a predominant bacterial pathogen on sputum culture and a compatible Gram stain
Light growth of a pathogen in which sputum Gram stain reveals a bacterium compatible with the culture results
Amplification of nucleic acid of *M. pneumoniae*; *C. pneumoniae*; influenza viruses A and B; parainfluenzae viruses 1, 2, 3; adenovirus, respiratory syncytial virus; human metapneumovirus from a nasopharyngeal swab specimen
Aspiration pneumonia as diagnosed on clinical grounds

TABLE 128-6 Risk Factors for a Complicated Course or Mortality in Patients with CAP

Age >65 years
Comorbid illnesses that are likely to be made worse by the pneumonia, especially chronic renal failure, ischemic heart disease, congestive heart failure, severe COPD, concurrent malignancy
Postsplenectomy state
Altered mental status
Alcoholism
Immunosuppressive therapy
Respiratory rate >30 breaths per minute
Diastolic blood pressure <60 mm Hg; systolic blood pressure <90 mm Hg
Hypothermia
Creatinine >150 mM/L or BUN >7 mM/L
Leukopenia <3000/μL or leukocytosis >30,000/μL
Po_2 <60 mm Hg or Pa_{O_2} >48 mm Hg while breathing room air
Albumin <30 g/L
Hemoglobin <9 g/L
Pseudomonas aeruginosa or *Staphylococcus aureus* as the cause of the pneumonia
Bacteremic pneumonia
Multilobe involvement on chest radiograph
Rapid radiographic progression of the pneumonia, defined as increase in the size of the pulmonary opacity of ≥50% within 36 h

TABLE 128-7 Community-Acquired Pneumonia Severity-of-Illness Scoring System: Assignment of Points[a]

Patient Characteristics	Number of Points
Demographic factors	
Age	
Men	Age in years
Women	Age in years minus 10
Nursing home resident	Age plus 10
Coexisting illnesses (definitions listed below)	
Neoplastic disease[b]	30
Liver disease[c]	20
Congestive heart failure[d]	10
Cerebrovascular disease[e]	10
Renal disease[f]	10
Physical examination findings	
Altered mental status[g]	20
Respiratory rate >30/min	20
Systolic blood pressure <90 mm Hg	20
Temperature <35°C (95°F) or >40°C (104°F)	15
Pulse rate >125/min	10
Laboratory and roentgenographic findings	
Arterial pH <7.35	30
Blood urea nitrogen >30 mg/dL (11 mmol/L)	20
Sodium <130 mmol/L	20
Glucose >250 mg/dL (14 mmol/L)	10
Hematocrit <30%	10
Partial pressure of arterial oxygen <60 mm Hg	10
Pleural effusion	10

[a]*Based on Pneumonia Patient Outcomes Research Team (PORT) cohort study data.*
[b]*Any cancer (except basal or squamous cell carcinoma of the skin) active at presentation or within 1 y of presentation for CAP.*
[c]*Clinical or histologic cirrhosis or chronic active hepatitis.*
[d]*Diagnosis documented by history or by findings on physical examination, chest film, echocardiogram, multiple gated acquisition scan, or left ventriculogram.*
[e]*Clinical diagnosis of stroke or transient ischemic attack, or stroke documented by MRI or CT.*
[f]*History of chronic renal disease or abnormal blood urea nitrogen and creatinine concentrations documented in this medical record.*
[g]*Disorientation as to person, place, or time that is not known to be chronic; stupor or coma.*

to 27% in class V (see Table 128-8). Patients in risk classes I and II can usually be treated at home; those in risk class III may require a period of observation in the emergency room before a decision is made about the optimal site of treatment. Patients with pneumonia generally prefer to be treated at home if it can be done safely. As more experience has been gained with this prediction rule, not unexpectedly we have learned that the rule is only a guide. It does not factor social circumstances into the score and since the score is heavily age dependent, many young patients fall into the first three classes when it is readily apparent that they should be admitted.

In the CURB-65 rule the score can range from 0 (none of the elements present) to 5 (all of them present). For a score of 0 the mortality rate is 0.7%; 1% to 3.2%; 2% to 3%; 3% to 17%; 4% to 41.5%, and 5% to 57% (see Table 128-9).[18]

TABLE 128-8 30-Day Mortality Rate for Patients with Community-Acquired Pneumonia According to Risk Class in the Pneumonia Severity of Illness Scoring System

Risk Class	Criteria	Outpatients Mortality	Inpatients Mortality
I	Age <50 y. No existing illnesses or vital sign abnormalities	0	0.5%
II	<70 points	0.4%	0.9%
III	71–90 points	0	1.25%
IV	91–130 points	12.5%	9.0%
V	>131 points	NA	27.1%
	Mean mortality rate	0.6%	8.0%

However, the most important element in the admission decision is the physician's judgment. Prediction rules are no substitute for this. Functional status of your patient in the week prior to admission is also a powerful predictor of mortality. In one study, for those who were fully functional, the in-hospital mortality rate was 3.9%; for those walking with assistance, it was 5.6%; for those who used a wheelchair, it was 20%; and for those who were bedridden, it was 25%.[19]

DIAGNOSTIC WORK-UP

Patients who are well enough to be treated as outpatients need minimal diagnostic work-up. This should include a chest radiograph, complete white blood count, electrolytes, creatinine, and oxygen saturation by pulse oximetry. It is worth noting that there is controversy as to whether or not all patients who present in an office setting and are suspected of having pneumonia should have the described work-up. However, there is no doubt that those who present to a hospital emergency department and are suspected of having pneumonia should at the very least have the work-up outlined earlier. All individuals who have pleuritic chest pain and symptoms and signs suggestive of pneumonia should have a chest radiograph, and pulmonary thromboembolic disease should be part of the differential diagnosis. Pulmonary infarction can mimic pneumonia on occasion. Despite the opinion of some experts, a sputum specimen should be submitted for culture whenever possible. Blood cultures should be done on all ambulatory patients with fever (oral temperature ≥38°C) and suspicion of pneumonia.

In patients who are ill enough to be admitted to the hospital, two sets of blood cultures should be performed. About 10% of patients with pneumonia have positive blood cultures. *S. pneumoniae* is the most common cause of bacteremic pneumonia, accounting for 60% of all cases. Despite the controversy about the utility of sputum Gram stain and culture, this is still a useful test. Take the time to obtain the specimen yourself. One of the chief reasons why this test has fallen into disrepute is that collecting the specimen is a task assigned to other members of a busy healthcare team. A sample collected hours after antimicrobial therapy has been initiated is useless.

All patients who present to the hospital with pneumonia should have their oxygenation status assessed. This can be done by pulse oximetry, and a blood gas analysis should be obtained if the oxygen saturation is less than or equal to 90%. Patients with chronic obstructive lung disease should have blood gases done because hypercarbia cannot be detected by pulse oximetry.

TABLE 128-9 CURB-65 Rule Severity of Illness Scoring System for Community-Acquired Pneumonia

Confusion : new mental confusion
Urea >7 mM/L
Respiratory rate >30 breaths per minute
Blood pressure: diastolic BP <60 mm Hg or systolic blood pressure <90 mm Hg
Age ≥65 y of age
Group 1: 0 or 1 of the above; mortality low – 1.5%. Likely suitable for treatment at home
Group 2: 2 of the above; mortality – 9.2%. Hospitalization for treatment
Group 3: 3 or more of the above; mortality – 22%. Likely requires admission to ICU

SPUTUM GRAM STAIN AND CULTURE

A sputum specimen should be cultured only if a smear of a representative portion shows more than 25 polymorphonuclear neutrophils and fewer than 10 squamous epithelial cells per low-power field. The Gram stain on such a specimen is useful. If only one morphologic type of bacteria is seen in such a specimen, it is likely that this microorganism is causing the pneumonia. Indeed, in one study, when more than 10 gram-positive lancet-shaped diplococci were seen, the sputum was considered positive for pneumococci. This criterion was met in 62% of specimens that were culture positive for *S. pneumoniae*. The value of sputum culture in the diagnosis, management, and outcome of CAP remains a matter of controversy. The Infectious Diseases Society of America pneumonia guidelines in 2000 recommended gram staining and culture of expectorated sputum for inpatients with CAP.[20] The reasons for this recommendation are to permit optimal antibiotic selection directed to causative agent; limit injudicious antibiotic use in terms of cost, inducible resistance, and adverse drug reactions; allow for a rational basis for change from parenteral to oral therapy and any change in therapy necessitated by an adverse drug reaction; identify drug-resistant pathogens and monitor trends such as penicillin-resistant *S. pneumoniae*, beta lactamase–producing *H. influenzae*, or MRSA; and prompt tracing of the contacts of those with *Neisseria meningitidis* pneumonia. On the other hand, the American Thoracic Society pneumonia guidelines recommend sputum culture only if a drug-resistant pathogen, or an organism not covered by usual empiric therapy, is suspected.[21] The most recent version of the Infectious Diseases Society of America Guidelines now state that a pretreatment Gram stain and culture of sputum should be obtained only if a good quality specimen can be obtained.[22]

In patients with HIV infection, sputum production may be induced by inhalation of hypertonic saline, which irritates the tracheobronchial tree and produces bronchorrhea. This results in a specimen that is useful for examination for *P. jiroveci*, thereby obviating the need for bronchoscopy.

Patients who are ill enough to require admission to an intensive care unit for the treatment of their pneumonia should have an aggressive diagnostic work-up. This will usually include at least a bronchoscopy, with use of a protected brush to sample respiratory secretions and bronchoalveolar lavage. If this is carried out before the initiation of antibiotic therapy, the diagnostic yield is up to 80%. When this procedure is performed after 72 hours or more of antibiotic therapy, however, the microbiologic yield is much lower, 18%.

Transthoracic needle aspiration can be used when the basal segment(s) of the lungs is (are) consolidated. A 20-gauge 3.5-inch needle is used to inject 2 to 3 mL of non-bacteriostatic saline into the lung. This is then aspirated and placed into a blood culture bottle. The diagnostic yield from this procedure ranges from 33% to 85%. This procedure is contraindicated in those who are receiving mechanical ventilation. Occasionally, patients with CAP require an open lung biopsy. However, this is usually a last resort in a patient whose condition continues to deteriorate and there is no etiologic diagnosis despite the usual work-up, including bronchoscopy.

An acute-phase serum sample should be obtained from all patients who are admitted to hospital with CAP. If the patient responds promptly to antibiotic therapy, there is no need to obtain a convalescent sample. If the patient responds poorly to therapy, however, a convalescent sample should be obtained 3 to 6 weeks after the acute-phase sample. The diagnostic battery ordered depends on local epidemiologic conditions. In general, *M. pneumoniae*, *C. pneumoniae*, *Coxiella burnetii*, *Legionella pneumophila*, adenovirus, influenza A and B viruses, parainfluenza viruses 1, 2, and 3, and respiratory syncytial virus antibodies can be measured in most laboratories. Antibody titers to *S. pneumoniae* pneumolysin and detection of immune complexes to this antigen maybe a tool for diagnosis of pneumococcal pneumonia in those who do not have sputum available for culture. However, this test is not widely available.

L. pneumophila serogroup 1 infection can be reliably diagnosed from detection of antigen in urine with a radioimmunoassay or an enzyme-linked immunosorbent assay. In the absence of an outbreak, *Legionella* spp. accounts for about 2% of cases of CAP. Thus, the dilemma is when to order this test. To some extent this depends on local epidemiology (in some hospitals the test is ordered for all patients sick enough to be admitted for treatment of CAP), but in general for patients with severe pneumonia this test probably should be done.

There is also a urinary antigen test for pneumococcal pneumonia. This test detects C polysaccharide, which is present in all serotypes of *S. pneumoniae*. It is reasonably sensitive and specific when bacteremic pneumococcal pneumonia is used as the gold standard. The question is, what is its usefulness in patients with negative blood cultures? There are false positives in children with nasopharyngeal colonization with *S. pneumoniae*.

Multiplex polymerase chain reaction (PCR) is a tool that may be useful in the etiologic diagnosis of CAP. Currently, from one specimen such as a nasopharyngeal swab or sputum, the following agents can be detected by multiplex PCR: *M. pneumoniae*; *C. pneumoniae*; *Legionella* spp.; influenza viruses A and B; parainfluenza 1,2,3 viruses; adenovirus; respiratory syncytial virus; human metapneumovirus; coronaviruses; and rhinoviruses. Using this technology, we have learned that viral pneumonia is more common in adults than was previously recognized. However, more study is necessary before we know the role of multiplex PCR in our diagnostic armamentarium.

Other Tests

C-reactive protein, serum procalcitonin, and neopterin have been used in an attempt to distinguish viral from bacterial infection. An ultrasensitive assay for procalcitonin looks promising in that at a level of less than or equal to 0.25 µg/L, antibiotic therapy has been successfully discontinued in patients with pneumonia. The inference is that patients with this level of procalcitonin have viral pneumonia or a non-infectious, non-inflammatory cause for the pulmonary opacity.

TREATMENT
