The initial therapeutic approach to pneumonia is empirical (see also Chapters 122 and 125).[23] Categorize the severity of the pneumonia as mild, moderate, or severe. It is then usually self-evident where the patient should be treated; at home, in the hospital, or in an intensive care unit. Table 128-10 outlines the guidelines for initial antimicrobial therapy for CAP as proposed by the American Thoracic Society and the Infectious Diseases Society of America. A key concept in selecting empiric antibiotic therapy is to inquire about antibiotic therapy in the past 3 months and then select an agent that has not been used in that time period. If a macrolide has been used in this time period, then up to 35% of *S. pneumoniae* isolates are resistant to a macrolide compared with 7% if the patient did not have macrolide therapy in this time period. For penicillin or a cephalosporin, resistance increases from 5% to 9% in this setting. Thus, use a different class of antibiotic than the one the patient received in the past 3 months.

Since in everyday practice an etiologic diagnosis is frequently not made, antibiotic therapy has to be empirical. Osterheet et al. attempted to answer the question of whether combination therapy or monotherapy with a fluoroquinolone (as recommended by the North American guidelines) is better than other therapy for the empiric treatment of CAP. They carried out a Medline search of studies published from January 1997 to April 2003. Only eight of the 135 articles fit their criteria for further analysis. In six of the eight studies, a significant reduction in all-cause mortality was found for patients treated with a combination of a beta-lactam plus a macrolide or with monotherapy with a fluoroquinolone. Three of these

TABLE 128-10 Initial Empiric Antimicrobial Therapy for CAP

Outpatient
• If previously healthy and no recent antibiotic therapy: a macrolide (strong recommendation), doxycycline (weak recommendation)
• Presence of comorbidities such as congestive heart failure, chronic obstructive pulmonary disease, diabetes, or malignancy or use of antibiotics within the past 3 mo: a respiratory fluoroquinolone–levofloxacin 750 mg or moxifloxacin or gatifloxacin. A beta-lactam plus a macrolide.
• In regions with a high rate (>25%) of infection with high level (MIC ≥ 16 µg/mL) macrolide-resistant Streptococcus pneumoniae, consider use of alternate agents listed above for patients with comorbidities.
Inpatient
Non-ICU
A respiratory fluoroquinolone
A macrolide plus beta-lactam
ICU
Pseudomonas infection is not a consideration: a beta-lactam plus either azithromycin or a respiratory fluoroquinolone
Pseudomonas infection is not a consideration but patient has a beta-lactam allergy: a respiratory fluoroquinolone and aztreonam
Pseudomonas infection is an issue: an antipneumococcal, antipseudomonal beta-lactam (piperacillin–tazobactam, cefepime, imipenem, or meropenem plus ciprofloxacin or levofloxacin 750 mg; or the above beta-lactam plus aminoglycoside and azithromycin. Or the above beta-lactam plus an aminoglycoside and an antipneumococcal fluoroquinolone (for penicillin-allergic patients use aztreonam instead of the beta-lactam)
If community-acquired MRSA is a consideration add vancomycin, or linezolid

Source: Modified with permission from Mandell LA, Wunderink RG, Bartlett JG et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on management of community-acquired pneumonia in adults. Clin Infect Dis. 2007;44 (Suppl 2):S27–S72.

studies involved only patients with bacteremic pneumococcal pneumonia and in one study an effect was noted in one study year, 1993, but not in 1995 or 1997. Seven of the studies were retrospective and two involved administrative data bases. Clearly, a properly designed and conducted randomized clinical trial is necessary to answer this, the most fundamental question in the treatment of CAP.

Data from several retrospective studies suggest that combination therapy of bacteremic pneumococcal pneumonia with a macrolide and a beta-lactam is better than single-agent therapy. Unfortunately, we do not have randomized control data to advise us. Recent data indicate that intravenous cefuroxime should not be used to treat bacteremic pneumococcal pneumonia, because the failure rate is higher than with other regimens.

Once an etiologic diagnosis has been made, treatment should be changed to the cheapest, narrowest-spectrum agent effective against that microorganism. For example, if penicillin susceptible *S. pneumoniae* is determined to be the cause of the pneumonia, penicillin therapy is still the most appropriate treatment.

The response of patients to treatment depends on the severity of the pneumonia and the presence of comorbidities that may be made worse by the pneumonia. Outpatients with mild to moderate pneumonia do very well. Mortality is rare (less than 1%), and only about 4% of patients fail therapy and require hospitalization. The issue of the most appropriate treatment for patients with pneumonia due to PRSP is unclear. We do know that pneumonia due to this microorganism can be treated successfully with high-dose intravenous penicillin. We also know that treatment with penicillin is not successful if there is concomitant pneumococcal meningitis. In this setting, vancomycin and ceftriaxone are recommended. If beta-lactam antibiotics are used, the concentration of the antibiotic must exceed the MIC of *S. pneumoniae* 40% of the time for cure of pneumococcal pneumonia. In one study, high-dose amoxicillin was the most effective oral beta-lactam antibiotic for the treatment of PRSP. Macrolide-resistant *S. pneumoniae* is also an issue in many communities. Because most cases of ambulatory pneumoniae are of unknown etiology and since there is less than 1% mortality among patients with pneumonia treated on an ambulatory basis, a worse outcome for macrolide treated patients versus other antibiotics may not be detected unless large RCTs are performed. Macrolide susceptibility of *S. pneumoniae* is defined as an MIC of up to 0.5 mg/L. The mean MICs for strains resistant because of an efflux mechanism is 10 mg/L; this accounts for 55% of the macrolide resistance in *S. pneumoniae*. Modification of the target (ribosomal) site accounts for 45% of the resistance and results in MICs of 64 mg/L. Thus, strains with resistance due to efflux mechanism may very well respond to treatment with a macrolide, whereas those due to target alteration will not. Resistance due to the efflux mechanism is more common in North America, while the reverse is true in Europe, that is, most resistance is due to target alteration.

The overall mortality for those admitted to hospital for treatment of pneumonia is 8% to 10%. In patients with NHAP, it may approach 40%. For many of these patients, pneumonia is the final common pathway for a variety of chronic debilitating illnesses.

A recent concept in therapy of pneumonia requiring hospitalization is early switch to oral antibiotics. Patients who are stable by hospital day 3 (as evidenced by temperature of 37.5°C or less for 16 hours, white blood cell count returning toward normal, normal hemodynamics, no requirement for auxiliary oxygen, no complications of pneumonia such as empyema, and ability to take antibiotics by mouth) can be switched to antibiotics and discharged shortly thereafter. About one-third of patients qualify for this therapy. Prompt administration of antimicrobial therapy following a diagnosis of pneumonia intuitively makes sense. One study showed a lower mortality rate for elderly patients who received the first dose of antibiotics within 8 hours of presentation to an emergency department. In another large administrative data base study of over 18,000 patients among the 24.4% who were receiving antibiotics prior to presentation, antibiotic therapy within 4 hours of presentation was associated with a reduction in length of stay but not in mortality. Among the 75.6% of patients who were not receiving antibiotics prior to admission, there was both a reduction in length of stay and mortality for those who received their first dose of antibiotic within 4 hours of presentation.

In a study of 399 patients with CAP treated on an ambulatory basis, symptoms had resolved within 14 days in 67%. The mean time to return to work in this population was 6 days compared with a median of 22 days for those who required hospitalization.

Some patients see their condition fail to improve or indeed worsen during therapy. Table 128-11 gives the factors that should be considered in this setting. One should not forget MRSA as a cause

TABLE 128-11 Considerations When Pneumonia Fails to Resolve or Worsens During Therapy

Reconsider the diagnosis of pneumonia: Could this be pulmonary infarction, malignancy, vasculitis, drug reaction, or eosinophilic pneumonia?
Reconsider the etiologic diagnosis: Are you treating the appropriate microorganism(s)?
Remember that 10% of cases of community-acquired pneumonia are polymicrobial.
Tuberculosis can mimic pyogenic pneumonia. Also consider unusual organisms such as *Actinomyces* or *Nocardia* species.
Are you dealing with a resistant microorganism? *Streptococcus pneumoniae* resistant to penicillin, erythromycin, and tetracycline is common in several European countries and the United States.
Has your patient developed nosocomial pneumonia? Such an event is common, particularly in patients who require endotracheal intubation and assisted ventilation. Is your hospital's potable water supply contaminated by *Legionella* spp.? If so, consider nosocomial Legionnaires' disease. Nosocomial Legionnaires' disease should be a consideration anytime a patient with CAP is improving and develops nosocomial pneumonia.
Could this be postobstructive pneumonia (i.e., is endobronchial obstruction present)?
Have you considered empyema? Pus in the pleural space will continue to cause fever until it is drained.
Has metastatic infection occurred? Occasionally, patients who are bacteremic as a result of their pneumonia develop endocarditis, meningitis, septic arthritis, or a deep abscess such as splenic or renal abscess.
Always consider drug fever.

Clin Infect Dis. 2003;37:1405–1433; Mandell LA, Marrie TJ, Grossman RF, et al. Canadian guidelines for the initial management of community acquired pneumonia: An evidence-based update by the Canadian Infectious Diseases Society and the Canadian Thoracic Society. Clin Infect Dis. 2000;31:383–421; Niederman MS, Mandell LA, Anzueto A, et al. American Thoracic Society. Guidelines for the management of adults with community-acquired pneumonia. Diagnosis, assessment of severity, antimicrobial therapy, and prevention. Am J Respir Crit Care Med. 2001;163:1730–1754.

of failure of initial treatment in patients with CAP. Also, in those who are admitted from nursing homes, consider extended spectrum beta-lactamase (ESBL) producing enterobacteriaceae. Radiographic evidence of resolution of pneumonia lags behind clinical resolution and correlates with age and the presence of chronic obstructive pulmonary disease (COPD). In general, those who are under 50 years of age and have no COPD show radiographic resolution of pneumonia within 4 weeks. In contrast, resolution requires 12 or more weeks for those with pneumonia who are older than 50 years and have coexistent COPD or alcoholism. In about 2% of patients, pneumonia is the presenting manifestation of carcinoma of the lung (postobstructive pneumonia). It is important to demonstrate that the pneumonia has resolved radiographically for those who are at risk for carcinoma of the lung. In general, all tobacco smokers and those who are 50 years of age or older and have pneumonia should have a chest radiograph to determine whether or not the pneumonia has completely resolved. Table 128-11 gives an approach to the patient whose pneumonia is not responding to therapy.

■ ADJUNCTIVE THERAPY

Low-dose corticosteroid therapy is beneficial to those who are relatively adrenal insufficient (less than 9 μg/mL response in cortisol level to a dose of adrenocorticotrophic hormone). Hyperglycemia has been shown to be associated with higher mortality rates in patients who require hospitalization for CAP, so it is likely that control of hyperglycemia will be beneficial to patients with pneumonia and elevated blood sugar.

■ TREATMENT OF PNEUMONIA IN THE NURSING HOME

In one study, if more than two of the following factors were present – respiratory rate greater than 30 per minute, temperature greater than 100.5°F, pulse rate greater than 90 beats per minute, and feeding dependence and mechanically altered diet – the failure rate of therapy of pneumonia in the nursing home was high. It is important to take patients' wishes into consideration in the decision to treat in the nursing home or transfer to the hospital. Treatment with ampicillin for NHAP was associated with a significantly higher failure rate than was treatment with ceftriaxone. It seems that, given their antimicrobial spectrum and almost complete absorption following an oral dose, treatment of NHAP with one of the "respiratory fluoroquinolones" is appropriate, although data from RCTs are still lacking for this group of patients.

PREVENTION

Influenza vaccination of the elderly results in reduction in the rate of hospitalization for pneumonia and influenza by 48% to 57%. The role of pneumococcal vaccine has not been as clearly defined as that of influenza vaccine; however, the Advisory Committee on Immunization Practice recommends pneumococcal vaccine for persons older than 65 years of age. A somewhat unexpected benefit of the use of a protein-polysaccharide conjugated pneumococcal vaccine during childhood has been the reduction of invasive pneumococcal disease in 20- to 39-year olds and among those equal to or greater than 65 years of age. Indeed, in the United States, the incidence of invasive pneumococcal disease among adults 50 years and older declined from 40.8 cases/100,000 prior to the introduction of the vaccine to 29.4 only 4 years later. The rate of death following an episode of invasive pneumococcal disease among adults aged 50 years or older decreased from 6.9 to 5.7/100,000. The authors estimated 6250 fewer cases and 550 fewer deaths per year among those 50 years of age and older in the United States compared with the years prior to introduction of the conjugate vaccine. A recent study by CDC found that one decade after the introduction of the conjugate vaccine there are 168,000 fewer hospitalizations for pneumonia annually among children and adults in the United States.[24] The rate of hospitalization for pneumonia among adults 85 years of age and older decline by 1300.8 per 100,000 per year.[24]

The United States Advisory Committee on Immunization Practices recommends dual vaccination with PPSV23 and 13-valent conjugate vaccine (PCV13) in adults with immunocompromising conditions (e.g., HIV infection, cancer, functional or anatomic asplenia, solid-organ transplantation), cerebrospinal fluid leaks, cochlear implants, chronic renal insufficiency, or nephrotic syndrome.[25]

Prevention of aspiration in those at risk (post-stroke, advanced Parkinson disease, and advanced Alzheimer disease) is difficult. Head positioning, stimulation techniques, exercises to enhance the swallowing reflex, and eating pureed foods can all help to reduce the risk of aspiration. In addition, intensive oral care (cleaning teeth after every meal with an applicator of povidone iodine, and frequent dental care to control plaque) reduced the rate of pneumonia from 19% in the control group to 11% in the treatment group.

Of course, all those who are asplenic should be vaccinated with pneumococcal vaccine, *H. influenzae* B vaccine, and meningococcal vaccine. If possible, this should be done prior to splenectomy.

Patients with hypogammaglobulinemia should have periodic infusions of gammaglobulin in a regimen designed to keep the levels high enough to prevent infection.

QUALITY OF CARE MEASURES: PNEUMONIA

The following have been adopted as quality of care measures for patients with CAP requiring admission to the hospital: blood cultures prior to administration of antibiotics; measurement of oxygenation status; administration of antibiotics within 6 hours of presentation to the emergency department; ascertainment of influenza; and pneumococcal vaccination status and administration of these vaccines as necessary. In addition, for those who smoke tobacco products, at the very least information about cessation, and preferentially counseling regarding cessation of smoking.[26]

A number of studies have examined the effect of using guidelines on patient care, and while the designs have differed, there is a strong suggestion that following guidelines has a "halo effect" in improving patient care and results in decreased mortality and, in some instances, reduced length of stay.[27]

END-OF-LIFE DECISION MAKING

Many patients with CAP are elderly and many of these enter the hospital with advance directives. For all of these patients it is important to discuss life-sustaining measures such as assisted ventilation and admission to an intensive care unit should the need arise.

SPECIFIC PATHOGENS

■ *STREPTOCOCCUS PNEUMONIAE*

S. pneumoniae is still a common cause of pneumonia. Patients with bacteremic pneumococcal pneumonia are more likely to have diabetes mellitus, COPD, or alcoholism than those who have other causes of CAP. Capsular polysaccharide types 14, 4, 1, 6A/6B, 3, 8, 7F, 23F, and 18C are the most frequent causes of pneumococcal disease. The minimal inhibitory concentration (MIC) of penicillin for susceptible strains is under 0.06 μg/mL; isolates with MICs of 0.1 to 1 μg/mL are of intermediate resistance, and those with MICs of at least 2 μg/mL are highly resistant. These levels were established for central nervous system infections, for which trough concentrations of penicillin at 10 times MIC are necessary for cure. Generally, with intravenous antibiotics, high concentrations can be achieved in pulmonary tissue; therefore, even resistant strains of *S. pneumoniae* usually respond to treatment with high doses of penicillin or third-generation cephalosporin. If there is concomitant meningitis, however, both a third-generation cephalosporin and vancomycin should be given.

S. pneumoniae antibiotic resistance may be associated with increased mortality and morbidity in patients with pneumonia due to this pathogen. While the most important factors influencing death in pneumococcal pneumonia, were older age and underlying disease, rather than resistance to beta-lactam agents, however, when deaths during the first 4 hospital days were excluded, mortality was significantly associated with infection by an isolate with a penicillin MIC ≥4.0 μg/mL or a cefotaxime MIC ≥2.0 μg/mL.[27] In a study of 192 patients with bacteremic pneumococcal pneumonia, those with isolates that were not susceptible to penicillin were four times more likely to have a suppurative complication.[28]

STAPHYLOCOCCUS AUREUS

Pneumonia due to this agent is usually of sudden onset, affects persons with comorbid illnesses (except during influenza outbreaks, when healthy young adults may be infected), and is frequently complicated by cavitation (20%), pneumothorax (10%), jaundice (8%), empyema (5%), acute renal failure (5%), and pericarditis (2%).

MRSA is a rare cause of CAP. It does occur, however, and once established in a region, it can be a major problem. Vancomycin or linezolid is used to treat MRSA, whereas cloxacillin or nafcillin is used to treat methicillin-susceptible strains. Surgical drainage is necessary for the treatment of empyema. If multiple-rounded opacities are seen in a patient with *S. aureus* pneumonia, suspect right-sided endocarditis. Toxic shock syndrome may complicate *S. aureus* pneumonia. Strains of *S. aureus* with the gene for PVL have been described recently. PVL is an extracellular product of *S. aureus.* It is associated with primary skin infections such as furunculosis, and severe necrotizing pneumonia. In a recent report of eight cases of severe CAP caused by *S. aureus* strains carrying the PVL gene, six were fatal. The patients were all immunocompetent children or young adults. All had a preceding influenza-like syndrome before developing pneumonia, and the six deaths occurred shortly after diagnosis. Necropsy showed diffuse necrotizing hemorrhagic pneumonia. In another study, PVL-positive infections were more often marked by temperature greater than 39°C ($p = 0.01$), heart rate above 140 beats per minute ($p = 0.02$), hemoptysis ($p = 0.005$), onset of pleural effusion during hospital stay ($p = 0.004$), and leucopenia ($p = 0.001$). The survival rate 48 hours after admission was 63% for the PVL-positive patients and 94% for PVL-negative individuals ($p = 0.007$). Histopathologic examination of lungs at necropsy from three cases of necrotizing pneumonia associated with PVL-positive *S. aureus* showed extensive necrotic ulcerations of the tracheal and bronchial mucosa and massive hemorrhagic necrosis of interalveolar septa. Both methicillin-sensitive and methicillin-resistant strains have been described. Current evidence would favor linezolid as the drug of choice for the treatment of MRSA pneumonia.[29] Newer antibiotics with activity against MRSA include ceftaroline and ceftobiprole.[30]

HAEMOPHILUS INFLUENZAE

This cause of pneumonia is more common in older patients with COPD. Both type B and non-B strains can cause pneumonia. About 30% of all *H. influenzae* isolates now produce beta-lactamase and hence are resistant to ampicillin and amoxicillin. Between 7% and 14% of *H. influenzae* isolates are resistant to trimethoprim–sulfamethoxazole. More than 90% of *H. influenzae* isolates are resistant to erythromycin; and 1% to 2% are resistant to tetracycline. Amoxicillin–clavulanic acid and a second- or third-generation cephalosporin reliably treat *H. influenzae* pneumonia.

STREPTOCOCCUS PYOGENES (GROUP A STREPTOCOCCUS)

This agent is uncommon as a cause of pneumonia. One of its presentations is pneumonia accompanied by explosive pleuritis. Cases of group A streptococcal (GAS) pneumonia maybe accompanied by "toxic strep syndrome." Clindamycin, 600 mg given intravenously every 8 hours is superior to penicillin for the treatment of serious GAS infections. Of 2079 cases of invasive GAS infection, 222 (11%) had pneumonia. The median age was 56 years. Underlying illness was present in 61% of cases. Most cases were community acquired (81%). The case fatality rate was 38% for GAS pneumonia, compared with 12% for the entire cohort with invasive GAS infection. In 2002, the largest outbreak of 127 cases of GAS pneumonia in the United States occurred among military recruits in San Diego. The epidemic continued despite prophylaxis with penicillin and required additional prophylaxis to end it.

MYCOPLASMA PNEUMONIAE

Mycoplasmas including *M. pneumoniae* are the smallest free living organisms with a size (125–150 μm) similar to that of myxoviruses. They are highly pleomorphic due to lack of a cell wall but do have a triple-layered cell membrane that is 75 to 100 Angstroms thick.[31] *M. pneumoniae* accounts for up to 30% of pneumonias treated on an outpatient basis. *M. pneumoniae* infections are endemic in densely populated areas with cyclic increases that result in prolonged epidemics and not infrequently when one member of the family has this infection it spreads to other members of the family.[32,33] Outbreaks have occurred in schools, military bases, and summer camps. The extrapulmonary manifestations of *M. pneumoniae* are many and include cold agglutinin–induced hemolytic anemia, thrombocytopenia, encephalitis, cerebellar ataxia, Guillain–Barré syndrome, Stevens–Johnson syndrome, and myocarditis. This is primarily a disease of younger patients, but it accounts for 5% of all cases of pneumonia in persons 65 years of age or older.

Antimicrobial susceptibility of *M. pneumoniae* can be determined by agar dilution or by the broth-dilution method usually in the form of the metabolism inhibition test. Using these methods, *M. pneumoniae* is susceptible to macrolides, tetracyclines, quinolones, streptomycin, pristinamycin, and ketolides.[34] Erythromycin-resistant strains of *M. pneumoniae* have been isolated from treated patients.[34] Such resistance is due to point mutations in 23rRNA gene and while worrisome so far it is uncommon. Macrolides (erythromycin, clarithromycin, and azithromycin) or tetracyclines are the treatment of choice. Such therapy results in resolution of fever in about 3 days compared with 10 days for placebo.[35] Diagnosis is confirmed serologically or by polymerase chain reaction. Culturing the organism is difficult and is only available in a few specialized laboratories.

LEGIONELLACEAE

From July 21 to 24, 1976, the 58th Annual Convention of the American Legion was held at a hotel in Philadelphia and 182 of the attendees at the convention developed pneumonia.[36] One hundred forty-seven (81%) were hospitalized, and 29 (16%) died. This outbreak of pneumonia of apparent unknown cause triggered an exhaustive epidemiologic and microbiologic investigation by the Centers for Disease Control and Prevention (CDC), culminating in the isolation of a new microorganism, *Legionella pneumophila,* about 6 months later.[37]

From 1976 to present, this family of microorganisms has been found to include 50 species and more than 70 serogroups (there are 15 serogroups of *L. pneumophila*). Two clinical syndrome result from infection with these microorganisms: Legionnaires' disease and a self-limited flu-like illness (Pontiac fever). *L. pneumophila* serogroup 1, the microorganism responsible for the 1976 outbreak in Philadelphia accounts for 70% to 90% of the cases of Legionnaires' disease. Legionnaires' disease can be community or hospital acquired, and it can occur in sporadic, endemic, and epidemic forms. Exposure to contaminated water (showers, cooling towers, or even ingestion of such water and subsequent microaspiration) is the prime mode of acquisition of this illness. Older age, male gender, immunosuppression (especially with

corticosteroids), nosocomial acquisition, end-stage renal disease, and infection with *L. pneumophila* serogroup 5 are risk factors for death from this infection. On a molecular level, a mutation leading to a stop codon at position 392 resulted in a dysfunctional toll-like receptor 5 protein unable to recognize flagellin. This was a risk factor for *Legionella pneumophila* infection. There is now considerable evidence that quinolone antibiotics are superior to macrolides for the treatment of Legionnaires' disease. Azithromycin appears to be the macrolide of choice if this class of antibiotics is used. The disease may continue to progress for up to 4 days despite optimal therapy. Other options are doxycycline, 100 mg given twice intravenously in 24 hours and then 100 mg OD intravenously. Mild to moderately severe LD can be treated for 7 to 10 days while severe cases or LD in immunocompromised hosts should be treated for at least 21 days.

Prompt therapy with agents listed earlier has lowered the mortality rate from LD from around 26% to 5%.[38,39]

HANTAVIRUS

In May 1993, reports of deaths due to severe pulmonary disease were received by the New Mexico Department of Health. Many of the affected persons were residents of the Navajo reservation located near the Four Corners area of New Mexico, Arizona, Colorado, and Utah. Within a few months a new Hantavirus (sin nombre, "no name" virus) had been isolated and shown to be responsible for this outbreak, which affected 17 persons.[40] Hantavirus pulmonary syndrome (HPS) is characterized by a flu-like prodromal illness, followed by rapidly progressive noncardiogenic pulmonary edema. Fever, myalgia, cough or dyspnea, nausea or vomiting, and diarrhea are the most common symptoms. Hypotension, tachypnea, and tachycardia are the usual findings on physical examination. Leukocytosis (often with a severe left shift), thrombocytopenia (median lowest platelet count 64,500/mm^3), prolonged prothrombin and partial thromboplastin times, and elevated serum lactate dehydrogenase concentration are the most common laboratory findings. The mortality rate was high (88%) in the Four Corners outbreak. The initial chest radiograph showed infiltrates in 65% and no abnormality in 24% of patients. Subsequently, 16 patients (94%) had rapidly evolving bilateral diffuse infiltrates. In the few months after identification of this new Hantavirus, two more new Hantaviruses were identified in the United States and cases of HPS continue to be reported. The deer mouse, *Peromyscus maniculatus*, is the primary rodent reservoir for this virus.

The pathogenesis of the infection is that Hantavirus non-lytically infects endothelial cells disrupting their integrity resulting in low-pressure pulmonary edema, which is manifest as severe pneumonia.[41]

CHLAMYDOPHILA PNEUMONIAE

In 1986, Grayston et al.[42] described a new species of Chlamydia as a cause of respiratory tract infections. This organism was later named *C. pneumoniae*.[43] This intracellular pathogen of humans is spread by aerosols. It causes sinusitis, pharyngitis, bronchitis, otitis media, and pneumonia. The last can be as a result of primary infection or as reactivation of latent infection. Primary infection affects mainly young adults and maybe followed by reactive airway disease. Two weeks of treatment with doxycycline is adequate. Clarithromycin is very active in vitro against *C. pneumoniae*, but whether it is superior to doxycycline is not known.

The reactivation type of infection occurs in older adults, often as part of a polymicrobial infection. The rate of *C. pneumoniae* in this setting is unknown.

Diagnosis is by isolation of the organism from respiratory secretions or by serology. A greater than fourfold rise in IgM or IgG by microimmunofluorescence test or a single IgM titer of at least 1:16 or an IgG titer of at least 1:512 is considered diagnostic.

In everyday practice it is probably not worthwhile trying to diagnosis *C. pneumoniae* infection because of its low impact and therapies that are empirically selected to treat pneumonia are effective against this agent.

SEVERE ACUTE RESPIRATORY SYNDROME (CORONAVIRUS)

In November 2002, an outbreak of severe acute respiratory syndrome (SARS) started in Guangdong Province in southern China and spread worldwide, affecting more than 8000 persons. SARS was due to a novel coronavirus that jumped the species barrier from civet cats to humans.[44] In 2013, it was shown that the reservoir of this virus is the Chinese horseshoe bat and that the virus uses the ACE-2 receptor to gain entry into human cells.[45] This bat virus uses angiotensin converting enzyme 2 as a receptor to enter the host cell and trigger a massive cleavage of this enzyme resulting in severe physiological derangements that manifest as severe pneumonia.[46]Patients with typical SARS usually present 2 to 10 days following exposure with nonspecific symptoms including fever, myalgia, headache, malaise, and chills. Three to five days later, a nonproductive cough and dyspnea develop. Twenty percent of patients subsequently develop worsening respiratory distress requiring admission to an intensive care unit. Approximately 10% of all patients die from progressive respiratory distress or complications of their hospital admission, typically around the third week of symptomatic illness.

Approximately 75% of patients have unilateral or bilateral infiltrates on chest radiograph at the time of presentation. The majority of those without visible infiltrates have ground-glass opacities detectable on high-resolution computer tomography at the time of presentation or progress to develop radiographic infiltrates. Generally, radiographic opacities peak between 8 and 10 days after onset of illness and then improve, correlating with the worsening and improvement of respiratory symptoms, but progressive radiographic deterioration may occur associated with a more protracted clinical course. There is no effective antiviral therapy. The management of severe cases is that of the management of severe respiratory failure. Attention to infection control measures designed to prevent spread of SARS is most important.

MIDDLE EAST RESPIRATORY SYNDROME (CORONAVIRUS)

In 2012 a novel coronavirus, Middle East respiratory syndrome coronavirus (MERS-CoV), causing severe respiratory illness emerged in Saudi Arabia. Additional cases and clusters of MERS-CoV infections have been detected subsequently in Saudi Arabia, other Arabian Peninsula countries, and other countries.[47] Just like SARS-CoV bats are the likely host and in the case of MERS-CoV it appears that camels are an intermediary host.[48]

HUMAN METAPNEUMOVIRUS

Human metapneumovirus is a newly described member of the *Paramyxoviridae* family. Since its initial description in 2001, when it was isolated from nasopharyngeal aspirates of young children in the Netherlands, it has been described worldwide. Despite almost universal infection in early childhood, repeat infections do occur in adulthood, and it appears to account for about 2% to 3% of cases of pneumonia in adults. Unfortunately, there are no clinical or routine laboratory features that allow one to distinguish this type of pneumonia from bacterial pneumonia.

MIMIVIRUS

Acanthamoeba polyphaga mimivirus (mimivirus) is a giant DNA virus which was isolated in 1992 during the investigation of an outbreak of CAP in Bradford (England). This giant virus was isolated in the water system of a cooling tower and was first suspected to be a Legionella-like amoebal pathogen by Rowbotham.[49,50] This virus stains gram-positive and it is an uncommon but definite cause of some cases of CAP.

CHAPTER 129

Healthcare-Acquired Pneumonia, Including Ventilator-Associated Pneumonia

Anthony F. Boyer
Marin H. Kollef

INTRODUCTION

Healthcare-associated infections (HAIs) impose a significant economic and clinical burden on healthcare systems. The burden is magnified by increasing infection rates due to multi-drug resistant (MDR) pathogens. Nosocomial pneumonia remains an important etiology of HAIs and consists of three distinct entities: healthcare-associated pneumonia (HCAP), hospital-acquired pneumonia (HAP), and ventilator-associated pneumonia (VAP).[1] Definitions for each of these conditions can be seen in Table 129-1. Three device-associated HAIs are reported to the National Safety Healthcare Network (NHSN), the surveillance branch of the Centers for Disease Control and Prevention (CDC). These include central line–associated blood stream infection (CLABSI), catheter-associated urinary tract infection (CAUTI), and VAP. According to an annual summary by the NHSN published in 2008, VAP accounted for 15.9% of all the reported HAIs, placing third among device-associated HAIs.[2] Nosocomial pneumonia results in excess healthcare utilization and leads to greater mortality. This chapter focuses on the microorganisms responsible for infection, the complexities surrounding the diagnosis, and the preventive and therapeutic management strategies used to combat nosocomial pneumonia.

EPIDEMIOLOGY

HAP, although not a reportable infection, is thought to occur at a rate of 5 to 10 cases per 1000 hospital admissions, and numerous studies indicate that VAP occurs in 9% to 27% of all intubated patients.[1] In a 1-day prevalence study involving critically ill patients across Western Europe, pneumonia was the most common ICU-acquired

TABLE 129-1 Definitions of Nosocomial Pneumonia[a]

Pneumonia Category	Definition
HCAP, healthcare-associated pneumonia	Pneumonia diagnosed in any patient who was hospitalized in an acute care hospital for 2 or more days within 90 d of the diagnosis; resided in a nursing home or long-term care facility; received recent intravenous antibiotic therapy, chemotherapy, or wound care within the past 30 d of the current infection; or attended a hospital or hemodialysis clinic
HAP, hospital-acquired pneumonia	Pneumonia diagnosed 48 h or more after hospital admission
VAP, ventilator-associated pneumonia	Pneumonia diagnosed 48 h or more after endotracheal intubation

[a]*Clinical criteria for pneumonia include new or progressive lung infiltrate and at least two of the following: hyperthermia or hypothermia, elevated white blood cell count, purulent tracheal secretions or sputum, and worsening oxygenation.*

TABLE 129-2 2010 NHSN VAP Rates Based on ICU Location in Major Teaching Hospitals

ICU Location	VAP Cases	Ventilator Days	Rate[a]
Burn	89	15,379	5.8
Medical	208	153,408	1.4
Medical/Surgical	307	167,857	1.8
Neurologic	71	14,837	4.8
Neurosurgical	165	53,966	3.1
Surgical	374	106,736	3.5
Cardiothoracic	218	132,307	1.6
Trauma	555	92,460	6.0

[a]*Expressed as number of VAP cases per 1000 ventilator days.*
Source: Data from Dudeck MA, Horan TC, Peterson KD, et al. National Healthcare Safety Network (NHSN) Report, data summary for 2010, device-associated module. Am J Infect Control. 2011;39(10):798–816.

infection occurring in 10% of patients and accounting for 47% of all ICU-acquired infections.[3] An additional large study conducted in Europe revealed a similar pneumonia rate of 9%.[4] These two studies, in addition to others,[5] demonstrated that mechanical ventilation served as the most important risk factor for nosocomial pneumonia. Therefore, the CDC now reports the incidence of nosocomial pneumonia as cases per 1000 ventilator days.

The NHSN functions as the CDC's surveillance system for HAIs and collects data from more than 5000 participating healthcare facilities. The NHSN data summary report from 2010 categorized rates of VAP based on ICU location.[6] Rates of VAP were highest in burn, surgical, trauma, and neurological/neurosurgical ICUs ranging from 2.5 to 6 cases per 1000 ventilator days. VAP was diagnosed less frequently in medical and medical/surgical ICUs occurring at a rate of 1 to 1.8 cases per 1000 ventilator days (Table 129-2). Recently, the validity of the surveillance system utilized by the NHSN to identify VAP has been questioned. The CDC/NHSN pneumonia (PNEU) definitions (Table 129-3) were thought to lack accuracy, objectivity, and consistency. As a result, the NHSN implemented a new surveillance algorithm for identifying ventilator-associated events (VAEs) in January 2013. The goal of the new algorithm is to identify complications of mechanical ventilation including, but not limited to, to VAP by using objective changes in ventilator parameters indicative of worsening oxygenation (Fig. 129-1).

VAP risk is highest early in the course of hospitalization and increases over time. A multicenter prospective cohort analysis conducted in Canada demonstrated a VAP rate of 14.8 cases per 1000 ventilator days, half occurring on or before day 7.[7] While the cumulative risk for developing VAP increased with duration of ICU stay, the daily risk increased until day 5 and then subsequently decreased. Early-onset VAP usually confers a better prognosis as culprit organisms are more sensitive to antibiotics as opposed to the MDR pathogens often responsible for late-onset VAP (see also Chapter 125).[1]

Determining the economic impact of VAP and the associated morbidity and mortality has been difficult. Critically ill patients have multiple, evolving, complex disease processes making it difficult to isolate VAP as the sole cause of excess cost, morbidity, or death. Multiple studies have been performed with variable results. A case-control analysis revealed a crude mortality of 54%, an attributable mortality of 27%, and a 13-day increase in ICU length of stay compared to matched controls.[8] The effect of VAP on clinical outcomes was slightly reduced in a larger, case-matched, prospective cohort study that demonstrated an attributable ICU length of stay of 4 days and an attributable mortality of 6%.[9] Other case-matched trials failed to show any difference in mortality. A retrospective, matched cohort study using a large US database estimated an increase of >$40000 in mean hospital charges per patient.[10] In addition, a more recent retrospective, matched cohort study using the ICD-9 code to identify VAP revealed a mean

TABLE 129-3 NHSN PNEU Definitions

PNEU Type	Definition
PNU1	Two or more serial chest radiographs with at least **one** of the following: new or progressive and persistent infiltrate, consolidation, or cavitation and At least **one** of the following: • fever (>38°C) • leukopenia (<4000 WBC/mm3) or leukocytosis (≥12,000 WBC/mm^3) • altered mental status in an adult ≥70 y of age without an alternative etiology and At least **two** of the following: • new onset of purulent sputum or change in character of sputum or increased secretions/suction requirements • new onset or worsening cough, dyspnea, or tachypnea • rales or bronchial breath sounds • worsening gas exchange
PNU2	Two or more serial chest radiographs with at least **one** of the following: new or progressive and persistent infiltrate, consolidation, or cavitation At least **one** of the following: • fever (>38 °C) • leukopenia (<4000 WBC/mm^3) or leukocytosis (≥12000 WBC/mm^3) • altered mental status in an adult ≥70 y of age without an alternative etiology and At least **one** of the following: • new onset of purulent sputum or change in character of sputum or increased secretions/suction requirements • new onset or worsening cough, dyspnea, or tachypnea • rales or bronchial breath sounds • worsening gas exchange and At least **one** of the following: • positive blood culture not related to another source of infection • positive pleural fluid culture • positive quantitative culture from minimally contaminated LRT specimen • ≥5% of BAL cells containing intracellular bacteria • histopathologic examination revealing **one** of the following: abscess formation, positive quantitative culture, or invasion of lung parenchyma by fungal hyphae or pseudohyphae

PNU3 is a separate definition applied to immunosuppressed patients. Definitions can be found at www.cdc.gov/nhsn.

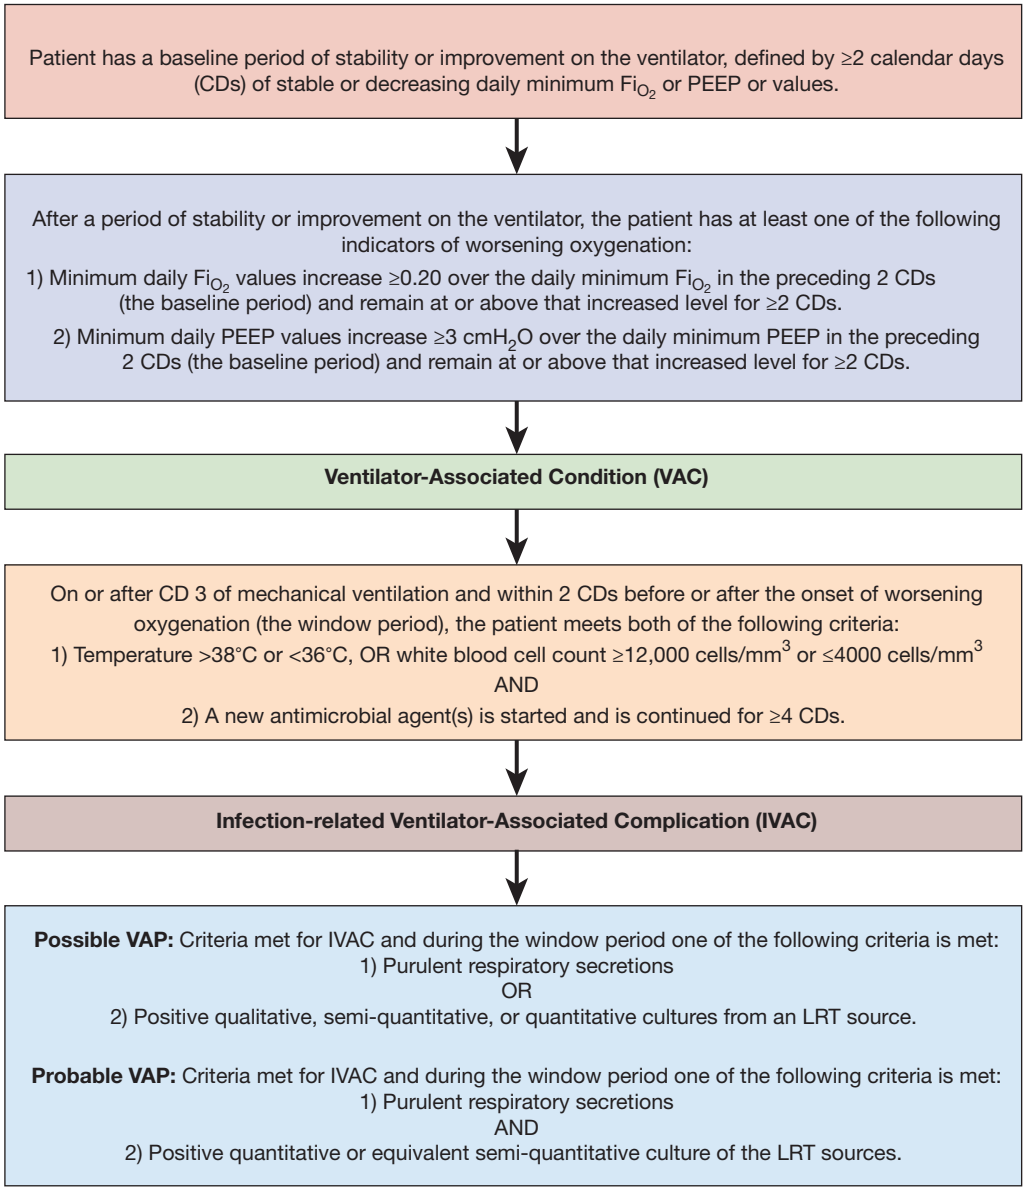

Figure 129-1 Abbreviated NHSN surveillance algorithm for ventilator-associated events.

hospitalization costs of $99598, $39828 greater than those patients without VAP.[11] Recent advances in statistical methodology allow for the control of the effect that severity of illness can have on the attributable mortality associated with VAP, not only at the time of infection but over the course of a hospitalization during disease evolution. Employing a statistical technique from the field of causal inference, an analysis of a large French national database resulted in a milder estimation of attributable mortality associated with VAP, 1% on day 30 and 1.5% on day 60.[12] Additional factors, particularly the timely initiation of appropriate antibiotics, certainly affect the aforementioned estimates. While debate continues over the attributable mortality of VAP, the condition imposes a significant clinical and economic burden.

MICROBIOLOGY

Etiologic agents for nosocomial pneumonia depend on multiple factors including underlying disease, geography, ICU population, duration of mechanical ventilation, previous antibiotic therapy, and the method used to obtain respiratory cultures. Historically, aerobic gram-negative bacilli (GNB) represent the most prevalent pathogens causing nosocomial pneumonia. Enterobacteriaceae embody an important group of bacteria given the importance of aerodigestive colonization in the pathogenesis of VAP. Microorganisms within this group include *Klebsiella*, *Escherichia coli*, *Enterobacter*, *Citrobacter*, *Proteus*, and *Serratia* species. Additional GNB include *Pseudomonas*, *Acinetobacter*, and *Stenotrophmonas* species. These bacteria are ubiquitous in the environment and have minimal nutritional requirements making them suitable for the colonization of hospitalized patients. Summarizing VAP data from 24 trials, GNB represented 58% of recovered organisms.[5] *Pseudomonas aeruginosa* was the most prevalent pathogen accounting for 24% of cases. According to a more recent report by the NHSN in 2008, at least 47% of cases of VAP reported in 2006 and 2007 were due to GNB (Table 129-4).[2]

With the emergence of MDR pathogens, gram-positive organisms, mainly methicillin-resistant *Staphylococcus aureus* (MRSA), have become an increasingly important cause of VAP. A review of the European Prevalence of Infection in Intensive Care study revealed that 31% of nosocomial pneumonias were due to *S. aureus*,[3] and the previously mentioned summary of 24 trials determined that *S. aureus* was responsible for 20.4% of cases of VAP.[5] In the NHSN report from 2008, *S. aureus* accounted for 24% of reported cases and

TABLE 129-4 Distribution and Rank of 5960 Isolated Pathogens Associated with VAP Reported to the NHSN between January 2006 and October 2007

Pathogen	Number of Isolates (%)	Rank
CoNS[a]	79 (1.3)	9
Staphylococcus aureus	1456 (24.4)	1
Enterococcus species	77 (1.3)	10
Candida species	160 (2.7)	7
Escherichia coli	271 (4.6)	6
Pseudomonas aeruginosa	972 (16.3)	2
Klebsiella pneumoniae	446 (7.5)	5
Enterobacter species	498 (8.4)	3
Acinetobacter baumannii	498 (8.4)	3
Klebsiella oxytoca	128 (2.2)	8
Other	1375 (23.1)	

[a]*Coagulase-negative staphylococci.*

Source: Data from Antimicrobial-Resistant Pathogens Associated With Healthcare-Associated Infections: Annual Summary of Data Reported to the National Healthcare Safety Network at the Centers for Disease Control and Prevention, 2006–2007. Infect Control Hosp Epidemiol. 2008;29(11):996–1011.

was the most common etiologic agent, greater than *P. aeruginosa* (16%).[2]

Bacteria responsible for community-acquired pneumonia such as *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Streptococcus pneumoniae* can cause VAP but occur less frequently and often earlier in an episode of mechanical ventilation. Anaerobes, fungi, and *Legionella* species are uncommon causes of VAP but cases have been reported. Also, multiple microorganisms can infect a host leading to polymicrobial infection.

As mentioned earlier, multiple factors can influence the specific microorganism responsible for VAP, but the most important and well studied are the duration of mechanical ventilation at the time of diagnosis, prior antimicrobial use, and local hospital infection patterns. An investigation into the role of stress ulcer prophylaxis on the development of nosocomial pneumonia demonstrated that common organisms such as *S. pneumoniae* and *H. influenzae* along with *S. aureus* were responsible for the majority of cases of early-onset pneumonia.[13] In contrast, GNB other than *H. influenzae* accounted for most cases of late-onset pneumonia. A multivariate analysis conducted in France determined that duration of mechanical ventilation and prior broad-spectrum antibiotic use were significant risk factors for VAP due to potentially drug-resistant bacteria such as MRSA, *P. aeruginosa*, *Acinetobacter baumannii*, and *Stenotrophomonas maltophilia*.[14] Furthermore, a Spanish retrospective review proved that previous antibiotic use resulted in higher rates of *P. aeruginosa* and increased mortality likely due to drug resistance.[15] The variability of microorganisms isolated in cases of VAP among four different centers in Spain and France despite similar patient characteristics highlighted the importance of recognizing a center's local infection profile.[16]

PATHOPHYSIOLOGY

Nosocomial pneumonia most often occurs through the aspiration of microorganisms colonizing the aerodigestive tract in a host with altered immunity. Direct inhalation or hematogenous dissemination of bacteria is less frequent route of infection. Aspiration during sleep is present in a large number of normal subjects, but the volume aspirated is small and more importantly the pathogenicity of the microorganisms is diminished. Hospitalized patients are considered more likely to aspirate larger volumes of virulent bacteria with greater frequency due to decreased sensorium, difficulty swallowing, and impaired gut motility.

The role of colonization of the upper respiratory and digestive tracts has been extensively evaluated. Previous studies demonstrated that 23% of patients admitted to a medical ICU colonized with GNB developed a nosocomial respiratory infection compared to only 3% of noncolonized patients.[17] Later, genomic DNA analysis proved that strains of bacteria isolated from the lower respiratory tract (LRT) in cases of nosocomial pneumonia were identical to those strains colonizing the oropharynx and/or stomach.[18] Hospitalized patients are at risk for colonization due to the potential for contaminated respiratory equipment and hospital water systems, the transmission of bacteria via healthcare workers, the spread of microorganisms through respiratory droplets, and pharmacologically induced alterations in gastric pH.

The endotracheal tube serves as a reservoir for bacteria from the upper airway to leak around the cuff and gain entry into the LRT. Manufacturers have developed novel endotracheal tubes with antimicrobial properties that prevent biofilm formation.[19] Humidifiers and nebulizers can be infected allowing for the transfer of microorganisms between patients by respiratory personnel. Contaminated water supply systems have led to previous outbreaks of nosocomial *Legionella* species. Fungal infections have resulted from hospital renovations and construction, contaminated air supply, and poor filtration.

Critically ill patients requiring mechanical ventilation are prone to develop stress ulcers and thus are often treated with histamine Type 2 (H_2) antagonists and proton pump inhibitors for prevention.[20] In addition, patients frequently require enteral nutrition. Although these strategies provide effective prophylaxis and nutrition, alterations in gastric pH promotes growth of bacteria in a normally sterile environment potentially increasing the risk for nosocomial pneumonia.[13,21]

The early, hyperinflammatory response that occurs in trauma and sepsis can cause multisystem organ failure and death. Improvements in the management of sepsis have decreased rates of early death and patients now often succumb to protracted or nosocomial infections. Recent evidence suggests that a subset of patients who survive the cytokine storm associated with the proinflammatory response of sepsis develop an immunodeficient state promoting viral reactivation and nosocomial infection including pneumonia. Immunomodulator therapies are currently being investigated.[21]

RISK FACTORS

Given the important pathophysiologic roles of aspiration and colonization of the aerodigestive tract, it is logical that the significant risk factors for nosocomial pneumonia involve these processes. A complete list of risk factors can be visualized in Table 129-5.

Mechanical ventilation is the single most important risk factor for nosocomial pneumonia increasing the risk up to 20-fold.[1,4,22] Reintubation also has been associated with the development of VAP.[23] Condensate within the ventilator tubing can become colonized with bacteria and lead to infection if introduced into the LRT. A 2012 Cochrane review found that heat-moisture exchangers that collect less moisture may reduce the incidence of VAP when compared to heated humidification.[24] There is no evidence that frequent changes of the ventilator circuit reduce VAP rates,[25,26] nor does early tracheotomy.[27]

Severity and type of disease are known risk factors for nosocomial PNA. An Apache II score ≥16 and an organ system failure index of 3 or greater have both been linked to VAP.[4,28] Nosocomial PNA occurs more frequently in postsurgical patients, particularly burn and trauma victims.[6,29] Incidence is also higher in COPD likely due

TABLE 129-5 Risk Factors for Nosocomial Pneumonia Determined by Regression Analysis

Aspiration	Colonization	Dual	Other
Supine position	Frequent ventilator circuit changes	Mechanical ventilation	Severity of illness (Apache, SOFA)
Nasogastric tube	Prior antibiotic use	Reintubation	ARDS
Enteral nutrition	COPD	Surgery (trauma, burn, neurosurgery)	Age >60
Decreased endotracheal tube cuff pressure			Transport out of ICU
Neuromuscular disease			PRBC transfusion
Coma/head trauma			
ICP monitor			

Source: Data from Cook DJ, Kollef MH. Risk Factors for ICU-Acquired Pneumonia. JAMA. 1998;279(20):1605–1606.

to greater colonization rates and ARDS as a result of prolonged mechanical ventilation.[30–32]

Aspiration occurs more frequently in the supine position and can be exacerbated by the presence of a nasogastric tube combined with early enteral nutrition.[33–36] Postpyloric feeding may reduce gastroesophageal reflux but the impact on VAP incidence is uncertain. Antacids and histamine Type 2 (H_2) antagonists used for stress ulcer prophylaxis have proved to be independent risk factors for nosocomial PNA as alterations in gastric pH promote colonization.[37,38] In addition, prior antibiotic administration can select for infection by MDR microorganisms.[14,28]

DIAGNOSIS

The diagnosis of nosocomial pneumonia has traditionally been difficult. It should be suspected in any patient with a new or progressive radiographic infiltrate and signs or symptoms indicative of infection such as fever, leukocytosis or leukopenia, purulent sputum, and worsening oxygenation. The accuracy of using the aforementioned clinical findings in diagnosing nosocomial pneumonia ranges depending on the number and type of clinical criteria and is complicated by the lack of a gold standard reference. Even postmortem histologic examination is not 100% specific. The addition of microbiological data to clinical criteria has not definitively improved diagnostic accuracy. The problems associated with diagnosing VAP produced challenges for surveillance systems such as the NHSN. Therefore, as mentioned previously, the CDC created a new surveillance algorithm for the identification of VAEs that include both infectious and noninfectious complications of mechanical ventilation (Fig. 129-1). Due to the lack of a proven diagnostic method, two different strategies have been used and compared using clinical or bacteriologic criteria, each associated with advantages and disadvantages.[1]

The clinical strategy employs the abovementioned clinical and radiographic criteria in diagnosing nosocomial pneumonia. A combination of two out of three clinical criteria and a radiographic infiltrate yielded a sensitivity of 69% and a specificity of 75% for the diagnosis of VAP in 25 mechanically ventilated patients using histology and quantitative lung tissue culture on autopsy as the reference. Increasing the number of clinical criteria resulted in greater specificity but at the cost of lesser sensitivity.[39] However, in a postmortem analysis of 39 mechanically ventilated patients, clinical criteria did not provide a reliable positive predicted value for histologic pneumonia.[40] A semiquantitative endotracheal aspirate culture can be used to identify a pathogen and, if positive, has been shown to correlate with quantitative cultures of the LRT obtained via protected specimen brush (PSB).[41] Also, a negative endotracheal aspirate culture has high sensitivity and good negative predictive value if antibiotics have not recently been changed.[42] However, semiquantitative cultures are not as reliable as quantitative cultures of the LRT due to an inability to differentiate between colonization and infection. The use of clinical criteria and a reliance on semiquantitative cultures can be overly sensitive resulting in unnecessary antibiotic use and potentially delay the identification of extrapulmonary infection.

The bacteriologic strategy uses quantitative cultures of the LRT via endotracheal aspirate, PSB, or bronchoalveolar lavage (BAL) to confirm or eliminate the diagnosis of nosocomial pneumonia based on thresholds of bacterial growth. These thresholds differ depending on the method of respiratory sampling and are as follows: $\geq 10^5$ colony-forming units (CFU)/mL for an endotracheal aspirate, $\geq 10^4$ CFU/mL for a BAL, and $\geq 10^3$ CFU/mL for a PSB. Results of these procedures guide decisions such as when to initiate or stop antibiotics and which drug should be used against the offending agent. There are no definitive data to support the use of one sampling technique over another; however, the cellular analysis of BAL fluid may provide an advantage as a sample containing <50% neutrophils produced excellent negative predictive value in one study.[40] Also, given the multifocal nature of VAP, even mini-BAL samples obtained blindly without the use of bronchoscopy can be effective.[43–45] The bacteriologic strategy has resulted in less and more narrowed antibiotic use, an important point given the surge of antibiotic-resistant microorganisms in the ICU setting.[46–48] A major disadvantage with this approach is the concern for false negatives, which could result in cases of nosocomial pneumonia going untreated, especially in the setting of recently introduced antibiotics.[49]

Multiple studies have compared the clinical and bacteriologic strategies. Only one prospective, randomized trial demonstrated a mortality benefit at 14 days when using the bacteriologic strategy.[46] Others have failed to reproduce these findings, including a large study conducted by the Canadian Critical Care Trials Group and a comprehensive meta-analysis.[50,51] In addition, the bacteriologic strategy does not seem to reduce the duration of mechanical ventilation or ICU length of stay. Ultimately, the decision to employ either strategy rests with the clinician on a case-by-case basis. If bronchoscopic sampling can be performed safely and the appropriate personnel is available, it is reasonable to utilize this approach as antibiotic decisions may change based on culture results. If the clinical strategy is used, the clinician should reevaluate the patient often for guidance on antibiotic usage. Regardless of the diagnostic strategy, an unstable patient with a high pretest probability of nosocomial pneumonia should be initiated on empiric antibiotics as a delay in antibiotic administration leads to higher mortality.[52–57] A diagnostic algorithm adapted from the Washington Manual of Critical Care Medicine can be seen in Figure 129-2.

PREVENTION

Prevention of nosocomial pneumonia centers on minimizing mechanical ventilation and reducing aspiration and bacterial

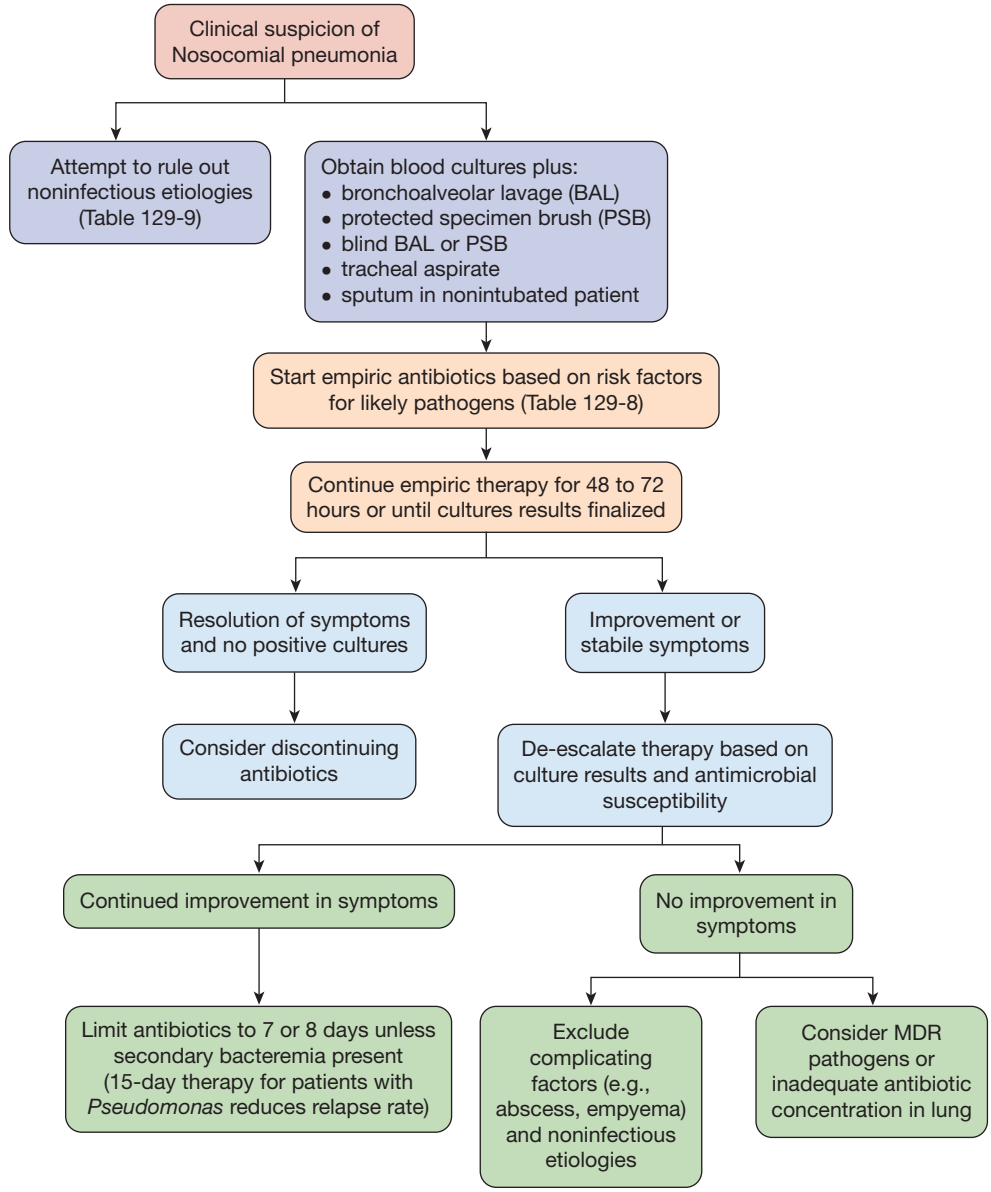

Figure 129-2 A step-by-step approach to the management of nosocomial pneumonia. *(Reproduced with permission from Kollef M, Isakow WA. The Washington Manual of Critical Care, 2nd edition. Philadelphia, PA: Lippincott Williams & Wilkins; 2013.)*

colonization. As mentioned previously, mechanical ventilation is the most important risk factor for nosocomial pneumonia.[1,4,22] Therefore, avoiding intubation and reintubation, shortening the duration of mechanical ventilation, and employing noninvasive methods to improve oxygenation and ventilation when indicated can prevent pneumonia.[22,23,58]

Multiple methods designed to reduce bacterial colonization of the aerodigestive tract have been evaluated for their impact on VAP incidence. Selective decontamination of the digestive tract (SDD) administers nonabsorbable antimicrobial agents directly to the oropharynx and stomach to prevent colonization with GNB and *S. aureus*. While SDD has been shown to have a beneficial effect on nosocomial infection rates and even survival, potential negative effects include cost and the selection for antibiotic-resistant microorganisms when utilized in ICUs with high rates of endemic antibiotic resistance.[59–62] Alternatively, selective oropharyngeal decontamination (SOD) with nonabsorbable antibiotics or chlorhexidine provides a cheaper approach with similar efficacy.[62,63] While systemic antibiotics given once at the time of intubation may reduce early-onset VAP, the routine use of prolonged prophylactic, systemic antibiotics cannot be recommended.[64,65] In addition, probiotics may reduce VAP rates but no studies to date demonstrate a survival benefit.[66]

Strategies to reduce aspiration have also been studied. Patients should not be managed in a supine position, but rather placed in a semi-recumbent position.[67] Continuous aspiration of subglottic secretions has decreased the incidence of VAP in cardiac surgery patients.[68,69] Also, postpyloric feeding may reduce aspiration but the effect on infection rates and mortality is unknown. In addition, there is no evidence favoring a specific time point for the initiation of enteral feeding.[70]

The Institute for Healthcare Improvement developed a programmatic bundle, used by many healthcare institutions in the United States, designed to improve the care of mechanically ventilated patients. Components addressing the prevention of VAP include positioning the patient with the head of the bed elevated at 45 degrees, daily sedation holidays coupled with an assessment of readiness to extubate, and daily oral care with chlorhexidine. Each component, when evaluated independently, has been associated with the prevention of VAP.[71] A similar bundling strategy

TABLE 129-6 Strategies for the Prevention of Nosocomial Pneumonia

Strategy	Recommendation	Evidence Level
Topical iseganan	No	1
Oro-digestive decontamination[b] (Topical/topical plus intravenous antibiotics)	No	1
Oral chlorhexidine	Yes	1
Aerosolized antibiotics[b]	No	1
Intravenous antibiotics[b]	No	1
Specific stress ulcer prophylaxis regimen	No	1
Short-course antibiotic therapy(when clinically applicable)	Yes	1
Routine antibiotic cycling/rotation/heterogeneity[a]	No	2
Restricted (conservative) blood transfusion	Yes	2
Use of noninvasive mask ventilation	Yes	1
Avoid reintubation	Yes	2
Avoid patient transports	Yes	2
Orotracheal intubation preferred for airways	Yes	1
Orogastric intubation preferred for feeding tubes	Yes	2
Routine ventilator circuit changes	No	1
Use of heat-moisture exchanger	Yes	1
Closed endotracheal suctioning	Yes	1
Subglottic secretion drainage	Yes	1
Shortening the duration of mechanical-ventilation	Yes	1
Adequate intensive care unit staffing	Yes	2
Silver-coated endotracheal tube	Yes	1
Polyurethane endotracheal tube cuff	Yes	1
Semi-erect positioning	Yes	1
Rotational beds	Yes	1
Chest physiotherapy	No	1
Early tracheostomy	No	1
Use of protocols/bundles incorporating multiple prevention elements	Yes	2

Evidence levels: 1, supported by randomized trials; 2, supported by prospective or retrospective cohort studies.
VAP, ventilator-associated pneumonia.
[a]May be useful in specific clinical circumstances (outbreaks of a multi-drug resistant bacterial infection).
[b]Routine antibiotic prophylaxis not recommended due to potential emergence of antibiotic-resistant bacteria.

developed by French investigators was evaluated prospectively in a single medical ICU. Components of the bundle included hand hygiene, head of bed elevation, maintenance of tracheal cuff pressure, avoidance of gastric overdistention, good oral hygiene, and minimization of tracheal suction. After an initial educational program for healthcare personnel, compliance with each component increased throughout the 24-month long study.[72] In a companion evaluation, total VAP rates decreased from 22.6 to 13.1 per 1000 ventilator days after implementation of the bundle.[73] A multicenter trial conducted in Spain employing a bundle with comparable measures reduced VAP rates from 12.9 to 9.8 per 1000 ventilator days despite a compliance rate of less than 30% for all five measures.[74] Thus, the bundling strategy appears to reduce VAP rates and could potentially produce a more substantial impact with improved compliance. Table 129-6 contains a list of recommended prevention strategies.

TREATMENT

When initiating empiric antibiotics for the treatment of nosocomial pneumonia, one first needs to assess the patient's risk for infection with MDR microorganisms. Table 129-7 lists these risk factors.[1] Patients with HCAP have been shown to have a comparable microbiological profile to those with HAP and VAP and should therefore be treated in a similar fashion.[75,76] Table 129-8 contains recommended antibiotic strategies for the treatment of nosocomial pneumonia after risk stratification for MDR microorganisms.[1]

Failure to initiate the appropriate antibiotics in a timely fashion results in excess morbidity and mortality.[52–57] Inappropriate

TABLE 129-7 Risk Factors for MDR Pathogens

Antimicrobials in previous 90 d
Current hospitalization for 5 d or greater
High rates of local antibiotic resistance
Hospitalization for 2 d or greater in the previous 90 d
Nursing home or extended care facility resident
Home infusion therapy
Chronic dialysis in previous 30 d
Wound care at home
Immunosuppression

TABLE 129-8 Antibiotic Recommendations for Nosocomial Pneumonia

Pneumonia Category	Microorganisms	Empiric Therapy	Additional Information
HCAP/HAP/VAP No risk for MDR pathogens and hospitalized <5 d	*Streptococcus pneumonia* *Haemophilus influenzae* *Methicillin-sensitive Staphylococcus aureus* *Escherichia coli* *Klebsiella pneumoniae* *Enterobacter* species *Proteus species* *Serratia marcescens*	Third-generation cephalosporin (Ceftriaxone) Or Ampicillin–sulbactam Or Respiratory fluoroquinolone (Levofloxacin or Moxifloxacin) Or Non-antipseudomonal carbapenem (Ertapenem)	Azithromycin should be considered for atypical coverage in very ill patients or ones with a high suspicion for atypical organisms or *Legionella* who are not on a respiratory fluoroquinolone
HCAP/HAP/VAP At risk for MDR pathogens or hospitalized for ≥5 d	*Pseudomonas aeruginosa* *Klebsiella pneumonia* (extended-spectrum β-*lactamase+)* *Acinetobacter* species *Legionella pneumophila* Methicillin-resistant *S. aureus*	Antipseudomonal cephalosporin (Cefepime, Ceftazidime) Or Antipseudomonal carbapenem (Imipenem or Meropenem) Or Antipseudomonal penicillin with β-lactamase inhibitor (Piperacillin–tazobactam) **Plus** Antipseudomonal fluoroquinolone (Ciprofloxacin or Levofloxacin) Or Aminoglycoside (Gentamycin, Tobramycin, or Amikacin) **Plus** Anti-MRSA agent (Linezolid or Vancomycin)	Carbapenems are often effective against ESBL organisms (*E. coli, Klebsiella*) or *Acinetobacter* species For patients with penicillin allergy consider substituting β-lactam with: • Aztreonam • Meropenem (<1% cross reactivity to penicillin allergy) Inhaled antibiotics have been used in selected populations and should be used only after consultation with a subspecialist

antibiotics are those that do not have in vitro activity against the offending pathogen. A large, multicenter study conducted in Spain demonstrated that in 565 cases of nosocomial pneumonia, a change in the initial empiric antibiotic regimen was required in 43.7% of cases. The most frequent reason for a change in therapy was inadequate antimicrobial coverage, which resulted in greater attributable mortality.[53] A multivariate analysis of 107 patients with VAP determined that a delay in appropriate antibiotics for ≥24 hours was an independent risk factor for in-hospital mortality.[54] A separate multivariate analysis proved that prior antibiotic use was an independent risk factor for inappropriate antibiotic therapy; therefore, one should consider the possibility of drug resistance associated with previous antimicrobial agents.[14,57,77] A protocol-based approach to empiric antibiotics resulted in a greater rate of appropriate antibiotics and a reduction in antibiotic duration.[78] In addition, knowledge of each healthcare facility's antimicrobial drug resistance profile is of paramount importance.[16]

Choosing the correct dose of an antibiotic and the route of administration are essential in the treatment of nosocomial pneumonia (see Chapter 125). It is important to know the mechanism of action of each antibiotic. For example, β-lactam antimicrobial agents kill in a time-dependent fashion requiring a serum concentration above the microorganism's minimal inhibitory concentration (MIC). This knowledge has led to the proposition of prolonged infusions, a practice that remains controversial.[79,80] On the other hand, aminoglycoside agents kill bacteria in a concentration-dependent manner leading to newer extended interval dosing parameters. Antibiotics should initially be given intravenously in all cases of nosocomial pneumonia; however, transitioning to oral therapy in certain cases has been proven to be safe and effective.[81] Aerosolized antibiotics offer an appealing treatment route as direct antibiotic delivery to the LRT can create high drug concentrations within the lung parenchyma avoiding systemic delivery and the associated toxicities. However, the challenges accompanying aerosolizing small particles through a mechanical ventilator have limited the use of inhaled antibiotics. While there is no proven clinical benefit, future advancements in nebulizers and drug delivery may create a role for the adjunctive use of aerosolized antibiotics, especially as a way to prevent the emergence of MDR pathogens.[82] Finally, while traditionally thought to have a synergistic effect on the eradication of gram-negative organisms, combination therapy rather provides a greater likelihood of appropriate empiric therapy in the case of MDR microorganisms.[83]

When determining treatment duration for nosocomial pneumonia, the goal is to eradicate the microorganism without allowing for colonization of the host with MDR pathogens. Clinical improvement with appropriate antibiotic therapy usually occurs in 3 to 5 days as shown in a cohort of 63 patients with VAP in which CPIS scores were obtained before and after antibiotic initiation.[84] Survivors had improving CPIS scores by day 3 compared with nonsurvivors. Currently, 7 days is a reasonable duration of treatment, but prolonged therapy should be considered in the case of *P. aeruginosa*. A large French analysis demonstrated that patients with VAP had similar mortality and infection recurrence rates when treated with 8 days of antibiotics versus 15 days. Patients infected with nonfermenting GNB who received only 8 days of treatment had a higher infection recurrence rate compared to the prolonged therapy group, but no difference in mortality was noted.[85] A recent systematic review found no mortality difference between a short course of antibiotics (7–8 days) versus a longer course (10–15 days) in the management of VAP. However, there was a strong trend toward lower relapse rates when using a longer course of antibiotics mainly limited to VAP cases caused by nonfermenting GNB.[86]

In addition, a 7-day course of doripenem compared to a 10-day course imipenem–cilastatin in the management of VAP due to GNB resulted in higher rates of clinical failure and mortality, particularly in those patients infected with *P. aeruginosa*.[87] Empiric antibiotics should be deescalated in responders. Nonresponders should be evaluated for emergence of antimicrobial resistance, extrapulmonary infection, complications of pneumonia such as empyema, and noninfectious causes of fever and pulmonary infiltrates (Table 129-9).

CHAPTER 130

Viral Infections of the Lung and Respiratory Tract

John Treanor

GENERAL PRINCIPLES

Viral infections of the upper and lower airways have a major impact on health. Acute respiratory illnesses, largely caused by viruses, are the most common illness experience for otherwise healthy adults and children (see Chapter 126). The National Health Interview Survey suggests that such illnesses are experienced at a rate of 85.6 illnesses per 100 persons per year, and account for 54% of all acute conditions exclusive of injuries.[1] A total of 44% of these illnesses require medical attention, and result in 287 days of restricted activity, 94.4 days lost from work, and 182 days lost from school per 100 persons per year. Estimates from family-based surveillance suggest that approximately one-fourth of these illnesses result in consultation with a physician. Illness rates for all acute respiratory conditions are highest in young children; children below the age of 9 are estimated to experience between five and nine respiratory illnesses per year, whereas adults experience between three and five such illnesses.[2,3]

Mortality due to acute viral respiratory infection in otherwise healthy individuals in economically developed countries is relatively rare, with the exception of epidemic influenza. However, acute respiratory infection is a major cause of childhood mortality in developing countries, and it is estimated that 4.5 million children under 5 years of age die annually from acute respiratory infection.[4] Viruses are identified in about 3% to 40% of cases of respiratory disease in this setting, and are estimated to play a contributing role in approximately 20% to 30% of deaths. In addition, new and emerging respiratory viruses such as Hantavirus, emerging coronaviruses associated with severe acute respiratory syndrome (SARS) or middle eastern respiratory syndrome (MERS), and transmission of influenza viruses from avian or swine sources to man, pose a continuing threat.

EPIDEMIOLOGY

Many of the viruses associated with acute respiratory disease display a significant seasonal variation in incidence. Although the exact seasonal arrival of each virus in the community cannot be predicted with precision, certain generalizations are useful diagnostically and in planning control strategies. For example, influenza and respiratory syncytial virus (RSV) epidemics both occur predominantly in the winter months, with a peak prevalence in January to March in the northern hemisphere. Parainfluenza virus type 3 (PIV-3) infections show a predominance in the spring, whereas types 1 and 2 (PIV-1 and PIV-2) cause outbreaks in the fall to early winter. Rhinoviruses may be isolated throughout the year, with increases in frequency in the spring and fall. The peak prevalence of enteroviral isolations is in late summer and early fall, whereas adenoviruses are isolated at roughly equal rates throughout the year. The herpes viruses also do not show significant seasonal variation in incidence, except for varicella, which occurs throughout the year, but more commonly in late winter and early spring.

The reasons for these seasonal changes are not entirely clear. One mechanism may involve seasonal effects on virus transmissibility either because of more favorable environmental conditions for virus survival[5] or behavioral changes that increase transmission, such as indoor crowding. Heretofore unknown effects of season on host susceptibility or response to infection could also play a role.

CHARACTERISTICS OF THE VIRUSES

Viruses of importance in the respiratory tract include both those considered to be principal respiratory viruses, whose replication is generally restricted to the respiratory tract, and others in which respiratory involvement is part of a generalized infection. The classification of these viruses depends in part on the type and configuration of the nucleic acid in the viral genome, the characteristics of the viral structural proteins, and the presence or absence of a lipid-containing envelope surrounding the virus particle (Table 130-1). The number of distinct antigenic types in each of the virus families varies. For example, the adenovirus and rhinovirus groups are composed of large numbers of antigenically (serotypically) distinct immunotypes, but other groups, such as paramyxovirus and coronavirus, are composed of only a limited number of immunotypes. The degree of antigenic stability of the virus is an important factor in determining the frequency of reinfection. This characteristic is particularly important for influenza type A virus, which periodically undergoes both minor and major changes in its surface antigens.

TRANSMISSION

The routes by which the different respiratory viruses spread from person to person are still not established with certainty. Rhinovirus and RSV spread, at least in part, by direct hand contact with contaminated skin and environmental surfaces. This is followed by self-inoculation of infectious virus onto the nasal mucosa or conjunctiva. Others, including influenza, measles, and varicella zoster viruses (VZV), spread at times in small-particle aerosols. Many viruses may spread by means of large-particle aerosols over short distances (1 m). The relative importance of the various transmission routes under natural conditions for each virus is unknown.

A number of respiratory viruses have been documented to cause outbreaks of infection in closed populations. In hospitals, nurseries, day care centers, and homes for the elderly, secondary spread to staff members and other patients may occur. Such outbreaks have been observed for viruses that appear to be spread by small-particle aerosols, including measles and VZV, and for those spread by direct contact with infectious secretions, such as RSV, rhinoviruses, and coronaviruses, where there is frequent close contact between patients and staff.

PATHOGENESIS OF INFECTION

The initial sites of infection and pathogenesis differ for the various virus groups. Some, such as rhinovirus, are associated mainly with upper respiratory tract involvement. Others, such as influenza, commonly invade the lower airways and sometimes pulmonary parenchyma in addition to causing upper airway disease. The viruses also differ in the amount of damage produced in the cells lining the respiratory tract. Extensive damage to the respiratory epithelium is a characteristic feature of the influenza virus infection, but biopsy

TABLE 130-1 Common Respiratory Viruses

Virus	Family	Genome	Seasonality	Diseases	Vaccine	Antivirals
Influenza virus	Orthomyxoviridae	ss RNA (–)	Yes (winter)	Influenza, croup, bronchitis, pneumonia	Yes	Yes (oseltamivir, zanamivir)
Respiratory syncytial virus (RSV)	Respiroviridae	ss RNA (–)	Yes (winter)	Bronchiolitis, pneumonia	No	Yes (ribavirin)
Metapneumovirus (hMPV)	Respiroviridae	ss RNA (–)	Yes (winter)	Bronchiolitis, pneumonia	No	No
Parainfluenza virus (PIV)	Paramyxoviridae	ss RNA (–)	Yes (winter)	Croup (PIV1), pneumonia (PIV3)	No	No
Measles	Paramyxoviridae	ss RNA (–)	No	Croup, pneumonia	Yes	No
Rhinovirus	Picornaviridae	ss RNA (+)	Yes (spring, rail)	Common cold	No	No
Coronavirus (CoV)	Coronaviridae	ss RNA (+)	No	Common cold (OC43), pneumonia (HuCoV-SARS)	No	Yes (interferon alpha?)
Sin nombre virus	Bunyaviridae	ss RNA (+/–)	No	Pneumonia	No	No
Adenovirus	Adenoviridae	ds DNA	No	Croup, pneumonia	Yes	No
Herpes simplex virus	Herpesviridae	ds DNA	No	Pneumonia	No	Yes (acyclovir, famciclovir)
Varicella zoster virus	Herpesviridae	ds DNA	No	Pneumonia	Yes	Yes (acyclovir, famciclovir)
Cytomegalovirus	Herpesviridae	ds DNA	No	Pharyngitis, pneumonia	No	Yes (ganciclovir, cidofovir)
Epstein–Barr virus	Herpesviridae	ds DNA	No	Pharyngitis	No	No
Bocavirus	Parvoviridae	ss DNA (+/–)	No	Bronchiolitis, colds	No	No

studies show little evidence of nasal epithelial damage in persons with rhinovirus colds. Instead, colds are related both to virus damage to the respiratory tract and to the host responses to infection, including immunologic events, release of mediators of inflammation, and neurogenic reflexes.

An additional important feature of respiratory virus infections is their effect on the resident bacterial flora of the upper airways. Respiratory virus infections have been found to alter bacterial colonization patterns, increase bacterial adhesion to respiratory epithelium, and reduce mucociliary clearance and phagocytosis. These impairments of host defenses by virus allow colonization by pathogenic bacteria and invasion of normally sterile areas, such as the paranasal sinuses, middle ear, and lower respiratory tract, resulting in secondary infection.

A summary of the specific viral etiologies most commonly associated with syndromes of upper respiratory tract infection is given in Table 130-2. These infections are discussed in detail in Chapter 126. The following sections briefly summarize the important points of viral respiratory tract infections.

TABLE 130-2 Virus-Associated Respiratory Tract Infections

Clinical Syndrome	Associated Viruses
Common cold	Rhinovirus, other picornaviruses, RSV, PIV, coronavirus, adenovirus
Pharyngitis	Rhinovirus, influenza, EBV, CMV, HSV, HIV
Tracheobronchitis	Influenza, adenovirus, rhinovirus
Croup	PIV1, PIV2, influenza, adenovirus, measles
Bronchiolitis	RSV, hMPV, HuCoV-NL63, bocavirus
Pneumonia: Adults	Influenza, adenovirus, RSV, PIV, measles, VZV, sin nombre virus, HuCoV-SARS
Children	RSV, PIV, influenza, measles, adenovirus, rhinovirus, CMV
Immunocompromised	CMV, HSV, VZV, adenovirus, RNA viruses

■ DIAGNOSTIC TESTS

While specific diagnostic tests will be discussed in the appropriate sections, the development of molecular diagnostic techniques, particularly multiplexed nucleic acid–based tests, has generally supplanted most other diagnostic modalities. In most cases, however, diagnostic testing should be considered in the context of whether the results will have an impact on patient management.

THE COMMON COLD

Below are considered the clinical features, etiology, pathogenesis, diagnostic evaluation, and management of the common cold.

■ CLINICAL FEATURES

The term "cold" really does not constitute a single entity, but rather a group of similar illnesses of differing cause (see also Chapter 126). However, all colds include symptoms of rhinitis with variable degrees of pharyngitis. Predominant associated symptoms include nasal stuffiness, sneezing, runny nose, and sore throat. Patients often report chills, but fever is not a typical feature of uncomplicated colds. Cough and hoarseness are variably present and may be more frequent in the elderly,[6] but other lower respiratory tract signs and symptoms are not typical of colds and should raise suspicion of other entities.

Physical findings are nonspecific and most commonly include nasal discharge and pharyngeal inflammation. More severe disease, with higher fever, may be seen in children. Although colds are generally self-limited, symptoms may last for a surprisingly long period of time, with a median duration of illness of approximately 9 to 10 days in adults.[7] Recognized complications of colds include secondary bacterial infections of the paranasal sinuses and middle ear, and exacerbations of asthma, chronic bronchitis, and emphysema. Colds are frequently associated with involvement of the middle ear, likely due to eustachian tube dysfunction. Colds are associated with symptomatic otitis media in approximately 2% of cases in adults, and in a higher proportion in young children.

Colds are also associated with detectable abnormalities of the paranasal sinuses, which may or may not be evident clinically. Mucosal thickening and/or sinus exudates have been observed in as many as 77% of subjects with acute colds.[8] These abnormalities are transient

and usually not associated with symptoms, although they may persist 21 days or longer. Colds are associated with symptomatic otitis media in approximately 2% of cases in adults,[9] and in a higher proportion in young children.[10] Rhinoviruses and other common cold viruses have been detected in middle ear fluids in approximately 20% to 40% of cases of otitis media with effusion in children.[11] Infections with RSV, influenza, and adenoviruses are often also associated with otitis media.[10] However, clinically manifest acute sinusitis is seen in a small (0.5%–5%) proportion of individuals with naturally occurring colds.

Clinical colds in atopic individuals may be more severe or more likely to result in wheezing than in normal individuals, and rhinoviruses have been identified as major causes of asthma exacerbations in children and adults.[12] Rhinovirus colds may increase asthma by augmenting airway allergic responses such as histamine release and eosinophil influx after antigen challenge. Rhinoviruses have also been identified as important causes of exacerbations of chronic obstructive pulmonary disease (COPD).[13,14]

VIRAL ETIOLOGIES AND DIFFERENTIAL DIAGNOSIS

Epidemiologic studies have established that the great majority of common colds are associated with infection with the human rhinoviruses or other picornaviruses. Other agents frequently associated with common colds include coronaviruses, PIV, and RSV, with a variety of other agents implicated occasionally. The clinical characteristics of illness due to each of these viruses are similar, and a specific viral etiology generally cannot be deduced on clinical grounds alone. Epidemiologic studies have indicated that on an annual basis, any one antigenic type of virus is responsible for less than 1% of all colds.

The differential diagnosis of individuals presenting with typical signs and symptoms is not extensive. However, in the presence of additional signs or symptoms that are not part of this clinical description, such as high persistent fever, signs of respiratory distress, or lower respiratory tract disease, alternative diagnoses should be sought. Allergic causes should be considered in individuals who present with recurrent symptoms restricted to the upper respiratory tract.

PATHOGENESIS

Studies of the pathogenesis of the common cold have largely focused on rhinoviruses, the most commonly implicated viral etiology. In situ hybridization studies of nasal biopsy specimens from rhinovirus-infected subjects demonstrate that infection is largely confined to relatively small numbers of ciliated nasal mucosal epithelial cells, although occasional nonciliated cells are also infected.[15] Sloughing of these epithelial cells is seen in naturally occurring colds, but the epithelial lining remains intact, with structurally normal cell borders. Infection is associated with significant increases in the numbers of polymorphonuclear leukocytes in nasal mucosa and secretions, probably due to elaboration of IL-8 by infected cells.[16] Although rhinoviruses are not able to grow efficiently at body temperature, virus can be detected within cells of the lower airway even in uncomplicated colds in healthy subjects.[17]

In general, the number of infected cells appears to be quite limited, even in fairly symptomatic individuals, and there is no clear correlation between the level of virus replication or the number of cells infected, and the level of symptomatology. These results have suggested that virus-induced cellular injury is not the direct cause of symptoms in rhinovirus colds, but rather that inflammatory mediators play an important role. Analysis of the nature of the mucosal exudate during rhinovirus colds suggests that the nasal secretions during the initial response to rhinovirus infection are predominantly the result of increased vascular permeability, as demonstrated by elevated levels of plasma proteins in nasal secretions,[18] whereas later glandular secretions (lactoferrin, lysozyme, and secretory IgA) predominate. Similar observations have been made in allergic rhinitis. However, in contrast to the situation in allergic rhinitis, histamine does not appear to play a role in the induction of symptoms in colds, as nasal histamine levels do not increase, and therapy with selective H1 antihistamine is not effective.[19,20] Nasal secretion kinin levels do correlate with symptoms in natural and experimental colds, and intranasal administration of bradykinin mimics the induction of signs and symptoms in the common cold,[20,21] including increased nasal vascular permeability, rhinitis, and sore throat.

DIAGNOSTIC TESTS

Molecular diagnostic tests have been developed for many of the viruses associated with the common cold. Since there is no specific therapy and the clinical characteristics of colds due to different viruses are similar, use of techniques for specific viral diagnosis in the common cold is generally limited to the research setting.

TREATMENT AND PREVENTION

The recommended treatment for colds is to use individual remedies to treat specific symptoms. Symptoms of sneezing and rhinorrhea can be alleviated with nonselective sedating antihistamines such as brompheniramine, chlorpheniramine, or clemastine fumarate.[22,23] The effect is probably due to the anticholinergic properties of these drugs but treatment with selective H1 inhibitors is not effective. Studies of pseudoephedrine have demonstrated measurable improvements in nasal air flow consistent with a decongestant effect. In previously healthy children and adults, there is no danger from the routine use of cough suppressants, although they should be used cautiously in patients with underlying COPD. Cough syrups–containing expectorants are of unproved value in common colds, although guaifenesin may reduce the cough reflex.

Symptomatic therapy with systemic anticholinergic drugs or anticholinergic-sympathomimetic combinations has not been shown to confer any benefit, and to be associated with significant side effects, especially in children.[24,25] In addition, the use of the decongestant phenylpropanolamine is associated with an increased risk of hemorrhagic stroke,[17,26] and this drug has been removed from over-the-counter cold remedies.

Topical application of vasoconstrictors such as phenylephrine or ephedrine provides relief of nasal obstruction, but may be associated with a rebound of symptoms upon discontinuation if used for more than a few days. Thus, nasal sprays–containing decongestants should be used for no more than 3 days. Topical application of ipratropium, a quaternary anti-cholinergic agent that is minimally absorbed across biologic membranes, reduces rhinorrhea significantly in naturally occurring colds.[27] This agent probably exerts its major effect on the parasympathetic regulation of mucus and seromucous glands.

There has been considerable interest in the development of antiviral agents for the common cold. Several problems confront the successful development of such an antiviral agent. Because of the numerous etiologic agents, the ideal drug would require a wide spectrum of activity. In addition, many drugs that appear to have excellent in vitro activity have failed in clinical trials, apparently because they did not reach sufficient levels within the nasal mucosa where virus replication occurs. Finally, because symptoms in colds are not clearly related to the level of virus replication, a successful treatment strategy may also require use of drugs to antagonize the effects of inflammatory mediators.[28]

LARYNGITIS AND PHARYNGITIS

In this section, the clinical features, etiology, differential diagnosis, pathogenesis, diagnostic evaluation, and management of laryngitis and pharyngitis are discussed.

CLINICAL FEATURES

Pharyngitis is a common complaint of both adults and children, and is one of the more common reasons for seeking outpatient medical care. In general, this syndrome refers to individuals who present with the primary complaint of sore throat, and should probably be

reserved for those individuals who manifest some objective evidence of pharyngeal inflammation as well. The clinical manifestations of pharyngitis are dominated by the specific causative agent. However, generally the syndrome can be divided into those cases in which nasal symptoms accompany pharyngitis, which are predominantly viral in nature, and those cases without nasal symptoms, which have a somewhat more diverse spectrum of etiologic considerations, including both group A and nongroup A streptococci, chlamydia (strain TWAR), mycoplasma, and other agents.[29]

VIRAL ETIOLOGIES AND DIFFERENTIAL DIAGNOSIS

Rhinovirus colds are frequently accompanied by pharyngitis, although objective signs of pharyngeal inflammation are uncommon. Adenovirus infections are frequently associated with pharyngitis, and a specific syndrome of pharyngoconjunctival fever, consisting of fever, pharyngitis, and bilateral conjunctivitis is associated with adenovirus types 3 and 7. A variety of enteroviral serotypes are associated with febrile pharyngitis. Herpangina is a specific Coxsackie virus-induced pharyngitis in which small (1–2 mm) vesicular lesions of the soft palate rupture to become small white ulcers. Pharyngitis is a typical component of acute influenza in which individuals experience the sudden onset of systemic symptoms of fever, myalgias, and malaise accompanied by upper respiratory signs and symptoms, including pharyngitis. Primary oral infection with herpes simplex virus may present with pharyngitis, typically with vesicles and shallow ulcers of the palate, and cervical lymphadenopathy.

Pharyngitis may be the presenting or predominating symptom in more generalized viral infections. Pharyngitis is a significant complaint in approximately one-half of cases of the acute mononucleosis syndrome due to Epstein–Barr virus. Pharyngitis in this syndrome is generally exudative and is accompanied by cervical and generalized lymphadenopathy, as well as fever, hepatosplenomegaly, and other systemic symptoms. The heterophile antibody test is typically positive in the second week of illness. Cytomegalovirus (CMV) can cause an identical syndrome that is monospot negative. CMV may be associated with pharyngitis more commonly in children than in adults. An acute mononucleosis-like syndrome with pharyngitis may also be the presenting manifestation of primary HIV infection. Viruses in the hemorrhagic fever group produce an acute pharyngitis that occurs early in the disease, before skin lesions appear. Also, exudative pharyngitis is a common clinical manifestation in Lassa fever.

The differential diagnosis of acute pharyngitis generally centers upon the differentiation of streptococcal from viral etiologies. Features suggestive of streptococcal pharyngitis include tonsillar swelling, moderate to severe tenderness on palpation, enlargement of lymph nodes, presence of scarlatiniform rash, and absence of coryza. The presence of nasal symptoms or of conjunctivitis favors a viral etiology, and as described, some viral syndromes may present with distinguishing characteristics that help in their identification. Generally, acute pharyngitis in children less than 3 years of age is predominantly viral in origin. The presence of exudate is suggestive of bacterial etiology, but exudates may also be seen with adenovirus or EBV.

PATHOGENESIS

As described, pharyngitis in the common cold is probably the result of chemical mediators of inflammation, which are potent stimulators of pain nerve endings. Potentially similar mechanisms may account for pharyngitis in other viral syndromes as well. Direct viral damage and other host inflammatory responses may also contribute. Pharyngitis occurs most often as part of the common cold syndrome and thus is usually associated with the same viruses that cause colds. In some cases, pharyngeal symptoms predominate to a degree that overshadows other complaints. The kinins are potent stimulators of pain nerve endings, and high levels of bradykinin and lysyl bradykinin are present in nasal secretions of patients with rhinovirus colds. Intranasal application of bradykinin promotes sore throat and nasal symptoms in volunteers, supporting a role for these agents in the pathogenesis of cold symptoms.

DIAGNOSTIC TESTS

Identification of viral causes of pharyngitis is generally possible through isolation in cell culture, but is seldom attempted in clinical practice. Rapid antigen detection tests are available for RSV and influenza A virus.

Rapid diagnostic tests are widely available for the office identification of group A streptococci, and are indicated in most cases in which the etiology is uncertain. When highly sensitive tests are used, backup cultures are generally not necessary. Routine studies for other bacterial and nonbacterial pathogens are usually not obtained. When guideline recommendations for the selective use of throat cultures are used with antibiotic treatment based only on positive rapid test or throat culture, results can reduce unnecessary use of antibiotics for treatment of pharyngitis.[30]

TREATMENT AND PREVENTION

The treatment of most cases of viral pharyngitis is symptomatic, as noted in the section on common colds. Patients suspected of having influenzal pharyngitis who are seen within the first 2 days of illness can be treated with antiviral therapy (see the discussion on influenza virus). In immunosuppressed patients with chronic herpetic pharyngitis or normal hosts with primary gingivostomatitis, acyclovir therapy is recommended (see the discussion on herpes simplex virus).

Treatment of group A streptococcal infections with antimicrobial agents is generally initiated to prevent rheumatologic complications of this infection, and because treatment of acute streptococcal pharyngitis is associated with more rapid resolution of symptoms,[31] although the absolute benefits are rather modest.

CROUP

Important clinical features, aspects of pathogenesis, diagnosis, and management of croup are presented below.

CLINICAL FEATURES

Croup, or viral laryngotracheobronchitis, is a clinically distinct illness that predominantly affects children under the age of 3. The illness typically begins with upper respiratory tract symptoms of rhinorrhea and sore throat, often with a mild cough. After 2 or 3 days, the cough deepens and develops a characteristic brassy, barking quality, which is similar to a seal's bark. Fever between 38 and 40°C is common, although those with croup due to RSV may have normal temperatures. The child may appear apprehensive and most comfortable sitting forward in bed. The respiratory rate is elevated, but usually not over 50; this contrasts with bronchiolitis, in which more severe tachypnea is often seen. Chest wall retractions, particularly in the supraclavicular and suprasternal areas, may be observed. Children with this finding on presentation have a higher risk of hospitalization or of requiring ventilatory support.

The characteristic physical finding of croup is inspiratory stridor. Inspiration is prolonged, and in very severe cases, some degree of expiratory obstruction may also be seen. Rales, rhonchi, and wheezing, which reflect the characteristic involvement of the lower respiratory tract, may be heard on physical examination. A fluctuating course is typical for viral croup, and the child may appear to worsen or improve within an hour. The typical duration of croup is 3 to 4 days.

Hypoxemia occurs in 80% of children with croup severe enough to require hospitalization. The degree of hypoxia is generally difficult to ascertain clinically, but pulse oximetry provides a reliable and noninvasive means to monitor the state of oxygenation. Children who develop respiratory insufficiency as a result of increasing fatigue also may have elevations in Pa_{CO_2}.

Children with croup characteristically exhibit subglottic narrowing of the tracheal air shadow on PA films of the neck, the so-called "steeple" sign). This finding may be useful in differentiating croup from epiglottitis. However, radiographs are limited in accuracy, and when the diagnosis is uncertain, radiologic and pharyngeal examination should be avoided because of the risk of cardiorespiratory arrest in acute epiglottitis. Emergency assessment by an otolaryngologist or an anesthesiologist is indicated in this situation. Chest X-rays may reveal parenchymal infiltrates which are part of the characteristic involvement of the lower respiratory tract in this syndrome.

VIRAL ETIOLOGIES AND DIFFERENTIAL DIAGNOSIS

PIV-1 and PIV-2 are the most common viruses responsible for croup, accounting for about 75% of cases,[32] and the seasonal incidence of croup reflects the seasonal variations in PIV incidence. Less common causes of croup include RSV, influenza A or B viruses, measles, rhinoviruses, and adenoviruses as well as *Mycoplasma pneumoniae.* PIV-2, influenza A viruses and measles are associated with more severe disease, but generally, the clinical presentation of the croup syndrome due to individual agents is similar.

The majority of cases of inspiratory stridor in children are caused by viral croup. However, it is critical to distinguish these syndromes from other, potentially more serious causes of airway obstruction such as bacterial epiglottitis and tracheitis early in clinical management. Epiglottitis is an acute cellulitis of the epiglottis and surrounding structures. Patients present with acute respiratory distress and drooling, but the barking cough of croup is absent. Since the introduction of effective vaccines for the major bacterial cause or epiglottitis, *Haemophilus influenzae* type b (Hib), the incidence of epiglottitis in children has also declined considerably. In adults, and rarely in children, epiglottitis may be caused by a variety of other bacterial agents such as *Haemophilus parainfluenzae* or alpha hemolytic streptococci, which may spread from a contiguous focus of infection. Bacterial tracheitis is a relatively rare syndrome that mimics croup. Abundant purulent sputum is often present. Bacterial tracheitis is usually caused by *Staphylococcus aureus* or Hib; other bacteria such as *Streptococcus pneumoniae* have also been associated with this syndrome. Other infectious causes of stridor, including peritonsillar or retropharyngeal abscess, or diphtheria, should be considered. Evidence of noninfectious causes of stridor such as trauma or aspiration of a foreign body, should also be sought in the history and physical examination.

PATHOGENESIS

The severity of clinical symptoms in PIV croup appears to be directly related to the level of virus replication.[33] The viral infection in croup produces inflammation both in the upper respiratory tract, and in the lung parenchyma. The classic signs of croup, including the barking cough and inspiratory stridor, arise mostly from inflammation occurring in the larynx and trachea. Inflammatory changes are seen by histology in the epithelial mucosa and submucosa of the larynx and trachea. The cellular infiltrate includes histiocytes, lymphocytes, plasma cells, and polymorphonuclear leukocytes. The inflammation and obstruction are greatest at the subglottic level, which is the least distensible part of the airway because it is encircled by the cricoid cartilage. Consequently, localized inflammation and edema lead to obstruction to airflow. The impeded flow of air through this narrowed area produces the classic high-pitched vibration. Obstruction is greater during inspiration because it occurs in the extrathoracic portion of the airway, and is enhanced in small children because the walls of the airways in these individuals are relatively compliant. Obstruction of airflow results in an initial decline in tidal volume, which is compensated by an increase in respiratory rate to maintain adequate alveolar ventilation. However, if the obstruction increases, the work of breathing may increase until the child tires, and as the respiratory rate declines, the child develops hypercarbia and respiratory failure.

Involvement of the lower respiratory tract with resulting hypoxia is integral to the pathophysiology of croup.[34] Inflammatory changes are noted throughout the respiratory tract, including the linings of the bronchi, bronchioles, and even the alveoli. Although some degree of hypoxia can be explained on the basis of hypercarbia, the major pathophysiologic mechanism is ventilation–perfusion mismatching.

Pulmonary edema may complicate severe croup and upper airway obstruction. The onset of pulmonary edema often is immediately following intubation. Pulmonary edema in these cases does not appear to be due to pulmonary artery hypertension, but to local hypoxia, and increased alveolar–capillary transmural pressure.

In addition to these anatomic pathophysiologic events, immunologic mechanisms may also play a role in some manifestations or in determining the severity of disease. Virus-specific IgE responses appear earlier and are of greater magnitude in patients with PIV-associated croup than in age-matched controls with simple upper respiratory illness. Histamine is also detectable in upper respiratory tract secretions in this condition. There also appears to be a relationship between croup and subsequent reactive airways disease and/or heightened responsiveness to bronchodilators, particularly in children with recurrent croup.

DIAGNOSTIC TESTS

PIVs and other viruses associated with croup can be isolated in cell culture, and specific viral diagnosis can be made by PCR, but the clinical syndrome is sufficient for the diagnosis, and management generally does not depend on identification of the specific agent.

TREATMENT AND PREVENTION

Because the majority of hospitalized children are hypoxic, oxygen is the mainstay of treatment for severe disease, and should be given to all hypoxemic patients. Use of helium as the carrying gas, rather than air, has been suggested as a method to decrease the work of breathing. However, this approach requires use of 70% helium to be effective and limits the amount of oxygen which can be delivered.[35] Humidified air, or mist therapy is commonly used, and has several potential roles. Desiccation of the inflamed epithelial surfaces is decreased, and the viscosity of the exudate is reduced. However, the value of mist therapy has not been proven, and it should be recognized that water from the standard home-use vaporizer cannot reach the lower respiratory tract because of the large particle size. In addition, removal of the child from the parents and placement in a mist tent can be more distressing to the child than beneficial.

Administration of nebulized racemic epinephrine generally gives rapid, symptomatic relief in croup.[36] It is believed that alpha-adrenergic stimulation by this drug causes mucosal vasoconstriction, leading to decreased subglottic edema. Several randomized trials have demonstrated a rapid beneficial effect on airway obstruction.[37,38] The onset of action is rapid, often within minutes, but the duration of relief is also limited, lasting 2 hours or less. Therefore, treated subjects should be observed closely for clinical deterioration. Although symptomatic relief is considerable, use of epinephrine is not associated with improvements in oxygenation, probably because the defect in oxygen is associated with ventilation–perfusion mismatching due to lower respiratory tract involvement. In addition, tachycardia may occur. Thus, inhaled epinephrine is generally reserved for children who fail to respond to more conservative management,[39] although some centers use it routinely.

Steroids have been shown to confer significant benefits in the management of mild, moderate, and severe croup, including more rapid improvement in symptoms, reduced length of hospital stay, and reduced rates of intubation. Administration of intramuscular, oral, or nebulized steroids appears to be equally effective.[40,41] Administration of single-dose steroid therapy in this setting has not been associated with significant side effects,[42] and should probably

be used in any patient with illness significant enough to require an emergency room or clinic visit.

Antiviral agents effective against some of the viruses responsible for croup are available, but have not been tested for efficacy in this situation. However, the potential benefit of the use of antiviral agents in the typical self-limited course of croup would likely be limited. Since croup is a viral illness, antibiotic therapy is of no benefit.

Effective prevention of croup will largely depend on the development of vaccines for the individual viral agents responsible for this syndrome. Vaccines are currently available for both measles and influenza. There are currently no vaccines available for PIV.

TRACHEOBRONCHITIS

Clinical features, pathogenesis, diagnosis, and management of tracheobronchitis are discussed below.

CLINICAL FEATURES

In addition to causing croup and bronchiolitis, viral infection of the trachea and bronchi may cause tracheitis or tracheobronchitis. The diagnosis of acute bronchitis is usually applied to cases of acute respiratory disease with severe and prolonged cough that continues after other signs and symptoms of the acute infection have subsided. Cough occurs during the first week of illness in 30% of rhinovirus colds in young adults and in 80% or more of cases of influenza A virus infection, in which it is often prolonged. Adenovirus infections characteristically involve the tracheobronchial tree, with resultant bronchitis that in military populations is part of the syndrome of acute respiratory disease. Tracheitis is characterized by tracheal tenderness, which can be elicited by gentle pressure on the anterior trachea just below the cricoid cartilage. Substernal discomfort on inhalation and nonproductive paroxysmal cough are noted. Paroxysmal nonproductive cough is also characteristic of tracheobronchitis, and is usually much more severe at night. Later in the course of illness, small amounts of clear or whitish sputum may be produced. Accompanying symptoms may include fever, headache, myalgias, malaise, and anorexia. After several days of coughing, chest wall or abdominal discomfort that is muscular in nature may be noted. Physical findings are generally nonspecific; examination of the chest may reveal no adventitious sounds, but more commonly diffuse rhonchi and occasional wheezing. Physical signs such as egophony, pleural friction rubs, or areas of dullness to percussion, are not present.

PATHOGENESIS

The mechanisms of cough production in viral infection are not well understood but may include direct damage to the respiratory mucosa, release of inflammatory substances in response to the infection, increased production and/or decreased clearance of respiratory secretions, and stimulation of airway irritant receptors. Intranasal application of several prostaglandins also produces cough in uninfected volunteers.[43] Infection may also enhance airway reactivity, leading to increased sensitivity to cold air and pollutants such as smoke.

VIRAL ETIOLOGIES AND DIFFERENTIAL DIAGNOSIS

Tracheobronchitis is most typically caused by influenza A or B virus. In adults other common respiratory viruses such as PIV or RSV may present with prolonged cough. Herpes simplex has been associated with necrotizing tracheobronchitis in nonimmunocompromised hosts. This syndrome is often accompanied by refractory bronchospasm.

The differential diagnosis of acute bronchitis includes nonviral infections and noninfectious etiologies such as cough-variant asthma. *M. pneumoniae* and *Chlamydia pneumoniae* infections cause prolonged cough. *Bordetella pertussis* infection should also be considered in the differential diagnosis. In otherwise healthy persons, workup of acute cough should be directed toward determining the presence of pneumonia.

DIAGNOSTIC TESTS

Influenza viruses can be isolated in cell culture, as can many of the other viruses associated with bronchitis. In addition, rapid antigen tests or nucleic acid tests are available for some of these viruses. Specific viral diagnosis is generally not necessary for appropriate management of bronchitis.

TREATMENT AND PREVENTION

Treatment in adults is best effected by prescribing rest, aspirin for headache and fever, cold water vapor inhalation; and a cough syrup such as guaifenesin with dextromethorphan. For children, a cough suppressant may be helpful. In the absence of signs of pneumonia, treatment of prolonged cough with antibacterial agents is of no benefit.[44,45]

BRONCHIOLITIS

Clinical features, pathogenesis, diagnosis, and management of bronchiolitis are discussed in this section. The reader is also referred to Chapter 51.

CLINICAL FEATURES

Bronchiolitis is a fairly characteristic syndrome whose presenting symptoms are dominated by the major pathophysiologic defect, obstruction to expiratory air flow.[46] The onset of lower respiratory symptoms is usually preceded by rhinitis, often with nasal congestion and discharge. More severe symptoms characteristically occur 2 to 3 days later, but in some cases are concurrent with the onset of upper respiratory symptoms. In many instances, there may be a history of exposure to an adult or sibling with a cold or other minor respiratory illness, or history of exposure to other cases of bronchiolitis in the day care setting.

The hallmark of disease is wheezing, which can be quite marked, with flaring of the nostrils and use of accessory muscles of respiration. Cough may or may not be prominent initially, and when cough is present, it may be paroxysmal in nature. Slight cyanosis is often observed, but the presence or absence of cyanosis is not a reliable indicator of the degree of oxygenation or of the severity of disease. Physical findings are generally confined to the chest, with the development of rales, which are usually musical in the beginning, and then become moister. Hyperresonance of the chest may be observed, and the liver may be displaced downward. The respiratory rate is elevated, with rates of from 50 to 80 breaths per minute. Fever is frequently present at the beginning of the illness, but may no longer be present at the time lower respiratory tract involvement develops. Among hospitalized infants, one-third or more are afebrile, but have marked lower respiratory tract disease. Thus, the presence or absence of fever does not indicate the severity of the child's illness. Mild conjunctivitis is noted in about one-third of cases, with pharyngitis of varied severity in about one-half, and otitis media in 5% to 10%. The hospital course is variable, but most infants show improvement in 3 to 4 days.[47]

Radiologic findings are generally nonspecific, with reported findings including air trapping, consolidation, and collapse.[48] However, there is no correlation between the chest X-ray findings and the clinical course.[49] Chest X-rays should be obtained to rule out alveolar-filling defects suggestive of bacterial pneumonia and in those infants with severe disease, sudden deterioration, or underlying disorders. Results of routine laboratory tests are generally unremarkable. The peripheral white blood cell count is usually not elevated. Electrolyte disturbances, most notably, hyponatremia, may be seen with severe disease, particularly if excessive amounts of hypotonic fluid are administered. Acute disease may be associated with elevations in pulmonary artery pressure, but echocardiographic studies are usually unremarkable in infants with structurally normal hearts.

Bronchiolitis is a disease predominantly of infancy, and the peak age incidence is between 2 and 6 months of age, with over 80% of cases occurring in the first year of life. The risk of hospitalization

and severe bronchiolitis is particularly high in infants with congenital heart disease, chronic lung disease, or immunodeficiency. In addition, infants born prematurely, and those who are less than 6 weeks of age at the time of presentation are also at increased risk of hospitalization. More severe disease has also been documented in children with a family history of asthma, and those exposed to cigarette smoke in the family setting.

VIRAL ETIOLOGIES AND DIFFERENTIAL DIAGNOSIS

RSV causes the majority of cases of bronchiolitis and during the RSV epidemic season, essentially all cases are due to this virus. Overall, RSV is recovered from about three-fourths of all infants admitted to the hospital with bronchiolitis.[46] Several other respiratory viruses are associated with bronchiolitis, including PIVs, influenza virus, mumps, and rhinoviruses. The epidemiology and pathophysiology of parainfluenza bronchiolitis are similar to that of RSV, and particularly severe disease may be associated with PIV-3. Adenoviruses types 3, 7, and 21 are relatively uncommon causes, but may be associated with more severe disease, including the development of bronchiolitis obliterans. Rhinoviruses represent a small but significant proportion of cases of bronchiolitis,[50] and may mimic RSV infection in infants with bronchopulmonary dysplasia. Rhinoviruses and *Mycoplasma pneumoniae* become more important causes of infection-induced wheezing as children become older. Surveys of bronchiolitis in various parts of the world have suggested a similar pattern of viral etiologies.

A significant number of cases are associated with the human metapneumovirus (hMPV).[51] The clinical picture most closely resembles that of RSV, and bronchiolitis is the major manifestation in children. Clinical features include wheezing and hypoxia. There are no clinical features that can distinguish between disease caused by hMPV and RSV, although generally those due to RSV may be more severe. Human coronaviruses have also been associated with lower respiratory tract disease in infants.[52] An additional recently described human parvovirus, the human Boca virus, has been found in as many as 20% of cases of acute wheezing in young children. This virus is often detected in the presence of other viruses, and the exact role it plays in this syndrome has not been determined completely.[53]

The differential diagnosis of diseases characterized by expiratory airflow obstruction in infants is relatively small. Pertussis can occasionally be confused with bronchiolitis; however, more frequent vomiting and more paroxysmal cough would be clues to the diagnosis. Anatomic defects such as vascular rings can cause obstruction of the airway. Foreign bodies should be considered strongly, especially in young infants. Gastroesophageal reflux is an additional consideration. The major differential diagnostic consideration is asthma, which is uncommon under the age of 1 year.

PATHOGENESIS

The pathophysiology of infectious bronchiolitis has been described most completely in the case of infection with RSV.[46] The average incubation period is 4 to 5 days, with a range of 2 to 8 days. Virus replication is limited to the respiratory tract mucosa, which may be involved through its entire length. Involvement of the lower respiratory tract probably occurs by cell-to-cell spread through the respiratory epithelium or aspiration of upper respiratory secretions. Pathologic findings in RSV bronchiolitis include necrosis of bronchiolar epithelium, loss of ciliated epithelial cells, and marked peribronchiolar mononuclear inflammation. Virus-induced cytopathology and associated submucosal edema leads to obstruction of smaller bronchioles, particularly in infants, with distal collapse or air-trapping.

Viral infection of epithelial cells of the bronchioles leads to destruction and necrosis of the ciliated epithelium. Lymphocytes can be seen in increased numbers in the peribronchial tissues. The submucosa becomes edematous, and there is increased production of mucus. Ultimately, dense plugs of alveolar debris and strands of fibrin form within small bronchi and bronchioles, which may partially or completely obstruct airflow. The pathogenic basis for respiratory difficulty in bronchiolitis is related to obstruction of these small airways. Hypoxemia is the major abnormality of gas exchange, with ventilation–perfusion imbalance the major cause of the hypoxemia. In addition to hypoxia, hypercarbia and respiratory acidosis have been observed in some severely ill infants.

Infants are particularly susceptible to the consequences of viral infection for several reasons. The peripheral airways are disproportionately narrow in the early years of life. In addition, collateral channels of ventilation, such as the pores of Kohn, are deficient both in number and size in the infant lung. Finally, the airways of infants are intrinsically more reactive to bronchospastic stimuli than are the airways of older children.[54]

The possibility that immune responses are involved in the pathogenesis of RSV bronchiolitis has received considerable attention. The presence of pre-existing infection-induced antibody does not appear to play a role in enhancing the severity of disease because maternal antibody, or passively transferred antibody is protective. It has also been postulated that cellular immune responses may be involved in the pathogenesis, since infants infected with RSV who have clinical bronchiolitis have higher levels of cell-mediated immunity to RSV than those with uncomplicated upper respiratory tract disease. Immediate hypersensitivity type reactions have also been postulated to play a role in the pathogenesis of wheezing in bronchiolitis. Production of virus-specific IgE and subsequent release of mediators of bronchoconstriction have been documented with RSV and PIV bronchiolitis. Leukotriene C4, a potent stimulant of airway smooth muscle constriction and mucus secretion, is also released into the airway in acute bronchiolitis.[55] Elevated levels of histamine and prostaglandin $F_2\alpha$ metabolite have been found during acute bronchiolitis and increased levels of eosinophilic cationic protein in nasopharyngeal secretions, suggesting that release of chemical mediators of inflammation in response to viral antigens is one factor contributing to the development of severe bronchiolitis.

The innate immune response also plays an important role in the pathogenesis of RSV disease in infants, and it has been recognized that single nucleotide polymorphisms in several genes that control the inflammatory response have an important impact on the severity of RSV disease. Examples include polymorphisms in the genes for IL-4, IL-8, and IL-13, and in TLR-4 and the CCR5 receptor, among others (see Chapter 121).

Following recovery from acute bronchiolitis, some children experience continued episodes of wheezing, especially during viral upper respiratory infections. Estimates are that from 5% to 50% of children diagnosed as having bronchiolitis in infancy go on to develop recurrent episodes of wheezing. Generally wheezing episodes wane in frequency over the next several years. After clinical bronchiolitis, some individuals also may demonstrate increased bronchial responsiveness to histamine or cold challenge, which generally decreases over time. The mechanism by which RSV or other viral infection might lead to increased episodes of wheezing is unclear. Some individuals develop elevated levels of viral-specific IgE, which may play a role in triggering bronchospasm upon re-exposure. In some studies, persistent wheezing correlates with a family history of asthma, and with higher levels of IgE.

DIAGNOSTIC TESTS

Rapid viral diagnosis can be made by identification of viral antigens in nasopharyngeal secretions. Both immune-based assays, such as immunofluorescence or enzyme-linked immunosorbent assay (ELISA), and nucleic acid–based techniques, such as hybridization or polymerase chain reaction (PCR), have been developed. Immune-based techniques are generally preferable for routine

diagnostic purposes, and several kits are commercially available. The sensitivity of such techniques is dependent on the quality of the nasopharyngeal specimen, with nasopharyngeal aspirates superior to brushings or swabs. Commercially available immunofluorescence or ELISA antigen detection has a sensitivity of about 75% to 90% relative to culture for specimens collected from children, who shed large quantities of virus. The sensitivity of such tests in adults, who shed lower quantities of virus, is much lower (generally less than 20%). In transplant patients with suspected RSV pneumonia, samples of the lower respiratory tract by bronchoalveolar lavage are more sensitive than throat swabs for the detection of RSV.

TREATMENT AND PREVENTION

Recommendations regarding the treatment and prophylaxis of bronchiolitis have been summarized recently.[56] Correction of hypoxemia is the most important aspect of managing RSV lower respiratory tract disease. Oxygenation should be monitored by pulse oximetry, and oxygen administered to infants whose oxygen saturation consistently falls below 90%. Since bronchiolitis is a viral disease which is infrequently complicated by bacterial superinfection, routine treatment with antibiotics is not warranted. Because of the dehydrating effect of tachypnea and reduced oral intake in some hospitalized infants, parenteral rehydration is often needed, but care must be taken to avoid inducing hyponatremia. Fluid intake and electrolyte concentrations should be carefully monitored in all infants with severe bronchiolitis, as hyponatremia and syndrome of inappropriate secretion of antidiuretic hormone (SIADH) may occur.

Data concerning the potential benefits of bronchodilator therapy are somewhat conflicting. Generally, bronchodilators produce modest short-term improvements in clinical scores, but do not improve oxygenation, rates of hospitalization, or duration of hospital stay.[57–59] In addition, bronchodilating drugs may contribute to increased restlessness and cardiovascular stress. Because some children do respond to these drugs,[60] a reasonable strategy is a short trial of nebulized bronchodilator with continued therapy only in selected children who respond.

The majority of studies of systemic corticosteroids have also failed to demonstrate a beneficial effect in acute bronchiolitis,[61,62] and oral corticosteroids do not appear to have a beneficial effect in terms of long-term outcomes, either. Steroids may also be associated with evidence for delayed viral clearance. Although a recent meta-analysis suggested that systemic steroids have a small but statistically significant effect in decreasing length of stay,[63] the clinical significance is minimal; therefore, corticosteroids should not be used routinely.

Antiviral therapy with ribavirin (1-β-D-ribofuranosyl-1,2,3-triazole-3-carboxamide) remains controversial. Ribavirin is a broad-spectrum antiviral agent with antiviral activity against multiple respiratory viruses including RSV in a variety of cell culture systems and animal models. It does not achieve suitable levels in respiratory secretions when administered systemically, so that therapy of bronchiolitis has used aerosolized drug. Although initial randomized placebo-controlled trials of ribavirin small–particle aerosol showed benefit in treatment of bronchiolitis, subsequent experience with use of the drug in clinical practice did not confirm this clinical benefit. These findings, and the expense of this drug, suggest that ribavirin should be considered only in selected infants and young children with severe illness or at high risk for serious RSV disease.

Bronchiolitis due to RSV can be prevented by passive transfer of antibody against this agent. A humanized neutralizing monoclonal antibody to the RSV F protein, palivizumab (Synagis) has significant protective efficacy in a population of infants with prematurity or bronchopulmonary dysplasia, as well as in children with hemodynamically significant congenital heart disease. Current recommendations for the use of passive antibody prophylaxis are to consider use in infants and children less than 2 years of age with chronic lung disease or congenital heart disease, and in infants born at 32 weeks of gestation or earlier (who would be expected to receive little placental transfer of maternal antibody). Palivizumab may be considered for infants born between 32 and 35 weeks who have at least two additional risk factors, such as exposure to second-hand smoke or attendance at day care.[56] Palivizumab is not effective for therapy of RSV disease.

Interruption of nosocomial transmission may be facilitated by thorough handwashing, decontamination of surfaces and inanimate objects, and isolation or cohorting of infected infants. Use of disposable eye–nose goggles by pediatric staff reduces the risk of nosocomial RSV infection in both staff and patients. Regular use of gowns, gloves, and possibly masks by hospital staff caring for infected children may also reduce the risk of nosocomial RSV spread. Protective isolation of high-risk infants or deferring their elective admission has been recommended during institutional outbreaks of RSV.

Vaccines are available to prevent bronchiolitis due to influenza virus and mumps, but there is no vaccine currently available for prevention of bronchiolitis due to RSV. There are multiple significant hurdles to the development of such a vaccine, including the very young age at which the disease presents, the suppressive effect of maternal antibody on vaccine responses, and the potential for enhanced disease in vaccine recipients.[64]

INFLUENZA

Clinical features, epidemiology, pathogenesis, and diagnosis of influenza are discussed below. Treatment and prevention are discussed separately in the section that follows.

CLINICAL FEATURES

The onset of influenza is typically abrupt, and the illness is characterized by the predominance of systemic symptoms, including fever, prostration, myalgias, and malaise. Respiratory symptoms may be relatively minimal, particularly early in the course, and include nasal complaints, sore throat, hoarseness, and nonproductive cough. Because of the involvement of tracheal epithelium in infection, complaints of burning throat and substernal pain may be seen. Among healthy adults, the best clinical predictors of influenza virus positivity are the presence of cough and fever in patients presenting during epidemics.[65]

Other than fever, there are usually few findings on physical examination. Affected individuals may exhibit rhinitis, pharyngitis, conjunctival injection, and tracheal tenderness. The chest is usually clear in uncomplicated cases. Most acute symptoms resolve in 3 to 5 days, but complete recovery may take weeks. The clinical features of influenza A and B virus infection are similar.

Influenza is an important cause of acute febrile illness in children during epidemics. Generally symptoms of influenza are similar to those in adults, although children may have higher fever with febrile seizures. As described, influenza may be associated with otitis media or croup in children.

Pneumonia represents the most severe complication of influenza virus infection in both normal and compromised hosts. Primary influenza viral pneumonia is characterized by rapid progression of dyspnea, cough and cyanosis, and the development of acute respiratory distress syndrome (ARDS). Chest roentgenographs reveal bilateral interstitial infiltrates, sputum production is scanty, and Gram stain reveals few organisms. Secondary bacterial pneumonia may present 1 to 2 weeks after apparent recovery from an acute influenza episode with recurrence of fever, and signs and symptoms of typical lobar pneumonia. Pneumonia is described in more detail below.

EPIDEMIOLOGY

Influenza is typically associated with seasonal epidemics of greater or lesser severity, which occur during the winter months in temperate climates in both the northern and southern hemispheres. Outbreaks in the northern hemisphere are usually noted between the months of November and March or April, and typically last for from 4 to

6 weeks in any given community. The reasons for the seasonal behavior of influenza are not known but have been the subject of much interest. Some suggested mechanisms have included the seasonal effects of heat and humidity on the viability of virus in the environment, behavioral patterns that facilitate transmission, such as attendance at schools, or sunlight effects on baseline immune function.

Seasonal influenza epidemics are regularly associated with excess morbidity and mortality,[66] and both influenza A and B can be associated with severe illness. During interpandemic years, influenza is characterized by a "U-shaped" epidemic curve, in which attack rates and medically attended illness rates are generally highest in infants and young children, whereas mortality is generally highest in the elderly. Young children are generally more susceptible to influenza infection than are adults, and shed higher levels of virus for longer periods. Healthy children younger than 1 year of age are hospitalized for influenza at rates comparable to those of older children and adults with chronic high-risk conditions[67,68] and are special targets of prevention measures.

Excess morbidity and mortality are particularly high in those with underlying medical conditions, including chronic cardiovascular or pulmonary disease, chronic metabolic disease including diabetes mellitus, renal dysfunction, hemoglobinopathies, or immunodeficiency, including HIV. Recently, it has been recognized that individuals with neuromuscular conditions affecting the ability to clear respiratory secretions,[69] and persons with morbid obesity,[70] are also at high risk for influenza hospitalization. Women in all stages of pregnancy, and in the immediate postpartum period, also have increased rates of hospitalization, ICU admission, and deaths during influenza epidemics.[71,72]

Antigenic variation is the hallmark of the epidemiology of influenza, and occurs in two forms referred to as antigenic "drift" and antigenic "shift." Drift refers to the gradual accumulation of mutations, primarily in the hemagglutinin (HA) and neuraminidase (NA) proteins of the virus, that allow the virus to escape from antibody generated against previous strains. New, drifted strains generally appear every several years, and tend to replace previous strains. Antigenic drift occurs in both influenza A and influenza B viruses. In addition, recent influenza B viruses have evolved into two antigenically distinct lineages termed the "Yamagata" and "Victoria" lineages,[73,74] which currently cocirculate.

Influenza A viruses exist as multiple antigenically distinct HA or NA subtypes. There are currently recognized 17 HA subtypes (H1–H17) and 9 NA subtypes (N1–N9), although current seasonal viruses are restricted to the H1N1 and H3N2 subtypes. When one influenza A subtype is replaced by another, a phenomenon recognized as antigenic shift, the new virus encounters a population with little or no prior immunity. World-wide epidemics of severe disease, referred to as pandemics, are usually the result.

Pandemics associated with antigenic shift have been noted multiple times in the 20th and 21st centuries. In 1918, H1N1 viruses emerged and replaced previous H3N2 viruses, in 1957 H2N2 viruses replaced H1N1 viruses, and in 1968 H3N2 viruses replaced the H2N2 viruses. In 1977, an H1N1 virus antigenically similar to H1N1 viruses from 1950 emerged to cause disease primarily in born after 1950, but did not replace previous H3N2 viruses. Finally, in 2009 a new H1N1 virus (the so-called pH1N1 virus or "swine flu") emerged that was antigenically similar to H1N1 viruses prior to 1947 and cause disease predominantly in young adults and children. Since then, both H3N2 and pH1N1 viruses have circulated in humans. Influenza A viruses are zoonotic in multiple animal species including migratory waterfowl and swine, and epidemiologic data strongly support the notion that new pandemic influenza A viruses arise from this reservoir (see below).

PATHOGENESIS

The mechanisms responsible for the transmission of influenza viruses from person to person have never been completely defined, and it is likely that both large particles (i.e., droplet) and small particles (aerosol) released from the airway during coughing and sneezing play a role. Once virus is deposited on the respiratory tract epithelium, it can attach to and penetrate columnar epithelial cells if not prevented from doing so by specific secretory antibody (IgA), by nonspecific mucoproteins to which virus may attach, or by the mechanical action of the mucociliary apparatus. The duration of the incubation period to the onset of illness and virus shedding varies from 18 to 72 hours depending in part on the inoculum dose. Viral shedding in the respiratory tract is first detected just before the onset of illness (within 24 hours), rapidly rises to a peak and remains elevated for 24 to 48 hours, and then rapidly decreases to low titers. Usually influenza virus is no longer detectable after 5 to 10 days of virus shedding. Both the duration as well as the level of virus shedding is typically longer in young children than in adults and in immunocompromised individuals. In general, the course of the clinical illness correlates temporally with the pattern of virus shedding, and severity is correlated with the quantities of virus shed.

Bronchoscopy of individuals with typical, uncomplicated acute influenza has revealed diffuse inflammation of the larynx, trachea, and bronchi, with mucosal injection and edema. Histologic findings on autopsy of more severe cases show extensive necrotizing tracheobronchitis, with ulceration and sloughing of the bronchial mucosa, extensive hemorrhage, hyaline membrane formation, and a paucity of polymorphonuclear cell infiltration. Abnormalities of pulmonary function are frequently demonstrated in otherwise healthy, nonasthmatic young adults with uncomplicated (nonpneumonic) acute influenza. Demonstrated defects include diminished forced flow rates, increased total pulmonary resistance, and decreased density-dependent forced flow rates consistent with generalized increased resistance in airways less than 2 mm in diameter,[75] as well as increased responses to bronchoprovocation. In addition, abnormalities of carbon monoxide diffusing capacity and increases in the alveolar–arterial oxygen gradient have been seen. Of note, pulmonary function defects can persist for weeks after clinical recovery.

VIRAL ETIOLOGIES AND DIFFERENTIAL DIAGNOSIS

Generally, clinical features alone cannot distinguish between the syndrome of influenza caused by either influenza A or B viruses, although attention to ongoing community surveillance can be very helpful in assessing the likely agents. Influenza-like illness can also be caused by a variety of other viruses, including RSV, adenovirus, and PIV. Knowledge of the currently circulating viruses can be very helpful.

DIAGNOSTIC TESTS

Rapid viral diagnosis based on immunologic detection of viral antigen in respiratory secretions is widely used for influenza diagnosis. All of these tests are designed to detect both influenza A and B, but only some of the tests differentiate between the two. Some of the tests that are minimally complex may be eligible for waivers that allow them to be used in the office setting. In general, sensitivities in adults and elderly patients tend to be lower than reported in young children, who tend to shed much larger quantities of virus in nasal secretions and therefore have much higher concentrations of antigen in their samples. Although all types of respiratory samples can be used in such tests, the sensitivity appears to be better with nasopharyngeal swabs and aspirates than with throat swabs or gargles.

Molecular diagnostic tests are becoming increasingly popular for influenza diagnosis, and are frequently coupled with the detection of other respiratory viruses, especially RSV. Nasopharyngeal samples remain the most sensitive of samples, but it has been noted that in some patients with pneumonia, sputum samples have been positive when nasal samples were negative. As is the case for all diagnostic testing, specific influenza testing should be focused on those cases where a specific diagnosis will have implications for therapy or infection prevention.[76]

TABLE 130-3 Features of Influenza Vaccines

	Trivalent Vaccine	Live Attenuated Vaccine
Produced in	Eggs	Eggs
Administration	Intramuscular infection	Intranasal spray
Immune response	Serum antibody	Mucosal immunity
Formulation	Inactivated	Live, attenuated
Storage	4C	4C
Side effects	Sore arm at injection site	Runny nose
	In some years, increased risk of Guillain–Barré syndrome	Increase in wheezing in children <1 y
Indications	Any person >6 mo	Healthy persons >1–49 y
Efficacy		
Children	++	++++
Healthy adults	++++	++++
Elderly	+++	+

TREATMENT AND PREVENTION

Treatment and prevention of influenza are considered with respect to vaccines, antiviral therapy, and antiviral prophylaxis.

VACCINES FOR INFLUENZA

Two types of vaccines, inactivated and live, are currently available for the prevention of influenza (Table 130-3). Inactivated influenza vaccines are designed to induce primarily serum antibody to the HA and NA. Multiple formats of inactivated vaccines are available, including inactivated, chemically disrupted and purified HA and NA antigens generated from viruses grown in embryonated hen's eggs or from viruses grown in cell culture, and purified HA recombinant protein expressed in insect cells using baculovirus technology. Virion-based vaccines are typically formulated to contain 15 μg of each HA in the final product, while the recombinant vaccine contains 45 μg, and a recent, high-dose vaccine containing 60 μg of each HA is licensed for use in individuals 65 and older. Current vaccines contain one example of influenza A (H1N1), and A (H3N2), based on the most current epidemiologic predictions of the likely circulating strains in the coming season, and may contain one example of influenza B (trivalent vaccine, or IIV3) or examples of both influenza B lineages (quadrivalent vaccine, or IIV4). Current recommendations do not include a preference for any specific format of inactivated vaccine, although this may change as more data become available.

The live attenuated influenza vaccine is primarily designed to induce mucosal antibody in the respiratory tract, although specific correlates of protection have not been developed. The vaccine is generated by genetic reassortment between circulating wild-type strains and attenuated master donor viruses for both influenza A and B, and is currently formulated as a quadrivalent preparation. The live vaccine is currently licensed for use in adults and children from 2 to 49 years of age.

Current recommendations for the use of influenza in the United States[77] and several other countries call for a strategy of universal vaccine, in which vaccine is offered annually to the entire population. Efforts at vaccination should be especially targeted at persons who, for reasons of age or medical conditions, are at increased risk for developing complications, hospitalization, or death due to influenza, and contacts who may transmit infection to these high-risk individuals. Persons who may transmit to high-risk persons include family members, out of family caregivers, and importantly, healthcare providers.

ANTIVIRAL THERAPY

Two classes of antiviral agents have been developed with efficacy against influenza A in humans (Table 130-4). The adamantanes (amantadine and rimantadine) are referred to as the M2 inhibitors, because their mechanism of action is the result of inhibition of the viral M2 protein, an ion channel involved in viral uncoating. M2 inhibitors are only active against influenza A viruses, because influenza B viruses do not contain an M2 protein. Although the M2 inhibitors are highly effective drugs for the prophylaxis and therapy of influenza A, resistant viruses are generated quite readily in treated individuals,[78] and can be transmitted to, and cause disease in contacts. Currently, the great majority of influenza A (H3N2) viruses worldwide, as well as most Clade 1 H5N1 viruses, are completely resistant to M2 inhibitors.[79] Therefore, M2 inhibitors are no longer recommended for use as antiviral agents against influenza.

A second class of agent is referred to as the NA inhibitors, because they are potent and selective inhibitors of the NA enzymes of both influenza A and B viruses. In cell culture, inhibition of NA function is predominantly manifested as inhibition of cell-to-cell spread of virus. The results of clinical trials of the two licensed drugs, oseltamivir and zanamivir, have been very similar, and both drugs also have an excellent safety profile.

TABLE 130-4 Antivirals Active Against Influenza

Drug	Dosage in Adults	Dosage in Children	Comments
Oseltamivir	75 mg PO BID for 5 d	≤15 kg: 30 mg twice daily	Controlled trials available in adults, elderly, and children
		>15–23 kg: 45 mg twice daily	Approximately 1–2 d earlier resolution of symptoms, reduced otitis in children
		>23 kg: 60 mg twice daily	Other effects demonstrated include earlier return to work, decreased diagnosis of bronchitis
		>40 kg: 75 mg twice daily	Meta-analysis shows reduced hospitalization rates
			Well tolerated, main adverse event is nausea
Zanamivir	10 mg via inhalation BID for 5 d	≥7 y: 10 mg via inhalation twice daily	Similar safety and efficacy profile as oseltamivir, without nausea
		<7 y: not recommended	Reports of exacerbations of reactive airways disease
Amantadine	<65 y: 100 mg twice daily for 5 d	1–9 y: 5 mg/kg/d, not to exceed 150 mg/d in two divided doses	High levels of resistance in current influenza A viruses
	>65 y: 100 mg once daily	10–12 y: 100 mg twice daily	
Rimantadine	100 mg twice daily for 5 d	≤12 y: not recommended	High levels of resistance in current influenza A viruses
	>65 y: 100 mg once daily		Not approved for use in children

As a general principle, it is clear that early initiation of therapy is critical to the effectiveness of antiviral therapy of acute influenza. This general observation is consistent with the typical pattern of viral shedding in an immunologically primed individual in which the peak of virus shedding is in the first few days of illness, and is rapidly controlled by the immune system. Therapy initiated beyond 48 hours of symptoms does not appear to be useful in immunocompetent adults and children, and the greatest benefit is seen when therapy is begun within 12 or 24 hours after the onset of symptoms. Relatively little controlled data are available related to the use of antivirals in immunocompromised individuals with influenza or in primary influenza infections, and it is unclear whether these same constraints would apply in these situations.

Meta-analysis of results of these trials has also suggested that early treatment may reduce the frequency of influenza-related complications, with reductions in the use of antibacterials and in hospitalization.[80] However, pooled analyses of these studies of early therapy with zanamivir[81] and oseltamivir[80,82] demonstrated a significant reduction in the rate of influenza complications in treated individuals. The subsequent experience in the emerging epidemic of pH1N1 virus has also suggested a beneficial effect of early therapy on complications. These include observations in hospitalized patients[83,84] and surveillance data suggesting that therapy as late as 5 days improved survival of hospitalized patients.[85] Surveillance data have also suggested that treated children had lower rates of complications.[86]

Although the benefits of antiviral therapy were initially demonstrated as a shortening of illness duration in healthy adults with uncomplicated influenza, this is generally not considered the priority target group for antiviral therapy. Current recommendations include the use of antivirals in individuals at risk for more severe influenza, or in individuals with severe disease or requiring hospitalization.[76] Treatment should be started as early as possible, but even delayed therapy can be of benefit in hospitalized patients.

ANTIVIRAL PROPHYLAXIS

Although not a substitute for vaccination, antiviral drugs can be used for prevention as well as treatment. Generally, two strategies for antiviral prophylaxis have been evaluated. Seasonal prophylaxis refers to the strategy of administration of drug throughout the entire period of potential influenza exposure, that is, the influenza season, typically 6 to 8 weeks in any given community. The second strategy administers prophylaxis for a relatively shorter period of time to a person who has close contact with an index case known or suspected to have influenza. Examples of this strategy include administering prophylaxis to family members of a person with influenza, and administering prophylaxis to patients who may be exposed during a nosocomial outbreak at a healthcare institution such as a nursing home or hospital.

VIRAL PNEUMONIA

Clinical features and specific etiologies of viral pneumonia in healthy adults, children, and immunologically compromised individuals are presented below.

CLINICAL FEATURES

As described, viral infections of the lower respiratory tract represent a wide spectrum of clinical entities including croup and bronchiolitis, tracheobronchitis, and reactive airway changes. The development of pneumonia is defined by inflammation of the lung parenchyma, often associated with visible changes on chest X-ray or abnormalities of other radiologic studies such as gallium scanning and accompanied by the development of abnormalities of alveolar gas exchange. Although there can be considerable variety to the presentation of this syndrome depending on the age and immunologic competence of the host and the specific viral pathogen, there are certain general features that are described in the following.

Viral pneumonia in adults is usually associated with nonproductive cough, although production of frothy, pink-tinged sputum is seen in some severely ill individuals. Cyanosis and hypoxemia are prominent features of severe primary viral pneumonia. Physical findings are often nonspecific. The patient may appear acutely ill, conjunctivitis and rhinitis may be noted, and the trachea may be somewhat tender if accompanied by viral tracheitis. There is an increased respiratory rate, and diffuse rales and wheezes. A variety of chest X-ray patterns have been described, including lobar infiltrates, but most typically primary viral pneumonia presents with diffuse, bilateral interstitial infiltrates. However, there are really no X-ray patterns that reliably differentiate between bacterial and viral pneumonia. The sputum is relatively scant, generally shows few polymorphonuclear leukocytes, and Gram stain reveals minimal numbers of bacteria.

The basic presentation of viral pneumonia in children is similar. The clinical presentation varies considerably with the specific causative agent, but typically includes fever and lower respiratory tract signs and symptoms, such as difficulty breathing, nonproductive cough, and physical findings of wheezing or increased breath sounds. Young infants may present with apneic episodes with minimal fever. The clinical presentation may be dominated by the associated croup or bronchiolitis, which are frequently present.

Underlying cardiopulmonary diseases, such as valvular heart disease or COPD, are well-recognized risk factors for viral pneumonia in adults and children. Pregnancy, particularly in the second and the third trimester, has been recognized as a risk factor for cardiopulmonary hospitalizations associated with influenza epidemics.

Bacterial superinfection is a common complication of viral lower respiratory tract infection, particularly in adults. The classic presentation is that of a typical episode of viral illness with more or less complete recovery, followed 2 to 14 days later by a recurrence of fever and development of cough and dyspnea.[87] CXR reveals lobar infiltrates, and the clinical course is typical of bacterial pneumonia. In addition, combined bacterial and viral pneumonia, with clinical features of each, are common in adults and with certain viruses in children. Bacterial superinfection of viral pneumonia can occur with many bacteria, but the most common bacteria responsible for bacterial pneumonia complicating influenza is *S. pneumoniae*. There are also increases in the relative frequency of staphylococci and *Haemophilus influenzae*.

VIRAL ETIOLOGIES AND DIFFERENTIAL DIAGNOSIS

Evaluation of the specific cause of acute pneumonia, and in particular, attribution of pneumonia to a particular viral etiology, is complicated by difficulty in obtaining appropriate samples for culture, in isolating or detecting certain pathogens, and the frequent asymptomatic shedding of some viruses, such as herpes viruses or adenoviruses. Serologic diagnosis essentially establishes a temporal, but not causal, relationship between viral infection and a clinical syndrome, which may be misleading during times of high prevalence of a particular viral agent. With these qualifications in mind, it is reasonable to make several broad generalizations regarding the role of viruses in acute pneumonia. The impact of viral pneumonia and the spectrum of associated viral agents are highly dependent on the age group and immune status of the host. Viruses are clearly important and are the frequent causes of pneumonia in young children. The role of viruses becomes less apparent in older children, and in healthy adults, pure viral pneumonia is rare, and is predominantly due to influenza. Elderly adults may experience more significant lower respiratory tract signs and symptoms following infection with agents which normally cause upper respiratory tract illness in younger adults, but generally have similar rates of viral pneumonia as do healthy young adults. Finally, viral pneumonia is an important cause of morbidity and mortality in individuals with compromised immune systems, with a broader spectrum of viral agents than seen in immunologically intact individuals.

■ IMMUNOLOGICALLY INTACT ADULTS

A variety of viruses may cause pneumonia in immunologically intact adults.

Influenza

The majority of cases of viral pneumonia in immunocompetent adults are probably due to, or associated with influenza viruses. The syndrome of primary influenza viral pneumonia was first well documented in the 1957 to 1958 outbreak. The illness begins with a typical onset of influenza, followed quickly by a rapid progression of fever, cough, dyspnea, and cyanosis. Physical examination and chest radiographs reveal bilateral findings consistent with the adult respiratory disease syndrome. Sputum Gram stain fails to reveal significant bacteria, and bacterial culture yields sparse growth of normal flora, whereas viral cultures yield high titers of influenza A virus. Such patients do not respond to antibiotics and the mortality is high.

Secondary bacterial pneumonia is an important complication of influenza. The classic description is of an influenza illness followed by a period of improvement lasting usually 4 to 14 days. Recrudescence of fever is associated with symptoms and signs of bacterial pneumonia such as cough, sputum production, and an area of consolidation detected on physical examination and chest X-ray. The most common bacteria implicated are *S. pneumoniae*, and a significantly increased frequency of *S. aureus*,[88,89] including methicillin-resistant *S. aureus* (MRSA).[90] Many patients present with mixed viral and bacterial pneumonia. Bacterial superinfections of influenza have been postulated as a major cause of death during the pandemic of 1918.[91]

Respiratory Syncytial Virus

RSV frequently causes detectably altered airway reactivity in adults, and on occasion, lower respiratory tract involvement becomes clinically manifest as pneumonia in otherwise healthy adults. RSV is being increasingly recognized as a cause of significant lower respiratory tract disease in the elderly.[92] It has been estimated that 2% to 4% of pneumonia deaths among the elderly in the United States may be due to RSV.[93]

Parainfluenza Virus

PIVs are most typically associated with viral pneumonia in children, particularly serotype 3 (PIV-3). However, occasionally these viruses may be associated with pneumonia in adults. Frequent contact with small children is probably a risk factor. PIVs have occasionally been reported as causes of pneumonia in adults and in the elderly.[94]

Adenovirus

Adenovirus was first recognized as a cause of viral pneumonia in military recruits and has since been recognized as a rare cause of pneumonia in civilian adults and children. Outbreaks in institutionalized populations occur. The clinical characteristics of adenovirus pneumonia are similar to those of other pneumonias, so that it is difficult to make an accurate etiologic diagnosis on the basis of clinical features. In fatal cases there has been extensive pulmonary damage, with death occurring 2 to 3 weeks into the illness. Intravascular coagulopathy has also been a late feature of some cases, and a septic shock picture has been described. Bacterial superinfection, particularly with *Neisseria meningitidis*, may occur. Since 1996, a specific variant of adenovirus type 7 (Ad7d2) has been responsible for several civilian outbreaks and a large military outbreak. The appearance of new Ad 7 genotypes may herald a shift in the predominant strains with greater disease impact.[95] Recent reports have emphasized the emergence of a relatively rare adenovirus serotype 14 responsible for severe community-acquired pneumonia in adults and children.[96]

Measles

Measles can be complicated clinically by severe pneumonitis in a small percentage of healthy adults, and bacterial superinfection is common.[97] In patients with altered cell-mediated immune function, and rarely in apparently normal persons, infection by wild measles virus can cause a lethal giant cell pneumonia with or, in about 30% of patients, without rash.[98] Measles has largely been controlled by vaccination, but outbreaks continue to occur.

Varicella Zoster Virus

Viral pneumonia is the major complication of VZV in normal adults, in whom it occurs with an estimated 25-fold higher frequency than in children.[99] Smoking is a significant risk factor. Pneumonia associated with varicella is usually apparent 1 to 6 days after the onset of rash. Symptoms include cough, dyspnea, pleuritic chest pain, and hemoptysis. Physical findings other than fever and tachypnea are often modest. The intensity of the rash does not necessarily correlate with the severity of pneumonia. The characteristic radiographic pattern is that of diffuse nodular (1–10 mm) infiltrates, which may resolve with miliary calcific densities. Hilar adenopathy, pleural effusions, and peribronchial infiltrates are frequently present. Pulmonary infarction may complicate the clinical picture. Pulmonary function studies have found normal spirometric values but decreased carbon monoxide diffusing capacity, which may persist for months. One prospective radiologic study of military recruits with varicella found abnormalities in approximately one in six patients, but only one-fourth of those with radiographic changes had cough, and none experienced severe disease.[100]

■ CHILDREN

A wide variety of viruses may produce pneumonia in children. Each is discussed below.

Respiratory Syncytial Virus

In most series, RSV has been associated with the largest proportion of viral pneumonia in young children, particularly if accompanied by bronchiolitis. It should be noted in this regard that bronchiolitis and pneumonia represent a spectrum of lower respiratory tract involvement with RSV, frequently coexist, and are not clearly distinguishable. The most typical finding is diffuse interstitial pneumonitis (Fig. 130-1). Lobar or segmental consolidation is evident by CXR in about one-fourth of children with RSV lower respiratory tract disease.

Parainfluenza Virus

PIVs are second only to RSV as causes of pneumonia in children. As described, lower respiratory tract involvement is integral to the pathophysiology of croup, but pneumonia with pulmonary infiltrates is most commonly associated with PIV-3.

Influenza Virus

Influenza A and B viruses are both significant causes of pneumonia in children, especially during periods of epidemic prevalence. In infants and children, the most frequent manifestation of influenza pneumonia is an interstitial pneumonitis similar in appearance and course to those of the other predominant viral agents of pneumonia in this age group, except that a secondary bacterial pneumonia may occur more frequently than with RSV or PIVs.

Adenovirus

Adenoviruses are frequently isolated from children with respiratory disease and are implicated in about 10% of childhood pneumonias. However, the true impact of adenoviruses as causes of pneumonia in this age group is difficult to assess because of the long and intermittent asymptomatic respiratory shedding of these viruses in children. Hilar adenopathy on CXR is somewhat more common with this form of pneumonia than other types.

Measles

Pneumonia is the most frequent serious complication of measles. The prodrome of typical measles lasts 2 to 8 days and is characterized by fever, malaise, anorexia, cough, coryza, and conjunctivitis. Koplik spots, which are erythematous macular lesions with central white-yellow or gray puncta, appear on the buccal or labial mucus membranes toward the end of the prodromal period. The maculopapular, erythematous eruption begins about the face and neck and progresses to involve the upper body, trunk, and extremities. The rash typically disappears after 5 to 6 days in the order in which it appeared. Defervescence and symptom improvement occur several days after the appearance of the rash, although persistent cough is common. Leukopenia is common during the prodromal and early exanthematous stages of measles. Pronounced leukopenia (less than 2000 cells/mm^3) is associated with a poor prognosis. The development of neutrophilic leukocytosis suggests the possibility of bacterial superinfection or other complications.

Cytomegalovirus

Respiratory distress is part of the clinical picture in infants with congenital CMV disease. Older infants and children may exhibit prolonged respiratory disease with bronchitis or pneumonia associated with CMV carriage.

Rhinovirus

Rhinoviruses have also been associated with a significant proportion of community-acquired pneumonias in children, despite the relative inability to grow efficiently at body temperature. Other viruses that may occasionally cause viral pneumonia in children include enteroviruses, rubella virus, and herpes simplex virus.

■ IMMUNOCOMPROMISED INDIVIDUALS

Individuals with diminished host immunity may develop severe, life-threatening pulmonary infections with the entire spectrum of RNA and DNA viruses, including both viruses that are typical causes of lower respiratory tract disease in normal hosts, and other, more opportunistic viral pathogens (see also Chapter 123).[101] DNA viruses have received the most recognition in this regard.

Cytomegalovirus

CMV is frequently detected in respiratory samples from immunosuppressed individuals, particularly transplant recipients, or individuals infected with the human immunodeficiency virus (HIV) with severe pneumonia. The highest risk in the transplant population without antiviral prophylaxis is 1 to 3 months posttransplantation, with the peak incidence at 8-week posttransplant. Diffuse interstitial pneumonitis is the most frequent presentation, but multiple other radiographic presentations have been reported, including nodular infiltrates resembling *Nocardia* infection. Multiple associated findings are present in severe infection, and reflect the disseminated nature of the infection; the presence of neutropenia, abnormalities of liver function tests, and mucosal ulcerations may be clinical clues to the diagnosis.

Characteristically, patients with CMV pneumonia have sustained fever, nonproductive cough, and dyspnea. Rales and tachypnea are often present, and marked hypoxemia is an indicator of life-threatening infection. Pneumonitis may be accompanied by mild neutropenia, thrombocytopenia, and elevated liver enzymes, which may be helpful in differential diagnosis. Chest radiographic changes are usually bilateral, with diffuse or focal haziness involving the mid and lower lung fields. Both miliary and interstitial radiographic patterns have been described. Often the perihilar distribution of the infiltrate is suggestive of pulmonary edema. Common CT scan findings include small nodules, consolidation, and ground-glass attenuation.

Assessing the role of CMV in an immunosuppressed patient can be challenging, since in HIV patients CMV is frequently detected along with other pathogens, such as *Pneumocystis*, and the role of CMV in the pneumonia can be unclear.[102] In transplant patients, the detection of CMV by itself does not necessarily indicate end-organ involvement. For transplant patients, it has been suggested that higher levels of CMV in pulmonary specimens or viremia may be more indicative of CMV pneumonia.[103]

Herpes Simplex Virus

HSV infection of the lower airway may occur either as the result of direct extension of infection from the tracheobronchial tree to the lung or as the result of hematogenous dissemination of virus from mucocutaneous lesions of the upper airway or genitourinary tract. Dyspnea, cough, and hypoxemia are usually seen, but the clinical features of the pneumonia generally do not permit an etiologic diagnosis to be made antemortem. Focal or multifocal infiltrates are thought to indicate direct extension, whereas diffuse bilateral infiltrates may occur due to presumed hematogenous dissemination of virus.[104] CT scan findings include multifocal segmental and subsegmental ground-glass opacities,[105] but are not distinctive. In one study, more than one-half of the patients had concomitant pulmonary infection with other microorganisms, including bacterial, *Candida* and *Aspergillus* species, and CMV.

Isolation of HSV from lower respiratory tract secretions is been common in mechanically ventilated patients and may be associated with a poor outcome.[106] However, clinical outcomes of HSV-positive patients are not significantly different from those of HSV-negative patients,[107] and it can be difficult to determine whether HSV is playing a specific role in the lower respiratory tract disease.

Varicella Zoster Virus

VZV is an important problem in individuals with hematologic malignancies and others with iatrogenic immunosuppression, with the greatest risk seen in organ transplantation. Prolonged fever and/or recurrent crops of lesions are predictors of visceral dissemination, and pneumonia is generally seen in this setting. Pulmonary manifestations may include pleuritic chest pain due to vesicular lesions of the pleura, and, as is also true in normal hosts, the CXR may demonstrate nodular lesions.

Adenoviruses

Adenoviruses are significant causes of morbidity and mortality in immunocompromised patients, particularly after transplantation. In contrast to infection in normal hosts, infection in immunocompromised subjects tends to be disseminated, with isolation of virus from multiple body sites including lung, liver, gastrointestinal tract, and urine.[108] In addition, the spectrum of serotypes includes both those found in immunocompetent individuals as well as a markedly increased frequency of isolation of higher-numbered serotypes found rarely in immunologically normal subjects.

RNA Viruses

RNA viruses have also received increasing recognition as potential causes of significant morbidity and mortality in this population.[109] RSV has been well recognized as a cause of pneumonia in recipients of bone marrow[110] and solid-organ transplantation.[111] Nosocomial transmission of RSV in this setting has been well documented, and may be the source of many infections in this susceptible population. The illness typically begins with nondescript upper respiratory symptoms that progress over several days to severe, life-threatening lower respiratory tract involvement. Mortality rates of 50% or higher are typical, particularly if disease occurs in the pre-engraftment period. PIVs have also been reported as an infrequent lower respiratory tract pathogen in both solid-organ and hematopoietic transplantation. PIV-3 has been most commonly serotype isolated, but all four serotypes have been implicated. Influenza may also cause severe disease in transplant recipients, but most subjects have survived. Rhinovirus infections in this population are also common, but tend to be associated less frequently with lower respiratory tract disease. However, chronic rhinovirus infection, with graft rejection, has been described in lung transplant recipients.

Measles giant cell pneumonia is a severe, usually fatal form of pneumonia associated with measles infection in immunosuppressed individuals. Most cases have occurred in those with hematological or other malignancies, or individuals with AIDS. Recent outbreaks of measles worldwide, coupled with the increasing incidence of HIV infection, has increased the frequency and impact of measles giant cell pneumonia. Giant cell pneumonia also occurs in significantly malnourished individuals. Multinuclear giant cells with intranuclear inclusions are seen, and may be demonstrable in fluid obtained by bronchoalveolar lavage. An important feature of measles pneumonia in immunocompromised hosts is that many patients present without rash or other typical manifestations of measles, and a high index of suspicion must be maintained. It has been speculated that such hosts may not mount the cellular immune responses involved in the pathogenesis of rash in immunologically intact individuals. In hospitalized patients, mortality rates are approximately 70% in oncology patients and 40% in HIV-infected patients.[112]

■ EMERGING VIRUSES

In addition to these viruses, which have a widespread distribution and cause sporadic cases of viral influenza, two novel emerging pathogens have caused severe outbreaks of respiratory disease in previously healthy adults.

Hantavirus Pulmonary Syndrome

Clinical features of the Hantavirus pulmonary syndrome (HPS) include onset of severe pulmonary dysfunction after a 2- to 3-day prodrome of nonspecific influenza-like symptoms of fever, myalgias, cough, gastrointestinal symptoms, and headache.[113] Laboratory abnormalities included leukocytosis, increased hematocrit due to hemoconcentration, and thrombocytopenia with coagulopathy.[114] However, clinical bleeding is unusual, in contrast to other systemic Hantavirus syndromes. Moderately elevated levels of serum lactate dehydrogenase and aspartate aminotransferase are typically seen. A variety of radiographic abnormalities have been described. Radiographic findings that may help to distinguish HPS from ARDS include early, prominent interstitial edema, and nonperipheral distribution of initial airspace disease.[115]

Presentation of HPS begins with a prodrome of fever, chills, and myalgias, occasionally accompanied by abdominal discomfort and gastrointestinal symptoms, and generalized malaise. Upper respiratory symptoms are usually absent. After a variable period of several days, the patient presents with mild, nonproductive cough and progressive dyspnea resulting from leakage of high-protein edema fluid into the alveoli. On physical examination patients are febrile, with tachypnea and tachycardia with mild hypotension. Examination of the chest may reveal rales but is otherwise unremarkable.

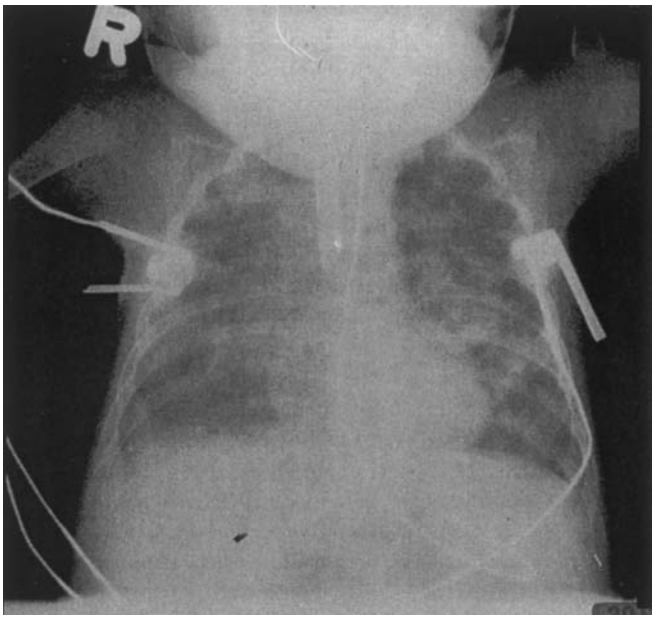

Figure 130-2 Chest radiograph showing diffuse interstitial and alveolar infiltrates in a patient with Hantavirus infection. *(Used with permission of Dr. Janet Englund, Baylor College of Medicine.)*

Laboratory studies generally reveal hemoconcentration, mild thrombocytopenia, and mildly elevated lung function tests (LFTs). The triad of thrombocytopenia, left shift with circulating myeloblasts, and circulating immunoblasts, is highly suggestive of HPS.[114] Multivariate analysis has identified dizziness, nausea, and the absence of cough as clinical symptoms predictive of HPS, as well as thrombocytopenia, elevated hematocrit, and decreased serum bicarbonate as features which help distinguish HPS from other causes of acute respiratory distress such as pneumococcal pneumonia and influenza.[116] Mild renal abnormalities may be detected, but unlike hemorrhagic fever with renal syndrome (HFRS), do not progress to a renal failure.

Chest radiographs typically shows both interstitial and alveolar infiltrates and resembles noncardiogenic pulmonary edema (Fig. 130-2). Pleural effusions are present in most cases. Early in the course of HPS these effusions are transudative, whereas later they develop higher fluid protein content and in severe cases have the protein characteristics of plasma. Cardiopulmonary manifestations in severe cases include a shock state with low cardiac index, low stroke volume index, and high systemic vascular resistance. Typically, the pulmonary artery wedge pressure is normal or low. Progression is associated with worsening cardiac dysfunction and development of lactic acidosis. The case-fatality rate averages approximately 30% to 40%. In those patients who survive, recovery is usually complete, but some patients have manifested long-term pulmonary dysfunction. The syndrome in children and adolescents is similar to that in adults.

Novel Coronaviruses (SARS and MERS)

In recent years, two previously undescribed coronaviruses have emerged to cause severe lower respiratory tract illness in humans. Both of these viruses share the property that they are indigenous to some other animal species, and were transmitted to humans with resulting severe disease (see Chapters 122 and 138). The first epidemic to be recognized was referred to as severe acute respiratory distress syndrome, or SARS. Epidemics of SARS were initially recognized in southern China in 2003 and subsequently spread throughout the world. The etiologic agent was identified as a novel coronavirus, designated the Human SARS Coronavirus (HuCoV-SARS).[117] After an intense

epidemic associated with 8096 cases and 774 deaths, the disease disappeared, largely due to aggressive infection control practices. Extensive sequence data strongly suggests that HuCoV-SARS was introduced into human populations from an animal species, likely the palm civet or a related animal. In 2012, cases of a similar severe respiratory illness were recognized in a variety of middle eastern countries, now referred to as the MERS has been named MERS-CoV. This virus is closely related to coronaviruses found in bats, but the epidemiologic data suggest that a currently unidentified intermediate animal host, possibly the camel, is involved in transmission to humans.

The two viruses differ in their epidemiologic behavior to date. In the case of HuCoV-SARS, transmission appeared to be by droplet spread and required close contact. The virus was quite contagious, with an estimated reproductive number of approximately 3. In addition, a poorly understood phenomenon was observed, in which certain individuals appear to be responsible for an extraordinarily large number of transmissions, or so-called "super spreaders." Virus shedding was at its peak at the time that illness was most severe,[118] and the preponderance of transmission occurred in the hospital setting. Ultimately, this allowed the pandemic to be controlled largely by isolation and other infection prevention procedures. In contrast, little if any sustained person-to-person transmission has been observed to date with CoV-MERS, although obviously there is concern that the virus could gain this ability at some later time.

Because of the far greater number of cases of SARS, much more is known about the presentation and clinical features of pneumonia due to this virus. The most common symptoms on presentation were fever, chills and/or rigors, and myalgias. Cough and dyspnea were the predominant respiratory symptoms but were not always present initially. Upper respiratory symptoms, such as rhinorrhea or sore throat, were infrequent. In addition, about one-third of patients had diarrhea at some point in the clinical course. Respiratory disease was progressive and became more severe over 4 to 7 days, leading to significant hypoxemia. About 20% of patients required respiratory support. The overall case-fatality rate was about 10%, but was much higher in older adults. In contrast, children appeared to have milder disease.[119] Although SARS in children had a similar presentation, younger children generally did not require oxygen therapy, and had a relatively benign clinical course. To date, MERS has had a similar presentation to SARS, although gastrointestinal symptoms may be more prominent.[120]

Radiologic abnormalities included unilateral or bilateral ground-glass opacities or focal unilateral or bilateral areas of consolidation. In hospitalized patients the abnormalities tended to progress to bilateral airspace consolidation. In most patients, peripheral involvement is seen, often involving the lower lung zones. Common findings on CT included ground-glass opacification, and interlobular septal and intralobular interstitial thickening. Pulmonary fibrosis may develop after recovery from the acute illness.[121]

HUMAN INFECTIONS WITH ANIMAL INFLUENZA A VIRUSES

Humans are susceptible to infections with influenza A viruses resident in a variety of animal species, such as swine, horses, and migratory waterfowl. The 2009 pandemic of H1N1, which originated in swine and was due to a virus with a complex genetic makeup of gene segments from human, avian, and swine influenza viruses, is the most recent example of how pandemic influenza arises from animal sources. For this reason, there has been substantial effort put into surveillance for influenza at the animal–human interface, and several small outbreaks of severe disease in humans resulting from transmission of viruses from avian sources have been recognized. The most severe cases have been due to viruses of the H5 or H7 HA subtype, but neither of these viruses have exhibited sustained human-to-human transmission to date.

The available data regarding the signs and symptoms of H5N1 infection is mostly from hospitalized patients.[122,123] Most patients present with the nonspecific complaints of cough and shortness of breath. In many patients, there is a progression of symptoms leading to respiratory failure requiring ventilation and other supportive measures. Atypical symptoms such as nausea, vomiting, encephalopathy, bleeding gums and nose have been reported. Watery diarrhea may be present prior to the onset of respiratory symptoms. The majority of patients have an abnormal chest X-ray with diffuse and multifocal or patchy infiltration, but pleural effusions are rare.

Aberrant cytokine responses (sometimes referred to as "cytokine storm") have been implicated in the pathogenesis of H5N1 disease. Autopsy findings in humans have revealed changes of a reactive hemophagocytic syndrome, ARDS and multi-organ failure, findings typically associated with production of high levels of cytokines like TNF-α and interferons.

H7 viruses have also caused large outbreaks in humans. In the Netherlands, an outbreak of H7N7 infection associated with a major epidemic in domestic poultry caused numerous human cases.[124,125] Most of these consisted of mild respiratory disease with conjunctivitis, but there was one death from pneumonia. More recently, an outbreak of human H7N9[126] infection was reported in several provinces in China. In contrast to previous reports of H7 disease in humans, this outbreak was associated with significant lower respiratory tract disease and a mortality rate of approximately 30%. In this outbreak, the majority of severe cases were seen in older adults, many of whom had comorbid conditions.[126,127] While these outbreaks have not spread widely and sustained person to person transmission has not been observed, human infections with novel avian viruses continue to pose a potential pandemic threat.

PATHOGENESIS OF VIRAL PNEUMONIA

The pathogenesis of viral infections of the lower respiratory tract can conveniently be considered in terms of infections initiated in and primarily confined to the respiratory tract, or so-called primary viral pneumonia, such as with influenza or RSV; processes in which infection is initiated in the respiratory tract with subsequent systemic manifestations, such as in measles or varicella, and processes in which respiratory tract involvement is secondary to a systemic infection, such as with CMV. Each of these situations may lead to what is recognized clinically as a viral pneumonia. In this discussion, the general features of primary viral pneumonia are discussed using influenza as a model, and pathogenesis of other forms of viral pneumonia are discussed briefly in comparison.

In primary influenza viral pneumonia, virus infection reaches the lung either by contiguous spread from the upper respiratory tract, or inhalation of small-particle aerosols. Infection initially occurs in ciliated respiratory mucosal epithelial cells of the trachea, bronchi, and lower respiratory tract, and leads to widespread destruction of these cells. The trachea and bronchi contain bloody fluid, and the mucosa is hyperemic. Tracheitis, bronchitis, and bronchiolitis are seen, with loss of normal ciliated epithelial cells. Submucosal hyperemia, focal hemorrhage, edema, and cellular infiltrate are present. The alveolar spaces contain varying numbers of neutrophils and mononuclear cells admixed with fibrin and edema fluid. The alveolar capillaries may be markedly hyperemic with intra-alveolar hemorrhage. Acellular, hyaline membranes line many of the alveolar ducts and alveoli.

The pathologic changes in the lower respiratory tract in children with viral pneumonia due to RSV and PIV are nonspecific and include epithelial necrosis with bronchiolar mucus plugging and widespread inflammation and necrosis of lung parenchyma, and severe lesions of the bronchial and bronchiolar mucosa as well. In fatal cases of RSV pneumonia in children, hemorrhagic pneumonia with peribronchial mononuclear infiltration and cytoplasmic inclusion bodies in epithelial cells are seen.

Bacterial superinfection is a well-recognized complication of viral pneumonia and accounts for a large proportion of the morbidity and mortality of viral lower respiratory tract disease, especially in adults. Consequently, the spectrum of disease and pathophysiology of bacterial superinfection have been studied intensively, and a number of factors identified in viral respiratory disease which could play a role in increasing the risk of bacterial infection.[128] The disruption of the normal epithelial cell barrier to infection, and loss of mucociliary clearance undoubtedly contribute to the enhancement of bacterial pathogenesis. The physiologic consequences of these alterations have been demonstrated as markedly decreased mucociliary clearance of labeled particles in human subjects with acute, naturally acquired influenza.[129] Animal models have also suggested that virally induced inflammatory responses, particularly the type I interferon response, also contributes to the downregulation of host antibacterial defense mechanisms.[130,131]

The HPS represents an additional example of a viral infection that involves the lung as part of a systemic infection. The pathogenesis of HPS involves extensive infection of endothelial cells throughout the body, which is particularly intensive within the endothelial cells of the lung. Abundant viral antigen and nucleic acid can be detected within these cells. Microscopic examination of the lung reveals mild to moderate interstitial pneumonitis with variable degrees of congestion, edema, and mononuclear cell infiltration. The cellular infiltrate is composed of a mixture of small and large mononuclear cells, which consist predominantly of T lymphocytes, and macrophage/monocyte cells. The picture is one of immune-mediated capillary leak and not of cell necrosis or inflammatory pneumonitis. High levels of cytokines have been detected in the blood and likely mediate the endothelial damage.

CMV pneumonia is a problem predominantly in individuals with compromised immune systems, particularly after transplantation, and also represents a systemic infection that involves the lung secondarily. There are several features of this disease in the transplant setting that suggest that both host and viral factors interact in pathogenesis.[132] CMV pathogenicity is enhanced in transplant recipients and frequently occurs at the site of the transplanted organ. The risk of CMV pneumonitis is highest in individuals at the highest risk for graft-versus-host disease. Finally, treatment with antivirals alone is ineffective, while treatment with antivirals and immune globulin, which serve to mitigate the graft-versus-host component, is effective.

The pathogenesis of CMV pneumonia is partly related to viral replication but also is thought to have an immunopathologic basis. The development of CMV pneumonitis reflects a complex interaction between viral infection and graft-versus-host disease, particularly in marrow transplant recipients. Two patterns of histopathology have been described in the lung tissue of bone marrow transplant patients with serious pneumonia. One is a miliary pattern, with multiple focal lesions showing extensive cytomegaly with localized necrobiosis, alveolar hemorrhage, fibrin deposition, and neutrophilic response. The other is of interstitial character, with alveolar-cell hyperplasia, interstitial edema, lymphoid infiltration, and diffusely distributed cytomegalic cells.

DIAGNOSTIC TESTS

Epidemiologic or clinical features of the presentation of viral pneumonia, such as the time of year, history of exposures, or, in some situations, presence of systemic signs or symptoms, such as rash, may be very useful in establishing the potential viral etiologies in specific cases of viral pneumonia. However, the clinical presentation is rarely distinctive enough to allow a specific viral diagnosis to be made on clinical grounds alone. Specific diagnosis generally depends on isolation of viral agents from appropriate respiratory specimens. Many of these viruses can be isolated from nasopharyngeal swab or wash specimens, or from lower respiratory tract secretions. Rapid antigen detection tests are available for the detection of RSV and influenza A virus in respiratory secretions. Definitive attribution of pneumonia to viruses that are typically shed asymptomatically in the upper respiratory tract, such as herpes simplex virus, is more difficult and requires detection of virus in the lower respiratory tract, usually in association with pathologic evidence of invasive disease.

Differentiation between viral and bacterial forms of pneumonia on clinical grounds can be difficult in children, and radiologic criteria do not always distinguish these entities well and mixed viral and bacterial pneumonia may be present. However, in normal infants and children with RSV or PIV pneumonia, bacteria do not appear to play an important role, and routine addition of antibacterial agents is not useful. The exception to this observation is in developing countries, where mixed viral and bacterial pneumonias in children are frequent and severe.

TREATMENT AND PREVENTION

Therapy of viral pneumonia is dependent on the severity of disease, the age and immune status of the host, and the specific causative viral agent. General supportive measures, particularly the management of hypoxia, are critically important, and some patients have required high-frequency ventilation or extracorporeal membrane oxygenation. Since mixed viral–bacterial infections or bacterial superinfections are common, antibacterial agents may be required, for example, in patients with lobar pneumonia or productive sputum.

Antiviral therapy is generally indicated for severe disease and in immunocompromised hosts, and should be guided by the results of diagnostic tests. As described above, the NA inhibitors zanamivir and oseltamivir have mostly been studied in uncomplicated influenza in healthy adults, but it seems reasonable to use antiviral agents if the patient is still virus positive at the time of presentation. Because of widespread resistance, use of the drugs amantadine or rimantadine is no longer recommended.

The only option available for the other RNA viruses is ribavirin, but there is little evidence of efficacy of this agent for any viral pneumonia. In immunocompromised hosts, treatment of established RSV pneumonia has not been successful. One approach that appears promising is treatment with ribavirin, possibly in combination with immunoglobulin, early in the illness when predominantly URI symptoms are present. Controlled trials in PIV infection are not available, although anecdotal reports suggest potential efficacy. Limited controlled trials have suggested that aerosolized ribavirin may reduce the severity of symptoms in children with measles, and some immunocompromised patients with measles pneumonia have done well following treatment with aerosolized or intravenous forms of the drug. Intravenous ribavirin is effective in the treatment of several human Hantavirus diseases, including Lassa fever and HFRS, but was not effective in a controlled trial of therapy of HPS.

Antiviral agents with proven clinical usefulness for human coronavirus infection are currently unavailable. However, the severity of the SARS coronavirus epidemic has led to an extraordinary effort to discover and develop effective antivirals, and it is likely that multiple agents will be reported in the near future. The most promising to date appears to be the type I interferons (alpha and beta), which are highly active in cell culture. Multiple agents have potential activity against SARS-CoV, including chloroquine, protease inhibitors, ribavirin, type I interferons, niclosamide, and anti-inflammatory agents such as indomethacin.[133–135] Treatment with parenteral interferon at doses used typically to treat hepatitis C virus infection appeared to lead to clinical improvement in a small series of patients in the Toronto epidemic.

Acyclovir is active in vitro against herpes simplex virus types 1 and 2; it is approximately 10-fold less active against VZV and does not have clinically useful activity against CMV or Epstein–Barr virus. Although controlled clinical trials of this drug in herpes simplex pneumonia have not been conducted, the drug has proven clinical efficacy in other herpesvirus infections and would be indicated in any serious HSV lower respiratory tract infection. Acyclovir is also effective in the therapy of varicella, and intravenous acyclovir has been effective when initiated early in the course of varicella pneumonia. The related drugs

famciclovir and penciclovir are similar to acyclovir in their spectrum of activity against herpes viruses. Viruses resistant to the activity of these drugs have been isolated from treated patients, and may be susceptible to the antiherpes drug phosphonoformic acid (foscarnet).

Once CMV pneumonitis is established, particularly in allogeneic bone marrow transplant patients, it is very difficult to treat. Ganciclovir is highly active against CMV in vitro but monotherapy is not always effective in pneumonitis in BMT recipients. The combination of ganciclovir therapy and intravenous CMV immune globulin can reduce mortality from approximately 90% to 50% or lower in these patients.[136] The effect of the immune globulin in this situation may be mostly to ameliorate graft-versus-host disease. Combination therapy is not generally required in solid-organ transplant recipients with CMV pneumonia. Cidofovir and foscarnet are other antiviral drugs with activity against CMV. Both have been used to successfully treat CMV retinitis, but their effectiveness for treating CMV pneumonia has not been established. All of the available CMV antivirals have serious side effects that limit their usefulness.

Guidelines for reducing the risk of CMV disease in stem cell transplant recipients have recently been published.[137] Transplant candidates should be screened for evidence of CMV immunity, and CMV-seronegative recipients of allogeneic stem cell transplants from CMV-seronegative donors should receive only leukocyte-reduced or CMV-seronegative RBCs and/or leukocyte-reduced platelets. In mismatched solid-organ transplant recipients (donor+/recipient−), posttransplant prophylaxis with oral ganciclovir or its prodrug valganciclovir significantly reduces the risk of CMV disease, although late-onset disease still occurs. Another strategy is preemptive therapy with ganciclovir or another anti-CMV agent when screening detects infection, but before disease develops. This strategy requires the use of routine monitoring using sensitive and specific laboratory tests for the diagnosis.

Antiviral treatment of proven value for adenovirus infection is not available. Both the broad-spectrum antiviral agents ganciclovir and cidofovir are active in vitro, and an increasing number of reports indicate that intravenous ganciclovir may be useful in seriously ill patients, although at the expense of significant renal toxicity. Cidofovir has also been used for preemptive therapy in high-risk immunocompromised patients.

Various forms of intravenous immunoglobulin have also been evaluated in viral pneumonia. As mentioned, IVIG is important in the treatment of CMV pneumonia in bone marrow transplant recipients; the effect is unrelated to the titer of CMV-neutralizing antibody contained in the preparation, and may act through modulation of the immune response. Intravenous immunoglobulin is effective for the prevention of measles after the exposure of susceptible individuals, and may be useful in the treatment of measles pneumonia, especially when combined with ribavirin. As described earlier, a humanized, neutralizing monoclonal antibody directed against the F protein of RSV (palivizumab) is highly effective for the prevention of severe RSV disease in at-risk infants, but is not effective for therapy of established disease.

CHAPTER 131 Tuberculosis

Karen Doucette
Ryan Cooper

INTRODUCTION

Tuberculosis (TB) is a severe and contagious disease caused by infection with members of the *Mycobacteria tuberculosis* complex (MTBC). Most often involving the lungs, TB is transmitted by cough, with an infectious dose of less than 10 bacteria.[1] Case fatality rates in untreated active pulmonary TB approach nearly 60%.[2] Major medical advances of the past half-century have brought effective treatment capable of cure in nearly all identified cases.[3,4] Despite this TB causes hundreds of thousands of deaths worldwide every year. The morbidity and mortality burden of TB is not uniformly distributed throughout the globe but rather disproportionately affects those living in poverty and those from resource-limited settings.[5]

EPIDEMIOLOGY AND MICROBIOLOGY

In this section, aspects of the epidemiology and microbiology of tuberculosis are presented.

GLOBAL BURDEN OF TB AND RECENT PROGRESS

In 1990, the World Health Organization (WHO) declared TB a global emergency and in response, developed the directly observed therapy strategy (DOTS), promising to "Stop TB" by finding and treating infectious cases in resource-limited settings.[6,7] Within a few years of its design, the World Bank labeled the DOTS strategy the most cost-effective health-intervention ever deployed and by 2012, an estimated 51 million people had been treated and an estimated 20 million lives saved.[8–10] Since 2004, TB incidence is falling in all WHO regions and in each of the 22 highest burden countries.

Although global TB incidence is falling, TB remains a leading cause of global infectious mortality, second only to HIV infection.[11,12] There were 8.7 million new cases of TB and 1.4 million deaths globally in 2011. Moreover, many TB deaths occur in young, previously healthy adults, and as such, TB is a top 10 cause of lost disease adjusted life years (DALYs).[7]

Broadly speaking, there are three major threats to global TB control: (1) Poor social conditions including inadequate housing and nutrition,[5] (2) Immune compromise related to the HIV pandemic,[2,13] and (3) Emergence of drug-resistant TB.[14,15]

POVERTY AND TB

Globally, TB distribution correlates closely with poverty and human development indices.[16–19] Population health factors such as water sanitation, childhood immunization rates, and life expectancy also independently predict TB incidence.[20,21] A corollary of these relationships is that only 1% of the global TB burden occurs in the industrially developed countries of North America and Europe while more than 90% arises in Asia and Africa (Fig. 131-1) (Table 131-1).[10]

HIV AND TB: CO-PANDEMICS

HIV-induced immune suppression increases the risk of progression to active TB nearly 100-fold.[22–26] Worldwide, TB is the most common opportunistic illness and a leading cause of death in patients with AIDS.[27] HIV coinfection complicates 13% of all TB cases worldwide.[10] As both a potent and common risk factor, HIV contributes substantially to TB incidence, especially in Sub-Saharan Africa.[2,13]

DRUG-RESISTANT TB

In 2011, there were over 600,000 prevalent cases of multidrug-resistant (MDR) TB, defined by resistance to the two most

important first-line antimicrobials, isoniazid and rifampin.[10,28,29] MDR-TB accounted for approximately 3.7% of newly diagnosed TB cases and 20% of relapsed cases globally. Reliable global estimates of MDR-TB are difficult to obtain since rigorous drug-susceptibility testing (DST) is not available in most resource-limited settings endemic for TB.[28,30] Eastern European countries have particularly high rates of MDR-TB; a phenomenon considered linked to the underinvestment in national TB programs and the social disruption that occurred following the collapse of the Soviet Union in the 1990s.[31] MDR-TB is 100 times more costly to manage than is drug-susceptible TB, requiring prolonged courses of expensive and difficult to procure second-line drugs.[32] In South Africa, MDR-TB prevalence is 3.2% but associated treatment costs account for one-third of the entire national TB program budget.[32] Treatment outcomes are substantially worse in MDR-TB.[29] Extensively drug resistant TB, or TB resistant to all currently available bactericidal agents, has been reported in nearly 60 countries.[29,30] The increasing prevalence of MDR-TB is particularly chastening because it is entirely a "man-made" phenomena.[31,33] With better management of TB programs, the emergence of resistance can be prevented and prevalence of MDR-TB can be reduced.[14,15]

NEWER THREATS TO GLOBAL TB CONTROL

Diabetes, smoking, and malnutrition can also impair immunologic containment of TB infection. Their prevalence continues to increase globally and the cumulative impact may well threaten global TB control in the future.[8,17,34]

TB EPIDEMIOLOGY IN THE UNITED STATES: HISTORICAL PERSPECTIVE

In the first half of the 20th century TB was a leading cause of morbidity and mortality in the United States. In 1920 pulmonary TB accounted for nearly 1 in 13 of all deaths, outranking cancer.[6,35,36] Improvements in social conditions and population health during the early 20th century led to significant reductions in TB incidence and, with the introduction of effective chemotherapy in the 1950s, incidence declined even further.[4] By the 1970s, TB incidence in the United States had reached historical lows, less than 10 cases per 100,000 people and TB seemed on the brink of elimination. Unfortunately, public health funding for TB control was then greatly reduced and by the mid-1980s a nationwide resurgence ensued, particularly in the major urban centers.[6,37–39] It is estimated that during the 1980s and early 1990s, when TB funding in the United States was nearly eliminated, 64,000 excess cases occurred.[37,40]

CURRENT US TRENDS IN TB EPIDEMIOLOGY

With renewal of Government investment in the mid-1990s TB control was reestablished and TB rates have since declined every consecutive year in the United States (Fig. 131-2).[41] By 2012, there were less than 10,000 total reported cases of TB in the United States, or just 3.2 cases per 100,000 people, the lowest rate ever reported.[41]

TB remains a concern within specific demographic groups. The foreign born, especially newly arrived immigrants, account for an increasing proportion of TB cases in the United States, representing nearly two-thirds of all US cases in 2012 (Fig. 131-3).[41] Mexico (22%) and the Philippines (12%) are the most common countries of origin of imported TB.[42,43] In foreign-born US residents, TB usually represents reactivation of infection remotely acquired in TB-endemic countries prior to arrival rather than new infection resulting from local transmission.[43]

Among the US born, TB burden is concentrated in indigenous peoples, incarcerated populations, and the unstably housed.[40,43–46] In these groups, "mini" outbreaks of TB resulting from recent transmission occur with some regularity, especially in major urban centers. Several authors have shown that race, substance abuse, malnutrition, and socioeconomic status are each independently correlated with TB incidence in the United States.[18,47–51]

Childhood TB incidence reflects ongoing TB transmission and as such, is important indicator of TB control within a community. In

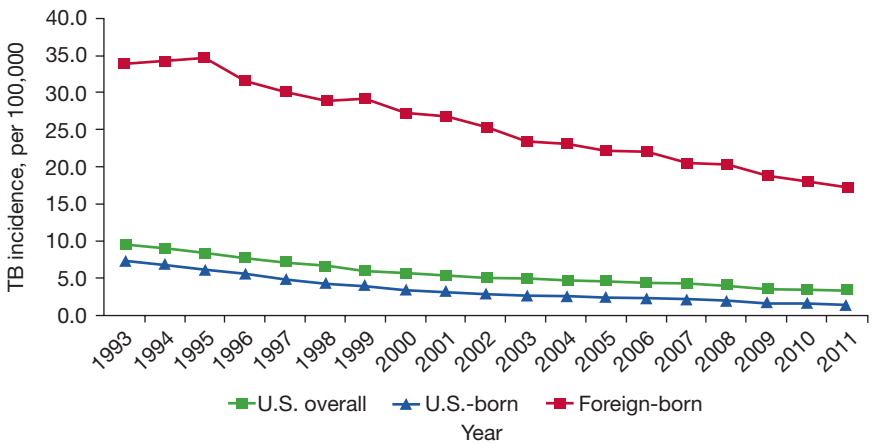

Figure 131-2 TB Case Rates in US-born versus Foreign-born persons, United States, 1993 to 2011. *(Reproduced with permission from Frieden T. Reported Tuberculosis in the United States, 2011. CDC; 2012).*

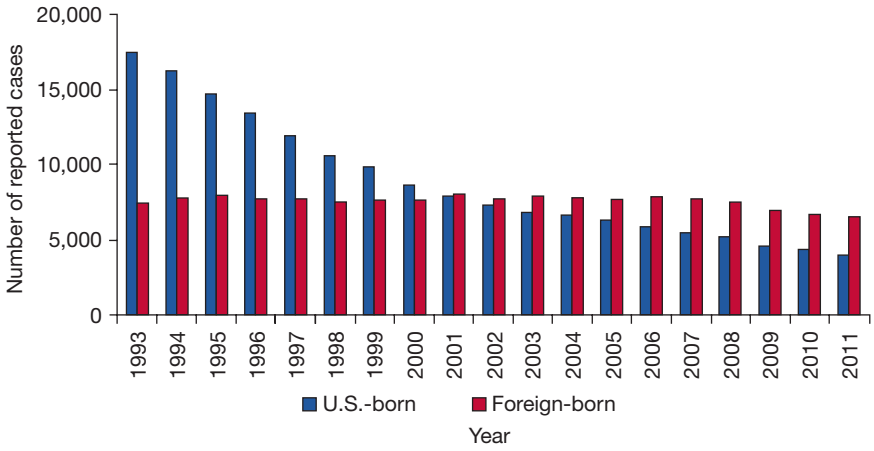

Figure 131-3 Number of TB cases in US-born versus Foreign-born persons United States, 1993 to 2011. *(Reproduced with permission from Frieden T. Reported Tuberculosis in the United States, 2011. CDC; 2012).*

the United States, 80% of childhood TB occurs in US-born children, and mostly those from racial and ethnic minority groups.[43]

MICROBIOLOGY OF TUBERCULOSIS

Mycobacterium tuberculosis as the causal agent of TB was first conclusively demonstrated in 1882 by Robert Koch and acknowledged with a Nobel Prize in 1905.[52]

M. tuberculosis is a slender, slightly curved, rod-shaped bacterium (or bacillus) averaging 3 by 0.3 μ in size and visible by light microscopy. It is nonmotile, nonencapsulated, and nonspore forming. *M. tuberculosis* is strictly aerobic.[53,54] Traditionally, mycobacteria are grown on solid, enriched media where rough, pigmented colonies generally appear 4 to 6 weeks after inoculation. MTBC can also be cultivated in specialized liquid media where characteristic "cords" visible by light microscopy are formed. Rapid liquid culture systems (e.g., BACTEC) have been adapted for use with mycobacteria and shorten time to detection of growth to a little as 9 to 16 days, depending on the initial concentration of the bacteria in the specimen tested.[55,56]

MTBC: Eight closely related mycobacterial species capable of causing human TB have been identified and together they comprise the MTBC: *M. tuberculosis* (Koch bacillus), *M. bovis* (the agent of bovine TB), *M. caprae* (bovine TB), *M. africanum* (a not infrequent cause of human TB in West Africa), *M. microti* (agent of rodent TB), *M. pinnipedii* (agent of TB in seals and a rare zoonotic disease in marine biologists attending to them), and *M. canettii* (an ancient bacillus and rare cause of human TB in East Africa) (Table 131-2).[55,57,58]

TABLE 131-2 Members of the Mycobacterium Tuberculosis Complex (MTBC)[a]

Species	Primary Reservoir Host	Geography
M. tuberculosis	Humans	Worldwide
M. bovis	Cattle, deer, elk, bison, badger, opossum	Worldwide
M. bovis BCG	Human	Worldwide
M. caprae	Goats	Worldwide
M. africanum	Human	West, Central Africa
M. microti	Vole, rodents	
M. pinnipedii	Seal, sea lion	
M. canettii	Human	East Africa

[a]*While all members of the MTBC can infect humans, some are zoonotic diseases.*

M. tuberculosis causes the vast majority of TB today. In the early 20th century, *M. bovis* accounted for up to 20% of all cases of human TB but with modern surveillance of animal herds and widespread use of milk pasteurization, *M. bovis* now causes less than 1% of reported TB cases in the United States.[59,60] Sporadic outbreaks of *M. bovis* infection still occur in the United States, and ongoing surveillance is important for food-chain safety. Human-to-human transmission of *M. bovis* has been demonstrated.[61]

MYCOLIC ACID AND THE *MYCOBACTERIUM* GENUS

The MTBC are members of the diverse *Mycobacterium* genus. The outstanding feature of the mycobacteria is their lipid-rich cell wall containing very high concentrations of mycolic acids.[53,54,56,62] This cell wall prevents reliable uptake of Gram stain. With phenol additive mycobacteria can eventually be stained to facilitate light microscopy. Once stained, removal of dye is extremely difficult, resisting even acid alcohol wash (hence "acid-fast bacilli" [AFB]). Lipids in the mycobacterial cell wall also help resistance to drying, a property that allows MTBC to retain infectiousness even within dried droplet nuclei. The metabolic investment required to produce mycolic acids significantly slows growth rate[56]and prolongs the time to detection in incubated clinical specimens submitted to laboratory.[53] The mycolic acid containing cell wall of mycobacteria is also a major virulence factor, helping mycobacteria avoid innate immune defenses and intracellular killing by nonactivated host phagocytes.[63]

COMPARISON TO OTHER MYCOBACTERIA

The nontuberculous mycobacteria (NTM) are free-living saprophytic bacteria, commensal inhabitants of the soil and/or aquatic environments (see Chapter 132). The NTM are nontransmissible under ordinary conditions, and only rarely infect humans as opportunists. In contrast, MTBC are transmissible, obligate primary pathogens without an environmental reservoir.[55]

TRANSMISSION

Important considerations in the transmission of tuberculosis are discussed below.

Droplet Nuclei

In the late 1930s, William Wells, sanitation engineer at Harvard University first conceived of "droplet nuclei" for airborne transmission of infectious diseases.[64] He found that forceful expiratory efforts such as coughing and sneezing, discharge minute respiratory droplets of sputum containing viable bacilli that, when increasingly reduced in size by evaporation, become infectious droplet nuclei, each measuring less than 5 μ.[65] Certain healthcare procedures, for example, bronchoscopy, sputum induction, autopsy, and even irrigation of abscesses, also produce infectious droplet nuclei.[66]

Due to small size, droplet nuclei have an extremely slow settling rate in air (0.5 mm/s or less). This permits their transport by air currents for significant distances. Larger respiratory droplets, on the other hand, settle out of the air quickly, and travel only a few feet from the source case. The microbes suspended within droplet nuclei are highly susceptible to germicidal levels of ultraviolet light.[2,67] The small size of droplet nuclei also facilitates penetration of the bronchial defenses allowing access to terminal alveolar macrophages. The fairly tortuous and branched path of the pharynx and bronchial tree ensures that larger respiratory droplets are instead deposited

TABLE 131-3 Key Distinguishing Features of Droplet Nuclei And Respiratory Droplets

	Droplet Nuclei Transmission	Respiratory Droplet Transmission
Particle size	1–5-μm-diameter particles (dried residua of larger particles)	>100 uM-diameter particles
Time for article to settle out of air	Suspended indefinitely	Settle within seconds, 1 m from source
Site reached by particle in recipient airway	Alveolar deposition	Upper airway deposition
Number of microbes per particle	Contain few microbes	Contain many microbes
UV-light susceptibility	Susceptible	Resistant
Example pathogens	Measles, TB, Varicella	RSV, influenza, staphylococcus

Source: Reproduced with permission from Garay S, Rom W. Tuberculosis, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.

on the mucosal lining of the airway or trapped in the mucociliary elevator and expelled (Table 131-3).[65]

Airborne Transmission of TB

In the 1950s, Richard Riley, a medical student working with Wells, elegantly demonstrated that TB is near exclusively transmitted by droplet nuclei. Riley commandeered a TB ward of six rooms for his study. The air from each individual room was ventilated to an upper chamber, where caged guinea pigs were kept, sometimes passing through an adjustable UV light source.[68] Guinea pigs are considered uniquely susceptible to infection with *M. tuberculosis,* even by dilute aerosols, and their use allowed quantification of degree of patient infectiousness.

Relatively few respiratory diseases are preferentially transmitted via the airborne route; these include TB, measles, varicella, and smallpox. Most infectious respiratory diseases (including, e.g., pertussis, influenza, the common cold, and pneumococcal pneumonia) are instead transmitted by direct contact with larger respiratory droplets leading to colonization of the host nasopharynx before subsequent lung invasion.

Risk Factors for TB Transmission

The risk of TB infection is a function of exposure to the tubercle bacilli. In turn, this depends on the interaction of three factors: infectiousness of the source case, environmental conditions that impact droplet nuclei concentration per volume of air, and duration of contact with the source (Table 131-4).

Source Case Infectiousness

An important finding from Riley's studies was the extreme variability in infectiousness of TB patients.[69,70] The dominant predictors of infectiousness in source cases are the presence of cough, lung cavitation on chest radiograph, and acid-fast bacilli visible in sputum by smear microscopy. Sputum-smear microscopy positive cases excrete about 10^8 bacilli per mL of sputum compared to less than 10^3 bacilli per mL of sputum in smear-negative cases.[66] About 35% of close contacts of sputum smear–positive patients will become infected, compared to less than 10% from sputum smear–negative cases (Fig. 131-4).[66,71–73]

Riley also demonstrated that effective anti-TB treatment could rapidly render patients noninfectious, usually within a few days of initiation.[74] The implications for discontinuing hospital isolation are somewhat controversial.[75] As a matter of convention, pulmonary TB patients are usually considered noninfectious after 2 weeks of effective chemotherapy, provided drug resistance and nonadherence are excluded.[76]

TABLE 131-4 Factors Associated with Number of Infectious Droplet Nuclei per Volume of Air and TB Transmission

Characteristics of Source Case	Environmental Factors
Sputum-smear positivity for AFB	Air circulation, ventilation
Cough strength and frequency	Room volume
Presence of lung cavitation	Humidity
Effective treatment	UV light
Delayed diagnosis	Proximity to the source case
Laryngeal tuberculosis	Duration of contact with infected air

Source: Data from Sepkowitz KA. How contagious is tuberculosis? Clin infect Dis. 1996;23(5):954–962.

Conducive Environment

Important environmental factors influencing TB transmission include ventilation (or room air changes per hour) and ultraviolet light.[66,77,78] Proximity and duration of contact with source case are also determinants of TB transmission. Household contacts are several times more likely to be infected than are casual contacts from the community.[66,72] Thus crowded housing with poor ventilation and inadequate natural lighting – such as occurs in prisons, homeless shelters, American inner-city housing projects, and the large urban slums of the developing world – are particularly conducive for TB spread.[16,79]

Host Susceptibility

Genetic determinants of innate immunity are likely important host susceptibility factors but are poorly understood.[63,80] Some studies suggest that previous TB infection (as manifested by tuberculin skin test positivity) may partially protect against reinfection, although the degree of protection has not been quantified.[81–83] Vaccination with attenuated *M. bovis* Bacille Calmette-Guérin (BCG) strain probably does not reduce the risk of infection with MTBC, even if it does reduce the subsequent chance of developing disseminated active disease once infected.[66,80,84]

NATURAL HISTORY AND PATHOPHYSIOLOGY OF TB INFECTION

It is estimated that one-third of all humans are infected with TB.[85] However, only a small fraction of the individuals within this massive reservoir ever develops active TB; most infections remain latent without apparent ill effect on the host. Risk factors associated with progression to active disease once infected are shown in Table 131-5.

■ FROM EXPOSURE TO INFECTION AND THE INNATE IMMUNE RESPONSE

The natural history of TB infection is outlined in Figure 131-5. Following exposure to an infectious source case, many contacts do not become infected, and will not convert their TST—either because infectious droplet nuclei did not reach their terminal alveoli or because any successful invaders were immediately cleared by intrinsic microbicidal activity of macrophages.[3]

However, in some individuals, invading mycobacteria engulfed by alveolar macrophages manage to evade intracellular killing.

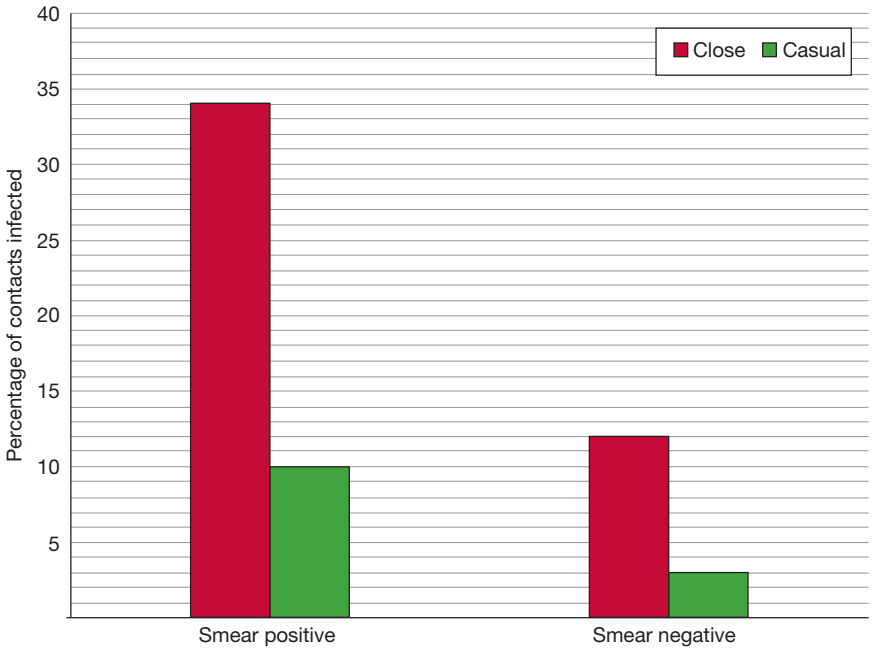

Figure 131-4 Infectiousness of tuberculosis by bacteriologic status of and proximity to source case. *(Reproduced with permission from Grzybowski S, Barnett GD, Styblo K. Contacts of cases of active pulmonary tuberculosis. Bull Int Union Tuberc. 1975;50(1):90–106).*

Mycobacteria bypass innate immune mechanisms and replicate without limitation, spreading to regional lymph nodes, and silently disseminate hematogenously.[1,57,80] After a few weeks, dendritic cells are activated and produce cytokines such as tumor necrosis factor alpha (TNF-α) that recruit blood-borne monocytes and lymphocytes to sites of infection, setting the stage for the adaptive cellular immune response.[80]

THE ADAPTIVE IMMUNE RESPONSE AND CONTAINMENT OF MYCOBACTERIAL INFECTION

The main effectors of the adaptive, cell-mediated immune (CMI) response to mycobacteria are the CD4-positive subset of T lymphocytes.[80] Once stimulated, T lymphocytes release their own battery of cytokines (including interferon-gamma [IFN-γ]) that serve to reciprocally activate infected macrophages and trigger-enhanced intracellular mycobacteria killing. This is the basis for the tuberculin skin test and IFN-γ release assays, which become positive with the development of a host CMI response. Over the next few weeks, the CMI directs necrotizing granuloma formation, which usually contains bacillary replication.

PRIMARY DISEASE

About 5% of immune competent individuals do not control initial mycobacterial replication and instead progress to primary TB disease, usually within 18 months. The risk of progression to primary disease is even higher in those with compromised CMI or other risk factors. Primary disease may occur at the initial site of lung entry (typically the mid and lower lung zones where greater airflow directs droplet nuclei deposition), regional lymph nodes, or rarely at metastatic sites initially seeded during early occult hematogenous dissemination.

TABLE 131-5 Risk Factors for Progression to Active TB in Those Latently Infected. Low-Risk Reactor—TST Positive with no Known Risk Factor, Normal Chest Radiograph

Risk Factor	Annual Risk of Infection	Relative Risk	Reference
Human immunodeficiency infection	5.0–10	50–100	Wood (2000), Selwyn (1989)

■ REACTIVATION DISEASE FROM LATENT INFECTION

For the individuals who successfully contain the initial infection and avoid primary disease, mycobacteria lie latent within healed, fibrotic and/or calcific granulomata. At this stage, mycobacteria cannot be cultured from host sputum or tissue specimens and symptoms are not present. It is believed that latent tuberculous infection (LTBI), with the potential for future reactivation, persists for life of the host.[86]

In a small minority, granulomas break down, mycobacteria replication increases, and symptomatic disease develops. Such reactivation can occur with age-related immune senescence or in those with acquired risk factors for active TB. Reactivation most commonly occurs in the apical-posterior segments of the lungs, where higher oxygen tension favors bacillary replication, but disease can occur at any previously seeded site.[1] Once reactivated, bacilli can usually be cultured from sputum and/or tissue samples.

■ CASEATION AND CAVITATION

Differences in quality of host adaptive immune response determine clinical presentation.[57,80] Some individuals develop a particularly robust, caseating granulomatous inflammatory response with resultant tissue destruction and lung cavitation—they discharge large amounts of bacilli into airways and are highly contagious. At the other end of the spectrum, a severely weak or immature granulomatous response allows hematogenous dissemination of bacilli, accompanied by widespread inflammatory foci of poorly formed granulomas. Each focus typically enlarges to about 3 mm in size, or about the size of millet seed. This severe form of TB (miliary TB) has a high case-fatality rate.

CLINICAL MANIFESTATIONS

TB had had a number of illuminating vernacular names through history. In ancient Greece, TB was called "phthisis" meaning to waste away. And in Rome, "tabes" was used, indicating wasting and overall decay. "Consumption," a term applied to TB in 19th century England is particular evocative, referring to the observation that TB sufferers appear to be gradually "consumed" by the disease, becoming lighter and less robust over months.[87]

■ SITE OF DISEASE AND CLINICAL PRESENTATION

TB is predominantly a respiratory disease, affecting the lungs in about 80% of cases (Table 131-6).[43,88] About 30% of TB cases involve an extrapulmonary site, occurring either with or without concomitant lung involvement. TB can affect virtually any organ, although peripheral lymph nodes and pleural space are the most common extrapulmonary sites.[89]

Classically TB presents insidiously over weeks, with persistent local symptoms correlating to granulomatous inflammation (e.g.,

cough in the case of pulmonary TB, neck mass for cervical lymph node TB) plus constitutional symptoms that correlate to the production of pyrogenic cytokines such as TNF-α (e.g., fevers, night sweats, anorexia, weight loss). Initially the cough may be dry but after several months becomes productive. Fever may be absent, especially in the elderly.[90] With advancing disease, hemoptysis, anorexia, and weight loss can occur.[91–93] Importantly, some patients are asymptomatic even with clear TB disease activity demonstrable on culture or radiography—a prospect that frustrates TB control program efforts at active case finding.[3,94]

■ PHYSICAL EXAMINATION

Even when relatively extensive disease is present, pulmonary TB most often produces no detectable abnormality on physical examination.[91,94] It is important to examine for signs of extrapulmonary disease such as lymphadenopathy, abdominal, or bone and joint involvement, particularly in HIV-infected individuals. Tachypnea and hypoxia are relatively rare except with extensive lung destruction or miliary disease.

■ CHEST RADIOGRAPHY IN PULMONARY TB

Radiographic findings of TB are well described.[94–96] Sensitivity for active TB is 70% to 80%, and even less in patients with HIV or other severe immune compromise. Further, chest radiography is only moderately specific and there is generally poor agreement between chest film readers.[97–99] Chest radiography alone also cannot reliable distinguish between active and healed, latent TB.[97,98,100]

Typical Chest Radiograph Patterns

Four radiographic features suggest active TB: (1) Nodular opacities located in the apical-posterior segments of the upper lobes or superior segment of the lower lobes, (2) associated volume loss and fibrosis, (3) lung cavitation, and (4) endobronchial spread. Endobronchial spread to dependent lung segments fills lung acinar units, resulting in 4- to 5-mm size nodular opacities on plain film (acinar shadows) and a "tree-and-bud" pattern on computed tomography (CT) (Figs. 131-6 and 131-7).[95,98,101]

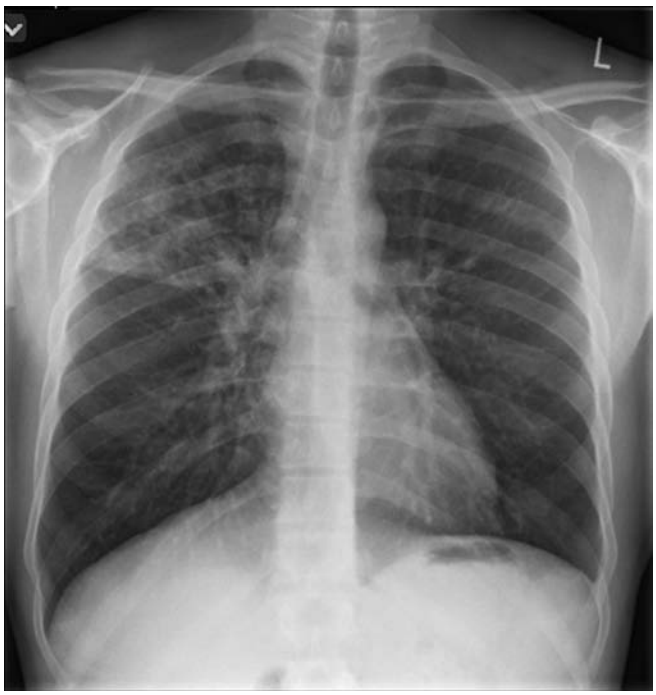

Figure 131-6 This 32-year-old male refugee recently arrived from Eritrea. He presented with persistent cough and fevers despite completing two courses of antimicrobial therapy directed against bacterial community–acquired pneumonia. Sputum sample was both smear positive and culture positive for MTBC.

Figure 131-7 This 36-year-old man Aboriginal man with history of homelessness. This radiograph demonstrates typical manifestations of reactivation TB: upper lobe nodular opacities, cavitation, acinar shadowing from endobronchial spread, and fibrosis.

Atypical Chest Radiograph Patterns

Atypical radiographic patterns are seen in children, the elderly, the immunocompromised, and those with primary disease.[96,100,102] Atypical features include lower lung zone infiltrates without cavitation, unilateral pleural effusion (Fig. 131-8), and ipsilateral hilar or

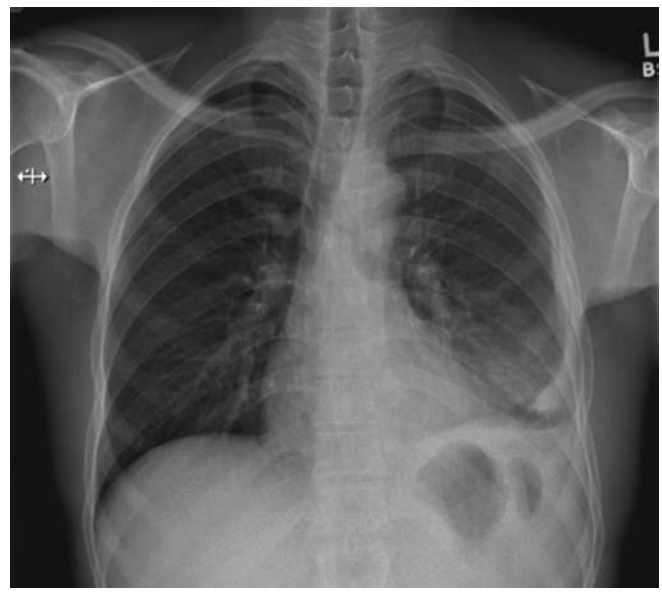

Figure 131-8 This 22-year-old man identified as a close household contact of a smear-positive case of pulmonary tuberculosis. Seven weeks later he developed fevers and cough. This radiograph demonstrates unilateral pleural effusion with compressive atelectasis. Diagnostic thoracocentesis revealed a transudate with cellular infiltrate, predominantly lymphocytic. Sputum was culture negative for mycobacteria but pleural specimen eventually grew MTBC.

Figure 131-9 This 42-year-old HIV+ man with a CD4 count of 150 cell/mm^3 presented with cough. Significant mediastinal and right hilar adenopathy are present without apparent lung parenchymal disease. Sputum cultures were smear negative but culture positive for MTBC.

mediastinal adenopathy (Fig. 131-9). Intrathoracic TB lymphadenitis is often better appreciated on CT where lymph node enlargement, rim enhancement, and low central attenuation are characteristic.[95]

Miliary TB is rare but when present, produces a distinctive, readily recognizable radiographic pattern: Innumerable, interstitial nodules uniformly distributed throughout all lung fields, without reduction in lung volumes (Fig. 131-10).

DIAGNOSIS OF TB

Most US clinicians will practice for years without ever encountering a case of TB. For every 450 ambulatory visits for community-acquired pneumonia (CAP), and for every few dozen cases of lung cancer, there is on average one case of TB in the United States.[103,104] In low-incidence settings, many patients diagnosed with TB will have experienced multiple contacts with the healthcare system before the diagnosis of TB is considered.[105,106]

Figure 131-10 This 36-year-old HIV+ man presented with fevers. Chest radiograph identified right upper lobe infiltrate and a background miliary pattern consisting of innumerable noncalcified nodules measuring 2 to 3 mm, randomly distributed.

Thus the diagnosis of TB requires a very high-index of suspicion considering epidemiologic risk factors and suggestive clinical–radiographic features (Fig. 131-11). Ultimately, the definitive diagnosis requires culture confirmation.

■ LABORATORY INVESTIGATIONS

Anemia is commonly observed in TB, usually due to chronic inflammatory state or malnutrition.[94] Syndrome of inappropriate ADH can complicate pulmonary or central nervous system TB.[107] Historically, disseminated TB was an important cause of adrenal insufficiency. Hypercalcemia is a relatively frequent complication of TB.[108] Activated macrophages within granulomas upregulate 1-alpha-hydroxylase, which can in turn activate vitamin D and lead to increase in calcium absorption.[109–111] Hypercalcemia of TB can be symptomatic and occasionally leads to nephrocalcinosis, nephrolithiasis, or acute volume depletion. Vitamin D supplementation during TB therapy may increase the risk of hypercalcemia.[112]

Specimen Collection

Protocols to ensure proper specimen handling, storage, transport, and labeling are available.[94] Ideally, specimen collection should occur before initiation of therapy to increase yield.

For the diagnosis of pulmonary TB at least three sputum samples, each 5 to 10 mL, should be collected at least 1-hour apart. For those patients unable to expectorate spontaneously, sputum induction (with nebulized hypertonic saline) or bronchoalveolar lavage (BAL) is an alternate established method.[113] Induced sputum samples produce slightly higher yield than do BAL samples (87% vs. 73%), and sputum induction is much better tolerated, less invasive, and lower cost.[114,115] If bronchoscopy is performed to evaluate other diagnostic considerations, then an additional sputum sample collected immediately after bronchoscopy may have particularly high-yield for mycobacterial identification.[113]

For diagnostic confirmation of extrapulmonary TB, tissue or fluid samples should be submitted fresh (or in sterile normal saline) without addition of preservative (e.g., formalin) because this will prevent subsequent identification, culture, and DST in the microbiology laboratory. It is important to notify both the laboratory and clinician before collecting a specimen if extrapulmonary TB is suspected to allow the laboratory to take appropriate biosafety precautions during specimen handling to prevent laboratory transmission of TB.

Direct Microscopy for AFB

Sputum-smear microscopy is more than 110 years old but remains the most widely used investigation for active TB today.[52] Two methods are commonly used for acid-fast staining of mycobacteria: carbolfuchsin (e.g., Ziehl–Neelsen [ZN]) and fluorochrome-based procedures (e.g., auramine–rhodamine dye). Fluorescent methods slightly improve sensitivity over ZN and also allow the use of lower microscopic magnification during inspection of the slide, significantly shortening the time required to examine an entire specimen.[116]

Sputum microscopy is widely available and low cost. It is performed directly on clinical specimens allowing rapid turn-around-time, thus facilitating prompt recognition, isolation, and treatment of infectious TB cases. Microscopy also provides prognostic information: Smear-positive TB cases are more infectious and have much higher case-fatality rates if untreated than do sputum smear–negative cases.[72,117,118]

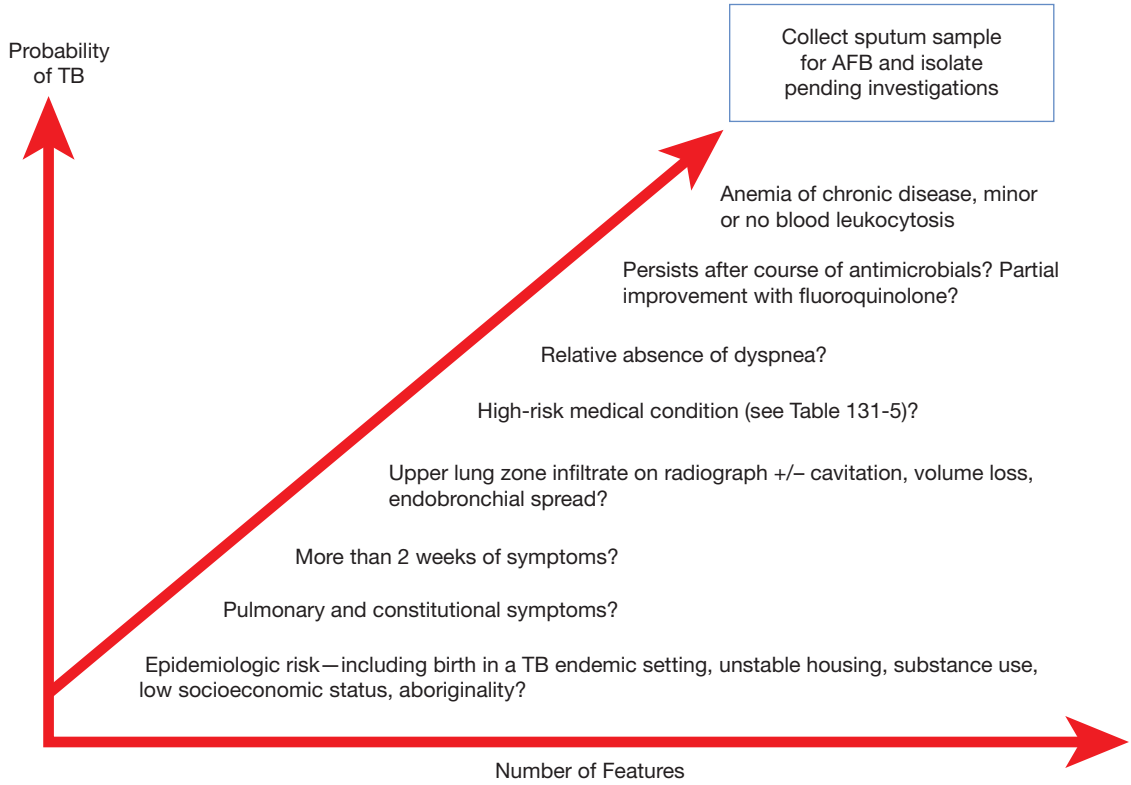

Figure 131-11 Clinical factors increasing index of suspicion for tuberculosis. Increasing probability of TB warrants further investigation, especially collection of respiratory samples for mycobacterial stain and culture. For hospitalized patients, or those in congregate living settings, increasing suspicion warrants prompt isolation pending results of investigations. *(Used with permission of Richard Long, unpublished observations).*

However, sputum-smear microscopy has well-known limitations. Sensitivity for pulmonary TB is only about 60% to 70%, and even lower in extrapulmonary specimens and in those with HIV coinfection. That NTM also stain acid-fast lowers the specificity of smear microscopy.[119–121] In low TB prevalence settings, NTM are recovered from about 30% to 50% of AFB smear–positive sputum samples.

Mycobacterial Culture

Mycobacterial culture remains the gold standard for the diagnosis of active TB. About 5000 to 10,000 bacilli per milliliter of specimen are required for detection by smear microscopy and about 100 bacilli per millimeter for nucleic acid amplification (NAAT); culture methods can detect as few 10 viable bacilli per millimeter of sample.[94] In addition, biochemical and phenotypic testing of isolated organisms provides near perfect specificity, distinguishing even between individual members of the MTBC. Of particular importance, isolation of the infecting organism permits DST and is required to conduct molecular subtyping (i.e., DNA fingerprinting).

Culture of MTBC from clinical specimens takes, on average, between 2 to 4 weeks, but as long as 8 weeks in some specimens with low initial concentration of organism.[122] Culture requires a Level III biosafety laboratory to prevent transmission to laboratory technicians and availability of such facilities is poor in most high-burden, resource-limited settings.

Nucleic Acid Amplification

NAAT is a useful tool in the diagnosis of TB offering higher sensitivity than microscopy and shorter turn-around-times than culture.[100,123,124] Sensitivity of NAAT in AFB smear–positive respiratory samples is excellent, usually greater than 95%.[123] However, in paucibacillary specimen types, such as AFB smear–negative sputum and extrapulmonary samples, the sensitivity is reduced to 40% to 60%, with a negative predictive value inadequate to exclude a diagnosis of TB.[125–129] Specificity of NAAT methods is very high, ranging between 90% and 100% for all specimen types.

Performance of traditional NAAT requires sophisticated laboratory facilities. Recently, an automated in-cartridge assay (Xpert/MTB-RIF [Cepheid, Sunnyvale, California]) was developed to allow NAAT directly from unprocessed clinical specimens, without the need for centralized reference laboratory, even in resource-limited settings.[130–132] The Xpert/MTB-RIF simultaneously detects mutations within the mycobacterial RNA-polymerase gene that correlate with rifampin-drug resistance, thus identifying MDR cases several weeks before culture-based testing. The WHO has signaled its intent to deploy this tool in high-burden, resource-limited settings throughout the world.[132]

Testing for Latent TB infection

There are two main tests for the identification of LTBI: (1) Tuberculin skin test (TST) and (2) IFN-γ release assays (IGRAs). Both are indirect, in that they evaluate the presence of host cell–mediated immunity rather than detect actual mycobacterial organisms or antigens.[133] As such, neither can distinguish active disease from latent infection. Both tests have very poor sensitivity and predictive value for active TB and use in this context is discouraged.[134,135] These tests are better used to assess candidates for LTBI treatment (discussed below).

MANAGEMENT OF ACTIVE TB

Prior to the availability of chemotherapy, prevailing wisdom prescribed fresh air, nutrition, sunlight, and rest for treatment of TB. In 1947, clinical outcomes of smear-positive pulmonary TB patients treated at a sanatorium in the United Kingdom were recorded: within 4 years of entry, 55% died, 20% remained chronically affected, and 25% experienced remission.[136] With the discovery of chemotherapy for TB, mortality dropped orders of magnitude and within a decade TB sanatoria were shuttered.[6,137]

TABLE 131-7 Drug Regimens for Treatment of Active Tuberculosis in Adults, Caused by Susceptible Organism

	Initial Phase (First 2 Mo)	Continuation Phase	Comments
Regimen 1	INH + RIF + PZA + EMB[a] Given daily or 5×/wk	4 mo INH + RIF Given daily or 3×/wk[b]	Extend continuation phase to 7 mo if risk of relapse present[c]
Regimen 2	INH + RIF + EMB[a] Given daily or 5×/wk	7 mo INH + RIF daily or 3×/wk	This "PZA-free" regimen can be used if risk factors for hepatotoxicity[d] or in pregnancy
Regimen 3	INH + RIF + PZA+EMB[a] Given 5×/wk for first 2 wk then ×wk for next 6 wk[e]	4–7 mo INH + RIF Given 3×/wk	Intermittent therapy should always be provide as DOT[e]
Regimen 4	INH + RIF + PZA + EMB[a] Given daily or 5×/wk	4 mo RPT weekly and INH 900 mg weekly	Not eligible for this regimen if cavitary disease, positive sputum cultures at 2 mo, or if HIV+

[a]*EMB is given pending results of INH susceptibility testing—if isolate confirmed fully susceptible than EMB is discontinued.*
[b]*Rifapentine and INH 900 mg given once-weekly in the continuation phase have been tested in small clinical trials but treatment outcomes were inferior and rifamycin resistance emerged on treatment in some patients; thus this schedule is probably best avoided.*
[c]*Risk factors for relapse include cavitation on chest radiograph, culture positive after 2 mo of therapy, poorly controlled HIV infection.*
[d]*Risk factors for PZA hepatotoxicity include advanced age or underlying liver disease.*
[e]*Intermittent therapy during the intensive phase is associated with slightly poorer treatment outcomes in patients with extensive disease or HIV coinfection. See text for adjunctive corticosteroid use recommendations.*

Am J Respir Crit Care Med. 2003;167(4):603–662 and Zumla A, Raviglione M, Hafner R, von Reyn CF. Tuberculosis. N Engl J Med. 2013;368(8):745–755.

■ PRINCIPLES OF TB THERAPY

The aims of TB therapy are to (1) Interrupt transmission by rapidly rendering patients noninfectious, (2) relieve symptoms and prevent mortality, (3) prevent the emergence of drug resistance, and (4) prevent future relapse by providing a definitive cure.

To achieve these aims, treatment regimens must include combination of potent bactericidal drugs which are provided for a minimum of 6 months. The choice of regimen should be guided by the results of DST. TB regimens are divided into an initial intensive phase, designed to quickly reduce large bacillary burden, followed by a prolonged continuation phase that consolidates antimycobacterial killing while allowing intermittent dosing and lower pill-burden. A high level of adherence is required to prevent relapse and emergence of resistance. Rifamycins have a critical role in preventing relapse and whenever possible should be provided throughout the treatment. Several randomized clinical trials have established standardized treatment regimens as outlined in Table 131-7. Reported success rates with these regimens approach 95%.[138–140]

■ FIRST-LINE TB DRUGS

Current first-line TB drugs include isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB) (see Table 131-8).

TABLE 131-8 TB Drug Dosing and Important Adverse Reactions

Drug[a]	Daily Dose (Maximum Dose)	Thrice-Weekly Dose	Renal Dose: for IHD or eGFR <30 mL/min	Selected Adverse Events
Isoniazid (INH)	5 mg/kg (300 mg)	10 mg/kg (600)	No change	Hepatotoxicity Peripheral neuropathy
Rifampin (RIF)	10 mg/kg (600 mg)[b]	10 mg/kg (600 mg)[b]	No change	Thrombocytopenia Drug–drug interactions[c]
Rifapentine (RPT)	—	10 mg/kg (600 mg), given once-weekly	No change	Drug–drug interactions
Pyrazinamide (PZA)	20–25 mg/kg (2000 mg)	30–40 mg/kg (4000 mg)	25–35 mg/kg 3×/wk	Hepatotoxicity Hyperuricemia Arthralgia
Ethambutol (EMB)	15–20 mg (1600 mg)	25–35 mg/kg (2400 mg)	15–25 mg/kg 3×/wk	Optic neuritis
Moxifloxacin or Levofloxacin	400 mg 750–1000 mg	NS	No change; 750 mg 3×/wk	GI upset QT prolongation Insomnia Tendinopathy

NS, not yet studied; IHD, intermittent hemodialysis.
[a]*All drugs are provided orally; however, INH, RIF, and the flouroquinolones are available as intravenous formulations.*
[b]*Higher doses of rifampin are well tolerated and perhaps more efficacious; ongoing trials are examining higher dosing schedules.*
[c]*Drug–drug interactions mediated mostly through cytochrome p450–3a4 enzyme induction.*
Source: Data from Blumberg H, Burman WJ, Chaisson RE, et al. American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: treatment of tuberculosis. Am J Respir Crit Care Med. 2003;167(4):603–662 and World Health Organization & Initiative, S.T., 2010. The treatment of tuberculosis guidelines. 4 ed. Geneva.

INH, first introduced in 1952, remains a cornerstone of TB treatment. It has potent bactericidal activity and effects rapid decline of sputum bacillary load within days of administration and thus rapidly reduces infectiousness.[141] INH is generally well tolerated but can cause hepatotoxicity, requiring cessation of therapy in a small subset of patients. Risk factors for severe INH-related hepatotoxicity include older age and pre-existing liver diseases.[142] Peripheral neuropathy can develop in elderly, malnourished, or diabetic patients taking INH, but this risk is lowered with concomitant administration of pyridoxine (vitamin B6).

RIF revolutionized TB therapy following its introduction in 1968 and has since become a critical component of modern, short-course TB regimens.[141,143,144] Rifampin and other rifamycins appear to have unique relapse-preventing properties that allow the duration of chemotherapy to be shortened to 9 months or less. In the absence of rifampin, relapse rates are unacceptably high, and treatment must be given more than 18 months.

RIF is very well tolerated in the vast majority of patients. Rarely, hypersensitivity reactions occur, including thrombocytopenia, flu-like syndrome, and neutropenia. Rifampin is a strong inducer of the cytochrome p450 oxidation system (CYP450) and interacts with a multitude of other medications.[145] Rifampin produces a benign orange-red discoloration of body fluids (urine, tears, sputum, feces, sweat) and can permanently stain contact lenses and dentures.

Rifapentine (RPT) is also a rifamycin but with a half-life 5 times longer than RIF, which allows the drug to be given once-weekly. The prolonged half-life makes RPT an attractive agent for use in intermittent treatment regimens in order to facilitate adherence.[146] However, use of weekly dosed RPT is associated with relapse and acquired resistance in those with extensive disease, slow sputum culture conversion, or HIV coinfection.[146–148] RPT strongly induces CYP450 leading to multiple potential drug–drug interactions. Other rifamycins (e.g., rifabutin) produce lower levels of CYP450 induction. RPT is generally well tolerated but hypersensitivity syndromes including fever, myalgia, and cytopenias occurred in about 3% of patients in a clinical trial of LTBI treatment.[149]

PZA is bactericidal and when added to treatment regimens containing RIF permits shortening duration to 6 months.[150] Arthralgias are the most frequently reported adverse event and can be alleviated by the administration of nonsteroidal anti-inflammatories. PZA can also cause severe hepatotoxicity, especially in the elderly and those with pre-existing liver disease.

EMB is the weakest first-line agent, contributing little to early bactericidal activity or to relapse prevention. However, it is effective in preventing the emergence of resistance to isoniazid. It is generally well tolerated. Optic neuritis, the main adverse drug event, occurs infrequently with the currently recommended dosages except in the presence of renal impairment. EMB is added to the initial phase of treatment regimens pending results of susceptibility testing; but absent confirmed drug-resistance, EMB is discontinued.

Later-generation fluoroquinolones (FQs) are well-tolerated oral drugs with potent bactericidal activity against MTBC.[151–155] Based on accumulating clinical evidence, FQs may enter first-line treatment regimens in the near future.[156] However, FQs are currently indicated for intolerance or resistance to other first-line drugs.[157]

FQs are not uncommonly prescribed for CAP that later proves to be pulmonary TB.[158] FQ monotherapy can temporarily alleviate TB symptoms and can reduce the yield of TB sputum cultures, thus significantly contributing to diagnostic delay.[159] Inadvertent monotherapy of TB initially mistaken for CAP also risks the development of FQ resistance, potentially compromising future TB treatment options.[158] FQs should be used cautiously for suspect CAP in patients at significant epidemiologic risk for TB.

ADJUNCTIVE CORTICOSTEROID USE

Treatment of TB is occasionally complicated by paradoxical treatment responses whereby clinical deterioration develops a few weeks into an otherwise effective treatment.[160,161] The response is characterized by a robust inflammatory reaction, typically at the site of initial disease, without apparent microbiologic failure or bacillary replication. The paradoxical response is most commonly observed in extrapulmonary disease.[162] Paradoxical responses are typically self-limited, even when TB treatment is continued. Symptomatic benefit is sometimes observed following a brief course of corticosteroid treatment.[161] Important differential diagnostic considerations of paradoxical responses that should be excluded prior to treatment with corticosteroids include treatment nonadherence, inadequate dosing, drug malabsorption, or drug-resistant TB.

For disease of the pericardium and the CNS, the consequences of a paradoxical response are potentially life threatening including increased intracranial pressure and constrictive pericarditis, respectively. Meta-analyses have suggested an appreciable benefit to simultaneous initiation of corticosteroids along with TB treatment for these forms of TB.[163–165] The regimens tested in the clinical trials varied but 40 to 80 mg of prednisone per day for 6 to 12 weeks is a common prescription.

DIRECT OBSERVATION OF THERAPY

Direct observation of therapy (DOT) ensures adherence, thus improving treatment outcomes and preventing emergence of resistance.[166] Because physicians are poor at predicting which patients will adhere to therapy, DOT is recommended for all patients.[138]

INTERMITTENT DOSING

Direct supervision of therapy by healthcare workers is facilitated by intermittent treatment regimens (e.g., 5 days per week, or Monday—Wednesday–Friday or even twice-weekly). Intermittent dosing schedules take advantage of the slow growth of MTBC and the postantibiotic effect of TB drugs.[167,168] However, acquired drug resistance has been documented with intermittent dosing schedules, especially in patients with extensive disease or poorly controlled HIV coinfection.

TREATMENT MONITORING

Bacteriologic monitoring (e.g., monthly sputum cultures until negative) is the preferred method of follow-up for pulmonary TB cases. A persistently positive sputum culture 2 months after starting effective treatment is a marker for relapse and treatment extension is suggested. Culture positivity at 3 months is highly suggestive of treatment failure and patients must be carefully evaluated to identify potential causes (e.g., nonadherence, malabsorption, acquired resistance, drug–drug interactions). Treatment failure is defined as persistently positive cultures 4 months into treatment.

ADVERSE EFFECTS

Severe side effects necessitating drug discontinuation are rare with standard TB treatment regimens. A commonly encountered adverse event is drug-related hepatotoxicity.[138,142] Transient, mild elevation in liver enzymes early in the course of therapy occurs in about 20% of patients and is usually inconsequential, usually resolving without intervention and without treatment interruption. However, for patients with symptomatic and/or marked elevation of transaminases (above 3–5× the upper limit of normal) treatment should be immediately discontinued and drugs cautiously reintroduced one at a time under close monitoring once the liver enzymes and function has returned to normal.

DRUG-RESISTANT TB

Drug resistance to any of the first-line TB drugs occurs in about 8% of TB cases in the United States.[41] Mono-resistance to INH, the most

TABLE 131-9 Hierarchy of Second-Line TB Drugs

Group		Drugs
Group 1	First-line oral—bacteriocidal	PZA, Ethambutol, Rifabutin
Group 2	Injectable agent	Amikacin, Kanamycin, Capreomycin
Group 3	Fluoroquinolones	Moxifloxacin, Levofloxacin, Gatifloxacin, Ofloxacin
Group 4	Second-line oral (BD-TID)—bacteriostatic	Ethionamide, PAS, Cycloserine
Group 5	Agents with unclear efficacy	Linezolid, Clofazimine, Clarithromycin, INH 900 TIW, Amoxicillin-clavulanate, Imipenem–Cilistatin

TIW, three times weekly.
Treatment regimens for MDR-TB should be guided by drug-susceptibility testing. Typically use between 4 and 6 agents with predicted activity. Wherever possible a fluoroquinolone and injectable agent should be used initially. The lower the group number, the more preferred are the drugs on the basis of efficacy and anticipated tolerability.
Source: Data from Drug-resistant Tuberculosis: a Survival Guide for Clinicians, 2nd ed. Curry National Tuberculosis Center; 2008.

common resistance pattern observed, does not appear to compromise TB treatment outcomes substantially as long as RIF, EMB, and PZA can be continued throughout.[138,169–171] Although definitive data are lacking, an FQ can probably replace INH in standard treatment regimens.

Multidrug resistance was demonstrated in less than 1.6% of all TB cases in the United States in 2012.[41] Among patients with a history of previous TB treatment, MDR-TB prevalence was 8.2%. The majority (86%) of MDR-TB cases in the United States occur in foreign-born individuals. Multidrug resistance has a great impact on treatment outcomes in TB, with success rates ranging from 52% to 77%.[172–176] Multidrug resistance also adds substantially to the costs of treatment.[32,177] Further, second-line agents used in treatment of MDR-TB have significant toxicities, high rates of intolerance, high-pill burdens, and inconvenient dosing regimens, making adherence difficult.[178] Finally, MDR-TB requires at least 18 to 24 months duration.[15,179,180] The management of MDR-TB is complex and referral to specialized centers that offer experience and expertise is strongly recommended. Second-line TB agents and important side effects are listed in Tables 131-9 and 131-10.

Several promising new drugs with novel mechanisms of action are in clinical development.[181] Bedaquiline and delamanid have each proven efficacious in phase 2b trials but demonstration of safety is pending larger trials.[182–184] PA-824, SQ-109, and sutezolid have also shown efficacy in small clinical studies and appear ready for further clinical development.[179,185] Linezolid, an oxazolidinone commonly used in treatment of resistant gram-positive infections, has been shown to be effective for the treatment of MDR-TB in controlled trials but treatment-limiting toxicities are common with prolonged durations.[186]

■ TREATMENT ISSUES IN SPECIAL POPULATIONS

Treatment considerations in two special patient populations—those coinfected with HIV and solid organ transplant recipients—are discussed below.

HIV Coinfection

Standard regimens used for the treatment of TB in HIV-uninfected individuals have similar efficacy in HIV-infected individuals, provided these patients are also effectively treated with antiretroviral therapy (ART).[187] However, the addition of ART to TB treatment can result in overlapping drug toxicity and intolerances including peripheral neuropathy, hepatotoxicity, and GI upset. Potent bidirectional drug–drug interactions between rifampin and several classes of antiretroviral drugs can amplify toxicity and undermine HIV virologic control. A number of studies have also found reduced serum concentrations of TB drugs in patients coinfected with HIV, thought to be due to decreased gastrointestinal absorption.[188] In turn, low serum drug concentrations may increase the risk of treatment relapse or acquired rifamycin resistance. Intermittent RPT in the continuation phase is associated with higher relapse rates in HIV-infected individuals and should be avoided.[146]

Successful HIV treatment with ART leads to immune reconstitution and, in patients with concurrent active TB, restores the host inflammatory response to TB infection. This can clinically present as transient worsening of TB disease a few weeks following initiation of ART (a phenomenon known as immune reconstitution inflammatory syndrome or TB-IRIS). TB-IRIS can occur following ART initiation in patients already on treatment for TB (paradoxical type) or in patients with previously undiagnosed TB (unmasking type). TB-IRIS produces significant morbidity, occasionally requiring glucocorticoid therapy for symptom control.[189] However, in patients diagnosed simultaneously with HIV and TB, treatment outcomes, relapse rates, and overall mortality are greatly improved when ART is added early, within a few weeks of initiating TB treatment, even if this strategy noticeably increases risk of TB-IRIS.[190,191]

TABLE 131-10 Second-Line TB Drugs and Selected Toxicities

Agent	Common and/or Important AEs	
Ethionamide (take with B6)	GI upset	Hypothyroidism
		Hepatotoxicity
		Neuropathy
PAS (p-aminosalicylic acid)	GI upset (less with PASER formulation)	Hypothyroidism
		Hepatotoxicity
Cycloserine (take with B6)	Headache	Neurologic and psychiatric impairment
Amikacin	Nephrotoxicity	Ototoxicity
Linezolid	Cytopenia	Irreversible and reversible
	MAO inhibition	Neuropathy and optic neuritis
Moxifloxacin	Nausea, GI upset	Tendinopathy
Capreomycin	Nephrotoxicity	Ototoxicity, Neuropathy

Solid-Organ Transplantation

The majority of TB cases in solid-organ transplant recipients arise from reactivation of latent infection acquired prior to transplantation.[192] Donor-derived TB transmitted with organ transplantation is very rare. Overlapping drug toxicity and significant drug–drug interactions complicates treatment of TB in transplant recipients.[193] Rifampin significantly lowers serum drug concentrations of immunosuppressant medications, which can precipitate organ rejection. Rifabutin, a rifamycin with less CYP450 activity than either RIF or RPT, has good activity against MTBC and can be used instead of RIF in standard TB regimens, albeit with a less robust evidence base.[194,195] Liver transplant recipients are particularly prone to INH and PZA hepatotoxicity and alternative treatment regimens may be required.[196]

TARGETED TESTING AND TREATMENT OF LATENT TB INFECTION

The use of anti-TB drugs in latently infected patients to prevent subsequent progression to active disease was first reported in the early 1950s.[197] Dozens of controlled clinical trials subsequently confirmed that isoniazid reduced the risk of TB in those with positive TST by 60% to 90%, depending on the level of adherence.[198–200] An estimated 4% of the US population is latently infected[201] but currently available tests do not reliably predict which infected individuals will eventually develop active disease.[202] Furthermore, up to 5% of those treated for latent infection will experience an adverse event, rarely this can be severe hepatotoxicity and fulminant hepatic failure.[142,203,204] Thus, the decision to treat LTBI must be individualized, balancing the risk of developing active TB against the potential for adverse events.

■ DIAGNOSIS OF LTBI

The diagnosis of latent TB infection hinges on a positive TST and/or IGRA (discussed above). Once infected with MTBC, it is believed that the potential for reactivation persists for the lifespan of the host.

■ TUBERCULIN SKIN TEST

The TST is more than 100 years old.[205] The most commonly used method for administering the TST is the Mantoux technique: Here, 5 tuberculin units of purified protein derivative (PPD) from *M. tuberculosis* are injected intradermally on the inner surface of the left forearm. In those individuals with cell-mediated immunity to PPD, a delayed type hypersensitivity (DTH) response will occur, manifest as a circular indurated skin reaction arising at the site of injection 48 to 72 hours later.

Several factors can undermine the predictive value of the TST for latent TB infection.[133] Potential causes of false-negative reactions include immune compromise, malnutrition, chronic renal failure, improper administration, and expiration of tuberculin.[204,206] TB disease itself reduces test sensitivity, with up to 25% of TB cases TST negative. The TST is also prone to false-positive reactions. PPD is a relatively crude extract of mycobacterial antigens, many of which are conserved between mycobacterial species. Sensitization to PPD can develop after routine exposure to environmental NTM or following previous vaccination with BCG.[133]

Although technically simple, significant training and expertise is required for reliable test performance and interpretation. Roughly speaking, the larger the reaction size, the more likely latent TB infection. The predictive value of the test varies by prevalence of LTBI and immunocompetence and different reaction size criteria are used to define positivity in different populations[204] (see Table 131-11).

■ INTERFERON-γ RELEASE ASSAYS

IGRAs are in vitro blood tests of CMI response; they measure T-cell release of IFN-γ following stimulation by synthetic peptide antigens specific to *M. tuberculosis*.

TABLE 131-11 Interpretation of Tuberculin Skin Test

TST—Reaction Size (mm)	Situation Where This Reaction is Considered Positive (i.e., Indication for Treatment of LTBI)
0–4	LTBI treatment not generally indicated
	Children <5 y who are recent close contacts should start INH pending repeat TST performed 8 wk from last contact
≥5	HIV infection
	Recent close contact of infectious case
	Fibrotic changes on chest X-ray consistent with old TB (but not previously treated)
	Organ transplantation
	Other immunosuppressed patients (TNF-α, chemotherapy, glucocorticoids[a])
≥10	Other high-risk conditions—silicosis, diabetes, malignancy,[b] underweight, CKD requiring dialysis
	Children less than 4 y of age
	Recent immigrants from TB endemic countries (>125 per 100,000 incident TB cases per year) within past 5 y
≥15	Healthy, low-risk reactor[c]

CKD, chronic kidney disease.
[a]Glucocorticoids at doses >15 mg/d prednisone equivalent for at least 1 month.
[b]Lymphoproliferative disease, head and neck and lung neoplasm.
[c]Healthy low-risk reactors may not require LTBI treatment as risk of treatment related toxicities may outweigh clinical benefit.
Source: Data from Horsburgh CR, Rubin EJ. Clinical practice. Latent tuberculosis infection in the United States. N Engl J Med. 2011;364(15):1441–1448.

Replacing the mixture of antigens contained in PPD with specific synthetic peptides greatly improves the specificity of IGRAs compared to TST, especially in populations previously vaccinated with BCG.[207,208] The sensitivity of the IGRA is comparable to the TST, even in immunocompromised hosts, although the absence of a gold standard makes precise estimation difficult.[209–211]

IGRA appear less reproducible on repeated testing than is TST, especially when values of IFN-γ release are near the quantitative threshold for reporting positive (i.e., borderline positive).[212] This can result in spontaneous conversions and reversion on serial testing of the same individual, with uncertain clinical implications.[213]

There are two currently approved IGRA tests available in the United States: the QuantiFERON-TB Gold In-Tube assay (Cellestis Limited, Australia) and the T-SPOT.TB assay (Oxford Immunotec, United Kingdom).

■ WHICH TEST TO USE IN LTBI

Either the TST or the IGRA are acceptable for the diagnosis of LTBI.[135] The improved specificity of IGRAs, and the need for a single patient visit, make this test attractive. IGRAs are associated with high testing costs and require laboratory infrastructure and significant technical expertise. The improved specificity of the IGRA might reduce the number of candidates for LTBI treatment but whether this translates to cost-effectiveness is controversial.[214] TST is preferred for serial testing, for example of healthcare workers repeatedly exposed to infectious TB, a setting where the IGRA performance has not been defined. Use of both tests simultaneously, where a positive result on either the TST or the IGRA signals latent

infection, may help improve sensitivity of LTBI screening in those with compromised immunity.[214,215]

■ DECISION TO TREAT LTBI

The first step in deciding whether to treat for LTBI is to assess the likelihood that a positive TST or IGRA represents true TB infection. Both tests perform poorly in low-prevalence populations and a true positive result is much more likely in those exposed to active TB or from high-risk epidemiologic groups such as foreign-born, travelers to TB endemic countries, homeless, and incarcerated populations.

The second step is to estimate likelihood of progression to active TB if actually infected[211] (see Table 131-2). The third step is to evaluate potential risks for adverse reactions to treatment. The main adverse effect of LTBI treatment is INH-related hepatotoxicity. The strongest predictor of hepatotoxicity is age. Those younger than 20 years old have less than a 0.1% chance of hepatotoxicity during LTBI treatment, whereas those over 65 years are exposed to a risk around 2% to 5%. An internet-based calculator is available to assist in balancing these probabilities and informing treatment decisions.[216]

Treatment of LTBI has only been demonstrated to be effective in those with a positive TST or IGRA. Several clinical trials have failed to demonstrate a benefit of treatment in immunocompromised individuals at risk but with a negative TST or IGRA.[217,218]

Before the treatment of LTBI is started, active disease must be excluded carefully by means of history, physical examination, chest radiography, and sputum culture, in order to avoid inadvertent monotherapy of active TB that could lead to resistance.

■ TREATMENT FOR LTBI

The best studied treatment of LTBI is self-administered INH taken daily for 9 months.[200,219] Other acceptable regimens are shown in Table 131-12. Shorter treatment regimens for LTBI typically result in improved completion rates. Intermittently dosed regimens have less supporting efficacy data but might be used in settings where adherence to unsupervised treatment is expected to be poor. Contacts of INH-monoresistant cases can be offered 4 months of RIF daily. Contacts of MDR-TB can be offered therapy with an FQ daily for 9 months although data are limited.

Patients receiving LTBI treatment should be monitored at least monthly for clinical symptoms of hepatitis. They should also be educated about the symptoms of hepatitis and instructed to stop the medication immediately and seek prompt evaluation to reduce risk for progression to severe disease.

TB VACCINATION

Laboratory attenuation of *M. bovis* by repeated sub-cultivations in bile acids by French researchers Albert Calmette and Camille Guerin eventually led to the creation of a TB live-attenuated vaccine BCG in 1928.[220,221] This vaccine is rarely used in the United States today, but worldwide remains one of the most commonly delivered childhood vaccines with coverage rates approaching 100% in most resource-limited settings. Despite its wide use, there remains some controversy as to its actual efficacy, and some concern that ongoing sub-culture to produce the vaccine is resulting in loss of activity.[222] Disseminated infection with BCG has been documented in severely immune-compromised children and universal vaccination is therefore no longer recommended in low-prevalence settings.[223] In the Unites States, BCG is perhaps more commonly encountered as a therapeutic agent for management of bladder transitional cell carcinoma. Disseminated TB has been documented in this patient group but human-to-human transmission is not reported.[224,225]

Ongoing research is directed toward a vaccine to replace BCG, ideally with improved efficacy against both infection and progression to TB.[226] However, after millennia of coevolution, the host–pathogen relationship is extremely complex and inadequate understanding of TB immunity and correlates of protection hamper progress in vaccine development.

CONCLUSION

TB has become an uncommon cause of cough in the United States and a high index of suspicion is required. Diagnostic delay occurs frequently despite availability of accurate diagnostic technologies. In settings of chronic medical illness, immunocompromise, and social depravation, TB can flourish. Treatment is effective and can significantly reduce a high case-fatality rate. Current research is directed to shortening the duration of therapy to facilitate adherence and treatment completion rates. New drugs are being developed and promise

TABLE 131-12 Acceptable Dosing Regimens for Treatment of Latent Tuberculosis Infection

Regimen	Adult Dosing (Oral)	Mode of Administration	Evidence Base
Isoniazid[a]	300 mg daily 9 mo	SAT	Strong evidence, based on several RCTS (Siamera, 2000); Higher efficacy with 9 mo
	300 mg daily 6 mo	SAT	
Isoniazid plus rifampin	Isoniazid 300 mg and rifampin 600 mg daily for 3 mo	SAT	Strong evidence (HKCS, 1992 Ena 2005; Whalen, 1997)
Rifampin	600 mg daily for 4 mo	SAT	Moderate evidence (HKCS, 1992; Menzies, 2008), 1 Cohort (Villarino, 1997)
Isoniazid Intermittent	900 mg 2×/wk 6–9 mo[b]	DOT	Weak evidence (Mwinga, 1998)
Isoniazid and Rifampin Intermittent	Isoniazid 600 mg and rifampin 600 mg twice-weekly for 3 mo	DOT	Weak evidence (McNab, 2000)
Isoniazid and Rifapentine Intermittent[c]	Isoniazid 900 mg and rifapentine 900 mg each weekly for 12 wk, each dose directly observed	DOT	Moderate evidence (Sterling, 2011; CDC/ATS, 2011)

SAT, self-administered treatment; DOT, directly observed treatment.

[a]Pyridoxine supplementation (25–50 mg daily) often provided to prevent INH-associated peripheral neuropathy, especially if risk factors including alcohol use disorder, diabetes, malnutrition, uremia, and HIV infection.

[b]Twice-weekly regimens should be provided under direct observation.

[c]This regimen not tested in children or pregnant women or those infected with HIV; the only trial of this regimen provided as DOP.

to improve outcomes in MDR disease. Ongoing national surveillance and funding of TB control programs is required to maintain low TB incidence in the United States. However, given that an increasing proportion of TB is imported, further reduction in TB incidence will ultimately require investment in TB control globally. Even in the wealthy countries of the West, TB is not conquered but continues to smolder, threatening reemergence where social injustice prevails and where the vigilance of TB control programs is relaxed.

CHAPTER 132

Diseases due to Nontuberculous Mycobacteria

Julie V. Philley
Richard J. Wallace Jr.

Nontuberculous mycobacteria (NTM) are ubiquitous in our environment so that exposure to these organisms is universal and unavoidable.[1] Unlike traditional tuberculosis, most of the approximately 150 currently identified NTM species are either nonvirulent or have low virulence for humans. The prevalence of NTM is rising in the United States, with many epidemiologic reports suggesting that NTM lung disease has surpassed tuberculosis.[2,3] Clinicians are encountering NTM infections with increasing frequency and a general knowledge of common pathogens and diagnostic criteria are essential for the care and successful treatment of these individuals.

Prior to the AIDS epidemic, most NTM cases presented as indolent, cavitating pulmonary infections in persons with underlying lung diseases such as chronic obstructive pulmonary disease (COPD) or previous tuberculosis. During the 1980s, infections due to the more common NTM (*Mycobacterium avium*, some *M. kansasii,* some unclassified) emerged as complications of acquired immunodeficiency syndrome (AIDS). *M. avium* and *M. intracellulare* were termed *M. avium* complex or MAC infections.[4,5] Subsequently, a syndrome of predominantly mid–lung zone bronchiectasis with MAC pulmonary infection was described in otherwise healthy middle-aged women, many with distinct body morphotypes including scoliosis, pectus excavatum, and mitral valve prolapse.[6,7] This syndrome is often referred to as Lady Windermere syndrome.[8] Mycobacterial infections after solid-organ and hematopoietic transplantation have also increased in frequency, reflecting both increased exposure and/or improved diagnostic methods, and almost universal use of central venous access devices.[9] In the absence of mandatory infection reporting, the true incidence of positive cultures or NTM disease in the general population and transplant recipients in the United States can only be estimated.

ORGANISMS AND DEVELOPMENT OF DISEASE

The microbiology, epidemiology, and pathogenesis of nontuberculous mycobacterial infections are considered below.

MICROBIOLOGY

Almost 150 NTM species have now been identified and speciated. The increased number of species reflects improved microbiologic techniques for isolating NTM from clinical specimens and the use of 16 S rRNA gene sequencing as a standard for defining new species.[10,11] To simplify understanding of these organisms, particularly as applied to clinical circumstances, they often are grouped into complexes of closely related species. The *M. avium* complex, for example, consists of multiple species, with the most frequent being *M. avium and M. intracellulare.* Certain species, such as *M. kansasii* are associated with human disease more often than others and are presumed to be more virulent while species such as *M. gordonae*, *M. terrae complex,* and *M. mucogenicum* most often represent contamination of the respiratory tract from exposure to tap water.[12]

A number of important considerations in the laboratory evaluation should be recognized:

1. Clinicians must be aware that these organisms may be present and request mycobacterial cultures in appropriate specimens. The Gram stain will not adequately detect mycobacteria. The preferred staining procedure is the fluorochrome method, although the Ziehl–Neelsen method and Kinyoun stain are less sensitive alternatives. NTM are often more sensitive to the acid-fast decolorization procedure.
2. Some specific guidelines have been adopted to avoid potential sources of contamination, especially tap water, in specimen collection. Mouth rinsing or brushing of teeth before collection should not be done. Specimens should be submitted without fixatives. Refrigeration of samples at 4°C should be used if transportation to the laboratory is delayed for over 1 hour.
3. Specimens should be cultured using both liquid and solid media. Species that are often associated with cutaneous and lymph node disease may require special growth conditions and/or lower incubation temperatures (28–32°C), including *M. haemophilum, M. genavense, M. marinum* and the rapidly growing mycobacteria (RGM). Methods for the isolation of NTM in clinical laboratories have been approved by the Clinical and Laboratory Standards Institute (CLSI).[13]
4. Molecular testing is used primarily (initially) to distinguish *M. tuberculosis* from NTM species. DNA probes exist for the most commonly encountered slowly-growing NTM species (*M. avium* complex or MAC, *M. avium, M. intracellulare, M. kansasii*, and *M. gordonae*). There are no probes for rapidly growing species such as *M. fortuitum* or *M. abscessus*.
5. NTM should be identified to the species level.
6. American Thoracic Society (ATS) guidelines and CLSI recommend that routine susceptibility testing be limited for MAC isolates to the macrolides (clarithromycin) and for *M. kansasii* isolates rifampin and clarithromycin.[12,13] For less frequently isolated, slowly growing mycobacteria such as *M. simiae, M. xenopoi,* etc. more extensive testing is recommended.[13]
7. For rapidly growing mycobacteria, in particular *M. fortuitum, M. abscessus, M. chelonae*, isolates should be tested against a more extended array of antibiotics including amikacin, imipenem, and clarithromycin.

Respiratory Specimens

To establish the diagnosis of NTM lung disease, sputum is often induced with 7% hypertonic saline or collected via bronchoscopy (Table 132-1). Alternatively, three expectorated specimens may be collected on different days. Respiratory specimens can be shipped to the laboratory by mail using standard shipping guidelines for laboratory samples. Lung biopsy or other tissue (e.g., lymph node) biopsy specimens can also be used for cultures.

EPIDEMIOLOGY AND PATHOGENESIS

NTM are ubiquitous in the environment, often isolated from soil and water, including household water sources. There is increasing concern that biofilms that form in municipal and household water supplies may be a significant harbor of NTM.[14–16] *M. avium*, *M. kansasii*, *M. simiae*, and *M. xenopi* are readily recovered from tap water in areas where these species are common. There has been no documentation of animal-to-human and rarely human-to-human transmission of NTM, including highly susceptible hosts (e.g., those with cystic fibrosis).[17–23]

NTM may cause both asymptomatic infection and symptomatic disease in humans. NTM are often detected in asymptomatic patients awaiting organ transplantation with diffuse nodular or interstitial lung disease. Skin test studies in adults indicate that a substantial proportion have had prior infection with NTM, notably in the southeastern

TABLE 132-1 Clinical and Microbiologic Criteria for Diagnosing Nontuberculous Mycobacterial (NTM) Lung Disease

Clinical (both required)

1. Pulmonary symptoms

   And

2. Radiographic abnormalities—nodular or cavitary opacities on chest radiograph or a high-resolution computed tomography scan that shows multifocal bronchiectasis multiple nodules

Microbiologic

1. Positive culture results from at least two separate expectorated sputum samples

   Or

2. Positive culture result from at least one bronchial wash or lavage

   Or

3. Transbronchial or other lung biopsy with mycobacterial histopathologic features (granulomatous inflammation or AFB) and positive culture for NTM or biopsy showing mycobacterial histopathologic features (granulomatous inflammation or AFB) and one or more sputum or bronchial washings that are culture positive for NTM

TABLE 132-2 Common Treatment Regimens for MAC

Nodular/bronchiectasis

1. Azithromycin 250–500 mg once daily or clarithromycin 500 mg twice daily orally three times weekly

   And

2. Ethambutol 25 mg/kg orally three times weekly

   And

3. Rifampin 600 mg orally or rifabutin 150–300 mg orally three times weekly

Cavitary disease

1. Azithromycin 250–500 mg daily or clarithromycin 500–1000 mg twice daily

   And

2. Ethambutol 15 mg/kg orally daily

   And

3. Rifampin 600 mg or rifabutin 150–300 mg orally daily

   Plus

4. Streptomycin 5–15 mg IM three times weekly or amikacin 5–15 mg IV three times weekly for at least 3 mo[a]

[a]*Peak levels should be monitored at least weekly with a goal of 20–25 μg/mL.*

United States.[24] While disease is often asymptomatic (and often in individuals with other underlying lung disease), in the immunologically normal host, NTM has not been shown to lead to latent infection. However, disease may be exacerbated by immune suppression.

The most common clinical manifestation of NTM infection is lung disease, but lymphatic, skin/soft tissue, and disseminated disease are also encountered.[25,26] CDC reports that of NTM isolates reported to the Public Health Laboratory System (PHLIS) database between 1993 and 1996, 75% were pulmonary, 5% were from blood, 2% from skin/soft tissue, and 0.4% from lymph nodes.[3] Disseminated NTM, primarily *M. avium*, infections occurs in HIV-infected patients with CD4+ T-lymphocyte counts below 50/cc.[27,28]

In individuals with congenital immune deficiencies such as chronic granulomatous disease, there may be defects in production of interferon (IFN)-γ or interleukin (IL)-12, or defects in receptors or pathways controlling responses to IFN-γ.[29,30] These IFN-γ pathway defects include receptor and signaling mutations in the nuclear factor-κB essential modulator, IFN-γ receptor 1 and receptor 2, IL-12 receptor 1 subunit, IL-12 subunit p40, and the signal transducer and activator of transcription 1 (STAT1). These defects are important given the role of macrophages in the innate immune response to NTM with IL-12 and IFN-γ essential for intracellular killing of mycobacteria. These patients, however, represent a small minority of patients with NTM disease.

Inhibitors of tumor necrosis factor (TNF-α) suggests that TNF also is essential in the prevention of disease activation.[31–34] These agents have been used in a variety of chronic inflammatory conditions, including inflammatory bowel disease and rheumatoid arthritis. The effect of these agents may persist for months to years after administration. In addition to NTM infection, such agents have been associated with activation of *Aspergillus species*, histoplasmosis, coccidioidomycosis listeriosis, and especially *M. tuberculosis*.[33,34]

Pulmonary Disease

There are two distinct prototypes of individuals with pulmonary NTM disease including nonsmoking postmenopausal women with nodular bronchiectasis, primarily involving the right middle lobe and the lingula (the Lady Windermere disease) and individuals with a long history of tobacco use and severe chronic obstructive lung disease (COPD) who present with fibrocavitary upper lobe changes. Women without obvious immune defects who have developed pulmonary NTM disease often have distinct body characteristics that may include scoliosis, low body mass index, pectus excavatum, mitral valve prolapse, and joint hypermobility.[6,7] The relationship between these physical traits and NTM infection remains elusive. Cavitary lung disease associated with COPD patients present formidable challenges to the clinician as treatment generally requires prolonged IV therapy as well as consideration of adjunctive surgery (Table 132-2). Disease (especially upper lobe fibrocavitary disease) should be treated as caused by *M. tuberculosis* until identification of the organism proves otherwise.

CLINICAL PRESENTATION

Most patients have pre-existing structural lung disease (Figs. 132-1 and 132-2) and present with chronic cough or sputum production, often with nonspecific signs, including dyspnea, fatigue, malaise, low-grade fevers, and weight loss. Both types of lung disease may present with hemoptysis. Physical examination is generally unrewarding, with auscultation of lungs ranging from diffuse rhonchi and wheezes to inspiratory squeaks. As noted, some women have a characteristic morphotype and are frequently otherwise in very good health.

Three forms of disease merit comment: hypersensitivity pneumonitis (HP) with NTM infection, infection in cystic fibrosis, and infection in transplant recipients. The hypersensitivity lung disease has been termed "hot tub lung." This unique form of HP is primarily seen after exposure to NTM from indoor hot tubs and spas, and occasionally contaminated showers, with aerosolization devices.[35–38] The hot tubs are often poorly maintained and the water contain large numbers of NTM (almost all *M. avium*). Treatment predominately includes exposure avoidance with the use of prednisone and/or antimicrobial agents.[12]

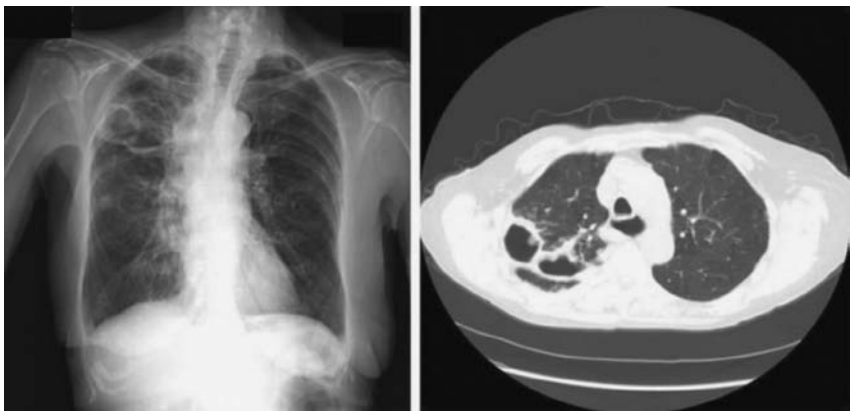

Figure 132-1 Right upper lobe cavitary MAC disease in a patient with COPD. **(A)** Chest radiograph. **(B)** CT scan.

A similar HP syndrome is seen in metal grinders (auto/machine workers, etc.) associated with exposures to metalworking fluids (paraffins, pine oils, and polycyclic aromatic hydrocarbons) containing mycobacteria.[39,40] This syndrome is associated almost exclusively with *M. immunogenum*, a rapidly growing mycobacterium. Onset of symptoms is subacute and is generally in nonsmokers without a clear disposition to infection. Chest radiographs and chest CT scans have diffuse small nodules with ground-glass infiltrates. Lung biopsy generally reveals centrilobular and bronchocentric nonnecrotizing granulomata, although some cases may have necrotizing granulomas, bronchiolitis and organizing pneumonia, or interstitial inflammation.

In cystic fibrosis, NTM are being increasingly isolated, often with uncertain clinical significance. As many as 20% of adolescent cystic fibrosis individuals, especially in the south in areas of Florida, Texas, and Louisiana, have at least one culture positive for NTM.[12,19] As a result, all routine sputum samples obtained in these patients should be cultured for both routine pathogens such as *Pseudomonas aeruginosa* and for NTM. This is especially important in patients who are given long-term azithromycin (a macrolide) for its anti-inflammatory properties. *M. abscessus* is the most common NTM in this setting and is increasingly being treated as a pathogen.

In solid-organ transplant recipients, NTM disease has been historically difficult to define with the most common manifestations of infection including cutaneous and pleuropulmonary disease (see Chapter 123).[9,41–43] Catheter-related infection is the most commonly reported manifestation of NTM disease in hematopoietic stem-cell transplant recipients.[9] In such hosts, skin and pulmonary lesions should be biopsied for histology, special staining, and microbiologic cultures, including bacteria, *Nocardia* species, fungi, and mycobacteria. NTM infections associated with catheters may be documented by tunnel or blood cultures. The RGM, especially *M. fortuitum,* are the most common pathogens. The pattern of NTM infection in transplantation differs from that of disseminated HIV-infection (more commonly *M. avium* complex), which limits extrapolation of therapeutic data from HIV-infected individuals to this population. Drug interactions are common and outlined in Table 132-3. Catheter-related infections have also been associated with a newly described pigmented RGM, *M. bacteremicum*.[44]

Figure 132-2 Chest CT scan showing bronchiectasis and nodular opacities in an 86-year-old female with MAC.

RADIOGRAPHY

Radiographic patterns associated with the aforementioned two phenotypes are uniquely distinct. The classic "Lady Windermere" pattern is associated with mid-lung field nodules and bronchiectasis, which may be accompanied by cavitations. On the opposite end of the spectrum, patients with COPD who have a long smoking history often present with large cavitary changes predominately located in the upper lobe lung zones, usually associated with a fibrotic pattern. There can be overlap of these disease spectrums making radiographic findings often diffuse and nonspecific.

TREATMENT

The approach to treatment varies with the species. Most species respond to regimens of several drugs. Toxicity and drug interactions are common (Tables 132-3 and 132-4). Therapy should be based on selected antimicrobial susceptibility testing that differs with each species or species complex. During therapy, monitoring for toxicity of drugs is essential. Such testing should include visual acuity, red–green color discrimination (ethambutol and rifabutin), liver enzymes (clarithromycin, azithromycin, rifabutin, rifampin, and isoniazid), auditory and vestibular function (streptomycin, amikacin, and azithromycin), renal function (streptomycin and amikacin), and leukocyte and platelet counts (rifampin, rifabutin, linezolid, trimethoprim–sulfamethoxazole and streptomycin). Clarithromycin enhances rifabutin toxicity (especially uveitis), whereas the rifamycin (rifampin more than rifabutin) is a potent inducer of the cytochrome p-450 system and can lower clarithromycin serum drug levels as well as steroids, anticoagulants, statins and β- blockers as a result of increased metabolism.

SURGERY

Lung resection for NTM was historically seen as a desperation or last resort measure in patients with severe, unresponsive disease. Surgery in the premacrolide era was often accompanied by significant perioperative complications.[45] Multiple studies have described surgical intervention in the era of macrolide use with relatively low operative mortality.[46–49] Surgery has also been shown to be an important adjunctive therapy for patients with *M. abscessus* lung disease, a pathogen that is especially difficult to treat effectively with medication alone.[50–52] The reports of surgical therapy for NTM disease thus far do not establish consensus guidelines for selecting the best patient candidates for surgery, choosing the most advantageous timing for operative intervention and choosing the specific surgical procedures with the best risk/benefit ratio in various clinical circumstances. Most specialists agree

TABLE 132-3 Interactions Between Drugs Used to Treat NTM and Immunosuppressive Medications

NTM Medication	Immunosuppressive Agent	Anticipated Reaction
Rifamycins (rifampin > rifabutin)	Calcineurin inhibitors (CNI) (cyclosporin, tacrolimus)	Decreased level of CNI
	Sirolimus	Loss of sirolimus efficacy
	Steroids	Decreased steroid effectiveness
Macrolides (clarithromycin, azithromycin)	Calcineurin inhibitors (CNI) (cyclosporin, tacrolimus)	Increased CNI level and risk of toxicity
Ethambutol	NS	N/A
Aminoglycosides (streptomycin, amikacin)	Calcineurin inhibitors (CNI) (cyclosporin, tacrolimus)	Possible additive or synergistic risk of renal impairment
Clofazimine	NS	N/A
Fluoroquinolones	NS	N/A
Isoniazid	NS	N/A
Doxycycline	NS	N/A
Cefoxitin	NS	N/A
Imipenem	Cyclosporin	May result in neurotoxicity (mental confusion, agitation, tremor)

NS, no significant interaction; N/A, not applicable.

that adjunctive surgical intervention in the hands of an experienced multidisciplinary team and center offers benefit to a selective population of NTM patients who have either NTM disease that is difficult to treat with antibiotic therapy or who have not responded favorably in spite of aggressive medical therapy. Surgical therapy is clearly beneficial to many NTM lung disease patients but many aspects of adjunctive surgical therapy have yet to be clearly defined.

■ TREATMENT OF SPECIFIC NTM INFECTIONS

Important pathogenic NTM species are considered below, including *M. avium* complex, *M. kansasii, M. abscessus, M. chelonae,* and *M. fortuitum*.

Pulmonary *M. Avium* Complex

Mycobacterium avium complex (MAC) is the most frequently encountered pathogenic NTM species in North America.[3,25] Treatment for MAC lung disease vastly improved in the era following the introduction of macrolides.[53–55] For patients with nodular lung disease and bronchiectasis, three times weekly dosing of clarithromycin 1000 mg or azithromycin 500 mg, ethambutol 25 mg/kg, and rifampin 600 mg are recommended by the American Thoracic Society.[12] Dosing adjustments are usually needed for patients who weigh less than 50 kg or are 80 years or older. These patients are generally intolerant of daily therapy.

For fibrocavitary or severe nodular/bronchiectatic disease, a daily regimen may be used that includes clarithromycin 500 to 1000 mg/d or azithromycin 250 mg/d, ethambutol 15 mg/kg per day and rifampin 10 mg/kg per day (maximum 600 mg) or rifabutin 150 to 300 mg/d. For patients with cavitary changes on either daily or three times weekly oral drugs, amikacin or streptomycin given IV or IM at a dose of approximately 7 mg/kg three times weekly for the first 3 months is recommended. For therapy with ethambutol, a baseline visit to an ophthalmologist as well as clinic visual acuity and color vision testing are recommended. In addition, a baseline

TABLE 132-4 Adverse Events of Drugs Used to Treat NTM

NTM Medication	Most Common Adverse Events
Rifamycins (rifampin, rifabutin)	Flu-like fever, rash, bone marrow suppression, uveitis (rifabutin), discoloration of body fluids, hepatotoxicity, nausea, drug interactions
Macrolides (clarithromycin, azithromycin)	Nausea, vomiting (azithromycin), QT prolongation, myopathy, granulomatous hepatitis (clarithromycin), hearing diminished
Ethambutol	Visual changes/optic neuritis, peripheral neuropathy, rash, renal insufficiency
Aminoglycosides (streptomycin, amikacin)	Perioral numbness, eosinophilia, nephrotoxicity, ototoxicity, neurotoxicity
Clofazimine	Skin discoloration, visual changes, joint pain, eosinophilic enteritis, nausea
Fluoroquinolones	Joint or muscle pains, tendon toxicity, QT prolongation, hepatotoxicity, nephrotoxicity, rash, dizziness, headache
Isoniazid	Hepatotoxicity, neuropathy, jaundice, rash, neurotoxicity, optic neuritis, drug interactions, lupus-like syndrome
Tigecycline	Nausea, vomiting, diarrhea, anorexia
Cefoxitin	Rash, nausea, diarrhea
Imipenem	Nausea, rash, visual disturbances, dizziness, seizures
Linezolid	Nausea, peripheral neuropathy, myelosuppression, rash, GI side effects, optic neuritis
Doxycycline/Minocycline	Photosensitivity, skin rash, nausea, vomiting, bluish skin discoloration
Trimethoprim–suflamethoxazole (TMP-SMX)	Rash (rarely Stevens–Johnson syndrome), fever, myelosuppression, renal insufficiency, agranulocytosis, hepatotoxicity, myalgias

hearing test is needed for patients on an aminoglycoside and should be repeated at intervals during the course of treatment. The primary microbiologic goal of therapy is 12 months of negative sputum cultures while on therapy. A macrolide with a single companion drug, ethambutol, may be adequate for minimal nodular/bronchiectatic MAC disease if the patient is intolerant to a rifamycin but this has not been studied. Patients are considered treatment failures if they have not had response (microbiologic, clinical, or radiographic) after 6 months of appropriate therapy or achieved culture negativity of sputum after 12 months of therapy. Common factors in such patients include medication nonadherence, the use of inadequate regimens (e.g., clarithromycin with a fluoroquinolone only) and emergence of a macrolide-resistant MAC isolates. Use of a quinolone and a macrolide and macrolide monotherapy are not recommended due to poor response and the frequent emergence of resistance.[56,57] It should also be noted that patients respond best to the first course of MAC treatment; therefore, adherence and use of a multidrug regimen are essential. Early specialist referral in patients with complex disease (i.e., cavitary changes, need for an aminoglycoside) is generally warranted.

M. Kansasii

M. kansasii can also present as upper lobe cavitary disease in smokers with COPD. This organism is susceptible to antituberculous agents, especially rifampin and ethambutol.[58–60] The standard recommended therapy in the United States by the ATS is a daily three-drug regimen of isoniazid, rifampin, and ethambutol plus pyridoxine (50 mg/d).[12] The rifampin dose is 10 mg/kg per day to a maximum of 600 mg daily, and ethambutol is given at 15 mg/kg per day. An initial 2 months of ethambutol at 25 mg/kg per day is no longer recommended. The duration of treatment is usually 18 to 24 months, although good results with 12 months of therapy have been reported.[59]

The role of isoniazid in this regimen is not clear (the MICs are 100× higher than with MTB). Clarithromycin, however, is highly active with *M. kansasii* as it is with other slowly growing NTM species. A three times weekly three-drug oral regimen (azithromycin or clarithromycin, rifampin, and ethambutol) with 12 months of culture negativity has been reported with 100% cure rate.[61,62] Other drugs usually given in three-drug combinations are effective for retreatment of disease that has become resistant to rifampin; they include clarithromycin, trimethoprim/sulfamethoxazole, streptomycin, and amikacin. Relapse after treatment with rifampin-containing regimens is uncommon.

M. Abscessus ssp *Abscessus* and *M. Abscessus* ssp *Massiliense*

M. abscessus is the third most frequently recovered NTM pulmonary pathogen in the United States. Pulmonary infections are the most common form of disease. Two major subspecies are recognized, subspecies (ssp) *abscessus* and ssp *massiliense*. These patients are generally women, nonsmokers, without previously recognized lung disease, presenting with symptoms of fatigue and bronchiectasis. CT scanning reveals mid-lung field small nodules with bronchiectasis ("nodular bronchiectasis"). These are the same patients who get similar disease due to MAC. Cavity formation is rare with this type of disease. Dual infection with MAC can occur. Disease is slowly progressive if left untreated. *M. abscessus* has complicated lung transplant surgery causing sternal osteomyelitis.

M. abscessus isolates are uniformly resistant to standard antituberculous agents. Approximately 80% of isolates of *M. abscessus ssp abscessus* carry a functional *erm* gene with subsequent in vivo macrolide resistance, which may not be reflected by the initial 3-day in vitro MIC of the organism for the macrolide.[63] Untreated isolates of *M. abscessus ssp massiliense* are all macrolide susceptible as their *erm* gene is nonfunctional (and hence the disease is much easier to treat).[64,65] Drugs that may be useful include the macrolides, linezolid, tigecycline, imipenem, amikacin, and cefoxitin. Combination therapy, usually for a minimum of 4 to 6 months, is mandatory for significant disease.

No antibiotic regimens based on in vitro susceptibilities have been shown to produce long-term sputum conversion for the 80% of patients with *M. abscessus ssp abscessus* lung disease with a functional *erm* gene.[50,52,66] For macrolide susceptible and resistant *M. abscessus* isolates, a combination of parenteral drugs should be used based on in vitro susceptibilities. Side effect monitoring and lower doses of antibiotics are often warranted to achieve therapeutic goals.

M. Chelonae and *M. Fortuitum*

M. chelonae is an RGM that causes skin and soft tissue disease similar to that of *M. abscessus.* Unlike *M. abscessus* and *M. fortuitum*, *M chelonae* does not carry an *erm* gene and therefore effective therapy with a macrolide may be more obtainable in these individuals.[63] This is one example that supports the need for mycobacteriology laboratories to offer molecular analyses with accurate species identification of RGM to guide and implement effective treatment regimens. Isolates of *M. chelonae* are susceptible to doxycycline (25% of isolates), ciprofloxacin (25% of isolates), tobramycin (100% of isolates), clarithromycin (100% of isolates), imipenem (70% of isolates), clofazimine, and linezolid (65% of isolates). *M. chelonae* are resistant to cefoxitin.[67–69]

M. fortuitum is also a rapid grower similar to that of *M. abscessus*. It is a recognized as a rare cause of lung disease, almost always associated in patients with achalasia and rarely other gastroesophageal reflux disorders with recurrent aspirational lung disease.[12,70] It is not a recognized cause of pulmonary disease in other settings. Multidrug therapy with agents shown to be susceptible in vitro including, amikacin, newer quinolones, tetracyclines and trimethoprim/sulfamethoxazole, should be given for 12 months or until clinical resolution of disease recognizing that without therapy for the underlying gastrointestinal disorder, symptoms rarely improve. *M. fortuitum* isolates are usually susceptible to fluoroquinolones, doxycycline and minocycline (50%), sulfonamides and trimethoprim/sulfamethoxazole, amikacin, imipenem, tigecycline, and approximately one-half of the isolates are susceptible to cefoxitin.[67,68,71] Most *M. fortuitum* isolates have a functional *erm* gene so most are macrolide resistant.[72,73]

CHAPTER 133

Aspergillus, Candida, and Other Opportunistic Mold Infections of the Lung

Georgios Chamilos
Dimitrios P. Kontoyiannis

PULMONARY ASPERGILLOSIS

Aspergillus is a ubiquitous saprophytic mold that plays an essential role in recycling carbon and nitrogen.[1] This fungus has a simple biological cycle characterized by a high sporulating capacity, which results in the release of conidia at high concentrations (1–100 conidia/m^3) into the atmosphere. *Aspergillus* conidia have a diameter small enough (2–3 μm) to reach the pulmonary alveoli.[1,2] However, while humans constantly inhale *Aspergillus* conidia, such conidia are effectively eliminated in immunocompetent individuals.[3]

EPIDEMIOLOGY

Infections by *Aspergillus* species cause a wide spectrum of illnesses in humans depending on the immune status of the host (Table 133-1). Hence, in immunocompetent hosts, isolation of *Aspergillus* spp. in respiratory secretions typically reflects colonization, not infection. Under physiologic conditions, inhalation of *Aspergillus* spp. does not trigger immune responses because fungal spores are covered by a hydrophobin layer that masks recognition of immunostimulatory fungal cell wall molecules by host immune cells.[1–3] In atopic individuals, the fungus triggers robust immune reactions, including allergic rhinitis, asthma, hypersensitivity pneumonitis, and allergic bronchopulmonary aspergillosis (ABPA).[4] In patients with pre-existing cavitary pulmonary lesions, saprophytic growth of *Aspergillus* spp. can lead to aspergilloma formation. Finally, in immunocompromised individuals, some *Aspergillus* conidia germinate into the lung to form hyphae, the invasive form of the fungus, which causes a severe, frequently fatal angioinvasive infection called invasive pulmonary aspergillosis (IPA).[5–7] The degree of fungal invasion, response to antifungal therapy, and outcome of invasive aspergillosis (IA) depend on the type and severity of immunosuppression. Thus, in patients with subtle or no immune defects, chronic forms of *Aspergillus* infections in the lung have been described, which are characterized by an indolent clinical course with the development of progressive cavitary lesions, and minimal or no evidence of parenchymal invasion.[8] A less acute form of IA, frequently called subacute IPA, has been described in patients with acquired immunodeficiency syndrome (AIDS) and those with genetic defects in NADPH oxidase (chronic granulomatous disease or CGD), whereas progressive IPA is encountered in severely immunocompromised hosts.[1,2,6,7] There is no doubt that since the first description in the 1940s, IA has emerged as the major problem of modern mycology. Currently, IA is a leading cause of death in severely immunocompromised individuals, with crude mortality rates approaching 50% to 70% in patients with leukemia and recipients of hematopoietic stem cell transplants (HSCTs).[5,6] In addition, invasive *Aspergillus* has

TABLE 133-1 Spectrum of Pulmonary Aspergillosis

Clinical Manifestation	Immune Status	Underlying Lung Architecture	Degree of Tissue Invasion
Simple colonization	Normal	Chronic obstructive airway disease	None
Hypersensitivity reactions			
Allergic bronchial asthma	↑[a]	Normal	None
ABPA	↑	Excess airway mucus	None
Bronchocentric granulomatosis	↑	Excess airway mucus	None
Extrinsic allergic alveolitis	↑	Normal	None
Saprophytic growth			
Aspergilloma	Normal	Pre-existing cavity	None
Invasive infection			
IBA[b]	↑	Lung transplantation	+ +
Bronchial stump aspergillosis	Normal	Pneumonectomy	+
CPA[c]	↓[d]	Chronic obstructive airway disease	+
IPA[e]	↓↓↓[f]	Normal	+ + +

[a] *↑Hyperactive humoral response.*
[b] *Includes tracheobronchitis, pseudomembranous tracheobronchitis, and ulcerative tracheobronchitis. The latter two forms typically manifest as anastomotic infections in lung transplant recipients.*
[c] *Includes the following forms: CNPA, CCPA, and CFPA. Aspergillus hyphae occasionally invade the lung parenchyma in CNPA. Significant overlap exists among these entities.*
[d] *↑Suppressed immune response.*
[e] *May have features of invasive disease surrounding the cavity. It occurs in two settings with distinct histopathologies and immunopathogenesis: angioinvasive IPA in profoundly neutropenic patients and nonangioinvasive IPA in immunocompromised nonneutropenic individuals, including those receiving corticosteroid-based treatment, recipients of HSCTs with severe GvHD, patients with AIDS, recipients of solid-organ transplants, and patients with CGD. Mixed forms and significant overlap exist.*
[f] *↓↓↓Severely depressed immune response, neutropenia.*

emerged as an important pathogen in an expanding spectrum of nonneutropenic patients with chronic debilitating diseases who receive corticosteroids and/or other immunosuppressive therapies. Thus, IPA is increasingly encountered in patients with inflammatory and autoimmune diseases, chronic obstructive lung disease, and prolonged ICU stays.[2] At the same time, over the past two decades, we have witnessed a significant expansion in the antifungal armamentarium with the introduction of several agents with anti-*Aspergillus* activity. In addition, promising new non–culture-based diagnostic methods are being developed, and considerable progress has been made in understanding the epidemiology and immunopathogenesis of IA. As a result, a significant improvement in IA-attributable mortality has been noted. As IPA currently accounts for more than 90% of invasive *Aspergillus* infections we devote a significant portion of this chapter to this type of pulmonary aspergillosis.

MYCOLOGY AND HOST DEFENSES

Of the nearly 200 *Aspergillus* spp., only 20 have been encountered as pathogenic in humans.[1] *Aspergillus fumigatus* is the most frequently identified of these species; however, other species, such as *Aspergillus flavus*, *Aspergillus niger*, *Aspergillus terreus*, and *Aspergillus nidulans* have emerged as important pathogens in immunocompromised individuals. Appropriate identification of *Aspergillus* species is important because of differences in epidemiology, host tropism, virulence, and susceptibility to antifungal agents. For example, *Aspergillus nidulans* is the second most encountered mold in CGD patients, causing almost exclusively invasive infections in this specific host. In addition, certain species including *A. terreus, A. flavus, and A. nidulans* are clinically resistant to AMB.[2,6] Recent studies using molecular identification methods discovered "cryptic" clinical isolates of *Aspergillus*, including *Aspergillus lentulus, Aspergillus calidoustus, and Aspergillus glaucus,* that had been misclassified as *A. fumigatus* and display inherent resistance to certain antifungal agents. Notably, *A. fumigatus* is nearly always the cause of allergic pulmonary disease.[4] *Aspergillus* spp. are rapidly growing, hardy molds identified by the macroscopic appearance of the colony and by microscopic examination of the spore-bearing structures.[1] Microscopically, *Aspergillus* spp. are characterized by the production of uniform 4- to 6-mm wide hyphae with parallel walls and distinct septa. Dichotomous branching of hyphae occurs at 45-degree angles.[1] However, other filamentous fungi, such as *Fusarium, Acremonium,* and *Scedosporium* species share the same histopathological features with *Aspergillus* spp.[1] A wide range of microscopic appearances may be observed in clinical specimens.

Sputum specimens obtained from patients and examined by direct mounting or with KOH and ink may reveal the typical 45-degree branching hyphal fragments of aspergilli, which are often associated with eosinophils and Charcot–Leyden crystals in patients with ABPA.[1] Stained tissue sections reveal regular hyaline septate hyphae that are best observed with the use of periodic acid–Schiff (PAS) and Gomori methenamine silver (GMS) stain.[1] Fungus ball specimens obtained from cavities connected to bronchi have hyphae that often appear to be lifeless and stain poorly. Also, although seldom seen, the fruiting heads and conidia may appear to be well formed.

HOST IMMUNE RESPONSES

Recent years have witnessed improvements in understanding of the immunological mechanisms of host resistance to *Aspergillus* spp. Protection of the normal host against *Aspergillus* infection is mediated by a highly coordinated response that involves both innate and adaptive immunity (see also Chapters 121 and 123).[3] Acquired quantitative and qualitative defects in phagocytic cell function associated with prolonged and profound neutropenia and corticosteroid-induced dysfunction of macrophages and monocytes have long been recognized as the major risk factors for IA. In addition, functional phagocytic defects due to mutations in NADPH oxidase seen in patients with CGD are associated with impaired phagocytic cell function and unique susceptibility to IA.[3]

Innate Immunity Consists of Three Main Effector Cell Types: (a) myeloid-derived dendritic cells that orchestrate innate and adaptive immune responses by transferring and presenting fungal antigens to T cells in resident lymph nodes; (b) pulmonary alveolar macrophages that ingest and kill inhaled conidia, primarily via oxidative reactive oxygen species (ROS)-dependent mechanisms; and (c) circulating polymorphonuclear and mononuclear cells, which are recruited to the lungs and actively participate in elimination of conidia and hyphae that escape killing by resident myeloid cells.[3] Intracellular killing of *Aspergillus* spores within professional phagocytes occurs in acidified phagolysosomes and depends on the production of ROS. Neutrophils are unique in the ability to cause damage to *Aspergillus* hyphae via the release of potent antimicrobial effector molecules that are stored in specialized granules. The release of DNA filaments decorated with antimicrobial effector molecules (neutrophil extracellular traps or NETs) upon neutrophil death is a recently identified antifungal effector pathway that is efective in patients with CGD.[3]

In addition to professional phagocytic cells, other innate immune cell subsets appear to play important roles in *Aspergillus* host defense, including platelets, plasmacytoid dendritic cells, natural killer (NK) cells, and invariant NK T (iNKT) cells. These innate immune cells mediate antifungal activities either directly via the release of cytotoxic molecules or indirectly via the production of cytokines that activate professional phagocytes.[3]

Humoral factors also participate in the initial events of host response to *Aspergillus* infection. Resting conidia, germinating conidia, and hyphae are all potent activators of both the alternative and classical components of the complement cascade, promoting opsonization and chemotaxis.[3] In addition, soluble C-type lectins, including mannose-binding lectins, and surfactant protein A (SP-A) and D (SP-D), which are present in alveolar fluid, enhance chemotaxis, binding, phagocytosis, and oxidative killing of conidia. C-type lectins also appear to be able to agglutinate, immobilize, and inactivate conidia.[3] Importantly, alteration in SP-D and polymorphisms in mannose-binding lectin encoding genes are associated with an increased risk of chronic pulmonary aspergillosis (CPA).[8] Another soluble pattern recognition receptor, the pentraxin PTX3, has been shown to bind to a range of microbial products, including *Aspergillus* conidia, and to confer resistance to the fungus.[3] PTX3-deficient mice were susceptible to IPA because of impaired recognition of aspergilli by alveolar macrophages and dendritic cells and inappropriate induction of a Th2 response.[3]

In recent years, the role of adaptive immunity in *Aspergillus* host defense has been increasingly appreciated. Activation and maturation of dendritic cells following uptake of *Aspergillus* spores are critical for antigen presentation, T-cell expansion, and initiation of adaptive immunity. Activation of different pattern recognition receptors in dendritic cells by microbial ligands, including *Aspergillus* immunostimulatory cell wall molecules, leads to the production of distinct sets of cytokines that drive development of different Th cell subsets. Activation of toll-like receptor (TLR)-2 and TLR4 in dendritic cells has been linked to the induction of IL-12 leading to interferon-γ (IFN-γ)–producing Th1 cells, which are considered to confer broad protective immunity against fungi. In contrast, Th2 responses mediated by IL-4 lead to increased susceptibility to fungal infections. More recently, a subset of Th

cells, called IL-17–producing Th (Th17) cells, has been identified and implicated in mucosal immunity against fungi. Sensing of the fungal polysaccharide β-glucan by *Dectin-1* receptor on dendritic cells drives activation of antifungal Th17 responses.[3] Impaired IL-17 production has been associated with increased susceptibility to IPA in mice. In humans, patients with mutations in STAT3 have selective impairment of IL-17–producing T cells and are prone to infections with *Aspergillus*. However, unabated Th17 responses can become detrimental for infectious outcome because of unbalanced inflammatory responses. Under physiologic conditions, Th17 cells are kept in check by IL-10–producing T-regulatory cells (T regs). However, defective ROS production in CGD is associated with compromised T reg activity, unrestrained Th17 proinflammatory responses and associated tissue pathology.[3]

Overall, a balanced inflammatory response is required for abrogation or effective resolution of invasive *Aspergillus* infection. Thus, while an early and effective proinflammatory response is required to restrict infection, an uncontrolled inflammatory response is detrimental and may eventually facilitate fungal persistence. To that end, high-level production of IL-10 by T regs may be beneficial by contributing to resolution of the inflammatory response.[3] On the other side, immune tolerance may lead to adverse outcomes of infection. For example, expansion of myeloid suppressor cells that result in defective Ag presentation and Th cell priming has been described in *Pneumocystis* pneumonia in mice and adoptive transfer of these cells had an adverse effect on the resolution of infection. Whether a similar expansion of myeloid suppressor cells occurs in IA is currently unknown.

Immune augmentation therapies have become a top priory in fungal immunology research. Administration of Th1 cytokines has been successfully employed in the mouse model of IA. Thus, tumor necrosis factor-alpha (TNF-α), IFN-γ, interleukin (IL)-12, and IL-15 enhance effector function of professional phagocytes and have been shown to confer protection against *Aspergillus* infection in animal studies.[3] The protective Th1 response was characterized by the presence of antigen-specific CD4+ T cells that produce IFN-γ and IL-2. Furthermore, dendritic cell–based vaccination strategies, generation of Th1/Th17 *Aspergillus*-specific T cells in naive mice or adoptive transfer of *Aspergillus*-specific CD4+ T cells in immunocompromised mice, all resulted in improved outcomes of IA in mice.[2,3] Finally, restoration of immune dysfunction via cooperative activation of TLR and C-type receptor signaling resulted in cure of a chronic fungal disease of the skin in mice and could be explored as a therapeutic strategy for IA.

However, in contrast to the animal studies, in severely immunocompromised patients with IPA, immune augmentation therapies have been of unclear benefit using myeloid growth factors, Th1 recombinant cytokines or T-cell–based adoptive transfer. Thus, translating recent advances in fungal immunology to novel therapeutics against IA in humans remains a challenge. In particular, translation of results of ex vivo experiments and studies in mice with genetic defects in receptors, signaling molecules, cytokines, or chemokines into clinical practice has been difficult in view of the complex and multifactorial pathophysiology of IPA in humans. Furthermore, immune augmentation strategies and vaccination-induced protective immune therapies could be suboptimal in profoundly immunocompromised individuals. Better understanding of the immunopathogenesis of IPA at the cellular and molecular level coupled with efforts to validate research findings from mice in humans could facilitate the development of immune-based augmentation therapies.

Aspergillus virulence factors

There is debate over which factors determine *Aspergillus* virulence and pathogenicity.[1,2] Several putative virulence factors in *A. fumigatus* have been identified, including various proteolytic enzymes (elastases, collagenases, trypsine), phospholipases, ribotoxin, hemolysin, gliotoxin, and many other enzymes and toxins.[1,2] The mycotoxin gliotoxin in particular has received attention and been studied extensively.[2] Gliotoxin exhibits immunomodulatory properties, as it has been shown to inhibit the phagocytosis of macrophages, promote apoptosis of macrophages, inhibit ROS production in human neutrophils and block B- and T-cell activation. Of interest, gliotoxin deletion mutants displayed attenuated virulence in corticosteroid-immunosuppressed mice but not in mice rendered neutropenic by treatment with cyclophosphamide, implying a direct in vivo cytotoxic effect of gliotoxin in cellular immunity.

Importantly, tissue necrosis and angioinvasion are prominent features of IA in immunocompromised patients. Of interest, gliotoxin has been shown to block angiogenesis during invasive *Aspergillus* growth.[2,3] In fact, restoration of anti-angiogenic activity of *Aspergillus* via administration of pro-angiogenic factors was recently shown to potentiate activity of antifungal therapy in murine IPA. In addition, adaptation in the hypoxic environment during tissue necrosis is a prominent feature of invasive *Aspergillus* growth. In fact, an *Aspergillus* mutant deficient in a sterol regulatory element-binding protein required for hypoxia adaptation (Δ*SrbA*) was completely avirulent in mice.[2,3] Iron metabolism is important for *Aspergillus* in vivo growth and mutants defective in siderophore secretion pathway fail to grow in vivo and are avirulent following infection of neutropenic mice. In addition, some have postulated that the production of catalases, superoxide dismutases, and mannitol by *Aspergillus* may protect the fungus from oxidative damage induced by phagocytic cells.[2,3] Moreover, the melanin pigment and rigid protein coat layer composed of hydrophobic rodlet fascicles on the *Aspergillus* conidial surface may confer resistance to phagocytosis.[2] In fact, melanin may act as a virulence factor by masking surface immunostimulatory molecules, blocking ROS production and acidification of fungal phagosomes. On the other hand, recent evidence from comparative genomic analysis across filamentous fungi suggests that *A. fumigatus* virulence results from the immunosuppression or possibly genetic susceptibility of the host rather than from specific, unique fungal determinants.[2,3] Hence, *A. fumigatus* appears to be a saprotrophic fungus that only becomes pathogenic for very simple biological reasons: it is present in high concentrations in the atmosphere, it grows faster than any other airborne fungi at physiologic mammalian temperatures (above 37°C), and it can overcome the defense of the host not because of specific virulence mechanisms but because of inefficient host immune responses. Taken together, these data suggest that approaches targeted at augmenting cellular immunity, such as neutralization of Th2 cytokines, enhancement of Th1 responses, and dendritic-cell vaccine-based vaccination warrant investigation as therapeutic modalities for invasive *Aspergillus* infections.[2,3]

■ CLINICAL MANIFESTATIONS

The varied clinical manifestations of disease related to Aspergillus species are considered in detail below.

Hypersensitive Reactions

Hypersensitivity lung diseases that result from exposure to *A. fumigatus* allergens include allergic asthma, ABPA, and hypersensitivity pneumonitis.[4,6] In atopic individuals, inhalation of *Aspergillus* spores triggers an IgE-mediated allergic inflammatory response in the bronchial mucosa, leading to excessive mucus production, bronchial obstruction, and asthma.[4,6] Similarly, ABPA develops following sensitization to *A. fumigatus* allergens in a unique subset of atopic individuals and patients with cystic fibrosis (CF), who are genetically susceptible for ABPA.[4] The immune response to *Aspergillus* antigens in both patients with allergic asthma and those with ABPA is characterized by a robust Th2 polarized CD4+ response.

TABLE 133-2 Hypersensitive Reactions to *Aspergillus*

	Asthma	ABPA	Extrinsic Allergic Alveolitis
Pathology	Hypertrophied mucus glands	Colonization of airways, viscid mucoid impaction, tissue eosinophilia	Lymphocytic infiltration of interstitium, noncaseating granuloma
Radiographic features			
Early	Normal, hyperinflation	Migratory peripheral infiltrates, atelectasis, bronchiectasis	Diffuse alveolar-interstitial infiltrates
Late	Normal, hyperinflation	Fibrosis	Reticulonodular interstitial opacities
Skin test reactions to *Aspergillus* antigens			
Immediate	Positive	Positive	Positive
Delayed	Negative	Positive	Positive
Peripheral eosinophilia	Negative[a]	Positive	Negative
IgG *Aspergillus* precipitins	Positive (up to 25%)	Positive	Positive
Serum IgE levels	Normal or mildly elevated	Marked elevation	Normal

[a]*Occasionally positive.*

In nonatopic individuals, persistent airway colonization and, more rarely, a type of hypersensitivity pneumonitis called *extrinsic allergic alveolitis* can occur as a result of massive or repeated inhalation of *Aspergillus* conidia.[4,8] Hypersensitivity pneumonitis in these patients manifests with dyspnea because of pulmonary constriction and an influenza-like syndrome with fever, malaise, and fatigue. In contrast to other allergic diseases caused by *A. fumigatus*, hypersensitive pneumonitis is characterized by extensive infiltration of neutrophils in the acute phase as a result of a Th1 CD4+ response.[4,8] Early recognition of these syndromes is important for early initiation of appropriate treatment to prevent progression to permanent lung damage. Table 133-2 summarizes the hypersensitivity syndromes that result from exposure to *Aspergillus*.

Simple Colonization

Although there is not a uniform definition of colonization, it should be considered in cases of isolation of *Aspergillus* spp. from cultures of the respiratory tract in patients without evidence of invasive or allergic disease.[8] Patients with structural lung diseases such as chronic obstructive pulmonary disease (COPD) are at increased risk for persistent *Aspergillus* colonization. Tissue invasion by aspergilli is not a feature of saprophytic colonization, although IPA following subsequent dysfunction of host defenses may develop. In fact, *Aspergillus* colonization has been shown to be a marker for the development of IA in immunocompromised individuals, particularly lung and bone marrow transplant recipients, and may precede invasion for up to 3 months.[8] Quantitative real-time polymerase chain reaction (PCR) and measurement of BAL *Aspergillus* galactomannan antigen are both highly sensitive and specific assays in distinguishing *Aspergillus* colonization from invasive infection.[2,6]

Allergic Bronchial Asthma

Asthmatic patients may become sensitized to *Aspergillus* conidia as a consequence of thick bronchial secretions that trap fungal spores.[4,8] These spores seldom germinate in the bronchial airways. Allergic bronchial asthma develops in patients who are atopic and is perpetuated by inhalation of *Aspergillus* antigens, which typically causes acute bronchospasm. The presence of transient infiltrates has been described during the immediate reaction but is not frequent. As is typical in asthma of other etiologies, eosinophils and serum IgE antibody are increased. Immediate skin reactions to *Aspergillus* antigens are positive, but specific precipitating antibodies (IgG) are usually negative.[4,8] Avoidance of exposure to *Aspergillus* spores can diminish the frequency and severity of bronchospasm in this group of patients. *Aspergillus* bronchitis is a rare, distinct clinical entity that has been recently described in immunocompetent individuals with structural lung disease, chronic pulmonary symptoms, and lack of response to antibiotic therapy. All of these patients had evidence of *Aspergillus* growth in their lungs, marked improvement following antifungal therapy and did not fulfill criteria for asthma or other forms of invasive or chronic aspergillosis.

Allergic Bronchopulmonary Aspergillosis

The important clinical entity of allergic bronchopulmonary aspergillosis (ABPA) is discussed below. The reader is also referred to Chapters 48 and 71.

Immunopathogenesis and Risk Factors It has been recently proposed that ABPA develops in genetically susceptible patients with asthma or CF because of increased activity of *A. fumigatus*-specific Th2 CD4+ cells (see also Chapter 48).[4] Hence, in addition to a history of atopy, predisposing factors for ABPA include immunogenetic human leukocyte antigen (HLA)-distinct phenotypes (e.g., HLA-DR 2- and HLA-DR 5-specific alleles), mutations in the CF transmembrane conductance regulator (CFTR) gene, polymorphisms of the collagen region of the SP-A2, and/or other collections (e.g., mannose-binding lectins).[4,8] In addition, particular physicochemical characteristics of respiratory secretions and a history of environmental exposure may play a role in ABPA pathogenesis.[4,8] The role of newly identified Th17 pathway, which has a critical role in inflammation via neutrophil recruitment has not been extensively evaluated in ABPA. However, in a mouse model of asthma, Dectin-1 dependent IL-22 production was important for disease development. In addition, TNF-α–producing inflammatory DCs have been recently shown to be important regulators of IL-17–producing T cells and neutrophilia in a mouse model of ABPA.

In patients with ABPA, inhaled *A. fumigatus* conidia are able to colonize, persist, and germinate, leading to growth of hyphae in mucus plugs, which are often observed in expectorated sputum.[4] During this process, *A. fumigatus* releases a panel of proteases and other toxins that are capable of further compromising mucociliary clearance, breaching the airway epithelial barrier, and activating the immune system in the lung.[4]

IgE molecules on the surface of mast cells initially recognize *A. fumigatus* antigens. Binding of these antigens with IgE causes mast-cell degranulation, releasing mediators that cause vasodilatation and vascular leakage so that serum components, including anti-*Aspergillus* IgG, enter the bronchi and combine with *Aspergillus* antigens to form IgG-containing immune complexes.[4] These complexes activate the

complement cascade leading to inflammation and pulmonary damage. Importantly, investigators have identified specific *Aspergillus* antigens capable of inducing IgE and IgG responses in patients with ABPA but not in patients who did not have ABPA, implying that an aberrant host response occurs in patients with ABPA.[4]

The key element in the immunopathogenesis of ABPA appears to be an abnormal T-lymphocyte cellular immune response to *A. fumigatus* conidia. Hence, A. *fumigatus* allergens released by mycelia are processed by antigen-presenting cells bearing HLA-DR 2 or HLA-DR 5 and presented to T cells within the lymphoid tissue of the lung.[4,8] The T-cell response to *Aspergillus* allergens is then shifted toward a Th2 CD4+ cell response with synthesis and secretion of the cytokines IL-4, IL-5, and IL-13.[4,8] In addition, production of chemotactic cytokines (chemokines) by inflammatory cells, including monocyte chemoattractant protein-1 (MCP-1/CCL2), eotaxin (CCL11), IL-8, and macrophage inflammatory protein-1α (MIP-1α/CCL3) appears to promote the Th2 cell response.[4,8] In addition, T cells, B cells, NK cells, and eosinophils may be hyperresponsive to IL-4.[4,8] This leads to a positive-feedback amplification loop of Th2 CD4+ cells, synthesis of IL-4, and polyclonal activation of CD23+ CD86+ B cells.[4,8]

Clinical Features ABPA is a hypersensitivity disease of the lung that is virtually almost always related to *A. fumigatus* (discussed in detail in Chapter 48). Some key points are highlighted here. Seven percent to 14% of patients with poorly controlled asthma and 7% to 9% of those with CF meet the diagnostic criteria for ABPA.[4] In fact, nearly all patients with ABPA have a history of chronic asthma. Rarely, patients present without symptoms or physical findings despite having radiographically detected abnormalities. Clinically, ABPA manifests with episodic wheezing, malaise, low-grade chronic fevers and cough, sputum containing brown flecks and plugs, chest pain, pulmonary infiltrates, and sputum and blood eosinophilia.[4,8] Patients may have a history of recurrent pneumonias and frequent use of antibiotic therapy. Mucus plugs form in the proximal bronchi and can progress to mucoid impaction, resulting in atelectasis with transient pulmonary infiltrates. Mucus plugs often yield aspergilli in culture (Figs. 133-1 and 133-2). As ABPA progresses, central bronchiectasis becomes a dominant feature of the disease and may result in chronic bronchorrhea and occasionally hemoptysis, development of clubbing, and fixed, characteristic radiographic abnormalities.[4,8] In patients with CF in particular, ABPA often manifests with hemoptysis and may be complicated by pneumothorax.[4]

Radiographic Findings The radiographic features of ABPA have an essential role in diagnosis, as they may distinguish ABPA from simple, chronic asthma. Pulmonary infiltrates in cases of ABPA are initially transient, but they ultimately progress to permanent radiographic changes.[4,8] In many instances, the "ring sign" indicative of bronchial wall thickening, "parallel" shadows or "tram lines" suggestive of bronchiectasis, and branching "finger-in-glove" opacification of the dilated bronchi because of mucoid impaction are seen on regular chest radiographs of patients with ABPA (Fig. 133-3).[4,8] The presence of proximal bronchiectasis (Figs. 133-3 and 133-4), which is characterized by normal filling of bronchi distal to the sacular bronchial lesion, is considered a hallmark for the diagnosis of ABPA.[4] ABPA lesions are either focal or bilateral and tend to occur more frequently in the upper lobes. Late radiographic findings in patients with ABPA include cavitation, local emphysema, contracted upper lobes, and honeycomb fibrosis.

Chest computed tomography (CT) has been a significant aid in diagnosing ABPA because it is more sensitive than regular chest radiography; however, there are no pathognomonic CT findings for this entity.[4,8] Besides central bronchiectasis, CT findings highly suggestive of ABPA include the presence of varicose or cystic bronchiectasis of segmental and subsegmental bronchi (90% in ABPA vs. 30% in simple asthma), mucoid impaction of the segmental and subsegmental airway (67% in ABPA vs. 4% in simple asthma), and small airway abnormalities such as centrilobular nodules and tree-in-bud opacities (93% in ABPA vs. 28% in simple asthma).[4,8] In patients with CF especially, CT diagnosis of ABPA is particularly challenging, as there is a significant overlap in the radiographic features of both entities.[4] In fact, the presence of high-attenuation mucus plugs because of dystrophic calcification is the only CT finding that favors the diagnosis of ABPA in patients with CF.

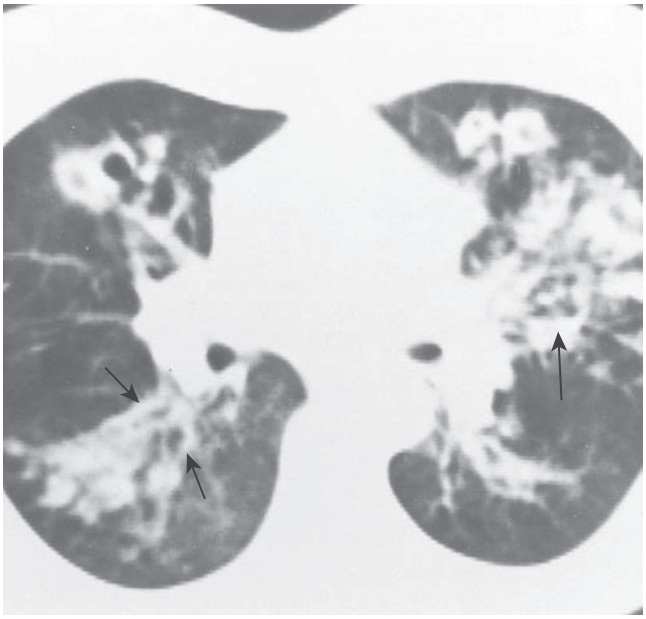

Figure 133-4 Proximal saccular bronchiectasis characteristic of ABPA. The CT scan reveals multiple rounded, dilated bronchi *(small arrows)*. Of note is the air–fluid level *(large arrow)*. *(Used with permission of Drs. S. Albelda and G.H. Talbot.)*

Diagnosis The "classic" patient with ABPA fulfills the criteria listed in Table 133-3. It has been suggested that the minimal essential criteria for the diagnosis of ABPA include the presence of (a) asthma, (b) immediate cutaneous reactivity to *Aspergillus* antigens, (c) elevated total serum IgE levels (>1000 U/mL), (d) elevated serum IgE and IgG levels to *A. fumigatus,* and (e) central bronchiectasis.[4,8] However, asymptomatic pulmonary involvement occurs in patients with ABPA and may lead to diagnostic uncertainty, delayed diagnosis, and irrevocable structural lung damage. Furthermore, corticosteroid-based therapy for asthma may mask the signs of ABPA, leading to a progressive decline in pulmonary function. Because the above criteria may not apply in such cases, some have proposed that serological evidence (all three serological tests listed in Table 133-3 and immediate skin reactivity test to *Aspergillus* antigens need to be positive) even without the presence of bronchiectasis may be sufficient to support an early diagnosis of ABPA.[4,8] In addition, the diagnostic criteria for ABPA in patients with CF were recently modified, because of the overlapping features between these entities. The new criteria consist of (a) clinical and/or pulmonary function deterioration from baseline status, (b) positive immediate cutaneous reaction to *A. fumigatus* antigens or elevated IgE *A. fumigatus* antibody serum level, (c) elevated serum total IgE level >1000 U/mL, (d) elevated serum IgG *A. fumigatus* antibody level or positive *A. fumigatus* precipitins, and (e) abnormal chest imaging findings or a change in baseline abnormalities.[4]

Important clinical clues that should alert clinicians to the possibility of ABPA include refractory asthma or asthma with any of the following features: bronchiectasis, radiographic infiltrates, prominent eosinophilia, and expectorated brown plugs that may contain eosinophils or hyphae (Fig. 133-2).[4] In addition, in patients with CF, prominent wheezing is considered to be suggestive of ABPA. Rarely, ABPA may be caused by non-*fumigatus* aspergilli or other fungi; in such cases, the serological tests will be negative.

Because no single clinical or immunological feature is diagnostic for ABPA, this disease is underdiagnosed. Until recently, serological diagnosis of ABPA was based on *Aspergillus* crude extracts, which are cumbersome, lack reproducibility, and frequently cross-react with other antigens. However, recent studies indicate that standardized recombinant *A. fumigatus* allergens have the potential to substantially increase the specificity and sensitivity of diagnosis of *A. fumigatus*-related diseases, including ABPA.[4,8] Several recombinant *A. fumigatus* allergens, including Aspf1, Aspf2, Aspf3, Aspf4, Aspf6, and Aspf16, show high specificity for the detection of sensitization to *A. fumigatus* and for the diagnosis of ABPA and appear to be superior to crude *Aspergillus* allergen extracts.[4] However, because the sensitivity of each recombinant *A. fumigatus* allergen is suboptimal, use of a panel of recombinant allergens is favored to increase the sensitivity of the diagnosis of ABPA. This diagnostic approach remains investigational. Further standardization and development of commercially available immunoassays containing a combination of these allergens holds promise for improving the diagnosis of ABPA.

Because patients with CF are at high risk for ABPA, initiation of annual screening in patients with >6 years of age for ABPA with monitoring of serum total IgE levels has been recommended with further diagnostic workup for ABPA in cases with IgE levels >500 U/mL.[4] Likewise, because treatment with corticosteroids has a significant impact on disease progression, screening CT has been advocated for asthmatics with a skin-prick hypersensitivity test positive for *A. fumigatus* extracts to identify ABPA at an early stage.[4,8]

Histopathology Because the diagnosis of ABPA is based on clinical and laboratory criteria, use of lung biopsy to confirm the diagnosis is usually not required. The presentations of the hypersensitivity syndrome associated with fungi are discussed in detail in Chapter 48. Some of the histopathological presentations associated with ABPA overlap those of invasive *Aspergillus* infection. Thus, eosinophilic infiltrates may be present in patients with a chronic invasive *Aspergillus* infection as well as in those with other allergic lung entities, such as Löffler syndrome, tropical eosinophilic pneumonia, and chronic eosinophilic pneumonia (see Chapters 71 and 137).[4,8] Mucoid impaction associated with ABPA or other fungi may predispose patients to bacterial superinfection (Figs. 133-1 and 133-2). Necrotizing granulomas in association with the presence of *Aspergillus* spp. in asthmatic patients may be observed and is

TABLE 133-3 Criteria for the Diagnosis of Allergic Bronchopulmonary Aspergillosis (ABPA)

Primary
Episodic bronchial obstruction (asthma)
Peripheral blood eosinophilia (>1000/mm^3)
Immediate type skin reactivity to *Aspergillus* antigens[a]
Precipitating serum antibodies (precipitins) against *Aspergillus* antigens[a]
Elevated serum IgE concentrations (>1000 ng/mL)[a]
Elevated serum IgE and/or IgG antibodies specific to *A. fumigatus*[a]
History of pulmonary infiltrates (transient or fixed) on chest radiographs or CT scans
Central bronchiectasis on chest CT scans
Secondary
A. fumigatus in sputum (by repeated culture or microscopic examination)
History of expectoration of brown plugs or flecks
Arthus reactivity (late skin reactivity) to *Aspergillus* antigen

[a]*Test must be positive for serological diagnosis in asymptomatic patients.*

TABLE 133-4 Staging System for Allergic Bronchopulmonary Aspergillosis (ABPA)

Stage	Symptoms	Radiographic Features	Laboratory Features	Management
I. Acute	Fever, productive cough, wheezing	Pulmonary infiltrates, mucoid impaction	Blood eosinophilia, elevated serum IgE level, positive skin test	Corticosteroids to achieve remission
II. Remission	Asymptomatic	Normal	Decrease in IgE and blood eosinophilia	Careful follow-up
III. Exacerbation	All or some of acute-stage symptoms	All or some of acute-stage findings	At least a doubling of IgE in asymptomatic patients and an increase in IgE in symptomatic patients	Retreat with steroids to induce remission
IV. Corticosteroid dependent	Symptomatic steroid-requiring asthma	Variable	Usually continued elevation of IgE	Long-term steroids to control asthmatic symptoms and keep IgE levels at baseline
V. Fibrotic	Severe dyspnea, fibrotic lung disease, as well as bronchospasm	Pulmonary fibrosis	Restrictive plus reversible and irreversible obstructive function tests; may have continued increased IgE	Long-term corticosteroid use

Source: Adapted with permission from Mendelson EB, Fisher MR, Mintzer RA, et al., Roenterographic and clinical staging of allergic bronchopulmonary aspergillosis. Chest 1985;87:334–339, and Patterson R, Greenberger PA, Radin RD et al. Allergic bronchopulmonary aspergillosis: Staging as an aid to management. Ann Intern Med 1982;96:286–291.

considered part of the ABPA syndrome.[4,8] The histopathological distinction between ABPA, with fungal elements restricted to the airways, and semi-invasive or fully IA may be obscured by tissue necrosis or poor granuloma formation. These presentations are discussed further below and in Chapter 51.

Treatment ABPA may progress through five stages based on clinical, serological, and radiographic findings, which are summarized in Table 133-4.[4,8] Importantly, the first four stages are potentially reversible without long-term sequelae; only the last stage, which is characterized by fibrosis and bronchiectasis, is irreversible. The goals of therapy for ABPA are to treat acute exacerbations of disease and prevent the development of fibrosis and bronchiectasis. Therefore, early diagnosis of ABPA before permanent lung damage occurs is critical. Therapeutic modalities for ABPA include oral corticosteroids, metered-dose inhaler medications, and systemic antifungal agents.[4,8]

Use of oral corticosteroids remains the cornerstone of the treatment of ABPA.[4,8] These agents suppress the inflammatory response provoked by *Aspergillus* infection rather than eradicate the fungus. Recommended corticosteroid doses for acute exacerbations of ABPA are 0.5 to 1.0 mg/kg of prednisone equivalent daily for 1 to 2 weeks, followed by 0.5 mg/kg per every other day for 6 to 12 weeks. The physician should then attempt to taper the patient's corticosteroid dosage. However, some patients cannot be successfully weaned off corticosteroids and may require a daily maintenance dose of at least 7.5 mg.

Increasingly, use of itraconazole, an azole antifungal with activity against *Aspergillus* spp., has been employed as adjunctive fungal antigen-reducing therapy for ABPA, especially in patients with frequent relapses or corticosteroid dependence.[4,8] A randomized controlled study reported that oral administration of itraconazole (200 mg twice daily) was beneficial in terms of significant improvement of symptoms, pulmonary function, chest radiographic findings, and serum IgE levels in asthmatic patients with ABPA; uncontrolled studies suggested a similar benefit in patients with CF and ABPA.[4,8] However, use of itraconazole requires determination of drug levels to ensure adequate absorption and poses significant issues with long-term tolerability and drug–drug interactions.[5,6] Another important issue of prolonged itraconazole use is the emergence of azole-resistant *Aspergillus* isolates. In addition, itraconazole has a 40% failure rate in ABPA treatment.[6] The newer triazole voriconazole has improved fungicidal activity against *Aspergillus* spp. and better bioavailability when compared with itraconazole.[5,6] A recent retrospective study in 20 ABPA patients who failed or were intolerant to itraconazole and received either voriconazole or posaconazole found sustained clinical and immunologic responses and reduced corticosteroid requirements at 12 months in over 75% of treated patients.[5–7] However, high relapse rates (up to 57%) have been reported following discontinuation of azole treatment in patients with ABPA, and there are concerns for the development of secondary resistance in *Aspergillus* following prolonged courses of antifungal therapy.

Use of inhaled corticosteroids may help control the symptoms of asthma but does not prevent episodes of eosinophilic infiltration and mucus impaction and is generally thought to have no influence on progressive lung damage.[4,8] Inhaled bronchodilators such as β agonists, anticholinergics, and leukotriene antagonists may be used to treat asthma-related symptoms.[4,8] Inhaled antifungal agents such as nystatin and amphotericin B deoxycholate (AMB-D) may offer temporary suppression of colonization, but penetration of these agents into plugged bronchi is limited and recolonization rapidly occurs once therapy ends. Meticulous bronchial toilet is important for clearance of *A. fumigatus* from the airway. Thus, physical therapy with postural drainage is an important adjunctive treatment. Increased hydration, use of expectorants, and in selected patients, bronchial lavage may aid in viscid mucus clearance. Avoidance of environmental reservoirs of *Aspergillus* spp. such as compost heaps, grain silos, and decayed organic matter may help prevent exacerbation of ABPA. In patients with CF ABPA, differentiating between a bacterial exacerbation of CF and an ABPA flare is important, because initiation of corticosteroids may have detrimental effects in patients with bacterial infection; a serological assessment is essential as part of this evaluation.[4]

Immunotherapy with the injection of conventional allergens has not been shown to be of value for ABPA.[4,8] However, newer immunomodulatory approaches, including immune modulation toward a Th1 response by using *A. fumigatus* synthetic peptides, DNA-based vaccines, and immunostimulatory molecules such as cytosine polyguanine oligonucleotides, are being explored in animal models with promising results.

Monitoring of treatment efficacy and toxicity is imperative. Long-term follow-up of patients with ABPA has shown that increasing serum levels of IgE is often a harbinger of a clinical flare of the disease and that the levels of IgE decline correlate with a clinical response to corticosteroids.[4,8] Thus, a prudent course of action is

to determine baseline serum IgE levels when ABPA has been controlled by corticosteroid-based therapy and then monitor serum IgE levels regularly (every 1—2 months). Total serum IgE levels usually should decrease by at least one-third within 6 weeks from the initiation of corticosteroid-based treatment; infiltrates should be resolved after 1 to 2 months, and the results of pulmonary function tests should improve. Although serum IgE levels seldom return to normal, reinstitution of corticosteroids should be considered even in asymptomatic patients if the serum IgE level is double that of the baseline value.[4,8] In patients with symptomatic ABPA, chest radiographs should be obtained every 3 months during the first year of follow-up and yearly thereafter; pulmonary function tests should also be performed yearly.[4,8] However, no one has identified certain prognostic indicators for progression or regression of ABPA, and whether "pre-emptive" treatment of asymptomatic flares alters the natural history of the disease remains controversial.

Bronchocentric Granulomatosis

Bronchocentric granulomatosis is a rare hypersensitivity syndrome that is characterized histologically by replacement of bronchial mucosa with necrotizing granulomatous tissue.[8] Also, eosinophilic infiltration of bronchioles and fibrosis is prominent, whereas there is no evidence of *Aspergillus* invasion. *Aspergillus* hyphae have been demonstrated within the lesions in approximately half of the cases of bronchocentric granulomatosis. This syndrome is associated with asthma in half of the patients described and likely represents a severe exuberant focal manifestation of ABPA rather than the more generalized pulmonary pathology evident in patients with ABPA.[8] Patients typically present with chronic symptoms, such as malaise, cough, low-grade fever, dyspnea, dull chest pain, and hemoptysis associated with a focal lesion on chest radiographs, often in an upper lobe. Occasionally, radiographic findings of multiple nodular or mass-like lesions simulate metastatic carcinoma.[8] Diagnosis of bronchocentric granulomatosis is made based on biopsy or often retrospectively after removal of the lesion, which is curative. Some patients, especially those with multifocal lesions, may need corticosteroid-based therapy for ABPA.[8]

Extrinsic Allergic Alveolitis

Heavy or repeated exposure to *Aspergillus* conidia and mycelia may result in a hypersensitivity reaction affecting the alveoli in nonatopic individuals known as *extrinsic allergic alveolitis (*see Chapter 58).[8] Malt workers, distillers, brewers, and others exposed to moldy straw or grain have suffered attacks consisting of cough, dyspnea, fever, chills, myalgia, and malaise 4 to 8 hours after exposure to *Aspergillus* antigens.[8] Repeated exposures may lead to malt worker's lung or farmer's lung or to the development of granulomatous disease or interstitial fibrosis. The immunopathogenesis of extrinsic allergic alveolitis involves cell-mediated immunity (type IV response) and immune complex deposition (type III response) and likely involves an intricate interaction between these immune mechanisms.[8]

Radiographic changes in the acute syndrome include diffuse alveolar-interstitial infiltrates that may resolve with the removal of the inciting antigen. Patients with chronic extrinsic allergic alveolitis may have fine reticulonodular interstitial infiltrates that may progress to pulmonary fibrosis with honeycombing.[8] Serum IgG antibodies (precipitins) against *Aspergillus* antigens are present in patients with extrinsic allergic alveolitis; however, the serum IgE level is typically normal. Skin tests usually demonstrate an Arthus reaction at 4 to 8 hours and occasionally may be preceded by an immediate wheal and flare reaction and followed by a delayed reaction (36–48 hours afterward). Removal or avoidance of the source of antigen exposure is crucial in the management of extrinsic allergic alveolitis, as spontaneous recovery often ensues once exposure has ended.[8] Administration of corticosteroids is helpful in aiding the resolution of acute symptoms and reduces the likelihood of structural damage. However, corticosteroids are not helpful once fibrosis has developed.

Aspergilloma

Saprophytic colonization of a parenchymal lung cavity by *Aspergillus* is referred to as *aspergilloma*, *mycetoma*, or a *fungus ball.*[8] A fungus ball consists of both dead and living mycelial elements, fibrin, mucus, amorphous debris, inflammatory cells, and degenerating blood and epithelial elements. The mycelial mass may lie free within the cavity or be attached to the cavity wall by granulation tissue. Spontaneous shrinkage or disappearance of aspergilloma has been reported in 7% to 10% of cases and is often associated with bacterial superinfection of the cavity.[8] Aspergillomas only rarely increase in size. Most aspergillomas are caused by *A. fumigates*, but some, especially in patients with diabetes mellitus, are caused by *A. niger*, in which case oxalic acid crystals may be seen in the sputum.[8] Rare cases of extrapulmonary sites of aspergillomas involving the skin, brain, retroperitoneal area, and sinuses have been described.

Pathophysiology The pathogenesis of aspergilloma usually involves colonization and proliferation of the fungus in a pre-existing pulmonary cavity (secondary aspergilloma). The cause of a pre-existing cavity is most commonly prior cavitary tuberculosis; aspergilloma has been reported in 11% to 17% of patients with post-tuberculosis cavities.[8] In fact, 20% of patients who recover from cavitary tuberculosis develop aspergillomas within the next 3 years. Of interest, in developing countries tuberculosis is the predisposing factor for over 90% of cases of aspergilloma. However, an aspergilloma may complicate a wide spectrum of cavitating pulmonary diseases, such as sarcoidosis, histoplasmosis, blastomycosis, AIDS (especially in cases of atypical *Pneumocystis jiroveci* pneumonia), pneumonia and/or lung abscess, pulmonary or bronchial cysts, bronchiectasis, pulmonary fibrosis, asbestosis, adenocarcinoma, ankylosing spondylitis, rheumatoid nodules, cyanotic heart disease, and pulmonary infarction.[8]

Primary aspergilloma, which arises within the bronchial tree with the proliferation of *Aspergillus* leading to a pulmonary cavity, is far less common. The clinical conditions leading to the initiation of a cavitary process and formation of a fungus ball include IPA, chronic necrotizing pulmonary aspergillosis (CNPA), and ABPA. IPA may lead to primary aspergilloma during bone marrow recovery, as the host is able to mount an inflammatory response and ward off the fungus. Pneumothorax may be a severe complication of pulmonary mycetoma that is reported as a rare occurrence in patients with hematological malignancies.[8] ABPA may cause bronchiectasis in the chronic phase of the disease and result in aspergilloma secondary to growth of a fungus distal to a plugged bronchus.[4,8] In fact, aspergillomas have been found in 7% of patients with ABPA in one study. Thus, aspergilloma may provide a stimulus for the perpetuation of ABPA.

Typical biofilm structures have been observed in aspergillomas from patients and in a murine model of IPA. Aspergilloma formation is linked with the ability of the fungus to form an extracellular hydrophobic matrix with typical biofilm characteristics under different static conditions including interaction with bronchial epithelial cells. This extracellular matrix is composed of galactomannan, α-1,3-glucans, monosaccharides and polyols, melanin and proteins including major antigens and hydrophobins. In particular, the presence of α-1,3-glucans in the extracellular matrix has a predominant role in the agglutination of *Aspergillus* germinating spores and hyphae and the subsequent aspergilloma formation. Melanin production during infection could also play a role in facilitating lung tissue invasion possibly by attenuating or evading immune response. Defective extracellular matrix penetration by most antifungal agents makes them significantly less effective when *A. fumigatus* is grown under biofilm versus planktonic conditions. Thus, chronic

exposure and suboptimal azole concentrations in fungal biofilms could explain the emergence of azole resistant *A. fumigatus* isolates reported in these patients.[2,3,8]

Clinical Features/Diagnosis Hemoptysis is the typical manifestation of aspergilloma, as it is seen in 50% to 90% of patients.[8] Hemoptysis is typically infrequent and mild but can be occasionally massive or even fatal. The presence of any other symptoms, including dyspnea, fever, malaise, and weight loss, in patients with aspergilloma should be attributed to the underlying cavitary pulmonary disease or bacterial superinfection or suggest the presence of an overlapping IPA syndrome such as CNPA. The diagnosis is usually made based on clinical and chest radiographic features coupled with serological evidence of precipitating antibodies to *Aspergillus* spp.

Chest radiographs reveal a solid round mass within a cavity (3–5 cm diameter) partially surrounded by a radiolucent crescent (Monod's sign) (Fig. 133-5).[8] Movement of the fungus ball within the cavity may be appreciated when comparing upright and decubitus images. A solitary lesion in the upper lung fields is the most common radiographic feature of aspergilloma, as pre-existing tuberculosis cavities is the most common predisposing condition. However, aspergillomas can be bilateral and multiple. In many cases,

S. Albelda and G.H. Talbot.)*

chest CT may be helpful in further delineating the radiographic features of an aspergilloma that are not apparent on chest radiographs. On CT scans, globules of gas are often seen within the hyphal mass. CT angiography may also provide useful information for patients with hemoptysis by identifying hypertrophic bronchial arteries that often supply the cystic wall of aspergillomas.[4,8]

Although sputum cultures are positive for *Aspergillus* in more than half of all patients with aspergilloma, culture is not a sensitive and specific diagnostic marker.[8] Precipitating antibodies to *Aspergillus* antigens are present in the sera of more than 95% of patients with aspergilloma; however, some patients receiving corticosteroids may be seronegative.[8] Eosinophilia, IgE, and skin-test reactivity may be seen in individuals who are allergic to the fungus, but these are not consistent findings. The main challenge for the clinician is to differentiate aspergilloma from other lung conditions, including lung cancer, cavitating Wegener granulomatosis, a blood clot in a pre-existing cavity, a disintegrating hydatid cyst, and a pulmonary abscess, all of which often share radiographic features with aspergilloma. Therefore, a positive precipitin reaction for *Aspergillus* is particularly helpful in establishing the diagnosis of aspergilloma. Clinical judgment and a low threshold for performing a lung biopsy in atypical cases are required.

Predictors of poor prognosis for aspergilloma include a progressive increase in the size and/or number of aspergillomas, severe underlying lung disease with a poor lung reserve, immunosuppressive therapy, AIDS, sarcoidosis, a rising *Aspergillus*-specific IgG titer, and repetitive episodes of severe hemoptysis.[4,8]

Treatment There is no consensus on the treatment of aspergilloma because of a lack of controlled studies. Because life-threatening hemoptysis occurs only in a minority of patients, subjecting all patients with aspergilloma to surgical therapy, which is often associated with significant morbidity and mortality, seems to be inappropriate.[8] Management options for aspergilloma currently include systemic or local administration of antifungal agents, surgical resection, and conservative management with careful follow-up without specific medical or surgical intervention.[8] Often, the best course of action for asymptomatic patients with aspergilloma is carefully repeated clinical evaluation with periodic chest radiographs without surgical intervention. Therapeutic considerations must include the individual patient's health status with attention to the potential risks of each treatment.

The definitive treatment of aspergilloma is surgical resection. However, in many patients, surgery is contraindicated because of severe underlying pulmonary dysfunction; the operation per se is associated with significant mortality and serious postoperative complications such as hemorrhage, bronchopleural fistula, bacterial superinfection, and empyema.[6,8] Therefore, it has been suggested that surgical resection of aspergilloma should be restricted to patients with severe, life-threatening hemoptysis and preserved pulmonary function. Surgical resection should also be considered for patients with poor prognostic features (e.g., chronic immunosuppression, sarcoidosis, and increasing *Aspergillus*-specific IgG titers).[6,8] Extrapleural resection has been reported to improve outcome. For patients who are unfit for surgical resection, an alternative approach is cavernostomy, which is performed under local anesthesia; however, cavernostomy is also associated with mortality and mediocre results.[6,8] This procedure should be considered as a last resort.

Intracavitary instillation of an antifungal agent is a promising alternative treatment in patients with severe pulmonary dysfunction who are poor candidates for surgery. CT-guided percutaneous instillation of AMB-D has been shown to be effective for aspergilloma in several cases of massive hemoptysis, with resolution of hemoptysis within 5 days.[8] The response to percutaneous injection of AMB-D was sustained with no recurrences for several months, improvement or even resolution of radiographic abnormalities, and reduction of serum *Aspergillus* antibody titers.[4,6,8] Endobronchial instillation of ketoconazole via fiberoptic bronchoscopy has also been successful.[8] Overall, topical therapy with antifungal agents is ideal for patients with a solitary aspergilloma who have severe hemoptysis and contraindications to surgical resection.

Bronchial arterial embolization (BAE) has been extensively used in the management of hemoptysis in patients with aspergilloma.[4,8] However, this approach has proven to be only temporarily effective, and recurrence of hemoptysis usually occurs because of the presence of collateral vessels in the involved area. Hence, BAE seems to be appropriate only as a "bridge" procedure in patients with massive hemoptysis until surgical resection of the aspergilloma can be performed. Also, radiation therapy has been shown to be effective for aspergilloma, even in patients with massive hemoptysis.[4,8] This modality has been recommended for cases of recurrence of life-threatening hemoptysis after BAE.

Itraconazole is an orally administered antifungal agent with activity against *A. fumigatus* and high tissue penetration into the lung. The use of itraconazole for aspergilloma has been reported in several noncontrolled studies.[4,8] Data from these studies showed that the use of itraconazole capsules at doses ranging from 200 to 400 mg/d for 6 to 18 months resulted in radiographic and symptomatic improvement in almost two-thirds of the patients and may have a place for the treatment of aspergilloma.[8] Serum itraconazole levels were not measured in most of these studies, but a recent study of treatment of pulmonary aspergilloma with itraconazole (100–200 mg/d) demonstrated sufficient itraconazole levels within the aspergilloma cavities.[4,8] The major limitation of itraconazole is that it works slowly; thus, use of it would not be prudent in cases of life-threatening hemoptysis. In addition, recurrence of aspergilloma often follows discontinuation of itraconazole treatment, whereas acquisition of secondary resistance of *A. fumigatus* isolates to itraconazole has been described in patients with aspergilloma following prolonged treatment. Voriconazole has been successfully used to treat pulmonary aspergilloma caused by itraconazole-resistant *A. fumigatus* isolates, although cases of voriconazole failure in patients with aspergillomas have also been reported. There is evidence of development of secondary resistance to voriconazole during long-term treatment of patients with aspergillomas.

Invasive Bronchial Aspergillosis

The term invasive bronchial aspergillosis (IBA) refers to infection involving the large airways. Further subclassification of IBA based on the bronchoscopic appearance has been proposed, including tracheobronchitis, pseudomembranous tracheobronchitis, and ulcerative tracheobronchitis. In fact, these entities represent a continuous spectrum of this infection.[7,8] An alternative, more functional classification based on the depth of tissue invasion by *Aspergillus* includes (a) superficial infiltration type; (b) full-layer involvement type; (c) occlusion type (airway occlusion ≥50% of the original diameter of involved bronchi; and (d) mixed type. The potential impact of this classification system on the management of IBA has not been validated.

Aspergillus tracheobronchitis is the least invasive form of IBA and is characterized by the presence of a superficial tracheobronchial inflammation, intact mucosa with no evidence of ulcers, and pseudomembranes or other abnormalities; *Aspergillus* spp. are identified in mucus exudates.[7,8] In contrast, pseudomembranous tracheobronchitis is characterized by significant necrosis of bronchial epithelium and formation of pseudomembranous plaques, which are white, gray, or black in color. These lesions may progress and result in extensive invasion of the large airways; however, in the majority of patients, the depth of invasion does not extend beyond

the bronchial cartilage.[7,8] Finally, ulcerative tracheobronchitis is the most aggressive form of IBA and manifests with endobronchial plaques, nodules, or areas of ulceration and necrosis; in addition, the infection may extend to the adjacent pulmonary parenchyma and pulmonary vasculature.[7,8] Late sequelae of ulcerative tracheobronchitis include the formation of excessive granulomatous tissue with resulting bronchial stenosis.

The pseudomembranous form of IBA is typically seen in lung transplant recipients, who accounted for almost 40% of published cases.[6,8] In fact, IBA is the most common infection within 3 months following lung transplantation, whereas IPA tends to occur much later in this patient population. Occasionally, pseudomembranous tracheobronchitis is found in various clinical settings including HSCT, hematological malignancies, metastatic renal cell carcinoma, post-influenza, COPD, AIDS, systemic lupus erythematosus, metabolic abnormalities including DM, and even in immunocompetent individuals.[7,8] Patients may be initially asymptomatic or have symptoms attributed to the underlying illness with negative chest radiographs. However, as the infection progresses, symptoms become more pronounced, including characteristic stridor, resulting in respiratory failure and ultimately death. Persistent stridor in neutropenic or severely immunocompromised patients should raise suspicion for IBA; however this symptom occurs in less than one-quarter of all cases. Importantly, *Aspergillus* galactomannan antigen has limited value in IBA diagnosis as it is positive in only 60% of the cases.[5,6]

The ulcerative form of IBA occurs almost exclusively at the site of bronchial anastomosis in lung transplant recipients.[6] Bronchoscopically, the appearance is that of severe tracheobronchitis with multiple ulcers at the site of anastomosis. The symptoms are similar to those of pseudomembranous IBA. Complications include acute IPA, severe bronchial stenosis, anastomotic dehiscence, and bronchial necrosis with bronchoarterial anastomotic fistula.[6] Rarely, ulcerative IBA develops in patients with AIDS or solid tumors.[6] Diagnosis of all forms of IBA requires a high index of suspicion and is established only by bronchoscopic examination.

Bronchial stump aspergillosis is an unusual complication of lung resection.[5–7] The period from pneumonectomy to the onset of infection usually ranges from 6 to 12 months, although noted to occur after 3 years in one case. Patients may present with a productive cough and hemoptysis, sputum that may be putrid, and occasionally, expectoration of fungal material or suture thread.[5–7] Chest radiographs are usually unchanged when compared with those taken at baseline. The cause is secondary *Aspergillus* infection of silk suture material used to close the bronchus after pulmonary resection. Local inflammation, compromised tissue viability, and the use of silk sutures favor the establishment of *Aspergillus* infection. Substitution of nylon monofilament for silk sutures at surgery has significantly reduced this infectious complication.[5–7]

All of the forms of IBA, including bronchial stump anastomosis, require prompt treatment with systemic antifungals for IA (discussed in detail below). Data from controlled studies of the treatment of IBA are lacking, however. A common, although unproven practice is to combine systemic antifungal therapy, such as intravenous AMB-D or voriconazole, with aerosolized AMB-D.[5–7] Notably, most reported failures occurred following cessation of the treatment. Finally, surgical resection and stent placement may be necessary in conjunction with antifungal therapy if dehiscence of the anastomosis occurs because of tracheobronchial aspergillosis.[5–7]

Chronic Pulmonary Aspergillosis

Chronic forms of *Aspergillus* infection of the lung have long been recognized.[8] CPA occurs in patients with chronic cavitary lung disease and is characterized by an indolent clinical course evolving over months to years, constitutional symptoms, serum precipitins to *A. fumigatus*, elevated acute phase markers of inflammation, and an immune status that ranges from normal to mild immunosuppression. Locally invasive (semi-invasive) *Aspergillus* infection may be evident histopathologically. However, both angioinvasion and dissemination are absent. A variety of terms have been used for CPA, including pulmonary aspergillosis with cavitation, complex aspergilloma, chronic granulomatous aspergillosis, semi-invasive pulmonary aspergillosis, and CNPA.[8]

In an attempt to better define CPA, a subclassification of this entity based on clinical and radiographic findings was recently proposed, introducing the terms CNPA, chronic cavitary pulmonary aspergillosis (CCPA), and chronic fibrotic pulmonary aspergillosis (CFPA).[8] CNPA comprises a syndrome of slowly progressive cavitary lung disease, chronic respiratory symptoms, and the presence of precipitating antibodies against *Aspergillus*. Some cases of CNPA have invasion of the lung parenchyma by *Aspergillus* spp. However, in most of the described cases, there is no tissue invasion despite the presence of extensive and progressive tissue damage. CCPA refers to cases in which there is formation and expansion of multiple cavities over time, whereas CFPA refers to cases in which cavity formation is followed by a pronounced fibrotic reaction.[8] In addition, it has been recommended that any case with proven hyphal invasion of tissue should be classified as CNPA.

Defects in mucociliary clearance associated with structural lung disease appear to be a critical factor in the pathogenesis of CPA.[8] Prior mycobacterial lung infection, emphysema and/or COPD, bullae, asthma, sarcoidosis, pneumoconiosis, lung cancer, thoracic surgery, upper lobe fibrosis complicating ankylosing spondylitis, marijuana use, and a history of *Legionella* infection have been described as predisposing conditions for CPA. In addition, subtle but essential defects in innate immunity may play a role in the pathogenesis of CPA (see Chapter 121). Hence, defects in mannose-binding lectins, alterations in SP-D, certain polymorphisms in cytokine encoding genes such as transforming growth factor-β, TNF-α, IFNγ, and IL-15, and systemic illnesses associated with a degree of immunosuppression, such as corticosteroid-based therapy, diabetes mellitus, AIDS, and alcohol abuse, have all been associated with CPA in humans.[8] However, the precise pathophysiological mechanism of new cavity formation remains uncertain.

CPA tends to affect middle-aged individuals who are relatively immunocompetent and more male than female individuals.[8] CPA has an indolent and progressive course that lasts for years. Chronic productive cough and weight loss with mild hemoptysis, dyspnea, and fatigue are the usual presenting symptoms. Pleural fibrosis and *Aspergillus* empyema appear to complicate some cases of CPA.[8]

Although the diagnosis of CPA may be suspected with a single chest radiograph, sequential chest radiographs are typically required to confirm the progressive nature of CPA lesions. CT is particularly useful in defining the precise pattern and extent of the disease. Typical radiographic findings include the presence of one or more cavities, which may or may not contain fungus balls, often located in the upper lobes.[8] New cavity formation and expansion of preexisting cavities are also characteristic of CPA. Pericavitary infiltrates and adjacent pleural thickening are frequently observed and appear to correlate with the overall disease activity.[8] With appropriate treatment, these radiographic abnormalities may regress, leaving residual thin-walled empty cavities.

The combination of characteristic clinical and radiological findings and either the presence of *Aspergillus* precipitins or the isolation of *Aspergillus* spp. from respiratory samples is highly indicative of CPA.[8] Although the demonstration of precipitating antibodies to *Aspergillus* is the cornerstone and a prerequisite for the diagnosis of CPA, these antibodies may be negative, especially in case of infection with non-*fumigatus Aspergillus* spp.[8] Histopathology demonstrates chronic inflammation and fibrosis, sometimes with granulomatous features with or without visible hyphae. The absence

of hyphae does not exclude the diagnosis of CPA because of the paucity of high fungal burden in patients with CPA.

Differentiating CPA from other serious lung conditions that require specific therapy, such as cancer and chronic cavitary mycobacterial and endemic fungal infections, as well as other inflammatory lung conditions is a major challenge as overlap is not uncommon. In fact, there is a strong association between CPA and atypical mycobacterial infections. In these cases, imaging is not helpful, so biopsy and comprehensive microbiological studies must be used to exclude the co-existence of CPA with such entities. In addition, CPA differs from simple aspergilloma because of the presence of constitutional symptoms, the development of persistent pericystic lung nodules or pleural thickening, consolidations or ground-glass opacities, and the development and/or progression of cavities.[8] Finally, one should always consider the possibility of a pyogenic infection in a cavity that may require drainage and appropriate antibacterial treatment.

CPA requires prolonged treatment with systemic antifungal agents. In the literature, most patients with CPA have received treatment with oral itraconazole, whereas IV AMB-D has been successfully used in refractory cases.[8] In a series of 18 patients, use of itraconazole capsules resulted in improvement or stabilization of disease in 71% of the cases.[8] Use of voriconazole has been associated with favorable responses in small case series with response rates ranging from 30% to 80% and should be considered as another treatment option. Posaconazole has also successfully used with 61% response rate in 79 patients with CPA. However, emerging rates of azole resistance in *Aspergillus* isolates recovered from patients with CPA have been reported, although there is controversy on whether in vitro resistance of *A. fumigatus* to azoles correlates with worse clinical outcome. In addition, serious side effects necessitating discontinuation of treatment with azoles occur in up to 27% of the patients. Alternative treatment strategies include intravenous use of polyenes or echinocandins. Although the reported response to IV AMB-D (81%) appears to be slightly better than that to itraconazole, administration of AMB-D may require prolonged hospitalization and is associated with considerable toxicity, especially nephrotoxicity.[8] In a recent randomized study, treatment with IV micafungin had comparable (60%) rates of response with IV voriconazole (51%) and significantly less adverse effects in patients with CPA and could represent an alternative especially in cases where azole resistance in a concern.[6] Anecdotal reports of improved outcome as a result of adjunctive immunomodulating treatment with IFN-γ have also been reported.[8]

Surgery plays a limited role in the treatment of CPA because of the poor overall lung function in many patients. Major postoperative complications, such as respiratory failure, bronchopleural fistulae, pleural extension of aspergillosis, and even dissemination of *Aspergillus* can occur.[8] Thus, surgery should be reserved for selected patients with a reasonable respiratory reserve for whom there are no other treatment options. For example, surgery may be appropriate for patients with severe hemoptysis if embolization fails.

Although systemic antifungal therapy for CPA seems to be beneficial, assessment of response to it is difficult to gauge because the activity of the disease may fluctuate over time. Weight gain and improved energy levels are the earliest and most reliable indicators of response. Inflammatory markers also improve albeit more slowly, and they usually remain elevated even during long-term therapy. Relapse months or years after discontinuation of treatment is frequently reported.

Invasive Pulmonary Aspergillosis

An important clinical manifestation of Aspergillus-related disease is invasive pulmonary aspergillosis, discussed in detail below.

Epidemiology *Aspergillus* has emerged as one of the most common causes of infectious death in severely immunocompromised patients, with mortality rates approaching 70% in patients with leukemia and recipients of HSCTs.[2,5–7] Surveillance studies demonstrated a three- to fourfold increase in the frequency of *Aspergillus* infections at major cancer centers over the past two decades. In fact, IPA has surpassed invasive candidiasis as the most common fungal infection found at autopsy at several institutions; approximately 15% to 20% of patients with leukemia die of fungal pneumonia caused by *Aspergillus* spp. Similarly, in allogeneic HSCT recipients, 15% to 30% of deaths are caused by refractory fungal infections, mainly caused by *Aspergillus* spp., and most of these infections occur late in the postengraftment period in the setting of graft-versus-host disease (GvHD).[2,5–7] Large prospective multicenter surveillance studies contacted by the Transplant-Associated Infection Surveillance Network (TRANSNET) and Prospective Antifungal Therapy (PATH) Alliance has furthered insights into the epidemiology of IA in the United States. From both studies, IA has emerged as the most common invasive fungal infection in HSCT and solid-organ transplant recipients (43% and 59% of all IFIs, respectively) over invasive candidiasis and mucormycosis, with a 12-month cumulative incidence of 1.6%. Overall mortality in these patients was estimated to be approximately 36% and 75% at 12 weeks and at 1 year, respectively.[5–7]

Changes in HSCT practices over the past decade have greatly impacted the epidemiology of IPA. Autologous HSCT is associated with a low risk of IPA because of shortened periods of preengraftment neutropenia and a lack of GvHD. On the other hand, IPA has a bimodal distribution in allogeneic HSCTs, with patients at risk before and after bone marrow engraftment. The increasing use of peripheral blood stem cells, growth factors, and nonmyeloablative conditioning regimens (mini-transplants) in allogeneic HSCT has shortened the duration of preengraftment neutropenia and the incidence of IPA shortly post HSCT. In contrast, late (40–80 days after engraftment) and very late (80+ days after engraftment) IPA has increased.[5–7] This trend is associated with increased use of matched unrelated-donor (MUD) allogeneic transplants and with interrelated risk factors, such as lymphopenia, chronic GvHD, corticosteroid-based therapy, and/or CMV infection.[5–7] Among HSCT recipients, IPA now predominantly occurs as a community-acquired rather as a nosocomial infection in nonneutropenic patients late after engraftment, in whom GvHD and management with increasingly intense immunosuppression have emerged as the major risk factors. Of interest, recent studies in HSCT recipients implicate geoclimatic changes, associated with high environmental spore counts following periods of high temperature and low precipitation, as a factor for the development of IPA.

In addition to the "classic" groups of patients at risk for IPA, such as those with prolonged, profound neutropenia because of a hematological malignancy (5%–25% risk) or aplastic anemia; recipients of allogeneic HSCTs (5%–30% risk), or lung transplants (17%–26% risk); those with AIDS, severe combined immunodeficiency, or CGD (25%–40% lifetime risk); burn patients; and patients receiving chronic corticosteroids, IPA has been increasingly described in new groups of patients.[5–7] Hence, patients with systemic lupus erythematosus, patients with multiple myeloma who receive high-dose steroids, and premature neonates are prone to the development of severe IPA. Furthermore, several cases of IPA have been lately reported in patients with Crohn disease or rheumatoid arthritis who received treatment with TNF inhibitors (e.g., infliximab).[5–7] Even the use of high-potency inhaled steroids may predispose some apparently normal hosts to IPA in rare instances. IA is considered an emerging infection in patients with prolonged stay in intensive care units (ICUs). ICU aspergillosis is a distinct clinical entity that is probably underreported.[2,5–7]

IPA caused by *Aspergillus* spp. less susceptible to antifungals than *Aspergillus fumigatus* such as *A. terreus and A. flavus* has also been

reported in individual institutions.[2,5–7] This phenomenon may be at least partially a reflection of antifungal selection pressure determined by extensive empirical and prophylactic use of antifungal agents in high-risk patients. Alternatively, because non-*fumigatus* aspergilli cause nosocomial infections more frequently than does *A. fumigatus*, an epidemiological niche for these species may also account for their predominance in some institutions. *A. terreus* is clinically resistant to AMB, but species, including *A. flavus, Aspergillus lentulus, Aspergillus nidulans, Aspergillus ustus, Aspergillus glaucus,* and others, can also demonstrate resistance to antifungal agents.

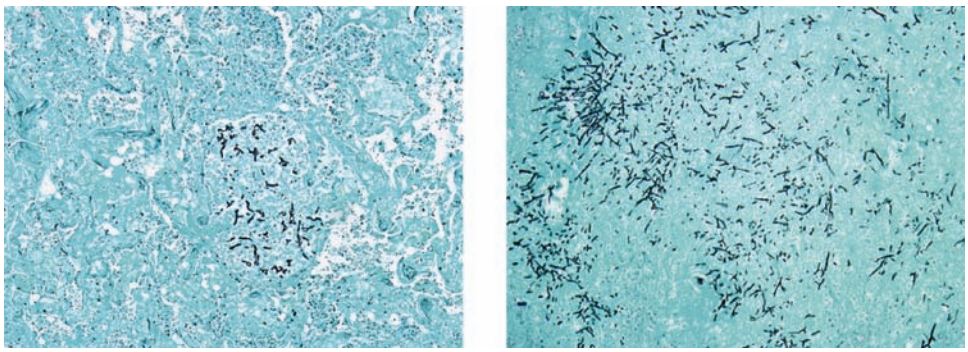
A number of nosocomial clusters of IPA have been reported over the past three decades mostly associated with hospital construction and defects in air-handling equipment. Air and environmental surfaces have been the focus of most investigations. Water has been implicated as an additional source of nosocomial transmission of *Aspergillus* spp., although this has not been confirmed in other studies.[2,5–7] An outbreak of IPA after major cardiac surgery caused by abnormally high levels of fungal spores in the air of the ICU has been recently reported.

Pathogenetic Mechanisms Because *Aspergillus* is a saprophytic mold that colonizes in the respiratory tract of immunocompromised patients, the pathogenesis of infection depends on the host's underlying immunosuppression. In the immunocompromised host, IPA typically occurs following inhalation of *Aspergillus* conidia, although hematogenous dissemination from a cutaneous or gastrointestinal source is seen occasionally.[1,2] Damage to respiratory epithelium because of radiation therapy, chemotherapy, GvHD, or prior infection (e.g., RSV, influenza) may facilitate attachment of *Aspergillus* conidia to the respiratory epithelial surface.[5]

Breach of mucosal host defense mechanisms in the setting of underlying immunodeficiency places the host at risk for invasive infection by *Aspergillus* spp. Thus, once *Aspergillus* has invaded the respiratory tract, control of the infection is highly dependent on functional adaptive immune responses. Lymphopenia and local/global dysregulation of the host adaptive Th1/Th2 polarization have been shown to play a key role in the subacute progression of IPA in nonneutropenic hosts.[5–7] Hence, in the late postengraftment period, allogeneic HSCT recipients have a low IFN-γ/IL-4 ratio, which is suggestive of a Th2 response that potentially accounts for their susceptibility to IPA.[3–5,7] In comparison, healthy individuals mount a predominantly Th1-type cellular response to *Aspergillus* infection. In humans, iatrogenic suppression of protective Th1 responses is common, particularly in the setting of chronic GvHD (an excessive Th1 response of allograft T lymphocytes) treated with high-dose corticosteroids and/or other immunosuppressive regimens.[3,5,7] Importantly, *Aspergillus*-mediated suppression of host Th1 responses by production of gliotoxin is also plausible.[2,3] Similarly, recent preclinical data indicate that herpes virus reactivation and bacterial co-infection in the lungs induce profound dysregulation of immune responses, facilitating the development of IPA.[2,3,5–7] For example, CMV infection can result in dysfunction of dendritic cells and phagocytes, which may predispose patients to IPA. Of interest, critically ill patients with prolonged ICU stay develop a systemic deactivation of the immune system following sepsis or any severe insult that has activated a systemic inflammatory response.[3] This sepsis-induced immune paralysis often results in superinfection with opportunistic pathogens, including *Aspergillus*. In agreement, mice recovering from sepsis remain exquisitely susceptible to *Aspergillus* and develop IPA upon pulmonary infection without the need for immunosupression.[3] Although the mechanism of increased susceptibility to *Aspergillus* in sepsis-induced immunosupression remains obscure, there is evidence of predominance of a deregulated myeloid cell response with increased levels of IL-13, IL-4, TGF-β in the lung of mice that develop invasive fungal infection. Importantly, deregulated cytokine release by myeloid cells and associated susceptibility to IPA in septic mice could be restored by adoptive transfer of bone marrow–derived dendritic cells from healthy mice.[3]

Once germination of conidia occurs, *Aspergillus* hyphae invade pulmonary arterioles and lung parenchyma, leading to ischemic necrosis. Hematogenous dissemination with thrombosis, hemorrhagic infarction, and invasion of distant organs may result from invasion of arterioles by *Aspergillus* hyphae and is found in approximately one-third of cases of IPA at autopsy.[2,5–7] Thus, IA, in addition to pneumonia, can present with a clinical picture similar to that of other thrombotic and embolic diseases, such as pulmonary embolism, cerebral vascular accidents, Budd–Chiari syndrome, and renal papillary necrosis. In addition, IA can spread to contiguous structures, across the diaphragm to the stomach, or from the lung to the heart or superior vena cava.

Importantly, it has been recently demonstrated that IPA has different pathophysiological mechanisms depending on the type of immunosuppression. Thus, a low *Aspergillus* tissue burden, extensive inflammatory injury, absence of angioinvasion, and localized infection have been observed in corticosteroid-immunosuppressed mice, whereas minimal inflammation, extensive angioinvasive *Aspergillus* growth, and disseminated infection are characteristic of IPA in cyclophosphamide-treated neutropenic mice.[2,5–7] In corticosteroid-treated mice, host immune effector cells appear to have limited activity against *Aspergillus* hyphae but cause extensive alveolar damage and exudative bronchiolitis, which appears to be more important than the *Aspergillus*-induced injury itself. This nonangioinvasive form of IPA has been increasingly recognized in a wide range of nonneutropenic hosts, including those who received corticosteroids, recipients of solid-organ transplants and allogeneic HSCTs with GvHD, patients with AIDS, and patients with CGD (Fig. 133-6).[2,5,7] Similar to the animal models of IPA, histopathology



A B

Figure 133-6 The characteristic pattern of *Aspergillus* invasion in tissue obtained from (**A**) an HSCT recipient with IPA and severe GvHD and (**B**) a patient with acute leukemia and severe neutropenia in whom IPA developed Extensive inflammation, less *Aspergillus* burden and absence of angioinvasion was observed in the patient with GvHD. In comparison, the histopathology of IPA in the patient with severe neutropenia was characteristic for scant infiltration by phagocytic cells, extensive coagulative tissue necrosis caused by angioinvasion, and a high fungal burden. in those nonneutropenic patients is characterized by extensive pyogranulomatous inflammatory reactions, inflammatory necrosis, and extensive cavitation.

Although deficiency of TLR adaptive protein MyD88 and Dectin-1 in humans is not associated with the development of IA, genetic polymorphisms in TLR-1, TLR4, TLR-6, and Dectin-1 predispose to the development of IA in allogenic HSCT recipients.[3] In addition, polymorphisms in IL-10 and plasminogen are associated with increased risk for IA. Thus, better understanding immunogenetics of IA in these high-risk individuals could facilitate risk stratification and design of preventive strategies.[3]

Clinical Features Symptoms of IPA begin with fever (unless the patient is receiving corticosteroids), which may be followed by a mild nonproductive cough suggestive of bronchitis. Pleuritic chest pain and progression to pneumonia occur within 1 to 2 days. Cavitation tends to occur in patients if immunosuppression is decreased, such as in leukemic patients during recovery of bone marrow hematopoiesis or when steroid-based therapy is reduced significantly, and on occasion gives rise to massive hemoptysis (Figs. 133-7 and 133-8).[2,5–7] Pleuritic pain and slight hemoptysis may suggest pulmonary infarction. Patients also may expectorate necrotic tissue filled with hyphae. Cough, sputum production, and pleural effusion are either absent or minimal. IA must be strongly considered when dealing with susceptible patients in whom treatment with broad-spectrum antibiotics fails.

Extrapulmonary sites may be involved including the highly vascular organs such as the kidneys, liver, spleen, and central nervous system. Invasive disease of the nose and paranasal sinuses occurs in immunocompromised patients, and contiguous invasive spread into the orbit or into the cranial vault can result in a syndrome similar to rhinocerebral mucormycosis.

Diagnosis Substantial delay in establishing an early diagnosis remains a major impediment to the successful treatment of IPA. Chest radiographs are not sensitive in detecting early forms of bronchopulmonary IPA, and up to 10% of patients with proven IPA have "normal" chest radiographs within a week of death.[2,5–7] High-resolution CT scans of the chest may reveal small wedge-shaped subpleural lesions or nodules typically surrounded by intermediate attenuation. This halo sign correlates with hemorrhage and edema surrounding an infarct caused by thrombosis and is highly suggestive of acute IPA, especially in neutropenic patients with leukemia.[2,5–7] However, the halo sign has been documented only in 33% to 60% of patients and is transient. In fact, to be useful for the diagnosis of IA, CT must be performed within 5 days of the onset of infection, because more than 75% of initial halo signs disappear within a week.[2,5–7] With neutrophil recovery, these lesions coalesce and cavitate, forming the "air crescent" sign, a classic sign of late filamentous invasive mold infection (IMI). However, the air crescent sign does not appear until the third week of the infection, and the appearance may be too delayed to be helpful in the diagnosis of IA. Importantly, lesions frequently increase in size in the first 7 to 10 days following effective antifungal therapy. In view of the angioinvasive nature of IPA, detection of vascular occlusion by CT-based pulmonary angiography was evaluated in a recent study as an early sign of IMI. Importantly, the presence of positive vascular occlusion sign was more sensitive and specific than the halo sign and comparable to serum galactomannan test for diagnosis of IPA. Thus, CT pulmonary angiography could represent a viable diagnostic tool for IPA, especially in patients at low-risk of contrast-induced acute kidney injury.

Persistently febrile neutropenic patients with leukemia would benefit from the use of early high-resolution chest CT to identify early radiologic signs of IPA such as the halo sign. In a recent study of febrile neutropenic patients, early and routine CT scanning coupled with early intensive antifungal-based treatment and surgery resulted in increased survival rates when compared with therapy initiated at the first sign of a pulmonary fungal infection.[2,5] CT also plays a critical role in determining the appropriateness of various downstream diagnostic procedures (bronchoalveolar lavage [BAL], percutaneous needle biopsy, and open lung biopsy) in patients with IPA. Nonetheless, clinical and radiologic presentations of IPA in the

expanding group of nonneutropenic patients who develop infection is atypical, including cases with tree-in-bud opacities or diffuse ground-glass appearance in CT.[2,5–7]

Respiratory cultures of *Aspergillus* from expectorated sputum, bronchial washings, or BAL specimens have low sensitivity (<30%) for diagnosing IA but a high positive predictive value (>60%) in heavily immunocompromised patients.[5] Early performance of CT-guided fiberoptic bronchoscopy with BAL in immunocompromised patients with pulmonary infiltrates has been shown to improve the diagnostic yield of this procedure. In addition, there is a need for the development of standardized BAL protocols in order to facilitate comparative clinical studies on the diagnosis of IPA. Blood cultures have little diagnostic value for IA but may reflect true disease cases of *A. terreus* infection. Ultimately, open lung biopsy may be required for a definitive diagnosis of IPA and may not be feasible until late in the course of infection or recovery of pancytopenia.

In recent years, efforts have been directed toward identifying non–culture-based markers for rapid, reliable diagnosis of IA.[5–7] Those based on the detection of anti-*Aspergillus* antibodies have very poor sensitivity for IA, especially in patients receiving immunosuppressive agents. Instead, tests based on identifying circulating fungal antigens or metabolites are promising. To date, the two approaches that have demonstrated the greatest promise in early clinical studies are detection of antigens and measurement of *Aspergillus* nucleic acids by using PCR.

Galactomannan is a polysaccharide cell wall component of *Aspergillus* spp. that is released into the circulation during fungal growth in tissues and can be detected in the serum of patients with IA.[5–7] A sandwich enzyme–linked immunosorbent assay (ELISA) capable of detecting galactomannan at concentrations as low as 0.5 ng/mL has been recently developed. Initial studies evaluating the role of galactomannan serum assay in the diagnosis of IA have been predominantly conducted with profoundly neutropenic patients undergoing chemotherapy for cancer or recipients of HSCTs who were on fluconazole prophylaxis. These studies have documented sensitivity rates ranging from 67% to 100% and specificity rates ranging from 86% to 99% in these patients.[5–7] When serially monitored, the galactomannan assay preceded the diagnosis of IA by an average of 6 to 14 days. However, in a recent study that evaluated the value of the galactomannan assay in the detection of early IA, the appearance of major lesions (halo sign, air crescent sign, and cavitation) on high-resolution CT scans almost coincided or even preceded the detection of the galactomannan antigen in serum.[5–7] Furthermore, uncertainties remain regarding the performance of this assay in other settings, such as breakthrough IA to mold-active antifungal prophylaxis, pediatric populations, and solid-organ transplant recipients. Other factors, such as the pretest probability of infection, the patient's immune status (neutropenia vs. GvHD), antifungal therapy, antibacterials, and diet may affect both the performance and interpretation of the galactomannan assay. Hence, sensitivity rates as low as 30% have been reported in nonneutropenic HSCT recipients receiving mold-active antifungal prophylaxis and lung transplant recipients.[5–7] In addition, false-positive results have been described in patients receiving β-lactam antibiotics, particularly piperacillin–tazobactam, as well as in those ingesting certain cereals, pastas, nutritional supplements, and soy sauce produced with fermentation products of *Aspergillus oryzae*, a fungus commonly used in food production.[5,7] In addition, false-positive galactomannan antigenemia has also been reported as a result of transfusion of blood products. Recent studies evaluated the performance of detection of galactomannan in other fluids, particularly BAL and showed that BAL GM has improved sensitivity compared to serum GM in high-risk patients with IPA.[2,5–7] A recent meta-analysis of 30 diagnostic studies with the use of BAL GM, using an otimal cutoff value of 1.0, the BAL-GM assay had 90% sensitivity and performed better compared to PCR and serum GM test although specificity was lower (89%).

A colorimetric assay for the detection of 1,3-β-D-glucan, an integral cell wall component in a number of pathogenic yeasts and filamentous fungi, recently became commercially available.[5,7] The sensitivity and specificity rates for this test in limited studies thus far have ranged from 67% to 100% and from 84 to 100%, respectively. Several false-positive test results have been reported in patients with cirrhosis, in patients undergoing hemodialysis, in patients following abdominal surgery, and in those receiving chemotherapy with particular agents.[5,7] Furthermore, the 1,3-β-D-glucan assay has been reported to be less sensitive and reproducible and become positive later in the course of IA when compared with galactomannan antigen assay.

PCR detection of *Aspergillus* nucleic acids is a promising method for early detection of IA. The sensitivity of PCR is excellent, but its specificity for invasive infections can be problematic, and false-positive results are common.[5,7] Multiple unresolved issues accompany the use of PCR for the diagnosis of IA, including the sample type (serum, BAL fluid), amplification strategy (nested vs. conventional PCR), protocol (real-time quantitative vs. conventional PCR), and primer selection (*Aspergillus*-specific or pan-mold, pan-fungal primers). There have been no good studies examining how PCR performs in comparison with galactomannan detection for the early diagnosis of IA. However, it has been shown that PCR is inferior to serum galactomannan assay in animal models and in some but not all human studies.[5–7] A recent meta-analysis of 19 studies comparing the value of BAL PCR with BAL GM concluded that although sensitivity and specificity of both tests were comparable, combination of both tests increased sensitivity without compromising specificity. Thus, like GM testing, PCR is likely to become an adjunctive diagnostic method alone or in combination with other biomarkers and standard microbiological, histological, and radiographic methods of diagnosing IA.

Novel investigational diagnostic approaches include the development of a breath test to detect volatile *Aspergillus* biomarkers that are not produced by other pathogens, and detection of circulating *Aspergillus* antigens in BAL and serum of patients with IPA by using an immunochromatographic lateral flow device.

Treatment of IPA Although the past two decades have witnessed improved outcomes of patients with IA, the mortality rate of this mycosis in severely immunocompromised patients remains unacceptably high. Several strategies have been applied in an attempt to improve the outcome of IA. These include the introduction of potent antifungal agents such as voriconazole, early onset of treatment triggered by CT and/or galactomannan antigen, use of delivery systems to improve the therapeutic index of currently available antifungals such as lipid formulations of AMB, and possibly combination antifungal therapy, surgical excision of sequestered necrotic lesions, and use of immunomodulating agents in selected patients.[6] There has not been a systemic evaluation of the merit of each of these strategies in the treatment of IA, however. This is not surprising in view of the complexity of IA and the paucity of organized, prospective controlled clinical studies in refractory IA.

Tables 133-5 and 133-6 list the principles of management of IPA. Until early 1990 s, AMB-D was the only drug available for the treatment of aspergillosis, and no prospective evaluations of this drug had been attempted.[5–7] Another major obstacle to evaluating the merit of antifungal therapy for IPA until the early 2000s was difficulty in establishing the diagnosis; hence, most patients received empirical treatment. The introduction of uniform diagnostic criteria for proven, probable, and possible IA by the European Organization for Research and Treatment of Cancer (EORTC)/Mycoses Study Group (MSG) consortium has been an advance.[9] These criteria are standardized and reproducible and consist of

TABLE 133-5 Therapeutic Options for Invasive Fungal Infections

Regimen	Advantages	Disadvantages
Amphotericin B-deoxycholate (AMB-D)	Broad-spectrum activity, lack of frequent resistance, fungicidal activity, lower cost	Acute and chronic toxic effects, minimally effective in patients with neutropenia and with chronic disseminated candidiasis, intravenous preparations only
Lipid formulations of AMB	Broad-spectrum activity, reduced nephrotoxicity, increased doses can be administered	Only prospective randomized trial showed no advantage in efficacy over AMB-D despite higher doses, more expensive, intravenous preparations only
Fluconazole	Oral and intravenous preparation, as effective as AMB in randomized trials of nonneutropenic individuals with candidiasis, minimal toxicity, more effective for chronic disseminated candidiasis, little experience in neutropenic patients but appears to be as effective as AMB	Variable activity against *C. glabrata* and *Candida dubliniensis*, inactive against *C. krusei*, some drug–drug interactions, inactive against molds
Itraconazole	Broad spectrum of activity, lower cost, oral, and intravenous preparations	Drug–drug interactions and poor absorption (capsules) are common causes of clinical resistance, marked interpatient variability in serum levels, expensive
Voriconazole	Oral and intravenous preparations; broad-spectrum activity, including fluconazole- resistant species (e.g., *C. krusei*); fungicidal against *Aspergillus*	Drug–drug interactions, erratic pharmacodynamics, more expensive than fluconazole, inactive against *Zygomycetes*, some cross-resistance with fluconazole, need for drug level monitoring, expensive
Posaconazole	Broadest spectrum of activity among all azoles, including *Candida* spp., *Aspergillus*, *Mucorales* sp. and most other filamentous fungi	Drug–drug interactions, poor absorption, no intravenous formulation available yet (under development, in clinical trials), some cross-resistance with Itraconazole, need for drug level monitoring, expensive
Echinocandins (caspofungin, micafungin, anidulafungin)	Fungicidal activity against most *Candida* spp., minimal toxicity, lack of cross-resistance with azoles, preferred regiment for candidemia, immune modulating properties	No oral preparation, poor central nervous system, and urinary penetration, narrow spectrum of activity (*Candida, Aspergillus*), limited experience in neutropenic patients
Flucytosine	Synergistic with AMB and fluconazole, combination of flucytosine and AMB may be superior to AMB alone for chronic disseminated candidiasis and *C. tropicalis* infection	No IV preparation, causes myelosuppression, often requires monitoring of serum concentrations, emergence of resistance in monotherapy

host-risk, microbiological, clinical/radiological, PCR, and/or galactomannan antigen criteria. Despite the fact that the EORTC/MSG criteria have been updated to incorporate biomarkers for the diagnosis of IMI, their clinical applicability was questioned in real word setting; for example, in an autopsy study more than 60% of proven cases of IA in patients with hematological malignancies were not identified antemortem according standard definitions.[10] In addition, there is lack of a standardized PCR protocol for the detection of *Aspergillus* DNA from clinical specimens with validated, high intralaboratory quality performance.

The introduction of the broad-spectrum triazole voriconazole represents a major therapeutic advance in the management of IA, including IPA.[5–7] Voriconazole is available in both intravenous and oral preparations and is much better tolerated than AMB-D. In a large prospective randomized trial comparing voriconazole with AMB-D in patients with definite or probable aspergillosis, the

TABLE 133-6 Drug Dosages for Serious Invasive Fungal Infections of the Lung

Drug	Loading Dose	Daily Dose	Route
AMB-D	—	1.0–1.5 mg/kg	IV only
Lipid AMB	—	3–5 mg/kg	IV only
Fluconazole	800 mg (12 mg/kg)	400 mg bid (6 mg/kg bid)	IV, PO
IV itraconazole	200 mg bid ×2 d	200 mg	IV
Itraconazole solution	200 mg bid × 2 d	200 mg	PO
Itraconazole caps	200 mg tid × 3 d	200 mg bid	PO
IV voriconazole	6 mg/kg bid × 2 d	4 g/kg q 12 h	IV
Voriconazole tab	—	200 mg q 12 h (≥40/kg) 100 mg q 12 h (<40/kg)	PO
Posaconazole solution	200 mg qid × 7 d	400 mg bid	PO
Caspofungin	70 mg	50–70 mg	IV
Micafungin	150 mg	100–150 mg	IV
Anidulafungin	200 mg	100 mg	IV

bid, twice a day; caps, capsule; d, day; h, hours; IV, intravenous; PO, oral; q, every; sol, solution; tab, tablet; tid, three times a day.

response rate was 53% and 32%, respectively, and the survival rate at 12 weeks was 71% and 58%, respectively.[11] Improved response was seen irrespective of the underlying condition, site of infection, and presence or absence of neutropenia. Patients in whom initial therapy failed received other medications; this occurred more frequently among the AMB-D population primarily because of drug toxicity. The improved survival observed in this comparative study made voriconazole the preferred drug for first-line therapy for IA and this has been endorsed by many guidelines.

Posaconazole is a newer triazole with broad-spectrum activity against most filamentous fungi, which has shown promising activity as salvage therapy in an open-label study for IA with response rates of 42% versus 26% for the control group. Although posaconazole has a better drug interaction profile than voriconazole, it is available only as oral formulation and has to be administered with a high fat meal for optimal absorption, which can be especially problematic in severely immunocompromised and debilitated patients with mucositis or poor oral intake.[5–7] Newer formulations of (IV and oral) posaconazole with improved pharmacokinetic characteristics are currently in phase II and III clinical trials.

Use of lipid formulations of AMB is an attractive alternative to AMB-D because of reduced nephrotoxicity.[5–7] Although no comparative trials between the lipid formulations of AMB have been conducted thus far, they appear to be equally efficacious, although both toxic effects and costs differ. Most of the available data have been derived from indirect comparisons and suggest that all lipid formulations of AMB, when given at the standard dosage of 5 mg/kg, appear to have comparable efficacy to voriconazole.[5–7] That higher dosages of L-AMB are not necessarily equivalent to greater response rate was recently demonstrated in a recent prospective randomized study that compared two different dosages of L-AMB (3 mg/kg/d and 10 mg/kg/d) for the primary treatment of proven and probable IA in 201 patients. Importantly, survival rates and overall response rates were similar among the two different study groups; however higher dosage of L-AMB was associated with greater toxicity.[12] The dose–response relationships for ABLC and ABCD have not been well studied.

The echinocandins, including caspofungin, micafungin, and anidulafungin, belong to a new class of antifungal agents that inhibit the synthesis of 1,3-β-D-glucan, an essential component of the cell wall of many fungi.[5,7] They are all available only in intravenous preparations. In addition, caspofungin and micafungin have been used as primary therapy in noncomparative studies of IA with response rates ranging from 33% to 60% for caspofungin and 50% to 71% for micafungin. In addition, use of caspofungin as salvage therapy has been associated with response rates in 45% (37/83) of patients, including 50% of patients with IPA.[5–7]

Combination Treatment The recent introduction of echinocandins, which have a different mechanism of action than other antifungals, reinforced the concept of combination therapy (e.g., azoles plus echinocandins, AMB plus echinocandins, AMB plus azoles and echinocandins) as a possible means to improve suboptimal long-term survival of high-risk patients with IA treated with monotherapy.[13] Many in vitro studies and animal models suggest that administration of an echinocandin with voriconazole may result in additive or synergistic effects, which can potentially translate into clinical benefits. This hypothesis has been supported by small clinical studies and noncomparative observations. A recently completed double-blind randomized clinical study in 454 patients with IA compared the efficacy of combination of voriconazole and anidulafungin versus voriconazole monotherapy with 6 weeks survival being the primary study endpoint. Importantly, treatment of IA with the combination of voriconazole and anidulafungin was associated with a clinically meaningful survival benefit in patients with hematological malignancies or after HSCT, particularly in patients with a diagnosis of IA based on GM antigen positivity and consistent radiological findings (6 weeks mortality 15.7% for combination and 27.3% for monotherapy, $P = 0.04$). This is the first study to demonstrate a significant impact of combination therapy in the outcome of patients with IA and a positive galactomannan assay.

In another randomized study the efficacy of L-AMB standard dose (3 mg/kg/d) in combination with caspofungin was compared with L-AMB high does (10 mg/kg/d) in 30 patients with hematological malignancies and IPA.[14] The combination of caspofungin plus L-AMB demonstrated higher overall responses rates when compared to L-AMB monotherapy and 100% survival at the end of the study, although differences in responses were not statistically significant, probably because of the small size of the study.

Therapeutic Drug Monitoring A growing body of evidence suggests patient-to-patient variability in the pharmacokinetics of triazoles used for treatment or prophylaxis in IA.[6] Absorption issues (for itraconazole and posaconazole), drug–drug interactions (for all triazoles, especially voriconazole), and pharmacogenetic differences (for voriconazole) may have significant impact in the management and outcome of patients with IA under triazole treatment. Thus, plasma drug level monitoring play an increasingly important role in optimizing the safety (for voriconazole) and efficacy (for itraconazole, posaconazole, and voriconazole) of antifungals with significant interpatient pharmacokinetic variability. The need to perform therapeutic drug monitoring should be individualized as determined by the clinical status of the host (e.g., specific organ function, comorbidities, and receipt of concomitant medications) and the overall treatment plans.[6]

Surgery The role of adjunctive surgery in the management of IPA also has not been demonstrated conclusively. Pulmonary infarcts and tissue sequestration are common causes of antifungal therapy failure and fatal hemorrhage in patients with IPA. Resection of infected pulmonary tissue is beneficial for selected patients.[5–7] Residual cavitary lesions, especially when containing fungus balls, after successful antifungal therapy may cause late exsanguinating hemorrhage or reactivation of infection during subsequent myelosuppressive chemotherapy. Removal of these lesions, if surgically feasible, should be considered and may provide survival benefit. Surgical intervention may be a life-saving procedure for patients with IPA who experience acute pulmonary hemorrhage, when performed early in the disease process. It is less evident whether early removal of well-circumscribed lesions close to pulmonary arteries is beneficial. Likewise, the value of late debulking of a pulmonary mass if the patient has multiple fungal lesions that cannot be completely resected is uncertain. Recent uncontrolled data suggest that resection of the lobe most adversely affected by IA is beneficial in treating pulmonary lesions that worsen despite the use of intense antifungal therapy.[5–7]

Immune Augmentation Treatment Because host immunodeficiency is the critical determinant of the outcome of IA, a large number of studies, mostly preclinical, over the past two decades have focused on strategies to augment cellular immune defenses against IMIs. The available preclinical data suggest that quantitative and qualitative deficiencies in host cellular immune responses can be corrected with adjunctive cytokine therapy, such as the use of myeloid growth factors (e.g., granulocyte colony–stimulating factor [G-CSF], granulocyte macrophage colony–stimulating factor [GM-CSF]), IFN-γ, or a combination of these cytokines plus infusion of host effector cells [e.g., IFN-γ plus granulocyte transfusions]).[5–7] Granulocyte transfusion therapy has become more feasible since the introduction of G-CSF/corticosteroid mobilization into the donor leukocyte collection process.[6] Currently, there are no data from randomized clinical trials examining the efficacy of granulocyte transfusions for

IA or other serious infections during neutropenia. Future studies in this area will likely examine the use of vaccinations and/or cellular transfer with or without adjunctive cytokines to boost adaptive Th1 immunity in immunosuppressed hosts. Importantly, WBC transfusions have been occasionally associated with serious adverse reactions including transfusion-related acute lung injury (TRALI). Clearly, this is a challenging area of investigation. Carefully designed clinical trials will be required to verify results from animal models and other preclinical observations and evaluate both the efficacy and safety of these interventions.

Prophylaxis in High-Risk Patients Reports on nosocomial outbreaks of IPA have linked cases to hospital construction, the absence of appropriate barriers between patients and the environment, and the presence of fungal spores in room air samples. Specialized air-handling systems such as high-efficiency particulate air (HEPA) filtration with or without laminar airflow ventilation have proven to be effective at excluding *Aspergillus* spores.[2,5–7] However, HEPA filters have not been shown to prevent *Aspergillus* infections during building renovation and may not prevent outbreaks of these infections related to building demolition or renovation. A meta-analysis of 16 controlled trials that evaluated the effect of HEPA filtration on neutropenic patients with hematologic malignancies or HSCT found that the placement of patients in protective environments appeared to be beneficial in preventing IFIs, but the data seemed insufficient to support firm conclusions. The Centers for Disease Control and Prevention guidelines for preventing opportunistic IMIs in allogeneic HSCT recipients recommend the use of HEPA filters in patient rooms (http://www.cdc.gov/hicpac/2007ip/2007ip_part4.html). However, highly immunocompromised stem cell transplant recipients are commonly managed as outpatients, where engineering standards of the inpatient protected environment are not feasible. More recently, hospital water systems have been implicated as potential sources of high-level spore bursts of pathogenic fungi. During bathroom activities such as showering and toilet flushing, patients may create aerosolized mists of fungal spores that increase the risk of IPA. In addition, researchers reported an association between molds (*Aspergillus* and *Fusarium* spp.) cultured on hospital sinks and water sources and IMIs in patients with leukemia.[5–7] As a result, some have recommended cleaning of patient showers and bathroom areas with a phenolic cleaning solution prior to use by severely immunocompromised patients. Although these preliminary data are intriguing, establishing a causal link between nosocomial exposure to *Aspergillus* spores and subsequent development of IA remains difficult and requires the demonstration of genetic relatedness of environmental *Aspergillus* strains and clinical isolates. In fact, one of the largest molecular epidemiological studies of IA suggested that any *Aspergillus* strain could be pathogenic in the appropriate host background and that isolates causing invasive disease are not necessarily nosocomially derived.[5]

The new oral, extended-spectrum triazoles such as voriconazole and posaconazole have a satisfactory pharmacokinetic profile and documented efficacy in the treatment of infections, which may make them suitable for prophylaxis in HSCT recipients and neutropenic patients. Posaconazole has been endorsed by several guidelines as the prophylactic azole of choice. Recently, antifungal prophylaxis with the echinocandin micafungin in HSCT recipients was shown to reduce the incidence of IA[5–7]; however, the fact that echinocandins are parenteral drugs limits use in extended antifungal prophylaxis during the postengraftment period, when IA is most likely to occur.

Secondary Prophylaxis Patients with a history of IA are at high risk of reactivation of the infection if they undergo further intensive chemotherapy or HSCT with relapse rates up to 30% to 50%. Patients receiving prophylaxis have fewer relapses than do those who do not.[5–7] In an open-label noncomparative study in 45 high-risk HSCT recipients with a previous history of invasive fungal infection (mostly IA), secondary voriconazole prophylaxis resulted in 6.7% incidence of relapse rate of IFI, which is considered lower than the relapse rate reported in historical control studies. Thus, in the absence of comparative clinical trials, triazoles such as voriconazole seem to be the most appropriate agents for secondary prophylaxis.

PULMONARY CANDIDIASIS

Candida, a commensal fungus of mucosal surfaces, is the predominant fungal pathogen in humans. The spectrum of *Candida*-induced illnesses is broad, ranging from mild, chronic mucocutaneous infections to life-threatening acute invasive infections involving potentially any organ.[15] Pulmonary candidiasis is an infrequent form of invasive *Candida* infection that occurs in cases of aspiration pneumonia in immunocompromised patients who have heavy colonization of *Candida* spp. in the oral cavity (primary *Candida* pneumonia) or as part of disseminated candidiasis.[15–18]

Candida pneumonia is a challenging infection because of a lack of established, reliable clinical criteria for making the diagnosis. *Candida* is frequently an asymptomatic colonizer, particularly among debilitated individuals who are receiving antibacterials.[15–18] Thus, cultures of sputum and/or BAL that are positive for *Candida* in a patient with a pulmonary infiltrate does not establish the diagnosis of *Candida* pneumonia. An autopsy study of patients with cancer demonstrated that whereas many high-risk patients with pneumonia had *Candida* spp. cultured from sputum and BAL specimens, the specificity (57%–60%) and positive predictive value (29%–42%) of cultures of both types of specimens were low.[15] Similarly, quantitative cultures of transbronchial lung biopsy samples in critically ill, mechanically ventilated patients have been of no predictive value for *Candida* pneumonia.[16] Therefore, only histopathological demonstration of yeast cells or pseudohyphae in lung tissue is confirmatory of *Candida* pneumonia, which is often impossible in many patients. Of interest, in a large prospective autopsy study including 233 ICU patients there was no evidence of *Candida* pneumonia despite frequent isolation of *Candida* from the airways. However, *Candida* airway colonization resulted in impaired macrophage effector function in a rat model of *Pseudomonas pneumonia* and has been associated with increased risk for ventilator associated pneumonia by MDR bacteria and overall worse clinical outcome. However, it is still unclear whether *Candida* colonization is causally related to poor outcomes or whether it is a marker of underlying host immunosupression and there are no studies to justify antifungal treatment for this entity.

EPIDEMIOLOGY

The true incidence of *Candida* pneumonia is unknown, and most of the data on this infection are extrapolated from autopsy series. The fact that only 55 patients with unequivocal evidence of primary *Candida* pneumonia had been reported in the literature up to 1993 emphasizes the rarity of this infection.[16] In large autopsy surveys in patients with cancer reported a prevalence of primary *Candida* pneumonia ranging from 0.2% to 0.4%.[17–20] In another autopsy study that included a general population of patients, primary *Candida* pneumonia comprised 17% of all *Candida* infections, with an overall prevalence of 0.3%.[20] On the other hand, primary *Candida* pneumonia has been a relatively frequent finding in autopsy studies of high-risk patients, such as premature neonates (1%) and critically ill, mechanically ventilated patients (8%).[16]

In contrast with primary *Candida* pneumonia, secondary lung involvement by *Candida* spp. is a common finding at autopsy, occurring in 42% to 81% of cases of disseminated candidiasis.[17–20] However, the clinical significance of *Candida* pneumonia identified at autopsy, especially in cases of hematogenous dissemination, has

been questioned. For example, a study demonstrated that almost half of such *Candida* infections were incidental autopsy findings without clinical significance.[20]

Although large surveillance studies to capture the prevalence of *Candida* pneumonia are lacking, *Candida* was the third most common fungal pathogen after *Aspergillus* and *Cryptococcus* in a series of 140 patients with biopsy-proven invasive fungal pneumonia.[19] Interestingly, an increasing number of patients with primary *Candida* pneumonia were reported during the last years of the study. However, whether these latter cases represented a true increase in the incidence of *Candida* pneumonia or simply reflected a bias because of improved diagnosis is not certain.

MYCOLOGY

Similar to the other forms of invasive candidiasis, *Candida albicans* is the predominant species in patients with primary *Candida* pneumonia, accounting for 40% to 70% of all reported cases.[17–20] Until the early 1990s, *Candida tropicalis* and *Candida parapsilosis* were the most common non-*albicans Candida* spp. in patients with primary *Candida* pneumonia. However, the widespread use of broad-spectrum azole antifungals over the past decade has led to the emergence of less susceptible non-*albicans Candida* spp., such as *Candida glabrata* and *Candida krusei*, as important causes of *Candida* pneumonia. Hence, *C. glabrata* is currently considered the second most common *Candida* spp. in cases of primary *Candida* pneumonia in immunocompromised individuals.[17–20] In cases of secondary *Candida* pneumonia caused by hematogenous dissemination, the distribution of the species appears to follow that in bloodstream candidiasis, with *C. albicans* being the predominant species followed by *C. glabrata*, *C. tropicalis*, *C. krusei*, and *C. parapsilosis*.[17–20]

PATHOGENESIS

Most of the data on the pathogenesis of *Candida* pneumonia have been gained from analysis of histopathological findings at autopsy and studies of animal models of aspiration-induced pneumonia. *Candida* pneumonia develops only rarely in normal hosts, and most of the reported cases of this infection occurred in heavily colonized, immunocompromised individuals. A constellation of factors suggests that primary *Candida* pneumonia has a distinct pathophysiology when compared with other forms of invasive candidiasis and develops in a particular clinical scenario.[16,17] Specifically, the very high percentage of intrabronchial and intra-alveolar fungal involvement without significant vascular invasion, the frequent finding of aspirated material at autopsy, and the concomitant presence of candidal esophagitis at autopsy in most of the patients with primary *Candida* pneumonia demonstrate that the mechanism of entry of *Candida* is aspiration of oropharyngeal contents.[17] In addition, several studies indicated that the typical risk factors for invasive candidiasis, such as chemotherapy-induced neutropenia, prolonged corticosteroid use, immunosuppressive agent use, prior antibiotic use, hyperalimentation, diabetes mellitus, and the presence of vascular devices were not significantly associated with the development of *Candida* pneumonia.[16–20] In contrast, alteration of mental status (with or without subsequent aspiration) was the most important contributing factor in the majority of these patients. Thus, individuals prone to aspiration who have heavy oral colonization with *Candida* spp., such as those with head and neck cancer receiving chemoradiation, premature neonates, and critically ill, mechanically ventilated patients, comprise the population at highest risk for primary *Candida* pneumonia.

However, a distinct type of secondary *Candida* pneumonia caused by hematogenous dissemination has been described occasionally in profoundly neutropenic patients with cancer.[17] The histopathological characteristics of *Candida* lesions reflect pulmonary seeding from systemic bloodstream infections. Specifically, autopsy examination of these patients found evidence of pneumonia with scant inflammation and clumps of *Candida* yeast cells and pseudohyphae present in large portions of the involved lung sections in a pattern that closely resembled *Candida* growth in culture medium. Furthermore, in contrast with primary *Candida* pneumonia, destruction of lung parenchyma is subtle, whereas hemorrhage and angioinvasion by pseudohyphae are prominent. Although speculating that typical risk factors for disseminated candidiasis may apply in cases of secondary *Candida* pneumonia is reasonable, the majority of cases of clinically significant infection have been described in profoundly neutropenic patients with leukemia.[17–21]

Innate immunity is the dominant protective mechanism against all forms of invasive candidiasis, including primary *Candida* pneumonia.[3,22] Different *Candida* morphotypes are sensed by distinct pattern recognition receptors including TLRs and C-type lectins in a collaborative fashion. In contrast, adaptive immunity appears to be dispensable for disseminated candidiasis in humans with innate or acquired T-cell and/or B-cell immunodeficiency and in the relevant mouse models. However adaptive immunity has a critical role in mucosal defense against *Candida* and mediates protective effect of vaccination.[3]

Notably, in murine models of aspiration-induced *Candida* pneumonia, immunocompetent animals were remarkably resistant to intratracheal inoculation of *Candida* whereas they succumbed to infection after intravenous injection of a much lower inoculum.[22] These studies revealed that resident pulmonary macrophages account for much of host resistance against *Candida* infection, with a remarkable ability to engulf and kill yeast cells.[22] The role of resident versus recruited monocytes/macrophages in immunity against systemic *Candida* infection requires further clarification. Of interest, monocytes were recently shown to confer superior protection following systemic *Candida* reinfection via functional reprogramming that involves the dectin-1/Raf-1 noncanonical signaling pathway and results in enhanced cytokine production. Induction of this type of innate immune memory (termed "trained immunity") in monocytes/macrophages appears to involve epigenetic mechanisms. In addition, neutrophils are recruited to the lung within a few hours after initial challenge and have a predominant role in clearing *Candida* infection from the lungs within hours after inoculation. Neutropenic mice are highly susceptible to *Candida* pneumonia. In contrast, although the use of corticosteroids somewhat delays the clearance of *Candida* cells by phagocytic cells, it does not significantly increase the susceptibility of mice to systemic infection.[22] On the other hand, genetically engineered mice deficient in myeloperoxidase and/or other components of respiratory burst are extremely susceptible to *Candida* pneumonia, indicating the importance of mechanisms of oxidative killing of phagocytic cells.[3,19] Blocks in NET release in NADPH- and MPO-defective neutrophils has been associated with defective effector function. Although the role of humoral immunity has not been explored extensively, production of IgA and IgG1 has been shown to be important for protection against *Candida* pneumonia in mice. In contrast with cases of disseminated candidiasis in which Th1 cytokines appears to be critical for outcome, a balanced Th2 anti-*Candida* response at the late phase of infection associated with synthesis of IL-4 and IL-5 is required for optimal resolution of *Candida* pneumonia.[3,19] Of interest, mucosal immunity against *Candida* is predominantly regulated by Th17 cytokines and related antimicrobial peptide induction. Thus, it is plausible that Th17 responses in respiratory epithelia play a critical role in pathogenesis of *Candida* pneumonia. Future studies in genetically engineered mice should allow better characterization of important host determinants for pulmonary host defense against *Candida*.

CLINICAL MANIFESTATIONS

The clinical manifestations of primary *Candida* pneumonia are nonspecific and include persistent fever and tachypnea.[16,17] Chest

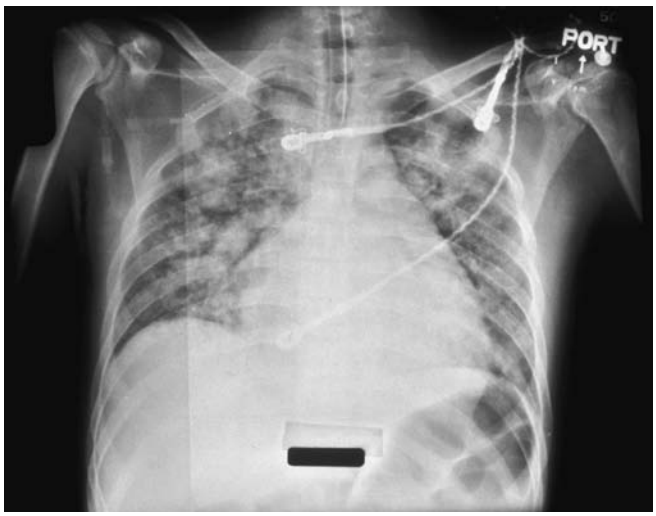

Figure 133-9 The radiographic features of *Candida* pneumonia in a patient with acute leukemia and severe neutropenia in whom disseminated candidiasis developed. Diffuse bilateral infiltrates along with the characteristic macronodular lesions are shown. *(Used with permission of Dr. G.P. Bodey.)*

pain, cough, and sputum production occur occasionally. Also, physical examination and routine laboratory studies are nonspecific. Chest radiographs may demonstrate a local or diffuse infiltrate involving one or both lungs, which is most often associated with infection acquired by the endobronchial route. A miliary-nodular pattern is most often associated with hematogenous seeding of the lung in cases of disseminated candidiasis and often appears late in the clinical course of the disease (Fig. 133-9).[16,17,20]

Extrapulmonary manifestations such as skin lesions, myositis, and endophthalmitis may be the first signs of *Candida* fungemia. Multiple organ involvement prior to or concurrent with pulmonary findings, particularly liver or kidney dysfunction and myocardial failure, may indicate hematogenous seeding that warrants investigation.

Lung transplant recipients occasionally develop an early (within 2 weeks after transplantation) and fulminant *Candida* pneumonia.[16] This association is probably caused by occult aspiration of *Candida* colonizing the donor lung followed by invasive pulmonary *Candida* infection after transplantation when immunosuppression is most intense.

Asthma related to an IgE-mediated allergy to *C. albicans* or allergic bronchopulmonary candidiasis can occur, although this is uncommon. Allergic bronchopulmonary candidiasis should be considered in patients with ABPA with serological and skin tests negative for *Aspergillus*. In addition, cases of chronic eosinophilic pneumonia with peripheral eosinophilia and selective sensitization to *C. albicans* occur rarely in the absence of asthma. Early diagnosis and corticosteroid-based therapy may prevent late fibrosis in those patients. Finally, fatal aspiration pneumonitis characterized by intense inflammatory response and lack of deep tissue invasion has been described in alcoholic patients.

■ DIAGNOSIS

Diagnosis of pulmonary candidiasis is challenging and depends on evidence of tissue invasion.[16–20] Isolation of yeast from sputum does not prove invasive yeast infection of the respiratory tract because of contamination by commensals from the oropharynx. *Candida* is present in the oropharynx of approximately 20% to 40% of all patients, especially those with chronic lung disease and those receiving prolonged antibacterial treatment.[16]

Bronchial washings and BAL specimens provide a more representative picture of the respiratory pathology compared to sputum. However, they can still be contaminated with mouth flora. At least in a selected group of patients with acute leukemia and severe neutropenia, if no other organisms are present and abundant *Candida* yeast cells and pseudohyphae are detected in the cytological examination of BAL specimens clinical suspicion of *Candida* pneumonia should be high.[16] On the other hand, cultures from lung specimens negative for *Candida* spp. have a high negative predictive value and virtually exclude *Candida* pneumonia.[16–18]

Histopathological demonstration of tissue invasion by *Candida* spp. in open lung biopsy or CT-guided fine-needle aspiration of peripheral nodular lesions is definitive, although such biopsies are difficult to perform in pancytopenic patients with pneumonia and are prone to sampling error. Transbronchial biopsy revealing tissue invasion by *Candida* spp. is also diagnostic.

Isolation of *Candida* from the blood may be helpful in the diagnosis of disseminated candidiasis; however, the organism may not be isolated even from multiple blood culture specimens in up to 40% of patients with widespread infection demonstrated at autopsy.[16–20] The use of lysis centrifugation, the BacT-Alert system that monitors CO_2 production, and the high-volume BACTEC system with infrared detection has improved the yield of *Candida*-positive blood cultures. A variety of methodologies have been developed to detect circulating *Candida* antigens, nucleic acids, and metabolites. Among these non–culture-based diagnostic methods PCR and β-D-glucan assays in serum hold most promise for adoption in routine clinical microbiology practice.[15] Of interest, in a recent prospective study of invasive candidiasis both PCR and serum β-D-glucan assays had higher sensitivity than blood cultures among patients with deep-seated candidiasis (88% and 62% vs. 17%, respectively); the combination of both the PCR and β-D-glucan assays resulted in 98% sensitivity. In addition, β-D-glucan levels seem to be a prognostic marker for treatment response in invasive candidiasis.

In cases of disseminated candidiasis, characteristic eye lesions suggestive of *Candida* infection may develop[15]; hence, a careful ophthalmological examination should be performed when this infection is suspected. In addition, typical maculopapular or nodular skin lesions, have been described in up to 10% of patients with hematogenous candidiasis.[15] Some of these patients also have associated myositis, particularly in cases of *C. tropicalis* infection. *Candida* spp. can be identified in the dermis and cultured from about half of all biopsy samples. Finally, CT scans of the abdomen may suggest hepatosplenic candidiasis in compromised hosts with an unrevealing microbiological evaluation.

■ TREATMENT

An unknown number of patients with primary *Candida* pneumonia may have had a response to empirical antifungal therapy but have gone unrecognized because of the difficulty in establishing the diagnosis of this infection. Primary *Candida* pneumonia is considered a life-threatening infection, with mortality rates approaching 70% in severely immunocompromised patients.[16–20] Therefore, rapid clinical diagnosis and prompt initiation of systemic antifungal therapy are important upon suspicion of the infection in the appropriate setting.

Given the rarity of primary *Candida* pneumonia, there are no controlled studies of the treatment of it. Historically, most patients with primary *Candida* pneumonia have received AMB-D (0.7–1.0 mg/kg/d) for a minimum of 2 weeks after all signs and symptoms of infection disappeared and until bone marrow recovery in those with neutropenia.[15–20] In cases of secondary *Candida* pneumonia associated with hematogenously disseminated infection, therapy directed at disseminated candidiasis rather than at *Candida*

pneumonia is indicated.[15] Over the past two decades, several antifungal agents, including fluconazole and the newer triazoles (especially voriconazole), lipid formulations of AMB, and the echinocandins, have become available for the treatment of invasive candidiasis, showing comparable efficacy and significantly less toxicity when compared with AMB-D in several prospective randomized trials.[15]

Although lipid formulations of AMB are less nephrotoxic, there is no convincing evidence that they are more effective than AMB-D. Because most patients with candidiasis do not require prolonged therapy, use of these more expensive preparations is usually not justified.

The introduction of the echinocandins has been a breakthrough in the treatment of invasive candidiasis.[15] All three available echinocandins, including caspofungin, micafungin, and anidulafungin, have shown comparable, broad-spectrum fungicidal activity against *Candida* spp., including azole-resistant non-*albicans Candida* spp.[15] In fact, because of their potency, minimal toxicity, and superior activity when compared to AMB-D and fluconazole in randomized controlled studies in patients with candidemia, the echinocandins have become the drug of choice for candidemia/candidiasis in seriously ill and unstable patients.

The accumulating experience with the treatment of other invasive pulmonary mycoses with echinocandins holds promise for the use of these agents in the treatment of *Candida* pneumonia. However, because of the rarity of *Candida* pneumonia a definite treatment of choice for this entity has not been endorsed in recently published guidelines on treatment of *Candida* infections.[15] Thus, with all of the limitations of the aforementioned studies, and given the fact that fluconazole has been used extensively for prophylaxis in many institutions, initiation of therapy for *Candida* pneumonia with an echinocandin with subsequent switch to an azole may be a reasonable approach in such cases.[15] Also, using higher doses of fluconazole (800 mg/d), at least initially, may be appropriate in neutropenic patients.

PULMONARY MUCORMYCOSIS (FORMERLY ZYGOMYCOSIS)

Mucormycosis (formerly Zygomycosis) has recently emerged as an important opportunistic mycosis in severely immunocompromised patients with hematological malignancies and recipients of stem cell or organ transplantation.[23,24] Zygomycosis, the previous terminology for infections caused by fungi of the order Mucorales, is no longer appropriate due to a recent taxonomic reclassification that abolished Zygomycetes as a class. Necrotizing pneumonia is a predominant feature of mucormycosis, especially in severely immunocompromised patients.[23,24]

Fungi of the order *Mucorales* are distributed in six families, each of which can cause serious invasive infections (Table 133-7). Species of the family *Mucoraceae* are isolated more frequently from patients with mucormycosis than are species of any other family.[23,24] Among the *Mucoraceae*, *Rhizopus oryzae* (*Rhizopus arrhizus*) causes the vast majority (>70%) of *Mucorales* infections. Other less frequently encountered species of the *Mucoraceae* family include *Rhizopus microsporus*, *Lichtheimia* (formerly known as *Absidia* species), *Apophysomyces elegans*, *Mucor* species, and *Rhizomucor pusillus*. *Cunninghamella bertholletiae* is an increasingly reported cause of mucormycosis and appears to be the most virulent *Zygomycetes* species in humans.[24] All of these organisms are indistinguishable by histopathology. Various terms have been used in the past to indicate infections caused by *Mucorales*, such as mucormycosis, phycomycosis, and simply mucor. However, the more accurate term mucormycosis is used throughout this chapter to indicate opportunistic mold infections in humans caused by *Mucorales*, because this is the taxonomically correct description.

TABLE 133-7 Classification of Fungi in the Class Zygomycetes, Order *Mucorales*[a]

1. MUCORACEAE
   - a. *Absidia (Lichtheimiaceae)*

DISEASE MANIFESTATIONS/EPIDEMIOLOGY/ RISK FACTORS

The *Mucorales* are saprophytic fungi ubiquitous in soil and decaying organic material. *Mucorales* species that are pathogenic in humans grow rapidly on any carbohydrate substrate and produce abundant sporangiospores.[24] Spores produced by the fungi become airborne, and inhalation of *Mucorales* conidia into the respiratory tract occurs daily. Even though these fungi grow in many ecological niches, the rarity of mucormycosis reflects the low virulence potential of *Mucorales* in immunocompetent hosts. For reasons that remain unclear, the incidence of *Mucorales* infections, particularly of *Cunninghamella, Absidia,* and *Apophysomyces* spp., is higher in male

patients (65%) than in female patients. The most common forms of mucormycosis based on anatomic localization include (a) rhinocerebral infection (39%), (b) pneumonia (24%), (c) disseminated infection (23%), (d) cutaneous/soft tissue infection (19%), (e) gastrointestinal infection (7%), and (f) uncommon presentations (7%). When compared to other opportunistic molds, *Mucorales* tend to infect a broad, more heterogeneous population of human hosts, including immunocompetent individuals. Specifically, *Mucorales* cause acute angioinvasive infections in patients with a variety of immunosuppressive conditions, including poorly controlled diabetes mellitus (especially with diabetic ketoacidosis), neutropenia, malignancies, burns, chronic renal failure, with iron overload; recipients of transplants, and patients with renal failure receiving the iron (and aluminum)-chelating agent deferoxamine.[24] Although rare, there have been a number of reports of pulmonary mucormycosis in patients with AIDS. It is important to emphasize that dissemination may occur from any of the primary sites of *Mucorales* infection, mainly in patients with profound immunosuppression.

Of note, particular host immune defects predispose to different forms of mucormycosis. For example, patients with diabetic ketoacidosis are prone to the development of the rhinocerebral form of mucormycosis but less often suffer from pulmonary or disseminated infection. In contrast, pulmonary mucormycosis typically affects severely immunocompromised individuals, including patients with high-risk hematological malignancies and recipients of hematopoietic stem cell and organ transplants. The predominance of pulmonary infection in those patients may be a result of chemotherapy-related defects in innate pulmonary host defenses associated with neutropenia and/or chemotherapy-induced mucociliary dysfunction. Prolonged and severe neutropenia is the sole identifying risk factor in approximately 15% of all reported mucormycosis cases. Nonetheless, like aspergillosis, mucormycosis is increasingly reported as a late (1–6 months), or very late (>6 months) community-acquired infection in nonneutropenic, HSCT recipients postengraftment, especially in the setting of multiple, overlapping, and cumulative mechanisms of immunosuppression during GvHD treatment. In these patients, severe immunodeficiency due to high-dose glucocorticosteroid therapy and/or other immunosuppressive therapies frequently coexists with other comorbidities that are interrelated and difficult to quantify, such as hyperglycemia, metabolic acidosis, renal failure, iron overload, malnutrition, advanced age, and CMV infection.

A significant increase in the rates of mucormycosis has been observed recently among severely immunocompromised individuals classically at risk for other opportunistic mold infections, such as patients with acute leukemia, and transplant recipients.[23–25] An autopsy study in hematological malignancy patients from a single cancer institution with high background rates of mucormycosis reported a significant threefold increase in prevalence of autopsy-proven mucormycosis cases from 0.9% to 3% during the study period (1989–2003). Importantly, most of these infections were diagnosed postmortem. Similarly, there was a fourfold increase in the overall incidence of mucormycosis during a period of active surveillance at 25 US transplant centers from 2001 to 2006 whereas the incidence of other opportunistic molds remained constant. In the aforementioned study the overall cumulative annual incidence (CI) of mucormycosis was the highest (0.29%) in HSCT recipients, particularly those receiving transplant from an HLA-unrelated donor (0.85%). Among solid-organ transplant recipients, the overall 12-month CI of mucormycosis was 0.07%, with lung transplants and liver transplants having the highest incidence of mucormycosis, at 0.18% and 0.16%, respectively. Of note, there was a seasonal variation in incidence of mucormycosis with declining rates among the groups transplanted in the first 4 months of each year. Recent national studies in Europe that used administrative data from hospital records to capture cases of mucormycosis, also demonstrated a significant increase in incidence of mucormycosis within a 10-year period.[23–25]

Of concern, a growing proportion of pulmonary mucormycosis cases manifest as breakthrough infections in patients receiving antifungal agents with activity against aspergillosis but not mucormycosis (i.e., voriconazole, echinocandins). Case series in high-risk leukemia and allogeneic HSCT patients suggest that mucormycosis should be considered whenever fungal sinusitis develops while on *Aspergillus*-active antifungal prophylaxis (i.e., voriconazole), especially in patients with prolonged immunosuppression, underlying diabetes or malnutrition, and in the setting of negative *Aspergillus* galactomannan assay and "therapeutic" voriconazole serum levels (e.g., voriconazole levels >2 ng/mL). Animal studies have demonstrated increased virulence of *Mucorales* spp. following voriconazole pre-exposure; previous voriconazole use has been independently associated with the development of mucormycosis in leukemia and transplant patients. Other studies have reported an increase in mucormycosis cases prior to the introduction of voriconazole and a recent randomized trial on voriconazole prophylaxis in low-moderate risk allogenic HSCT recipients with favorable prognostic features did not find a higher incidence of mucormycosis. Hence, it is difficult to establish a causal relationship between voriconazole use and development of mucormycosis as this association may reflect a changing patient risk profile, including hosts at higher risk or increased time at risk, with evolving transplant practices and immunosuppressive strategies that ultimately result in improved posttransplant survival. Very late-onset mucormycosis, occurring 2 years or more after transplantation, has been reported in a significant proportion of HSCT (13.8%) and SOT (33.3%) recipients in a multicenter prospective surveillance study.

There are inherent problems with epidemiological studies on mucormycosis related to challenges in establishing a diagnosis and capturing shifts in prevalence of classic or unknown risk factors of infection in high-risk populations. Furthermore, surveillance strategies to capture the true incidence of mucormycosis are imperfect given that the diagnosis is difficult to achieve antemortem. Instead of registries that create databases based on hospital coding diagnoses, development of active surveillance programs is needed with long-term follow-up in selected high-risk patient groups such as transplant recipients.

MYCOLOGY

Mucorales are molds characterized by growth of hyphae in the environment and in tissue. They grow rapidly – within 2 to 5 days on most culture media – as fluffy gray or brownish colonies, with many of the species demonstrating aggressive vertical growth toward the lid of the Petri dish; these species are referred to as "lid lifters."[24] As the *Mucorales* colony matures, the mycelium may darken and exhibit a black pepper-like effect as large numbers of sporangia are formed. Cycloheximide inhibits the growth of these fungi, and media that contain this compound, such as Mycosel and mycobiotic agar, should not be used. Clinical tissue samples potentially infected with the *Mucorales* should be chopped, not ground, for inoculation into microbiologic cultures. All pathologic species grow well at 37°C.[24]

Microscopic examination for the presence and location of rhizoids and apophyses and to determine the morphology of the columellae differentiates the genera. Isolating and speciating the organism is important for selection of treatment. However, morphological identification of *Mucorales* species is often imprecise.

PATHOGENESIS

Understanding molecular mechanisms of host-fungal interplay is critical in order to develop better therapeutic strategies and

improve mucormycosis outcome. The pathogenesis of pulmonary mucormycosis begins with the inhalation of conidia into the respiratory tract, where infection may remain localized in the lung or disseminate hematogenously. In healthy individuals mononuclear and polymorphonuclear phagocytes efficiently eliminate fungal spores and hyphae by oxidative and nonoxidative killing mechanisms.[3,24] Quantitative (i.e., neutropenia) or qualitative (i.e., associated with glucocorticoids, hyperglycemia and/or acidosis) defects in phagocytic cell activity permit unrestricted growth of the hyphal form and invasive infection. In particular, both hyperglycemia and acidosis are known to impair chemotaxis and the killing activity of phagocytic cells against *Mucorales* by impairing oxidative and nonoxidative mechanisms.[24] Likewise, corticosteroids impair migration, ingestion, and phagolysosome fusion in human macrophages.[3] However, receipt of corticosteroids per se is not the predominant risk factor in the absence of underlying severe immunosuppression. The molecular mechanisms that account for attenuated phagocytic function in patients with hyperglycemia, ketoacidosis, or steroids are only partially characterized. For example, as opposite to *Aspergillus* spp. *Mucorales* spp. rarely infect GGD patients and direct genetic evidence for a role of NADPH-dependent ROS production in ex vivo killing of *Mucorales* by phagocytes is missing. Thus, comparative genetic studies on the mechanisms of phagocytosis, phagosome maturation, and killing of *Aspergillus* vs. Mucorales by phagocytes are required.

Of interest, when compared to *Aspergillus*, *Mucorales* hyphae display inherent resistance to killing by both *Drosophila* and human phagocytes, which might partially account for the increased virulence of these fungi and the ability to infect a broad range of hosts. Whether this resistance to killing by phagocytes is related to the release of virulence factors or is result of a different cell wall composition is currently unknown. Of interest, a recent study found that sporangiospore size dimorphism is linked to virulence of *Mucor* spp. Investigators discovered that asexual reproduction of *Mucor circinelloides* results in formation of larger sporangiospores and increased virulence in vivo when compared to isolates containing a (+) sex allele. In addition, larger sporangiospores germinated inside and lysed a murine macrophages cell line within few hours of uptake, whereas smaller sporangiospores exhibited delayed intracellular growth. Of interest, there was a correlation between spores size and virulence in clinical isolates of *Mucor*. Importantly, when compared to *Aspergillus*, *Mucorales* infection induces macrophage cell death via unknown mechanisms that could be related to the release of virulence factors.

Little is known about the innate sensing of *Mucorales* spp. by immune and/or nonimmune (e.g., endothelial) cells and the role of adaptive immunity in patients with pulmonary mucormycosis. Of interest, similar to *Aspergillus*, β-glucan exposure during germinating growth of *Rhizopus* triggers dectin-1 signaling in human dendritic cells and results in robust induction of the IL-23/Th17 responses. Until recently, the role of adaptive immunity in mucormycosis was underappreciated because acquired T-cell deficiency is not associated with increased susceptibility to infection by the *Mucorales*. However, investigators recently indicated the presence of *Mucorales*-specific T cells in patients and healthy individuals, which enhanced effector function of professional phagocytes and could be harnessed for adoptive immunotherapy strategies.

Iron metabolism has a central role in pathogenesis of mucormycosis.[3,24] Thus, patients with iron overload states, including those undergoing chelation therapy with deferoxamine, are uniquely predisposed to mucormycosis. Deferoxamine abolishes the fungistatic effect of serum and increases in vitro fungal growth by acting as a siderophore for *Mucorales spp*.[24] The key role of iron utilization in pathogenesis of mucormycosis is further illustrated by the fact that conditional inactivation of *R. oryzae* high-affinity iron premease gene, FTR1, renders the fungus nonpathogenic in mice.[24] Similarly, the increased susceptibility to mucormycosis of patients with acidosis, including diabetic acidosis, is attributed to increased availability of serum iron partially due to diminished affinity of transferrin for free iron at a lower pH (<7.4). Unlike deferoxamine, the other iron chelators, such as deferiprone and deferasirox that lack xenosiderophore activity for *Rhizopus*, induce an iron-starvation effect to the fungus and have shown to be protective in animal models of mucormycosis and in anecdotal reports of human infection.

Figure 133-10 Pulmonary mucormycosis in a 63-year-old diabetic kidney transplant recipient with a rapidly expanding pulmonary mass. *(Used with permission of Jay A. Fishman, Massachusetts General Hospital.)*

A hallmark of mucormycosis is extensive angioinvasion with resultant vessel thrombosis and tissue necrosis **(Fig. 133-10)**. Interaction of *Mucorales* spores with endothelial cells appears to play a critical role in angioinvasion. Ibrahim et al. identified glucose-regulated protein-78 (GRP78) as a novel host receptor that selectively and specifically interacts with *Rhizopus* mediating invasion and damage of human endothelial cells by the fungus.[24] Of interest, elevated glucose and iron levels upregulate GRP78 expression and promote endothelial cell invasion and damage by *R. oryzae* in a receptor-dependent manner.

CLINICAL MANIFESTATIONS

Although concomitant sinus infection is suggestive of pulmonary mucormycosis, the clinical manifestations of pulmonary infection are almost indistinguishable from those caused by the more common opportunistic mold *Aspergillus*.[23–25] Therefore, timely diagnosis is critical in the outcome of this infection because first-line

antifungal agents typically used for aspergillosis such as voriconazole, lack activity against *Mucorales*.

Clinical symptoms of pulmonary mucormycosis are subtle and nonspecific even at late stages of infection, especially in neutropenic patients and those receiving immunosuppressive therapies that dampen immune responses. Pulmonary mucormycosis frequently manifests with persistent fever on broad-spectrum antibiotics, nonproductive cough, progressive dyspnea, and pleuritic chest pain.[23–25] Infection has a propensity to traverse tissue planes in the lung, including the bronchi, diaphragm, chest wall, and pleura. Hyphal invasion of blood vessels results in necrosis of the surrounding parenchyma, ultimately leading to cavitation or potentially fatal hemoptysis. In patients with hematological malignancies, clues for distinguishing pulmonary mucormycosis from IPA may include the presence of necrotic lesions in palate, severe sinusitis, rhino-orbital extension, prophylaxis with antifungals that possess activity against aspergillosis but not mucormycosis (i.e., voriconazole and the echinocandins), and possibly the repeated absence of detectable *Aspergillus* galactomannan antigen and/or b-glucan in the serum.[24,25] Unfortunately, the frequent coexistence of bacterial or mixed fungal pneumonia (up to 22% in a single-institution observational study) in high-risk hematological malignancy patients can further complicate early diagnosis and management of pulmonary mucormycosis. Pulmonary mucormycosis rapidly spreads to the contralateral lung and distal organs if not promptly treated. While patients with pulmonary mucormycosis usually die from disseminated disease before respiratory failure occurs, dissemination is rarely detected antemortem. The overall mortality rate of pulmonary mucormycosis ranges from 50% to 70%, but exceeds 90% with extrathoracic dissemination.[23–25]

A multitude of patterns may be present in a regular chest radiograph of patients with pulmonary mucormycosis, including lobar consolidation, nonspecific infiltrates, cavities, masses, and nodules. Similar to IPA, high-resolution chest CT is the best method of determining the extent of pulmonary mucormycosis and typically demonstrates evidence of the infection earlier than standard chest radiographs. While nodular opacities without an air bronchogram indistinguishable from those of aspergillosis are the most common findings on CT scan, the presence of multiple nodules (≥10) and, to a lesser degree, pleural effusions may favor the diagnosis of pulmonary mucormycosis.[24] Halo and air crescent signs are encountered less frequently in leukemic patients with pulmonary mucormycosis compared to pulmonary aspergillosis. However, the presence of air crescent sign in centrally located lesions reflects an increased risk of pulmonary artery erosion and massive hemoptysis. One case series suggested that a reverse-halo sign, a focal round area of ground-glass attenuation surrounded by a ring of consolidation, may be a common early radiographic finding in patients with invasive pulmonary mucormycosis versus aspergillosis.[24,25]

Atypical presentations of pulmonary mucormycosis include chronic infection with constitutional symptoms that last for several months in relatively immunocompetent hosts, multiple mycotic pulmonary artery aneurysms and pseudoaneurysms, bronchial obstruction, asymptomatic solitary nodules, or even normal chest radiographs. Of interest, patients with diabetes mellitus have an apparent predilection for the development of endobronchial lesions, accounting for more than 80% of reported cases in the literature. Furthermore, pulmonary mucormycosis tends to present with a less fulminant, subacute clinical course in these patients. However, endobronchial lesions may occasionally lead to obstruction of major airways or erosion of major pulmonary blood vessels and fatal hemoptysis. In lung transplant recipients, ulcerative tracheobronchitis at the bronchial anastomotic site is rarely caused by *Mucorales* when compared to *Aspergillus*; however, changes in immunosuppressive and antifungal prophylaxis practices could lead to the emergence of this infection in the future.[25]

Similar to *Aspergillus* spp., *Mucorales* spp. rarely produce an asymptomatic mycetoma within a pre-existing lung cavity. Allergic *Rhizomucor* sinusitis has been also reported in immunocompetent individuals. In addition, hypersensitivity pneumonitis caused by *Rhizopus* has been described in farm workers as well as in Scandinavian sawmill workers (wood trimmer's disease).[24]

DIAGNOSIS

Little improvement has been made over the past few decades in the diagnosis of mucormycosis, which still relies on histopathology and traditional culture methods. Timely diagnosis of mucormycosis requires a high index of suspicion and largely depends on histopathological demonstration of tissue invasion by the characteristic hyphae or by isolation of *Mucorales* spp. in cultures of sterile tissue, which necessitates implementation of an invasive procedure. Tissue swabs, sputum, or bronchial alveolar lavage fluid cultures are usually nondiagnostic, but provide an important indication of disease and allow for the establishment of probable infection in immunocompromised patients.[25] Blood cultures rarely, if ever, grow *Mucorales* species despite the angioinvasive nature of these pathogens.

Mucorales stain poorly with the PAS and Gram stains but stain very well with the Grocott–Gomori methenamine-silver. Treatment with fluorescent stains such as **calcofluor-white** or blankofluor may aid in detection of hyphal elements and improve the discrimination between septated and aseptated molds. In tissue specimens *Mucorales* appear as broad (10–20 μm in diameter) nonseptate hyphae with branches occurring at right angles (Fig. 133-11). Differentiation of *Aspergillus*, *Fusarium*, *Scedosporium* spp., or other hyalohyphomycetes from *Mucorales* hyphae in tissue involves visualizing thinner, more regularly shaped fungal elements with more frequent acute angle branching and the presence of septae in the former group.[24]

In the majority of patients with pulmonary mucormycosis, establishment of a definite diagnosis with biopsy is hampered by the presence of comorbidities, such as thrombocytopenia. Furthermore, routine laboratory cultures, even if performed from tissue specimens with abundant *Mucorales* hyphal growth, have a yield of less

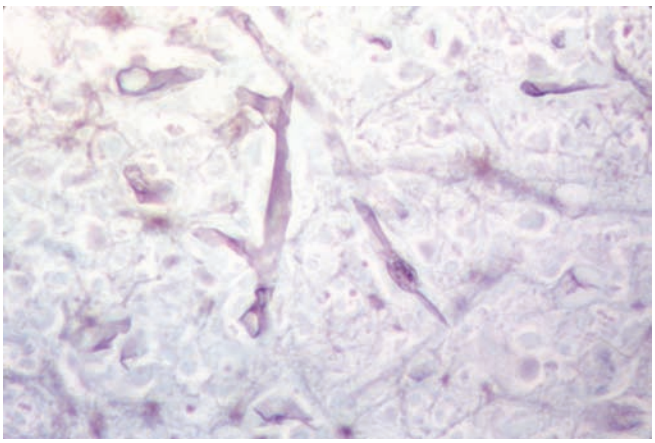

Figure 133-11 Histopathological features of *Zygomycetes* hyphae in a profoundly neutropenic patient with leukemia in whom pulmonary mucormycosis developed. Of note is the characteristic broad nonseptate or rarely septate hyphae with branches at right angles. H&E stain, ×400. *(Used with permission of Dr. G.P. Bodey.)*

than 50%. Recovery from tissue can be improved by mincing (not homogenizing) tissue and use of culture techniques that simulate in vivo growth, including incubation at 35° to 37°C in semi-anaerobic conditions.[24,25]

The importance of early differentiation of pulmonary mucormycosis from other IMIs has generated considerable interest in the development of surrogate diagnostic tests such as detection of specific antigens or nucleic acid by PCR. Unfortunately, serology-based diagnostic assays such as *Aspergillus* galactomannan and b-glucan are not useful for detection of mucormycosis. Other molecular diagnostic techniques using PCR assays in serum samples or paraffin wax embedded tissue or in situ hybridization techniques are promising, but remain investigational. In a prospective study of CT-guided percutaneous lung biopsy samples from high-risk patients with suspected fungal pneumonia, investigators demonstrated that early diagnosis and differentiation of pulmonary mucormycosis from IPA could be improved using a three-step analysis approach of biopsy specimens of lung lesions that included: Calcofluor-white staining to rapidly distinguish septated versus aseptae hyphae, *Aspergillus* galactomannan and PCR testing for rapid identification, and PCR testing of DNA in selected biopsy specimens where aseptate hyphae were observed or *Aspergillus* markers were negative.[24] These promising results require validation in a wider range of patients before PCR becomes a standardized adjunctive diagnostic test for mucormycosis.

TREATMENT

Successful treatment of pulmonary mucormycosis relies on timely diagnosis, reversal of underlying predisposing factors, early and broad surgical debridement of infected tissue (when possible), and rapid administration of effective antifungal therapy in the context of a multidisciplinary approach.[25] Cooperation among the primary care physicians, infectious disease consultants, surgeons, microbiologists, and pathologists is essential in the early stages of infection to avoid unnecessary diagnostic and treatment delays that increase patient mortality. For example, patient outcomes can be improved if initial treatment decisions are based on frozen tissues biopsy rather than from paraffin embedded tissue samples. Similarly, delays in the administration of effective systemic antifungal therapy within the first few days of diagnosis increase the probability of patient death due to progressive and/or disseminated infection. In addition, rapid correction of underlying conditions such hyperglycemia and/or diabetic ketoacidosis, tapering of corticosteroids, and other immunosuppressive drugs is critical to outcome. Notably, there have been rare cases of pulmonary mucormycosis with spontaneous regression of infection after correction of diabetic ketoacidosis.[24]

Antifungal treatment

With the exception of the recently completed DEFEAT *Mucor* study, there are no other prospective studies for the treatment of pulmonary mucormycosis because of the rarity and heterogeneity of the infection. Most evidence on the activity of existing antifungal agents comes from small case series, anecdotal case reports, and animal studies. Based on consensus guidelines,[23] the liposomal formulations of AMB have become the mainstay for treating mucormycosis in view of their favorable toxicity profile and comparable clinical outcomes with those historically reported for conventional AMB-based therapy. Thus, in the largest reported case series of mucormycosis including 24 patients who received a lipid complex of AMB for refractory disease or intolerance of conventional AMB, the overall response rate was 71%, without significant toxic effects even in patients with pre-existing renal disease. Animal models of pulmonary mucormycosis suggest a possible benefit for early administration of higher dosages of lipid AMB, and a phase II clinical study of 10 mg/kg/d liposomal AMB in mucormycosis will address further this question (http://clinicaltrials.gov/ct2/show/NCT00467883).[24]

Alternative routes of administration of amphotericin B as an adjunct to systemic therapy have been reported in pulmonary mucormycosis, although the efficacy of this approach is difficult to discern. For example, case reports describe the successful treatment of cancer patient with pulmonary mucormycosis using systemic therapy and ABLC aerosolized with a Respigard II nebulizer, direct instillation of amphotericin B within pulmonary cavities or into the pleural space.

Posaconazole (800 mg daily in four divided doses), an orally available broad-spectrum triazole, is the only drug of this class that appears to possess potent activity against *Mucorales*. In an open-label salvage trial, the overall success rate of posaconazole was 70% in 24 patients and was associated with minimal toxicity. Similarly, a retrospective review of posaconazole-based salvage therapy in 91 patients who had refractory mucormycosis indicated an overall success rate of 61% including a success rate of 65% in the group of patients with pulmonary mucormycosis.[24] Nonetheless, posaconazole exerts limited activity against *Rhizopus* spp. in neutropenic mouse models and cases of breakthrough mucormycosis in HSCT recipients while on posaconazole prophylaxis have been reported. Therefore, despite encouraging preliminary clinical data, the FDA has not approved posaconazole for primary or salvage therapy of mucormycosis, indicating the need for further studies.

Treatment with oral posaconazole has important pharmacokinetic limitations related to drug interactions and the poor absorption of the drug especially in patients with mucositis and those with poor dietary intake, while steady-state plasma concentrations of posaconazole are not reached until around 1 week of therapy.[25] Drug interactions can be problematic especially in patients receiving drugs that accelerate CYP P450 metabolism (i.e., rifampicin), or acid suppression therapy particularly with proton pump inhibitors. Therefore, it is preferable that patients with mucormycosis should initially receive several days of a lipid AMB formulation before started on posaconazole therapy and plasma drug level monitoring may be necessary in selected patients. Patients with persistently low or undetectable serum drug levels, poor oral intake or GI dysfunction (severe nausea, diarrhea) often must be transitioned back to intravenous liposomal AMB even in the absence of obvious disease if they are receiving additional immunosuppressive therapy. Overall, posaconazole seems to be a favorable option for less severely immunocompromised patients who need to be on continuous long-term antifungal therapy given the high risk for relapse of mucormycosis. The development of new (IV and oral) formulations of posaconazole with improved pharmacokinetics is currently undergoing phase II/III trial testing (www.clinicaltrials.gov/ct2/show/NCT01075984).

Echinocandins lack activity against *Mucorales* in vitro, and clinical experience with caspofungin in the treatment of mucormycosis is extremely limited. Nevertheless, in case reports and a study with a model of disseminated mucormycosis in diabetic mice, echinocandins appear to have some role, especially in combination with a polyene, in serious cases of mucormycosis.[25] A combination ABLC-caspofungin treatment regimen was associated with improved therapeutic success (100% vs. 45%; $P = 0.02$) in 41 diabetic patients with biopsy-proven, mostly rhino-orbital cerebral mucormycosis.[25] Further studies are required to compare this combination regimen to amphotericin B-based monotherapy for mucormycosis.

The duration of treatment required for mucormycosis should be highly individualized. Near normalization of radiographic imaging, negative biopsy specimens, and cultures from the affected site, and

recovery from immunosuppression are indicators that a patient is a candidate for stopping antifungal therapy.

Surgical treatment

Because mucormycosis is a highly angioinvasive infection with resulting extensive thrombosis and tissue necrosis, antifungal agents often display poor penetration at the site of infection. Therefore, even if the causative *Mucorales* strain is susceptible to the antifungal agent in vitro, the agent may be ineffective in vivo. Surgical debridement of infected lung tissue should be performed on an urgent basis. In patients with pulmonary mucormycosis, surgical treatment in conjunction with antifungal therapy has been shown to significantly improve survival when compared with antifungal therapy alone. Hence, a comprehensive review of cases of pulmonary mucormycosis showed that the mortality in patients who received antifungal agents alone was 55% versus 27% in patients who received antifungal agents and surgery.[25] Removal of as much of the infected or devitalized tissue as possible while the infection is localized has the greatest benefit. Lobectomy is often required, and pneumonectomy may be necessary for proximal or extensive involvement. Also, repeated procedures may be needed. The benefit of pulmonary resection diminishes as dissemination occurs.

Other adjunctive therapies

Small case series implicate that treatment with hyperbaric oxygen (HBO) may be a beneficial adjunct to standard therapy for mucormycosis, particularly in patients with diabetes mellitus who have rhinocerebral disease.[25] HBO has pleiotropic properties by promoting wound healing, phagocytic cell function, and oxidative killing mechanisms of *Mucorales* by AMB and also displays direct antifungal activity. However, data on treatment with HBO of pulmonary mucormycosis are scarce, and a role in this setting remains uncertain.

The role of adjunctive cytokine therapy for mucormycosis has not been extensively studied. Cytokines that activate phagocytic activity, such as IFN-γ and GM-CSF, increase the killing efficacy of phagocytic cells against *Mucorales* spp. in vitro. Case reports indicate a favorable outcome in selected patients with rhinocerebral mucormycosis who received IFN-γ and GM-CSF adjunct salvage treatment. In selected neutropenic patients, granulocyte transfusion may be a useful bridge until neutrophil recovery, although the clinical benefit remains unproven and serious adverse effects that resemble immune reconstitution inflammatory syndrome (IRIS), including pulmonary toxicity and accelerated cavitation/bleeding, have been reported in patients with opportunistic lung mycoses.[24,25] Importantly, granulocyte transfusions contain not only neutrophils but also substantial number of lymphocytes and HLA alloimmunization can be a major complication of granulocyte transfusions. Thus, the benefits and risks of granulocyte transfusions should be carefully assessed on an individual basis, particularly for patients who are candidates for HSCT. Adoptive T-cell–based immunotherapeutic strategies are feasible and could represent an attractive future strategy in the management of mucormycosis.

The central role of iron metabolism in the pathogenesis of mucormycosis supports the hypothesis of using iron chelators without xenosiderophore activity, such as deferiprone and deferasirox, as adjunctive antifungal therapy.[25] In contrast with deferoxamine, such iron chelators induce iron starvation in the fungus, thereby inhibiting growth in vitro in the presence of iron and improving survival in a diabetic ketoacidosis animal model of mucormycosis. Case reports imply that deferasirox with antifungals may be less effective in neutropenic patients than in diabetic ketoacidosis patients. Moreover, the bioavailability of oral deferasirox in immunocompromised patients with mucositis due to chemotherapy or GvHD of the gut is unknown. Importantly, a recently completed phase II, double-blind, randomized, placebo-controlled trial of adjunctive deferasirox therapy failed to demonstrate a benefit of the combination regimen in 20 patients with mucormycosis (DEFEAT MUCOR trial, NCT00419770).

EMERGING OPPORTUNISTIC MOLDS

Over the past decade, and with the ever-expanding spectrum of immunocompromised patients, we have witnessed the emergence of less common but medically important opportunistic fungal pathogens, including septate filamentous fungi such as hyalohyphomycetes (e.g., *Fusarium*, *Scedosporium*, and *Trichoderma* species), dematiaceous fungi (e.g., *Phaeohyphomycetes*), endemic dimorphic pathogens (e.g., *Penicillium marneffei*), and rare pathogenic yeasts (e.g., *Trichosporon* species).[26–29] The diagnosis of invasive fungal pneumonia caused by these uncommon filamentous fungi is challenging because of the similarity of the manifestations and histopathological features of these mycoses with those of IA. Given the fact that most of these infections have a poor outcome because of broad-spectrum resistance to conventional antifungal agents, timely diagnosis is critical for outcome. Therefore, pulmonary infections caused by hyalohyphomycetes, including *Fusarium* and *Scedosporium* species, are discussed below.

PULMONARY FUSARIOSIS

Fusarium spp. are ubiquitous filamentous fungi found in soil, water, and decaying material. Although *Fusarium* is a well-known plant pathogen, only a few of the 50 different species have been reported to be pathogenic in humans, including *Fusarium solani, Fusarium oxysporum, Fusarium moniliforme, Fusarium verticilloides, Fusarium dimerum*, and *Fusarium proliferatum.*[28] *Of these species, F. solani* is the most virulent, causing half of all cases of invasive fusariosis reported in humans. Since the description of the first case of disseminated fusariosis in a child with acute leukemia in 1973, invasive fusariosis has emerged in some tertiary care oncology centers as an important IMI in profoundly immunocompromised patients with hematological malignancy.[29]

There seems to be a distinct seasonal peak and geographic distribution of invasive fusariosis. The vast majority of cases have been reported in the United States during the rainy summer season, when the dispersion of fusarial conidia in the air is most pronounced.[29] More than 90% of human invasive fusariosis cases occur in neutropenic patients with hematological malignancies, especially those with acute leukemia. Another risk factor for invasive fusariosis is GvHD treated with high doses of corticosteroids during the postengraftment period in HSCT recipients.[28]

The skin and respiratory tract are the primary portals of entry for *Fusarium* infection. Inhalation of *Fusarium* conidia through the lung and paranasal sinuses by a severely immunocompromised host may lead to sinopulmonary infection characterized by angioinvasion, extensive tissue necrosis, and secondary dissemination. In addition, disruption of skin integrity because of local trauma or placement of a central venous catheter or in the setting of onychomycosis with associated cellulitis appears to be a relatively common portal of entry for disseminated *Fusarium* infection that involves the lung in immunocompromised hosts. The ability of *Fusarium* spp. to undergo adventitious sporulation with formation of microconidia in vivo facilitates dissemination and may account for the high rates of positive blood cultures and associated skin lesions in cases of fusariosis.[28] Neutrophils probably play the most critical role in the control of human *Fusarium* infections. Several studies have demonstrated that the prognosis for patients with fusariosis is associated with the prompt recovery of neutrophil counts. In fact, the mortality rate in patients with fusariosis in the setting of profound, prolonged

TABLE 133-8 Differentiating Features Among the Major Opportunistic Mold Infections of the Lung

Incidence	• *Aspergillus* causes the vast majority of cases of fungal pneumonia, followed by *Zygomycetes*
Predisposing factors	• *Zygomycetes* spp. are associated with the presence of diabetes mellitus, malnutrition, iron overload states, and voriconazole prophylaxis
Clinical features	• Skin lesions are more common in disseminated fusariosis (50–70%) than in disseminated IA (<10%) and disseminated mucormycosis (<10%) • Skin lesions in fusariosis are different from those in IA and mucormycosis (*Aspergillus and Zygomycetes* skin lesions are fewer, less widespread, have a larger diameter, and present with a black eschar with a thinner erythematous halo) • Fungemia is more common in fusariosis (60–70%) than in IA (<5%) and mucormycosis (virtually absent) • Fungemia also often occurs earlier in fusariosis than in IA (shortly before death or after death) • The *Zygomycetes and Fusarium* spp. are highly resistant to antifungal agents and develop as breakthrough infections to antifungals with anti-*Aspergillus activity*
Histopathological features	• Broad-based nonseptate or pauciseptate ribbon-like hyphae are pathognomonic for *Zygomycetes* • The presence of chlamydosporia in histopathology is pathognomonic for *Fusarium* spp.
CT features	• On CT scans, multiple nodules, and pleural effusions favor the diagnosis of pulmonary mucormycosis vs. IPA • Pulmonary mucormycosis has a predilection for the upper lung lobes
Serology	• Positive galactomannan antigen is virtually diagnostic for IPA; cross-reactivity of *Aspergillus* galactomannan antigen with *Fusarium* spp.

neutropenia is essentially 100%, even with aggressive antifungal treatment, compared with a rate of approximately 30% in the setting of neutrophil recovery.[28]

Fusariosis in immunocompromised patients manifests in four major patterns: refractory fever of unknown origin, sinopulmonary infection or pneumonia, disseminated infection, and a variety of focal single-organ infections.[28] Sinopulmonary fusariosis and pneumonia occurs in more than 80% of patients and is most often clinically and radiographically indistinguishable from the much more common IA and other IMIs. Sinus involvement is also frequent, as it has been observed in up to 80% of cases in some reports.[28] One of the diagnostic challenges in immunocompromised patients with fungal pneumonia is differentiating between IA, invasive fusariosis, and mucormycosis. Hence, recovery of *Fusarium* spp. from cultures of appropriate specimens is essential for a definite diagnosis.

The histopathological picture of *Fusarium* is identical to that of *Aspergillus* and other hyalohyphomycetes (e.g., *Scedosporium spp.*) and may lead to misidentification. Even so, there are subtle differences in the histopathological features of *Aspergillus* and *Fusarium* spp. that can facilitate differentiation between the two species based on the histopathology itself, including the presence of *Fusarium* chlamydosporia in tissue (Table 133-8).

Because hyalohyphomycetes (*Aspergillus* vs. *Fusarium* vs. *Scedosporium* spp.) have different levels of susceptibility to antifungal agents, the ability to differentiate between these molds in histopathology positive but culture-negative cases using molecular identification methods could have significant implications on therapeutic decision making. In situ hybridization directed against ribosomal 18 S RNA sequences was recently shown to rapidly and accurately distinguish *Fusarium*, *Aspergillus*, and *Scedosporium* spp. from histopathological specimens.[28] However, further standardization of these promising molecular methods is needed. Proteomic-based approaches with the use of mass spectroscopy (MALTITOF) are capable to provide rapid diagnosis of clinical isolates of *Fusarium*. These techniques are promising in diagnosis of fungal pathogens but require further standardization and are not widely available. Thus, tissue cultures remain the gold standard for differentiation between these fungi.

Despite the clinical similarities between pulmonary fusariosis and IPA, there are some characteristics that favor the diagnosis of invasive fusariosis (Table 133-8). First, *Fusarium* spp. are usually recovered from blood specimens in the setting of disseminated disease. The reported rate of positive blood cultures in patients with disseminated fusariosis ranges from 50% to 70%, and fungemia may be the only manifestation of the infection.[28] *Fusarium* is the most common mold associated with true fungemia in HSCT recipients. This feature contrasts with disseminated IA and mucormycosis cases in which these molds are rarely (<5%) isolated from blood specimens, with the notable exception of *A. terreus*.

Another distinctive feature of invasive fusariosis is the high incidence (50%–70%) of skin lesions in patients with disseminated disease. This contrasts with the low incidence of skin lesions in patients with disseminated aspergillosis (<10%). In fact, skin lesions are frequently the sole diagnostic material for invasive fusariosis in a high-risk patient with presumed fungal pneumonia. Several patterns of skin lesions can be seen: subcutaneous nodules, purpura, red or gray macules and/or papules with or without progressive central necrosis, flaccid pustules, vesicles, and hemorrhagic bullae.[28] The most characteristic skin lesions encountered in cases of disseminated fusariosis are "ecthyma gangrenosum-like" lesions, which are red or gray macules with central ulceration or black eschar. *Fusarium* skin lesions are often tender, especially subcutaneous nodules, and can involve any skin site, although they appear predominantly in the extremities. Most patients have lesions at different stages of evolution. Accompanying myalgias are also common, reflecting concomitant muscle involvement.

Fusarium species are quite resistant to the arsenal of modern antifungal agents, and breakthrough infections to AMB or triazoles are common.[29] In particular, *F. solani* is the most resistant species within the genus. The mainstay in the treatment of fusariosis has traditionally been AMB-D. However, the in vitro susceptibility of *Fusarium* spp. to AMB-D is, at best, mediocre. Whether the in vitro susceptibility of *Fusarium* spp. alone can predict outcome is unclear, because other factors, such as neutrophil recovery, are probably the most critical determinants of the prognosis for fusariosis. There have been reports of improved outcome of fusariosis with the use of high-dose lipid formulations of AMB. Hence, the mortality rate in patients who received high doses of a lipid complex of AMB (>5 mg/kg/d) was significantly lower (<30%) than that observed

in patients who received conventional AMB-D doses (>75%) in a previous study.[28]

Among the antifungal triazoles, fluconazole and itraconazole are not active against *Fusarium* spp. However, the newer broad-spectrum triazoles voriconazole and posaconazole have variable in vitro activity against *Fusarium* spp. and may show promise in the management of fusariosis. A recent retrospective study evaluated the outcome of 73 patients with fusariosis treated with voriconazole either as frontline (22%) or salvage (78%) therapy, with an overall response rate of 47%. Another retrospective study in 21 patients with fusariosis refractory or intolerant to AMB-based therapy reported a 48% response rate in 10 patients receiving salvage posaconazole.[28] Given that AMB and the newer triazoles voriconazole and posaconazole are the most active agents against *Fusarium* spp., a strategy combining a lipid formulation of AMB with one of these triazoles is frequently employed in clinical practice. A retrospective study examined the rationale of combination therapy in 44 hematological malignancy patients with fusariosis. The majority of these patients (73%), received combination therapy, with amphotericin B and a triazole with 41% response at 12 weeks after diagnosis. Overall, the rational of combination therapy for fusariosis is reasonable and merits further investigation.[28]

Because the neutrophil count seems to be the most crucial prognostic determinant in fusariosis cases, a potentially beneficial adjuvant therapeutic strategy is to transfuse granulocytes obtained from G-CSF- and GM-CSF–stimulated donors.[28] Granulocyte transfusion has been suggested to result in more favorable response rates (33%–50%) in profoundly neutropenic patients by shortening the duration of neutropenia.[28]

■ PULMONARY SCEDOSPORIOSIS

The genus *Scedosporium* comprises a group of filamentous fungi found ubiquitously in the environment. The two major human pathogenic species are *Scedosporium apiospermum* – the asexual state of *Pseudallescheria boydii* – and *Scedosporium prolificans*.[26,27] Both of these species histologically resemble *Aspergillus* spp. with hyphae that are septate and branching at acute angles. Although *Scedosporium* infections can occasionally occur in immunocompetent individuals, the overall incidence has increased over the past decade because of improved diagnostic modalities and the expanding population of immunocompromised individuals. These fungi can cause fatal angioinvasive infections in immunocompromised hosts that manifest with sinopulmonary, central nervous system, osteoarticular, ocular, endovascular, and lymphocutaneous involvement.[26,27] Disseminated infection is associated with high (>75%) mortality rates. *Scedosporium* spp. are known to be remarkably resistant to most conventional antifungals, such as AMB; treatment with newer triazoles, such as voriconazole, appears to be more efficacious.[26,27]

Spores of *Scedosporium* spp. enter the respiratory tract by inhalation and the skin by direct inoculation to areas of trauma. Germination of conidia results in hyphal invasion in tissue with the potential to disseminate hematogenously to distant anatomic sites. Similar to *Fusarium* spp., dissemination may be facilitated by the ability of *Scedosporium* spp. to undergo adventitious sporulation in vivo. In general, strains of *S. prolificans* are more virulent than strains of *S. apiospermum*. *S. prolificans* produces melanin, which may be an important virulence factor contributing to in vivo protection against host defense mechanisms.[26,27]

Patients with AIDS, congenital or acquired immunodeficiency, or hematological malignancies as well as recipients of stem cell and solid-organ transplants and those receiving antineoplastic or immunosuppressive medications are especially susceptible to these filamentous molds.[28] In these immunocompromised individuals, sinopulmonary disease with hematogenous dissemination to various organs most often occurs. Of interest, a recent review of 189 cases of pulmonary scedosporiosis reported that 11% of all cases were in immunocompetent patients following near-drowning. This association implies the higher virulence of *Scedosporium* spp compared to other opportunistic molds.[26,27]

The spectrum of pulmonary scedosporiosis largely mimics aspergillosis, ranging from respiratory tract colonization, to allergic bronchopulmonary hypersensitivity, to saprophytic fungus ball formation in pre-existing pulmonary cavities, and finally to invasive pulmonary or disseminated scedosporiosis.[26,27] Invasive disease without pre-existing lung tissue damage caused by *S. apiospermum* generally occurs only in immunocompromised hosts during or immediately after periods of prolonged neutropenia or with intensification of immunosuppression, and fever is the most common clinical presentation. Onset of infection may also be manifested by pulmonary symptoms, maculopapular skin lesions that later may become necrotic, myalgias, and central nervous system and other organ involvement.[26,27] On rare occasions, pulmonary infections that spread to involve the central nervous system are reported in immunocompetent individuals after massive inoculation with *S. apiospermum* by aspiration of polluted water.[26,27] Fungemia is diagnosed in more than two thirds of patients with disseminated *S. prolificans* and *S. apiospermum* infection. The radiographic appearance of pulmonary infections caused by *S. apiospermum* and *S. prolificans* is essentially indistinguishable from that of IPA. Because no radiographic findings are truly pathognomonic for *Scedosporium* infections, diagnosis relies on prompt histopathological and microbiological evaluation.

Histopathological features of *Scedosporium* spp. in tissue sections can be confused with those of other fungi that have acute-angle–branching septate hyphae. The melanin-specific Fontana–Masson stain may be used to confirm the presence of dematiaceous hyphae of *S. prolificans* in tissue.[26,27] Nevertheless, definitive diagnosis requires fungal culture and is crucial for antifungal susceptibility testing.

In general, *S. prolificans* is resistant to all clinically available antifungal agents, whereas *S. apiospermum* may be susceptible to miconazole, voriconazole, and posaconazole.[26,27] Both species are inherently resistant to the polyenes, including AMB. Data from clinical studies are limited. In a multicenter study of voriconazole administered as salvage therapy for scedosporiosis, the overall response rate of voriconazole for scedosporiosis outcomes of voriconazole therapy for *S. apiospermum* (33%) was somewhat better than that for *S. prolificans* (25%).[26,27]

Severe *S. prolificans* infections have been successfully treated with a combination of voriconazole and terbinafine.[26,27] In combination with azoles, terbinafine, an allylamine that blocks squalene epoxidase in the ergosterol synthesis pathway, has demonstrated synergistic interactions in vitro against clinical isolates of *S. prolificans*. Limited experience in patients with disseminated *S. prolificans* suggests that the combination of voriconazole and terbinafine is a legitimate treatment option, although the unfavorable pharmacokinetic characteristics of terbinafine preclude use as monotherapy.

Surgical debridement in cases of pulmonary scedosporiosis should be considered, especially for abscess drainage as well as for localized infections. In general, neutrophil recovery has been associated with an improved prognosis. IFN-g and GM-CSF have been shown to enhance neutrophil oxidative mechanisms of killing against *S. prolificans* hyphae.[26,27] Although clinical data are scarce, in view of the dismal prognosis for patients with *Scedosporium* infections, immunomodulating therapy, including G-CSF, GM-CSF, IFN-γ, and primed white blood cell transfusions, should be considered as an adjunct treatment modality for these infections.[26,27]

CHAPTER 134

Cryptococcosis and the Endemic Mycoses

L. Joseph Wheat
Mitchell Goldman
Chadi A. Hage
Kenneth S. Knox

Histoplasmosis and blastomycosis mostly afflict those living in the Mississippi and Ohio River Valleys, while coccidioidomycosis occurs primarily in the Southwestern desert of the United States (Fig. 134-1). Histoplasmosis and coccidioidomycosis also are endemic in parts of Mexico and Central and South America. Infection with *Cryptococcus neoformans* var. *gatti* is endemic to parts of British Columbia, the Pacific Northwest region of the United States and Australia while *C. neoformans* var. *neoformans* exhibits no geographical predilection. These mycoses are often mistakenly diagnosed and incorrectly treated as community-acquired pneumonia or sarcoidosis, resulting in serious morbidity or death in many cases.[1–3]

These organisms are found in the soil, and infection occurs following inhalation of the infectious forms of these fungi when sites containing the organism are disturbed. In some endemic areas over one-half of residents have acquired these mycoses early in life. In healthy individuals the infections are usually asymptomatic or clinically self-limited. In others, especially those who are immunosuppressed, the course of infection may be progressive and fatal without treatment. While these mycoses are less often seen in patients with acquired immunodeficiency syndrome (AIDS) who have access to effective antiretroviral therapy, they are occurring more frequently in those with other immunosuppressive conditions, and continue to be pathogenic for individuals without underlying disease. The majority of those hospitalized due to infection with endemic mycoses in the United States in fact have no identifiable immunologic deficits. In a study of patients hospitalized with histoplasmosis, blastomycosis, or cocciodiodomycosis, only 13% of those infected were immunosuppressed. Hospital costs alone exceeded $250 million,[4] providing an estimate of the impact of the endemic mycoses in the United States. Advances in diagnosis and treatment provide opportunities to improve the outcome of these mycoses.

CRYPTOCOCCAL INFECTIONS

Cryptococcosis is caused by infection with the encapsulated fungus *C. neoformans,* an organism with a worldwide distribution. Inhalation of *C. neoformans* initiates the infection in the lung with hematogenous dissemination most often involving the meninges. Although pulmonary infection may be discovered in the presence or absence of disseminated infection, meningoencephalitis remains the most commonly diagnosed form of cryptococcal infection. The spectrum of disease ranges from asymptomatic pulmonary infection in the immunocompetent host to diffuse pulmonary disease associated with respiratory failure and widespread disseminated disease in the immunocompromised host. It is estimated that nearly 1 million cases of cryptococcal meningitis occur worldwide annually, with the majority of cases occurring in those with HIV infection.[5] The incidence of cryptococcosis in patients with AIDS in the United States has declined since the introduction of potent antiretroviral therapy; most cases now occur in those with limited access to care.[5,6]

MYCOLOGY

C. neoformans is a yeast that is characterized by a thick polysaccharide capsule. The yeast measures 4 to 6 μm in diameter but the capsule thickness varies from 1 to more than 30 μm. Organisms are smaller and less well encapsulated in the environment, explaining the ability to reach the terminal airways following inhalation. *C. neoformans* grows readily in fungal media, allowing isolation in less than 48 hours and identification by biochemical tests or DNA probes. Four serotypes of *C. neoformans* have been described—A, B, C, and D.

EPIDEMIOLOGY

Serotypes A and D predominate in North America and Europe and grow best in composted bird droppings or rotted vegetation. Serotypes B and C are classified as *C. neoformans* var. *gatti* and are more common in tropical and subtropical regions in association with eucalyptus trees rather than avian excreta. Recently outbreaks of infection caused by *C. neoformans* var. *gatti* have been reported in British Columbia and the Pacific Northwest region of the United States (Fig. 134-1). Otherwise outbreaks or clusters of cases are rare in cryptococcosis, and in most cases a history of exposure to birds or dust is lacking. Person-to-person transmission does not occur if cryptococcosis has been transmitted through organ transplantation; cutaneous infection has occurred after direct inoculation.

Patient populations at increased risk for progressive cryptococcosis include those with T-cell–mediated immune defects caused by AIDS, lymphoreticular malignancy (particularly Hodgkin

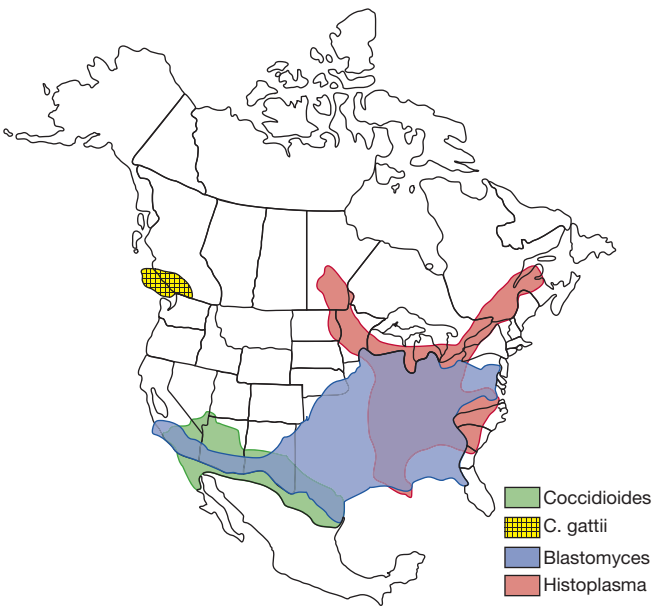

Figure 134-1 Geographical distribution of endemic mycoses in the United States. The area of histoplasmin skin test reactivity in the southwestern US represents cross-reactivity caused by coccidioidomycosis, not endemic histoplasmosis.

disease), or immunosuppressive medications, including tumor necrosis factor (TNF) inhibitors. The disease also appears to be more frequent in diabetics. *While C. neoformans* var. *gatti* infection was initially reported as occurring almost exclusively in immunocompetent hosts, in a recent surveillance study, half of patients infected with this organism had underlying immunosuppression.[7]

■ PATHOGENESIS

Cryptococcosis is acquired by inhaling aerosols containing the yeast but rarely by direct inoculation. Progressive disease often follows exposure in patients with impaired cellular immunity. In tissues, a mixed macrophage, lymphocyte, and plasma-cell response is seen, but inflammation may be minimal in immunodeficient subjects. Granulomas are uncommonly found in the nervous system but may be seen in other tissues.

Macrophages, natural killer cells, and T lymphocytes play the key roles in cellular defense against *C. neoformans*. Inflammatory cytokines (interleukin [IL]-2, IL-12, interferon [IFN]-γ) and macrophage colony-stimulating factor enhance the antifungal activity of these cellular mechanisms. Humoral immunity complements cellular mechanisms in defense against *C. neoformans*.

■ CLINICAL FINDINGS

Cryptococcal infection results in asymptomatic or self-limited pulmonary disease in most healthy individuals. While symptomatic isolated pulmonary cryptococcosis may be diagnosed, meningoencephalitis is the most commonly recognized manifestation of cryptococcosis and the most common cause of death. Hematogenous dissemination to almost any tissue occurs in fewer than 25% of cases.

Pulmonary

Isolated pulmonary infection is not uncommon, and saprophytic colonization has been observed. Pulmonary cryptococcosis often is asymptomatic, discovered when chest radiographs are done for other reasons. Concurrent disseminated disease occurs in about 15% of cases. In symptomatic cases, common complaints include dry cough, dull chest discomfort, and low-grade fever. Less commonly night sweats, fatigue, weight loss, or hemoptysis may occur. Nodular infiltrates are typical of pulmonary cryptococcosis in the normal host (Fig. 134-2). Pulmonary cryptococcosis in nonimmunosuppressed patients usually resolve without therapy. Occasionally pulmonary cryptococcosis progresses slowly or may be accompanied by meningoencephalitis or dissemination to other organs after improvement of the pulmonary process.

In contrast to nonimmunocompromised patients, most immunocompromised patients exhibit fever and cough. Diffuse interstitial infiltrates or widespread alveolar consolidation causing respiratory failure is common in severely immunodeficient hosts. Radiographs in patients with less profound cell–mediated immune defects usually show nodular or patchy alveolar infiltrates (Fig. 134-2). Mortality is high in immunosuppressed patients with diffuse pulmonary involvement. Mass lesions are not uncommon and may resemble malignancy. Cavitation is uncommon and mediastinal adenopathy, pleural effusion, and calcification are rare. A halo sign, usually attributed to aspergillosis, may be observed in cryptococcosis. Empyema, pleural disease suggesting a Pancoast tumor, and pneumothorax have been reported. As immunosuppressed patients with pulmonary cryptococcosis often have meningoencephalitis, a lumbar puncture is recommended in these patients even in the absence of signs or symptoms of central nervous system (CNS) infection.

Meningoencephalitis

Meningoencephalitis is the most common manifestation of cryptococcosis. A gradual onset is typical, but a more rapid presentation may be seen in patients with severe immunodeficiency. Symptoms include fever, headache, nausea, and vomiting, while less than one-third of patients exhibit meningismus, altered mentation, or focal neurological abnormalities. Elevated intracranial pressure is common and may cause brain-stem herniation. Focal brain lesions occur in about 10% of cases, alone or in combination with meningoencephalitis.

Other Sites of Dissemination

Extraneural involvement may be seen in patients with meningoencephalitis or pulmonary cryptococcosis. Hepatosplenomegaly and bone marrow suppression are seen most commonly while lesions involving the skin, eyes, bones, or joints occur in about 5%. Other sites of dissemination include the heart, pericardium, muscle, gastrointestinal tract, peritoneum, thyroid, larynx, breast, placenta, urinary tract, prostate, and organ of Corti.

Immune Reconstitution Syndrome

Up to 30% of patients with AIDS and a recently diagnosed cryptococcal infection may exhibit an immune reconstitution inflammatory syndrome (IRIS) following initiation of highly active antiretroviral therapy (HAART) (see Chapter 123).[8] In AIDS patients, levels of serum cryptococcal antigen titer[9] as well as CSF cryptococcal antigen titers[8] prior to the administration of HAART have been positively correlated with the risk of IRIS. Similar findings have been reported following organ transplantation with reductions in immunosuppression during therapy. Clinical findings have included worsening of meningitis with the development of intracranial hypertension, hypercalcemia, intrathoracic lymphadenopathy, cavitation of pulmonary lesions, and soft tissue abscess. These findings represent inflammation resulting from an enhanced inflammatory response made possible by immune reconstitution. While such changes may resolve spontaneously at times, the inflammatory changes within the CNS have led to death.[10] A recently published study that randomized patients with newly diagnosed AIDS and cryptococcal meningitis to early HAART (approximately 7 days following initiation of antifungals) versus delayed HAART approximately (28 days after initiating antifungals) demonstrated significantly more IRIS events in those treated with early HAART.[11] These findings would support the recommendation by the Infectious Disease Society of America (IDSA) that HAART should be withheld for individuals recently diagnosed with cryptococcal meningitis, for 2 to 10 weeks after initiation of antifungal therapy.[12]

■ DIAGNOSIS

Approaches to the diagnosis of cryptococcal pneumonia and meningoencephalitis are discussed below.

Pneumonia

The diagnosis of pneumonia is usually made by cytology or histopathology of respiratory secretions or lung tissue, and confirmed by culture (Table 134-1).[13–15] Once a diagnosis of pulmonary cryptococcosis is made, an evaluation for extrapulmonary dissemination should be initiated. A serum cryptococcal antigen test should be performed along with fungal blood culture. Cerebrospinal fluid (CSF) examination is recommended if the patient has any symptoms of meningitis or brain involvement, or is immunosuppressed. IDSA guidelines indicate that for immunocompromised patients with pulmonary cryptococcosis, a lumbar puncture to rule out asymptomatic CNS involvement should be considered.[12] However, for normal hosts with an asymptomatic

pulmonary nodule or infiltrate, no CNS symptoms, and a negative or very low serum cryptococcal antigen, a lumbar puncture can be avoided.

Histopathology and Cytology *C. neoformans* can be recognized in tissue as a globose or oval to lemon-shaped yeast with a polysaccharide capsule (Fig. 134-3). Cryptococci are readily identified by the Gomori methenamine silver (GMS) and periodic acid–Schiff (PAS) stains. More specific stains for *C. neoformans* include the Mayer's mucicarmine stain, which stains the fungal capsule and the Masson–Fontana melanin stain, which may detect capsule-deficient cryptococci. Direct microscopic examination of bronchoalveolar lavage (BAL) fluid sediment stained with India ink can identify the organism. The sensitivity of histopathology in patients with AIDS is about 67%. In the nonimmunocompromised host, fungal stains of respiratory specimens are rarely positive (approximately 5%) despite isolation of the fungus in over two-thirds of cases.

Antigen Detection In patients with cryptococcal pneumonia, the serum cryptococcal antigen is usually not detected unless extrapulmonary dissemination has occurred, the pneumonia is extensive, or the patient is immunosuppressed. A negative serum cryptococcal test should not be used to exclude the diagnosis of cryptococcal pneumonia. In patients with AIDS with pulmonary cryptococcosis the serum cryptococcal antigen is positive in most cases. Cryptococcal antigen also may be detected in BAL and pleural fluid. Cryptococcal antigen detection using a lateral flow device simplifies

point-of-care testing.[19] Cryptococcal serum antigen screening of patients with HIV-infection and a CD4 count <100 cells/mm^3, who reside in an area with a high rate of cryptococcal disease, can identify those at risk to develop cryptococcal meningitis over the subsequent year.[20]

Culture *C. neoformans* often can be isolated from sputum in patients with cryptococcal pneumonia. However, isolation from sputum may represent mere colonization. In patients unable to produce sputum, bronchoscopy may be useful. Cultures of BAL or lung tissue yield the organism in 50% to 90% of cases while fungal stains are positive less often. Needle aspiration of focal lesions also may be useful. Thoracentesis may yield the organism in patients with pleural involvement. Blood cultures may be positive in immunocompromised hosts.

Meningoencephalitis

The diagnosis of meningitis can be made initially by India ink stain or detection of antigen in CSF and confirmed by isolation of the organism from fungal cultures. Antigen also can be detected in serum, providing a clue to the diagnosis before lumbar puncture is performed. Antigen may be detected in the serum in 92% to 100% and the urine in 98% to 100% of immunocompromised patients

with cryptococcal meningitis,[16–18] but in a lower proportion of nonimmunocompromised patients.[21] Cultures also may be positive from extrapulmonary sites in up to two-thirds of patients.

TREATMENT

Treatment is indicated in patients with symptomatic pulmonary infections, especially if they are immunocompromised and in all patients with meningoencephalitis or disseminated infection (Table 134-2). The rationale and supporting evidence for these recommendations are discussed in an IDSA guideline document published in 2010.[12] Patients with a diagnosis of cryptococcosis at any site should be provided close follow-up for at least 1 year as the majority of relapses occur during this time period.

Indications for Treatment

For asymptomatic and immunologically normal patients without extrapulmonary disease (e.g., pulmonary nodules), antifungal therapy may be withheld for up to a month if patients can be followed closely. Increasing size or numbers of lesions would be indications for the treatment. For symptomatic patients, those who are immunocompromised, and patients showing progression during observation, treatment is advised.

Treatment of meningoencephalitis and and extrapulmonary dissemination (even without meningoencephalitis) is indicated in all cases.

Selection of Antifungal Agent

Selection of an antifungal agent for treatment is considered below for pneumonia, meningoencephalitis, and disseminated disease.

Pneumonia For nonimmunosuppressed patients, fluconazole 400 mg/d for 6 to 12 months is recommended, and itraconazole (200 mg twice per day orally), voriconazole (200 mg twice per day orally), and posaconazole (400 mg twice per day orally) may be considered acceptable alternatives only if fluconazole is unavailable or contraindicated.[12] In more severe cases, amphotericin B and flucytosine should be given as recommended for meningitis (see below). Treatment guidelines for meningitis should be followed in immunosuppressed patients.

Meningitis Amphotericin B 0.7 to 1.0 mg/kg/d and 5-flucytosine 100 mg/kg/d are favored and should be given for 2 weeks (induction) followed by fluconazole 400 mg/d for 10 weeks (consolidation). 5-flucytosine accelerates sterilization of the CSF, improves the overall response rates for meningitis and reduces the risk for relapse. Lipid preparations of amphotericin B (3–5 mg/kg/day) are less toxic and may be preferred over the standard formulation, notably in patients with renal impairment or those who are thought to be at increased risk for amphotericin B nephrotoxicity. Amphotericin-containing preparations with or without flucytosine for 4 to 6 weeks without additional therapy can be potentially curative in patients with negative cultures after 2 weeks of therapy who are without any immunosuppression, neurologic complications or meningeal symptoms, though for most some form of antifungal consolidation therapy is recommended. Fluconazole alone is not recommended as induction therapy in immunocompromised hosts when amphotericin and 5-flucytosine are available. Combinations of therapy using amphotericin B and fluconazole at various doses as induction therapy have been studied in cryptococcal meningitis in resource poor settings where 5-flucytosine cannot be administered.[26,27] Compared to amphotericin B alone, combined amphotericin B plus fluconazole was associated with a trend toward improved outcomes.[12] Improved responses using this combination have been associated with a daily dose of fluconazole of 800 mg rather than 400 mg[12,27] and correlated with the ability to achieve higher CSF and serum fluconazole levels.[27] Fluconazole 800 to 1200 mg daily given with 5-flucytosine has been studied as induction therapy and when compared to treatment with fluconazole alone this combination appears to be associated with improved responses though greater toxicities.[28]

Fluconazole alone as induction therapy can be considered when amphotericin and 5-flucytosine are not available as is not uncommon in resource-limited settings. Induction doses of fluconazole of 1200 mg daily are associated with higher response rates than 800 mg fluconazole daily in a recent study.[29] Itraconazole 200 mg twice daily is an alternative in patients unable to take fluconazole for consolidation therapy.

Aggressive management of elevated intracranial pressure through removal of large volumes (about 25 mL) of CSF is essential to achieve the highest survival. Addition of IFN-γ led to clinical improvement in two patients with CD4 lymphopenia unresponsive to amphotericin B.

In patients with active AIDS or other immunosuppressive conditions, so-called maintenance or suppressive treatment with fluconazole 200 mg/d is recommended. Itraconazole is inferior to fluconazole for chronic maintenance therapy and is not advised. If itraconazole is used, 200 mg twice daily is recommended. Amphotericin B at a dose of 1 mg/kg one to three times weekly is another alternative maintenance regimen.

With the use of HAART, studies have indicated that maintenance fluconazole can be safely discontinued in most patients responding to HAART with a CD4 cell count >100 cells/mm^3, an undetectable or low HIV RNA level sustained for 3 months, and at least 1 year of antifungal drug treatment. Patients require careful monitoring for relapse and continued response to HAART. Resumption of antifungal therapy is recommended if the CD4 count falls below 100 cells/mm^3. Monitoring serum cryptococcal antigen should also be performed, as a rising titer would support resumption of antifungal therapy.[12]

For immunosuppressed patients without AIDS, a 6- to 12-month course of fluconazole is recommended. As in patients with AIDS,

careful follow-up is required after antifungal therapy is stopped. In some patients who relapse following such a course of therapy, lifelong maintenance therapy may be appropriate.

Disseminated/Extrapulmonary, without Meningoencephalitis
Trials have not been performed evaluating treatment of non-CNS extrapulmonary disease, and recommendations are based upon experience of the IDSA guideline committee. Recommendations outlined earlier for pneumonia should be followed in nonimmunosuppressed patients and for meningitis in those who are immunosuppressed.

Role of Antifungal Resistance

Resistance may be a cause for fluconazole failure. The minimum inhibitory concentration (MIC) of fluconazole required to inhibit greater than 90% of strains of *C. neoformans* is likely somewhere between 8 and 16 μg/mL, which can be used as a breakpoint for defining resistance.[30] In one study from Spain, patients infected with *C. neoformans* isolates with MICs ≥16 μg/mL failed to respond to fluconazole therapy.[31] In a recent study from Africa evaluating relapses of meningitis in individuals treated with primary fluconazole therapy alone, 76% of relapses associated with positive cultures demonstrated resistance to fluconazole with MICs to fluconazole of ≥64 μg/mL.[32] It is recommended that testing of isolates for fluconazole resistance should be reserved for those who do not respond to therapy, those who relapse and those who develop cryptococcal meningitis after prolonged exposure to azole therapy.[12] As 5-flucytosine susceptibilities have not been demonstrated to be predictive of response, such testing is not routinely recommended. While there are no recommendations to routinely tests isolates for primary amphotericin B resistance, reduced susceptibility of *C. neoformans* isolates to amphotericin B was associated with greater day 14 mortality in one study of meningitis treatment in AIDS patients treated with amphotericin B alone as induction therapy.[33]

Newer Antifungal Agents

Alternatives to itraconazole and fluconazole are needed for patients who fail or do not tolerate those agents. Voriconazole is slightly more active in vitro than posaconazole, with an MIC_{90} levels in the range of 0.12 to 0.25 μg/mL.[34] Voriconazole penetrates CSF, but not as well as fluconazole. Furthermore, strains with high-level resistance to fluconazole may be cross-resistant to voriconazole.[35] Posaconazole was effective in a rabbit model of cryptococcal meningitis.[36] While not studied adequately case reports from salvage studies support the potential effectiveness of voriconazole[37] as well as posaconazole.[38] Neither would appear to offer advantages over fluconazole, however as primary therapy. The echinocandins are not active in vitro,[39] have not been studied in animal models, and are not recommended in patients with cryptococcal infection.

Adjunctive Therapy

Adjunctive IFN-γ immunotherapy has been used in randomized controlled trial in patients with cryptococcal meningitis receiving amphotericin B and 5-flucytosine.[40] While no mortality benefit was seen in those who received IFN-γ in addition to standard antifungal treatment, clearance of *C. neoformans* from the CSF was noted to be significantly faster in those who were treated with adjunctive IFN-γ.[40] Given the expense of this adjunctive therapy and lack of mortality benefit, routine use of IFN-γ for cryptococcal meningitis would appear to be unwarranted. Some however have recommended consideration of this adjunctive therapy or refractory cases.[12]

■ PREVENTION AND SCREENING FOR CRYPTOCOCCOSIS

Although fluconazole and itraconazole reduced the incidence of cryptococcosis in patients with AIDS, prophylaxis is not recommended in resource rich settings, largely because of the low attack rate. In such regions, unlikely cost-effectiveness, limited impact on survival, and potential to induce fluconazole resistance among other fungi are reasons this strategy is not recommended. On the other hand in areas where cryptococcal infections are much more common and associated with high mortality prophylaxis may reduce mortality and represent an effective strategy.[41] Serum cryptococcal antigen screening on all HIV-infected individuals with CD4 counts less than 100 cells/mm^3 living in resource-limited settings characterized by high rates of cryptocccal meningitis, can identify those at high risk for clinical cryptococcal disease.[42] It has been suggested that identifying such individuals who may benefit from antifungal therapy in the absence of clinical disease may represent a cost-effective strategy.[41,42]

HISTOPLASMOSIS

Histoplasmosis is the most common endemic mycosis and a major cause of morbidity in patients who live in endemic areas. Progressive disseminated histoplasmosis (PDH) is an important complication of AIDS, immunosuppression for the prevention of transplant rejection,[43] treatment of inflammatory diseases[44,45] or malignancies, and immunodeficiency disorders.[46] Understanding of the clinical syndromes and untreated course of the infections is essential in the diagnosis and management of patients with histoplasmosis. Improved laboratory tests have made it possible to rapidly diagnose the more severe cases. Expanded treatment options are available using newer triazole antifungal agents and liposomal formulations of amphotericin B.

■ MYCOLOGY

Histoplasma capsulatum grows as a mold in the soil and converts to a yeast in tissues (Fig. 134-3). Microconidia measuring 2 to 4 μm in diameter are the infectious particle in the mold phase of the organism. *H. capsulatum* also grows as a mold on fungal media in the laboratory. Definitive identification of a mold as *H. capsulatum* is made by DNA probe or exoantigen detection. At temperatures above 35°C, *H. capsulatum* grows as a yeast, which is the pathogenic form found in the tissues. The yeast measures about 2 to 5 μm and exhibits narrow-based budding.

■ EPIDEMIOLOGY

H. capsulatum is endemic in areas of North and South America (see Fig. 134-1) but can be found throughout the world. Bird and bat excrement enhance growth of the organism by accelerating sporulation. Cases outside the endemic region may have been acquired by exposure during travel or prior residence in the endemic area, or exposure to microfoci containing the organism within the nonendemic area. In the endemic areas between 10% and 90% of individuals exhibit histoplasmin skin test positivity as evidence of past histoplasmosis.[47]

■ PATHOGENESIS

Infection develops when conidia are inhaled and germinate into yeast. In many cases primary infection is asymptomatic and goes undiagnosed. Clinical illness most often follows exogenous infection or reinfection. With the development of cell-mediated immunity during the first month following initial infection, IFN-γ and IL-12 arm macrophages to kill the fungus and halt progression of the disease.[48] TNF-α also is very important for immune defense against *H. capsulatum*.[49] These defense mechanisms are sufficient to

control the infection in immunocompetent individuals, explaining the subclinical or self-limited course characteristic of acute histoplasmosis.

Reactivation of latent infection may account for some cases occurring in individuals with past histoplasmosis who become immunocompromised. Studies showing a low incidence of histoplasmosis following immunosuppression in children,[50] organ transplantation,[51] or treatment with TNF inhibitors,[44] however, suggest reactivation is rare. Also, latency could not be demonstrated experimentally in calcified lung lesions identified as incidental findings at autopsy.[52]

■ CLINICAL MANIFESTATIONS

Heavy exposure can cause severe illness even in healthy subjects. Low-level exposure is more common, however, and usually causes asymptomatic infection or clinically self-limited infection. The common self-limited presentations include acute and subacute pulmonary histoplasmosis, pericarditis, and rheumatological syndromes.

Asymptomatic Infection

In endemic areas, between 10% and 90% of residents exhibit histoplasmin skin test reactivity by age 20.[47] In most of these cases, infection was presumed to have been asymptomatic. Most asymptomatic cases are identified as an incidental finding on chest radiographs or computed tomography (CT) scans performed for other reasons. The most common findings are enlarged mediastinal or hilar lymph nodes or pulmonary nodules.[1] The main significance of such findings is the need to differentiate them from malignancy or tuberculosis. Asymptomatic infection also may be identified by demonstration of seropositivity during evaluation of another condition.

Pulmonary Syndromes

A variety of pulmonary syndromes may be seen with histoplasmosis. Each is considered below.

Acute Pulmonary Histoplasmosis

Following heavy exposure, patients present with diffuse pulmonary involvement often causing respiratory insufficiency.[1,53] Chest radiographs usually show diffuse interstitial, reticulonodular infiltrates, nodular, or patchy airspace disease, but a miliary pattern suggestive of hematogenous dissemination may be seen (Fig. 134-4). Initial radiographs may appear normal, evolving to show infiltrates over the next few weeks. Mediastinal adenopathy is common. Evidence for extrapulmonary dissemination is present in about 40% of cases.[22] While patients may recover without therapy,[54] recovery may be slow,[55] respiratory failure may develop,[56] and some infections may be fatal.[56,57]

Subacute Pulmonary Histoplasmosis More commonly, the inoculum is small and the presentation is subacute.[1,53] Patients present with fever, cough, and chest pain. Chest radiographs show mediastinal lymphadenopathy with patchy infiltrates. Most patients recover in a few weeks but some experience persistent fatigue.

Chronic Pulmonary Histoplasmosis Chronic pulmonary histoplasmosis occurs in patients with underlying lung disease and is characterized by persistent or recurrent pulmonary symptoms, progressive lung infiltrates, fibrosis, and cavitation.[58,59] Upper lobe infiltrates and cavities are characteristic, resembling the findings in tuberculosis. Progression is manifested by cavity enlargement, formation of new cavities, spread to other areas of the lungs, and bronchopleural fistula. Bacterial pneumonia, *Aspergillus* superinfection, and malignancy also must be considered in evaluation of new masses or infiltrates.

Nodules Nodules need to be differentiated from malignancy.[1,53] Calcification suggests histoplasmosis, but does not exclude malignancy. Conversely, absence of calcification, does not exclude histoplasmosis. Positive positron emission tomography (PET) scan, assumed to support malignancy, is common in histoplasmosis. Rarely, nodules may cavitate, but cavitation of nodules does not represent chronic pulmonary histoplasmosis and does not require therapy. Nodules also may rarely enlarge up to 2 mm/y, but enlargement is not caused by progressive infection and is not a basis for treatment.[60] Calcification occurs in the necrotic central and surrounding fibrous tissue. An approach to the evaluation of pulmonary nodules has been reviewed.

Broncholithiasis Lymph nodes and pulmonary granuloma calcify and may erode into adjacent bronchi causing hemoptysis or obstruction.[1] Patients may expectorate rock-like particles of tissue and experience recurrent and severe hemoptysis, bronchial obstruction, or tracheoesophageal fistula.

Relationship to Sarcoidosis Sarcoidosis and histoplasmosis share several clinical and radiographic findings.[1] Angiotensin-converting enzyme (ACE), sedimentation rate, C-reactive protein, and immunoglobulin elevations occur in both conditions.[61] Noncaseating granulomas are seen with each, and caseation, which is more typical of histoplasmosis, also occurs in sarcoidosis. Histoplasmosis is one of the most common infections that must be excluded before sarcoidosis is diagnosed to prevent mistakes in patient management, most notably administration of immunosuppressive therapy to patients with active histoplasmosis.

Mediastinal Syndromes

Mediastinal adenitis, mediastinal granuloma, and fibrosing mediastinitis are three mediastinal disorders which may complicate histoplasmosis.

Mediastinal Adenitis Mediastinal lymph node involvement is present in most cases of acute and subacute pulmonary histoplasmosis.[1,53] Although usually asymptomatic, chest pain is the most common manifestation. Rarely, the airways, esophagus, or superior vena cava (SVC) may be impinged, causing obstructive symptoms. Airway obstruction is more likely in children because the airways are less rigid.

Mediastinal Granuloma Histopathology shows a necrotic central core, often containing yeast, surrounding caseating and noncaseating granuloma,[1,53] fibrous tissue, and a thin-walled (less than 5 mm) capsule. The fibrosis is less exuberant than in fibrosing mediastinitis, and does not invade adjacent structures. Symptoms are usually caused by compression of the superior vena cava (SVC) esophagus, or airways, and in some cases the nodes liquefy and drain into adjacent structures.[62,63] Disruption of the capsule, either spontaneous or caused by surgery, may create fistulae to the airways, pericardium, skin, or esophagus. Esophageal involvement may result in diverticulum formation.

Mediastinal Fibrosis Mediastinal fibrosis represents an exuberant scarring reaction to mediastinal histoplasmosis.[1,64] The SVC is most commonly involved, but the fibrosis also may occlude airways, pulmonary arteries or veins, or esophagus, and invade the thoracic duct, recurrent laryngeal nerve, or atrium in rare cases. Chest radiographs show subcarinal or superior mediastinal widening, while CT scans reveal fibrotic restriction and invasion of mediastinal structures and calcification of the lymph nodes. Recurrent and often serious hemoptysis results from lung or airway damage and vascular compromise. Respiratory failure ensues in one-third of cases.

Other Inflammatory Syndromes

Inflammatory syndromes complicating histoplasmosis include rheumatologic syndromes and pericarditis.

Rheumatological Syndromes Patients with subacute histoplasmosis may experience arthritis or arthralgia accompanied by erythema nodosum,[65] a manifestation often misdiagnosed as sarcoidosis.[66] Chest radiographs usually show mediastinal lymphadenopathy and focal pulmonary infiltrates, but may be normal. These findings represent a systemic inflammatory response rather than disseminated infection, and are managed by anti-inflammatory treatment, not antifungal therapy. The illness may recur when treatment is stopped.

Pericarditis Pericarditis is another inflammatory complication of primary histoplasmosis, occurring in less than 10% of cases.[67,68] Findings include chest pain, pericardial friction rub, and occasionally signs of pericardial tamponade. Chest radiographs usually show mediastinal lymphadenopathy and increase in the cardiac silhouette, while CT scan and echocardiogram may show pericardial effusion. These patients respond to anti-inflammatory treatment but may require drainage of the

pericardial fluid for the management of tamponade. Late constriction is rare.

Progressive Disseminated Histoplasmosis

PDH occurs in about 1 in 2000 cases, usually in patients who are immunosuppressed or at the extremes of age. AIDS,[69] solid-organ transplantation,[70] and treatment with TNF-α inhibitors[44] are common predisposing conditions. PDH develops during the first year of therapy in nearly half of cases, but may occur more than 10 years after transplantation. Vigilance for dissemination should be maintained throughout the course of immunosuppression.

Fever and weight loss are the most common findings in PDH.[71,72] Examination reveals hepatomegaly or splenomegaly in about one-half of cases and lymphadenopathy in one-third of cases. A syndrome resembling sepsis may be seen in cases with severe immunosuppression, in whom corticosteroids are given for presumed inflammatory or autoimmune disease, or in which diagnosis is delayed. Meningitis or focal brain lesions occur in about 5% to 10% of cases.[72] Other common sites of dissemination include the oral mucosa, gastrointestinal tract, skin, and adrenal glands in 5% to 10% of cases. Chest roentgenograms are abnormal in 70% of patients, usually showing diffuse interstitial or reticulonodular infiltrates, and less often a miliary pattern.[71,73]

In patients who experience improvement in immune function during treatment for histoplasmosis, an immune reconstitution syndrome has been reported.[44,74,75] Manifestations have included respiratory failure, elevation of hepatic enzymes, hepatic or splenic abscesses, lymphadenitis, arthritis, uveitis, and intestinal obstruction.[74]

■ DIAGNOSIS

Histopathology, cytology, and antigen detection are most useful for rapid diagnosis in patients with acute pulmonary and PDH, cases that require therapy (Table 134-3).[22–25] A serological test for antibodies forms the basis for the diagnosis in subacute manifestations in most of the cases.[24,25] Serology or culture of respiratory secretions usually provides the basis for the diagnosis of chronic pulmonary histoplasmosis. Culture results may not be available for up to 1 month, limiting its usefulness for the rapid diagnosis of severe disease.

Antigen Detection

Detection of antigen in the body fluids offers a valuable approach to rapid diagnosis in patients with PDH and acute pulmonary histoplasmosis, providing results within 24 to 48 hours.[25] Antigen is found in urine of over 90% of patients with PDH and 80% with acute diffuse pulmonary disease.[22,25] Sensitivity is improved by testing both serum and urine.[22] Antigen detection is less sensitive in subacute pulmonary histoplasmosis.[25] Detection of antigen in BAL fluid may improve the sensitivity for the diagnosis of pulmonary histoplasmosis.[85] Antigen may be found in CSF in 50% of patients with *Histoplasma* meningitis.[72] Positive results caused by cross-reacting antigens occur in patients with African histoplasmosis, blastomycosis, paracoccidioidomycosis, and *Penicillium marneffei* infection.[25] Antigen levels decline during treatment and increase with relapse, providing a tool for monitoring therapy.[86,87]

Histopathology

Fungal staining permits rapid diagnosis but has a lower sensitivity than antigen detection.[25] The highest yield is from bone marrow. Fungal stain of BAL is positive in 70% of cases of diffuse pulmonary histoplasmosis in patients with AIDS with PDH. The sensitivity of fungal stain of sputum or BAL in patients with other types of pulmonary histoplasmosis has not been reported but appears to be low. Yeast may be seen in peripheral blood smears in patients with severe PDH. *Pneumocystis jirovecii, Candida glabrata*, *Blastomyces dermatitidis, C. neoformans, Toxoplasma gondii,* and *P. marneffei* may be misidentified as *H. capsulatum.*

Serological Tests

Antibodies to *H. capsulatum* measured by immunodiffusion or complement fixation develop in most of the patients.[88] Antibodies require up to 12 weeks to develop following exposure. In acute pulmonary histoplasmosis, antibodies can be detected about 15% of cases during the first 2 weeks of infection, increasing to about 75% by the sixth week.[89] Elevated levels of antibodies persist for several years.[90] The antibody response is greater in patients with heavy exposure and/or more severe clinical disease. Patients with asymptomatic or mild infection[91] and those who are receiving immunosuppressive medications following solid-organ transplantation[25] may not mount an antibody response. Antibody responses do not appear to be impaired by treatment with TNF inhibitors[25,44] and are only slightly impaired in patients with AIDS.[25]

Serology is most useful in patients with subacute manifestations of histoplasmosis (pulmonary, rheumatological, pericarditis, mediastinal syndromes) and chronic pulmonary infection, and is positive in 90% of such cases. Sensitivity is higher while specificity is lower using complement fixation rather than immunodiffusion methods. Complement fixation titers greater than or equal to 1:32 are more suggestive of active infection but titers of 1:8 to 1:16 should not be disregarded. Cross-reactions occur in patients with other fungal diseases. Also, antibodies persisting following prior histoplasmosis may cause confusion in patients with other lung diseases.

Fungal Cultures

Cultures provide the strongest proof for histoplasmosis but are limited by low sensitivity in self-limited infections and delayed growth (2–4 weeks). Cultures are most useful in patients with chronic pulmonary histoplasmosis and PDH. Sputum production is rare in patients with acute pulmonary histoplasmosis, but organisms can be cultured from BAL or other bronchoscopy specimens in some cases. In chronic pulmonary histoplasmosis patients commonly expectorate sputum, and organisms can be found in sputum or bronchoscopy specimens in 60% to 85% of cases.[25,59,85] Multiple specimens must be cultured to achieve the highest yield. In PDH, the highest yield is from bone marrow or blood, positive in over 75% of cases, and in BAL of patients with pulmonary infiltrates.[85] Cultures are usually negative in pulmonary nodules and mediastinal nodes representing subacute or old healed lesions despite demonstration of yeast by histopathology.

Polymerase Chain Reaction

Several studies report diagnosis of histoplasmosis by polymerase chain reaction (PCR) in tissues or body fluids,[92,93] but PCR was less sensitive than fungal stain for the examination of tissue specimens in one report.[92] PCR was positive on only 8% of urine specimens with elevated *Histoplasma* antigen,[94] 22% of BAL specimens[95] but not in CSF or serum.[95] A role of PCR for the diagnosis of histoplasmosis remains to be determined.

■ EXCLUSION OF HISTOPLASMOSIS IN WORKUP OF PATIENTS WITH COMMUNITY-ACQUIRED PNEUMONIA AND SUSPECTED SARCOIDOSIS

Other conditions to be distinguished from histoplasmosis include community-acquired pneumonia and sarcoidosis.

Community-Acquired Pneumonia

Histoplasmosis is always community acquired and often is initially suspected to be caused by other agents of community-acquired pneumonia.[2] Failure to suspect and correctly diagnose

histoplasmosis may result in mistakes in patient care, which can cause improper therapy, unnecessary morbidity or even death, and higher cost for diagnosis and management. Workup for histoplasmosis should be considered in patients from endemic areas with exposure history, if other causes cannot be established, or if empiric antibiotics do not result in prompt clinical improvement.

Sarcoidosis

Considering the similarity between the two conditions, and the risk for progression of histoplasmosis during immunosuppression for presumed sarcoidosis, active histoplasmosis must be excluded before immunosuppressant therapy is initiated.[1,61] If immunosuppressive therapy was initiated in patients with laboratory findings suggestive of histoplasmosis, the patient should be followed closely for evidence of progression of histoplasmosis. Also, if patients initially respond to immunosuppressive treatment but later relapse, testing for histoplasmosis should be repeated, as immunosuppression may have accelerated the progression of histoplasmosis.

Treatment Most infections are asymptomatic or clinically self-limited, requiring no therapy. Furthermore, treatment has only been studied in PDH and chronic pulmonary histoplasmosis, precluding assessment of effectiveness in the other syndromes. While treatment in cases of acute pulmonary histoplasmosis appears to be effective, studies showing that therapy hastens the response or reduces morbidity have not been conducted. Antifungal therapy for the subacute pulmonary, inflammatory, and mediastinal syndromes is rarely indicated and probably has no effect on the course of the illness, as the pathogenesis appears to involve the inflammatory response and/or mass effects of the enlarged nodes rather than progressive infection.

Treatment guidelines have been published and should serve as reference for indications for the treatment, selection of antifungal agents, duration of therapy, and testing to monitor response.[96,97] An earlier IDSA guideline summarized prior studies evaluating therapy for histoplasmosis.[96]

Indications for Treatment

Treatment of histoplasmosis is considered below according to the type of pulmonary involvement.

Acute Pulmonary Histoplasmosis Patients with symptomatic acute pulmonary histoplasmosis manifested by diffuse infiltrates following heavy exposure appear to benefit from antifungal therapy (Table 134-4).[55,98] Adjunctive therapy with corticosteroids may hasten recovery in such patients. Amphotericin B 0.7 to 1.0 mg/kg/d would be preferred as initial therapy in patients who are more severely ill. Itraconazole, 200 mg once or twice daily, is recommended in patients with milder illnesses, and following response to amphotericin B. A 6- to 12-week course is recommended in the absence of PDH, which should be excluded.

Subacute Pulmonary Histoplasmosis Patients with subacute pulmonary histoplasmosis usually recover without treatment, and there have been no studies to determine if treatment alters the course or prevents complications. Nevertheless, treatment is reasonable in patients who show no improvement of symptoms after a month of observation. Oral therapy with itraconazole would be appropriate, 200 mg once daily for 6 to 12 weeks.

Chronic Pulmonary Histoplasmosis Treatment improves survival, reduces symptoms, promotes radiographic healing, and eradicates *H. capsulatum* from the sputum. Most patients with chronic pulmonary histoplasmosis can be managed without hospitalization and respond well to treatment with itraconazole 200 mg once or twice daily for 12 to 24 months. Amphotericin B (0.7 to 1.0 mg/kg/d) or lipid amphotericin is recommended for initial therapy in patients with more severe respiratory insufficiency to achieve a more rapid response.

Mediastinal Adenitis and Granuloma Patients with obstructive symptoms or fistula caused by mediastinal granuloma should be treated, but whether treatment alters the outcome remains unknown. Itraconazole, 200 mg daily for 6 to 12 weeks, is recommended, after which imaging studies should be repeated to assess response. If the enlarged nodes show reduction in size, therapy might be continued for a total of 3 to 6 months. Surgery should be considered if symptoms persist and are sufficiently bothersome. Antifungal treatment or resection of enlarged mediastinal lymph nodes to prevent fibrosing mediastinitis is not indicated since progression of enlarged mediastinal nodes to fibrosing mediastinitis has not been documented.[64,105]

Mediastinal Fibrosis

Antifungal treatment is not thought to improve the outcome of mediastinal fibrosis, but therapy with itraconazole, 200 mg daily for 6 to 12 weeks, is commonly tried and is not unreasonable considering the seriousness of this complication. Occasionally patients benefit from the placement of stents in pulmonary vessels or the SVC.[106] Stenting of the airways is not recommended because of the risk for growth of inflammatory tissue causing obstruction of the stent. Surgery is associated with a high mortality and limited efficacy, and should be discouraged. In patients with no other options, care should be taken to select a surgeon experienced with this rare manifestation of histoplasmosis.

Broncholithiasis Surgical therapy is required for patients with significant hemoptysis or recurrent pneumonia and for repair of fistulae. Antifungal therapy would not be expected to reduce the symptoms since active infection is uncommon in such cases.

Inflammatory Syndromes Rheumatological syndromes and pericarditis are noninfectious, inflammatory manifestations, and respond to anti-inflammatory therapy. Antifungal therapy is not indicated unless the bone, joint, or pericardium is the site of disseminated infection, or if corticosteroids are used for treatment of the inflammatory syndrome.

Disseminated Treatment is indicated in all patients with PDH. The mortality of untreated disseminated histoplasmosis is 80% but can be reduced to less than 10% with therapy.[44,63,87,107,108] Amphotericin B 0.7 to 1.0 mg/kg/d, liposomal amphotericin B 3 mg/kg/d, and itraconazole 200 mg once or twice daily are highly effective. A total duration of 12 to 24 months is recommended in most of the cases.

Selection of Antifungal Agents

Amphotericin B acts more rapidly than triazole antifungal agents, and is recommended for moderately severe or severe cases, which require hospitalization, and women who are pregnant. While the IDSA guideline recommends use of lipid formulations of amphotericin B,[97] the ATS guidelines recommends the original deoxycholate formulation. Liposomal amphotericin B was superior to the deoxycholate formulation in AIDS patients with histoplasmosis, with improved overall response, reduce mortality, and reduce side effects,[109] forming the basis for the IDSA recommendation.

In patients with AIDS who also have PDH, liposomal amphotericin B is more effective than standard amphotericin B, with more rapid resolution of fever, higher overall response, better survival, and lower toxicity.[109] Liposomal amphotericin B, 3 to 5 mg/kg/d, is preferred for patients with severe or moderately severe PDH. Treatment can be changed to itraconazole after the patient improves, usually in 3 to 14 days.

Itraconazole is highly effective in most mild to moderately severe cases of PDH and in chronic pulmonary histoplasmosis.[96] Itraconazole capsules require an acidic gastric environment for solubilization and should be given with food or cola. Medications that reduce gastric acidity should be avoided. Itraconazole solution is a good alternative in patients who require gastric acid suppression or who have low blood levels while taking the capsule formulation.

Itraconazole blood levels should be measured after 2 to 3 weeks of therapy with a sample obtained just before a dose, striving for a trough concentration between 1 and 10 μg/mL when measured by high pressure liquid chromatography (HPLC).[110] Levels measured by bioassay should generally be about two times higher than HPLC in the target concentration is between 3 and 10 μg/mL. The solution formulation achieves concentrations that are about 30% higher than the capsule formulation.

Hepatic enzyme inducers reduce itraconazole concentrations and should be avoided. Itraconazole also inhibits intestinal and hepatic cytochrome P450 3A4, causing accumulation of several drugs and increasing associated toxicities.[111] As the list of contraindicated medications continues to evolve, physicians should review potential drug interactions before starting itraconazole and when new medications are added to the regimen. Furthermore, itraconazole is eliminated by hepatic metabolism and may be ineffective in patients receiving medications that induce cytochrome P450 enzymes. Itraconazole also may cause congestive heart failure and should be avoided in patients with heart disease unless the benefit outweighs the risk.[112] If itraconazole is used in patients with cardiac disease, careful follow-up for the development of heart failure is essential, and if heart failure develops, itraconazole should be stopped.

Fluconazole is less active in vitro than itraconazole in histoplasmosis. In patients with AIDS and PDH treated with 800 mg/d of fluconazole for 12 weeks followed by 400 mg/d indefinitely, failure occurred in up to one-half of patients within 6 months.[113] Isolates from patients who failed fluconazole exhibited at least a fourfold reduction in susceptibility to fluconazole in over two-thirds of cases.[114]

Newer Antifungal Agents

Posaconazole and voriconazole are active against *H. capsulatum,*[114] and posaconazole was effective in an experimental model of histoplasmosis.[115] However, voriconazole MICs are higher than itraconazole and posaconazole, and fluconazole treatment induced an increase in MIC to voriconazole.[114] A few patients have been treated with voriconazole, with inconsistent results, while posaconazole was highly effective, and appears to be the preferred alternative to itraconazole.[116] Echinocandins are not active in vitro or effective in murine models and have not been studied in patients with histoplasmosis.[117]

Maintenance Therapy

Lifelong maintenance therapy was the standard of care in patients with AIDS complicated by PDH before the advent of HAART. With HAART, maintenance therapy can be discontinued in patients who have received at least 1 year of itraconazole, antigen levels less than 2 ng/mL in urine and serum, and a CD4 count greater than 150 cells/mm^3.[97,118] Unpublished studies suggest that adherence to therapy and absence of CNS involvement should also be considered in decisions to stop treatment. Patients must be carefully monitored for relapse and continued response to HAART. Resumption of antifungal therapy is recommended if the CD4 count falls below 100 cells/mm^3 or if antigen levels in urine or serum increase, providing evidence of relapse.

■ PREVENTION

Patients at high risk for dissemination should avoid activities that expose them to *H. capsulatum*, such as caving or remodeling old buildings inhabited by bats or birds. Hand washing reduces the risk for acute histoplasmosis among persons exposed while crawling in a bat-inhabited cave, while use of loose-fitting paper masks does not. A placebo-controlled study using itraconazole, 200 mg daily, in persons with AIDS demonstrated reduction in the incidence of histoplasmosis.[119] However, since the introduction of HAART, the incidence of these infections has declined, and is too low to justify prophylaxis. Prophylaxis may be reasonable in areas where the combined incidence of systemic fungal infections exceeds 10 cases/100 patient-years.

COCCIDIOIDOMYCOSIS

Coccidioidomycosis is the most serious of the endemic mycoses, prone to reactivation and often failing therapy. Furthermore, large outbreaks in Arizona and southern California, increasing population in the southwestern states, and travel have placed large numbers of persons at risk. *Coccidioides immitis* is listed as a "select agent" of bioterrorism, complicating its use in the clinical and research laboratory.

■ MYCOLOGY

Coccidioidomycosis is caused by the pathogenic fungus, *Coccidioides,* which includes two species, *C. immitis* and *C. posadasii.* Except for different geographical locations (*immitis* in California and *posadasii* in Arizona), the laboratory properties, virulence factors, pathogenesis, clinical findings, diagnostic approach, and treatment are the same, hence, *Coccidioides* will be used to refer to both species in this section.

Coccidioides is highly virulent, causing infection upon exposure to only a few conidia and severe disease with larger inoculum. *Coccidioides* has been designated as a select agent by the Centers for Disease Control, requiring that it be destroyed upon identification in the laboratory except at facilities approved for handling select agents. *Coccidioides* grows as a mold with septate hyphae in the soil and on culture media and as an endosporulating spherule in the tissues of patients. Its arrow-shaped arthroconidia are 2.5 to 4 × 3 to 6 μm in size and are the infectious particles found in soil.

Coccidioides converts to an endosporulating spherule at 37° to 40°C. Spherules measure 30 to 60 μm in diameter and contain numerous 2 to 5 μm endospores (Fig. 134-3). Growth on fungal media occurs rapidly, usually within 3 to 5 days.

TABLE 134-3 Diagnostic Studies in Coccidioidomycosis (Percent Positive Assays)

Serology	90[81]	54	<50[82]	95	95[80]
Antigen	70[83,84]				

EPIDEMIOLOGY

Coccidioidomycosis, often referred to as Valley Fever (from a San Joaquin Valley outbreak), occurs in a spotty distribution in the southwestern United States, northern Mexico, and Central America (Fig. 134-1). Counties of southern California and southern Arizona are perhaps the most recently well studied and show an increased incidence of disease.[120] Exposure to *Coccidioides* is heaviest in the late summer and fall when the soil is dry and conditions are windy. In Kern County, coccidioidomycosis incidence has a yearly cycle, with the number generally increasing toward the late fall (17 per month per 100,000 population), decreasing in the winter, and reaching a minimum in the spring and summer.[121] Coccidioidomycosis is laboratory-reportable and an abundance of information is available, for example, on the Arizona Department of Health website: (Arizona Department of Health Services 2012); http://www.azdhs.gov/phs/oids/epi/disease/cocci/index.htm.

Coccidioidomycosis is a common cause of community-acquired pneumonia in the southwest endemic areas.[122,123] Cases classically are identified in construction workers, archaeologists, or military personnel. However, dust storms (haboobs) can carry the spores for miles exposing persons with no direct contact with contaminated soil. Cases are identified outside the endemic area in travelers or past residents of the endemic area, often years after exposure. Reports of coccidioidomycosis occurring in otherwise healthy young adults[124] and reports of acquisition of disease outside traditionally defined endemic areas contribute to delays in diagnosis.[125] Coccidioidomycosis also is a threat to laboratory personnel working with the organism outside of biosafety cabinets. African Americans and Hispanics experience a disproportionately higher frequency of disease in some studies. Predictably, coccidioidomycosis is a serious opportunistic infection in immunosuppressed patients, including those with AIDS, transplant recipients, and those receiving immunosuppressive treatment.[126,127]

PATHOGENESIS AND PATHOLOGY

Infection occurs following inhalation of arthroconidia of the mycelial phase of the fungus or reactivation of latent infection during immunosuppression. Person-to-person transmission does not occur and exposure by direct inoculation is rare. Transmission by transplantation of an infected allograft has been reported and causes rapidly progressive disease in the recipient.[128]

In the lungs, the arthroconidia enlarge to form thick-walled spherules, which contain multiple endospores. Spherules rupture releasing endospores, which spread locally and disseminate hematogenously. Cellular immunity and neutrophils both are involved in host defense in coccidioidomycosis.[129] Patients with deficient cellular immunity experience severe progressive forms of coccidioidomycosis.

Coccidioides produces several mixed pyogranulomatous reactions in the tissues. The neutrophil response and caseous necrosis may lead to the development of large abscesses, which often require surgical drainage. Abscesses also may spontaneously rupture or produce fistulas. Tissue and blood eosinophilia can be prominent.[130]

CLINICAL FINDINGS

Coccidioidomycosis is asymptomatic in over one-half of cases, and in the remainder, symptoms appear 1 to 4 weeks following exposure. In symptomatic cases, a pulmonary illness is most common. True coccidioidal infections are difficult to diagnose since the symptoms of early infection overlap substantially with those of other respiratory infections. While most immunocompetent patients recover without treatment over a course of several weeks, many do receive treatment. Nevertheless, serious infections occur and in one outbreak following an earthquake 27% were hospitalized and 1.5% died.[131]

Primary Pulmonary Infection

Symptoms develop within a few weeks following exposure, depending on the intensity of the inoculum and the immune status of the patient. Low inoculum exposure in the nonimmunocompromised host usually results in a localized pneumonia, and can be mistaken for bacterial community-acquired pneumonia. Symptoms include pleuritic or dull chest pain, nonproductive cough, headache, fever, and fatigue.[132] Macular rash, erythema nodosum, and erythema multiforme are common and help to distinguish from bacterial pneumonia. A constellation of fever, arthralgia, and erythema nodosum is referred to as "desert rheumatism." Infection is more severe in older persons, those with diabetes, and smokers. Diffuse bilateral pneumonia suggests dissemination or fungemia, often in an immunosuppressed host.

Although resolution is the norm, acute infection can set the stage for chronic progressive, often apical cavitary pneumonia resembling tuberculosis. In acute disease, chest radiographs show patchy infiltrates, often with mediastinal adenopathy. Pulmonary nodules occur in about 20% of cases and thin-walled cavities in 10%, which are usually asymptomatic and clear without therapy (Fig. 134-5). The main CT finding in acute disease is multiple nodules.[133] When the history of coccidioidomycosis is not secure, residual often asymptomatic nodules may be biopsied or surgically removed as they mimic malignancy.[134] Rarely cavities rupture into the pleural space causing pyopneumothorax, bronchopleural fistula, or empyema.

Disseminated Disease

Approximately 1% of patients will have disseminated infection with the most common extrathoracic sites being skin, soft tissue, bone, and meninges.[135] Progressive disseminated disease is, however, reported in nearly one-half of cases occurring in patients with underlying immunosuppression.[136] Disseminated disease may be first recognized years following exposure. Risk factors for disseminated disease include nonwhite race, extremes of age, and pregnancy.[78,137,138] Pulmonary involvement is common in disseminated disease. Chest radiographs usually show diffuse reticulonodular or miliary infiltrates, but focal pulmonary lesions, nodules, cavities, adenopathy, and pleural effusions also may be seen (see Fig. 134-2).

Meningitis is the most common and severe manifestation of disseminated disease and approximately 300 cases are reported in endemic areas per year.[139,140] Patients complain of headache, nausea, vomiting, and confusion. Meningitis carries a poor prognosis and tendency to relapse, despite long-term maintenance therapy. Abscesses may develop in the brain or spinal cord. Hydrocephalus and vasculitis are dreaded complications of meningitis. Coccidioidomycosis can mimic many diseases. Less frequently involved extrapulmonary sites include liver, peritoneum, kidneys, epididymis, prostate, testes, retina, ears, larynx, heart, thyroid, adrenal, and pituitary glands, esophagus, and pancreas.

DIAGNOSIS

Because the clinical diagnosis of coccidioidomycosis can be difficult, specific radiologic and laboratory testing is usually required to establish a diagnosis. A battery of tests including fungal stain, culture, and serology are useful for the diagnosis of coccidioidomycosis.[76–84,141–143] The sensitivity of these methods is affected by the extent of exposure, immune status of the patient, and the type of infection.

Imaging Studies

The radiologic findings of coccidioidomycosis are diverse (Fig. 134-5).[121,144] Pulmonary infiltrates are identified in the majority of patients. Pleural effusions and adenopathy are commonly identified on chest radiographs. Pulmonary nodules and cavities can be seen. Immunosuppressed patients may manifest a diffuse "miliary" pattern. CT scans of the chest are more sensitive, identifying effusions,

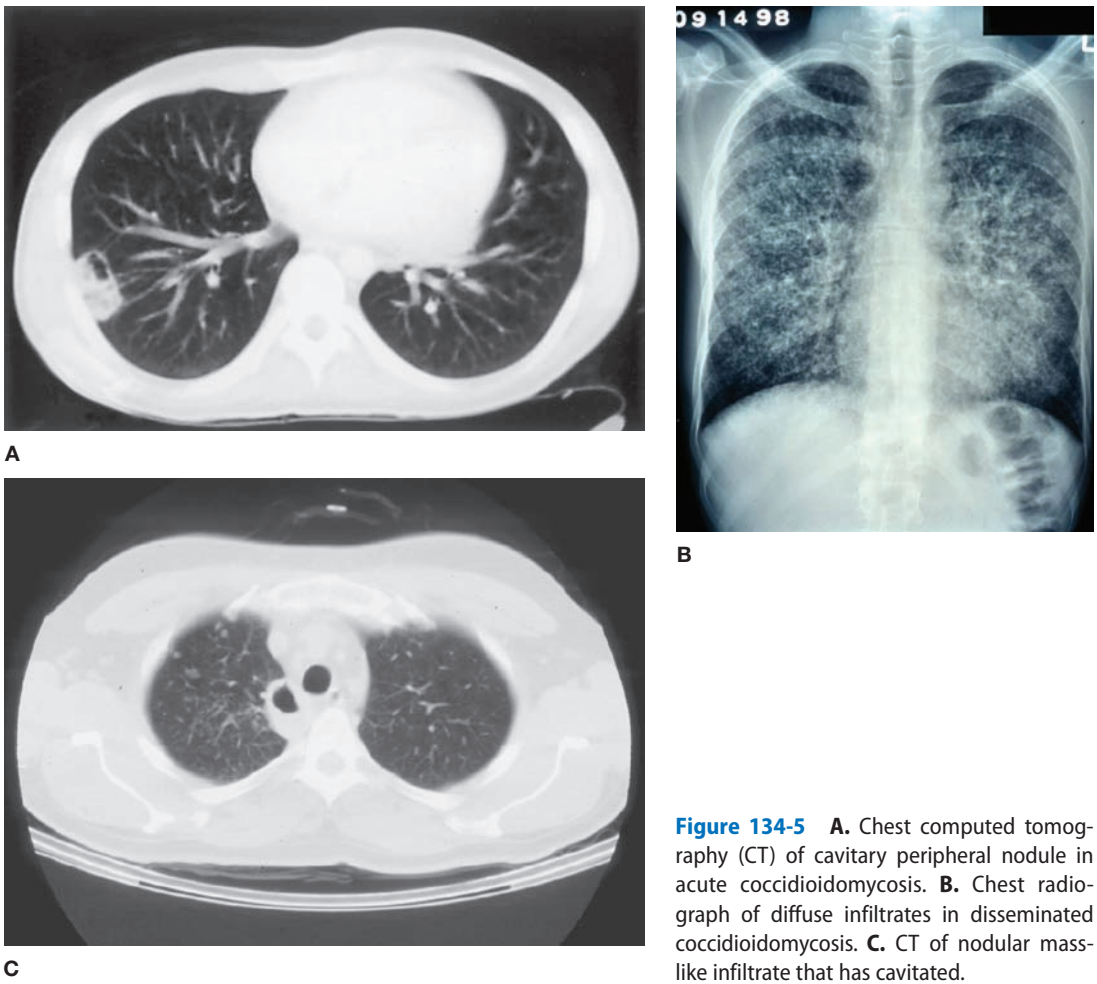

Figure 134-5 **A.** Chest computed tomography (CT) of cavitary peripheral nodule in acute coccidioidomycosis. **B.** Chest radiograph of diffuse infiltrates in disseminated coccidioidomycosis. **C.** CT of nodular mass-like infiltrate that has cavitated.

hilar lymph nodes, micronodular infiltrates, and multifocal ground-glass infiltrates more readily.[133,145] Pulmonary nodules as sequelae of past coccidioidomycosis infection are less than 5 cm in diameter, but can be confused with malignancy. Nodules do not calcify; rather, they may evolve into thin-walled cavities by shelling out the nodule contents. These cavities can predispose to secondary infection, pneumothorax, hemoptysis, and mycetoma. Lymph nodes and nodules exhibit varying degrees of uptake on PET scans.

Serology

Serological tests are useful and the most widely used method of diagnosis.[135] Serology is positive in 90% of clinically recognized cases, and the magnitude of response correlates with the extent of infection. Serology may be negative early in the course of infection, in asymptomatic cases, and those with mild illness, including thin-walled cavities and solitary nodules. Immunocompromised patients may have negative serology due to inefficient antibody production[146] and repeat testing is often performed. Sensitivity may be increased by concentrating the specimen, as is done in some reference laboratories.[81] Detection of antibody in CSF is useful for diagnosing meningitis.[140]

The immunoglobulin M (IgM) response can be measured by enzyme immunoassay (EIA), tube precipitation (TP), or agar gel diffusion (IDTP) and is positive in the majority of cases by the end of the first month of the illness, fading over the next 6 months.[81,147] EIA is emerging as the more commonly utilized initial test. False-positive results are a possibility and an isolated positive EIA IgM warrants further clinical assessment and diagnostic testing.[148,149] Blair et al.[146] found EIA was positive in 87% of healthy patients with coccidioidomycosis compared to 67% of immunosuppressed patients. Sensitivity improved to 95% and 84%, respectively when sequential and confirmatory tests were employed. Serology may be falsely negative in about one-quarter of solid-organ transplant patients with coccidioidomycosis, and two-thirds to three-quarters if positive EIA results alone are not considered diagnostic.[143]

The immunoglobulin G (IgG) response measured by EIA, complement fixation (CF) or immunodiffusion (IDCF) follows the IgM and peaks during the fourth month of illness, and then slowly fades. The commercial IgG EIA tests are commonly used and are generally highly sensitive and specific. Nevertheless, a positive IgG EIA should be sent to specialized reference laboratories for confirmation and quantification. The IgG IDCF quantitative testing or traditional CF testing is often performed as the confirmatory test and provides prognostic information with higher titers (>1:16) suggesting dissemination. However, this finding is neither sensitive nor specific for dissemination, especially in the setting of meningitis.[78] Antibody titers decline with treatment, assisting in monitoring therapy and identifying relapse. Serial testing is also useful in patients who are not receiving therapy, as rising titers suggest progressive infection and support evaluation to exclude dissemination.

Antigen Detection

Two studies highlight the clinical utility of testing *Coccidioides* galactomannan antigenemia and antigenuria in predominantly immunocompromised patients with moderately severe to disseminated disease. In this severely ill patient population, antigenemia can be

detected in up to 71% of urine specimens and 73% of EDTA-treated serum samples.[83,84] Cross-reactivity with other endemic fungi, can occur and clinical context is needed for accurate diagnosis.

Cytology, Histopathology, and Culture

Sputum can be useful in diagnosis when produced. Other respiratory secretions may improve sensitivity. As such, cytology was positive in 35% of culture-positive bronchoscopy specimens from patients with pneumonia, (diffuse infiltrates, 46% and focal infiltrate, 26%).[83,150,151] In a study of severe diffuse pneumonia in patients with AIDS, Papanicolaou smear was positive in 9 or 14 BAL specimens, compared to KOH wet mount in only 3, calcofluor white stain in 2, and culture in 12.[76] Histopathology is positive on needle-biopsy specimens from lung nodules in about one-half of cases. The sensitivity in extrapulmonary lesions has not been reported but presumably is high, except for meningitis.

Interestingly, cultures of respiratory specimens are infrequently positive in patients with acute pneumonia. The sensitivity of culture for diagnosis is uncertain because culture positivity is often a basis for inclusion in the published studies. Nevertheless, culture of lung specimens is more sensitive than cytology but can take weeks to identify and thus cannot be relied upon for a rapid diagnosis.[152] Cultures of skin or bone lesions are positive in the majority of cases of disseminated coccidioidomycosis. However, blood, urine, and CSF cultures are frequently negative, complicating the diagnosis. As such, serology and antigen testing play an important complimentary role in the diagnosis of ill patients.

Polymerase Chain Reaction

Once *Coccidioides* is cultivated in the laboratory, confirmation typically occurs via chemiluminescent DNA probe or by DNA sequencing methods shortening the time to diagnosis. In addition, a few reference laboratories, are applying PCR and real-time PCR methodology to clinical samples.[153] Binnicker et al.[141] applied real-time PCR to 66 fresh tissue specimens that yielded 93% sensitivity and 98% specificity compared to culture. The assay was sensitive enough to be used on paraffin-embedded tissue. Subsequently, clinical sensitivity was shown to be 56% versus 44% for fungal culture, similar to the sensitivity of fungal culture in past studies.[141,142] Molecular methodologies hold great promise for the future of fungal diagnostics.

Skin Test

Skin test reagents are not readily available and have not been used clinically for several years. However, *Coccidioides immitis* Spherule—Derived Skin Test Antigen (Spherusol) is FDA approved (FDA 2012) but not offered for commercial use as of 2013; (http://www.fda.gov/BiologicsBloodVaccines/Allergenics/ucm266802.htm). Any role for this skin test in clinical practice remains undefined.[154]

■ TREATMENT

Guidelines for treatment are continually being updated.[155,156] Most infections are asymptomatic or self-limited pulmonary infections, and require no treatment in the absence of immunosuppression. Before withholding treatment, however, patients must be evaluated carefully for the extent of disease and evidence for extrapulmonary dissemination. In rare cases, a bone scan to identify skeletal lesions or lumbar puncture to assess CNS symptoms may be indicated. In patients in which treatment is withheld, radiographic and clinical follow-up at 4 to 6 weeks and then at 3- to 6-month intervals for 2 years is recommended to identify evidence for progressive infection.

Indications for Treatment

Treatment of coccidioidomycosis is considered below according to the type of pulmonary involvement.

Acute Uncomplicated Pneumonia Some physicians recommend treatment to prevent long-term complications, but most recommend observation without therapy. Circumstances warranting treatment include symptoms for 4 to 6 weeks, immunosuppression, other chronic diseases or conditions affecting recovery from the acute infection, such as diabetes, COPD, pregnancy, age greater than 55 years, African American or Filipino descent, and severity of illness. Indicators of severe illness include weight loss greater than 10%, intense night sweats for more than 3 weeks, infiltrates involving more than one-half of one lung or portions of both lungs, prominent or persistent hilar adenopathy, inability to work, and symptoms persisting for more than 4 to 6 weeks.[156]

Persistent Cavities or Nodules Approximately 10% of patients with acute pulmonary coccidioidomycosis will develop residua of the acute infection (nodules or cavities), which often are asymptomatic, and require no therapy. However, these residua can "reactivate" and symptoms may include pain, cough, hemoptysis, and bacterial superinfection. Antifungal therapy is appropriate in patients with persistent symptoms or rising serologic titer. Treatment also is recommended in those with lesions contiguous with the pleura, or exhibiting progressive enlargement.[156] Biopsy of nodules may be required if a history of infection is not secure to exclude malignancy. For cavities that rupture into the pleural space, drainage is needed. Surgical drainage or in some cases thoracostomy is appropriate. Like chronic pulmonary histoplasmosis, antifungal treatment is recommended in patients with chronic progressive fibrocavitary disease.

Diffuse Pulmonary, Extrapulmonary or Disseminated Treatment is indicated in all patients with diffuse pulmonary or disseminated coccidioidomycosis. More controversial is the role of antifungal therapy in the immunosuppressed host with serological, radiographic, or clinical evidence of prior coccidioidomycosis. Death from coccidioidomycosis was reduced by antifungal therapy used as secondary prophylaxis in solid-organ transplant patients with a history of symptomatic coccidioidomycosis up to 5 years before transplantation, supporting a recommendation for preventive treatment.[157]

Selection of Antifungal Agents

Fluconazole is used in the majority of outpatients treated for pneumonia. Consultation may be warranted for complicated patients. Amphotericin B (0.7 to 1.0 mg/kg/d) is indicated in severe cases, immunosuppressed patients with diffuse pneumonia, and during pregnancy. The lipid formulations are recommended in patients who cannot take the standard formulation because of underlying renal disease or risk for amphotericin-induced nephrotoxicity.[155,156]

Itraconazole and fluconazole are effective in milder nonmeningeal cases. In patients with bone disease, outcome was better with itraconazole.[158,159] Recommended dosages for fluconazole and itraconazole are 400 mg/d for nonmeningeal disease. Drug interactions and inadequate drug exposure occur more often with itraconazole than fluconazole.

Treatment for meningitis is less effective than for other forms of coccidioidomycosis. Fluconazole 400 to 1000 mg per day is recommended because of excellent penetration into CSF.[156,160] Some physicians also administer amphotericin B intrathecally. Consultation with an infectious diseases or pulmonary physician who specializes in coccidioidomycosis treatment is prudent. Treatment for coccidioidal meningitis is lifelong. Response to therapy must be documented.

Newer Antifungal Agents

The newer triazoles exhibit in vitro and in vivo activity against *Coccidioides* and there are a few reports of successful treatment with posaconazole and voriconazole, including cases with meningitis.[161]

Because of poor in vitro activity and inconsistent results caspofungin is not currently recommended.

Duration of Therapy

In patients with acute pulmonary coccidioidomycosis, up to 3 months of therapy may be sufficient. Patients should be re-evaluated before treatment is stopped to identify evidence for chronic infection or extrapulmonary dissemination, in which case treatment should be continued for 12 to 18 months or longer.[156] Treatment should be continued indefinitely for patients with meningitis or those with severe underlying immunodeficiency states.

Adjunctive Surgical Therapy

Surgical debridement or resection of infected tissue often is necessary as an adjunct to antifungal therapy. Chronic foci of pulmonary necrosis or cavitation may require resection to prevent progression or relapse. Hydrocephalus may require surgical or percutaneous intervention. Soft tissue, joint, or bony abscesses may require drainage or debridement.[159]

Adjunctive Steroid Therapy

Although not routinely used, corticosteroid therapy plays a limited role as adjunctive therapy in coccidioidomycosis. In coccidioidomycosis, an intense eosinophilic pneumonia can occur resembling a hypersensitivity reaction and clinical improvement has been noted with concomitant steroid therapy.[130] Steroids may also be of utility as adjunctive therapy in coccidioidal IRIS.

■ PREVENTION

Recommendations exist for the prevention of coccidioidomycosis in high-risk occupations.[162] Patients with diseases that impair cellular immunity probably should avoid activities involving dust or soil, areas experiencing active outbreaks, and the desert during dry and windy periods. Antifungal prophylaxis for high-risk patients is not recommended outside secondary prophylaxis for organ transplant recipients, however, some clinicians have questioned this strategy in the era of biologics. Some clinicians would recommend screening for coccidioidomycosis by chest radiograph and serology before initiating TNF-α inhibitor therapy, and treatment of those with positive results.[127] Efforts to develop a vaccine to prevent coccidioidomycosis in humans have been unsuccessful to date.[163]

BLASTOMYCOSIS

Blastomycosis is the least common of the endemic mycoses.[4] Although recognized in immunocompromised individuals, in whom manifestations are more severe, it is less common than histoplasmosis or coccidioidomycosis in this setting. Unfortunately, the diagnosis is often overlooked until late in the course of the disease[164,165] leading to delayed treatment and potentially poor outcome.

■ MYCOLOGY

B. dermatitidis is a thermally dimorphic fungus–producing mycelia with 2 to 10 μm dumbbell-shaped conidia at 25°C and doubly retractile, broad-based budding yeasts varying in size from 8 to 15 μm at 37°C (Fig. 134-1). While *B. dermatitidis* mycelia may be grown from a primary specimen in less than 2 weeks, final identification may require several weeks including the thermoconversion of the mold form into yeast. Definitive identification is made using DNA probes or exoantigen tests.

■ EPIDEMIOLOGY

B. dermatitidis is found in microfoci, often near waterways, that are enriched with animal excreta. The endemic area for blastomycosis overlaps with that of histoplasmosis for the most part, except that blastomycosis area stretches further north into northern Minnesota, northern Wisconsin, Canadian provinces adjacent to the great lakes and the areas surrounding St. Lawrence Seaway in New York and Canada (Fig. 134-1). Outside North America, blastomycosis is most common in Africa. Fewer cases have been reported from Central and South America and Western Europe. The organism has been isolated from soil in areas inhabited by farm animals and from beaver lodges or dams. Decaying organic matter enhances its growth in the environment. Most cases occur sporadically in endemic areas. Infection usually occurs in the setting of outdoors activity and near waterways.[166] Few point source outbreaks have been reported where most patients present with an acute illness after exposure to contaminated excavation sites and in association with outdoor activities such as hunting, camping, or canoeing in wooded or swampy environments.[167]

■ PATHOGENESIS AND PATHOLOGY

Pulmonary disease follows inhalation of conidia and often is accompanied by hematogenous dissemination. Neutrophils are first recruited to sites of infection, followed by lymphocytes. Cellular immunity plays a lesser role in host defense in blastomycosis than in histoplasmosis, but disease is more severe in immunosuppressed individuals.[108,168]

Pathologically, blastomycosis is characterized by granuloma formation with central microabscesses, so-called pyogranulomas, but not by caseation as seen in histoplasmosis or tuberculosis. Histological changes in the skin may resemble those of squamous-cell carcinoma or keratoacanthoma. Calcification is uncommon.

■ CLINICAL MANIFESTATION

Following exposure, the incubation period ranges from 21 to 106 days with a median of 45 days.[104] As the portal of entry, lungs are the most commonly affected organs in blastomycosis.[169,170] The majority of infected individuals are either asymptomatic or manifest a mild self-limited illness. The typical patient is a middle aged man with history of outdoor activity. The disease is rarely seen in children.

Most patients are otherwise healthy with no underlying systemic or pulmonary illnesses.[164,171]

Pneumonia

Acute pulmonary blastomycosis is commonly seen in the setting of an outbreak. Symptoms are abrupt and most commonly include cough productive of purulent sputum, fever, night sweats, dyspnea, chest pain, weight loss, myalgia and occasionally hemoptysis.[164,165,172] The illness is often confused with bacterial community–acquired pneumonia,[2] and the diagnosis of pulmonary blastomycosis is suspected only after the patient's symptoms fail to respond to antibacterial therapy. As a result the proper diagnosis is usually delayed. In one series it took more than 30 days from presentation to a physician to diagnosis in 43% of the cases. Only a quarter of the patients were diagnosed within a week of their presentation.[164,165] Most common radiographic findings in acute pulmonary blastomycosis include lobar consolidation, air bronchogram, and nodular infiltrates (Fig. 134-6).[101,171,173] Cavities may also be seen within areas of consolidation.[171] In contrast with histoplasmosis, mediastinal and hilar lymphadenopathies seem less prominent in pulmonary blastomycosis.[171] Similarly calcified lymph nodes and pleural effusions are seldom seen on chest imaging of patients with acute blastomycosis.[174] The abnormalities do not seem to follow any particular distribution, involving any lobe on one or both sides of

A

Figure 134-6 **A.** Chest radiograph of infiltrate resembling bacterial pneumonia in acute blastomycosis. **B.** Computed tomography scan showing lobar infiltrate. **C.** Chest radiograph of diffuse infiltrates associated with acute respiratory distress syndrome. **D.** Chest radiograph of cavitary blastomycosis.

the chest.[173,174] Military nodules and interstitial infiltrates are often in severe blastomycosis with ARDS.[173]

Chronic pulmonary blastomycosis is often seen in sporadic cases. It is clinically similar to reactivation tuberculosis. Fibrocavitary disease, as seen in histoplasmosis and coccidioidomycosis, is uncommon in blastomycosis, occurring in only less than 10% of such cases. The onset of the illness is gradual. Symptoms include cough productive of purulent sputum, fever, night sweats, malaise, and weight loss.[175] Mass-like lesions, nodules, and adjacent adenopathy can be seen with chronic pulmonary blastomycosis.[171] The lesion is often mistaken for lung cancer triggering a needle biopsy especially if the patient smokes cigarette. Depending on the radiographic findings, the illness can be mistaken for tuberculosis (upper lobe cavitary disease) or lung cancer (lung mass). The illness tends to progress if untreated.

Acute Respiratory Distress Syndrome

In up to 10% of the patients with acute pulmonary blastomycosis the illness rapidly progresses leading to acute respiratory distress syndrome with bilateral disease and severe hypoxia requiring mechanical ventilation and sometime vasopressor support for shock.[176] This presentation carries a grim prognosis, with up to 60% mortality rate.[165] The delay in recognition and diagnosis of the illness and consequent delay in proper treatment are often blamed for this poor outcome. Pathology is characterized by dense consolidation, microabscesses, hyaline membranes, and alveoli packed with yeast forms. Severe pulmonary blastomycosis is more often seen in immunocompromised patients,[177] such as those with AIDS,[178] transplant recipients,[108,168] patients receiving treatment with TNF inhibitors.[179] Extrapulmonary dissemination and mortality rates are higher. Diabetes mellitus also seems to be a risk factor for more severe blastomycosis.[165]

Disseminated Blastomycosis

Extrapulmonary dissemination is a hallmark of blastomycosis.[171,180] Dissemination is seen in up to third of cases, more likely with chronic than acute disease. Skin lesions are the most common manifestations, followed by bone, genitourinary, and CNS involvement. Cutaneous or bone lesions in a patient with community-acquired pneumonia who resides in the endemic area, should rise the suspicion for blastomycosis. Dissemination to the CNS occurs in 5% to 10% of cases, more commonly in patients who are immunocompromised, and is associated with a mortality rate approaching 20%.[181] Other sites include the sinuses, ears, eyes, thyroid gland, heart, pericardium, pancreas, spleen, liver, and adrenal glands.

Immunocompromised Host

Blastomycosis is more aggressive in this group, with a mortality of nearly 30%.[177] CNS involvement or ARDS was reported in 5% to 10% of cases. Except for the higher mortality rate and a tendency to relapse, the clinical findings are similar to that in nonimmunocompromised individuals.

■ DIAGNOSIS

The diagnosis of blastomycosis is often delayed.[164] The delays is usually due to the nonspecific nature of the clinical presentation confusing the diagnosis with community-acquired bacterial pneumonia in the case of acute pulmonary blastomycosis[2] and lung cancer or tuberculosis in chronic infection.[182] This is particularly true when the disease is limited to the lungs. The presence of associated extrapulmonary manifestations (skin or bone) usually raises the clinical suspicions.[164] Limitations in the available diagnostic tests also contribute to the difficulties in making a timely and accurate diagnosis of blastomycosis. Until recently the diagnosis of blastomycosis relied heavily on microscopic examination and culture of respiratory specimen. Currently, the detection of *Blastomyces* antigen detection has proven useful for rapid diagnosis of pulmonary and disseminated blastomycosis.[99] Sensitivity may be achieved by use of several diagnostic methods.[85,99–102,104,171,180,183]

Culture

Definitive diagnosis of blastomycosis requires the isolation of the organism by culture. Sputum, tracheal aspirates, and skin lesions exudates are appropriate for fungal culture. BAL fluids or bronchial washings may improve the yield in patients who cannot produce adequate sputum samples and when sputum culture is negative.[102,171] While positive in the vast majority of patients (>85%), culture is time consuming, requiring up to 4 weeks for the final identification of the organism. The organism may grow within one to 2 weeks of inoculation; however, specimen with lower fungal burden may requires up to 4 weeks to grow the fungus. Confirmation of the organism also requires either thermoconversion into the characteristic yeast or the use of DNA hybridization probe. Therefore, one cannot rely on fungal culture to make a timely diagnosis and treatment decisions in symptomatic pulmonary blastomycosis.

Cytology and histopathology

A timely diagnosis of blastomycosis can be made by visualizing the organism in respiratory specimens or sites of extrapulmonary involvement using calcofluor white stain, KOH wet mount cytology or histopathology. The characteristic yeast is a round to oval multinucleated cell, 8 to 15 μm in diameter, with a thick retractile cell wall and single broad–based bud. The yield of cytology is quit variable, ranging from 38%[171] to 97%,[184] depending on the quality of the specimen being examined, the stains used and the experience of the cytopathologist.[102] The yield seems to improve when BAL specimens are used and when culture and cytology are applied to the same specimen.[183] Histopathologic examination of biopsy specimen has been reported to yield the diagnosis in up to 81% of patients.[171,185] Invasive procedure may be required either by performing bronchoscopy or surgical biopsy, or percutaneous needle aspiration to collect the diagnostic specimen used in cytology, potentially adding to the morbidity.

Antigen detection

Blastomyces antigen can be detected in serum, urine, and BAL fluid, providing a noninvasive method for rapid diagnosis. The test is positive in 80% to 93% of patients[85,99,100,171,186] with 98% specificity in patients without endemic mycoses. Nearly complete cross-reactivity occurs in patients with histoplasmosis.[99,100] The sensitivity is highest in patients with acute pulmonary disease and those with severe and disseminated blastomycosis.[99,186] Blastomyces antigen can also be detected in BAL fluid, adding to the diagnostic yield of bronchoscopy in pulmonary blastomycosis.[85,187] Antigen also can be detected in CSF of those with CNS involvement. The current quantitative version may be followed as a mean of assessing the response to treatment similar to the Histoplasma antigen test.[86] A high degree of cross-reactions has been reported with histoplasmosis, paracoccidioidomycosis, and penicilliosis marneffei.[99,100,171,186]

Serology

Unlike histoplasmosis and coccidioidomycosis, currently available tests for blastomyces serology are of little use in the diagnostic workup of blastomycosis because of low sensitivity and specificity. The sensitivity of immunodiffusion ranges between 29% and 64% and that of the complement fixation between 25% and 43%.[88,102,188,189] EIA using the blastomyces A antigen provides better sensitivity (77%–83%) but significant cross-reaction occurs with histoplasmosis.[104,190]

Molecular testing

Molecular assays have been attempted for the detection of *Blastomyces* with limited success. Recently a real-time PCR method

was used on culture isolates as well as primary clinical samples with high sensitivity and specificity; 12 out of 14 (86%) confirmed clinical specimen tested positive in this PCR assay. The test also distinguished between Histoplasma and Blastomyces isolates with no cross-reactivity.[93] This test seems promising and needs to be validated in a larger scale with diverse clinical presentations.

TREATMENT

Although patients with self-limited pulmonary blastomycosis have been reported,[191,192] current guidelines recommend treatment to all patients diagnosed with blastomycosis because of the high likelihood of progression or recurrence of the infection if untreated.[156,193]

Indications for Treatment

Treatment is indicated in all patients with diffuse pneumonia, disseminated disease, underlying immunosuppression, or persistent symptoms more than a month following acute infection. In some cases of acute pneumonia, the course is self-limited and resolves without treatment. Some authorities recommend treatment for all cases, but if observation is under consideration, the following conditions should be met: mild illness and absence of immunosuppression or extrapulmonary dissemination. Furthermore, such patients should be followed carefully for several years for evidence of progression or dissemination.

Whether pregnancy alters the course of infection in the mother is unknown, but there is risk for transplacental transmission to the fetus. Treatment of the mother may reduce the risk for transmission to the fetus. Amphotericin B is recommended as the triazoles are contraindicated because of embryo toxicity and teratogenicity.

Selection of Antifungal Agent

There are no published randomized, blinded studies comparing different regimens for the treatment of blastomycosis. Itraconazole is recommended for most patients with pulmonary blastomycosis with over 90% success rate in mild-to-moderate disease.[194] The recommended dose is 200 mg three times a day for three days followed by 200 mg twice a day for at least 6 months. A longer course is recommended for immunosuppressed patients, those with bone disease, and those who relapse after shorter duration of therapy.

Fluconazole is less effective than itraconazole for blastomycosis[195] and therefore is not recommended. However, fluconazole can be used, at high doses (800 mg/d) in patients who cannot tolerate itraconazole.[196]

Amphotericin B (0.7 to 1.0 mg/kg/d) is recommended for patients with severe pulmonary blastomycosis and those with CNS disease.[193] Response to amphotericin B ranges from 85% to 90%.[197,198] Amphotericin B is usually used until clinical improvement (1–2 weeks) and is followed by itraconazole for the remainder of the treatment course. Lipid formulations of amphotericin B tend to be the first line therapies due to their safety profile.

Despite antifungal therapy, the mortality rate of blastomycosis-associated ARDS is still very high (50%–89%).[176,189,199] Corticosteroids, in addition to amphotericin B, have been used successfully to treat blastomycosis-associated ARDS in few reported cases.[199,200]

Newer Antifungal Agents

Voriconazole and posaconazole are active against *B. dermatitidis* and effective in a murine model of blastomycosis. Neither has been studied in humans, but there are anecdotal reports of successful use of voriconazole for blastomycosis.[181,201] The echinocandins showed variable activity in vitro but have not been studied in animal models or humans, and are not recommended.

Duration of Therapy

Treatment should be continued for at least 6 months[156,193] until clinical and laboratory findings have normalized including antigen levels in urine and serum, and radiographic abnormalities have resolved or at least stabilized to represent residual healed lesions. Some experts recommend chronic maintenance treatment for patients with AIDS or other underlying immunosuppressive conditions. Experience in AIDS is insufficient to assess the safety of discontinuation of maintenance with HAART. If maintenance therapy is stopped, the patient should be followed clinically for relapse, and antigen levels should be monitored. Treatment should be resumed if CD4 counts decline below 100 cells/mm^3 or antigen levels increase.

CHAPTER 135

Pneumocystis Pneumonia

Stanley I. Martin
Jay A. Fishman

Despite widespread use of effective antimicrobial prophylaxis in susceptible immunocompromised patient populations, *Pneumocystis jiroveci* remains an important opportunistic pathogen. The incidence of *Pneumocystis* pneumonia (PCP) has decreased with the appropriate deployment of antimicrobial prophylaxis in susceptible hosts and with the advent of highly effective antiretroviral therapy (HAART) in HIV-infected individuals. PCP remains, however, an important syndrome in HIV infection in the developing world with high mortality. *Pneumocystis* also impacts the growing population of immunocompromised individuals following organ and hematopoietic stem cell and bone marrow transplantation, and with the broader use of immunosuppressive therapies in connective tissue, cancer, and immune disorders. The change in nomenclature this past decade, renaming of *Pneumocystis carinii* as *P. jiroveci*, reflects knowledge about the organisms responsible for this syndrome in different host species. This change has generated significant controversy among scientists, clinicians, and journal editors. Advocates and detractors alike agree that no matter the species name, *Pneumocystis* pneumonia or PCP should continue to be used to describe disease caused by this organism in humans.

HISTORY AND BACKGROUND

The cyst form of *Pneumocystis* was first described in 1909 by the famous parasitologist, Chagas and in 1910 by his colleague Carinii, and was described as a parasite and part of the life cycle of *Trypanosoma cruzi*.[1] The organism was first associated with pulmonary infection in rats by Delanoe and Delanoe but was not recognized in humans until 1942 (Van der Meer and Brug) and was not associated with human disease until 1952 (Vanek and Jírovec) when it was found in association with "plasma cell interstitial pneumonitis" among malnourished children and neonates.[2] Small epidemics of plasma cell interstitial pneumonitis had been noted in children in orphanages in Europe in the 1930s and following World War II and the Vietnam War. In the 1950s, recognition of congenital immune deficiencies and the development of immunosuppressive therapies identified new hosts for PCP. At that time, PCP was recognized in patients receiving corticosteroids and chemotherapeutic drugs and in immunosuppressed rats receiving corticosteroids.

The increasing incidence of PCP led to epidemiologic and therapeutic studies of the disease by the Centers for Disease Control (CDC) in the 1970s, based on the provision of the sole therapeutic agent available at that time (pentamidine). Clusters of *P. carinii* were reported at a variety of clinical oncology and transplant centers. However, the development of pyrimethamine, sulfadoxine, and of trimethoprim (TMP) and sulfamethoxazole (SMX) for the treatment and prevention of *Pneumocystis* infection greatly reduced the occurrence and the morbidity of the infection. These agents are now generally used in a fixed combination (TMP-SMX, or cotrimoxazole). *P. carinii* became known the world over as being the first disease-defining illness associated with AIDS in the 1980s, causing over one-fourth of community-acquired pneumonias in HIV-infected persons and more than 200,000 cases of PCP since 1979. What was once an obscure, poorly understood opportunistic disease, became a common clinical entity in a matter of a decade as a result. By the mid-1990s genetic diversity among isolates of *Pneumocystis* from different host species had been described suggested that the organism was a fungus rather than a parasite and that there was host species specificity. The basis of that specificity (i.e., receptors, nutritional requirements) remains unknown. The organism causing infection in humans was renamed *P. jiroveci* after the Czech parasitologist, Otto Jírovec.[3]

STRUCTURE AND LIFE CYCLE

In humans and animals, three forms of the organism have been identified: trophozoite, cyst, and sporozoite (or intracystic bodies) (Fig. 135-1). The trophozoite, 2 to 5 μ in diameter, is either round or sickle-shaped and contains a nucleus, mitochondria, and vacuoles. It also includes pseudopodia and filopodia, used in limited motility. The cyst usually measures between 3 and 6 μ in diameter. Its cell wall consists of three layers, and its cytoplasm contains eight small pleomorphic intracystic oval bodies called sporozoites.[4] Two other cystic forms have been described, but these are probably intermediates including empty or developing cysts (Fig. 135-1). Many small surface projections, or tubular expansions, form a branching network over the surfaces of the cysts and the trophozoites.

In the alveolus, *Pneumocystis* are covered with a variety of glycoproteins derived from both the organism and the host. Specific and

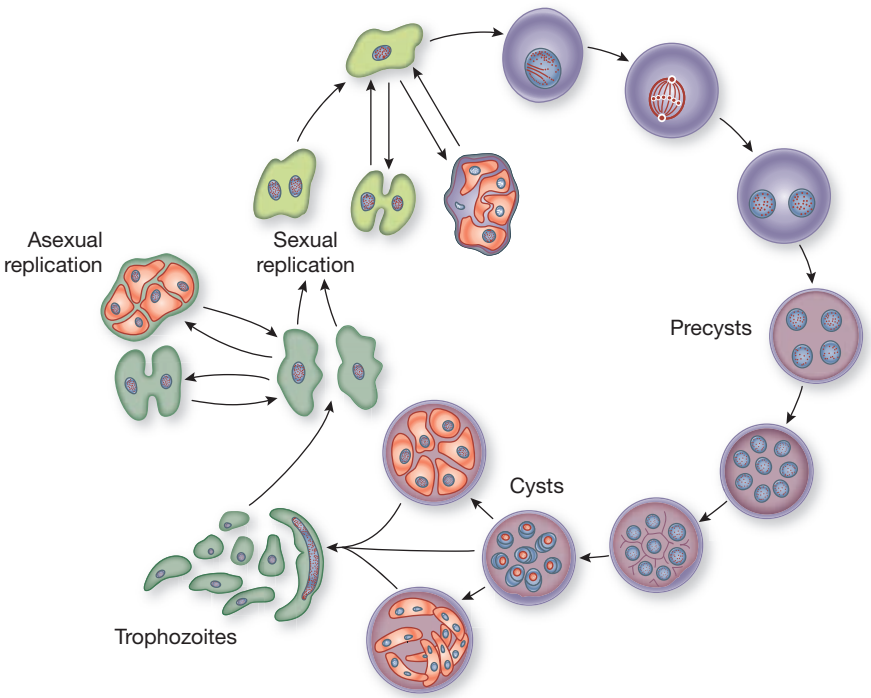

Figure 135-1 The life cycle of *Pneumocystis carinii*.

nonspecific immunoglobulins, albumin, surfactant proteins, laminin, fibronectin, and other serum and lung proteins coat the surface. The organism produces a relatively limited array of surface glycoproteins that share antigenic epitopes. These, and some minor components, are found on both animal- and human-derived organisms. *Pneumocystis* from different species share antigenic epitopes in addition to carrying unique epitopes.[5] The cell wall contains cholesterol but no ergosterol and does not appear to synthesize sterols de novo; this likely accounts for the lack of susceptibility to the azole and polyene antifungal antibiotics.[6] The presence of chitin in the cell wall is controversial. The surface of *P. jiroveci* is carbohydrate-rich with glucose, mannose, and β-1,3-glucan, the latter of which may play a role in phagocytosis of the organism by macrophages and may provide a potential diagnostic and therapeutic target for echinocandin antifungal agents. The surface also contains carbohydrate-binding moieties, which may play a role in attachment to epithelial or surfactant layers.

The life cycle of *Pneumocystis* is incompletely understood (Fig. 135-1). Many of the studies of the life cycle have used organisms derived from infected animals and passaged on a feeder cell layer of epithelial or fibroblastoid cells in tissue culture. Continuous growth has not been achieved in this system, and the human-derived organisms have not been grown consistently in vitro. Success with axenic or cell-free cultivation of *P. jiroveci* has been limited. It is now believed that the sporozoites, or daughter forms, emerge from the cyst to develop into trophozoites. These trophozoites mature to form cysts and then repeat the cycle.[7] This sequence is far from settled, however, and both sexual and asexual intermediate stages have been postulated. It is likely that some differences exist in *Pneumocystis* growth in different hosts and with different immune defects.

Research on *Pneumocystis* has been hampered by the difficulties encountered in propagating the organism in vitro. Studies have been performed on organisms derived from immunosuppressed rodents, which develop PCP in the absence of prophylaxis or respiratory isolation. Researchers have used this model to demonstrate the aerosol transmission of *P. jiroveci*.[8] To this day, unfortunately, cell culture techniques remain useless diagnostically because of the difficulty in culturing the organism from the infected human tissues.

TAXONOMY AND MOLECULAR BIOLOGY

Phylogenetic data support the identification of *P. jiroveci* with the taxonomic kingdom of fungi (*Rhizopoda, Myxomycetes, Zygomycota, Schizosaccharomyces, Neurospora, Candida,* and the red yeasts in various studies), rather than the parasitic kingdom of protozoa. This is based on conserved mRNA sequences and other findings.[9] The presence of separate genes encoding the thymidylate synthase and dihydrofolate reductase of *P. jiroveci*, the presence of a cyst wall rich in β-glucan that stains with periodic acid–Schiff and silver stains, the poorly developed mitochondria, the absence of typical protozoan intracellular organelles, and the airborne spread of infection all support this taxonomic position. The neutral lipid fraction of *P. jiroveci* includes a variety of phytosterols shared by plants and fungi, including *Physarum* species.[10] However, the appearance of the organism with a thick-walled cyst with internal sporozoites and ameboid trophozoites, the absence of ergosterol, susceptibility to antibiotics used in the treatment of protozoan infections (pentamidine, atovaquone, SMX), and the existence of antigenic variation in the major surface glycoprotein (gp120, gpA, MSG) lend credence to the original identification with the protozoa.

Complicating the taxonomy of this organism is the existence of different strains of *Pneumocystis* that have been demonstrated using pulsed-field gel electrophoresis and DNA sequencing.[11] This diversity is greatest between strains infecting different host species, giving rise to the eventual renaming of the organism.[12] It appears that many infections in individuals are often clonal, though multiple strains may coexist in any one single infected person (see below).[11]

P. jiroveci expresses both unique and some common antigens in different host species. Surface antigens have been characterized at the glycoprotein and molecular levels. The MSG represents the main humoral immunogen in the rat model, although other antigens (gp45–55) may have importance in human infection.[13] Several MSG types have been observed simultaneously in single infected humans and animals with monoclonal antibody staining and genetic characterization. The MSG appears to represent a large family of related genes (approximately 50–80), many of which are located in tandem repeated arrays in the subtelomeric regions and may contribute to the generation of the variety of antigenic types. Cross-reactive T cell responses to MSG variants is uncommon and suggests the possibility that *Pneumocystis* utilizes MSG switching to evade human immune responses.[14]

EPIDEMIOLOGY OF INFECTION DUE TO *PNEUMOCYSTIS*

Over the past 60 plus years, PCP has been transformed from a medical curiosity into an important respiratory infection that affects four categories of immunocompromised host: (1) *congenital*, caused by inborn immune defects in antibody-synthesizing capacity and/or the cellular mechanisms responsible for delayed hypersensitivity; (2) *induced*, by immunosuppressive therapy, especially corticosteroids (3) *acquired*, occurring as an identifying opportunistic pathogen in HIV infection or with exogenous immune suppression; and (4) *nutritionally deficient with epidemic infection*, described primarily in susceptible neonates and infants.

P. jiroveci causes pneumonia in persons with a wide variety of underlying immune deficiencies (Table 135-1). Studies performed in immunosuppressed animals and clinical experience indicate that T cell immune defects predominate in individuals with *P. jiroveci* infection. In HIV infection, the progressive depletion of CD4+ T cells heralds the onset of risk for PCP, though CD8+ T cells likely play an important role in responding to *Pneumocystis* infection. Passive transfer of immune CD8+ effector T lymphocytes is protective against PCP in mice.[15] Other immune defects such as neutropenia and hypogammaglobulinemia enhance the risk of PCP by contributing to the overall net state of immunosuppression, and disease may be seen in patients with persistent defects in leukocytes and antibodies, but appears less important for protection than is cellular immunity. Passive immunoglobulin transfer in mice does not have a significant protective effect.[16]

The relative risk of infection with *Pneumocystis* is predictable in most hosts in which infection occurs, including the non-transplant and non-HIV infected populations (Table 135-2). The risk of PCP is greatest in the first 6 months after solid-organ transplantation, after 3 to 6 months of oral corticosteroid therapy (in excess of 15–20 mg prednisone equivalent), and during periods of intensified immune

TABLE 135-1 Conditions Associated with *Pneumocystis* Pneumonia

Acquired immunodeficiency syndrome (AIDS) (without HAART)
Chemotherapy (especially corticosteroids)
Radiation therapy
Organ transplantation
Prematurity
Malnutrition (protein and calorie)
Malignancies (especially hematopoietic)
Congenital immune deficiency diseases (cellular and/or humoral)
Collagen vascular disease
Hematologic disorders
Cushing syndrome
Nephrotic syndrome

TABLE 135-2 Reported Attack Rates for PCP in Non-Transplant Recipients and Non-HIV-Infected Patients Not Receiving Prophylaxis by Underlying Condition

Underlying Disorder	Attack Rate (%)
Acute lymphoblastic leukemia	6.5–42.9
Severe combined immunodeficiency syndrome	27–42
Rhabdomyosarcoma	4–25
Granulomatous polyangiitis (formerly known as Wegener granulomatosis)	3.5–12
Hodgkin's disease	1.3
Collagen vascular disease	<2
Primary or metastatic central nervous system tumor	1.3–1.7

suppression, as with the use of bolus corticosteroids or lymphocyte-depleting antibody therapies for graft rejection.[17] Disease occurring outside this host population or predicted timeframe should suggest an excess epidemiologic hazard or unidentified immune deficiency. PCP has also complicated the syndrome of rapamycin lung, an idiosyncratic syndrome of diffuse pulmonary infiltrates in solid-organ transplant recipients receiving sirolimus-based immune suppression. In untreated AIDS, the risk for PCP increases with the progressive fall of the CD4+ lymphocyte counts to below 200 cells/mm^3 or to less than 20% of the total lymphocyte pool. The correlation with T-lymphocyte numbers is such that the rate of infection nearly doubles with a drop in CD4+ lymphocyte counts from between 100 and 200 to below 100/mm^3.[18] The presence of thrush has also been shown to be an independent predictor of risk for PCP in patients with HIV as has a previous bout of PCP. Rarely, PCP occurs at CD4 counts greater than 200 cells/mm^3 and prophylaxis should be offered to such patients starting around the level at which PCP occurred. The occurrence of PCP infection in persons not in these categories should suggest exposure to infected persons, other immunosuppressive effects (e.g., coinfection with cytomegalovirus (CMV), lymphoma, neutropenia), or in the HIV-infected person, a rapid progression of viral infection with the accompanying decline in systemic immune function.

The spectrum of patients developing PCP has changed with the advent of HAART for HIV infection and the routine use of prophylaxis for most patients with hematologic malignancies and after organ transplantation. Inconsistent use of prophylaxis, however, has been linked to some of the published outbreaks of PCP in solid-organ transplant recipients in recent years.[19] In most HIV-negative, immunocompromised patients, the risk of disease is of the order of 5% to 15%, though the risk following organ transplantation varies with the immunosuppressive regimen and the organ transplanted. The attack rate is highest in the lung and combined lung–heart recipients.[20] The major risk factors for PCP are reflected in a retrospective study of 116 HIV-negative patients with PCP of which 30.2% had hematologic malignancies, 25% were organ transplant recipients, 22.4% had inflammatory disorders, 12.9% had solid tumors, and 9.5% had other conditions. Corticosteroids use was reported in 90.5% of these patients. The median daily dose was 30 mg of prednisone; however, 25% of the patients had received as little as 16 mg/day of prednisone. The median duration of corticosteroid therapy before the diagnosis of PCP was 12 weeks. However, 25% of the patients developed PCP after 8 weeks or less of corticosteroid use.[21] Ultimately, specific immunosuppressive drugs may be less important than the overall net state of immunosuppression that can be engendered by multiple factors (metabolic factors, age, immune cell quantity and quality, viral coinfection, underlying lung disease).

In children, epidemiologic studies suggest that PCP may occur in the setting of concomitant viral infection and may be found in infants who die unexpectedly in the community. Beard et al. demonstrated that different strains of *Pneumocystis* appeared to be present in specimens obtained from infants compared with those from HIV-infected adults. This suggests that different strains circulate among non–HIV-infected infants and in HIV-infected adults.[22] The basis for this difference remains unclear and requires confirmation among larger populations.

The natural reservoir of infection remains unknown, though *Pneumocystis* species are thought to be fairly ubiquitous in nature. Aerosol transmission of infection has been demonstrated in animal models, and clusters of infection have developed in clinical settings. Outbreaks among solid-organ transplant recipients and among HIV patients have been documented in hospital wards.[19,23–27] Molecular typing studies have implied that some of these outbreaks could be due to person-to-person transmission.[19,23,24] *P. jiroveci* DNA has also been detected by polymerase chain reaction (PCR) in the air of hospital rooms, bronchoscopy suites, and clinics used by infected subjects.[28,29] Whether or not these outbreaks are due to person-to-person transmission or some common environmental source remains unclear. These data have led some experts to recommend strict hospital segregation of immunocompromised hosts with PCP and the use of facemask filtering in the clinical setting, but the efficacy or need for these approaches has not been demonstrated. Prophylaxis remains likely the most effective method at preventing infection in any setting where patients may be at risk of disease.

The prevalence of infection with *P. jiroveci* in patients with AIDS prompted a large effort to study the epidemiology of PCP more closely by developing diagnostic serologic tests that might be applied to the general population. Serologic testing reinforced the view that subclinical infection, exposure, or colonization is common. Most people have serologic evidence of exposure by age 4 years.[30] Other studies have uncovered the presence of *Pneumocystis* in the respiratory tract of asymptomatic nonimmunocompromised hosts. One such study found that as many as one in five people may have *Pneumocystis* DNA in bronchoalveolar lavage (BAL) fluid.[31] These data, along with animal models, have supported the possibility of reactivation of previously established infection as being a potential cause of disease in susceptible hosts. However, data regarding outbreaks, evidence that the infection can be eliminated, subsequent infection with distinct genotypes, and the geographic variability in disease, all combine to suggest that alternative modes of transmission besides reactivation of latent disease is predominant.

In HIV patients, a clear correlation with circulating HIV viral loads is not well established. Historically, the rate of PCP in AIDS was halved by the use of zidovudine for the duration of the effective antiviral effect of this agent.[32] More pronounced effects have been observed in individuals who regain immune function for more than 6 months under HAART therapies; such patients may be able to avoid primary prophylaxis. The rate of infection appears to double in men who have sex with men with AIDS when compared with intravenous drug users. In the absence of effective prophylaxis or HAART, more than 80% of AIDS patients are expected to develop PCP.[18] Clinically symptomatic infection may emerge during the weaning of immunosuppressive agents or as a part of the immune reconstitution syndrome seen with HAART in AIDS. This is consistent with the limited inflammatory response generated by the organism in the susceptible host.

CLINICAL PRESENTATION

The hallmark of infection due to *P. jiroveci* is the presence of marked hypoxemia, dyspnea, and cough out of proportion to physical or radiologic findings. In the transplant recipient or the person undergoing corticosteroid therapy, PCP is generally acute-to-subacute in development and often masked by other processes, including allograft rejection, graft dysfunction or secondary infection. In the AIDS

Davis Allen, Jr., New England Deaconess Hospital.)*

patient with a first episode of infection, the evolution is more gradual (often 2–5 weeks) and constitutional symptoms such as weight loss can be prominent. Subsequent infections may evolve more rapidly. In the cancer patient receiving chemotherapy or in the organ or bone marrow–stem cell transplant recipient, the use of corticosteroids, poor lung infection, abnormal pulmonary lymphatics (after heart, lung, or liver transplantation), and neutropenia may contribute to the absence of radiologically apparent disease. The rate of development of clinical infection is exacerbated by the presence of pre-existing lung disease (e.g., cyclophosphamide lung or pulmonary fibrosis) or other infections (e.g., CMV, *Legionella,* mycobacteria) (Fig. 135-2). In the organ transplant recipient, PCP most frequently occurs approximately 2 to 4 months after the initiation of immune suppression or during periods of increased immune suppression (pulsed corticosteroids, antilymphocyte therapies, CMV infection). The incidence and timing of infection vary between institutions, however, and can be dependent on the prophylactic regimens employed. In some series of patients receiving lung or heart–lung transplants the rate of asymptomatic isolation of *P. jiroveci* can be higher than expected, approaching 10% or higher.[33,34]

In AIDS patients without HAART, the presentation of PCP is often complicated by a variety of factors. Prophylaxis with aerosolized pentamidine or subtherapeutic levels of other antibiotics (e.g., dapsone, atovaquone) may delay or alter the presentation of disease and confound diagnostic assays. As in most immunocompromised hosts, coinfection with other organisms may accelerate the progression of disease or alter the radiographic pattern; in particular, CMV, *Histoplasma capsulatum, Legionella* spp., and mycobacterial species may contribute to the constitutional symptoms, hypoxemia, and the localization of pulmonary lesions.

Acute exposure to *Pneumocystis* is rarely documented. In animal models, inoculation of *P. jiroveci* induces a neutrophilic infiltrate that is rapidly (2–3 days) replaced with lymphocytes and macrophages. Similarly, in transplant recipients and despite therapy with cyclosporine, *Pneumocystis* induces lymphocyte- and neutrophil-predominant infiltration into the lungs acutely, followed by macrophage infiltration and clearance of organisms. This contrasts with the macrophage- and neutrophil-predominant infiltrates seen in AIDS patients with acute disease. The lymphocytes are primarily T lymphocytes with normal CD4/8 ratios. Coinfection with CMV and other pathogens will be detected in more than half of *Pneumocystis*-infected patients and likely play a role in the individual immune response of each patient.[21,22] The nature of the immune suppression determines the types of other opportunistic pathogens that coinfect the compromised host and the overall risk of PCP. When cyclosporine began being used widely as an alternative immunosuppressant agent to azathioprine in solid-organ transplantation, the incidence of PCP increased among susceptible transplant recipients.[35] The subsequent development and use of tacrolimus seemed to increase the risk further.[36] The net state of immunosuppression these complex patients experience appears to play a bigger role than any single agent.

EXTRAPULMONARY PNEUMOCYSTOSIS

Pneumocystis was known to cause extrapulmonary disease in the pre-AIDS era, but metastatic infections have been most commonly observed in patients with untreated AIDS. Even in the untreated AIDS population, the incidence of extrapulmonary *Pneumocystis* infection is probably less than 1% of cases.[37] It has been thought that susceptible AIDS patients might be more likely to develop extrapulmonary disease while on inhaled pentamidine prophylaxis since this modality of prevention is largely lung-specific and does not achieve significant systemic drug levels like TMP-SMX. The evidence for this is minimal and difficult to assess with a low incidence of extrapulmonary disease. The diagnosis of extrapulmonary disease is challenging, and clinicians must have a high suspicion to identify infection outside the lungs. Respiratory disease may be minimal or absent in patients with extrapulmonary infection. In addition to the liver and spleen, sites of extrapulmonary disease have included eye, ear, lymph nodes, thymus, skin, mastoids, ascites, gastrointestinal tract and omentum, pleura, kidney, bone marrow, pancreas, and adrenal glands, and it has been reported as a cause of thromboembolic disease. Vasculitis has been reported due to *P. jiroveci* as a cause of ischemic necrosis of the digits and has been associated with granulomatous inflammation on tissue biopsies.[38]

The presentation of extrapulmonary infection is generally a mass lesion with accompanying fever, sweats, and malaise. Visual loss may accompany retinal lesions, hepatitis with liver impairment, and ascites and gastrointestinal tract obstruction with peritoneal and omental lesions. By computed tomographic (CT) scan, many nonenhancing, low-attenuation masses, often with necrosis and/or hemorrhage, may be seen in the liver or spleen (Fig. 135-2). Calcification may occur at the edge of such necrotic lesions during the acute infection, often in the hepatic or renal parenchyma. Histopathology will demonstrate granulomas with giant cells, calcification, or cavities. Distant sites may also contain the same frothy hyaline material seen in the alveoli in pulmonary disease (Fig. 135-3). *P. jiroveci* may be seen adherent to the blood vessel walls with myointimal inflammation and thrombosis. Dual infections at extrapulmonary sites may occur with other opportunistic organisms just like in the lung, including mycobacteria, *Histoplasma*, *Legionella*, other fungi, or common bacteria. Unless superinfection has occurred or splenic rupture or other life-threatening condition is imminent, systemic treatment of multiple small abscesses due to *Pneumocystis* infection should be adequate without surgical intervention.

THORACIC IMAGING

Imaging modalities useful in clinical assessment for PCP include chest radiography, nuclear medicine techniques, and CT scanning.

■ THE CHEST RADIOGRAPH

The chest radiograph plays a central role in the diagnosis of PCP (Figs. 135-4 and 135-5). No radiographic pattern is pathognomonic for *Pneumocystis* infection. PCP presents with hypoxemia and fever without significant sputum production and is more often than not, a diffuse interstitial process on chest radiograph.[39] The radiographic pattern ultimately depends on the patient's underlying or accompanying disease, state of immunosuppression, and duration of infection. Sometimes the chest radiograph is normal despite overt pulmonary disease. More often, the early stage of PCP is manifested by fine, bilateral, perihilar, diffuse infiltrates that progress to an interstitial alveolar butterfly pattern; from the hilar region, the infiltrates often spread to the apices or bases. Despite therapy, this pattern can often be succeeded in 3 to 5 days by progressive consolidation, the appearance of air bronchograms, and complete opacification of the lung fields. Unusual courses and patterns are often observed: nodules, unilateral infiltrates, or even lobar consolidations right from the start (Figs. 135-4 and 135-5). Small pleural effusions may also occur. Distortions in pattern are commonly produced by prior irradiation, drug-induced pulmonary injury, or concurrent infections with other organisms. The patient with recurrent disease may develop chronic interstitial markings, small cysts, or honeycombing on chest radiograph. The distribution of cysts in pneumocystosis, when present at all, is more often diffuse, whereas peripheral or apical bullae are often seen without infection in intravenous drug abusers. Rarely, cavitary disease is seen in the absence of other pathogens; however, *P. jiroveci* can superinfect fungal or mycobacterial cavities.[40]

The use of aerosolized pentamidine for the therapy and prophylaxis of PCP in AIDS created some new problems in the diagnosis and treatment of pneumocystosis (Fig. 135-5). Breakthrough disease in patients receiving aerosolized pentamidine classically presents largely or solely in the upper lobes on chest radiograph. Similar presentations may be seen without pentamidine use, suggesting a predilection of infection for the upper lobes. Pneumothorax is another classic finding associated with PCP. Evaluating this particular complication is challenging, but in AIDS patients may be seen in close to 5%. Most pneumothoraces are spontaneous in nature, but roughly half can also be attributed to mechanical ventilation and complications of other procedures. Underlying cystic disease may be a contributing factor to this phenomenon and it may cause significant morbidity and mortality, particularly in patients already requiring mechanical ventilation.[41]

In lung transplant patients, both rejection of the lung allograft and infection often produce similar abnormal chest radiographs. In the first month after transplant, rejection of the allograft lung will cause radiographic changes in up to 75% of patients. These changes include nodular and interstitial infiltrates in the perihilar area and the lower lobes, which may progress to consolidation. These changes may also occur with infection, of which CMV is not uncommon. CMV may be indistinguishable from PCP or organ rejection without biopsy. After the first month, rejection less often yields radiographic changes (about 25%), and the radiographic findings of infection are more often similar to those of other immunocompromised hosts.

■ NUCLEAR IMAGING

Nuclear medicine scans are generally nonspecific and add little to the diagnosis of pulmonary pneumocystosis. However, a normal scan will generally exclude diffuse pulmonary infection due to *Pneumocystis*. Gallium citrate, technetium, indium-immunoglobulin, white blood cell, and diethylenetriamine penta-acetate (DTPA) scans are abnormal in more than 90% of patients with *Pneumocystis* infection. These may be most useful in following the resolution of infection. Gallium scintigraphy can be entirely normal for patients with opportunistic pneumonia with or without AIDS. Conversely, AIDS patients may have abnormal gallium scans in the absence of other infection. Gallium scans often become abnormal before the radiographic appearance of pulmonary disease. Lymph node uptake alone may indicate the condition formerly referred to as AIDS-related complex (ARC), due to HIV infection. The pattern of lymphoid interstitial pneumonitis (LIP) in children with AIDS is indistinguishable from that of PCP as well.[42] Diffuse pulmonary uptake may indicate occult infection in the asymptomatic patient, which would allow early intervention for therapy or prophylaxis, but the cost of routine gallium scanning for AIDS patients outweighs utility when compared with the judicious use of antiviral or anti-*Pneumocystis* antibiotics based on CD4 cell counts, viral load measurements, or other clinical data, and are generally not used for these reasons.

The role of other nuclear medicine–based imaging scans remains unclear. ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET) scan imaging has been evaluated in a few small series. Abnormal uptake in the lungs has been seen in confirmed cases of PCP and has even been documented prior to the development of other abnormalities on routine chest radiography.[43] Thus, PET scans may be useful as an early diagnostic tool, although lacking the specificity required for the diagnosis and guidance of specific therapy.

■ COMPUTED TOMOGRAPHY AND OTHER RADIOGRAPHIC DIAGNOSTIC TECHNIQUES

Sometimes, early in the disease process, chest CT may demonstrate abnormalities not appreciated on routine chest radiography. Among HIV patients, the most frequent pattern early in the disease process will be a ground-glass opacification in the central/hilar and apical regions of the lungs bilaterally.[44] In non–HIV-infected immunosuppressed patients, the opacification patterns may be more dense and distorting of the underlying lung architecture.[45] Resolution of abnormalities can be quickly appreciated by CT imaging as well in patients receiving appropriate therapy. Other imaging modalities, such as magnetic resonance imaging (MRI) scans and ultrasound imaging are probably better suited defining extrapulmonary lesions such as pneumocystomas occurring in the soft tissues or intra-abdominal organ systems (discussed above; see Fig. 135-2). Their role in isolated pulmonary disease remains undefined.

LABORATORY FINDINGS

A number of nonspecific indicators of pulmonary processes have been used in the presumptive diagnosis of PCP. In general, the patient will have a P_{O_2} less than 60 mm Hg and a respiratory alkalosis. The serum lactic dehydrogenase (LDH) enzyme will be elevated in almost all cases of PCP (over 300 IU/mL). Because LDH is likely a marker of underlying lung injury in PCP, the degree of elevation correlates with underlying hypoxemia and may have prognostic value.[46] Unfortunately, LDH is nonspecific, and should generally be avoided as a diagnostic tool alone in cases of PCP. Lymphoma, hemolysis, other infections, ischemia, and LIP may also raise the LDH level. Respiratory distress and respiratory failure requiring intubation carry a poor prognosis. The marked hypoxemia of PCP is accompanied by a PA_{O_2}–Pa_{O_2} gradient rise; gradients over 30 mm Hg at the start of therapy are associated with a high mortality (and are an indication for the use of adjunctive corticosteroid therapy—see below). Both LDH and the arterial oxygenation gradient will return to normal with successful therapy. Another nonspecific indicator of lung injury in PCP is the angiotensin-converting enzyme (ACE) level (also nonspecific in that it can be elevated by smoking and sarcoidosis, among other causes). KL-6, a mucin-like glycoprotein expressed on pneumocytes and bronchiolar epithelial cells can also be detected in the serum of patients with PCP, but once again is likely a nonspecific marker of pneumonitis in general.[46] While pulmonary function testing may reveal abnormalities in oxygen exchange and compliance in PCP, they are not useful diagnostically in the acute setting.

Recent interest has been garnered by the plasma-based (1,3) β-D-glucan assay. (1,3) β-D-glucan is a polysaccharide monomer found in a number of fungal cell walls including *Pneumocystis* species. It initially gained use as diagnostic assay in other forms of invasive fungal infections including candidiasis, aspergillosis, and fusariosis.[47] Other

Figure 135-5 Atypical pneumocystosis. **A.** Upper lobe pneumonia in an AIDS patient on prophylactic aerosolized pentamidine therapy for a history of *Pneumocystis* pneumonia. The patient had both *P. jiroveci* and *Legionella pneumophila* infections. **B.** Persistent pulmonary infiltrates in a patient undergoing chemotherapy for non-Hodgkin lymphoma. Despite 21 days of therapy for *P. jiroveci,* oxygenation and pulmonary infiltrates failed to improve. An open lung biopsy revealed cytomegalovirus pneumonitis (which responded to therapy with ganciclovir) and drug-induced interstitial fibrosis.

opportunistic fungi, like *Mucor* species and *Cryptococcus neoformans* have little-to-no (1,3) β-D-glucan in the cell walls and the assay has not been useful for these infections. The presence of (1,3) β-D-glucan in *Pneumocystis* cell walls, however, makes this assay an attractive noninvasive laboratory test for PCP. A number of case series have examined the use of the assay and found a high sensitivity (>90%).[48–54] Because β-D-glucan can be found in other fungal infections, the specificity is lower (less than 80%) in an unselected population. False positive assays occur with immunoglobulin and albumin therapies, and after hemodialysis and exposure to gauze. The assay also has limitations as a marker of response to therapy. Small retrospective evaluations have shown that some patients actually experience serum elevations of (1,3) β-D-glucan while on therapy and showing clinical improvement.[55] The utility of this assay in determining prognosis or in therapeutic monitoring is unclear.

Given the ubiquity of the organism in the environment and the finding that the majority of children have detectable antibodies, use of serologic testing in the diagnosis of PCP is not recommended. Serologic testing may be complicated by inadequate antibody production in many immunosuppressed patients producing a lack of specificity and sensitivity in the diagnosis of acute disease.

SPUTUM EXAMINATION AND HISTOLOGIC DIAGNOSIS

Despite advances in imaging and laboratory testing, the gold standard for the diagnosis of PCP remains the identification of characteristic organisms on examination of pulmonary specimens (Table 135-3). The organism cannot be routinely cultured in the clinical laboratory, and thus direct visualization and correct identification are required.

TABLE 135-3 Diagnostic Techniques for *Pneumocystis jiroveci*

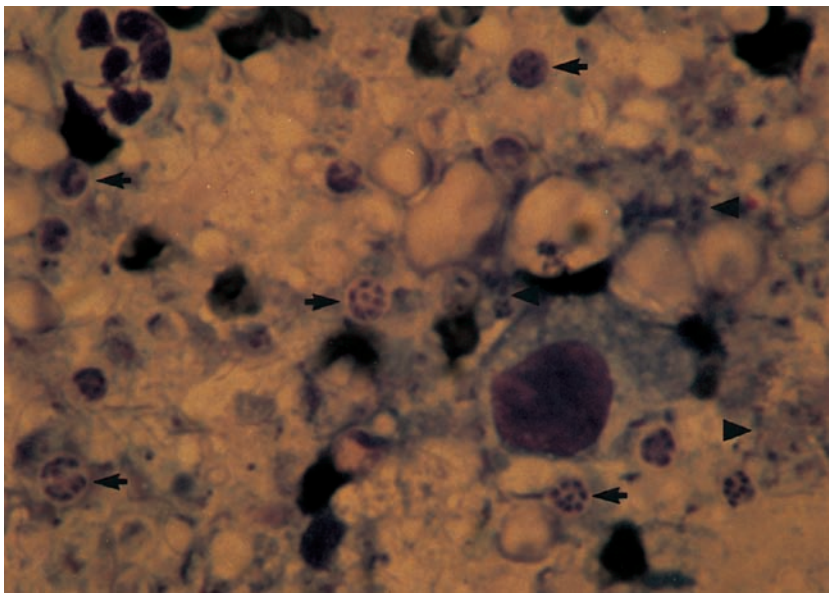
Technique	Yield	Complications	Comments[a]
Routine sputum	Poor	Rare	Routine cultures needed
Induced sputum	30–75%	Rare	First choice; excellent in AIDS
Transtracheal aspiration	Fair (with experience)	Common: bleeding, subcutaneous air	Rarely worthwhile
Bronchoalveolar lavage (BAL)	>50% (>95% in AIDS)	Bleeding, aspiration fever, bronchospasm	Wedged terminal BAL with immunofluorescence
BAL/brushing	As for BAL alone	As for BAL	Not useful for *P. jiroveci*
BAL/transbronchial biopsy	>90% (all patients)	See BAL; pneumothorax	Impression smears; cultures/pathology
Open lung biopsy	>95% (all patients)	Anesthesia, air leakage, altered respiration, wound infection	"Gold standard" noninfectious/infectious processes; large sample
Needle aspirate	≤60%	Pneumothorax, bleeding	Best in localized disease

[a]*All samples should be cultured and stained for bacteria (including mycobacteria), fungi, and viruses, and examined for protozoa. Optimal procedures will depend on the locally available expertise.*

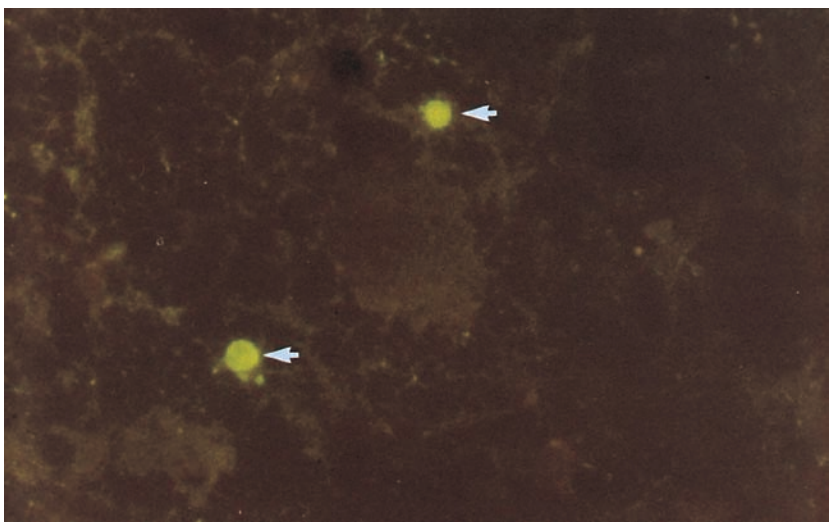
The methods used in making the diagnosis have been changed by the use of the induced sputum examination and bronchoalveolar lavage (BAL) without biopsy, and by immunofluorescent staining using monoclonal antibodies to *P. jiroveci*. As a result, the morbidity associated with diagnostic procedures has been reduced at the same time the diagnosis of coinfecting pathogens has been reduced.

The initial step in the diagnosis of PCP is a realization that the patient is at risk for opportunistic infection. In the appropriately identified patient, the first procedure should be to obtain a sputum sample for bacterial, mycobacterial, and fungal stains and cultures to look for any of the infectious processes consistent with the presentation of pulmonary infection in an immunocompromised host. The selection of diagnostic tests will depend on the status of the patient (ability to cooperate with sputum induction), the distribution of pulmonary disease, and the urgency of diagnosis. Given the opportunity for only a single procedure, or a mixed radiographic appearance, a more invasive test may be preferred. The diagnostic test of choice is the induced sputum examination coupled with direct immunofluorescent staining for *P. jiroveci* along with more routine smears and cultures. Induced sputum may be collected after 20 to 30 minutes of exposure to aerosolized hypertonic saline or water, or after oral hydration. Some bacteria and fungi may not survive the hypertonic saline used for induction, and the yields for these pathogens do not exceed those of routine sputum samples.

Before the availability of immunofluorescent antibody staining techniques, smears were prepared from the mucoid, nonpurulent portion of the specimen and stained with Giemsa or Diff-Quik stain for intracystic bodies, or sporozoites, and trophozoites (see Fig. 135-6). Other usable stains include toluidine blue O or silver, which readily stains only the cyst wall. Because cysts represent only 5% to 10% of the organism burden, this staining procedure may miss the majority of trophozoites in any one sample. Many laboratories prefer the Giemsa to the more complex silver stain, for ease of use and also because the Giemsa, along with the Wright stain, can be used to detect trophozoites, the most common form of the organism in the alveolus. Giemsa-stained smears, unfortunately, are more difficult to read and require expertise to perform and interpret correctly. Overall, Diff-Quick staining (a modified Wright stain) is somewhat less sensitive, while calcofluor white and silver stains may be the most predictive for routine clinical use when monoclonal antibody staining is not available.[56]



A



B

Figure 135-6 Rapid staining of sputum and biopsy specimens for *P. jiroveci*: **A.** Impression smear (touch preparation) from the cut surface of a human lung biopsy stained with Diff-Quik stain reveals the nuclei of clumped trophozoites *(arrowheads)* and of the sporozoites within cysts *(arrows)*. **B.** Human *P. jiroveci* cysts in an induced sputum specimen that has been stained with fluoresceinated monoclonal antibodies raised to the 116-kd surface antigen of human *P. jiroveci*.

The staining method of choice for respiratory secretions from BAL specimens is also direct immunofluorescent staining with monoclonal antibodies (Fig. 135-6). Rapid staining with immunofluorescent monoclonal antibodies directed against surface antigens of *P. jiroveci* has a high degree of specificity and a sensitivity for screening of sputum smears. This method is costly, but significant cost savings can be achieved in terms of the rapidity of specimen preparation and examination. This technique may detect 12% to 16% of *Pneumocystis* beyond standard histologic stains.[57] (Fig. 135-2). Some commercially available antibodies produce high backgrounds and some nonspecific staining; each laboratory must individually optimize the fluorescent staining technique. Smears may be improved through the use of mucolytic agents (Mucomyst, dithiothreitol) in preparation.

The heightened sensitivity of immunofluorescent staining, coupled with the use of either induced sputum or BAL samples, may detect "infections" that are of uncertain clinical significance, particularly when other pathogens are identified. Owing to the broad antibacterial spectrum of TMP-SMX, response to therapy is only a partial confirmation of the existence of PCP. AIDS patients often have residual organisms in their sputum for many weeks after successful treatment, representing dead or nonviable *Pneumocystis*. This makes follow-up testing of sputum in infected patients of little value in tracking response to therapy.[58] However, organisms found in the symptomatic non–AIDS-immunosuppressed patient should suggest disease meriting therapy. This disparity may be exacerbated by the findings that organismal burden tends to be less in the infected transplant

recipient compared to the HIV-infected patient with PCP.[59] Of note, because of the vagaries of sample collection and distribution of infection, a negative smear from any single respiratory specimen cannot be used to exclude PCP.

PCR techniques have been developed to increase the sensitivity of detecting *Pneumocystis* in respiratory specimens. Numerous techniques have been applied, using single-step, nested, and quantitative real-time PCR assays. Most targets for PCR have included areas of ribosomal RNA and the MSG genes. Nested PCR techniques in general may be more sensitive than both routine microscopy and immunofluorescent monoclonal antibody staining, while suffering a loss in specificity in the diagnosis of PCP.[60,61] False-positive results and low positive predictive values limit the ability of molecular assays to distinguish between asymptomatic colonization and infection.[62] Using real-time quantitative PCR may increase the specificity of the approach if clinically relevant cutoff values can be established. A multicenter, prospective study using a commercially available real-time PCR for *Pneumocystis* (targeting mitochondrial ribosomal large subunit genes) showed that the specificity may be increased to >90% while positive predictive values remain limited. This study included primarily non–HIV-infected patients where the organismal burden may be lower, helping to increase the specificity.[63] These assays require further development and validation. The use of such assays in blood samples has not yet been validated.

The histopathology of *Pneumocystis*-infected lung is usually distinctive and diagnostic even when organisms cannot be identified, which is uncommon. In the adult, the disease is predominantly alveolar. The airspaces are filled with a foamy eosinophilic exudate and appear honeycombed. The intra-alveolar exudate consists of organisms, large amounts of surface glycoprotein, proteinaceous exudate from the lungs, and debris of macrophages and inflammatory cells. At the same time, the alveolar interstitium is infiltrated by polymorphonuclear leukocytes and lymphocytes (Fig. 135-3). Patchiness in the distribution of disease within the lungs is common. In contrast to the adult disease, PCP in malnourished infants has a major interstitial component: the interstitium is filled with fluid, plasma cells, and lymphocytes. These formed elements seem to overflow into the airspaces, which are also filled with a frothy eosinophilic exudate. In both forms, the organisms usually appear intermingled with alveolar macrophages in the alveolar exudate (Fig. 135-3). By light microscopy, trophozoites predominate numerically (in more than 90% of the organisms), but cysts are more readily identified.

The earliest indication of disease is the presence of organisms adjacent to the epithelial layer. Cysts or clumps of trophozoites may be seen, with a minimal inflammatory infiltrate. As the number of organisms increases, epithelial injury occurs. The mechanism of alveolar epithelial cell injury is uncertain. The organism preferentially adheres to and injures the surface of type I alveolar epithelial cells, while the adjacent type II cells undergo hyperplasia. Desquamation of alveolar epithelial cells occurs early in the course of disease; denuded basement membrane is occasionally seen. Epithelial injury is followed by mononuclear cell infiltration in the interstitium. Organisms may be seen within vacuolated alveolar macrophages, as well as free in the proteinaceous and cellular debris that fills the airspace (Fig. 135-3).

In AIDS, the interstitial inflammation is less marked than in other adult forms of PCP, and greater numbers of both cysts and trophozoites are seen in the alveoli. While HIV-infected alveolar macrophages appear to bind organisms normally, internalization of *P. jiroveci* may be impaired and clearance of organisms delayed. Many dead macrophages are found in BAL samples from HIV- and *Pneumocystis*-infected lungs. In children with AIDS, the appearance is similar to that of adult AIDS, with the addition of some degree of plasma cell infiltration of the interstitium. Although hyaline membranes may line alveoli, they are not diagnostic of infection with *Pneumocystis*, since oxygen toxicity, alveolar proteinosis, or acute respiratory distress syndrome (ARDS) can evoke similar changes. These may coexist with *Pneumocystis* infection. In pediatric AIDS, LIP, without evidence of an infectious origin, and bacterial pneumonia may mimic or coexist with PCP.

Even when chest radiography indicates that PCP has cleared, interstitial fibrosis is likely to be found at rebiopsy or autopsy. Unfortunately, the contribution of *Pneumocystis* to the residual fibrosis is often obscured by the tendency of superimposed infection, therapeutic agents, or intervening radiation therapy to elicit inflammatory responses in the interstitium. Subsequent infections are likely to present with more rapid progression to hypoxemia due to persistent restrictive lung disease. In AIDS patients, pulmonary interstitial fibrosis has been observed in up to 27% of autopsy and biopsy series, and emphysematous changes are also common. These changes do not appear to be associated with prior *Pneumocystis* infection. A pathogenic role for chronic or recurrent viral (HIV, CMV, etc.) infections or immunologic injury has been postulated.

When looking for common coinfecting agents, it is important to note that demonstration of CMV by culture is not helpful in regard to the presence of CMV disease. Coinfection due to CMV and *P. jiroveci* is common among susceptible hosts and may necessitate treatment for both entities. Diagnosing CMV and other coinfections should always be a priority when managing the patient with PCP.

INVASIVE DIAGNOSIS OF PNEUMOCYSTOSIS

In the immunocompromised patient with significant pulmonary disease, the inability to make a diagnosis of infection on examination of the induced sputum, or the failure to respond to appropriate therapy should lead to a more invasive diagnostic procedure: BAL (with biopsies if possible), radiologically guided needle aspiration (for accessible cystic or mass lesions), or open lung biopsy. The choice of the specific test depends on the clinical condition of the patient and the expertise available at the institution (Table 135-3).

Invasive procedures for the diagnosis of PCP fall into several categories: tracheal aspiration, fiberoptic bronchoscopy, transthoracic aspiration, and open lung biopsy. Attempts to avoid the use of invasive procedures by resorting to empiric therapy run a great risk of inappropriate medications and undesirable side effects, missing coinfecting organisms, as well as delaying effective therapy. Pulmonary specimens obtained by invasive approaches should be processed for bacterial (including mycobacteria, *Nocardia, Actinomyces,* and *Legionella*), fungal, and viral evaluation in addition to making slides for rapid staining with fluorescent antibodies, toluidine blue O, silver, Diff-Quik, Giemsa, or Wright stain. Early diagnosis can be made and therapy initiated on the basis of such smears, especially in cases of AIDS.

■ TRACHEAL ASPIRATION

The yield from transtracheal aspiration is generally low, and the hazards, particularly in inexperienced hands, are high. In intubated patients, respiratory secretions should be carefully smeared on slides, stained, and examined. If the physician or the microbiology technician has had little experience with *Pneumocystis* smears, and direct immunofluorescence techniques are not available, fiberoptic bronchoscopy or open lung biopsy is indicated for the immunocompromised patient with pulmonary disease, followed by methenamine silver staining of the tissue sections.

■ FIBEROPTIC BRONCHOSCOPY

The importance of knowing the success rate of the institution as a basis for selecting the optimal invasive technique is illustrated by published reports of diagnostic yields from fiberoptic bronchoscopy. In patients with AIDS, use of bronchoscopy and BAL for diagnosis can yield positive results in >90% of cases. The yield of BAL versus

induced sputum alone in cases of PCP in AIDS remains unstudied.[64] Because the organismal burden is oftentimes less in the non–HIV-infected host with PCP, sputum may be less revealing and bronchoscopy with BAL may have a higher yield.[65] Sampling from multiple lobes may increase the diagnostic yield even further.[66] As a rule, institutions with a large experience with PCP are more successful in identifying the organism from respiratory samples. Indeed, when BAL and transbronchial lung biopsies are part of the diagnostic procedure, the success rate often exceeds 90% in these settings.[66] To improve yield, lavage specimens must be gathered from a wedged bronchoscope with at least 50 mL of physiologic saline for alveolar washings. Lavage should be performed from the upper lobes if diffuse disease is present. Trophozoites predominate in bronchial washings, so Giemsa or Diff-Quik staining should be performed routinely to back up other staining methods. In general, lung biopsy is not essential for the diagnosis of PCP in AIDS patients. Patients suspected of harboring multiple pathogens may still benefit from any of the more invasive procedures. Although bleeding from the biopsy site is common (in up to 25% of patients), it is rarely life threatening if the coagulation indices are normal.

PERCUTANEOUS NEEDLE ASPIRATION

High success rates when using percutaneous needle aspiration in finding *P. jiroveci* have also been reported in patients with PCP, particularly when aspiration of localized radiologic infiltrates is performed under fluoroscopic or CT guidance. Yield may be similar to other approaches at close to 90%. Needle aspiration is also advantageous when a focal process (e.g., abscess) is peripherally located in the lung parenchyma. Pneumothoraces may occur in up to 20% of patients as a result of the procedure, making this a less ideal first-line diagnostic approach.[67]

LUNG BIOPSY

Thoracotomy or video-assisted thoracoscopic (VATS) procedure followed by open lung biopsy affords the most unequivocal avenue for the diagnosis. Although the patient may be quite ill by the time this step is taken, in the hands of skilled surgeons these procedures are generally safe, even for the patient on mechanical ventilation. Thoracoscopic biopsies can often be performed as minimally invasive procedures. VATS may provide histologic information that allows separation of significant infection of the lower respiratory tract from colonization of the upper respiratory tract by a variety of respiratory pathogens. This information may be critical to therapeutic decision making, as in the use of antiviral agents in the treatment of CMV infection.

Accurate diagnosis in the non-AIDS patient may require invasive procedures (Table 135-3). The choice of the procedure depends on the clinical state of the patient: patients who have an uncorrectable coagulopathy are poor candidates for invasive testing. Patients with atypical presentations or unique epidemiologic exposures have a higher incidence of dual processes or non-*Pneumocystis* infections. Institutions unfamiliar with the proper technique for sampling or handling specimens for the diagnosis of *Pneumocystis* infection should probably use open lung biopsies, which are likely to be more rewarding. Because disease caused by PCP may progress rapidly, the likelihood of success in treatment is greatest at the outset. Therefore, invasive procedures to disclose the organism and any secondary infections should be undertaken early in the course of the disease.

The demonstration of *Pneumocystis* organisms is necessary for the diagnosis in the transplant recipient. The incidence of PCP is affected by the use of prophylaxis, the degree of immunosuppression, and regional and underlying disease-specific variations.[68] Empiric therapy is more reasonable in the untreated AIDS patient not receiving prophylaxis; however, dual infections remain common. Empiric therapy in the transplant recipient may delay specific treatment for other opportunistic pathogens and subject the patient to avoidable toxicities of TMP-SMX or pentamidine. Demonstration of infection due to *P. jiroveci* should lead to successful treatment, barring superinfection, ARDS, or other complications.

PROPHYLAXIS AND PROPHYLACTIC STRATEGIES

In the pre-AIDS era, the prevention of PCP was associated with time-limited antibiotic use in the setting of prolonged neutropenia due to cancer chemotherapy. Because many of the chemotherapeutic regimens included corticosteroids, the incidence of PCP was predictably high. Prophylactic TMP-SMX was pioneered by Walter Hughes and his colleagues at the St. Jude's Children's Research Hospital for use in children with hematopoietic malignancies and severe combined immunodeficiency (SCID) syndrome.[69] This combination agent became the standard for prophylaxis in the AIDS era as well and continues to this day. In pre-HAART AIDS, such prophylaxis was lifelong rather than time-limited in the absence of immune reconstitution. With HAART, prophylaxis can generally be stopped in patients with undetectable viral loads for at least 3 months and CD4 counts that surpass 200 cells/mm^3 for that period.[70] Without HAART, however, more than 60% of those cured of PCP in AIDS will suffer a recurrence within 1 year. Although TMP-SMX is generally well tolerated among non–HIV-infected individuals with side effects reported in <10%, the incidence of side effects among the AIDS population appears to be higher. In at least one study, the incidence of any one side effect was reportedly as high as 80%.[71] The increased incidence of side effects due to TMP-SMX in AIDS patients has led to the development of alternative regimens for prophylaxis against *P. jiroveci*.

The use of appropriate prophylaxis should prevent PCP. In AIDS patients and in transplant recipients, the failure to utilize appropriate prophylaxis is generally a reflection of the toxicities associated with the necessary medications or a failure in compliance due to the large number of medications these patients may be expected to consume. This can be particularly problematic in solid-organ and hematopoietic stem cell transplant recipients. Routine anti-*Pneumocystis* prophylaxis is recommended for any transplant center that otherwise might have an incidence of PCP of at least 3% annually.[72] Widespread use of prophylaxis and the diversity of immunosuppressive regimens among transplant centers obscures the true incidence. The highest risk is generally thought to be within the first 6 months after the transplantation, though numerous factors influence that risk. For that reason, prophylaxis should be maintained in the stable transplant patient for at least 6 months after surgery. In lung transplantation and in stem cell transplant recipients with significant graft-versus-host disease or overall poor recovery, risk for PCP remains high, and prophylaxis may need to be lifelong.[17] Many cardiac and liver transplant programs also advocate lifelong prophylaxis. It should be noted that in transplant centers without a fixed, high incidence of PCP, prophylaxis may be reserved for patients in whom chronic, high-level immune suppression, especially with corticosteroids (now uncommon), is needed to maintain graft function. If immune suppression cannot be reduced after a course of treatment for PCP, prophylaxis should be maintained indefinitely. Recent studies have documented cases of PCP occurring in transplant recipients several years after transplantation in patients not taking effective prophylaxis.[73] In cases where prophylaxis is not deemed necessary or initially withheld, reinstitution should be considered with increases in immune suppression, including those resulting from pulse corticosteroids or antilymphocyte antibody therapies in transplantation, CMV infection in AIDS or transplantation, treatment of graft-versus-host disease following bone marrow transplantation, new-onset neutropenia, or similar conditions.

In untreated HIV infection, adults and adolescents with CD4 counts of fewer than 200 cells/mm^3 (or <15%–20% of the total

lymphocyte number), unexplained fever for more than 2 weeks, a history of oropharyngeal candidiasis, or rapid progression of disease, as measured by rising viral titers or falling CD4 counts, should receive evaluation and prophylaxis. Prophylaxis in HIV-infected children is recommended for CD4 counts of fewer than 1500 cells/mm^3 for less than 11 months of age, fewer than 1000 cells/mm^3 between 1 and 5 years, or fewer than 500 cells/mm^3 after age 5, and in any child in whom the CD4 percentage falls to less than 24%. The greatest risk for children may be in the 3 to 6 months of age range, making the identification of the HIV-infected infant critical to survival.

Resistance of *P. jiroveci* to antibiotics has been proposed based on some clinical failures while receiving prophylaxis. Resistance *may* develop in association with mutations in the dihydropteroate synthase gene of *P. jiroveci,* but is extremely rare. Predictably, the use of prophylaxis both for *P. jiroveci* and for yeasts and the resultant improved survival of HIV-infected persons have increased the relative frequency of other causes of pulmonary disease, including both infectious (e.g., CMV, other invasive mycosis, mycobacteria) and noninfectious processes.

TMP-SMX (cotrimoxazole) is the agent of choice for the prevention of *Pneumocystis* infection in any patient who can tolerate this fixed-combination agent. At a dose of one single-strength tablet per day (80-mg TMP and 160-mg SMX), a wide variety of opportunistic infections are prevented, including *P. jiroveci*, *Toxoplasma gondii, Listeria monocytogenes, Isospora belli*, and susceptible bacteria, including some strains of pneumococci, *Haemophilus influenzae,* community-acquired staphylococci, and some enteric gram-negative rods. Another common opportunistic infection, nocardiosis, which is often sensitive to TMP-SMX, may be incompletely prevented by prophylaxis.[74] While the protection against *T. gondii* is incomplete in AIDS patients (80%–90% effective) at this dosage (generally a double-strength tablet a day might be used in seropositive persons without a history of *T. gondii* infection), breakthrough infection has not been seen in transplant recipients (notably cardiac) or in cancer patients. Studies of low- and high-dose regimens for prophylaxis (single- or double-strength TMP-SMX) in HIV-positive subjects suggest no advantage to the higher dose (no disease in either group when compliant) and earlier occurrence of toxicity in the high-dose group.[75] Administering TMP-SMX three times weekly has also been widely utilized to cut down on potential toxicity but sacrifices other advantages. Randomized studies of HIV-infected patients have shown that using TMP-SMX double-strength tablets three times weekly compared to daily may have a slightly higher risk for PCP, with adverse events more common with the higher strength tablets daily.[76]

Drug toxicity is commonly observed even with low-dose; mild bone marrow suppression occurs, but is generally overestimated. Such bone marrow toxicity is notable in combination with other marrow suppressive agents (e.g., azathioprine, ganciclovir, cyclophosphamide, allopurinol, zidovudine), malnutrition, or infection (HIV, mycobacteria, or CMV). Most toxicity has been related to serum levels of the sulfa component in AIDS. Some patients will not tolerate any dose of sulfa drugs, owing to significant rash (occasional Stevens–Johnson syndrome), hepatitis, eosinophilic nephritis, pancreatitis, aseptic meningitis, or neutropenia. Generally, significant toxicities evolve within the first month of therapy. Hyperkalemia may be observed in the setting of normal renal function as a result of TMP interfering with the secretion of potassium in the renal distal tubule. This is reversible and more common during therapy than with prophylaxis. Patients taking TMP-SMX may benefit from laboratory monitoring of renal function, electrolytes, and cellular blood counts. In general, neutropenia should not be treated with folate as this has been associated with treatment failures. Both oral and intravenous desensitization regimens will allow the use of TMP-SMX in many patients otherwise intolerant of the combination. Reintroduction of TMP-SMX at reduced dose is often tolerated in AIDS patients not severely intolerant of this agent. This is generally preferable to the use of any alternative agent. Non–AIDS-immunocompromised patients appear to be less able to tolerate desensitization.

Alternative regimens are available for the patient intolerant of TMP-SMX. These have historically been primarily dapsone and aerosolized pentamidine. Dapsone (diaminodiphenylsulfone), with or without TMP or pyrimethamine, is in wide use in a variety of combinations. In general, neutropenia (especially in the G6PD-deficient host), hepatitis, and rash can be limiting for each of these regimens, and they offer no benefit over low-dose TMP-SMX. Any patient starting dapsone therapy for prophylaxis should be screened for G6PD deficiency. Because of a long half-life, dapsone may be administered in doses of 50 to 100 mg per day to 100 mg per week. Breakthrough infection has been observed in AIDS patients at 50 mg per day. Therefore, pyrimethamine may be administered weekly (25 or 50 mg) to supplement dapsone in a dose of 50 mg a day. Clinical trials and at least one meta-analysis of dapsone compared to TMP-SMX and aerosolized pentamidine have shown equivalent efficacy at preventing PCP.[77–79] TMP may replace pyrimethamine in this regimen (100–200 mg per day) in patients with creatinine clearances over 15 mL/min. The incidence of intolerance to dapsone varies from study to study. Up to half of the patients who discontinue prophylactic therapy with either of these agents will be able to tolerate the other drug. This strategy is not recommended for any person with severe allergic reactions, however, including desquamation to sulfa drugs, persistent bone marrow suppression, G6PD deficiency, or severe hepatitis. Toxicities observed with dapsone may be even higher than expected in solid-organ transplant recipients.[80] Dapsone alone, like aerosolized pentamidine, does not protect against toxoplasmosis—necessitating dual therapy for prophylaxis in the susceptible host.

The use of prophylaxis with aerosolized pentamidine isethionate (300 mg every 3–4 weeks) was pioneered in AIDS patients and is well tolerated in organ transplant recipients. Clinical trials comparing aerosolized pentamidine to TMP-SMX or dapsone have typically shown there to be a higher incidence of failure with aerosolized pentamidine.[78,81,82] Pentamidine aerosol prophylaxis is generally only effective after the second or third dose administered by experienced personnel with a nebulizer, producing droplets in the range of 1 to 3 μ. The Fisons nebulizer has also been used with an alternative schedule of five 60-mg doses over 2 weeks, followed by 60 mg every 2 weeks. Because the distribution of drug may not reach the upper lobes, or because the growth of *Pneumocystis* may be favored in the upper lobes, adjusting patient positioning during inhalation may be useful. Though generally well tolerated, cough and bronchospasm can occur, as well as pneumothorax in some instances. Prevention of some of these symptoms can be done via preemptive use of albuterol or other beta-agonist therapy. Breakthrough infection has been observed in patients receiving aerosolized pentamidine prophylaxis (particularly in the upper lobes). In single-lung transplant recipients, prophylactic failures have been observed in the residual (native) lung despite successful protection of the allograft. When breakthrough occurs with aerosolized drug, diagnosis by examination of the sputum is often complicated by reduced organism numbers resulting in false negatives and biopsy may be required to confirm the diagnosis.[83] Intravenous pentamidine (4 mg/kg every 2–4 weeks) has also been used, but is less well studied and its use may be complicated by systemic toxicities.

Atovaquone is a structural analog of ubiquinone with potent activity against a number of protozoa as well as *Pneumocystis*. It appears to be active by inhibiting the binding of ubiquinone to the electron transport system of mitochondria. The drug has been approved by the FDA for the treatment of mild-to-moderate *P. jiroveci* infections and may be equally useful for prophylaxis because it is well tolerated, undergoes enterohepatic circulation without metabolism, and has a long half-life. Studies of HIV-infected patients have shown

that in individuals who could not take TMP-SMX, doses of 1500 mg orally once daily was equally efficacious at preventing PCP compared to dapsone or aerosolized pentamidine.[84,85] Atovaquone is only available as a liquid suspension because of bioavailability limitations in tablet form. The high cost of atovaquone can also be a limiting factor in widespread utilization compared to TMP-SMX and dapsone. It otherwise appears to be well-tolerated. Rash, nausea, and elevated liver transaminases have been occasionally documented. Some patients complain about the flavor and color of atovaquone liquid (which stains clothes), but many ultimately find it preferable to aerosolized pentamidine. Prophylactic doses of reformulated liquid drug in the range of 1000 to 1500 mg a day exceed the MIC in serum for *P. jiroveci,* but doses at 1000 mg or less daily have resulted in breakthrough infection.[86] In small numbers of transplant recipients, interactions of atovaquone with cyclosporine and other toxicities have been insignificant.

Less well-studied regimens for prophylaxis might include the combination of clindamycin and pyrimethamine.[87] These two drugs appear to be active against *Pneumocystis* in vitro, and limited data in small numbers of patients suggested efficacy.[88] No prospective trials have been performed with this combination, but retrospective reviews of clindamycin at 300 mg daily with pyrimethamine at 15 mg daily showed it may be of benefit. Analyses suggest, however, that it may not be as efficacious as TMP-SMX or dapsone and breakthrough infections do occur. [87] Gastrointestinal intolerance of clindamycin over an extended period of time may also be a limiting factor for this regimen.

Patients receiving prophylaxis for toxoplasmosis (sulfadiazine, TMP-SMX, clindamycin/primaquine, atovaquone) generally have also been protected against *P. jiroveci.* In patients who are not receiving TMP-SMX or dapsone, who may benefit from antibacterial prophylaxis, an additional agent such a fluoroquinolone may be needed. Transplantation recipients receiving a fluoroquinolone alone for postoperative prophylaxis, however, will be at the same risk for PCP as the general transplant population.

TREATMENT OF PNEUMOCYSTIS PNEUMONIA

The incidence of *Pneumocystis* infection in AIDS patients has led to the development of a number of options for the treatment of this infection in all susceptible hosts (Table 135-4). Because of the severity and rapidity of disease morbidity, which can occur after the infection becomes clinically apparent, treatment should be initiated as soon as the suspicion of PCP is entertained. The short-term use of treatment (48 hours) will not impair the diagnosis of infection if, for example, bronchoscopic or laboratory support services are unavailable. It is likely to be more useful clinically to obtain specimens for *P. jiroveci,* mycobacteria, *Legionella,* other fungi, and routine cultures when these can be properly handled by the clinical laboratory. Further, because the pneumonia can be rapidly progressive, early therapy is essential. Retrospective studies of non–HIV-infected patients with PCP have identified delay in therapy to be a risk factor for death.[89,90] Treatment of *Pneumocystis* should be successful if a 14- to 21-day course of therapy is tolerated.

The incidence of adverse reactions to antibiotics, necessitating switching of agents, is increased in the solid-organ and bone marrow transplant recipient, as it is in AIDS patients. In general, side effects in transplantation are related to synergistic drug toxicities. For example, the bone marrow suppression seen in infection with CMV and treatment of this infection with ganciclovir may be further exacerbated with TMP-SMX. Generally, elevations in liver function tests in the liver transplant recipient or depression in the leukocyte count in the stem cell recipient or chemotherapy patient due to therapy with TMP-SMX is of concern but often tolerable. Nephrotoxicity is common in transplant recipients (both renal and extrarenal) receiving therapy with TMP-SMX, even with adjustment of dosing for renal dysfunction. Thus, while the incidence of intolerance by transplant recipients to one or another agent is somewhat less than the 50% seen in AIDS patients, significant toxicity remains a common feature of therapy. As was noted, resistance to antibiotics by *P. jiroveci* is a rare phenomenon. Thus, changing antibiotics other than for toxicity does not appear to be indicated. While there are patients who appear to do better on one agent than another, it is much more common to recognize a second process (infection, tumor, allergy, ARDS) as complicating PCP than a resistant infection. The chest radiograph is a less reliable indicator of failure than is oxygenation or other clinical parameters. Adding pentamidine to TMP-SMX offers no advantage over simply switching agents. Indeed, animal experiments suggest the possibility of antagonism between these agents when used in combination. As a rule, patients who need to be switched from TMP-SMX to pentamide, or vice versa, do not fare as well as those who can be treated for 14 to 21 days with either agent alone. The prognosis of therapy is most tightly linked with degree of respiratory failure at the time of presentation. Older studies in HIV-infected patients suggested a mortality rate close to 10% in cases of mild-to-moderate disease, but twice that in more severe cases.[91,92] Adjunctive therapies (see below) may provide further benefit.

The proper duration of therapy has not been well studied but is generally 14 to 21 days in all patients.[93] Residual organisms persist after treatment for a number of months, but the role of these organisms in recrudescent or persistent infection is not clear and may just reflect nonviable microbes. Relapse in the non–AIDS-immunocompromised

TABLE 135-4 Treatment of *Pneumocystis jirovecii*[a]

Agent(s)(route)[b]	Dose	Options[b]
Trimethoprim-sulfamethoxazole (TMP-SMX) (IV/PO)	15 mg/kg/d TMP (to 20) 75 mg/kg/d SMX (to 100)	Treat through mild rash: reduce TMP or SMX by one-half; desensitize; first choice
Pentamidine isethionate (IV)	4 mg/kg/d 300 mg/d maximum	IM not advised
Dapsone (PO) with TMP (PO/IV)	100 mg/d 15–20 mg/kg/d (900 mg)	Methemoglobinemia, G6PD; *may* be tolerated in sulfadiazine allergy
Clindamycin (IV/PO) and primaquine	450–600 mg q6h 15–30 mg base qd	Methemoglobinemia, diarrhea (pyrimethamine for primaquine)
Pyrimethamine (PO) with sulfadiazine (PO)	Load 50 mg bid × 2 d, then 25–50 mg qd Load 75 mg/kg, then 100 mg/kg/d	Not studied fully in clinical trials
Atovaquone (PO) suspension	750 mg (PO) tid to 1500 bid	Variable absorbance, improved with fatty food; rash, GI intolerance

IV, intravenous; IM, intramuscular; PO, oral.

[a] *Adjunctive therapies (see text): Corticosteroids (high dose with rapid tapering), possibly γ-interferon, granulocyte-macrophage colony–stimulating factor.*

[b] *Based on clinical judgment of physician; some agents are not FDA-approved for this indication.*

patient should not be expected as long as immunosuppression can be reduced somewhat, notably, with tapering of corticosteroid therapy after disease resolution. Subsequent lifelong prophylaxis may be warranted in these situations.

TMP-SMX is the agent of choice for the treatment of PCP and extrapulmonary disease in all hosts. This combination antibiotic has the advantage of excellent tissue penetration, the most rapid clinical response of anti-*Pneumocystis* agents (3–4 days), and bioavailability from oral therapy comparable with that of parenteral administration. The incidence of some of the side effects is related to serum concentrations. Generally, TMP-SMX should be tolerated when corrected for measured rather than calculated renal function. In part, this is a reflection of dosage schedules derived for children in adults who may not require the same high doses. Therapy is initiated at 15 to 20 mg/kg per day of the TMP component (100–150 mg/kg per day of SMX), divided into three or four doses. Therapy should be initiated intravenously if there is uncertainty about gastrointestinal absorption or marked hypoxemia. For mild-to-moderate PCP, treatment with TMP-SMX can be done using an oral regimen. Two double-strength (160-mg TMP/800-mg SMX) tablets three or four times daily are most often applied depending on overall body mass.

Therapy can be continued (with adjustments) despite mild side effects (rash, transaminase elevations, neutropenia) tolerable to the patient and physician. Dose reduction will often eliminate toxicity in AIDS patients. Desensitization to TMP-SMX may be used in the patient with mild intolerance. With renal dysfunction, dosing must be reduced; daily dosing is sufficient (3–5 mg/kg per day) for a glomerular filtration rate of 10 to 50 mL/min. Renal impairment developing in a patient taking TMP-SMX should prompt a search for urinary eosinophils and an assessment of the need for further therapy with this agent. Nephrotoxicity occurs frequently in the renal transplant recipient on full-dose therapy; this toxicity is both idiosyncratic and dose related. Nephrotoxicity often occurs without demonstrable urinary eosinophils, perhaps as a reflection of the use of corticosteroids for immune suppression. In these patients, interstitial eosinophils may be found on renal biopsy. The transplanted liver is particularly susceptible to TMP-SMX toxicity (eosinophilic infiltrates, hepatocyte necrosis, bilirubinemia) and may be confused with, or complicate treatment for, early graft rejection or systemic infection. The side effects of TMP-SMX are generally those of sulfa allergy: rash (including Stevens–Johnson syndrome), transaminase elevation, neutropenia, thrombocytopenia, erythema multiforme exudativum, and nephrotoxicity. The bone marrow suppression is marked in patients with underlying hematologic disorders; folinic acid supplementation is rarely useful and should be avoided in patients with acute leukemia.

For mild-to-moderate disease, dapsone (100 mg orally per day), in place of SMX and in combination with oral TMP (15 mg/kg per day), is an effective alternative therapeutic regimen. Clinical trials comparing oral TMP-SMX to oral dapsone-TMP and clindamycin-primaquine have shown relatively equivalent efficacy.[92] Many AIDS patients intolerant of SMX will tolerate dapsone, which is metabolized by the liver (half-life at least 30 hours). However, the long half-life and side-effect profile in the non-AIDS patient (hemolysis in G6PD deficiency, methemoglobinemia, rash, hepatitis) may be particularly disadvantageous in the transplant recipient. As noted in the section on prophylaxis, any patient starting dapsone therapy should be screened first for G6PD deficiency. Manifestations of sulfa and TMP toxicity may be masked by corticosteroids. Similarly, side effects of azathioprine (hepatitis, macrocytic anemia, neutropenia, hepatic veno-occlusive disease) or mycophenolate and sirolimus (neutropenia) may be accentuated by TMP-SMX. In AIDS, the toxic side effects of TMP-SMX are generally those of the sulfonamide; however, TMP allergy is not uncommon, and allergies to the "carriers" in the various preparations of TMP-SMX (dyes, coatings, filler) have also been reported. Both components of TMP-SMX interfere with folate metabolism.

Intravenous pentamidine isethionate is the first alternative agent for the treatment of PCP, particularly in severe cases or those with significant hypoxemia. Pentamidine isethionate was first administered intramuscularly during an epidemic of the infantile form of the disease. Small clinical trials of PCP comparing intravenous pentamidine to intravenous TMP-SMX have shown mixed results. Two studies showed pentamidine to be equivalent while one showed improved survival in the TMP-SMX group.[94–96] Clinical responses are generally faster with TMP-SMX. Pentamidine isethionate may be administered intravenously or, if essential, intramuscularly, although only the intravenous route is recommended. Complications with early therapy occurred in up to 50% of patients, notably sterile abscesses at the site of intramuscular injection. Intravenous pentamidine isethionate is given by slow (1—2 hours) infusion in 5% glucose solution as a single dose of 4 mg/kg per day. Pentamidine achieves therapeutic levels in the lungs slowly (in 5–7 days), owing to high levels of extrapulmonary tissue binding. Slow accumulation of pentamidine in pulmonary tissue may account for the delayed onset of activity when compared with TMP-SMX. However, increased serum levels and a long serum half-life and gradual accumulation in the lungs may play a role in the continued therapeutic effect after the cessation of therapy. Because this agent has a long serum half-life (6.4 hours) and delayed excretion due to extensive tissue binding (more than 240 hours), pentamidine tends to accumulate during therapy. The reduction of symptoms by pentamidine may be due, in part, to suppression of the secretion of tumor necrosis factor by alveolar macrophages as well as to treatment of infection. Pentamidine has largely been supplanted by TMP-SMX for therapy of *Pneumocystis* infection in the non-AIDS patient, but pentamidine remains a viable option for treating infection in patients with adverse reactions to TMP or to sulfonamides.

Idiosyncratic side effects of pentamidine include transient hypoglycemia, pancreatitis, diabetes (after prolonged therapy, with or without prior pancreatitis), pancytopenia, hypotension, and renal dysfunction. These side effects are exacerbated by intravenous administration and in the presence of decreased renal function. Pentamidine should be avoided in pancreas transplant recipients, owing to the potential for islet cell necrosis.

Alternative regimens have been developed as a reflection of toxicities observed in AIDS patients treated with either TMP-SMX or pentamidine. Atovaquone (750 mg orally twice daily) has been approved by the FDA for the treatment of mild-to-moderate PCP. Higher doses are commonly used. Preliminary studies showed that the drug resulted in clinical improvement in 85% of those treated. Toxicity was unusual, and was reported in just over 10%. Treatment limiting reactions included fever and rash while elevated hepatic enzymes, though common, were typically not severe enough to warrant discontinuation.[97] When it was prospectively compared to TMP-SMX for the treatment of HIV-infected patients, efficacy was not as good as TMP-SMX, and failure rates were as high as 20%. Diarrhea and low serum levels leading to potential problems with oral absorption contributed to treatment failure with atovaquone. Tolerability of the drug compared to TMP-SMX appeared to be much greater, however.[98] Use of this drug for treating PCP should probably be limited to patients who cannot tolerate TMP-SMX, who lack significant hypoxia and who have functional gastrointestinal tracts where absorption and adequate food intake is not a concern.

The combination of clindamycin (600–900 mg intravenously every 6–8 hours) and primaquine (15–30 mg base per day orally) is effective in mild-to-moderate infection. When compared to TMP-SMX and dapsone–TMP, this regimen appeared to be equivalent, though toxicity was higher.[92] Clindamycin can be limiting due to gastrointestinal intolerance and in today's increased prevalence of *Clostridium difficile* colitis in some inpatient settings, persistent use is a concern. Primaquine can also be associated with rash, hemolytic

anemia, neutropenia, and methemoglobinemia. As with dapsone, any patient to be treated with primaquine should be screened for G6PD deficiency. Studies evaluating this regimen in more severe disease have not been performed in any randomized trial, and thus should probably be avoided in cases of marked hypoxia.

Pyrimethamine (50–100 mg a day by mouth after 100–200 mg load) and sulfadiazine or trisulfapyrimidines (4–8 g a day) are also effective, but require folinic acid (10 mg a day) supplementation. Pyrimethamine will decrease the renal clearance of creatinine without affecting the glomerular filtration rate. The newer macrolides (azithromycin, clarithromycin) have little efficacy alone but appear to enhance the efficacy of SMX. However, this combination provides little benefit over TMP-SMX by itself.

The echinocandin antifungal agents have garnered some interest in recent years as potential therapeutics for PCP infection. These drugs exhibit antifungal activity by inhibiting β-1,3-glucan synthesis, an important component of the *Pneumocystis* cell wall. In vitro studies have suggested that caspofungin may be active against the cyst and trophozoite forms of *Pneumocystis*.[99] Clinical reports have been mixed, however, and no controlled studies have been performed to date on the clinical utility of echinocandins for treating PCP.[100,101] The echinocandins require study before use as a single agents for the treatment of PCP.

Adjunctive therapies in the treatment of PCP include aggressive supportive care, corticosteroids and, potentially, colony-stimulating factors (CSFs). Because the disease can take a severe course, aggressive respiratory management is often necessary and may even lead to intubation and mechanical ventilation. In cases of extreme ventilator and circulatory collapse, temporizing support through use of extracorporeal membrane oxygenation (ECMO) may be of value in institutions where such support can be performed by experienced personnel. Successful cases of ECMO support have been reported in both adults and children with PCP.[102,103] Delayed response to therapy or the inability to reduce immune suppressive therapy may allow progressive disease despite appropriate therapy for PCP in any case, and the time course for improvement in the best of situations can oftentimes be a week or more. In HIV-infected patients, treatment of the underlying PCP should also be accompanied by treatment of the underlying HIV infection with HAART. The AIDS Clinical Trial Group Protocol 5164 was a randomized trial that demonstrated the implementation of antiretroviral therapy within 14 days of the setting of an acute opportunistic infection like PCP reduced AIDS progression and mortality by 50%.[104] Thus, delaying HAART in otherwise untreated AIDS patients presenting with PCP should be avoided.

Given the risks of nosocomial superinfection associated with intubation for assisted ventilation, the use of adjunctive corticosteroids was developed to prevent the early deterioration of AIDS patients with documented PCP. The use of corticosteroids (prednisone, 40–60 mg three or four times a day, orally or equivalent intravenously) in the first 72 hours after admission may reduce pulmonary inflammation to a degree sufficient to avoid intubation. When studied in AIDS patients, the use of corticosteroids in patients with a Pa_{O_2} of 35 to 72 mm Hg or with a hypoxemia ratio of 75 to 350 was of significant benefit in terms of preventing deterioration in oxygenation in the first 7 days of therapy, mortality, and the avoidance of intubation (50% reduction).[105] After such therapy, the exercise tolerance and survival of patients were improved. Steroid tapering is necessary to avert relapse of pulmonary inflammation. Patients may experience an increase in oral thrush and herpes simplex after 2 to 3 weeks of therapy and tapering. The impact of corticosteroids in the non–AIDS-compromised host and in AIDS patients failing initial therapy appears to be similar. However, the utility of additional steroids in the transplant or cancer patient has not been subjected to a controlled clinical trial.

Cytokines, including γ-interferon, have been shown to reduce the amount of *Pneumocystis* found in animal models of disease without greatly increasing the inflammatory response.[106] CSFs including those for the monocyte/macrophage (M-CSF), granulocytes (G-CSF), and granulocyte/macrophage (GM-CSF) lineages, have come into use to supplement immunity in the immunocompromised host. G-CSF has been used successfully in many of our neutropenic cancer and organ transplant recipients without adversely affecting the transplanted organs. GM-CSF has been used with systemic antifungal therapy in patients with acute fungal infections with some success. Preliminary data suggest that M-CSF and GM-CSF may be useful in enhancing the clearance of *P. jiroveci* by resident alveolar macrophages. As of yet, no controlled human data exist and ideal dosing or administration remains unknown. The impact of CSFs on graft rejection has also not been studied.

The response to therapy is generally excellent in patients who receive a diagnosis before respiratory failure. The ability to reduce immune suppression or to supplement the immune response (see above) also improves the rapidity of clearance of infection. Clinical improvement should be seen in most patients being treated with ideal dosing of TMP-SMX in 4 to 5 days. Radiographic improvement may lag behind. The failure to see clinical improvement after a week should suggest the presence of another process such as fibrosis, ARDS, dual infection (especially CMV), abscess, bronchial obstruction, drug allergy, or carcinoma. Bronchoscopic lavage and biopsy for microbiology and pathology, or chest tomography (CT scan), may be revealing in these patients.

CHAPTER 136

Protozoan Infections of the Thorax

Louise C. Ivers
Edward T. Ryan

AMEBIASIS: *ENTAMOEBA HISTOLYTICA*

Entamoeba histolytica is a protozoan infection of humans that is found worldwide and is globally responsible for up to 100,000 deaths annually. It is endemic in most temperate and tropical areas of the world, particularly in areas with poor socioeconomic development and limited sanitation. Serologic evidence of prior or current infection with *E. histolytica* is present in 5% to 50% of individuals in impoverished populations. *E. histolytica* is infectious in the cyst form. Transmission usually occurs as a result of contamination of food or water, but may also occur by means of oral–anal contact. Infection is common in developing countries. In Europe and the United States, infection is most commonly seen in individuals who have lived in endemic areas of the world. Institutionalized individuals are also at increased risk of infection. Sexually active men who have sex with men are also at increased risk of infection. There does not appear to be an increased risk of invasive disease in persons with HIV infection.

A morphologically identical, but nonpathogenic protozoan, *Entamoeba dispar*, also infects the human gastrointestinal tract. It can be distinguished from *E. histolytica* by antigenic, genetic, and immunologic methods. Infection is 10 times more prevalent with *E. dispar* than with *E. histolytica*; however, the former does not cause invasive disease. Many older epidemiologic studies relied on microscopic diagnosis alone, and inadvertently incorporated both pathogenic and nonpathogenic species in estimates of prevalence of infection.

E. histolytica has a simple life cycle involving an infectious cyst and an ameboid trophozoite phase. Cysts may survive in the external environment for several weeks to months, especially in damp conditions and temperatures between −5°C and 40°C. After ingestion by humans, cysts excyst in the small intestine, each forming eight daughter trophozoites. These motile trophozoites can adhere to the intestinal wall; it is in this form that they may invade the mucosa, causing symptomatic invasive disease. In the colon, trophozoites encyst to complete the life cycle and are excreted. Trophozoites do not survive outside the human host.

CLINICAL MANIFESTATIONS

The incubation period for intestinal amebiasis is usually 1 to 4 weeks, but ranges from a few days to months. Infection with *E. histolytica* is asymptomatic in up to 90% of cases, but may cause a range of gastrointestinal symptoms from mild diarrhea to severe colitis with bloody diarrhea. Symptoms result from penetration of the trophozoites through the mucosal barrier with invasion of the colon wall. In the absence of frank blood, stool is usually positive for occult blood. Fever is present in less than half of cases. Fecal leukocytosis is usually less marked than in bacterial colitis. Rarely, progression of invasive intestinal disease may lead to severe colitis and bowel perforation. On occasion, granulation tissue formation surrounding a localized area of invasive disease may form an inflammatory mass (an "ameboma") and manifest as a tender abdominal mass.

Extraintestinal disease most commonly occurs in the liver, and manifests as a liver "abscess." In this instance, trophozoites migrate to the liver via the portal veins, and infection results in inflammation, necrosis, and ultimately a fluid collection. The collection is often referred to as an abscess; however, it does not contain polymorphonuclear cells like a true abscess, but only cellular debris. Eighty percent of amebic hepatic abscesses are solitary, and 80% occur in the right lobe of the liver. Extraintestinal disease may present years after residence in an endemic area and should be considered in all patients with an appropriate travel history and suggestive symptoms. Liver abscesses occur more frequently in men than women, and usually in the age range of 18 to 50 years.

Thoracic manifestations of *E. histolytica* infection are rare; they have been reported in 2% to 3% of cases of invasive amebiasis. They can be considered chiefly as either pleuropulmonary or pericardial. A case of *E. histolytica* osteomyelitis of the rib has been reported, as has a case of pulmonary amebiasis presenting as superior vena cava syndrome.[1]

PLEUROPULMONARY DISEASE

Amebic pulmonary disease may occur by a number of mechanisms.[1–3] It most often occurs as the result of a concomitant liver abscess. The abscess may result in a sympathetic pleural effusion that does not require specific therapy. A liver abscess may alternatively rupture through the diaphragm into the pleural space, causing respiratory distress, empyema, and subsequent parenchymal lung abscesses (Figs. 136-1 to 136-3). Pulmonary parenchymal disease in the form of lung abscesses and consolidation less often occurs in the absence of hepatic disease, but may occur if there has been hematogenous spread of trophozoites to the lung.

Most patients with extraintestinal amebiasis have not had symptomatic intestinal disease, so the absence of preceding gastrointestinal symptoms does not exclude the diagnosis. Patients with liver abscess often present with insidious onset of fever, right upper quadrant pain, and hepatic tenderness on palpation. Pleuritis, respiratory symptoms such as cough, dyspnea, and/or physical examination consistent with pleural effusion further suggest involvement of the pleuropulmonary system. Sputum production may range from scant to copious, and sputum may contain purulent material, particularly if a hepatobronchial fistula has developed. Classically, the purulent material of amebic abscess is reddish "anchovy paste." Jaundice is uncommon. Leukocytosis may be present, but eosinophilia is not a feature of the disease.

PERICARDIAL DISEASE

Pericardial disease can result from either sterile inflammation of the pericardium as a result of a contiguous liver abscess in the left lobe of the liver, or may be a purulent infection as a result of rupture of a hepatic amebic abscess into the pericardial space (Fig. 136-4). Chest pain, pericardial friction rub, and symptoms and signs of pericarditis may be presenting features. Presentation may be acute and severe, with symptoms and signs of pericardial tamponade.[4]

DIAGNOSIS OF PLEUROPULMONARY AND PERICARDIAL DISEASE

Stool microscopy may reveal the presence of *E. histolytica* trophozoites or cysts, but microscopy is neither a sensitive nor a specific method for the diagnosis of amebiasis. Microscopy is unable to distinguish *E. histolytica* from nonpathogenic *E. dispar*, and extraintestinal disease is associated with presence of the pathogen in stool

in only a minority of cases. Stool may be concentrated and stained with iodine to evaluate for the presence of cysts. Trophozoites are best seen on a fresh smear with iron hematoxylin and trichome stain. Microscopy of abscess fluid occasionally may reveal presence of trophozoites. Diagnosis of extraintestinal disease is best made by a combination of microscopic examination of samples, antigen detection, and serology tests.

■ ANTIGEN DETECTION

Antigen detection methods detect *E. histolytica*. These tests are able to distinguish *E. dispar* from *E. histolytica*. Stool antigen tests are over 95% sensitive and specific for the diagnosis of intestinal disease. Antigen detection assays are also highly sensitive and specific when applied to abscess fluid.

■ SEROLOGY

Most patients infected with *E. histolytica*, but not *E. dispar*, develop a serum antibody response. Amebic serology is positive in over 90% of patients with extraintestinal disease. Serologic analysis may be negative in early infection. The presence of IgG antibodies does not always indicate active disease; IgG may persist for many years after active infection.

TREATMENT

Metronidazole or tinidazole is effective in the treatment of individuals with intestinal and extraintestinal amebiasis. To prevent a relapse, a luminal agent such as iodoquinol or paromomycin also should be administered. Sympathetic pleural effusions do not need specific therapy, other than treatment of the underlying liver abscess. Amebic empyema and amebic pericarditis are best treated with aspiration or percutaneous drainage, in combination with administration of antiamebic microbial therapy.

FREE-LIVING AMEBA: ACANTHAMOEBA

Free-living amebae are rarely associated with human infection; however, when infection does occur, disease tends to be progressive and difficult to treat.

Acanthamoeba spp. are ubiquitous, and have been isolated from a wide variety of locations, including the nasal passages of healthy adults, water sources, soil, and contact lens fluid. Infection in humans usually manifests as either keratitis or systemic disease. Systemic disease usually involves the central nervous system, manifesting as granulomatous amebic encephalitis. Amebic infection of skin also has been reported.

CLINICAL FEATURES

Acanthamoeba sp. keratitis is usually a disease of healthy individuals, often contact lens wearers. Infection is thought to result from direct deposition of ameba into the eye. In contrast, systemic disease results from hematogenous dissemination of ameba, which are thought to first enter the human host via the respiratory tract or skin. Systemic disease is primarily a disease of immunocompromised or debilitated persons, including individuals with acquired immunodeficiency syndrome (AIDS), and those who have undergone bone marrow transplantation, organ transplantation, or are otherwise immunosuppressed. Pulmonary nodular infiltrates and pneumonitis have been reported in cases of systemic disease.[5]

DIAGNOSIS

Diagnosis of systemic acanthamebiasis is usually made late in the clinical course, and unfortunately, very often at autopsy. Evaluation of cerebrospinal fluid from individuals with granulomatous amebic meningoencephalitis may disclose hypoglycorrhachia and elevated protein, but amebae are not usually seen. Evaluation of biopsies of lesions of skin or brain usually provides the definitive diagnosis. *Acanthamoeba* spp. can be identified on histopathology, and may be cultured on nutrient agar overlaid with *Escherichia coli*. Radiographic imaging of the central nervous system is often helpful.

TREATMENT

No single drug is effective against systemic *Acanthamoeba* spp. infection. Combinations of treatment with amphotericin B, azithromycin, voriconazole, fluconazole, 5-fluorocytosine, pentamidine, and sulfadiazine have been attempted, with success in some cases and failure in other cases that used similar regimens. Most individuals with systemic amebiasis do not survive, regardless of therapy. Individuals with acanthamebic keratitis are usually treated topically and may require corneal grafting.

SYSTEMIC COCCIDIOSIS: TOXOPLASMOSIS

Toxoplasmosis is caused by *Toxoplasma gondii*. Asymptomatic disease is common. Symptomatic disease usually occurs in persons with suppressed cell-mediated immunity and infants born with congenital infection.

EPIDEMIOLOGY AND LIFE CYCLE

Understanding the life cycle of *T. gondii* is important in understanding the disease process. The parasite is found worldwide. It has both sexual and asexual stages, the latter being the pathogenic stage in humans and other animals. Cats are the definitive host, and in the feline, oocysts develop after an intestinal intraepithelial sexual cycle. Oocysts are then passed in cat feces, and after 2 to 3 days become infectious. They may persist in soil. If ingested by humans or other animals (sheep, pigs, rodents, or cats), oocysts produce rapidly dividing tachyzoites. Tachyzoites invade varying cell types, and result in cell death and tissue necrosis. Eventually the host immune response curtails this process, and tachyzoites give rise to slowly dividing bradyzoites, which encyst and persist indefinitely in host tissues. Bradyzoites are infectious if ingested, giving rise to tachyzoites in the new host. Bradyzoites may also revert to tachyzoites if a host becomes immunocompromised, leading to "reactivation" of disease. Humans and other animals may be infected, not only by ingestion of oocysts, but also by ingestion of tissue cysts, such as following the consumption of undercooked infected meat. Toxoplasma infection may also be acquired by transplacental passage of tachyzoites, resulting in congenital infection, or by organ transplantation.

Serologic studies demonstrate a wide geographic variation in prevalence of infection between 10% and 90%. In the United States, rates range from 3% in Denver, Colorado, to 17% in Massachusetts, and 30% in Birmingham, Alabama.

CLINICAL FEATURES

Infection may be primary or due to reactivation. After ingestion of infectious oocysts or tissue cysts, tachyzoites disseminate and invade organs, replicating intracellularly. Acute infection may result in tachyzoites being found in all organs, especially muscle, lymphatic tissue, and the central nervous system. Primary infection may be subclinical or asymptomatic. If symptomatic, the most common manifestations of acute disease include fever, painless lymphadenopathy, and a mononucleosis-like syndrome. More rarely pneumonitis, myocarditis, and myositis may occur.

Congenital infection is usually the result of primary infection in the mother, with transplacental passage of tachyzoites resulting in infection of the fetus. Infected infants may be symptomatic at birth, or may have hepatosplenomegaly, pneumonitis, myocarditis, rash, or jaundice. Congenitally infected children may be asymptomatic initially, but may subsequently develop central nervous system or ocular manifestations.

Reactivation disease occurs in persons who are immunocompromised, particularly those with deficiency in cell-mediated immunity. Patients with HIV infection and CD4 cell counts less than 100 cells/mm^3 are at particular risk of life-threatening disease, and although primary infection may occur in these individuals, reactivation disease is most common. Reactivation disease may be prevented in those at particular risk with the prophylactic use of trimethoprim–sulfamethoxazole. Necrotizing central nervous system disease is the most common manifestation of reactivation toxoplasmosis in AIDS patients. Affected individuals usually present with altered mental status, fever, headache, and clinical findings suggestive of focal CNS disease, and neuroimaging often reveals multifocal, ring-enhancing lesions.

PULMONARY DISEASE

Pulmonary involvement in toxoplasmosis is common, and is usually reported in patients with AIDS or in individuals who have undergone bone marrow or solid-organ transplantation (Fig. 136-5).[6,7]

Shortness of breath and cough are the most common presenting symptoms of pulmonary involvement during toxoplasmosis. In one review, immunocompetent patients with toxoplasmic pneumonitis were more likely than immunocompromised individuals to

Gutierrez.)*

have evidence of hepatosplenomegaly at presentation, but clinical findings were otherwise similar. Bilateral interstitial pulmonary infiltrates are most often evident in radiography; however, a variety of other findings, from discrete pulmonary opacities to cavitary disease, also have been described. Severe disease or the acute respiratory distress syndrome (ARDS) may develop. *T. gondii* organisms can invade myocytes, and during acute or reactivation disease, myocarditis may occur and may be severe.

■ DIAGNOSIS

In primary toxoplasmosis, the differential diagnosis is broad, but IgM-specific antibodies will usually be present. During reactivation of toxoplasmosis, IgM and IgG antitoxoplasma antibodies are usually present in serum. Absence of antitoxoplasma IgG antibodies makes the diagnosis of reactivation toxoplasmosis unlikely, but the presence of the antibody itself does not differentiate between latent and active diseases.

Biopsy can confirm the diagnosis. Polymerase chain reaction (PCR) analysis of tissue samples or cerebrospinal fluid is sensitive, and PCR analysis of amniotic fluid is particularly helpful in the antenatal diagnosis of congenital infection. PCR has been used to detect toxoplasma in sputum specimens, but the sensitivity of this method for diagnosing pulmonary toxoplasmosis has not yet been determined. In pulmonary disease, microscopic or molecular analysis of bronchoalveolar lavage fluid or open lung biopsy may be required for confirmation of the diagnosis.[8]

TREATMENT

Except in the case of pregnant women or individuals with severe or persistent symptoms, primary toxoplasmosis in immunocompetent individuals usually does not require treatment. Reactivation disease in immunocompromised individuals is usually treated for the duration of the period of immunosuppression, as therapy does not fully eradicate the parasite. Standard therapy is pyrimethamine and a sulfonamide, usually sulfadiazine. Leucovorin is added to overcome the bone marrow suppressive effects of pyrimethamine. Clindamycin or atovaquone may be used as an alternative in those intolerant of sulfonamides. After acute disease has been controlled, secondary suppressive therapy should be continued for the duration of immunosuppression to prevent relapse. Unfortunately, mortality in immunocompromised patients with *Toxoplasma* pneumonia diagnosed antemortem has been as high as 40%.

INTESTINAL COCCIDIOSIS: CRYPTOSPORIDIOSIS

Cryptosporidium spp. *(C. hominis/parvum* and *C. muris)* are intracellular protozoans that mainly cause intestinal pathology (Fig. 136-6). Disease may occur in immunocompetent hosts, but is more common and severe in immunocompromised individuals, particularly in patients with AIDS, in whom cryptosporidiosis may result in severe and persistent diarrhea. The organism also causes infection in a variety of animals, and fecal contamination of water or food is a common source of infection in humans, although person-to-person transmission also occurs.

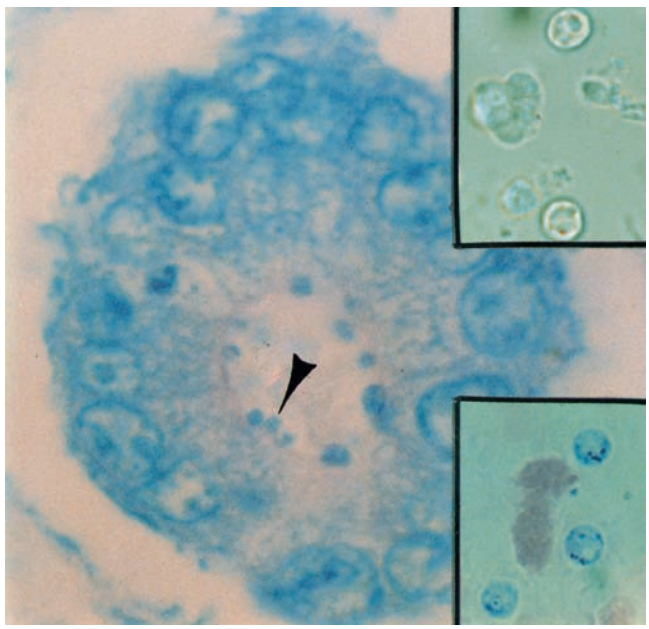

Figure 136-6 *Cryptosporidium parvum* infecting an intestinal crypt *(arrowhead)*. Parasites line the apical surface of the epithelial cells and are covered by host membranes. *Insets*: Oocysts isolated from feces. Upper, organisms isolated after a Sheather's sugar flotation, ×1360. Lower, Giemsa–Jenner stain, ×1360. *(Used with permission of J.A. Fishman, Massachusetts General Hospital.)*

The life cycle of *Cryptosporidium* spp. begins when the infectious oocyst is ingested. These organisms, which are 4 to 5 μm in diameter, may remain viable in the environment for months. After ingestion, they excyst in the small intestine, and release four motile sporozoites, which invade epithelial cells of the intestinal wall. Asexual maturation then results in merozoites being released back into the intestinal lumen. These merozoites either result in reinvasion of epithelial cells, or undergo maturation to become oocysts. The oocysts may then be excreted, or may excyst while still in the lumen to "autoinfect" the host.

CLINICAL FEATURES

Cryptosporidial infection may be asymptomatic, or may be associated with a range of illness from mild diarrhea to severe gastroenteritis. Invasion of the intestinal epithelium results in secretory diarrhea. The biliary tree may be infected, causing cholangitis, and hepatitis and pancreatitis also have been described. Infection may be associated with systemic symptoms such as malaise, nausea, and abdominal cramps. In some patients, diarrhea is voluminous and has been described as "cholera-like." In patients with a normal immune system, cryptosporidial diarrhea usually resolves within 2 weeks. In immunocompromised individuals, especially those with HIV infection and CD4 cell counts less than 100 cells/mm^3, symptoms often continue until the immune status of the individual is restored. In such individuals, cryptosporidiosis may result in a severe wasting syndrome.

PULMONARY CRYPTOSPORIDIOSIS

Respiratory infection with *Cryptosporidium* spp. is rare, but has been reported, usually in patients with AIDS (Fig. 136-7).[9] Pulmonary involvement, as with other extraintestinal manifestations of cryptosporidiosis, usually occurs in the setting of intestinal disease. At least one case of pulmonary infection, however, has been reported with no apparent evidence of intestinal infection. Pulmonary involvement may appear as an interstitial infiltrative process or as areas of focal consolidation. Some authors suggest that the prevalence of pulmonary cryptosporidiosis is underestimated, and one study reported a prevalence of 17% in HIV-positive patients with respiratory symptoms.

DIAGNOSIS

Cryptosporidium may not be cultured in vitro, and diagnosis of cryptosporidiosis relies largely on demonstration of pathologic findings in tracheal or bronchial tissues, and visualization of cryptosporidial cysts by microscopy. The cysts may be best seen by acid-fast staining of specimens. Oocysts have been detected in bronchoalveolar lavage, open lung biopsy, and sputum specimens.

TREATMENT

Nitazoxanide decreases diarrhea in immunocompetent individuals with intestinal cryptosporidiosis. However, reliable efficacy has not been demonstrated in individuals with disseminated cryptosporidial disease, or those who are immunocompromised. Thus, in most individuals, treatment is predominantly supportive while attempts are made to restore immune function; in patients with AIDS, this is chiefly through the use of antiretroviral therapy. In addition to nitazoxanide, other agents have been administered to individuals with cryptosporidiosis, although efficacy has not been demonstrated. Administered agents have included paromomycin, trimethoprim–sulfamethoxazole, and metronidazole. Anecdotally, azithromycin has been successfully combined with paromomycin in the therapy of pulmonary infection.

Ma.)*

CYCLOSPORIASIS

Cyclospora cayetanensis is a protozoan organism, usually associated with diarrheal illness in humans. It is ubiquitous, and transmitted usually as a result of contamination of food or water. The protozoan is usually detected as an approximately 10-μm organism on acid-fast stains of specimens. Infection usually responds to trimethoprim–sulfamethoxazole. A single case report of possible pulmonary cyclosporiasis has been reported. A 60-year-old Brazilian man with a history of treated tuberculosis was found to have *C. cayetanensis* organisms in sputum specimens examined for evaluation of respiratory distress and pulmonary infiltrates. No other organisms were detected, and the patient's symptoms resolved following administration of trimethoprim–sulfamethoxazole (and treatment of concomitant intestinal parasitosis).

SARCOCYSTIS

Sarcocystis spp. are intracellular protozoal coccidian two-host parasites. Humans can be a definitive host for *Sarcocystis hominis* and *Sarcocystis suihominis,* and following ingestion of tissue cysts in undercooked beef *(S. hominis)* or pork *(S. suihominis)*, can develop acute gastroenteritis and excrete oocysts. Alternatively, humans can ingest the oocysts of other predator animals and develop a vasculitis that can manifest as myositis, cardiomyositis, or involve the lungs, kidneys, and liver. Eosinophilia is prominent. Eventually the parasites encyst in musculature, including cardiac tissue. Diagnosis is usually based on clinical recognition, myositis associated with eosinophilia and a negative trichinella serology, and/or biopsy of muscle. Treatment is usually supportive, often involving steroids. Cases are usually sporadic, although recurrent outbreaks have been associated with Tioman Island, Malaysia.[10]

MALARIA

Malaria in humans is the result of infection by one of five species of plasmodia: *Plasmodium falciparum, P. vivax, P. ovale, P. malariae,* and *P. knowlesi*. Human malaria is endemic in parts of sub-Saharan Africa, India, Southeast Asia, the Caribbean, and Central and South America. Approximately 800,000 deaths annually are attributed to malaria, usually among pregnant women and children under the age of 5 years who live in endemic areas. The majority of malaria-related fatalities are a result of infection with *P. falciparum*.

Malaria is acquired by the bite of an infective female *Anopheles* sp. mosquito. In nonendemic areas, malaria cases are found largely in travelers who have returned from malaria-endemic areas, but the parasite also may be transmitted by contaminated blood products, in utero from mother to child, and by organ transplantation. Malaria infection in persons coinfected with HIV is associated with increased HIV viral load, and increased symptoms in the setting of parasitemia.

LIFE CYCLE

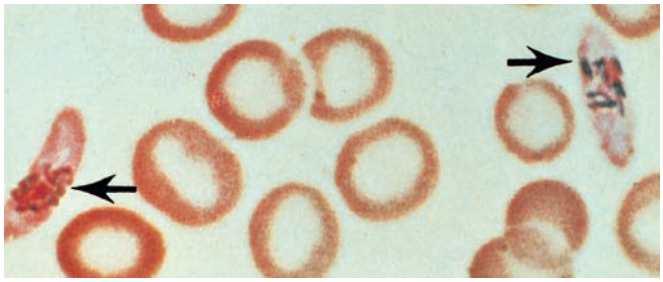
When bitten by an infective mosquito, malarial sporozoites enter the host and travel to the liver, where they invade hepatocytes and divide, forming tissue schizonts in an asymptomatic stage. These schizonts then rupture, releasing thousands of daughter merozoites into the bloodstream. These merozoites invade erythrocytes, and develop to form mature ring forms and ultimately erythrocytic schizonts. A small percentage of merozoites develop into sexual forms called gametocytes. Gametocytes do not cause symptoms, but when another mosquito bites an infected human host, the gametocytes are ingested by the feeding mosquito, permitting the malarial life cycle to continue. *P. falciparum* may infect red blood cells of all ages, resulting in the potential for very high levels of parasitemia.

Infection with *P. vivax* and *P. ovale* may result in a dormant liver phase in which parasites remain in the liver in the form of hypnozoites, potentially causing relapse many months after first infection. *P. falciparum* and *P. malariae* do not have such a dormant stage, and do not cause late relapsing disease. *P. knowlesi* is a simian malarial parasite that has been diagnosed in humans in areas of Asia.

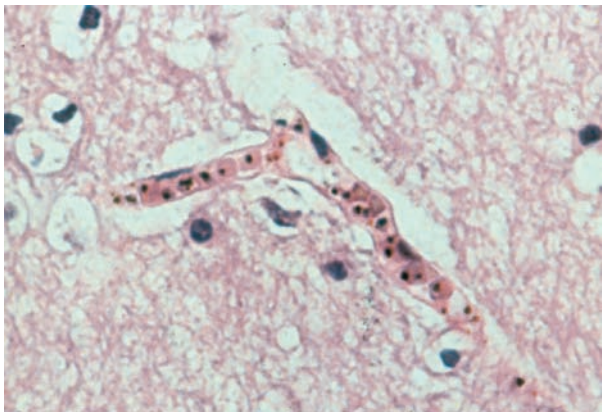
PATHOGENESIS

Malaria-related morbidity and mortality occurs predominantly in children and pregnant women. Most individuals who live in endemic areas develop partial immunity to symptomatic disease as they age. This immunity does not prevent infection, but reduces the frequency of symptoms and severity of disease despite ongoing parasitemia. Infection with any of the five species of malaria causes hemolysis, resulting in anemia that may be severe.

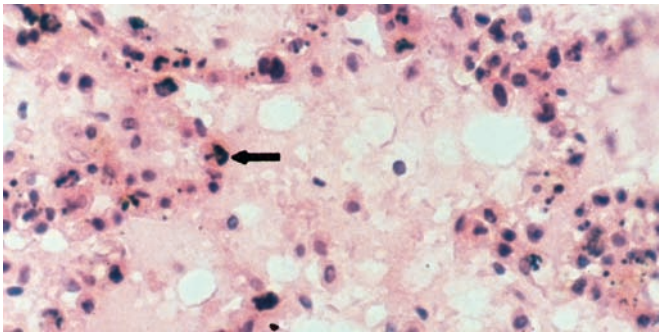
Certain genetic traits associated with hemoglobin structure or erythrocyte surface antigens are associated with decreased infection rates or decreased symptomatic disease. For example, absence of the Duffy antigen on the surface of erythrocytes protects against *P. vivax* infection, and sickle cell trait is protective against severe *P. falciparum* infection. *P. falciparum* also causes the formation of "sticky knobs" on the surface of infected erythrocytes. These knobs comprise host cell and parasite antigens, and mediate binding of infected erythrocytes to endothelial surfaces. This binding results in sequestration of infected erythrocytes, and may result in "sludging"



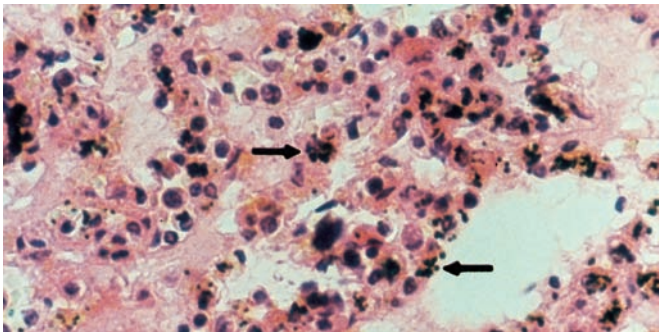
A



B



C



D

Figure 136-8 *Plasmodium falciparum*. **A.** Banana-shaped gametocytes on peripheral blood smear *(arrows)*. This form is only seen with falciparum malaria (Wright stain, ×1375). **B.** Cerebral vessels obstructed by parasitized red blood cells *(arrow)* with surrounding edema (hematoxylin and eosin stain, ×1375). **C.** Acute pulmonary edema due to pulmonary venular occlusion (organism at *arrow*; hematoxylin and eosin). **D.** Deposition of malarial pigment *(arrows)* in vicinity of occluded pulmonary vessels.

of blood flow. This sequestration and sludging contributes to microvascular obstruction that can result in organ dysfunction.

CLINICAL FEATURES

Patients with malaria typically present with fever and a constellation of other nonspecific symptoms such as headache, chills, and myalgias. Vomiting, nausea, diarrhea, and cough also may be present. Anemia, thrombocytopenia, and hepatosplenomegaly may be present. Sequestration of infected erythrocytes in the brain may cause cerebral malaria. Individuals with cerebral malaria may present with altered mental status, seizures, focal neurologic findings, or coma. Even with treatment in modern intensive care units, mortality during cerebral malaria is high. Other organ-specific complications of infection are also largely related to microvascular sequestration of parasitized red blood cells in specific tissues, and may manifest as placental, renal, or pulmonary dysfunction (Fig. 136-8).

PULMONARY FEATURES

Pulmonary symptoms such as cough and increased respiratory rate are common during malaria.[11] In African children, malaria frequently presents with symptoms and signs suggestive of pneumonia. Metabolic acidosis is an important cause of respiratory distress in these children, but pneumonitis as a result of sequestered parasitized red blood cells is also responsible. In more severe disease, noncardiogenic pulmonary edema may develop. Initial acute lung injury may progress to ARDS (Fig. 136-9).[12] Tachypnea and dyspnea, followed by hypoxemia and respiratory failure may develop. Studies have confirmed the development of impaired alveolar–capillary membrane function in patients with severe malaria. Lung injury in severe disease is postulated to be not only the result of pulmonary microvascular sequestration, but also a consequence of the inflammatory response to infection.

In a recent study of uncomplicated symptomatic malaria, altered pulmonary physiology, including increased airflow obstruction, decreased gas transfer, impaired ventilation, and increased pulmonary phagocytic activity were found in both *P. vivax*- and *P. falciparum*-associated infections, but were worse in cases of *P. falciparum* malaria.[13] ARDS has also been reported in cases of malaria caused by *P. vivax,* and one case of pulmonary edema has been reported complicating a case of *P. ovale* malaria; however, significant pulmonary morbidity is largely confined to infection by *P. falciparum*, and usually occurs in the context of multisystem involvement.[14] The principal differential diagnosis for pulmonary disease in malaria infection is metabolic acidosis and bacterial pneumonia.

DIAGNOSIS

The diagnosis of malaria should be considered in any symptomatic patient who has had exposure to the parasite in a malaria endemic area. Rare cases of transmission by blood products, organ transplantation, or congenital infection also have occurred. Individuals with malaria caused by *P. falciparum* usually develop symptoms within 3 months of the mosquito bite, and usually within 1 month. Since *P. vivax* and *P. ovale* have potentially dormant liver phases, individuals infected with these parasites may not develop symptoms for many months after exposure (usually within 1 year of the mosquito bite).

Malaria is usually diagnosed through microscopic examination of blood smears, or with antigen-based rapid diagnostic tests (RDTs).

TREATMENT

Appropriate treatment of individuals with malaria depends on the infecting species, severity of disease, age and pregnancy status, and the ability of the patient to take drugs by mouth. Non-falciparum malaria is generally susceptible to chloroquine phosphate, although to date, resistance has been reported in parts of Indonesia, Papua

Figure 136-9 ARDS in a 31-year-old man with *P. falciparum* malaria. Chest radiograph demonstrates patchy bilateral areas of increased opacity. *P. falciparum* trophozoites were found in a thick blood smear. *(Reproduced with permission from Martinez S, Restrepo CS, Carrillo JA, et al. Thoracic manifestations of tropical infections: a pictorial review. RadioGraphics. 2005;25(1):135–155.)*

New Guinea, India, Myanmar, and Brazil. The World Health Organization now recommends that individuals with chloroquine resistant *P. falciparum* malaria be treated with artemisinin-based combination therapies (ACTs) that include an artemisin derivative with a second agent such as lumefantrine, amodiaquine, pyronaridine, piperaquine, or mefloquine. Less optimal alternatives include oral atovaquone–proguanil or mefloquine, or quinine sulfate in combination with either doxycycline or clindamycin. Individuals with severe disease can receive intravenous artesunate in the United States, coadministered with a second agent such as doxycycline or clindamycin. Less optimal alternatives include parenteral quinine dihydrochloride or quinidine gluconate with a second agent.

Individuals with malaria caused by *P. vivax* or *P. ovale* also should be treated with primaquine to treat the hypnozoite form of disease. Primaquine should not be administered to individuals deficient in glucose-6-phosphate dehydrogenase or pregnant women. Pulmonary manifestations and other organ-specific complications of severe infection are treated supportively. Mechanical ventilation may be required. Early institution of renal replacement therapy may prevent subsequent development of ARDS in severe malaria. Exchange transfusion has been recommended for patients with severe falciparum-associated disease with parasitemia levels over 5%, although data on efficacy are controversial.

BABESIOSIS

Babesiosis is a tick-borne infection usually caused by *Babesia microti* in the United States, and *Babesia divergens* in Europe. In the United States, the disease has been reported from Minnesota, Maryland, Virginia, California, Washington State, Georgia, Wisconsin, and Indiana; however, most cases occur in the Northeastern states. Transmission also may occur as the result of infected blood transfusions.

Babesia parasites invade, multiply within, and lyse red blood cells. In immunocompetent hosts, disease is most commonly asymptomatic or relatively mild, and characterized by fever, flu-like illness, myalgias, and nausea. More severe manifestations may include thrombocytopenia, hemolytic anemia, jaundice, meningismus, noncardiogenic pulmonary edema, disseminated intravascular coagulation, hypotension, and shock. Severe disease is most common among the elderly or individuals with compromised immunity. Asplenic individuals are at particular risk of severe disease, and individuals infected with HIV or following organ transplantation are at particular risk of persistent disease. Pulmonary disease in babesiosis occurs in association with multisystem disease, and usually presents as ARDS or noncardiogenic pulmonary edema or ground-glass opacification.[15]

The diagnosis of babesiosis should be considered in any patient with appropriate exposure history who presents with fever or a sepsis syndrome. Diagnosis is usually confirmed by microscopic examination of peripheral blood. Atovaquone, azithromycin, quinine, and clindamycin all have anti-Babesia activity; combination therapy is usually administered.

TRYPANOSOMIASIS

American and African trypanosomiasis are considered below.

AMERICAN TRYPANOSOMIASIS (CHAGAS DISEASE)

Chagas disease is caused by infection with *Trypanosoma cruzi*, a protozoan parasite transmitted to humans most often via the feces of an infected reduviid bug. The disease is endemic in certain South and Central American countries. Clinical manifestations may occur acutely after initial infection. More commonly, clinical manifestations may not become evident until years or decades after initial infection. When acute symptoms do occur, they may include fever, peripheral edema, hepatosplenomegaly, and myocarditis. Chronic sequelae may occur in up to one-third of infected individuals, and usually involves the heart, esophagus, or large bowel (Fig. 136-10).

Cardiac disease usually manifests clinically as congestive-dilatory cardiomyopathy.[16] Chronic dilatation of the esophagus or colon resulting from denervation of the gut may result in Chagasic mega-esophagus or mega-colon. Acute myocarditis may result in pulmonary edema. Pulmonary involvement during Chagas disease is usually secondary to cardiac or intestinal disease, and may include pulmonary edema secondary to congestive heart failure, pulmonary hypertension secondary to right-sided dilatory cardiomyopathy, or aspiration pneumonia secondary to vomiting and regurgitation associated with mega-esophagus or mega-colon. Recurrent aspiration and pneumonitis may lead to lung abscesses, fibrosis, scarring, and bronchiectasis. The debilitation of chronic Chagas disease may lead to cachexia, and may be associated with a higher rate of tuberculosis. In an autopsy review of 69 adult cases of Chagasic mega-esophagus in Brazil, 35% of patients had pneumonia, and 22% had pulmonary tuberculosis—rates that were higher than in a cohort of patients in the same study who had Chagasic cardiac disease, but no mega-esophagus.

Congenital Chagas disease has been associated with pneumonitis; and in an autopsy review of 10 congenital cases, pathologic findings have included diffuse pulmonary interstitial edema and endothelial swelling in lung tissues.

Diagnosis in acute Chagas disease may be made by detecting parasites on blood smear. Culture of parasites from specimens is possible using specialized media, although the usefulness of this method is limited because culture may take several weeks. In chronic disease, parasites are not usually visualized. Diagnosis is usually based on serologic analysis, suggestive radiology, and, more rarely, pathologic examination of tissues. Treatment in acute disease and in patients with immunosuppression is warranted, and nifurtimox and benznidazole are the mainstays of therapy. Posaconazole may also have some activity. The utility of treating individuals with established, chronic disease with antiparasitic agents is currently unclear.

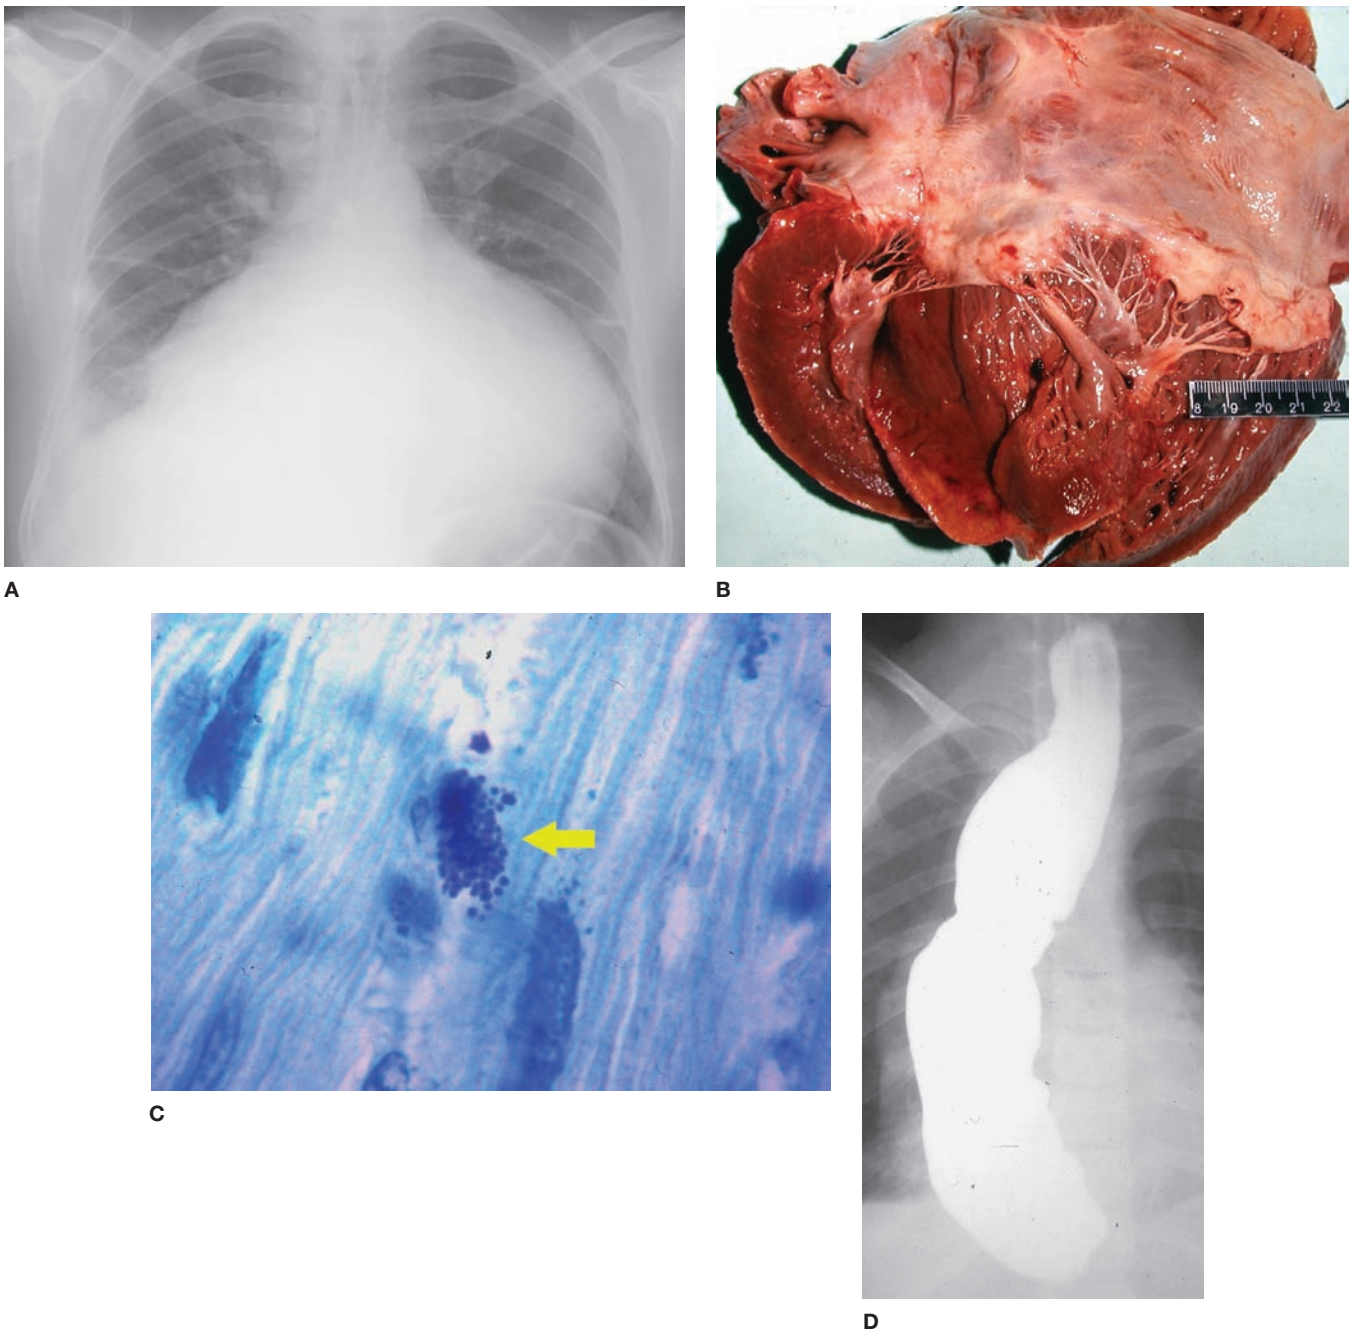


Figure 136-10 Chronic Chagas disease in a 39-year-old man with chronic dilated cardiomyopathy. **A.** Chest radiograph shows global cardiomegaly with pulmonary congestion. **B.** Photograph of the gross specimen demonstrates dilatation of the cardiac chambers with thickening of the ventricular myocardium. Scale is in centimeters. **C.** Low-power photomicrograph (original manifestation, ×10; Giemsa stain) shows *T. cruzi* amastigotes within a myofiber *(arrow)*. **D.** Chagasic achalasia in a 13-year-old girl with Chagas disease. Thoracic manifestations of tropical infections: a pictorial review. RadioGraphics. 2005;25(1):135–155.)*

■ AFRICAN TRYPANOSOMIASIS (AFRICAN SLEEPING SICKNESS)

Trypanosoma brucei gambiense and *Trypanosoma brucei rhodesiense* are the causative agents of African trypanosomiasis (African sleeping sickness). African sleeping sickness is usually transmitted by the bite of an infective tsetse fly. East African trypanosomiasis is caused by *T.b. rhodesiense*. Individuals with East African trypanosomiasis are often acutely ill with fever, lymphadenopathy, headache, and myalgia. Disease may be fulminant, and individuals may develop disseminated intravascular coagulopathy, ARDS, hypotension, and shock. The most common pulmonary manifestations during acute disease are noncardiogenic pulmonary edema and ARDS. West African trypanosomiasis is caused by *T.b. gambiense*. Individuals with West African trypanosomiasis usually do not develop severe disease during the acute stage. Rather, months or years after initial infection, infected individuals present with mental status changes, personality changes, recurrent fever, lymphadenopathy, weight loss, and disorders of circadian rhythm. QTc prolongation can occur.[17]

The most common pulmonary manifestation during late-stage disease is pneumonitis second to recurrent aspirations associated

with inanition and altered mentation. Direct pulmonary involvement is not common in West African trypanosomiasis. A single case report describes an African child who presented with severe respiratory symptoms, and was later found to have African trypanosomiasis.

LEISHMANIASIS

Leishmaniasis is caused by an intracellular protozoa parasite in the *Leishmania* genus. The Leishmania parasites are widely distributed, and are usually transmitted through the bite of an infective sand fly. Infection of humans may be asymptomatic, or may involve the skin (cutaneous leishmaniasis), the mouth or nose (mucocutaneous leishmaniasis), or be systemic (visceral leishmaniasis). Human infection is most common in South and Central Asia, the Middle East, the Mediterranean, Balkans, North Africa, sub-Saharan Africa, and Central and South America. Specific organisms are often responsible for specific clinical syndromes, although overlap occurs. Disease is often considered as "New World" or "Old World," based on geographic location. The parasite exists as an intracellular organism (amastigote) in host macrophages, and as an extracellular promastigotes in the sandfly gut—being inoculated into the host's skin during the bite of the fly.

CLINICAL FEATURES

Cutaneous syndromes may range from localized disease, usually on exposed areas of skin, to widespread cutaneous involvement. In localized disease, painless ulcers develop and most often resolve spontaneously over months. Classically, "Old World" cutaneous leishmaniasis is caused by *L. major, L. tropica, L. aethiopica,* or *L. infantum*; "New World" cutaneous disease is usually caused by *L. braziliensis* or *L. mexicana* complex organisms. Some New World species are associated with the development of mucocutaneous disease months to years after resolution of the initial skin lesions. Severe destruction and disfiguration of the face with resultant aspiration pneumonitis may occur.

Visceral leishmaniasis is usually caused by *L. donovani, L. infantum,* or *L. chagasi*. Individuals with visceral leishmaniasis usually present with fever, hepatosplenomegaly, weight loss, pancytopenia, and hypergammaglobulinemia. Lymphadenopathy is commonly present. Gastrointestinal symptoms are common in advanced disease, and individuals with untreated visceral leishmaniasis develop a wasting syndrome. Pneumonia and tuberculosis may be the cause of death.

PULMONARY DISEASE

Pulmonary involvement from leishmaniasis in immunocompetent hosts is rare, but interstitial pneumonitis has been reported. However, immunosuppressed patients, particularly those with HIV infection, are at increased risk of atypical disease. In areas surrounding the Mediterranean, where seroprevalence for *L. infantum* in young adults may be as high as 30%, an increase in the incidence of HIV infection has caused an increase in the number of advanced cases of visceral leishmaniasis; a result either of new infections or reactivation of old infections. Patients with leishmaniasis and HIV infection may present with cough, dyspnea, hemoptysis, granulomatous mediastinal lymphadenopathy, solitary pulmonary nodules, or pleural effusions. Advanced visceral leishmaniasis may be complicated by suprainfecting pneumonia even in immunocompetent hosts.[18]

Treatment of leishmaniasis depends on type of disease (cutaneous vs. mucocutaneous vs. visceral), infecting species, parasite resistance patterns, severity of disease, and status of the host. Therapeutic options include liposomal preparations of amphotericin, amphotericin B, pentavalent antimony (sodium antimonylgluconate or N-methylglucamine antimonate), pentamidine, and miltefosine.

CILIATE INFECTIONS: *BALANTIDIUM COLI*

Balantidium coli is the only ciliated protozoa that infects humans. Infection of humans usually occurs in individuals with contact with pigs, and human disease usually manifests as an infectious colitis very similar to amebiasis. Rare cases of pulmonary infection have been reported in humans: in a leukemic patient who presented with pulmonary lesions, in a 71-year-old woman with anal cancer and pneumonia, and a patient with chronic colitis and an intrapulmonary mass.[19,20]

Diagnosis is usually made through histologic examination of tissue samples. Treatment with tetracycline, metronidazole, or iodoquinol is usually effective.

FLAGELLATES

Two flagellates are discussed briefly below: *Trichomonas* species and *Giardia lamblia*.

TRICHOMONAS SP.

Trichomonads are flagellated protozoa. Pulmonary disease has been attributed most commonly to *Trichomonas tenax*, an organism that is most often considered a commensal in the human oropharynx, especially in individuals with poor oral hygiene. In one study of symptomatic patients, prevalence of *T. tenax* by PCR among 100 immunocompromised and 100 patients with chronic pulmonary disease was 10%.[20]

Diagnosis is most often made by examination of a wet mount of sputum or bronchoalveolar lavage specimen. Chronic purulent, necrotic pulmonary disease, or pleural involvement has been described, often thought to be a result of aspiration.[21] Affected individuals have responded to metronidazole therapy.

GIARDIA LAMBLIA

Giardia lamblia is a pathogenic intestinal flagellate of humans. In humans, it usually causes chronic diarrhea and malabsorption. There is one case report of uncertain significance of recovery of *G. lamblia* trophozoites from bronchoalveolar lavage fluid.

MICROSPORIDIOSIS

Microsporidia is the name given to a group of spore-forming obligate intracellular organisms from the phylum *Microsporidia*. These organisms have been variously considered with the protozoa and fungi. Over 1200 microsporidia species occur worldwide, but the most common human pathogens are *Enterocytozoon, Encephalitozoon, Nosema, Pleistophora*, and *Septata* spp.

The microsporidia spore is the infective form of the organism, and when ingested or inhaled, it extends a polar tubule that infects the host cell. Within the host cell, replication occurs and more spores are formed. When spores sufficiently fill the cell, the cell membrane ruptures and spores are released; they may then proceed to infect nearby cells, or be passed into the environment in stool, urine, or respiratory secretions.

Most clinical cases of microsporidiosis in humans occur in immunocompromised hosts. In immunocompetent patients, infection with *Enterocytozoon bieneusi* can be asymptomatic or may cause acute and very rarely chronic diarrhea. In patients with HIV infection, symptomatic microsporidiosis tends to occur in advanced disease, such as when CD4 cell counts are less than 100 cells/mm^3. *E. bieneusi* and some species of Enterocephalitozoon (*E. hellem, E. cuniculi,* and *E. intestinalis*) have come to be recognized as major causes of diarrheal enteritis and disseminated infection in patients with AIDS. Disseminated disease caused by *Trachipleistophora* also has been described. Microsporidial species have been associated with disseminated disease including biliary tract disease, sinusitis, myositis, respiratory infection, and keratoconjunctivitis.

Pulmonary Disease

Microsporidial disease with specific pulmonary involvement has been described in cases of patients with HIV infection, and in individuals who have undergone bone marrow or organ transplantation (Fig. 136-11).[22]

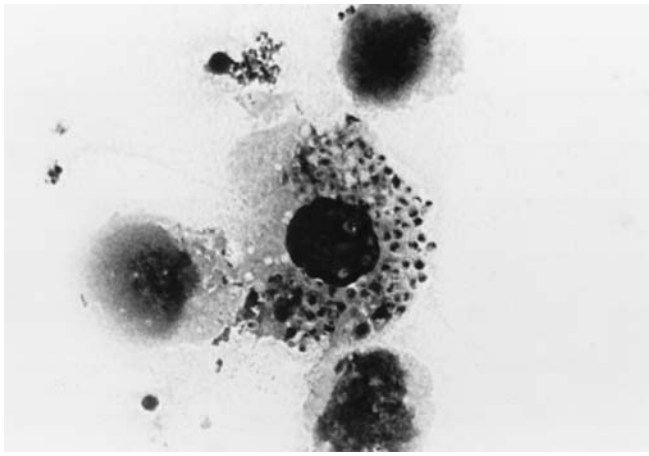

Figure 136-11 Pulmonary microsporidiosis. Tiny organisms (~1 μm) within a pulmonary macrophage obtained via bronchoalveolar lavage (Giemsa–Wright stain, ×1000). *(Used with permission of Dr. C. Wanke.)*

Pulmonary disease usually occurs in the setting of concomitant intestinal infection. In one retrospective review of 42 patients with HIV and microsporidial infection, 24% had respiratory symptoms, and four of six patients who had specimens examined had sputum or bronchoalveolar lavage positive for microsporidia.[23]

Diagnosis

Diagnosis of microsporidiosis is based on identification of organisms in specimens of tissue or stool. Modified trichome staining allows detection of organisms on light microscopy, but electron microscopy is currently the definitive diagnostic method. Tissue culture, serologic assays, and PCR testing are used in research settings, but are not yet commercially available.

Treatment

Albendazole has activity against *Encephalitozoon* species, but is only partly effective against *E. bieneusi*. In immunocompromised individuals, treatment is directed at enhancing the immune status of the patient, that is antiretroviral therapy in patients with HIV infection, and decreased immunosuppression in transplant recipients. Duration of albendazole therapy depends on the severity of illness. *E. bieneusi* infections may be refractory to treatment.

CHAPTER 137

Helminthic Diseases of the Lungs

Alissa Jade Wright
Jay A. Fishman

Parasitic helminths are a distinct group of infectious agents that are among the most prevalent causes of morbidity and mortality in humans worldwide. Billions of people harbor parasitic worms. People with helminthic infections of the lungs often seek medical advice because of one or more common chest complaints—cough, pain, or breathlessness. They may also have unexplained laboratory abnormalities, including eosinophilia or pulmonary nodules. They can pose a diagnostic challenge, particularly in areas where helminthic infections are not endemic. More common causes of chest complaints have to be excluded, a history of residence in certain geographic locations or of dietary or other exposures has to be elicited, and the proper procedures for making the diagnosis of helminthiasis selected.

The helminths that parasitize humans include the nematodes (roundworms) and the platyhelminthes (flatworms), with the flatworms divided into the cestodes (tapeworms) and the trematodes (schistosomes and other flukes). The biology of each of these groups is distinct. Ectoparasites (e.g., the Annelida, such as leeches, ragworms, or earthworms) are uncommonly associated with lung disease and are not discussed here.

In humans, worms produce a variety of pulmonary parenchymal and vascular diseases (Table 137-1). Familiarity with the biologic behavior of each organism is essential for proper diagnosis and treatment because several stages in the life cycle of the parasite are typically found in humans, and pulmonary lesions can occur at different stages, depending on the infecting parasite.

BIOLOGY AND IMMUNOLOGY

Worms are multicellular organisms that vary substantially in size—from a few millimeters to several meters. They are covered by a tegument cuticle that protects them from the environment. Reproductive organs – both sexual and hermaphroditic – take up a large portion of the body. They are among the most developed and elaborate of human parasites, and their parasitic capabilities are such that they often inhabit more than one host and survive different hostile environments. Despite their relatively large adult size, the infective stages of the worms invade human tissues by ingestion, penetration of skin, or the bite of insect vectors. Furthermore, parasitic helminths have developed a myriad of mechanisms by which they may evade the defense system of the host.

The life cycle of the helminths includes an egg form, several larval stages, and an adult form. Human infection is by ingestion of the eggs or larvae, penetration of the skin by larvae, or insect transmission of larvae. Humans may be the only host (in whom both development and reproduction of the parasite occur), an accidental host (in whom neither development nor reproduction occur), an intermediate host (in whom only asexual development occurs), or a definitive host (in whom sexual reproduction occurs). A basic biologic generalization about helminthic infections is that the worms, as a rule, cannot multiply within the mammalian host. This phenomenon is important for understanding the dynamics of helminthic infection and the relationship between the intensity of a particular worm load and its pathologic consequences to the host. However, there are exceptions to this rule. For example, *Strongyloides stercoralis* and *Echinococcus granulosus* can increase their numbers within a host, even though the host is not exposed to additional infective forms. This ability of *S. stercoralis* to autoinfect the same subject is of considerable clinical significance, especially in immunosuppressed patients, in whom it can lead to a fatal hyperinfection. A different example is that of echinococcosis, where dissemination is usually a consequence of leakage or rupture of a hydatid cyst, which allows its contents to initiate similar lesions elsewhere.

Another biologic characteristic of worm infections is the association with tissue and peripheral blood eosinophilia and increased levels of immunoglobulin E, similar to that seen with atopic disease.[1] When eosinophilia is marked, this association provides a clinically useful sign of a migratory worm infection. The prominent peripheral blood eosinophilia of tissue migratory worm infections contrasts with the lack of eosinophilia seen in people in whom the worm infection is confined to the gut lumen or in whom the infection is due to another agent (e.g., viruses or bacteria). It should be

TABLE 137-1 Pulmonary Parenchymal and Vascular Diseases Produced by Worms

Major Pulmonary Presentation	Infection	Causative Organism	Infective Stage	Pathogenic Stage
Loeffler-like syndrome	Ascariasis	*Ascaris lumbricoides*	Embryonated eggs in soil	Migrating larvae
	Hookworms	*Ancylostoma duodenale, Necator americanus*	Larvae in soil	Migrating larvae
	Strongyloidiasis rhabditiform	*Strongyloides stercoralis*	Larvae in soil	Migrating larvae
	Hyperinfection with filariform	*S. stercoralis*	Larvae in bowel	Migrating larvae
Pulmonary eosinophilia	Lymphatic filariasis	*Wuchereria bancrofti, Brugia malayi*	Larvae in mosquito	Microfilariae
Eosinophilia, cough	Visceral larva migrans	*Toxocara canis, T. cati*	Egg ingestion	Larvae
Space-occupying lesions	Echinococcosis	*Echinococcus granulosus*	Eggs in soil	Hydatid cysts
	Paragonimiasis	*Paragonimus westermani*	Metacercariae	Adult worms
	Schistosomiasis	*Schistosoma mansoni, S. japonicum, S. haematobium*	Cercariae in fresh water	Eggs

noted that patients who lack *cellular* immune function are often unable to produce this characteristic sign. Corticosteroids may also lyse eosinophils and complicate diagnosis.

Although it has long been thought that eosinophils play a vital role in the host defense against helminths, our understanding of their role has become much more sophisticated in recent years.[1,2] Although eosinophils – along with antibodies or complement – kill the larval forms of several helminths in vitro, not all animal and human studies confirm the importance of eosinophils in host protection.[1,3,4] Moreover, eosinophils may actually contribute to the pathogenesis and tissue destruction seen with certain helminthic infections.[2] Currently, it is thought that immunity to the helminths does not rest on any single cell type, but rather a coordinated effort from multiple immune pathways. Although the adaptive immune system plays a vital role in coordinating this attack via *sensitized* lymphocytes, much of our immunity to parasites rests with innate pathways of host defense.[2,5] It has also become increasingly recognized that sterilizing immunity to helminths is rarely achieved, likely due to their sophisticated mechanisms of immune evasion and the high cost of fully eradicating these large, multicellular organisms Rather, most of the time, humans and helminths exist in a state of evolutionary-derived tolerance.

HOST–PARASITE RELATIONSHIP IN PULMONARY HELMINTHIASES

Human disease caused by pulmonary helminthiases results from various factors. Many helminths can reside in human lungs during one or more of their parasitic stages. However, the stage of the life cycle that causes human pulmonary disease varies—for example, larvae of nematodes, eggs of schistosomes, and adult worms in paragonimiasis or cestode infections. The multiplicity and complex structure of these etiologic agents lead to a heterogeneous set of responses, both immunologic and nonimmunologic. Moreover, disease may result from the mechanical presence of worms (i.e., space-occupying lesions) and the associated inflammatory response, as a byproduct of the host immune response, or both. For example, in echinococcosis, hydatid cysts displace lung tissue, but in pulmonary schistosomiasis, the vascular obstructive lesions are predominantly the outcome of the delayed-hypersensitivity response of the host causing granuloma formation. Therefore, the understanding of the host–parasite relationship in pulmonary helminthiasis is based on an appreciation of the heterogeneity of these etiologic agents and the corresponding host responses.

The immune responses of the host often feature prominently in shaping the pathologic consequences of helminthic infection of the lungs. In experimental animals, the degree of tissue injury and host responsiveness to several helminthiases has been shown to be regulated by modulatory antibody, cellular, and cytokine responses. Whether humans acquire resistance to helminthic infection and whether resistance can be induced has not been fully resolved. Resistance against several helminths occurs in experimental and wild animals after primary infection and can be induced by defined antigens.[6] It can also be seen in individuals who avoid certain parasitic infections, such as lymphatic filariasis, despite living in worm endemic areas.[7]

An additional and biologically relevant factor concerning helminthic infections and their role in the etiology of human disease is the intensity of infection. Since most worms that infect humans cannot increase their population without additional exposure to the infective stages, the worm load largely determines the degree of pathologic sequelae. For example, the number of schistosome eggs reaching the pulmonary circulation is an essential determinant of the severity of the induced disease. Although the number of eggs reaching the lungs may be influenced by several factors, the most important determinant is the number of adult worms in the infected person.

APPROACH TO THE PATIENT WITH HELMINTHIC INFECTION OF THE LUNGS

The major symptoms and signs of pulmonary disease are similar across different etiologic agents—infectious and noninfectious alike. Certain clues in the history are necessary to trigger the consideration of a helminthic infection. The geographic distributions of the major helminthic infections are roughly known. Therefore, a history that the patient has lived overseas or in certain parts of the United States is helpful in alerting the examiner to the possibility of a helminthic infection. Although helminthic infections are generally more common in temperate and hot areas of the world, certain parasites may be acquired in the United States and other colder areas. Other infections are acquired from specific animal exposures or occupations, such as *E. granulosus* and exposure to dogs and sheep. Therefore, infection with *E. granulosus* is more likely in sheep-raising countries and in certain sheep-raising areas in the United States.

Eosinophilia in peripheral blood, sputum, or pulmonary tissue is a helpful clue in directing the diagnostic workup. Although increased eosinophil counts do occur in several other pulmonary diseases, the close association with helminthic infections necessitates appropriate diagnostic procedures to determine whether a worm is implicated. However, eosinophilia may not be present for all individuals. Knowledge of the immunologic status of the patient can be valuable in suggesting helminthic infection in the absence of eosinophilia—for example, the hyperinfection syndrome caused by *S. stercoralis*.

Definitive diagnosis of pulmonary helminthic infections requires isolation and identification of the parasite that routine examination of appropriate specimens may miss. Laboratory personnel should always be alerted when the examiner is considering the possibility of a worm infection so that proper samples can be obtained and preserved for special examinations. Serologic testing for helminths is particularly useful in nonendemic settings. It should be considered an adjunct to isolation of the pathogen and an important diagnostic procedure.

DISEASES DUE TO NEMATODES (ROUNDWORMS)

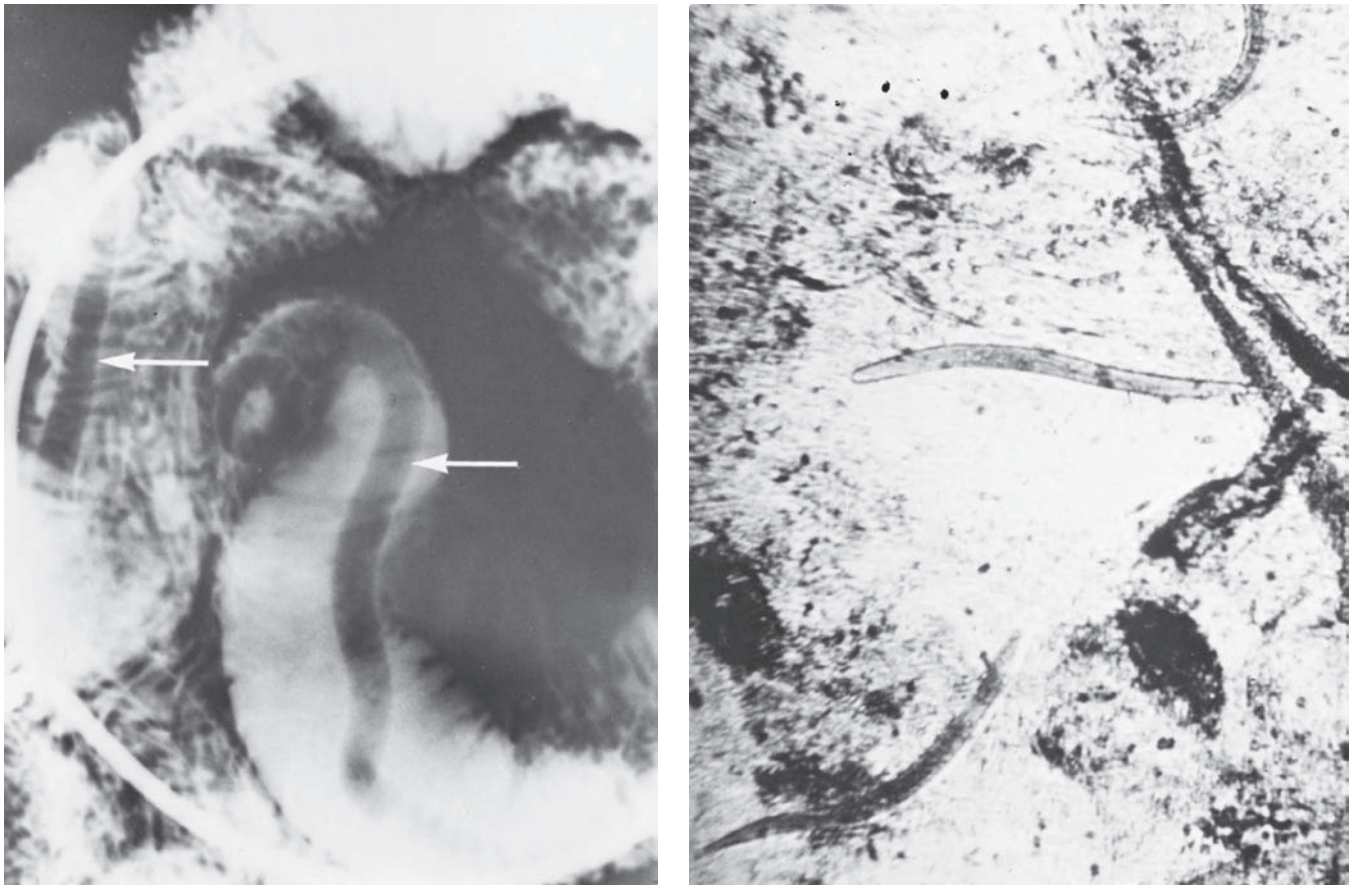
Among the most important helminthic infections of humans are the nematodes. The biology, clinical manifestations, and management of nematode infections are discussed below.

■ ASCARIASIS, HOOKWORMS, AND STRONGYLOIDIASIS

Human infections with *Ascaris lumbricoides,* the hookworms *Ancylostoma duodenale* and *Necator americanus,* and *S. stercoralis* are among the most prevalent helminthiases worldwide. Transmission is seen in the southeastern United States.

Etiology

Human ascariasis (Fig. 137-1) results from ingestion of embryonated *A. lumbricoides* eggs that are contained in feces-contaminated soil. Ingestion of contaminated fruits and vegetables that have not been properly washed is the most frequent transmission vehicle. *Ascaris* eggs hatch in the gastrointestinal tract, producing larvae that penetrate the gut wall and migrate via venous blood and the right side of the heart to the lungs. Hookworms (*A. duodenale* and *N. americanus*) and *S. stercoralis* infect humans when infective larvae in the soil penetrate intact skin. The larvae then travel via the bloodstream to the lungs (Table 137-1). Next, they migrate via the pulmonary capillaries into the alveolar spaces. Once in the alveolar spaces, they ascend in the trachea and, ultimately, are swallowed to begin their final route to habitation in the small intestine. Here, the adults lay eggs that



A B

Figure 137-1 Nematodes. **A.** Ascariasis. Barium in the small intestine outlines two *Ascaris* worms *(arrows)*. **B.** *Strongyloides stercoralis.* Rhabditiform larvae. *(Used with permission of Dr. Stanley H. Abadie.)*

are either directly passed in the stool (*A. lumbricoides, A. duodenale,* and *N. americanus*) or hatch into larvae within the intestinal tract *(S. stercoralis)* and then passed into the stool. Although larvae are sometimes found in the sputum of infected persons, more often examination of the stool yields the diagnosis. Passage to the outside environment, where the noninfectious stool forms develop into forms infective for humans, completes their life cycle.

Pathogenesis and Pathology

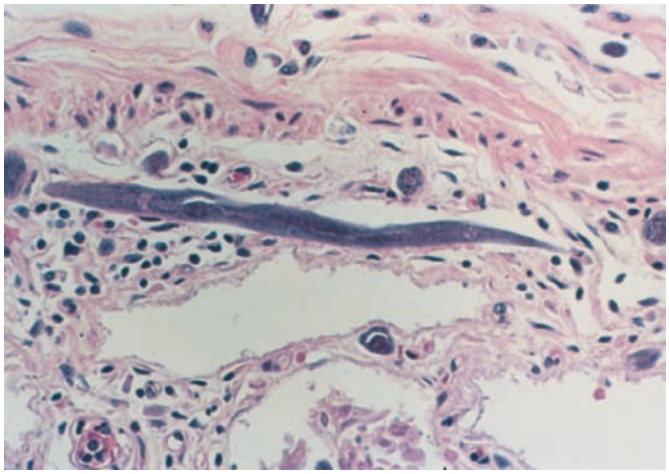
In nematode infections, the most prominent pulmonary pathologic changes occur in persons with ascariasis or the hyperinfection syndrome of strongyloidiasis. Pulmonary symptoms from *Ascaris* may occur 1 to 3 weeks after primary infection. Portions of larvae are seen in the pulmonary parenchyma, surrounded by a patchy infiltrate of neutrophils and eosinophils. The alveoli contain a serous exudate and the production of bronchial mucus is increased. Later, migrating larvae are destroyed within aggregates of eosinophils. The intensity of the reaction depends on the number of parasite larvae and previous sensitization. In areas in which transmission of *Ascaris* eggs occurs seasonally, pulmonary reactions are usually more frequent during these periods.[8]

In *immunocompetent* subjects, pulmonary disease caused by hookworms or *S. stercoralis* is minimal as the worm burden is usually low. It should be noted that infection with *Strongyloides* is lifelong. In nonimmunosuppressed subjects, the majority of the rhabditiform larvae found in the stool have to go to the outside world to transform into the infective filariform larvae. Only a few infective filariform larvae develop in the gut and penetrate the intestinal mucosa to restart the developmental cycle (autoinfection).

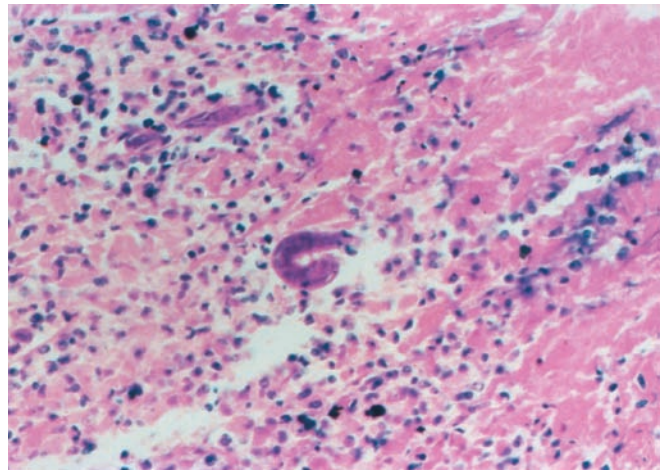
The sequence of events in *immunosuppressed* patients indicates that a change has occurred in the reproductive cycle of the parasite. In immunosuppressed patients, adult females may replicate by pathogenesis and the change to infective filariform larvae more frequently occurs within the gut lumen leading to a sharp increase in worm burden.[9] The infective filariform larvae penetrate the intestinal mucosa resulting in massive invasion of almost every organ, including the lungs. Consequently, life-threatening infection with *S. stercoralis* results from the premature development of large numbers of filariform larvae in immunocompromised persons that invade across the gut wall or perianal skin, carrying intestinal bacteria into the peritoneum and bloodstream.[9] Tissue migration of the worms occurs through most body organs, including the lungs. Initially, the pulmonary lesions resemble those of *Ascaris* pneumonia. In some patients, bronchopneumonia and lung abscesses develop while the lungs of fatal cases show intra-alveolar hemorrhages and inflammatory changes.[10]

Clinical Features

The major clinical manifestations caused by infection of the lungs with the larval forms of intestinal nematodes resemble those described by Loeffler;[11] these manifestations occur typically in patients with *Ascaris* pneumonia, but rarely have been reported in patients with hookworm pneumonia.[8,12] Symptoms include persistent, irritating, and nonproductive cough, substernal pain, and – in the severely ill – hemoptysis and dyspnea. Eosinophilia is the most consistent laboratory finding. Radiographic signs – for example, patchy or miliary infiltrate – are sometimes seen. *Ascaris suum* (pig roundworm) may cause a similar pulmonary process, although it



A



B

Figure 137-2 Strongyloidiasis. **A.** A 55-year-old man with chronic lymphocytic leukemia who presented with abdominal discomfort and weight loss. The patient developed progressive pulmonary congestion and edema with dyspnea, fever to 103°F, and progressive hypotension before death. Blood cultures revealed *Escherichia coli.* Histologic section of colon at autopsy shows adult *S. stercoralis* in wall. **B.** A 24-year-old man with AIDS who developed diarrhea, weight loss, and, finally, shock with *E. coli* bacteremia and strongyloidiasis. The larval form is shown in the jejunum. *(Used with permission of Dr. Jay A. Fishman.)*

does not exhibit all of the same developmental stages as *A. lumbricoides* since humans are only accidental hosts.[13]

The onset of the Loeffler-like syndrome caused by intestinal nematodes usually occurs 1 to 3 weeks after infection, coincident with larval migration from the pulmonary circulation to the alveoli. This timing was illustrated in a report of a group of students exposed to eggs of *A. suum.*[14] Typical pulmonary symptoms occurred 10 to 15 days later, and some of the students developed marked respiratory failure. In locations in which transmission of ascariasis is cyclic because of environmental factors, pneumonitis occurs seasonally.[8] Mild symptoms are occasionally encountered in persons with hookworm infection or in immunocompetent subjects who have strongyloidiasis.

The most clinically significant pulmonary syndrome induced by intestinal nematodes is that caused by hyperinfection with *S. stercoralis* (Fig. 137-2). As a rule, the syndrome occurs in patients with compromised cell-mediated immunity because it is a consequence of a high worm burden. However, it is occasionally encountered in normal persons. Immunosuppression may be the result of neoplastic diseases, including lymphomas and leukemias, or nonmalignant conditions that are being treated with corticosteroids – for example, organ transplantation. However, the autoinfection cycle means that disease due to *S. stercoralis,* including hyperinfection, may develop as late as 75 years after initial exposure.[15]

The major pulmonary clinical features include asthma, pulmonary opacities, which include cavitation, consolidation, and diffuse patchy infiltrates.[10] Usually, widespread dissemination of the nematode is accompanied by secondary infection caused by gram-negative bacteria carried along with *S. stercoralis* from the gut. Consequently, gram-negative meningitis and sepsis may also be prominent features of this syndrome. Eosinophilia is often absent in patients with the *S. stercoralis* hyperinfection syndrome, due to either defective cell-mediated immunity or the use of corticosteroids in many patients. The *S. stercoralis* hyperinfection syndrome is often fatal; mortality occurs in up to 87% of people with disseminated infections.[16]

Management

The diagnosis of infection with intestinal nematodes that causes a Loeffler-like syndrome may be difficult. Only occasionally is the search for parasite larvae in sputum rewarding. Stool examination is negative at this point because the adults have not yet reached the small intestine and begun producing eggs. Not infrequently, definitive diagnosis is delayed for weeks until the adult worms mature in the small intestine. At this stage, fecal examination discloses the characteristic eggs of hookworms or *Ascaris* or the larvae of *S. stercoralis.* The management of patients with the pulmonary manifestations of these parasitic worms is nonspecific and symptomatic. Reduction of exposure in areas in which transmission of ascariasis is seasonal decreases the prevalence and severity of clinical presentations. Specific antihelminthic therapy is ineffective during the pulmonary stage but can cure the infection once the parasites reach maturity in the small intestine.

Albendazole, 400 mg orally once, or mebendazole, 100 mg per day for 2 to 3 days (or 500 mg orally once) are the drugs of choice for treating ascariasis and hookworms (Table 137-2). Ivermectin, 200 μg/kg per day for 2 days (longer for hyperinfection syndrome) is recommended for strongyloidiasis.[17] This treatment may be repeated at 2 weeks (the duration of one autoinfection cycle) to ensure eradication is complete. Albendazole, 400 mg orally daily for 2 days may be used as an alternative, but it is less effective.[17,18]

In patients suspected of having the hyperinfection syndrome, early diagnosis leading to modification of immunosuppressive therapy, prompt anti-*Strongyloides* chemotherapy, and adjunctive antibacterial therapies are important elements in averting a fatal outcome. Thus, a high degree of suspicion for strongyloidiasis is needed in dealing with pulmonary disease associated with bacteremia in immunosuppressed patients. Most instances of strongyloidiasis in these patients are diagnosed only shortly before death or at autopsy. Aggressive efforts at demonstrating *S. stercoralis* larvae entail repeated examination of stools and duodenal aspirates. Sputum and bronchial washings should also be examined for parasite larvae and serology may be of help, particularly in nonendemic areas. In these patients, therapy should be started as early as possible and continued daily for at least 2 weeks after the last positive stool examination (the duration of one autoinfective cycle).[9] Some may require longer or repeat therapy, depending on the cause of their immune suppression and their risk of relapse—for example, HTLV-1 infected individuals.[18] Serologically positive individuals for *Strongyloides* should be treated prior to the start of immunosuppression for organ transplantation or cancer chemotherapy, generally with empiric ivermectin.

TABLE 137-2 Therapies of Pulmonary Diseases Produced by Worms

Organisms	Common Therapies	Comments
Ascaris lumbricoides	Albendazole, mebendazole, pyrantel, ivermectin, piperazine	Infection may persist for 1–2 y
Ancylostoma duodenale		Infection for ~1 y
Necator americanus	Albendazole, mebendazole, levamisole, pyrantel	Infection may persist for 3–5 y
Strongyloides stercoralis	Ivermectin, albendazole, thiabendazole	Hyperinfection with *S. stercoralis* with meningitis or sepsis requires therapy for gram negative or mixed infection; infection may be latent for >30 y (lifetime)
Wuchereria bancrofti, Brugia malayi	None satisfactory; diethylcarbamazine citrate or ivermectin reduces worm burden but no effect on clinical course	Prevention by mosquito control; possible addition of albendazole to other therapies
Echinococcus granulosus	Albendazole, mebendazole	Space-occupying lesion may require surgical resection in toto; may risk dissemination without cysticidal therapy (hypertonic saline, 0.5% cetrimide, 70–95% ethanol, iodine); PAIR procedure—percutaneous aspiration and cysticidal therapy
Paragonimus westermani	Praziquantel (bithionol not always available)	
Schistosoma mansoni, S. japonicum, S. haematobium	Praziquantel (oxamniquine for *S. mansoni* and metrifonate for *S. haematobium* not always available)	
Toxocara canis, T. cati	None proved (albendazole, thiabendazole, mebendazole, diethylcarbamazine citrate, others)	Anti-inflammatories for cough; corticosteroids for symptoms or with therapy

PULMONARY FILARIASIS (TROPICAL PULMONARY EOSINOPHILIA)

Persons living in areas endemic for *Wuchereria bancrofti* and *Brugia malayi* may present with an acute or chronic lung disease, usually referred to as *tropical pulmonary eosinophilia.* This is still a poorly defined clinical entity. Its main features are a history of residence in filaria-endemic areas (particularly India), chronic nocturnal paroxysmal cough, marked eosinophilia, positive serology, and a therapeutic response to the administration of diethylcarbamazine citrate (DEC).

Etiology

Human infection with the tissue nematodes *W. bancrofti* or *B. malayi* can cause several syndromes, including tropical pulmonary eosinophilia.[19] Infection is transmitted by the bite of several mosquito species, thereby introducing the infective third-stage larvae. These organisms undergo ill-defined maturational stages, culminating in the development of adult male and female worms (macrofilaria) that are usually situated in lymphatic vessels and lymph nodes. Mature worms deposit microfilariae that appear in peripheral circulation, often at maximum numbers during specific times of the day (periodicity). However, some filariae show no periodicity with respect to the appearance of their microfilariae in peripheral blood. Microfilariae are taken up by mosquitoes during feeding, thereby completing the life cycle of the parasite.

The life span of adult filariae is not known, but disease is not limited to times when microfilaremia is present. Serologic or histopathologic evidence of infection still can be obtained in *amicrofilaremic* states. For example, in tropical pulmonary eosinophilia, high concentrations of antifilarial IgG and IgE in serum and bronchoalveolar lavage (BAL) fluid have been demonstrated despite invariably negative blood examinations for parasites. Furthermore, microfilariae have been found in lung and lymph node biopsies of patients with tropical pulmonary eosinophilia confirming the filarial origin of this syndrome.

Pathogenesis and Pathology

Only a small number of individuals are susceptible to tropical pulmonary eosinophilia given the lack of pulmonary symptoms in most filarial infections.[7,19] Patients with pulmonary filariasis show evidence of humoral hyperreactivity manifested as increased serum levels of total IgE and antifilarial IgG and IgE. Currently, these antibodies are thought to play a causal role in the disease through either rapid clearance of microfilariae and acute IgE-mediated responses, which manifest as eosinophilic pulmonary infiltrates, or cross-reactivity between specific filarial and human lung proteins and induction of autoimmunity.[20,21] Histopathologically, the earliest lesions are histiocytic infiltrates in the interstitium and alveolar spaces. In established cases, the cell infiltrate consists predominantly of eosinophils, lymphocytes, and histiocytes, and it assumes a nodular configuration. Without therapy, end-stage disease with fibrosing alveolitis and honeycombing occurs.[22]

Clinical Features

For unexplained reasons, young males are predominantly afflicted by tropical pulmonary eosinophilia. The syndrome is characterized by episodes of dry night cough, low-grade fever, and general fatigue. Clinically, it may be mistaken for asthma.[23] Examination of the chest may reveal coarse crackles and rhonchi, along with wheezing. In many patients, pulmonary function tests disclose a restrictive pattern with superimposed obstruction in which vital lung capacity, total lung capacity, and residual volumes are all decreased.[22] Some patients with chronic disease have perfusion impairment. Radiographically, the syndrome may be associated with reticulonodular opacities and increased bronchovascular markings. The sera and BAL fluid of these patients usually demonstrate high IgE levels and specific antibodies to filariae. Eosinophil counts in peripheral blood generally exceed 3000/mm^3.

Management

As the patient is amicrofilaremic in tropical pulmonary eosinophilia, diagnosis is based on the typical clinical, radiographic, and immunologic findings in the setting of an appropriate epidemiology history—that is, previous residence in a filaria-endemic area.[22] Currently, the World Health Organization recommends DEC as the drug of choice for TPE (6 mg per kg daily for 21 days).[24] A favorable

response to doxycycline, 100 mg orally twice daily for 4 to 6 weeks has also been documented—a regimen that works by killing the symbiotic *Wolbachia* bacteria necessary for nutrition and fertility.[25] As adult females are rendered sterile, this agent reduces both microfilaria and the adult macrofilaria populations. Recurrences of tropical pulmonary eosinophilia may occur in 20% of individuals, which would warrant a second course of antihelminthic chemotherapy (WHO suggests DEC 6–12 mg per kg orally daily for 21–30 days).[24] Unfortunately, symptoms may also persist after therapy due to the lung damage incurred prior to treatment.

Dirofilariasis

Another filarial parasite, *Dirofilaria immitis* (dog heartworm), may be transmitted to humans by the bites of the mosquito intermediate vector (Fig. 137-3). Several cases of dirofilariasis have been reported in the United States.[26] In most, the infection was discovered as a pulmonary nodule on the chest radiograph after a worm lodged in the pulmonary arteries. It is often mistaken as cancer. Occasionally, patients have cough, chest pain, hemoptysis, and eosinophilia. Definitive diagnosis is usually obtained from microscopic examination of excised lesions.[27]

■ TOXOCARIASIS (VISCERAL LARVA MIGRANS)

Toxocariasis is due to human infection with animal parasites (dog or cat ascarids). It is most commonly encountered in children. As humans are accidental hosts, the invading larvae migrate in human tissues, but cannot mature to adult worms. *Toxocara canis* and *T. cati* are the two most common etiologic agents of human visceral

Knight.)*

larva migrans, although other worms – for example, *A. suum,* the pig roundworm – can cause the same disease. *Toxocara* species are widely distributed, in both developing and developed countries alike.

Etiology

The eggs of *T. canis* and *T. cati* are passed in the stools of dogs and cats, respectively. Transmission to humans occurs by ingestion of embryonated eggs in contaminated food or direct ingestion of contaminated soil.[28] Larvae hatch in the small intestine and penetrate the gut wall. They then migrate to the liver, where they are carried via systemic veins to the systemic arterial circulation for distribution throughout the body. Larval migration through the host tissues and the associated inflammatory responses induced by migration are considered responsible for the manifestations of disease.[29] Most of these features relate to liver pathology, eosinophilia, and pulmonary invasion.

Pathogenesis and Pathology

Tissue injury results from both the invasion of different organs by the parasite larvae and from encapsulation and death of some organisms by the immediate and delayed-hypersensitivity responses of the host.[30] The parasite is capable of evading the immune system for a prolonged period of time due to alterations in the ability of the host to respond to the antigenic challenge and the ability of the parasite to change antigenic identity over time.[31,32] The degree of damage, organ affected, and clinical manifestations varies between individuals. The most commonly affected organ is the liver, where eosinophilic granulomas surround parasite larvae. Similar lesions can be induced in experimental animals (Fig. 137-4). In a few fatal cases of toxocariasis, autopsy revealed that the major pathologic lesions were in the central nervous system.

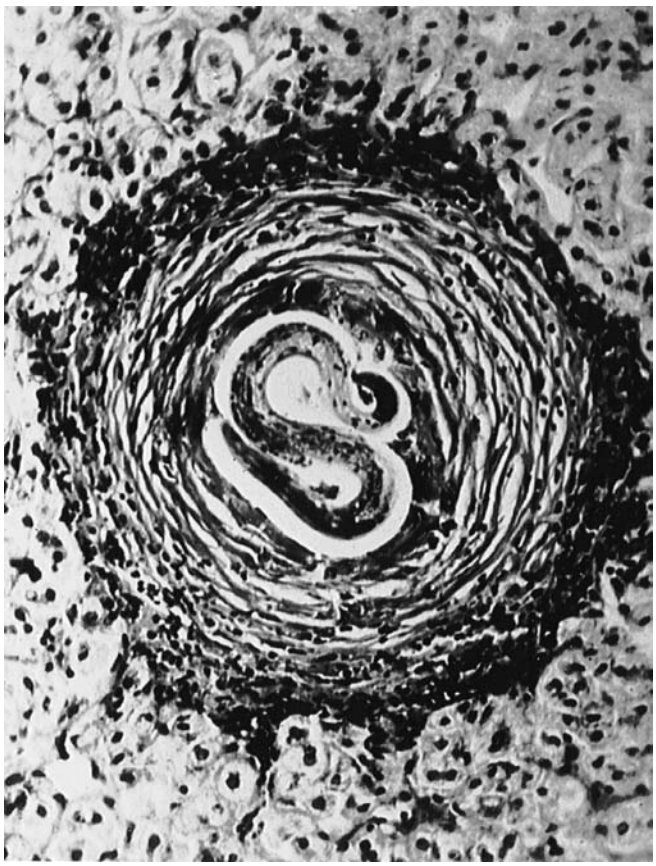

Figure 137-4 *Toxocara canis.* Granulomatous response to larvae in the liver. *(Used with permission of the American Society of Pathologists.)*

Clinical Features

Toxocariasis is generally a disease of children between the ages of 1 and 5 years.[33] It is particularly common in those with a history of pica. However, it may be seen in older individuals, in whom it is often associated with a history of raw meat intake.[34,35] The two main presenting features relate to the chest and abdomen. Pulmonary complaints, such as cough and wheezing, and pulmonary infiltrates occur in more than one-third of symptomatic children.[36] Hepatomegaly, and less commonly splenomegaly, may also be found.[37] Peripheral eosinophilia is usually marked and can persist for years. The concentrations of both total and specific immunoglobulins are also increased in the serum. In recent years, it has become recognized that subtle or covert disease manifestations are also possible, including the suggestion it may trigger asthma or epilepsy in certain afflicted individuals.[30,36]

Management

A diagnosis of toxocariasis is usually made by the clinical presentation and serologic evidence of anti-*Toxocara* antibodies. Imaging of the chest may show transient and migratory infiltrates.[34,35] Since the disease is usually benign and self-limited and the efficacy of most antihelminthics doubtful, no specific therapy is recommended in most cases. In those with severe symptoms, albendazole has been used.[37] Corticosteroids may be necessary to limit the inflammatory response in patients with extensive disease of the lungs or central nervous system.

Rare Nematode Infections

Pulmonary infection from *T. spiralis* is possible. The pulmonary syndrome follows the intestinal phase of infection and is usually associated with other allergic manifestations of trichinosis, including periorbital edema, muscle swelling, and weakness. In severe *T. spiralis* infection, pneumonitis is typically accompanied by eosinophilia.[38]

Anisakiasis in humans results from infection with the larval form of a marine mammal nematode. The disease has been reported in Japan and Western Europe. Although it usually manifests as an intestinal eosinophilic disorder, it has been implicated as the cause of cough, eosinophilia, and pleural effusion as well as anaphylaxis in certain individuals.[39,40]

DISEASES DUE TO CESTODES (SEGMENTED WORMS)

A variety of segmented worms may cause human disease, including Echinococcus.

■ ECHINOCOCCOSIS

Human infection with the larval stage of the canid tapeworm *E. granulosus* is one of the most important helminthic pulmonary diseases. *E. granulosus* is worldwide in distribution, but it occurs most commonly in pastoral communities, such as Australia, South America, the Mediterranean, and some parts of Africa. The infection has also been reported in the United States.

Etiology

There are two unique life cycles for *E. granulosus.* One is the pastoral life cycle, in which the definitive host is the dog and the intermediate hosts are pigs, sheep, and cattle. The other is the sylvatic life cycle, in which the definitive hosts are wolves, foxes, or coyotes, and the intermediate hosts are herbivores, such as moose, deer, elk, and caribou. The pastoral life cycle is generally the more common cause of human disease and results in more severe disease manifestations.[41]

Adult *E. granulosus* worms are found in the intestines of their definitive host. They release eggs from their gravid segments

that are passed in the feces. Humans acquire the infection by ingesting the eggs; embryos are then released and migrate to the liver, where most cysts in humans are found. Embryos may also migrate to the lungs or other tissues. Once the parasite has lodged in human tissues, it develops in a space-occupying hydatid cyst. The inner lining of these cysts is a germinal layer capable of producing daughter cysts that may seed other organs upon spontaneous rupture or surgical manipulation of the original cyst (Fig. 137-5).

Pathogenesis and Pathology

Hydatid cysts are most frequently found in the lungs of children, but can also be seen in older adults.[42] In most instances, the slowly enlarging, space-occupying lesion is well tolerated. Cysts in the lungs are usually discovered early in the course of the disease because radiographic examinations of the chest are now so common. Pulmonary cysts are solitary in 60% of cases and in 50% to 80% of cases affect only one lobe.[10] The cyst is surrounded early in the course of infection by a granulomatous reaction on the part of the host; later, the inflammatory reaction is succeeded by fibrosis leading eventually to a calcified solid mass. Not all cysts are viable—that is, capable of producing new daughter cysts upon rupture. Spontaneous rupture of a viable hydatid cyst can occur through a bronchus, leading to expectoration of scoleces in the sputum while rupture into the mediastinum or pleural cavity can lead to secondary implantations and new daughter cysts. The fluid content of a hydatid cyst is believed to be immunogenic, and leakage of the cyst can evoke an anaphylactic response.[43] Eosinophilia has been

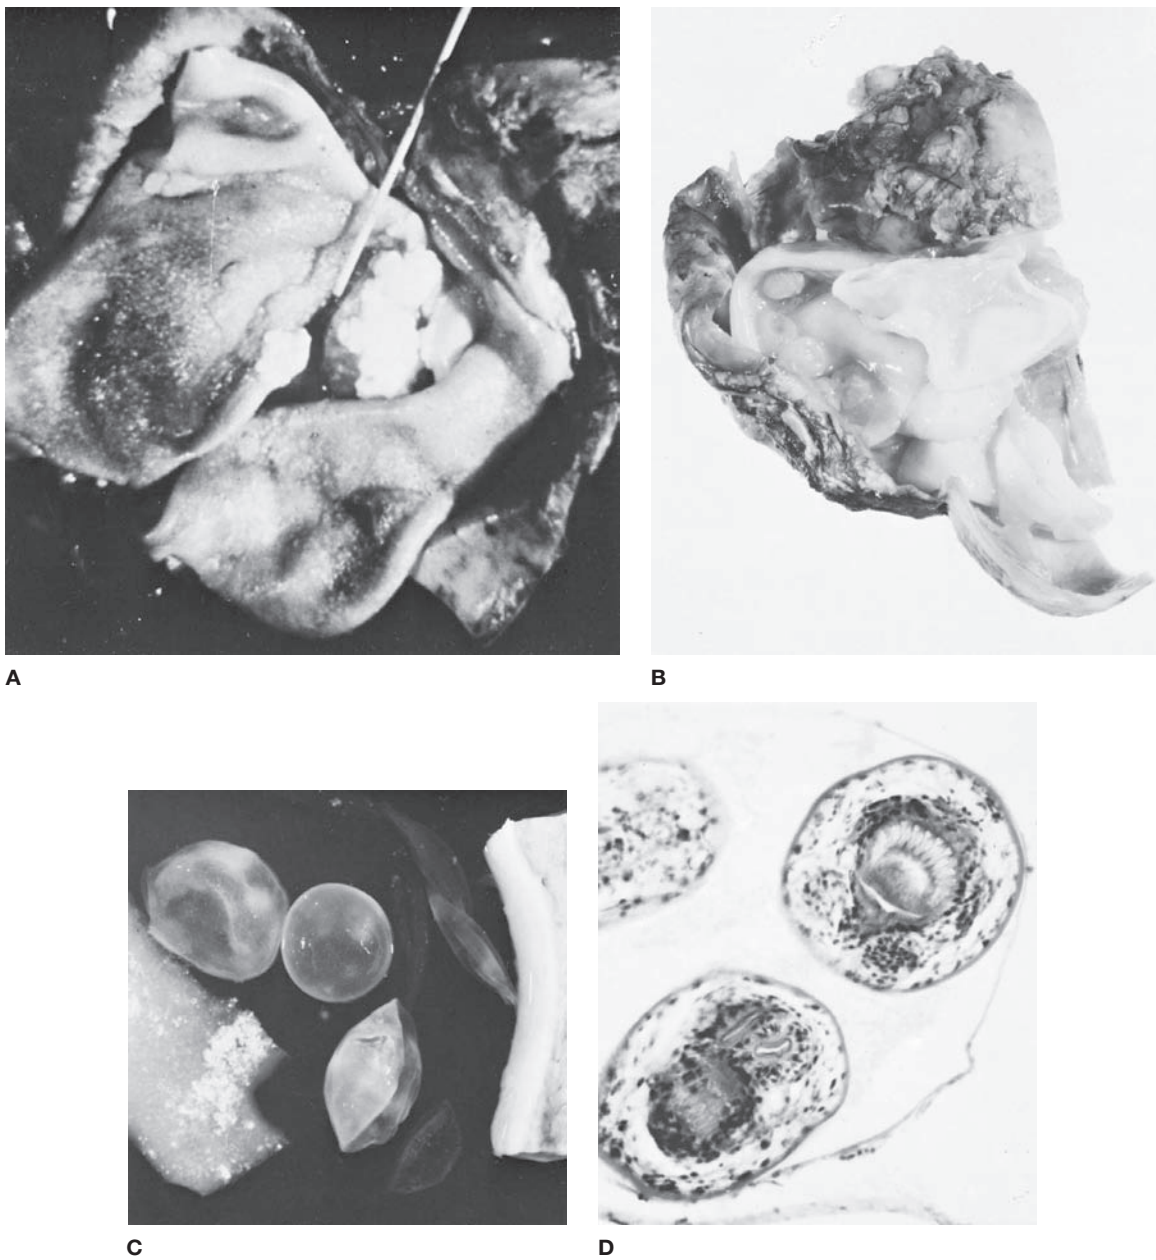

Figure 137-5 Echinococcosis. **A.** Hydatid cyst in the lung. The glistening membrane constitutes the wall of the cyst. **B.** Hydatid cysts in mesentery. Connor, Armed Forces Institute of Pathology.)*

reported to accompany hydatid disease, but it is not common, with reports ranging from 0% to 25% of cases.[42]

Clinical Features

Hydatid cysts are usually asymptomatic; approximately one-fifth of the clinically diagnosed cysts are in the lungs.[44,45] Most patients with pulmonary hydatid disease are children, while adults usually have cysts confined to the liver. Approximately half of the patients present with cough; smaller fractions present with dyspnea or chest pain. On chest radiography, the lesions vary in diameter from 1 to 20 cm; sometimes the cyst is surrounded by an area of pneumonitis or atelectasis. Less often, a fluid level – the so-called, "water lily sign" (Fig. 137-6) – or calcification is seen. Other diagnostic procedures – for example, serology, computed tomography, and magnetic resonance imaging – may be useful in improving the characterization of the lesions.[10,44]

Management

Diagnosis of a hydatid pulmonary cyst often depends on a combination of epidemiologic, clinical, and laboratory findings—that is, imaging or serology.[44] Surgery is the treatment of choice for hydatid disease of the lungs and it will confirm the diagnosis. Depending on the size and location of the cysts, enucleation of the intact cyst, cystotomy, or removal of the cyst after aspiration may be chosen.[46] If the cyst is large, a drain may need to be left for a period of time in the residual pericystic area. More extensive procedures, such as lobectomy and segmental resection, are usually not necessary.[45] The use of the "PAIR procedure," including *P*ercutaneous *A*spiration,

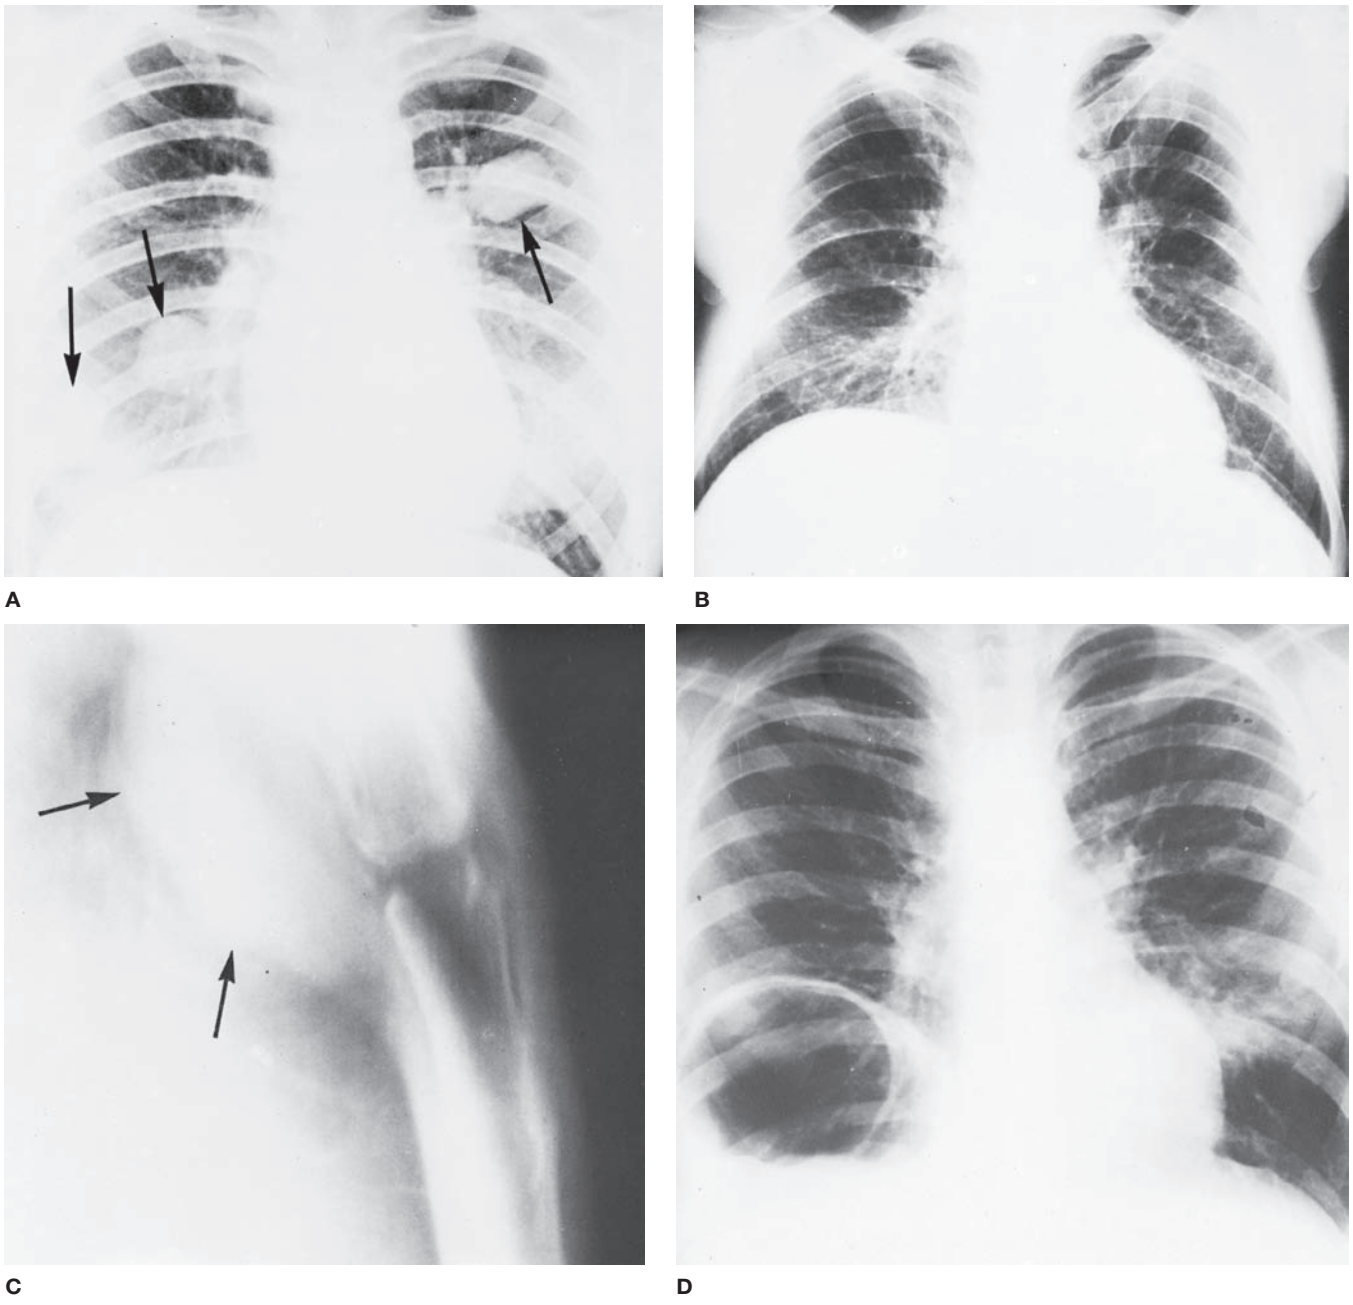

Figure 137-6 Echinococcus. **A.** Multiple pulmonary cysts *(arrows). (Used with permission of Dr. Carl Heitz.)* **B.** Another patient with echinococcus cyst behind the sternum. The retrosternal mass is difficult to discern on the posteroanterior radiograph. **C.** Lateral view. Mass (cyst) is seen *(arrows)*. **D.** Hydatid cyst, right lower lobe. *(Used with permission of Dr. Philip Lerner.)*

*I*njection of cysticidal agent (hypertonic saline, absolute alcohol, or other agents), and *R*e-aspiration using radiographic guidance is well described. Although success has been described in multiple cases, the current recommendation from the World Health Organization is that PAIR should not be used for pulmonary cysts.[44] If PAIR is chosen, it is coupled with administration of albendazole, beginning 4 hours before, and continuing for 28 days after drainage (400 mg orally twice daily for patients >60 kg, and 15 mg/kg divided into two doses for patients <60 kg).

DISEASES DUE TO TREMATODES (FLAT WORMS)

Schistosomiasis and paragonimiasis represent two trematodes that are important in causing human disease. Each is discussed in subsequent sections.

■ SCHISTOSOMIASIS

Schistosomal infections represent one of the major endemic helminthic infections in Southeast Asia, the Middle East, Africa, the Caribbean, and South America. Five species represent the most common and clinically significant infections in humans: *Schistosoma haematobium, S. mansoni, S. japonicum, S. mekongi,* and *S. intercalatum.*

Etiology

The schistosomes are blood flukes. Human infection is initiated by penetration of intact skin by the free-living cercariae that are shed by specific freshwater snails. The cercariae change within a few hours into schistosomula, which migrate from the subcutaneous tissues to the lungs and then to the liver, where they mature into adult worms. Fecund adult parasites then migrate to their final habitat: the veins around the ureters and urinary bladder *(S. haematobium)* and the mesenteric veins (all other species). Adult worms deposit eggs that pass through the lumen of ureters or gut to the outside environment to complete the life cycle of the parasite. However, some of these ova become trapped in the surrounding host tissues. Other ova may be carried by the venous circulation to the heart and then the lungs.

Pathogenesis and Pathology

Schistosome eggs are the major cause of human pulmonary disease. They reach the pulmonary circulation by routes that depend on the species of the parasite, their final habitat, and the stage of infection. Since *S. haematobium* worms parasitize the vesical venous plexus that connects directly with the inferior vena cava, egg seeding to the lungs may occur at any phase of infection. By contrast, the anatomic location of adult worms of the other species in the mesenteric veins does not allow parasite ova to travel directly through the portal vein to the hepatic and systemic circulations. Eggs of these species typically reach the lungs only in the late stages of infection, after portal hypertension develops and anastomotic channels open between the portal and systemic circulations. Despite this, pulmonary symptoms may still occur early in the infection as a result of immune-complex deposition or because the infection occurs in an individual who has early opening of the portocaval shunts.[47,48]

Upon reaching the pulmonary circulation, schistosome eggs usually gather in small arterioles, where they induce the formation of delayed-hypersensitivity granulomas, made up of eosinophils, lymphocytes, and macrophages (Fig. 137-7), as well as neovascularization and fibrosis. In an autopsy study of 32 cases of *S. mansoni* cor pulmonale, two characteristic histopathologic lesions were identified: (1) focal changes related directly to the presence of schistosome eggs; these were located either within the alveolar tissue or within the pulmonary arteries or arterioles; and (2) plexiform or angiomatoid lesions consisting of thin-walled and dilated vessels.[49] The most prominent vascular lesions were associated with the focal changes surrounding mature schistosome eggs in the lumen of pulmonary arteries or arterioles. The curtailment of the pulmonary vasculature and the decreased distensibility caused by the perivascular fibrosis leads to pulmonary hypertension and cor pulmonale. Pulmonary function testing reveals a predominantly restrictive pattern of disease and is accompanied by a decrease in the diffusing capacity.

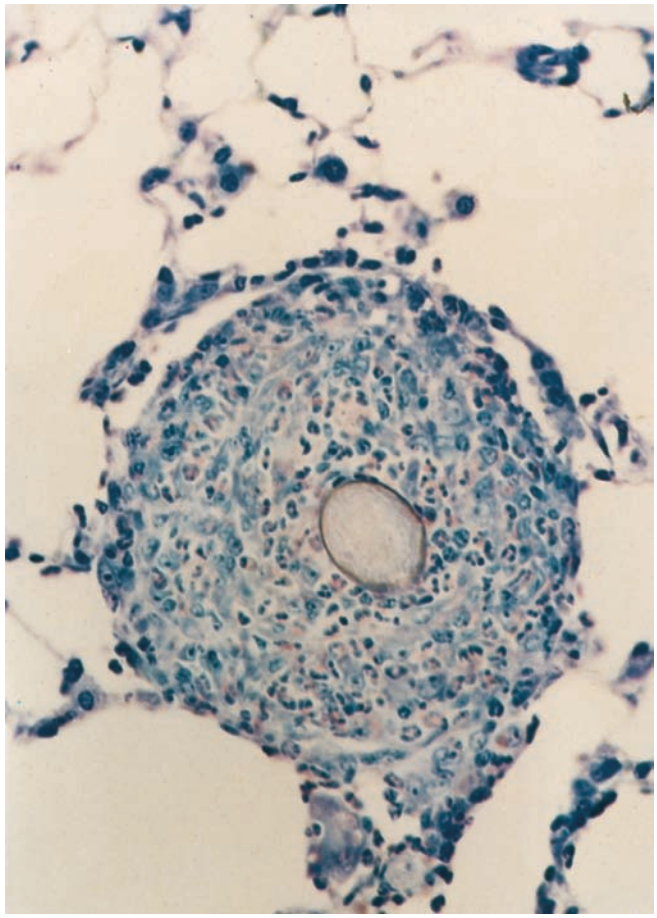

Figure 137-7 Schistosomal granuloma. *(Used with permission of Dr. Jay A. Fishman.)*

Clinical Features

It is not clear whether very early schistosome infection is associated with appreciable pulmonary disease. Migration of schistosomula through human lungs may provoke cough and bronchospasm and may be associated with immune-complex deposition.[47] After the onset of oviposition (approximately 3–6 weeks), some ova may reach the lungs, particularly in *S. haematobium* infection. Immune-complex deposition may also cause symptoms. Patients may present at this point with a myriad of nonspecific symptoms including fever, dyspnea, and a dry cough.[47,50] If chest imaging is obtained, small nodules with or without ground-glass halos may be seen in a hematogenous parenchymal distribution.[10] If the infection is not treated, chronic infection can result in sufficient deposition of eggs in the lungs to cause the development of cor pulmonale. However, the clinical features and radiographic findings in schistosomal pulmonary hypertension and cor pulmonale are not distinctive and the prevalence of the pulmonary hypertensive syndrome in schistosome-infected patients is not fully known.[10,48] In Egypt, 7.5% of patients hospitalized with schistosomal hepatomegaly had cor pulmonale; in another study from Brazil, authors estimated that up to 30% of patients with pulmonary hypertension at the country's reference centers may be due to schistosomiasis.[48]

Management

Diagnosis of pulmonary disease due to schistosomiasis may be achieved by finding the parasite eggs in urine or stools of persons with suggestive clinical manifestations. However, the most severe pulmonary disease typically occurs years after infection, and finding parasite ova in the urine or stool may be difficult. Under these circumstances, demonstrating the characteristic pathologic changes, finding ova directly in the tissue, or positive serology in the nonendemic setting may confirm the diagnosis.

Active schistosome infections are treated with praziquantel, which kills adult worms and stops further destruction of tissue by ova deposition. The drug is administered at a dose of 20 mg/kg body weight twice daily for 1 day (two total doses) for *S. mansoni* and *S. haematobium* infection and three times a day (three total doses) for *S. japonicum* infection. However, reversal of pathologic lesions in the lungs after antischistosomal chemotherapy has not been documented.

■ PARAGONIMIASIS

Human infection with species of the lung fluke *Paragonimus* is prevalent in the Southeast Asia, Africa, and South and Central America. Infection is maintained in endemic areas through contamination of water sources with feces or sputum of infected individuals. Water contamination then results in infection of the intermediate snail and crustacean hosts.

Etiology

Human infection with *Paragonimus* is acquired from food sources. This is classically described in individuals consuming raw or pickled crustacea (freshwater crayfish and crabs) that harbor the infective parasite stage (metacercariae), but infection may occur with the consumption of other foods, such as raw, wild boar.[51] The metacercariae excyst in the duodenum, penetrate the intestinal wall, and migrate via the diaphragm and pleural cavity to the lungs, where they mature into adult worms (12 × 6 × 5 mm). Adult *Paragonimus* worms are hermaphroditic; they produce golden-brown eggs, which are then coughed up and excreted through either sputum or feces. The life cycle of the parasite outside the human host goes through a specific snail intermediate host; metacercariae then encyst on freshwater crustacean to start the cycle again.

Pathogenesis and Pathology

The primary site of infection in humans is the lungs. The worm is also found in the brain in 25% of patients, but it is less often seen in other tissues. Three stages of parasite development occur within the lungs—primary infection, encystation, and death. During the initial invasion of the lungs by the maturing adult worms, parasite tunnels in the pulmonary parenchyma may be found, particularly in peripheral areas. The tunnels and parasites are surrounded by a granulocytic reaction made of eosinophils and neutrophils. Charcot–Leyden crystals, which are formed by the enzymes left after eosinophil and basophil degranulation, are often seen. In patients with encysted worms, the parasites are enclosed within cystic lesions that may communicate with each other or with a nearby bronchus. Death of the worms usually leads to collapse of the cyst, disintegration of the parasite, and fibrosis or calcification. The surrounding pulmonary tissue may show evidence of atelectasis, bronchiectasis, or compensatory emphysema. In some patients, secondary infection and lung abscess develop in the cystic lesions.

Clinical Features

The incubation period between infection and the development of maturing adults in the lungs is 2 to 20 days. Few specific symptoms have been described during this stage. In persons with established infection, the worm load seems to determine the extent of clinical features unless secondary infection has occurred. Light worm infection is usually asymptomatic. In moderate to heavy worm loads, complaints of cough, respiratory discomfort (particularly upon rising in the morning), and rusty, blood-tinged sputum containing parasite eggs, necrotic material, and Charcot–Leyden crystals are common.[52] Frank hemoptysis, ranging from mild to severe, may occur. Individuals may be mistaken for having tuberculosis or malignancy. Eosinophilia may be the only clue that the cause is parasitic, as it is found in 80% to 90% of affected individuals.[53]

The chest radiograph is normal in 10% to 20% of infected persons. Radiographic signs in the others include infiltrates, cavitation, fibrosis, pleural effusions, and pulmonary thickening.[10] Findings may be unilateral or bilateral. Radiographic changes over time correspond roughly to the three stages of parasite development within the lungs: (1) on arrival to the lungs, maturing worms are associated with the development of radiographic opacities; (2) these are succeeded by nodules that correspond to the parasite cysts; and (3) eventually, fibrosis or calcification ensues. The characteristic ring shadow with a crescent corona may also be seen in some infected persons.

Management

The diagnosis of paragonimiasis can be made from detection of the characteristic eggs in the sputum or stools of infected persons. Serologic testing is helpful in egg-negative cases. The drug of choice for treating paragonimiasis is praziquantel. It is administered orally, 25 mg/kg three times per day for 2 days, or bithionol 30 to 50 mg/kg orally on alternate days for five doses. Therapy usually leads to cessation of egg passage in sputum and stools, clearing of the chest radiograph in almost two-thirds of treated patients, and a decrease in serum IgG antibodies directed against the parasite.

CHAPTER 138

Zoonotic and Other Unusual Bacterial Pneumonias

Camille Nelson Kotton
Arnold N. Weinberg

INTRODUCTION

Many different microorganisms can infect the lung parenchyma; this chapter focuses on zoonoses, human commensals, and other unusual bacterial pathogens. Routes of spread to the lungs are few, clinical presentations overlap, radiologic appearance often is nonspecific, and pathophysiologic mechanisms are limited. Making a clinical diagnosis of pneumonia is relatively easy; defining the causative agent can be difficult. The search for the specific etiologic agent is driven by the desire to administer a specific antimicrobial drug as soon as possible hopefully to avoid progressive functional impairment and to contain spread to other individuals or to a community. Identifying a pathogen may, in turn, expand epidemiologic considerations and public health awareness.

In the almost four decades that have passed since the epidemic of acute respiratory disease due to *Legionella* erupted among delegates to the American Legion Convention in Philadelphia in 1976, physicians, microbiologists, and epidemiologists have become increasingly prepared for the diagnostic challenges of patients with unusual pneumonias. More recent examples of this multidisciplinary approach include the rapid diagnosis of Q fever (due to *Coxiella burnetii*), early identification of cases of *Chlamydia pneumoniae* and *Chlamydia psittaci,* and the etiology of acute respiratory infections due to obscure viral agents like Hantavirus pulmonary syndrome and the newer Coronavirus respiratory illnesses including severe acute respiratory syndrome (SARS). SARS was an excellent example of a zoonotic infection with an initiating event and subsequent person-to-person spread. Similarly, Middle East respiratory syndrome coronavirus (MERS) has been linked to dromedary camel exposure, with subsequent inter-human spread. The complexity of the definition of an etiologic agent in the diagnosis of pneumonia of obscure origin is highlighted in many of the examples mentioned here. Most are discussed in detail elsewhere in this text; the focus will be exclusively on bacterial pathogens most often associated with animals or animal products.

Zoonotic infections can reflect an initial event, followed by person-to-person secondary cases, typical of viral diseases like SARS coronavirus, and occasionally observed with *Yersinia pestis*. While the avian influenza virus (H5N1) has primarily spread to individuals in proximity to chickens, the novel H1N1 influenza in 2009 to 2010 demonstrated an anthropocentric cycle that led to a worldwide pandemic, despite being of zoonotic origin. New zoonoses are continually emerging: A recent outbreak in a monkey colony of deadly titi monkey adenovirus, not known to infect humans, was shown to infect a researcher and a family member, without further spread.[1] Similarly, *Streptococcus equi* subsp. *zooepidemicus (Streptococcus zooepidemicus)*[2] has recently been shown to cause pneumonia in humans after exposure to horses, dogs, and unpasteurized milk.

Companion animals have been the etiology of numerous zoonotic pneumonias, including *Pasteurella multocida,*[3,4] *Chlamydia psittaci,*[5] *Rhodococcus,* and *Bordetella bronchiseptica* (especially in immunocompromised hosts[6–9]). In a study in Spain, contact with pets was associated with an increased risk for community-acquired pneumonia, which tended to be higher as the number of pets increased; the relative risk was similar for birds, cats, and dog exposure.[10] There are multiple examples of animals serving as reservoirs of antibiotic-resistant bacteria, such as methicillin-resistant *Staphylococcus aureus* (MRSA) (companion animals,[11,12] pigs[13]), some in association with nosocomial ventilator-associated pneumonia,[11] and highly resistant Enterobacteriaceae.[14] Nonetheless, experts usually permit companion animals even for immunocompromised hosts, balancing the risk of infection with perceived benefit.[6,15] Wild and farm animals may also harbor zoonotic pneumonia pathogens. *P. multocida* has been associated with pneumonia in bighorn sheep,[16] lambs,[17] and pigs.[18] *Y. pestis* has been associated with numerous wild mammals; recent work suggested a correlation between seropositivity in coyotes and human disease.[19]

Many of the zoonotic bacteria discussed in this chapter are recognized as pathogens that can be weaponized for use by terrorist organizations. The global community is developing rapid diagnostics and countermeasures to warn, protect, and treat people exposed to a biologic weapon. Unfortunately, we have the experience of the "mailroom" anthrax event of September 2001 to illustrate the potential of an inhalational disease causing illness, casualties, public panic, diagnostic and therapeutic decisions, as well as the expenses of decontamination and the challenges of criminal investigations.[20] Physicians need to become familiar with the typical and atypical spectrum of disease caused by these pathogens, including the impact and variable expression of a large inoculum aerosol release in a crowded urban area or building.

This chapter focusses on the epidemiologic and clinical features that should be helpful in evaluating typical and atypical features of pneumonia (Table 138-1). The unique properties of these bacteria exemplify how bacteriology, molecular biology, ecology, epidemiology, and pathogenesis serve as clues to earlier etiologic diagnosis and specifically targeted therapies (Table 138-2). The movements of immigrant populations, adventure and other forms of travel, the immune status of individuals, the latency of pathogens, and the legal and illegal transportation of live animals and animal products contribute to the importance of zoonotic pneumonias. Ultimately, the diagnosis is heavily dependent on a detailed history along with appropriate diagnostic studies.

ZOONOTIC BACTERIAL PNEUMONIAS

This section focuses on diseases that are spread to humans predominantly from animal contact, including pasteurellosis, the plague, tularemia, and *Rhodococcus*. The diagnosis usually depends on a careful animal exposure history. Once alerted, the clinician can request appropriate studies, as these diseases may be more elusive to diagnose.

PASTEURELLA MULTOCIDA

P. multocida is a common commensal of the oral cavity of most felines and many dogs and a frequent respiratory pathogen in animals and birds.[3] The respiratory tract is the second most common site of *Pasteurella* infection following skin and supporting tissues. Respiratory infections are probably underreported. Elderly people with structural lung diseases such as emphysema, bronchiectasis, or malignancy are at higher risk for pulmonary infection. Immunocompromised patients, including those with AIDS, may be prone to spontaneous infection without close contact or traumatic dog or cat exposures.

TABLE 138-1 An Overview of Zoonotic and Other Unusual Pneumonias

Environmental Niche	Microorganism	Disease	Epidemiologic Associations	Distribution
Live animal contact or via arthropod	*Francisella tularensis*	Tularemia	Contact with wild and pet animals, birds, or arthropods (ticks, deer fly)	North America, Europe, Asia
	Pasteurella multocida	Pasteurellosis	Feline and dog contact; chronic lung disease	Worldwide
	Rhodococcus equi	Rhodococcus pneumonia	Airborne droplets; contact with soil contaminated with horse, cow, or swine excrement	Worldwide
	Yersinia pestis	Plague	Contact with rodents, fleas; contact with plague pneumonia case	Worldwide, including Asia, southwest US
Soil, stagnant water, and inert animal products	*Bacillus anthracis*	Inhalation anthrax or woolsorter's disease	Industrial; use of or contact with animal products in hobbies	Worldwide in warmer regions inhabited by grazing animals
	Brucella species	Brucellosis	Ingestion or contact with infected animal products, slaughterhouses	Worldwide
	Burkholderia pseudomallei	Melioidosis	Direct penetrating contact of wounds with soil, water	Latitude 20°N to 20°S, especially rural Asia, northern Australia
	Yersinia enterocolitica	Yersiniosis	Ingestion of contaminated foods, water; cirrhosis	Worldwide
Obligate human commensal	*Neisseria meningitidis*	Meningococcal pneumonia	Airborne droplets, human to human; postviral, nosocomial	Humans worldwide
	Moraxella catarrhalis	Moraxella pneumonia	Aspiration, especially individuals with underlying lung disease	Humans worldwide

Bacteriology

P. multocida is a small gram-negative bipolar-staining coccobacillary organism that resembles *Haemophilus* spp. and may form pairs and chains. Rapid growth on blood agar and inhibition by MacConkey medium separate this microorganism from other common components of the respiratory flora, including *Haemophilus* spp. Numerous virulence factors in *P. multocida* have been identified. These include the capsule in serogroups A and B (which interferes with phagocytosis), a toxin in strains causing atrophic rhinitis in pigs, lipopolysaccharide endotoxin, several iron acquisition proteins (e.g., TonB, ExbD, and ExbB), and the putative filamentous hemagglutinins PfhB1 and PfhB2.

Ecology, Epidemiology, and Pathogenesis

In cats and other felines, the organism resides periodontally in the anterior regions of the mouth. Isolates from dogs are characteristically from the posterior pharynx. Many birds and domestic and wild animals worldwide harbor this organism as a commensal in oral or gastrointestinal areas. *P. multocida* is occasionally found in the secretions of persons with chronic lung disease, especially those

TABLE 138-2 Diagnostic Studies and Treatment Recommendations in Zoonotic Pneumonias

Disease	Gram's Stain Morphology	Culture Methods	Identifying Tests
Anthrax	Large gram-positive bacillus (rarely seen)	BAP, blood cultures	FA
Brucellosis	Small gram-negative coccobacillus (rarely seen)	Media enriched with serum, $CO_2 + O_2$; notify laboratory that pathogen may be cultured	Rise in AA, prozone
Melioidosis	Bipolar-staining gram-negative bacillus	BAP, MAC	Morphology, FA, AA
Pasteurellosis	Small bipolar-staining gram-negative bacillus	BAP, CO_2	Inhibited by MAC, biochem. tests
Plague	Enteric bipolar-staining gram-negative bacillus	BAP, MAC, enteric media, blood cultures; notify laboratory that pathogen may be cultured	Biochem. tests, FA, AA
Rhodococcus	Gram-positive coccobacilli (slightly acid-fast positive)	BAP	Biochem. tests
Tularemia	Small gram-negative coccobacillus	Enriched media with cysteine, serum; notify laboratory that pathogen may be cultured	FA, AA, rarely cultured
Yersiniosis	Enteric gram-negative bacillus	BAP, MAC, enteric media, blood cultures	Biochem. tests, motility 25°C

BAP, blood agar plate; FA, fluorescent antibody; AA, agglutinin antibody; MAC, MacConkey agar.

with bronchiectasis and domestic animal contacts. A recent report links the domestic cooking and ingestion of pig trotters (feet) with subsequent pneumonia.[21] Human-to-human transmission has been documented from mother to newborn infant, resulting in neonatal pneumonia. The organism can survive in soil and water for more than 3 weeks and in animal carcasses for approximately 2 months. In about half of the cases of respiratory disease, no clue to airborne spread exists, but there are usually cats in the local environment.

Pathogenic strains have a polysaccharide capsule that inhibits phagocytosis, and they contain endotoxin in the cell envelope. Exotoxins and other pathogenicity-promoting factors have not been specifically identified (see Bacteriology). Almost all patients who develop respiratory infections have underlying chronic pulmonary disease. Aspiration probably initiates active infection. Necrosis and lung abscess, empyema, septicemia, and transbronchial spread to other lung segments have been described.

Clinical and Radiologic Features

The clinical features of *P. multocida* respiratory disease include worsening of the patient's baseline pulmonary function—especially when high fever, tenacious secretions, and pleural effusions develop. Radiologic changes include lobar, multilobar, or diffuse patchy infiltrates, usually sparing the upper lobes, superimposed on underlying chronic lung disease (Fig. 138-1). Effusions, including empyema, have been noted in approximately 20% of cases. Bacteremia has been reported in up to 55% of patients with pneumonia, and endocarditis has occasionally complicated bloodstream invasion.[3]

Diagnosis and Differential Diagnosis

Diagnosis depends on isolation of the organism from sputum, pleural fluid, or blood. Usually the pathogen can be identified with the routine methods of the diagnostic laboratory. The bipolar gram-negative staining bacilli resemble *Brucella* spp., *Y. pestis, Francisella tularensis, Burkholderia* (formerly *Pseudomonas*) *pseudomallei,* and *Haemophilus* spp., but the clinical history of exposure to cats and/or dogs and bacteriologic characteristics can rapidly clarify the identification.

Figure 138-1 Bilateral pneumonia due to *Pasteurella multocida* in a 69-year-old woman suffering from chronic obstructive pulmonary disease and a prior right lower lobectomy for carcinoma. Infiltrates disappeared with penicillin therapy.

Treatment

Most strains are exquisitely susceptible to penicillin or ampicillin. The third-generation cephalosporins, cefotaxime and ceftriaxone, are as active as penicillin and more potent than earlier-generation relatives. Oral preparations of cephalosporins and penicillins are not recommended for treating pneumonias caused by *P. multocida* due to reduced bioavailability. The newer fluoroquinolones, including moxifloxacin and levofloxacin, are very active in vitro against *P. multocida* and other *Pasteurella* spp., although there is limited published experience in humans. Chloramphenicol, with consideration of potential toxicities, and tetracycline are effective alternatives when a history of allergic reactions precludes use of a β-lactam agent.

■ *YERSINIA PESTIS*

This organism left an indelible mark on humanity long before its late 19th-century isolation and characterization. The cause of three major pandemics from the 6th through the 19th centuries, pulmonary disease in a few victims led to aerosol spread to countless others, resulting in acute primary pneumonia and the "black death" of epidemic plague. During the period from 1932 through the end of World War II (1945) the Japanese biologic warfare program included the use of aerosol drops of *Y. pestis* as well as infected flea disseminations in occupied China and at the infamous experimental Unit 731. The effectiveness of the flea drops remains in question to this day but the aerosol dispersal definitely led to clinical pneumonic plague. A contemporary global scare emanated from India's Maharashtra state in 1994, with reports of suspected pneumonic and bubonic plague; interestingly, some suspected cases were subsequently found to be due to *B. pseudomallei*.[22] In the United States, fewer than 20 cases of plague are reported yearly, of which one in five has lung involvement but without any secondary cases. Early recognition and specific therapy, combined with isolation procedures and appropriately directed prophylaxis of contacts should help maintain the record of no human-to-human transmission in the United States since the 1920s. When plague is diagnosed outside an endemic area, bioterrorism should be considered. When *Yersinia* pneumonia occurred in a couple who recently became ill in New York City, the event was originally investigated as a potential bioterrorism event until their travel from an endemic area of plague (Santa Fe County, New Mexico) was discovered.[23] Although the bacteria are difficult to process, handle, and disperse in an aerosol form, person-to-person airborne spread is very efficient and laboratory accidents have occurred.

Bacteriology

Y. pestis is a bipolar-staining, gram-negative bacillus closely related to *Escherichia coli* and other *Enterobacteriaceae*. It grows well on blood or MacConkey agar and is identified definitively with differential biochemical tests, agglutination reactions, and direct fluorescent antibody staining. Concerns for laboratory safety have led to routine of Biosafety level 2 (BSL-2) laboratory procedures as well as better communication between clinicians and microbiology laboratory personnel in suspected cases.

Ecology, Epidemiology, and Pathogenesis

In the United States, *Y. pestis* is endemic in rock squirrels, prairie dogs, rabbits, rats, and other small ground animals primarily in the Southwest. Spread among animals occurs via several species of rodent fleas, especially *Xenopsylla cheopis*. Domestic animals that wander outdoors, like cats, can become infected by direct contact with sick rodents or via rodent flea bites. In addition, cats and dogs can inadvertently

carry fleas to the home. Occasionally rodent die-offs, called epizootics, occur, and many dead animals can be found with viable organisms in carcasses and in the soil surrounding ground dwellings.

In the United States, spread to humans occurs when an infected flea feeds on a susceptible person. Living or working in proximity to local enzootic "hot spots" places certain groups (such as Native Americans, geologists, hikers, veterinarians, and pet owners) at risk. Bubonic and cutaneous plague are usually acquired on exposed areas by contact with infected fleas, but aerosols from ill animals or carcasses can lead to primary pneumonia, pharyngitis, or conjunctivitis. Several cases of cat-to-human aerosol spread have been associated with respiratory infection or submandibular abscesses in pets. A great concern of physicians caring for patients with respiratory infection is the potential for rapid airborne dissemination, especially during coughing and face-to-face contacts, resulting in primary pneumonia and the rapid development of acute respiratory distress syndrome (ARDS).

After the organism gains access to human tissues at 37°C, rapid multiplication occurs. The polysaccharide capsule imparts virulence properties that include resisting phagocytosis and persistence of bacteria within nonsensitized monocytes. Virulence factors include a potent endotoxin and V and W antigens of the cell envelope, which influence intracellular survival. Recent work with a mouse model has demonstrated a biphasic illness with an initial anti-inflammatory phase that rapidly progresses to a highly proinflammatory state by 48 hours and death by 3 days. Microarray analysis demonstrates a change in the expression of about 10% of the bacterium's genes after it infects a host.

Clinical and Radiologic Features

Clinical presentations are highly varied and include subclinical cases (positive serology without evidence of disease), a chancriform skin lesion (pestis minor abortive bubonic plague), pharyngitis, bubonic plague, septicemic plague, pneumonic plague, and meningitis. The clinical presentation of pneumonia depends on the mechanism of spread. In contemporary experience in the United States, cases have all been secondary to bubonic plague, primary septicemia without an overt skin lesion, or inhalation of droplets from an infected pet cat. The onset of respiratory disease follows after days to a week of a febrile illness, and is ushered in by the gradual onset of cough, dyspnea, and increasing toxicity. Pink to hemorrhagic frothy sputum, pleurisy, and respiratory distress are additional symptoms. The unique feature in most cases of pneumonia is the epidemiologic association with classic bubonic plague; that is, in a person in or from an endemic area or who has had contact with a pet cat ill with respiratory symptoms or a facial abscess. From histories of primary inhalation pneumonia described previously, exposure to an index case may be followed by the rapid development of a fulminating respiratory illness, with dyspnea, cyanosis, and thin, watery sputum that rapidly becomes hemorrhagic. The clinical picture is not unlike that of overwhelming pneumococcal pneumonia, with marked toxicity and mental torpor associated with progressive cyanosis.

The radiologic features of secondary pneumonia include basal segment nodular to hazy air space infiltrates, hilar and mediastinal node hypertrophy, and occasionally pleural effusions.[24] In primary pneumonia, infiltrates may be minimal during the first 24 hours, followed by progressive air space disease resembling ARDS or pulmonary edema.

Diagnosis and Differential Diagnosis

The presence of characteristic bipolar-staining gram-negative bacilli in sputum suggests the diagnosis when epidemiologic clues are present. Cultures of blood, sputum, and lymph node aspirates often yield positive results. Direct fluorescent antibody staining can provide immediate etiologic confirmation. A passive hemagglutination test can be performed as a confirmatory study on acute and convalescent sera at selected reference laboratories such as CDC. Rapid assays for diagnosis of plague are under active development, especially given the interest in its potential as a bioterror agent. Other acute respiratory infections caused by microorganisms that appear as gram-negative bacilli with bipolar staining must be considered, including *F. tularensis* and *P. multocida.*

Treatment and Prevention

The combination of streptomycin and tetracycline has been the treatment of choice for serious plague infections. Gentamicin can be substituted for streptomycin if intravenous therapy is necessary or streptomycin is not available. Doxycycline and fluoroquinolones such as ciprofloxacin may also be effective in treating pneumonia; chloramphenicol is a potential option, noting toxicities. Multidrug-resistant plague has been reported and clinicians should be aware of local trends as well as the potential for terrorist-instigated modifications in antibiotic susceptibility.

Persons suspected of having plague pneumonia should be rapidly isolated, and strict contact, respiratory, and conjunctival precautions instituted. Anyone exposed face to face with a coughing patient, including healthcare workers, should be given preventive tetracycline or ciprofloxacin (trimethoprim/sulfamethoxazole is used in pregnant women and children). Isolation procedures are continued until productive cough is no longer present or sputum cultures are negative for *Y. pestis.*

A vaccine is available for laboratory workers and others with frequent exposure to the microorganisms or hyperendemic areas, although it does not appear to protect against pneumonic plague. Careful surveillance of ground rodent populations, posting warnings in endemic regions, watching for die-offs that indicate epizootic spread, and spraying for local flea control may also be effective preventive measures along with public education.

■ *FRANCISELLA TULARENSIS*

Tularemia is a common animal disease in the United States as well as many other regions of the temperate globe. The causative agent, *F. tularensis,* is ubiquitous, distributed among many species of wild and domestic animals and birds. As with plague, the major clinical manifestations include skin lesions and swollen or draining regional lymph nodes. In addition to primary inhalation pneumonia, pulmonary invasion is seen following bacteremia in 10% to 15% of ulceroglandular cases and in more than 50% of patients with the typhoidal syndrome. Approximately 150 human cases are reported in the United States yearly, but this is probably an underestimate; approximately 40% of all tularemia cases each year occur in Arkansas, Oklahoma, and Missouri.[25] In the summer of 2000, an outbreak of pneumonic tularemia occurred on Martha's Vineyard, Massachusetts, and 11 of 15 patients were diagnosed as primary pneumonic tularemia; lawn mowing and brush cutting were found to be risk factors for infection.[26] An epidemic of tularemic pharyngitis from ingestion of contaminated well water and food occurred in war-torn Western Kosovo primarily among young children originally suspected of having group A Streptococcal pharyngitis, with no secondary pneumonias reported.[27]

Bacteriology

F. tularensis is a fragile-appearing gram-negative coccobacillary organism that is quite fastidious and grows poorly on artificial media unless fortified with serum and cysteine (or sulfhydryl compounds). The potential for laboratory-acquired inhalation or ingestion-associated disease is great. Most routine laboratories will not attempt to culture the organism, leaving this to special reference centers. Identification is on the basis of morphologic and biochemical determinants, but direct fluorescent staining or agglutination reactions with specific antisera are also useful.

Ecology, Epidemiology, and Pathogenesis

The organism is associated with more than 100 species of wild and domestic animals and birds, including aquatic mammals, but most clinical cases arise from contact with rabbits, squirrels, or arthropods. Of great concern is the recent fad for exotic pets; tularemia in prairie dogs has led to spread in holding pens and to human transmission. In cold weather the organism can persist in water and mud environments for weeks to months. Bloodsucking arthropods, especially ticks and deerflies, act as reservoirs capable of harboring the pathogen for long periods and are responsible for dissemination among wildlife species as well as infecting people. Domestic cats represent a potentially increasing problem.[28]

Less than half of human cases are acquired from contact with infected animals during hunting, trapping, and other outdoor pursuits, especially during colder months. In southern areas, or in the summer season in northern latitudes, gardening and lawn mowing without animal contact are becoming important methods of dissemination from disturbed soil. Bloodsucking arthropods constitute a significant and increasing mode of spread, especially in warmer seasons. Ingestion of contaminated food or water,[27] animal bites, conjunctival contact, and aerosol dissemination are also important mechanisms for acquiring the pathogen. In recent years, cases secondary to arthropods have been more frequent than those associated with direct animal contact, although domestic cat bites[28] and airborne spread appear to be increasing. Human-to-human transmission is rare, in contrast to the significant theoretical potential for spread of pneumonic plague. If *F. tularensis* were to be used by terrorists, aerosol release would most likely be the mode of spread, with respiratory as well as other locations (skin, conjunctival, pharynx) occurring in the exposed population. Those criminally processing this organism would be at great risk for laboratory infection.

F. tularensis contains a number of protein and polysaccharide antigens in the cell envelope as well as an endotoxin component that is similar to endotoxins of other gram-negative microorganisms. Very little is known about other mechanisms of pathogenesis. The organism is capable of remaining viable within the reticuloendothelial cells of nonimmune subjects and in macrophages that have not been activated by recent exposure to other intracellular pathogens. As few as 10 to 50 organisms can initiate disease following cutaneous penetration or by inhalation, but a significant number are required when the challenge is through ingestion of contaminated water or foods. Local growth usually is followed by regional node suppuration and occasionally bacteremic dissemination to many organs, including the lungs. Primary pneumonia follows inhalation of organisms, resulting in numerous areas of inflammation, necrosis, a tendency to granuloma formation, hilar and mediastinal adenopathy, and pleural inflammation and effusion.

Clinical and Radiologic Features

Respiratory disease is heralded by the onset of a nonproductive cough, usually in a febrile patient ill with the ulceroglandular form of tularemia.[29] In the absence of a local chancriform lesion or a tender swollen lymph node (bubo), the disease may be dominated by constitutional symptoms, with high fever, severe headache, prominent myalgias, and shaking chills (typhoidal tularemia). Pneumonia following an inhalation exposure results in cough, dyspnea, and occasionally pleurisy. Respiratory disease can be subtle, and the diagnosis may be apparent only if a chest radiograph is done. Pleural effusions may be serosanguineous or frankly bloody, an uncommon finding with other pulmonary infections except anthrax.

Radiologic changes include evidence of parenchymal and pleural diseases, which is often out of proportion to the findings on examination. Diffuse areas of bronchopneumonia occur, with hilar node enlargement and occasionally mediastinal widening, similar to radiologic appearance of anthrax. Unilateral or bilateral pleural effusions are often noted (Fig. 138-2).

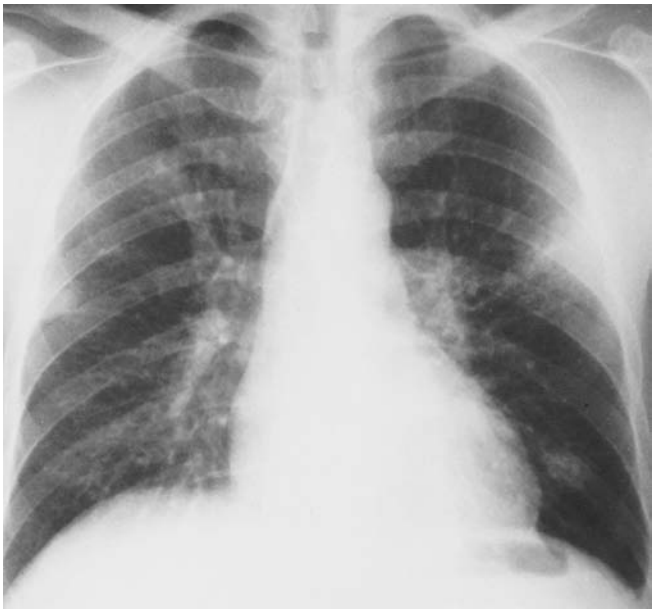

Figure 138-2 Patchy nodular and bronchopneumonia, hilar adenopathy, and left pleural effusion due to *Francisella tularensis* in a 38-year-old veterinarian exposed to a cat dying with a respiratory infection. All the findings resolved with tetracycline therapy.

Diagnosis and Differential Diagnosis

Any febrile patient with animal, arthropod, or landscaping exposure in an endemic region, especially presenting with a chancriforme skin lesion and/or a tender lymph node should be evaluated for tularemia. Cough, when present, is usually nonproductive, and blood cultures are seldom positive. Characteristic organisms are rarely seen in pleural fluid or aspirates of suppurating nodes. Direct fluorescent antibody staining of exudates can confirm the diagnosis, but this method is not widely available. Serologic testing remains the method of choice for confirming a diagnosis. ELISA and microagglutination methods may be more sensitive than tube agglutination testing. A single convalescent titer of 1:160 or greater is considered highly suspect for active disease, but a fourfold rise in titer between acute and convalescent (1–5 weeks) sera is more reliable, since antibodies can persist for many years after infection. Polymerase chain reaction and other molecular biologic techniques have successfully diagnosed tularemia in human specimens. An elevated blood level of creatine phosphokinase may be a clue to tularemia-induced rhabdomyolysis in response to acute infection, especially in highly endemic areas.

Perplexing diseases that are also associated with outdoor and animal exposures, such as psittacosis and Q fever, may be confused with tularemia. Legionnaires' disease and mycoplasma pneumonia can present with similar clinical courses, without diagnostic sputum. Plague, tuberculosis, and systemic fungal infections produce a spectrum of acute to chronic respiratory manifestations that can mimic pulmonary tularemia.

Treatment and Prevention

Streptomycin was the first effective antibiotic for treating all forms of tularemia, and it remains the agent of choice.[29] Gentamicin appears to be equally potent and has the advantage of a broader spectrum of activity if one is initiating treatment when the etiologic diagnosis is less secure.[29] In addition, it can be given intravenously, and blood levels can be monitored. *Tobramycin, however, appears*

to be unreliable and therefore should not be substituted for other aminoglycosides. Recent experience confirms that results of therapy are optimal when an aminoglycoside is chosen early in the clinical illness. Tetracycline/doxycycline, ciprofloxacin, and chloramphenicol may be useful alternatives when an aminoglycoside is contraindicated. Relapse rates are higher with the bacteriostatic agents tetracycline/doxycycline and chloramphenicol, especially when given for less than 2 weeks. β-Lactam antibiotics are not effective. The prognosis is excellent with appropriate antimicrobial therapy.

Cautious practices are required when one is dealing with animals and their carcasses. Using gloves, cooking wild animal meat thoroughly, and wearing protective clothing and repellants to avoid blood-sucking arthropods are helpful measures. An attenuated live vaccine strain (LVS) has been available for over 50 years, although it is not fully licensed (in part due to a lack of knowledge regarding the basis of attenuation), and does not offer a high level of protection against respiratory challenge. With the increase in concern over bioterrorism, numerous groups are working to develop an improved vaccine.

■ *RHODOCOCCUS EQUI*

Rhodococcus equi, formerly known as *Corynebacterium equi,* was first isolated in 1923 by Magnussen when it was identified as a cause of suppurative pneumonia in foals. It was later shown to be a frequent pathogen in horses, cattle, and swine. First described as a pathogen in humans in 1967, the majority of recognized cases in recent years have been in immunocompromised patients, especially individuals receiving corticosteroids, those infected with the human immunodeficiency virus,[30] or those who have undergone solid organ transplantation.[31]

Bacteriology, Ecology, Epidemiology, and Pathogenesis

Rhodococcus is a pleomorphic gram-positive bacillus in the order *Actinomycetales*. It grows well aerobically on most media, at 37°C, as mucoid pale-pink or salmon-pink colonies that are usually observed by 48 hours of incubation. *R. equi* has a high cell wall mycolic acid content and is acid-fast, similar to *Nocardia* spp. and *Mycobacteriaceae*. Some strains ferment glucose, but the majority will not ferment carbohydrates. Most produce catalase and hydrogen sulfide. β-Lactamase is present in some strains.

The majority of reported cases occurring in humans without HIV infection have been in patients who had significant contact either with livestock (including horses) or soil and environments that were heavily contaminated with livestock waste. In contrast, HIV-related *Rhodococcus* disease appears to occur in patients who do not have any particular environmental exposure history—implying a wider distribution of the organism.[30] There is no known geographic endemicity.

R. equi usually is inhaled, although soft tissue infections after cutaneous inoculation can occur. As an intracellular pathogen it causes disease primarily in patients with impaired cell-mediated immunity and defects in phagocytic processing of organisms. Diseased tissues usually show a necrotizing granulomatous reaction, with histiocytes and macrophages frequently containing bacteria. In contrast to lesions associated with *Mycobacterium tuberculosis* and systemic fungi, there is also a prominent infiltration of neutrophils in the affected areas, a characteristic shared with other *Actinomyces* spp.

Clinical and Radiologic Features

Patients frequently complain of indolent symptoms, such as fever, nonproductive cough, and mild dyspnea.[31] Typically there is a paucity of findings on physical examination of the chest, but signs of consolidation and pleural friction rubs may be present. Patients with untreated HIV infection generally present in a manner similar to patients without HIV infection, although pleuritic chest pain may be more common. In untreated HIV-infected patients, *R. equi* disease tends to occur after there has been significant deterioration in the immune system, with CD4 lymphocyte counts less than 200 cells/mm^3.[30] It is often found associated with other pulmonary infections. Extrapulmonary dissemination occurs in HIV-infected and non–HIV-infected patients, but there appears to be a significantly greater rate of recovery of the organism from blood cultures in HIV patients. The central nervous system is a recognized site of metastatic infection, as it is for *Nocardia* spp.

The most common radiographic abnormalities are lobar infiltrates, which usually evolve into nodular or cavitating lesions within weeks or months. There is no predilection for involvement of any particular lobe. Pleural effusions are common, occurring in up to 40% of HIV patients with pulmonary *R. equi* infection. Significant hilar adenopathy is unusual.

Diagnosis and Differential Diagnosis

R. equi can readily be cultured from sputum, bronchial lavage, pleural fluid, or other infected tissue and often from blood. Since the organisms stain as pleomorphic gram-positive bacilli, grow readily on most media, and are usually catalase producers, they can be mistaken for "diphtheroid" or "Coryneform" contaminants unless further testing is done. Therefore it is important for the clinician to alert the microbiology laboratory staff if the possibility of *R. equi* is entertained. *R. equi* is slightly acid fast with modified Ziehl–Neelsen stain.

Rhodococci share many microbiologic features with *Mycobacteria* and *Nocardia,* and this may account for similarities in the subacute to chronic evolution of the disease. The high mycolic acid content of their cell walls results in their acid-fast staining properties and may also play a role in their similar clinical and pathologic manifestations. *Nocardia* spp., *M. tuberculosis,* and nontuberculous mycobacteria also should be considered when acid-fast organisms are found in clinical specimens, especially in immunocompromised patients with nodular or cavitary pneumonia (Table 138-3).

Other considerations in the differential diagnosis of nodular or cavitating pulmonary lesions include malignancy, fungal infection such as *Cryptococcus neoformans,* anaerobic lung abscess, and necrotizing pneumonia caused by facultative bacteria such as *S. aureus* or *Klebsiella pneumoniae.*

Treatment and Prevention

Antibiotic therapy alone is usually adequate to achieve cure.[31] As with mycobacterial infections, multidrug regimens and therapy of at least 2 to 6 months' duration may be needed, especially in immunocompromised patients. Because *R. equi* is an intracellular pathogen that multiplies in phagocytes, antibiotics capable of achieving high intracellular levels, such as rifampin or fluoroquinolones and especially erythromycin and the expanded-spectrum macrolides, clarithromycin or azithromycin, are preferred. Chloramphenicol, sulfonamides, and aminoglycosides are active against most isolates. In some patients, surgical resection of a nodular or cavitating lesion may be necessary to achieve cure. Immunocompromised hosts should avoid contact with horses and their environments.

TABLE 138-3 Diagnosing *Rhodococcus equi* Respiratory Infection

History of exposure to horses, cattle, or their environment
Immunocompromised host: Malignancy, steroids, HIV
Cavitary or nodular infiltrates on radiograph
Gram-positive pleomorphic bacilli
Modified acid fast
Pale-pink or salmon-pink mucoid colonies
Grows rapidly, aerobically on most media
Differential diagnosis includes *Nocardia* species, mycobacteria

ENVIRONMENTAL AND ANIMAL PRODUCT PNEUMONIAS

This section focuses on four diseases that are spread to humans predominantly from contact with contaminated soil, water, foods, or animal structural elements. The diagnosis usually depends on a careful history focused on epidemiologic and ecologic characteristics. Once alerted, the clinician can request studies that may reveal the cause of these often-obscure diseases. It should be apparent that this distinction – an association with environmental contamination and animal products – can be somewhat arbitrary. For example, anthrax bacilli can spread directly from animals to humans, and *R. equi* contamination of soil could place it in this group rather than in the group infected via direct animal exposure.

■ *BACILLUS ANTHRACIS (ANTHRAX)*

Inhalation anthrax was common enough in the 19th and early 20th centuries to be referred to variously as Bradford's disease, after the English town, and woolsorter's disease for the epidemiologic association with the sheep industry. Fortunately, inhalation anthrax has become a rare spontaneously acquired disease.[32] An epidemic of anthrax following an accidental release at a bioweapons facility occurred in the area of Sverdlovsk (now renamed Ekaterinburg) in the former USSR in 1979, resulting in 42 deaths due to inhalational anthrax.[33] In 2001 there were 18 confirmed cases of inhalational and cutaneous anthrax and an additional four suspected cases of cutaneous anthrax in the United States; of the 22 cases, ≥20 were definitively related to mail contaminated with the same strain of *B. anthracis*. The potential zoonotic as well as terrorist-induced exposure of susceptible persons to *B. anthracis* spores argues for including this devastating, often lethal, disease in this chapter.

Bacteriology, Ecology, Epidemiology, and Pathogenesis

B. anthracis is a large (red blood cell diameter), square-ended bacillus that stains gram-positive and has a tendency to form chains. Growth on sheep blood agar results in dull, sticky, irregularly shaped colonies within 24 hours. The organism possesses a polyglutamic acid capsule, produces a complex potent trivalent exotoxin, and, under adverse conditions, forms highly refractile, centrally located spores that are very resistant to temperature and moisture extremes.

Anthrax is primarily a disease of herbivores. The resistant spores present after animals dying of the disease contaminate the soil. Anthrax "hot spots" are found in milder regions in the United States, such as Oklahoma, Texas, and California. Optimal conditions for germination of spores and multiplication of bacilli include alkaline soils containing adequate calcium and low areas that are wet for prolonged periods, termed *incubator areas,* with thick vegetation that produces heat with decay. Periods of extreme drought after a rainy season favor spore formation. Animals grazing in these areas inhale, ingest, or pick up spores on their fur. The cycle is completed when an animal develops the disease, dies, and returns organisms to the soil for eventual sporulation.

Inhalation anthrax rarely occurs from contact with live infected animals, and there is no human-to-human transmission. The animal hide industry, exposure to bone meal fertilizer,[34] and use of imported goat skins and raw wool in home crafts can lead to inhalation of spores and clinical disease in susceptible persons.[35] Inhalation of spores from wind-disturbed soil can also cause infection.

Inhalation results in activation of bronchial clearing mechanisms and entrapment of spores in hilar and mediastinal nodes, where reversion to vegetative bacilli can occur. The polyglutamic acid capsule is antiphagocytic, and the extracellular microorganisms produce a trivalent protein exotoxin that leads acutely to profound local edema, accompanied by hemorrhage in the mediastinal and hilar areas, with compromise of airflow. Studies have clarified the mechanisms involved in the pathogenesis of this tripartite toxin, which consists of a protective antigen, an edema factor, and a lethal factor. The protective antigen fragment of the toxin serves as the binding domain, essential for cell penetration by both the edema factor and the lethal portions of the molecule. Edema factor is a potent adenylate cyclase; activation within mammalian cells stimulates production of cAMP, and the resultant flux of sodium, potassium, and water leads to abundant local edema. When this process takes place in hilar and mediastinal nodes and surrounding tissues, profound airway obstruction ensues, with pooling of secretions and if the patient survives, secondary bacterial pneumonia. Lethal factor is a potent protease that acts primarily in macrophages, activating intracellular mitogen–activated protein kinase, leading to production of proinflammatory cytokines and reactive oxygen intermediates. The pathogen rarely invades lung tissue, as death from asphyxia occurs rapidly, usually associated with pleural effusions (secondary to lymphatic obstruction) and hemorrhagic septicemic lesions in many organs. In a large inoculum exposure, as occurred in the 2001 "mail room" criminal outbreak, patients can develop disease within the pulmonary parenchyma and the gastrointestinal tract.[32]

Clinical and Radiologic Features

In spontaneously occurring disease, the onset is insidious, usually resembling a nonspecific febrile influenza-like illness.[20,32] Malaise and muscle aches, low grade fever, mild headache, coryza, mild and nonproductive cough, pharyngitis, and chest pains have been described as early symptoms. At this stage, it is hardly possible for the physician to entertain a presumptive or possible diagnosis of anthrax unless a history of industrial or craft-related exposure to imported animal hair or hides or to animal products such as bone meal is obtained. Watery nasal discharge can be indicative of nasal or paranasal sinus involvement. Cough may represent hilar and mediastinal node swelling, and careful auscultation may reveal prolonged expiratory wheezes or evidence of a pleural effusion. Chest pain may be the first clue that hilar and mediastinal inflammation is present.

Within hours to a few days, the mild complaints abruptly worsen and acute airway obstructive features dominate the clinical picture. Any activity precipitates severe dyspnea, stridor, and wheezing. Impairment of the nervous system (hemorrhagic meningitis) and hypoxemia result in decreasing levels of consciousness. Edema of the pharynx, neck, and anterior chest may develop. Chest pain, fever, and cyanosis are progressive. Worsening airway obstruction can lead to intercostal space retraction, and pleural effusions are noted on examination. Death usually occurs within hours to a day once acute respiratory symptoms are present. In the 2001 exposure to a significant spore burden, some patients had a biphasic illness with early upper respiratory and gastrointestinal symptoms, followed by respiratory distress days later.

Inhalation anthrax is primarily a mediastinitis, and the radiologic features mostly reflect the pathologic findings.[36] Widening of the mediastinum or prominence of hilar nodes is the earliest radiologic finding, sometimes accompanied by pleural effusion. In advanced cases, the mediastinal shadow is greater than 9 cm in width and sharply demarcated from surrounding lung tissue because of absence of air space consolidation. There may be perihilar and peribronchial streaking associated with edema and hemorrhage.

Diagnosis and Differential Diagnosis

A physician alerted to the possibility of inhalation anthrax has few laboratory studies to rely on. Nasal secretions and sputum rarely reveal the characteristic bulky gram-positive bacilli. Half of the reported cases of inhalation disease are complicated by meningitis, and hemorrhagic cerebrospinal fluid with observable organisms can confirm the diagnosis. There are no available data on examination of buffy-coat smears, and therapy must be instituted before

blood culture results become available. Microscopic examination of pleural fluid may reveal the characteristic organisms. The most commonly recognized form of anthrax, the cutaneous chancriform necrotic lesion, does not usually accompany inhalation cases in naturally occurring disease.

Differential diagnosis includes other causes of acute mediastinitis, such as esophageal perforation. Tuberculosis, histoplasmosis, and tularemia rarely produce acute respiratory failure as part of hilar and mediastinal node involvement. Hantavirus pulmonary syndrome is associated with similar central pulmonary changes, including edema, but should be separable from anthrax by epidemiologic data, the presence of air space disease, and absence of mediastinal involvement. Lymphoproliferative diseases, like nodular sclerosing Hodgkin disease, evolve at a slower pace. Chest wall and neck edema, associated with acute breathing difficulties, can accompany diphtheria or *Streptococcus pyogenes* pneumonia, with bilateral pleural effusions an early manifestation of streptococcal pneumonia. Acute epiglottitis, caused by *Haemophilus influenzae,* was an occasional disease of preteen children prior to vaccine development and can mimic some of the manifestations of inhalation anthrax.

Treatment and Prevention

Combination therapy is currently recommended based upon the "mail room" epidemic of 2001.[20] Regimens with ciprofloxacin or doxycycline, plus clindamycin (to block toxin production) and rifampin (which penetrate CSF and intracellular sites) are favored. Monotherapy with penicillin should not be used in inhalation disease since multiple strains, including the 2001 "mail room" outbreak, produce an inducible β-lactamase. Treatment is recommended for 60 days to avoid activation of persistent spore forms.[20] Corticosteroids should be considered for treatment of significant mediastinal edema or meningitis and early thoracentesis appears to be beneficial. Unfortunately, the airway obstructive manifestations are not reversible once acute respiratory manifestations have progressed. Assisted ventilation and use of diuretics are all reasonable support efforts, but they are generally not successful due to the continued effects of tissue-bound toxin. Before 2001, mortality in inhalation anthrax approached 100% of cases, compared with the rarity of death from cutaneous disease. In the 2001 experience, mortality was 45% (5 of 13 respiratory cases) and knowledge gained from that experience might prove helpful in future cases.

In the animal hide industry, vaccination is the cornerstone of preventing anthrax. Plant workers and others in contact with potentially infected animal products should be immunized with the currently available vaccine. Numerous new vaccines are under development, many based upon the protective antigen segment of the toxin. Animal products imported from endemic regions of the world (e.g., Africa, the Near East, and the Indian subcontinent) are steam sterilized, and there is modern ventilation in the workplace. At-risk subjects, then, are people who service these plants, such as ventilation specialists and other transients who are unlikely to be vaccinated. Bone meal should be treated by heat sterilization before packaging for use by commercial and home gardeners.[34] Those who import yarn from endemic areas are at special risk unless the rules for commercial hide sterilization are also imposed on casual animal hair imports.[35] A recent case of inhalation anthrax in a drum maker who carried goatskins into the United States emphasizes the need for appropriate education and importation controls.[35,37]

■ *BRUCELLA SPP.*

In the approximately 200 cases of brucellosis that are reported yearly in the United States, acute respiratory manifestations are usually insignificant. Lung involvement is an uncommon presentation of brucellosis.[38] Brucellosis is often a prolonged and perplexing illness however, and in chronic cases pleurisy, hilar adenopathy, and nodular lung lesions can be encountered. Exposure to animals, animal-based foods (cheeses or meats), or residence in an endemic region is usually found.

Bacteriology, Ecology, Epidemiology, and Pathogenesis

Brucellae are slow growing, small coccobacillary, gram-negative, nonmotile, aerobic, nonencapsulated organisms that are now classified with the alpha-Proteobacteria, closely related to *Rochalimaea* and *Bartonella* spp. Carbon dioxide is essential for growth of *Brucella abortus,* and all four pathogenic species require growth medium enriched with vitamins and serum. With the aid of a battery of biochemical, metabolic, and immunologic criteria, *Brucellae* pathogenic for humans can be classified as *B. abortus, B. suis, B. melitensis,* and *B. canis.* In general, the species designation corresponds to the animal usually colonized or diseased.

Brucellae spp. are distributed worldwide. Infection and disease occur primarily in domestic animals in geographic regions such as the Mediterranean littoral (*B. melitensis*), worldwide except areas of Europe and Japan (*B. abortus*), the midwestern United States (*B. suis*), and North and Latin America (*B. canis*). Spread from one region to another occurs with live animal movements or when infected animal products are commercially or privately shipped.

The epidemiology of brucellosis is intimately related to the association of susceptible persons with infected animals and animal products. Abattoir workers (especially slaughterers) and others in the meat-processing industry, farmers, dairy workers, veterinarians, and bacteriology laboratory technicians account for most cases in the United States, with a general preponderance of male patients. Fifty percent to 60% of brucellosis infections in the United States now occur in California and Texas, mostly among Hispanics.[39] Also at risk are military personnel and travelers to endemic regions who eat local foods and people who consume imported goat cheese, sausage, and other unpasteurized edibles from endemic areas. The organisms are usually acquired by ingestion, through skin abrasions and lacerations, or via conjunctival inoculation. Aerosol spread can be a route in abattoir workers[40]; inhalation of only 10 to 100 bacteria can cause disease in humans.[41] No human-to-human transmission has been reported.

Organisms invade the local reticuloendothelial system and lymph nodes, followed by bacteremic spread to many organs during the following weeks. There is increasing evidence that the aerosol route may be a rare but especially efficient portal of entry. The distribution of nodular lesions in lung tissue is primarily in basal segments, however, which argues for bacteremia rather than primarily an inhalation mechanism for most cases of pulmonary disease.

A race between bacterial growth and the development of cell-mediated immunity ensues, primarily in lymph nodes and the reticuloendothelial system. As with tuberculosis, the end result is often containment within granulomas that eventually become fibrotic or calcify. Species and strain differences account for the wide variety of tissue reactions encountered, including granulomas, necrosis, and abscess formation. Smooth variants appear to be more virulent than rough forms, and many contain polysaccharide polymers in their superficial envelope that, like true capsules, inhibit phagocytosis and intracellular destruction. Lipopolysaccharide endotoxin is present in the cell envelope and may be responsible for profound metabolic and cardiovascular effects as organisms are killed during therapy, releasing endotoxin. *Brucella* spp. are able to survive within nonstimulated macrophages while escaping host antibodies and antibiotic therapy. As macrophages become activated, they develop the capacity to rapidly kill *Brucella* organisms. Host immunity appears to be primarily cell mediated. Impairment of cell-mediated immunity can lead to reactivation of latent *Brucella* or greater susceptibility and severity with primary infection.

Clinical and Radiologic Features

Clinical brucellosis is dominated by nonspecific flu-like constitutional manifestations, including fever and headache. Nonproductive cough has been described in 10% to 33% of cases, but other indicators of respiratory involvement are rarely or poorly described. In one review of 59 cases, dyspnea and pleuritic chest pain were present in 10% of the patients. Hoarseness, bronchitis, and, rarely, mucopurulent, purulent, or hemorrhagic sputum have been noted. Only one patient with verified pulmonary invasion was described in a review of 160 acute and subacute cases of brucellosis reported in 1974. In a recent description of 37 patients with *Brucella* respiratory disease, 32% had typical lobar pneumonia, 41% had an interstitial pattern on chest x-ray, and a honeycomb pattern was seen in 11%, with pleural effusion(s) in the same number.[42] Extrapulmonary disease was found in 76% of patients, with 22% having greater than one extrapulmonary complication. Unilateral hilar adenopathy and granulomas occur occasionally.

Diagnosis and Differential Diagnosis

During the acute illness or in relapse, blood cultures may be positive. In the presence of an infiltrate or pleural effusion, material for Gram stain and culture should be obtained, although the yield is small. A positive culture may be obtained from a lymph node or pulmonary granuloma biopsy. In most cases the diagnosis is made from a fourfold rise or a single value of at least 1:160 in the agglutination titer. Occasionally "inhibitory" or blocking antibodies are present in the serum, and a positive titer is discovered only if the serum is further diluted (so-called prozone phenomenon). The standard tube agglutination test utilizes *B. abortus* as the antigen and will detect antibodies to *B. suis* and *B. melitensis,* but not to *B. canis.* Diagnostic confusion and numerous alternative diagnoses are the rule in cases of brucellosis. Direct comparison of the clinical manifestations of *B. abortus* with *B. melitensis* reveal that the latter presents more acutely as fevers of unknown origin with statistically significant higher rates of abdominal tenderness, hepatomegaly, splenomegaly, thrombocytopenia, pancytopenia, and hepatic dysfunction. Acute disease can be confused with miliary tuberculosis, endocarditis, tularemia, disseminated histoplasmosis, and lymphoproliferative diseases. Subacute and chronic cases must be differentiated from subacute bacterial endocarditis, tuberculosis, histoplasmosis, other systemic fungal infections and sarcoidosis.

Treatment and Prevention

The combination of doxycycline with rifampin for 4 to 6 weeks is one of the most effective and easiest of the oral antibiotic regimens.[38] Doxycycline combined with streptomycin or gentamicin, or trimethoprim/sulfamethoxazole are also effective alternative regimens. Fluoroquinolones are active in vitro, but they are associated with an unacceptably high relapse rate as monotherapy.

Rigorous control measures such as herd inspections and vaccination procedures have dramatically reduced enzootic and epizootic disease in many regions. Quarantine and inspection activities have diminished the risk of importing infected animals into the United States. The program for *B. suis* eradication has been ineffective, and human cases of *B. suis* now outnumber those due to *B. abortus.* The efficacy of human vaccines is marginal. Education programs for workers in abattoirs have been aimed at protecting and preventing skin lacerations, eye contamination, and aerosol spread.

■ *BURKHOLDERIA (PSEUDOMONAS) PSEUDOMALLEI*

Melioidosis ranges from an acute necrotizing to a chronic fibronodular cavitating process indistinguishable from tuberculosis.[43] It is a disease of tropical latitudes, and most cases have been seen in Southeast Asia, associated with rural settings.[44] A number of cases were noted in survivors of the 2004 tsunami,[44] and after flooding in Puerto Rico.[45] Infection with *B. pseudomallei* has been seen in the United States almost exclusively after a latent period of months to years in military personnel returning from regions such as Vietnam and in refugees from endemic areas, although case reports from areas such as the Caribbean,[45] Africa, the Middle East, and Brazil have also been reported. The mortality rate can reach 40%.[43]

Bacteriology, Ecology, Epidemiology, and Pathogenesis

The organism is an aerobic, bipolar-staining gram-negative bacillus that is motile and lacks a well-defined capsule. Similar to the pseudomonads, *B. pseudomallei* grows well on minimal as well as enriched media, including blood and MacConkey agar, used in most routine laboratories. Typical colonies are distinctive in appearance, rough or wrinkled, and cream to orange in color; they may resemble a flower with folds radiating from a central core. Colonies have the typical musty, fruity odor of the pseudomonads but lack pyocyanin and other pigments that characteristically color the surrounding medium. Identification rests on a battery of biochemical reactions, and confirmation is based on agglutination or fluorescent antibody studies.

B. pseudomallei occupy an environmental niche that includes moist soils, rice paddies, and other stagnant water in tropical and subtropical regions, approximately subtended by latitude 20°N to 20°S. Evidence of subclinical and clinical diseases occurs in wild and domestic animal populations, as well as in humans living permanently or transiently in rural endemic areas, especially in southeast Asia and northeast Australia. As many as 10% to 30% of native populations have evidence of prior infection based on serologic data. Approximately 1% to 2% of healthy American military personnel who served in Southeast Asia have antibodies, and almost 9% of soldiers wounded in Vietnam have titers for *B. pseudomallei.* A significant number of the approximately 3 million U.S. soldiers who fought in the region constitute a reservoir of latent disease that, like tuberculosis, can become active even decades later, far removed from an endemic area. Refugees from Southeast Asia represent another important group of potential carriers.

Transmission is mainly by direct contact with contaminated soil or water through minor abrasions or major wounds. Ingestion and inhalation are probably less frequent modes of spread, but common source outbreaks occur in animals and humans. Animal-to-human disease is very rare, with only three cases reported from Australia. Human-to-human spread has also been exceptional, associated with breastfeeding, urinary catheter contamination, or between siblings with cystic fibrosis. In endemic regions, lack of previous exposure and debilitating circumstances, including malnutrition and uncontrolled diabetes, may increase susceptibility to infection and disease. In a survey of 524 patients with melioidosis in northeast Thailand, coinfection with HIV was detected in only 8 of 524 adults (1.5%); clinical presentation and acute outcome were similar in HIV-positive and -negative patients. Although it is not clear if solid organ transplant alters the risk for melioidosis, pleuropulmonary melioidosis with septicemia has been reported in a renal transplant patient in Australia; although she was not from an endemic region, on revisiting her travel history, it was found that the patient had travelled to the endemic tropical northern Queensland part of Australia during the rainy season.[46]

Pathogenesis and Pathophysiology

The presence of potent endotoxin and the absence of an antiphagocytic capsule have been noted. Acute infections are associated with necrotic lesions containing polymorphonuclear neutrophils (PMNs) in lung and other tissues. Chronic infections, especially in the respiratory tract, resemble tuberculosis with granuloma formation, Langhans or foreign-body giant cells, central caseating necrosis, and occasionally a PMN response in the necrotic area. Activation of latent infection after a period of months to even decades occurs. This "awakening" can be in the wake of influenza and other acute

infections, acute stress (trauma, thermal burn, surgery, etc.), and immunosuppressing illnesses or therapies, but spontaneous activation also occurs. The location of dormant microorganisms and the specific molecular events that stimulate recurrent disease are unknown but remain an area of active investigation.

An antecedent local infection in an area of broken skin can be followed by acute septicemia in nonimmune subjects. Initial pulmonary lesions occur predominantly in the better-vascularized basal segments consistent with bacteremic spread to the lungs. Eventually other areas of the lungs and other tissues are affected. Subacute and chronic disease may result from a subclinical primary focus, often localized in an apical segment, resembling tuberculosis in location and propensity for granuloma formation and cavitation. Subpleural invasion can result in empyema or sympathetic sterile effusions.

Clinical and Radiologic Features

Primary melioidosis occurs within a few days to 3 weeks of exposure, usually via a cutaneous wound in persons from (or with recent exposure to) an endemic area. The portal of entry may be present as a small necrotic skin lesion in an area of known trauma, with accompanying cellulitis or lymphangitis. Although the acute phase of melioidosis is the most common manifestation in endemic areas, it is very rarely seen in the United States. In addition to marked toxicity and high fevers, the respiratory complaints include cough, dyspnea, pleuritic pain, and purulent sputum. Bibasilar rales may be heard, but objective physical findings are often minimal in the face of severe toxicity.

Milder types of subacute and chronic pneumonia are often seen. In addition to fever, productive cough, and pleuritic pain, many patients experience marked weight loss and a clinical picture resembling tuberculosis or fungal disease. Secondary skin manifestations are rarely seen unless bacteremia ensues. Physical changes are often subtle but can include localized rales, a pleural friction rub, signs of an effusion, and manifestations of disease localized to soft tissues, lymph nodes, bones, or joints.

Radiologic findings reflect the stage of disease present. In acute fulminant infections, air space disease can be absent or miliary to larger nodular densities seen in basal segments. In subacute and chronic cases, fibronodular or cavitary apical lesions are found, similar to reactivation tuberculosis.

Diagnostic Features

Melioidosis should be seriously entertained in any febrile patient with a history of residence in a major endemic region such as Southeast Asia or northeast Australia. If sputum is available, the gram-negative bipolar-staining bacilli may be seen, and the organisms can be readily cultured and identified in the routine laboratory. Blood and urine cultures are frequently positive in acute cases. In more indolent infections, biopsy may be necessary. Molecular biology techniques such as polymerase chain reaction are being developed for diagnostic use. Serologic studies can be helpful in active and recrudescent disease, especially in patients residing in nonendemic areas. A specific IgM immunofluorescence test is often positive in recent infections and recrudescent disease. Complement fixation and indirect hemagglutination tests are available and require testing of paired sera over several weeks to confirm active disease.

Differential Diagnosis

In patients from Southeast Asia, acute fulminating infections with pneumonia may be due to traditional bacteria and viruses, but may also be caused by infection with *Y. pestis* (plague) and *F. tularensis* (tularemia) (see Section on *Francisella Tularensis*). Chronic forms of melioidosis resemble tuberculosis and fungal infections such as histoplasmosis and blastomycosis. Occupation, travel, and history of respiratory illness should help to clarify the cause.

Treatment and Prevention

Recommendations for therapy of acute septicemic melioidosis must be couched in cautious statements. During the Vietnam War, mortality greater than 50% occurred, even with use of three-drug regimens in massive doses. In subacute and chronic pneumonias and recrudescent disease cure rates approach 100%. Treatment must be prolonged and surgical intervention for drainage or removal of cavitary lesions is sometimes necessary to prevent relapse.

Imipenem/meropenem or the third-generation cephalosporin ceftazidime in high doses are considered first-line therapy. Some centers add trimethoprim/sulfamethoxazole for better intracellular activity and to potentially decrease the emergence of antimicrobial resistance with combination therapy. Once a good clinical response is seen, usually after at least 14 days, oral therapy may be initiated. Such subsequent oral eradication therapy is considered necessary to prevent recrudescence or later relapse of melioidosis. Eradication regimens are varied and include such agents as doxycycline, chloramphenicol, trimethoprim/sulfamethoxazole, and (less effective) azithromycin and ciprofloxacin. Amoxicillin–clavulanic acid may be used in children. A recent trial in 140 subjects in Thailand showed that trimethoprim/sulfamethoxazole alone is as effective as and better tolerated than cotrimoxazole plus doxycycline for the eradication treatment of melioidosis.[47] With the exception of kanamycin, other aminoglycosides are ineffective.

No prophylactic antimicrobial studies are available, nor has a vaccine been developed. People traveling, living, or working in endemic regions should be advised of this soil- and water-dwelling organism. Traumatic injuries should be avoided, and wounds contaminated with soil or stagnant water should be assiduously cleaned.

■ *COXIELLA BURNETII (Q FEVER)*

Initially described in abattoir workers in Brisbane, Australia in 1935 as Q (for query) fever, Q fever generally causes systemic symptoms, which can progress to atypical pneumonia, occasionally complicated by acute respiratory distress syndrome (ARDS). In temperate-zone countries, the prevalence of acute Q fever in pneumonia patients ranges from 0% to 2.3%: 1.2% in the United Kingdom, 0.9% in the rest of Europe, and 2.3% in the United States.[48] Among endemic regions, rates vary; in the late 1960s in Riyadh, Saudi Arabia, 8.4% of residents >5 years of age were seropositive,[49] while of those with pneumonia, in Greece, the frequency of acute Q fever was 4.7% among 3686 patients with atypical pneumonia.[50] In Israel, a study conducted in 1995 among 346 in patients with pneumonia showed that 20 (5.8%) had Q fever pneumonia,[51] and a study in the Spanish Basque region demonstrated a prevalence of 18.8% in patients with pneumonia.[52] Recent work in French Guiana showed a prevalence of 24%.[48] Although the Middle East is an endemic region, only three soldiers developed Q fever during Desert Storm, probably because most troops had very limited or no contact with herds of animals.[53]

Bacteriology, Ecology, Epidemiology, and Pathogenesis

C. burnetii has traditionally been grouped with the Rickettsiae, which also includes typhus and spotted fevers. Recent phylogenetic studies, based on 16S rRNA sequence analysis, have demonstrated that *C. burnetii* is more closely related to *Legionella*, *Francisella,* and *Rickettsiella.* The organism is now classified in the family Coxiellaceae and order Legionellales in the gamma subdivision of Proteobacteria.[54] *C. burnetii* is an acid-fast, pleomorphic, small coccoid or filamentous organism. It is an obligate intracellular pathogen. Although gram negative, it is often not detected by Gram stains. *C. burnetii* forms spore-like structures that are highly resistant to even severe environmental conditions; it can survive like this for extended periods, especially in very arid soils.

Q fever exists worldwide, except for New Zealand. From 1999 to 2004, there were 18 reported outbreaks of Q fever from 12 different

countries involving 2 to 289 people.[54] The largest outbreak ever described occurred in the Netherlands in 2009. Large outbreaks have been reported in Switzerland, Great Britain, Germany, and in southern France. In North America, Nova Scotia has been the location of a significant number of cases. There are case reports of Q fever in armed forces personnel returning from Iraq.

Transmission occurs via contact with contaminated birthing products, milk, meat, and wool, or inhalation of windblown dust from areas contaminated by placentae and other animal products. Ticks can facilitate transport to other animals. Transfer between humans has been very rarely described, primarily during autopsies or to healthcare workers.[54] Risk factors for spread among animals include relatively closely located bulk milk small ruminant farms, spread from vermin and companion animals, imported straw, and use of artificial insemination.[55] A classic outbreak was described in 12 poker players in Nova Scotia after exposure to a parturient cat, subsequently termed "poker player's pneumonia."[56]

C. burnetti has two distinct antigenic phases. Phase I and II cells are morphologically identical, although differ in certain biochemical characteristics including their lipopolysaccharide composition. Organisms isolated from infected animals or humans express phase I antigens and are very infectious; the ID50 (number of bacilli needed to infect 50% of individuals) is considered to be 1, making it among the most infectious agents known. Organisms expressing phase II antigens are less infectious and are recovered after the bacteria have been repeatedly passaged in cell cultures or eggs. Experimentally infected animals and humans first produce antibodies to phase II antigens and later produce antibodies to phase I antigens, which may be used to distinguish acute from chronic infections.

Monocytes and macrophages are the target cells for *C. burnetti* infection. Phagocytosis of *Coxiella* creates acidic phagolysosomes in which the organisms can persist and multiply. The formation of pseudopodal extensions and transient reorganization of filamentous actin are stimulated by virulent (but not avirulent) bacteria. Cell-mediated immunity and granuloma formation is important for control of primary infection. Chronic Q fever is characterized by defective cellular immunity; lymphocytes from patients with Q fever endocarditis do not proliferate in response to *C. burnetii* antigen, compared to lymphocytes from those with acute Q fever.[54] Severe inflammation is common with Q fever endocarditis, characterized by upregulated levels of TNF and IL-6 (two inflammatory cytokines), type II TNF receptors and IL-1 receptor antagonist.[54]

Clinical and Radiologic Features

The incubation period can be as long as 2 to 3 weeks, stressing the importance of recent travel and exposure history. Acute symptomatic infection develops in 40% of patients, while 60% are asymptomatic.[54] Illness may present acutely, with fever, severe headache, arthralgias, myalgias, cough, and other influenza-like symptoms.[57] Q fever can cause endocarditis, hepatitis, and pneumonia. Unlike the other rickettsial diseases, Q fever primarily affects the lungs, with pneumonia in approximately half of cases. The combination of pneumonia and hepatitis should suggest Q fever. Rashes are rare, unlike in the other rickettsial diseases. There can be variation in the predominant symptoms, with pneumonia more common in some outbreaks, and hepatitis more common in others, perhaps due to strain variation or the method of inoculation (ingestion vs. inhalation).[54]

Chest radiograph findings are nonspecific. Pleural effusion may be present, as may pericardial effusion. In the 1989 West Midlands outbreak, 10% of films were normal, and the features of 62 abnormal films were varied; there were no specific aspects to help distinguish Q fever pneumonia from other pneumonias.[58] Complete radiographic resolution frequently took up to 6 months. In another series in the north of Spain, 87% had a single lobar or segmental alveolar opacity, most commonly in the lower lobes, and chest radiographs returned to normal in 70% of patients within 2 months.[59]

Diagnosis and Differential Diagnosis

Most often normal, the leukocyte count may be elevated in 25% of cases,[57] but is less commonly elevated than with routine community-acquired pneumonia.[48] Elevations in the erythrocyte sedimentation rate, liver enzymes, and creatine phosphokinase as well as thrombocytopenia may be seen.[57] Autoantibodies sometimes develop, including antimitochondrial, antismooth muscle, and antibodies to phospholipids (i.e., anticardiolipin or lupus anticoagulant).

Sputum is infrequent and often nondiagnostic. Diagnosis of Q fever is most commonly made in patients with epidemiologic risk and confirmed by serology using an immunofluorescence assay against phase I (acute infection) and phase II (chronic infection) antigens, comparing acute and convalescent samples. Seroconversion usually occurs by 7 to 15 days after the onset of clinical symptoms, with roughly 90% of patients seropositive by 3 weeks.[57] A significant number of people are exposed and never develop symptoms. In one series, sera of 268 people living or working on 111 dairy goat farms in The Netherlands were tested for *C. burnetii* IgG and IgM antibodies using immunofluorescence assay: The seroprevalence in asymptomatic farmers, spouses, and children (12–17 years) was 73.5%, 66.7%, and 57.1%, respectively.[60] Recent work in French Guiana on development of a predictive score may help accurately identify patients with Q fever pneumonia.[48]

C. burnetii can be cultivated in embryonated eggs, laboratory animals, and *in vitro* cell culture systems; it must be cultured in biosafety level 3 laboratories due to its extreme infectivity. Culture is challenging and is not be readily available. Molecular diagnostics, amplifying bacterial DNA, are increasingly useful, especially for early diagnosis of acute Q fever; *C. burnetii* DNA becomes undetectable in serum as the serologic response develops. With hepatitis, liver biopsy may show the classic granulomas with open space surrounded by a fibrin ring, called "doughnut granulomas." In the placenta, organisms can be identified in exudates or areas of inflammation with a modified Ziehl–Neelsen, Gimenez, Stamp, Giemsa, or modified Koster stain.

Given the relatively nonspecific findings with Q fever, the differential diagnosis is broad, appropriately narrowed at times based on epidemiology. For pneumonia, other diagnoses would include atypical pathogens such as *Chlamydophila pneumoniae, Chlamydia psittaci, F. tularensis, Legionella pneumophila,* and *Mycoplasma pneumoniae.* Viral etiologies may also mimic Q fever. A case report from Turkey describes Q fever mimicking Crimean–Congo hemorrhagic fever.[61]

Treatment and Prevention

Treatment usually involves the use of doxycycline, fluoroquinolones, or rifampin.[54] Trimethoprim/sulfamethoxazole can be used in pregnant woman. In chronic Q fever, recommended treatment in adults is at least 18 months of doxycycline given with an alkalizing agent like hydroxychloroquine (added to neutralize the acid environment of the phagosome). In children, trimethoprim/sulfamethoxazole is the preferred agent.[54]

A whole-cell vaccine for Q fever (Q-Vax), developed in Australia, has effectively protected humans in occupational settings; this vaccine is not commercially available in the United States. An acellular vaccine (CMR) is available in the United States for individuals engaged in research with pregnant sheep or live *C. burnetii*; data is limited on this vaccine. Prior to vaccination, people should have a skin test for previous exposure to *C. burnetii*; those with previous exposure should not receive the vaccination because of severe local reactions. Vaccination of farm animals against Q fever is effective in curtailing spread.

■ YERSINIA ENTEROCOLITICA

Most infections caused by *Y. enterocolitica* are gastrointestinal, resulting in a self-limited gastroenteritis or appendicitis-mimicking mesenteric and terminal ileum adenitis. Septicemias and involvement of the lungs and other viscera are extremely rare, mostly in immunocompromised hosts, alcoholics, and cirrhotics.

Y. enterocolitica is a gram-negative, facultative bacillus that resembles many other enteric microbes. Identification procedures include the ability to grow, exhibit motility on diagnostic media at room temperature, and utilize a battery of biochemical and serologic tests. Most strains are nonlactose or slow-lactose fermenters, causing confusion with *Y. pestis, Salmonella, Shigella,* and several other members of the Enterobacteriaceae family. Cold enrichment techniques and highly selective media, extensively used to identify this organism in feces, are not necessary for other specimens.

Y. enterocolitica has been isolated from a variety of rodents and other wild species, and from cats, dogs, and farm animals. There is little evidence for direct transmission or for spread among people other than by the fecal–oral route. Most cases occur singly, but epidemics involving families and hundreds of people have been described. Disease is initiated by ingestion of contaminated milk or other food. Direct aspiration may be the mechanism for initiation of pulmonary disease, following an initial pharyngitis focus. Bacteremia can complicate pharyngeal disease, although the most likely mechanism entails ulceration of Peyer patches in the terminal ileum, mesenteric adenitis, and portal bacteremia. Systemic shunting to the lungs can follow, especially in cirrhotics, the group that most frequently develops septicemia. Strains virulent for animals and causing human disease have plasmid-mediated V and W envelope antigens, temperature-sensitive calcium dependency (as with *Y. pestis*), a factor that enhances cell penetration, and endotoxin. The development of immune complex manifestations such as erythema nodosum and nonsuppurative polyarthritis may contribute to pathogenicity.

In the past three decades, approximately 15 cases of pneumonia have been described in the literature.[62] Respiratory infections occur in association with an acute febrile septicemic illness or as a primary respiratory process, with cough, dyspnea, and signs of consolidation. The history is usually vague for gastrointestinal symptoms, animal exposure, or unusual food intake. Radiologic findings include nodular basilar densities consistent with septicemic spread, dependent segment infiltrates suggesting an aspiration mechanism, occasional cavitation, and fluffy widespread densities consistent with septic emboli.

The diagnosis often depends on routine blood or sputum cultures. Enteric gram-negative bacilli can be seen in sputum. Pharyngeal cultures should be done if signs of local inflammation are present. Suppurating nodes and peritoneal or joint fluids are other sources of material that may contribute to the diagnosis.

Cases of respiratory infection have responded well to a variety of antibiotics, including ampicillin or second-generation cephalosporins. Third-generation cephalosporins, chloramphenicol, aminoglycosides, fluoroquinolones, and trimethoprim/sulfamethoxazole may also be effective. Treatment should be based on antibiotic susceptibility testing. Underlying diseases influence the outcome, but when pneumonia is the major problem, prognosis is excellent. Treatment is usually continued for a total of 3 to 6 weeks.

Preventive measures include avoiding rodent or domestic animal contamination of food and water supplies. Opportunities for susceptible individuals to come in contact with this zoonotic microorganism may be increasing as well, as healthy and immunocompromised people turn to organically grown foods, natural springs, and mountain streams for improved health but with potential contamination with pathogens from animal droppings.[63]

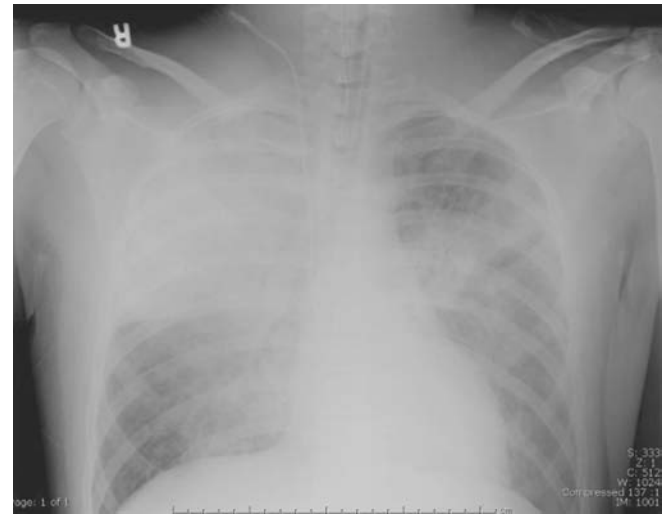

Figure 138-3 Patchy bronchopneumonia, predominantly in the right upper lobe, in a 16-year-old boy with *Neisseria meningitidis* pneumonia and bacteremia. *(Used with permission of Holly Rawizza, MD.)*

PNEUMONIAS CAUSED BY OBLIGATE HUMAN COMMENSALS

Most bacterial pneumonias caused by encapsulated obligate human commensals are easy to isolate, such as *Streptococcus pneumoniae;* among the less common causes, *Neisseria meningitidis* (the meningococcus) and *Moraxella* (formerly *Branhamella*) *catarrhalis* stand out as pathogens or opportunists that may escape routine bacteriologic identification and therefore present problems in diagnosis and therapy.

■ NEISSERIA MENINGITIDES

During the influenza viral pandemic of 1918 to 1919, *N. meningitidis* was an important respiratory pathogen (Fig. 138-3). Afterward, few references to the meningococcus appeared in the medical literature on bacterial pneumonias, as reports of meningococcal disease focused on its role in causing meningitis and septicemia. With the advent of improved bacteriologic techniques, an increasing number of cases of *N. meningitidis* pneumonia have been recognized.[49]

Bacteriology and Immunology

Neisseria are oxygen-requiring, gram-negative cocci recognized by their characteristic paired, kidney-shaped diplococci. They are fastidious, succumbing rapidly to the external environment and extremes of temperature or humidity. Although *Neisseria* can grow on blood agar, optimal conditions include enriched media, such as chocolate agar, and incubation in an atmosphere of 6% CO_2 at 35° to 37°C with 50% humidity. Isolation and identification of *N. meningitidis* in sputum are facilitated by the use of a selective medium, such as modified Thayer–Martin agar (MTM), which contains antibiotics that suppress competing respiratory microorganisms. *N. meningitidis* is distinguishable from other *Neisseria* spp. that are residents of the oral-respiratory region by sugar fermentation reactions and serologic identification (Fig. 138-4).

N. meningitidis is a typical gram-negative organism containing a potent lipopolysaccharide endotoxin in the outer membrane layer of the cell envelope. Exterior to this layer is a polysaccharide capsule, by which *N. meningitidis* can be separated into at least 13 chemically defined serogroups. Groups A, B, C, Y, and W-135 are currently the most important clinically. The less frequently observed serogroup Y meningococci accounted for 44% of isolates in one series of 58 cases of meningococcal pneumonia.

Figure 138-4 Gram stain of expectorated sputum from a patient with proven *Moraxella* pneumonia. In this black-and-white photomicrograph, the distinguishing features include the presence of morphologic kidney-shaped diplococci (gram-negative) associated with polymorphonuclear neutrophils. This appearance suggests *Neisseria* or *Moraxella* infection. Culture confirmed the identity as *Moraxella*.

Ecology, Epidemiology, and Pathogenesis

An obligate human pathogen, there are no records of nonhuman carriage or disease from *N. meningitidis*. Respiratory disease due to meningococci was recognized early in the 20th century, especially during the influenza pandemic of 1918 to 1919. In the mid-1970s, outbreaks of serogroup Y meningococcal pneumonia occurred in military installations.[64] Over the past 25 years, isolated respiratory disease, primarily due to serogroups Y and W-135, has been more frequently detected in civilian populations and nosocomially in persons in contact with an index case.[65] Nosocomial spread of *N. meningitidis* has been recognized in recent decades.[66] Nasopharyngeal carriage of various serogroups of meningococci occurs in approximately 5% to 25% of subjects. Spread is probably by aerosol droplets during close contact, since drying rapidly kills meningococci. A case of meningococcal disease in a family is often associated with an increased prevalence of meningococcal isolation from relatives with symptoms of upper respiratory infection. People ill with influenza or adenoviral respiratory infections appear to be more susceptible to bacterial pneumonias, including meningococcal pneumonia. Stimulation of excessive airway secretions, damage to surface epithelial structures, and interference with clearance of microorganisms all serve to augment the risk of bacterial pneumonia.

Initiation of infection begins when an encapsulated strain colonizes the nasopharynx of a person lacking immunity to that serogroup. Attachment to mucosal cells is facilitated by filamentous pili and outer membrane proteins such as Opa and Opc, and by the action of bacterial IgA1 protease. The capsule helps evade complement fixation and subsequent phagocytosis. Lipopolysaccharide (endotoxin) stimulates release of inflammatory mediators, including TNF-α, IL-1β, IL-6, and IL-8, and thus has a crucial role in the pathogenesis of meningococcal septic shock. Meningitis, petechial eruptions diffuse intravascular coagulation, and ARDS seldom accompany pneumonia, supporting a postulated aspiration rather than hematogenous mechanism.

Clinical and Radiologic Features

The clinical presentation of meningococcal pneumonia ordinarily is a community-acquired pneumonia that resembles pneumococcal infection. Productive cough, pleuritic pain, chills, and fever are associated with rales and consolidation. Unlike pneumococcal disease, pleural rubs and hemoptysis are unusual. The spectrum of respiratory disease includes pharyngitis, common in outbreaks, and purulent tracheobronchitis. Invasive meningococcal respiratory disease carries a mortality rate of 5% to 10%.

Radiologic features are nonspecific and include patchy bronchopneumonia and lobar air space infiltrates. Bilateral involvement occurs in 20% of cases and an effusion is noted in about 13% of cases. Occasionally, the radiologic appearance resembles diffuse pulmonary edema or an antecedent viral infection.

Diagnosis and Differential Diagnosis

Diagnosis depends on isolation of predominantly *N. meningitidis* from a carefully collected sputum specimen that has characteristic gram-negative diplococci and PMNs on the stained smear (Fig. 138-4). Attention to these criteria is essential, since pathogenic and nonpathogenic *Neisseria* and *Moraxella* spp. are part of the normal respiratory flora. Invasive procedures such as bronchoscopy are not necessary if adequate sputum samples are available, and the Gram stain appearance prompts culturing the specimen on MTM media. Alternative methods of identification include the classical capsular swelling technique (to rule out pneumococcal infection), latex bead coagglutination, and fluorescent antibody staining. Recent purification of all of the major group-specific capsular polysaccharides should lead to expansion of these rapid diagnostic methods. Blood cultures were positive in a significant number of recent cases.

Respiratory infections due to other causes, especially when there are clusters of cases, must be considered in the differential diagnosis. Viral agents such as influenza A or B or adenoviruses can cause acute respiratory infections affecting a number of people, especially under institutional or crowded circumstances. Mycoplasmal pneumonia is frequently biphasic, with upper respiratory inflammation and headache prominent early symptoms, and, occasionally, bullous tympanitis producing severe ear pain. The sputum is often purulent, with a mixture of PMNs and mononuclear cells, but no dominant microorganism is observed with Gram stain. Diagnosis is usually confirmed by a cold agglutinin titer of 1:32 or greater, a rising titer of complement-fixing antibody, or PCR of sputum. Other atypical pneumonias to consider include *Legionellae*, *Chlamydia psittaci*,[5] and *Chlamydia pneumoniae*.

In the wake of antecedent viral respiratory infections, *S. pneumonia* and *S. aureus* infections are differentiated with microscopic examination, culture of sputum, and the results of blood cultures. In hospitals, especially among immunocompromised patients or patients on respirators, a variety of gram-negative microorganisms can produce pneumonia, including *H. influenzae* and *M. catarrhalis*.

Treatment and Prevention

Low-dose penicillin is effective for most cases of susceptible *N. meningitides* pneumonia, although those complicated by cavitation

or empyema should be treated with a minimum of 6 million units daily. Cephalosporins (ceftriaxone, cefotaxime) are commonly used. Patients allergic to β-lactam antimicrobials can be given chloramphenicol, although resistance to this agent is increasing worldwide. In contrast to meningitis or meningococcemia, respiratory infections appear to respond uniformly well to treatment.

Meningococci spread via droplet aerosols, so isolation of suspected cases is essential, especially during the first 24 hours of treatment. Chemoprophylaxis is effective in epidemics of meningitis, but no data are available for respiratory disease protection. Penicillin, the drug of choice for treating active disease, does not reliably eradicate the carrier state or protect intimately exposed contacts. Rifampin is an effective prophylactic agent probably due to its transport into oral and respiratory tract secretions in high concentrations. Minocycline diffuses into upper respiratory secretions in high concentrations and is a useful alternative to rifampin. Fluoroquinolones such as ciprofloxacin are also effective. Immunoprophylaxis has been safe and effective when given systematically to large at-risk groups in military installations, schools, day care centers, or defined communities. A protein conjugate quadrivalent vaccine containing serogroups A, C, Y, and W-135 is commercially available and has largely replaced the polysaccharide vaccine. Vaccines for serogroup B are in development or available presently in other countries. There are no contemporary data for efficacy of the vaccine against respiratory infections. Use of influenza viral vaccines should eliminate some cases of secondary bacterial infections, including those caused by *N. meningitidis.*

■ *MORAXELLA (BRANHAMELLA) CATARRHALIS*

Formerly considered a nonpathogenic respiratory commensal, *M. catarrhalis* has aroused renewed interest as an opportunist and primary pathogen.[67] Resemblance to *Neisseria* on Gram stain can be confusing and encourages its inclusion in this section.

Bacteriology

Moraxella are gram-negative cocci that pair as kidney-shaped diplococci, thus indistinguishable morphologically from *Neisseria*. The organisms grow well on nonselective media such as sheep blood agar and enriched chocolate agar, especially with supplemental CO_2. Growth of *Moraxella* is variable on selective media such as MTM, in contrast to pathogenic *Neisseria,* which thrive on that medium. Other biochemical tests and their failure to utilize a variety of sugars help to distinguish them from *Neisseria.*

Epidemiology, Pathogenesis, and Pathophysiology

A member of the resident microflora of the nasopharynx and pharynx, *M. catarrhalis,* can also colonize the mucosa of the genital tract. There is no evidence for human-to-human transmission, although infections in the hospital occur and are probably related to nosocomial spread and the selective pressures from the various antimicrobials used. In normal children and adults, otitis media, sinusitis, and laryngotracheobronchitis probably result from direct invasion from colonized mucosal surfaces.

In contrast to pathogenic *Neisseria, Moraxella* lack antiphagocytic capsules and IgA proteases. Neutrophils as well as humoral immunity have been reported as significant factors in natural host defense of this member of the normal flora. The mechanism of initiation of respiratory disease appears to be primarily related to underlying obstruction and chronic inflammation. Aspiration of nasopharyngeal secretions, stimulated by an acute viral upper respiratory infection, is the most common predisposing pathophysiologic event. Contributing immunocompromising conditions – such as steroid therapy, malignancy, hypogammaglobulinemia, and neutropenia – are present in a large number of patients.[67] Paranasal sinus and ear infections occur predominantly in children, probably because of anatomically crowded drainage ducts. Rarely, *Moraxella* cause primary invasive diseases outside the respiratory tract, including meningitis, endocarditis, septic arthritis, and, in immunocompromised patients, septicemia.

Clinical and Radiologic Features

Respiratory infections from *M. catarrhalis* occur mostly in adults with chronic lung disease from smoking, industrial exposures, or bronchitis and bronchiectasis. Purulent bronchitis or bronchopneumonia can follow an intercurrent viral infection. Signs of consolidation or pleural fluid may be present, along with persistent obstructive changes. Normal adults may develop primary laryngitis and children a nonproductive cough as other manifestations of respiratory tract disease.

The underlying chronic lung disease influences the radiologic appearance. No acute changes may be observed, but increased markings can be seen superimposed on the findings of obstructive lung disease and fibrosis. Patchy consolidation is often noted. Lobar infiltrates, cavitation, and pleural effusions are distinctly unusual findings and suggest mixed infections or other complications of the underlying disease.

Diagnostic Features and Differential Diagnosis

The unique challenge in cases of *M. catarrhalis* respiratory infections is identifying this organism when gram-negative kidney-shaped diplococci associated with a PMN exudate are noted and suggest a meningococcal infection (Fig. 138-4). Diagnosis depends on careful examination of an adequate expectorated sputum sample and culturing the specimen on appropriate media, assuring that these fastidious organisms will be identified even in a crowd of other commensals. Serologic tests are not available.

Diagnostic confusion can result from the presence in sputum of *Neisseria* spp. and other potential pathogens, such as *S. pneumoniae* and *H. influenzae*; such mixed infections make it impossible to ascribe pathogenicity to a specific organism. Coccobacillary microorganisms or gram-negative bacilli that demonstrate bipolar staining (e.g., *Pasteurella, Brucella*) can be mistaken for *M. catarrhalis.*

Treatment

Once the pathogenicity of *M. catarrhalis* was recognized, it became apparent that many isolates produced β-lactamase and were resistant to penicillin and ampicillin. Therapy should be initiated with either a second- or third-generation cephalosporin such as cefuroxime, or trimethoprim/sulfamethoxazole. Alternatives include the expanded-spectrum macrolides clarithromycin or azithromycin, amoxicillin–clavulanic acid (Augmentin), or a fluoroquinolone. In vitro testing may deceptively demonstrate susceptibility to penicillin, amoxicillin–clavulanic acid, or first-generation cephalosporins if β-lactamase production is at a low level; clinical failures may occur if these drugs are used. Supportive therapy with adequate hydration, bronchodilators, and other measures directed at treating the underlying respiratory disease is essential for a favorable outcome.

CHAPTER 139

Respiratory Failure: An Overview

Michael A. Grippi

Respiratory failure is a condition in which the respiratory system fails in one or both of its gas-exchanging functions; that is, oxygenation of, and carbon dioxide elimination from, mixed venous (pulmonary arterial) blood. Hence, respiratory failure is a syndrome rather than a disease. Many diseases result in respiratory failure, as discussed elsewhere in this volume.

Respiratory failure may be acute or chronic. The clinical presentations of patients with acute and chronic respiratory failure usually are quite different. While acute respiratory failure is characterized by life-threatening derangements in arterial blood gases and acid–base status, the manifestations of chronic respiratory failure are more indolent and may be clinically inapparent.

Although the causes of respiratory failure are diverse, common underlying pathophysiological mechanisms and management strategies merit a general discussion. This chapter begins with a focus on the definition of respiratory failure and underscores distinctions between acute and chronic varieties. Hypoxemic and hypercapnic respiratory failure are described, and the pathophysiological underpinnings of each type are reviewed. The concepts of ventilatory supply and demand are considered before an overview of the many categories of disease that result in respiratory failure. Finally, an approach to clinical evaluation and management is outlined, followed by a summary of complications, comments on prognosis, and consideration of sites of care for survivors of respiratory failure who remain "chronically critically ill."

CLASSIFICATION OF RESPIRATORY FAILURE

As noted previously, respiratory failure is characterized by inadequate blood oxygenation or carbon dioxide removal. "Adequacy" is defined by tissue requirements for oxygen uptake and carbon dioxide elimination. In the absence of bedside techniques for direct measurement of these metabolic parameters, clinicians must rely on arterial blood gas values.

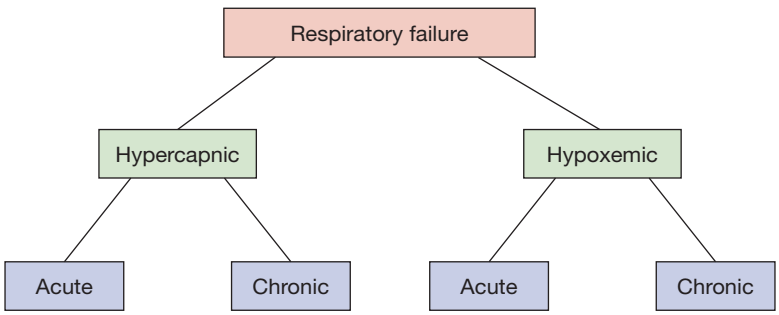

Figure 139-1 Classification of respiratory failure. Although depicted as distinct entities, hypercapnic and hypoxemic respiratory failure frequently coexist. Either may be acute or chronic.

Respiratory failure may be classified as *hypercapnic* or *hypoxemic* (Fig. 139-1). *Hypercapnic respiratory failure* is defined as an arterial P_{CO_2} (Pa_{CO_2}) greater than 45 mm Hg. *Hypoxemic respiratory failure* is defined as an arterial P_{O_2} (Pa_{O_2}) less than 55 mm Hg when the fraction of oxygen in inspired air (FI_{O_2}) is 0.60 or greater. In many cases, hypercapnic and hypoxemic respiratory failure coexist. Disorders that initially cause hypoxemia may be complicated by respiratory pump failure (see below) and hypercapnia. Conversely, diseases that produce respiratory pump failure are frequently complicated by hypoxemia due to secondary pulmonary parenchymal processes (e.g., pneumonia or atelectasis) or vascular disorders (e.g., pulmonary embolism).

Distinctions between *acute* and *chronic* respiratory failure are summarized in Table 139-1. In general, acute hypercapnic respiratory failure is defined as a Pa_{CO_2} greater than 45 mm Hg with accompanying acidemia (pH less than 7.30).[1] The physiological effect of a sudden increment in Pa_{CO_2} depends on the prevailing level of serum bicarbonate anion. In patients with chronic hypercapnic respiratory failure – for example, due to chronic obstructive pulmonary disease (COPD) – a long-standing increase in Pa_{CO_2} results in renal "compensation" and an increased serum bicarbonate concentration. A superimposed acute increase in Pa_{CO_2} has a less dramatic effect than does a comparable increase in a patient with a normal bicarbonate level.

Distinction between acute and chronic hypoxemic respiratory failure may not be readily made on the basis of arterial blood gas values.[1] The presence of markers of chronic hypoxemia (e.g., polycythemia or cor pulmonale) provides clues to a long-standing disorder, whereas abrupt changes in mental status suggest an acute event.

An important fact to bear in mind is that even though the definition of hypoxemic respiratory failure rests on measurement of Pa_{O_2}, the major threat of arterial hypoxemia is inadequate tissue oxygenation, reflected in tissue *oxygen delivery*. Tissue oxygen delivery is determined by the product of cardiac output and blood *oxygen content* (see Chapter 15, Blood-Gas Transport); the latter, in turn, depends on hemoglobin concentration and oxygen saturation. Therefore, factors that lower cardiac output or hemoglobin concentration, or inhibit dissociation of oxygen from hemoglobin at the tissue level, may promote tissue hypoxia without technically producing respiratory failure.

PATHOPHYSIOLOGY

Respiratory failure can arise from an abnormality in any of the "effector" components of the respiratory system—central nervous system, peripheral nervous system, respiratory muscles and chest wall, airways, or alveoli (Fig. 139-2). A defect in any of the first four components, which constitute the "respiratory pump," may cause coexistent hypercapnia and hypoxemia; at least initially, disorders of the alveoli are more apt to result in hypoxemia.[2,3]

HYPOXEMIC RESPIRATORY FAILURE

As described in Chapters 14–16, four pathophysiological mechanisms account for the hypoxemia seen in a wide variety of diseases: alveolar hypoventilation, ventilation–perfusion mismatch, shunt, and diffusion limitation.[2] Alveolar hypoventilation occurs in neuromuscular disorders that affect the respiratory system. In the absence of underlying pulmonary disease, the hypoxemia accompanying alveolar

TABLE 139-1 Distinctions Between Acute and Chronic Respiratory Failure

Category	Characteristic
Hypercapnic respiratory failure	Pa_{CO_2} >45 mm Hg
Acute	Develops in minutes to hours
Chronic	Develops over several days or longer
Hypoxemic respiratory failure	Pa_{O_2} <55 mm Hg when $F_{I_{O_2}} \geq 0.60$
Acute	Develops in minutes to hours
Chronic	Develops over several days or longer

hypoventilation is characterized by a normal alveolar–arterial oxygen gradient,[4] as defined by Equation 1:

$$PA_{O_2} - Pa_{O_2} = [PI_{O_2} - Pa_{CO_2}/R] - Pa_{O_2} \quad (1)$$

where

PA_{O_2} = alveolar P_{O_2}
Pa_{O_2} = arterial P_{O_2}
PI_{O_2} = inspired P_{O_2}
Pa_{CO_2} = arterial P_{CO_2}
R = respiratory exchange ratio

In contradistinction, disorders in which any of the other three mechanisms are operative are characterized by widening of the alveolar–arterial oxygen gradient, which is normally less than 20 mm Hg. With ventilation–perfusion mismatching, areas of low ventilation relative to perfusion contribute to the hypoxemia. Similarly, with shunt, either intrapulmonary or intracardiac, deoxygenated mixed venous blood bypasses ventilated alveoli, resulting in "venous admixture." Finally, diseases that increase the diffusion pathway for oxygen from the alveolar space to pulmonary capillary impair oxygen transport across the alveolar-capillary membrane.

Although changes in minute and alveolar ventilation can change Pa_{CO_2} considerably, this is not so for Pa_{O_2}. Increases in minute ventilation and, secondarily, in alveolar ventilation modestly increase Pa_{O_2}. Indeed, at a Pa_{O_2} above 55 to 60 mm Hg, the effect of increasing ventilation on oxygen content is minimal, since the oxyhemoglobin dissociation curve is flat in this range.

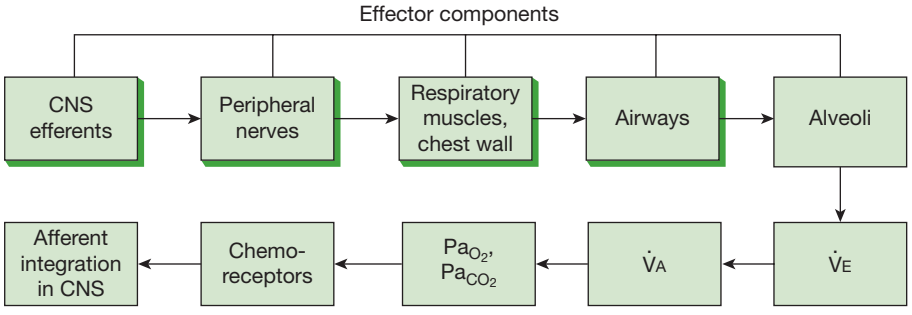

Figure 139-2 Functional components of the respiratory system and its controller. Abnormalities in any of the effector components can result in respiratory failure. The central and peripheral nervous systems, respiratory muscles and chest wall, and airways constitute the "respiratory pump" (*shaded boxes*). Hypercapnia is the hallmark of respiratory pump failure, while hypoxemia constitutes the primary disturbance in alveolar disorders producing respiratory failure. *(Reproduced with permission from Lanken PN. Pathophysiology of respiratory failure. In: Grippi MA, ed. Pulmonary Pathophysiology. Philadelphia. PA: JB Lippincott; 1995.)*

HYPERCAPNIC RESPIRATORY FAILURE

At a constant rate of CO_2 production ($\dot{V}_{CO_2}$), Pa_{CO_2} is determined by the level of alveolar ventilation.[5] The relationship between alveolar ventilation, rate of CO_2 production, and Pa_{CO_2} is described by Equation 2:

$$\dot{V}_A = K \cdot \dot{V}_{CO_2}/Pa_{CO_2} \quad (2)$$

where

$\dot{V}_A$ = minute alveolar ventilation
K = a constant
$\dot{V}_{CO_2}$ = rate of CO_2 production.

When $\dot{V}_{CO_2}$ is constant, Pa_{CO_2} is determined by $\dot{V}_A$, which, in turn, is dictated by two factors: minute ventilation ($\dot{V}_E$) and the relationship between $\dot{V}_E$ and $\dot{V}_A$. The latter is determined by the proportion of $\dot{V}_E$ that constitutes dead space ventilation—that is, the dead space to tidal volume ratio (V_D/V_T):

$$\dot{V}_E = K\,(\dot{V}_{O_2} \cdot RQ)/(Pa_{CO_2}/[1 - V_D/V_T]) \quad (3)$$

where

$\dot{V}_{O_2}$ = rate of O_2 consumption
RQ = respiratory quotient (the respiratory exchange ratio in the steady state)
V_D = dead space volume
V_T = tidal volume.

Inspection of Equation 3 indicates that disorders reducing $\dot{V}_E$ or increasing the proportion of dead space ventilation may result in hypercapnia.

VENTILATORY SUPPLY VERSUS DEMAND

A useful theoretical construct for understanding the pathophysiological basis for hypercapnic respiratory failure is the relationship between ventilatory supply and ventilatory demand (Fig. 139-3).[1]

Ventilatory supply is the maximal spontaneous ventilation that can be maintained without development of respiratory muscle fatigue; ventilatory supply is also known as *maximal sustainable ventilation* (MSV).

Ventilatory demand is the spontaneous minute ventilation, which, when maintained constant, results in a stable Pa_{CO_2} (assuming a fixed rate of CO_2 production).

Normally, ventilatory supply greatly exceeds ventilatory demand. Hence, major changes in minute ventilatory requirements (e.g., during exercise) may occur without hypercapnia. In lung disease, significant abnormalities may be present before ventilatory demand encroaches on MSV. Consequently, hypercapnia is a late finding. When ventilatory demand exceeds MSV, Pa_{CO_2} increases.

As a general rule, MSV is approximated as one-half the *maximal voluntary ventilation,* or MVV (see Chapter 33, Pulmonary Function Testing). A 70-kg adult has an MVV of about 160 L/min, an MSV of 80 L/min, and, under basal conditions, a $\dot{V}_E$ of approximately 6 to 7 liters per minute (90 mL/kg/min). Normally, therefore, there is a 10- to 15-fold difference between resting $\dot{V}_E$ and MSV. In disease states, the $\dot{V}_E$ requirement may approach a markedly reduced MSV. Further reductions in MSV result in ventilatory demand exceeding supply, and hypercapnia occurs.

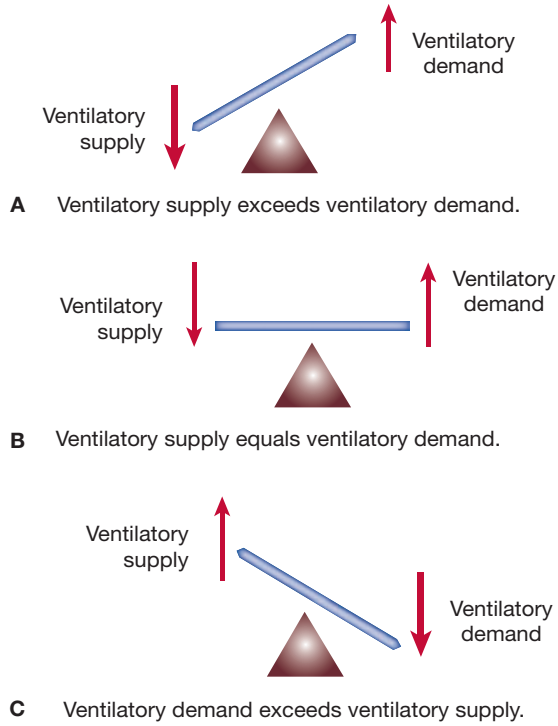

Figure 139-3 Relationship between ventilatory supply (maximal sustainable ventilation) and ventilatory demand (overall level of ventilation specified by the CNS controller). Relative size of the arrows indicates levels of supply and demand in each of the three circumstances illustrated. **A.** Normal. Ventilatory supply greatly exceeds ventilatory demand. Physiological "reserve" is maintained. **B.** Ventilatory supply is decreased and ventilatory demand increased (e.g., acute asthma attack). "Borderline" respiratory failure exists. **C.** Ventilatory demand exceeds ventilatory supply (e.g., sepsis in a patient with COPD). Respiratory muscle fatigue develops, and hypercapnic respiratory failure ensues. See text for details. *(Reproduced with permission from Lanken PN. Pathophysiology of respiratory failure. In: Grippi MA, ed. Pulmonary Pathophysiology. Philadelphia, PA: JB Lippincott; 1995.)*

FACTORS THAT REDUCE VENTILATORY SUPPLY OR INCREASE VENTILATORY DEMAND

Disruption of any component of the efferent arm of the respiratory control system may diminish ventilatory supply (Table 139-2). While a variety of diseases produce specific abnormalities along the efferent pathway (e.g., phrenic nerve and respiratory muscle disorders), some result in respiratory muscle fatigue—the biochemical, cellular, and molecular mechanisms of which remain poorly understood.

As described previously, ventilatory demand can be assessed according to Equation 3:

$$\dot{V}_E = K \cdot (\dot{V}_{O_2} \cdot RQ)/(Pa_{CO_2}/[1 - V_D/V_T])$$

Any factor that affects terms on the right-hand side of the equation may result in ventilatory demand exceeding supply. Selected clinical examples are given in Table 139-3.

CATEGORIES OF RESPIRATORY FAILURE

Although many different diseases cause respiratory failure, they may be grouped conveniently according to primary abnormalities in the individual effector components of the respiratory system.[1,2]

■ ABNORMALITIES OF THE CENTRAL NERVOUS SYSTEM

A variety of pharmacologic, structural, and metabolic disorders of the CNS are characterized by suppression of the neural drive to breathe.[3] The resultant hypoventilation and hypercapnia may be acute or chronic.

An overdose of a narcotic or other drug with sedative properties is a common cause of respiratory failure. While the most striking clinical picture occurs with an acute overdose, long-standing use of some agents (e.g., methadone) may result in chronic hypercapnia.

"Structural" CNS abnormalities producing hypercapnic respiratory failure include meningoencephalitis, localized tumors or vascular abnormalities of the medulla, and strokes affecting medullary control centers. Usually, respiratory failure is observed in the context of other neurologic findings.

A variety of metabolic derangements may produce hypercapnia through depression of respiratory control centers. Examples include severe myxedema, hepatic failure, and advanced uremia. In addition, elevation of P_{CO_2} in the CNS results in neural depression, further enhancing CO_2 retention. A common clinical setting in which

TABLE 139-2 Factors That Diminish Ventilatory Supply

Factor	Clinical Examples
Decreased respiratory muscle strength	
Muscle fatigue	Recovery from acute respiratory failure, high respiratory rates, increased inspiratory time
Disuse atrophy	Prolonged mechanical ventilation, following phrenic nerve injury
Malnutrition	Protein–calorie starvation
Electrolyte abnormalities	Low serum phosphate or potassium concentrations
Arterial blood gas abnormalities	Low pH, low Pa_{O_2}, high Pa_{CO_2}
Fatty infiltration of diaphragm	Obesity
Unfavorable alteration in diaphragm length–tension relationship	Flattened domes of diaphragm caused by hyperinflation
Increased muscle energy requirement or decreased substrate supply	
High elastic work of breathing	Low lung or chest wall compliance, high respiratory rate
High resistive work of breathing	Airway obstruction
Reduced diaphragm perfusion	Shock, anemia
Decreased motor neuron function	
Decreased phrenic nerve output	Polyneuropathy, Guillain–Barré syndrome, phrenic nerve transection or injury, poliomyelitis
Decreased neuromuscular transmission	Myasthenia gravis, use of paralyzing agents
Abnormal respiratory mechanics	
Airflow limitation	Bronchospasm, upper airway obstruction, excessive airway secretions
Loss of lung volume	After lung resection, large pleural effusion
Other restrictive defects	Pain-limited inspiration; tense abdominal distention due to ileus, peritoneal dialysis fluid, or ascites

TABLE 139-3 Factors That Increase Ventilatory Demand

Factor	Clinical Examples
Increased V_D/V_T	Acute asthma, emphysema, late phase of acute respiratory distress syndrome, pulmonary emboli
Increased $\dot{V}_{O_2}$	Fever, sepsis, trauma, shivering, increased work of breathing, massive obesity
Increased RQ	Excessive carbohydrate feeding
Decreased Pa_{CO_2}	Hypoxemia, metabolic acidosis, anxiety, sepsis, renal failure, hepatic failure

Source: Data from Lanken PN. Pathophysiology of respiratory failure. In: Grippi MA, ed. Pulmonary Pathophysiology. Philadelphia. PA: JB Lippincott; 1995.

elevation of Pa_{CO_2} is observed is chronic metabolic alkalosis (e.g., due to diuretic use), as detailed in Chapter 17 (Acid–Base Balance).

Finally, obesity hypoventilation syndrome is characterized by hypercapnia due to hypoventilation on a central basis.[6]

■ ABNORMALITIES OF THE PERIPHERAL NERVOUS SYSTEM OR CHEST WALL

A wide variety of disorders of the peripheral nerves, neuromuscular junction, and chest wall may be associated with hypercapnic and hypoxemic respiratory failure.[3,7–16] While the hallmark is an inability to maintain a level of $\dot{V}_E$ appropriate for the rate of CO_2 production, many of these disorders are complicated by impaired expiratory muscle strength, atelectasis, and aspiration. Through mechanisms outlined previously, hypoxemia develops in conjunction with the hypercapnia.

Among the most common neuromuscular causes of hypercapnic respiratory failure are Guillain–Barré syndrome,[17] myasthenia gravis,[18] polymyositis,[19] the muscular dystrophies, amyotrophic lateral sclerosis (ALS),[20] and a large number of metabolic muscle disorders. In addition, acute poliomyelitis and traumatic spinal cord injury are associated with hypercapnia. Development of respiratory muscle fatigue and atrophy[10,21–23] during prolonged weaning from mechanical ventilation may cause recurrent hypercapnia in the critical care setting.

Pharmacologic causes of hypercapnia in the intensive care unit are frequently encountered. Early reports on use of depolarizing and nondepolarizing paralyzing agents,[24] particularly in conjunction with systemic corticosteroids (e.g., in management of status asthmaticus) have been well documented; cholinergic crisis during therapy of myasthenia gravis, and administration of aminoglycosides to patients with myasthenia gravis are additional examples.

Primary disorders of the chest wall constitute another important category of neuromuscular respiratory failure. The prototype is severe kyphoscoliosis. Additional examples include flail chest (Chapter 106, Thoracic Trauma), extensive thoracoplasty, morbid obesity, and massive abdominal distention due to ascites[25] or distended loops of bowel.

In each of these disorders, a common pathophysiological sequence develops. Because of inadequate activation of inspiratory muscles or limited thoracic excursion, tidal volume falls. While an increase in respiratory rate compensates initially for the fall in $\dot{V}_E$ (and in $\dot{V}_A$), $\dot{V}_E$ eventually declines. In addition, the sigh mechanism is impaired, which, in conjunction with the low tidal volume, results in atelectasis and reduced lung compliance. Reduced lung compliance produces a further fall in tidal volume and an increase in the elastic work of breathing (Chapter 10, Pulmonary Mechanics). Hence, ventilatory supply becomes limited, while ventilatory demand increases due to a rise in V_D/V_T (as a result of atelectasis and other factors noted below). An imbalance between ventilatory supply and demand arises, and hypercapnia ensues. Furthermore, an impaired gag reflex in the setting of bulbar weakness, coupled with impaired cough due to respiratory muscle involvement, may result in aspiration pneumonia and secondary hypoxemia.

In addition to the pathophysiology described, structural abnormalities of the thoracic cage (e.g., severe kyphoscoliosis, ankylosing spondylitis, thoracoplasty, and fibrothorax)[7,26,27] are characterized by an increase in the elastic component of the work of breathing. This results in a higher $\dot{V}_{O_2}$ and a higher proportion of total O_2 consumption by the respiratory muscles (normally, less than 5% of $\dot{V}_{O_2}$).

■ ABNORMALITIES OF THE AIRWAYS

Obstructive diseases of the airways – either upper or lower – are common causes of acute and chronic hypercapnia. Examples in the upper airways include acute epiglottitis, aspirated foreign body, tracheal tumor, and narrowing of the trachea or glottis by fibrotic tissue. Disorders of the lower airways include COPD,[28] asthma, and advanced cystic fibrosis. Increasingly, the development of bronchiolitis obliterans, a manifestation of allograft rejection in patients who have undergone lung transplantation, has been recognized as an important cause of respiratory failure.[29]

The underlying mechanisms in airway abnormalities as causes of respiratory failure are multifaceted and variable. However, several common pathophysiological pathways are operative.

Airway narrowing results in a greater transthoracic pressure gradient requirement for inspiratory airflow. The resistive component of the work of breathing is increased, and the increase is associated with an elevation in $\dot{V}_{O_2}$. In addition, tidal volume falls and dead space ventilation increases. Respiratory muscle fatigue may develop; the consequences of a shallow breathing pattern ensue.

Finally, in some disorders (e.g., acute asthma or an acute exacerbation of COPD), air trapping and lung hyperinflation occur, resulting in diaphragm flattening and worsening diaphragm mechanics (see Chapter 10, Pulmonary Mechanics). The overall effect is a growing imbalance between ventilatory supply and demand.[1]

■ ABNORMALITIES OF THE ALVEOLI

Although diseases characterized by diffuse alveolar filling frequently result in hypoxemic respiratory failure, hypercapnia may complicate the picture. Common clinical examples in this category include cardiogenic and noncardiogenic pulmonary edema,[30] diffuse pneumonia, extensive pulmonary hemorrhage, aspiration of stomach contents, and near drowning.

Diffuse alveolar filling creates a large right-to-left shunt as pulmonary blood flows through nonventilated or poorly ventilated regions of the lung. In addition, coexisting interstitial edema may impair diffusion across the alveolar-capillary membrane, further impairing oxygenation of mixed venous blood.

In extensive, acute pulmonary disease characterized by alveolar filling, ventilatory demand is high because of hypoxemia and increases in V_D/V_T, the elastic work of breathing (due to reduced lung compliance), the resistive work of breathing (due to airway narrowing and increased airway reactivity), and the neural drive to breathe (mediated by pulmonary parenchymal vagal fibers). In conjunction with heightened ventilatory demand, ventilatory supply is reduced because of alveolar flooding, reduced lung elasticity, respiratory muscle fatigue, and, possibly, reduced blood supply to the diaphragm secondary to shock. Once again, the imbalance between ventilatory supply and demand results in hypercapnia.

APPROACH TO THE PATIENT

The diagnosis of acute or chronic respiratory failure begins with clinical suspicion of its presence. Confirmation of the diagnosis is based on arterial blood gas analysis. Evaluation for an underlying cause must be initiated early, frequently in the presence of concurrent treatment for acute respiratory failure. While the diagnosis of chronic respiratory failure is usually easily established with clinical findings of chronic hypoxemia (with or without findings of hypercapnia), the diagnosis of acute respiratory failure requires more careful analysis.

TABLE 139-4 Changes in Arterial Blood Gases, $P_{A_{O_2}}$–Pa_{O_2}, and Ventilation in Acute Respiratory Failure

Failed Respiratory System Component	pH	Pa_{CO_2}	Pa_{O_2}	$P_{A_{O_2}}$–Pa_{O_2}	$\dot{V}_E$	$\dot{V}_A$

[a] Pa_{O_2} may decrease when pneumonia or atelectasis occurs as a complication.
[b] ($P_{A_{O_2}}$–Pa_{O_2}) widens when pneumonia or atelectasis occurs as a complication.
[c] $\dot{V}_E$ declines when frank respiratory muscle failure occurs.
[d] Pa_{CO_2} may increase during an exacerbation.
Source: Data from Lanken PN. Pathophysiology of respiratory failure. In: Grippi MA, ed. Pulmonary Pathophysiology. Philadelphia. PA: JB Lippincott; 1995.

Signs and symptoms in acute respiratory failure reflect the underlying disease process and associated hypoxemia or acidemia due to hypercapnia. Localized pulmonary findings reflecting the acute causes of hypoxemia (e.g., pneumonia, pulmonary edema, asthma, or COPD) may be readily apparent. Alternatively, the predominant findings may be systemic (e.g., hypotension due to sepsis). The principal manifestations may even be remote from the thorax – for example, abdominal pain in acute pancreatitis or leg pain due to a long-bone fracture – each associated with acute respiratory distress syndrome (Chapter 140, Acute Respiratory Distress Syndrome: Pathogenesis and Chapter 141, Acute Respiratory Distress Syndrome: Clinical Features, Management, and Outcomes). Frequently, neurologic or cardiovascular symptoms and signs predominate. Neurologic manifestations include restlessness, anxiety, confusion, seizures, or coma. Asterixis may be seen with severe hypercapnia. Common cardiovascular findings include tachycardia and a variety of arrhythmias. Finally, there may be few or no findings other than a complaint of dyspnea, as in some patients with hypoxemia due to pulmonary embolism.

Once respiratory failure is suspected on clinical grounds, arterial blood gas analysis is performed to confirm the diagnosis, to assist in the distinction between acute and chronic forms, to assess the magnitude and metabolic impact, and to help guide management (Table 139-4).

PRINCIPLES OF MANAGEMENT

The principles of management of patients in acute respiratory failure include those that are general[2,3,6–8,20,31–36] and those that are more cause-specific.[28] Triage of the patient to the proper clinical setting, airway maintenance, correction of hypoxemia and hypercapnia, and management of the underlying cause are of paramount importance.

■ TRIAGE DECISIONS

The first step in management is to determine the appropriate setting for care—admission to a standard inpatient medical floor or to an intensive or "intermediate care" unit. Factors that constitute the basis for this decision include the acuity of the respiratory failure; the degree of hypoxemia, hypercapnia, and acidemia; the presence of comorbid conditions (e.g., cardiac disease or renal insufficiency); and the clinical direction that the patient takes over the first few minutes or hours of observation. At one end of the spectrum is the patient with fulminant hypoxemic respiratory failure, metabolic acidosis, and imminent cardiovascular collapse, who needs emergent intubation, mechanical ventilation, and admission to a critical care unit. At the other end of the spectrum is the patient with COPD and chronic, compensated hypercapnic respiratory failure, who requires observation in an intermediate care unit.

■ AIRWAY MANAGEMENT

Assurance of an adequate airway is key in the patient with acute respiratory distress. Whether emergency intubation is required depends on the clinical circumstances described previously. For patients with chronic respiratory insufficiency, the need for intubation also depends on critical arterial blood gas values and the patient's early acute course. When progressive hypoxemia or hypercapnia is observed over the first few minutes or hours of care, intubation and mechanical ventilation are warranted.

In recent years, a number of studies have indicated that, in selected patients, use of noninvasive mechanical ventilation may obviate the need for intubation.[34–39] Such patients include some with hypercapnic, as well as some with acute, hypoxemic respiratory failure (other than ARDS-related). The use of noninvasive mechanical ventilation to facilitate weaning and early extubation[40,41] is controversial. Although studies also point to the use of noninvasive mechanical ventilation for management of recurrent respiratory failure following extubation, a multicenter, randomized trial found no reduction in the need for reintubation or mortality.[42]

Contraindications to a trial of noninvasive ventilation include respiratory arrest, ill-fitting face mask, hemodynamic or cardiac instability, patient agitation, swallowing difficulty, excessive respiratory secretions, inability to protect the airway, and recent upper airway or upper gastrointestinal surgery.[34]

■ CORRECTION OF HYPOXEMIA AND HYPERCAPNIA

Once the airway is secured, the clinician must turn attention to the treatment of hypoxemia—the most life-threatening aspect of acute respiratory insufficiency. The goal is to assure adequate oxygen delivery to tissues, generally achieved with a Pa_{O_2} of about 60 mm Hg (assuming an adequate hematocrit and cardiac output). In patients who have coronary or cerebrovascular disease, a slightly higher level of arterial oxygenation may be desirable in order to provide a "buffer" for any sudden, unpredictable changes in gas exchange.

The means by which supplemental oxygen is administered is determined by the clinical circumstances. While some patients may simply require nasal prongs or a face mask to achieve an adequate Pa_{O_2}, others are best treated with controlled-flow oxygen delivered via a Venturi mask—for example, the patient with COPD and chronic hypercapnia (see Chapter 42, Course and Treatment of Chronic Obstructive Pulmonary Disease). Generally, if an acceptable level of oxygenation, as judged by arterial blood gases, cannot be attained using a face mask, or if administration of supplemental O_2 causes hypercapnia to worsen significantly (e.g., in some patients with COPD), mechanical ventilation (invasive or noninvasive) is required.

While correcting hypoxemia, the clinician must also address any coexisting hypercapnia and respiratory acidosis. Once again, the immediacy of correction depends on the magnitude of the acidosis and its attendant effects (e.g., elevation of serum potassium). A partly compensated respiratory acidosis in a patient with COPD usually constitutes a less urgent clinical circumstance than does profound respiratory acidosis in a patient with a drug overdose.

■ SEARCH FOR AN UNDERLYING CAUSE

Finally, as therapy is initiated to correct the hypoxemia, hypercapnia, and acidosis of respiratory failure, a search for the cause of the problem and its management must be undertaken. In some cases, the cause and management are straightforward (e.g., administration of a narcotic antagonist to the patient with a narcotic overdose). In others, a more protracted course may be in store (e.g., long-term ventilator management of fulminant acute respiratory distress syndrome due to sepsis).

In both brief and prolonged cases of respiratory failure, attention to details of management is important in order to minimize the risks of complications of therapy, as discussed in the following section.

MONITORING PATIENTS WITH ACUTE RESPIRATORY FAILURE

Repeated assessment of the patient with incipient or resolving respiratory failure, as well as the patient with frank hypoxemic or hypercapnic failure, is critical in formulating decisions about therapy. Monitoring methods range from routine bedside observations to use of invasive techniques (see Chapter 147, Hemodynamic and Respiratory Monitoring in Respiratory Failure).

For many patients with acute respiratory failure, simple observation of respiratory rate, tidal volume, use of accessory muscles, and presence of paradoxical breathing movements provides evidence of worsening respiratory failure and the need for intubation and mechanical ventilation. The patient with asthma or an acute exacerbation of COPD will frequently manifest rapid, shallow breathing and paradoxical thoracoabdominal breathing movements as respiratory mechanics deteriorate.[15]

Once placed on mechanical ventilation, the patient must be carefully monitored for ventilator-associated complications (see below). In addition, placement of indwelling arterial and venous catheters, patient immobilization, and use of a broad range of pharmacologic agents present additional potential threats to the acutely ill patient.

While many monitoring techniques are routine and may be universally applicable to patients in a critical care setting (e.g., pulse oximetry), others may be of particular importance in selected clinical circumstances. For example, routine assessment of static respiratory system compliance in a mechanically ventilated patient with acute respiratory distress syndrome or pulmonary fibrosis may provide an early warning of changes in lung edema, atelectasis, or barotrauma.[43] In the patient with status asthmaticus requiring mechanical ventilation, development of hypotension due to intrinsic positive end-expiratory pressure (intrinsic PEEP or "auto-PEEP"),[44] as discussed in Chapter 148, may signal the need to alter ventilator settings or implement sedation or pharmacologic paralysis.

COMPLICATIONS OF ACUTE RESPIRATORY FAILURE

The respiratory patient in a critical care unit must navigate not only the obstacles presented by the underlying pulmonary process, but also the hazards associated with use of mechanical devices and pharmacologic agents. Complications of acute respiratory failure may be broadly categorized as pulmonary, cardiovascular, gastrointestinal, renal, infectious, nutritional, and other (Table 139-5). For details in each of these areas, the reader is referred to chapters elsewhere in this volume.

■ PULMONARY

Common pulmonary complications of acute respiratory failure include ventilator-associated pneumonia ("VAP"),[45–48] ventilator-induced diaphragmatic dysfunction,[49,50,23] critical illness polyneuropathy and myopathy,[51] pulmonary emboli, pulmonary barotrauma, pulmonary fibrosis, and complications directly related to use of mechanical devices.[52]

Pulmonary emboli have been reported in up to one-fourth of patients with respiratory failure in intensive care units. The diagnosis is difficult in this setting, since patients typically have diffuse underlying lung disease, abnormal gas exchange, and many coexisting potential causes for the clinical, radiographic, and physiological consequences of pulmonary emboli.

Pulmonary barotrauma, identified as the presence of extra-alveolar air in structures that do not normally contain air, may occur in patients receiving mechanical ventilation for a variety of indications, including the acute respiratory distress syndrome.[31,53] Manifestations of barotrauma include pulmonary interstitial emphysema, pneumothorax, pneumomediastinum, pneumoperitoneum, subcutaneous emphysema, tension lung cysts, and subpleural air cysts.[54] Pulmonary fibrosis may follow acute lung injury associated with acute respiratory distress syndrome. In addition, use of high inspired concentrations of oxygen may enhance development of fibrosis in the presence of acute lung injury.

A strategy of low-stretch ventilation is currently the standard for managing patients with acute lung injury or ARDS and is aimed at minimizing the risks of ventilator-induced injury.[2,30–32,55–61] Use of such a strategy is outlined in the chapters on ARDS (Chapter 141, Acute Lung Injury and the Acute Respiratory Distress Syndrome: Clinical Features, Management, and Outcomes) and mechanical ventilation (Chapter 148, Principles of Mechanical Ventilation). More limited experience has been described using extracorporeal membrane oxygenation[62,63] and high-frequency oscillation[64] in this setting.

Common device-related complications include those due to pulmonary artery flotation catheters (see Chapter 147, Hemodynamic and Respiratory Monitoring in Respiratory Failure), endotracheal intubation, and tracheostomy (see Chapter 146, Intubation and Upper Airway Management).

New approaches to the use of intravenous sedation, namely, daily interruption of sedative infusions, has been shown to reduce duration of mechanical ventilation and length of stay in the ICU.[65–68]

■ CARDIOVASCULAR

Common cardiovascular complications in patients with acute respiratory failure include hypotension, reduced cardiac output, arrhythmias, pericarditis, and acute myocardial infarction. These complications may be related to the underlying disease process, mechanical ventilation, or use of pulmonary artery flotation catheters.

TABLE 139-5 Complications of Acute Respiratory Failure

Pulmonary
Pulmonary emboli
Pulmonary barotrauma (interstitial emphysema, pneumothorax, subcutaneous emphysema, pneumoperitoneum, tension lung cyst, subpleural air cyst)
Pulmonary fibrosis
Related to Use of Mechanical Devices
Complications of mechanical ventilation (infection, arterial desaturation, hypotension, barotrauma, others)
Complications of insertion and maintenance of pulmonary artery catheter (pneumothorax, air embolism, arrhythmias, infection, thrombosis, pulmonary artery rupture)
Complications of tracheal intubation
Related to prolonged intubation attempt (hypoxemic brain injury, cardiac arrest, seizures, others)
Related to right main bronchus intubation (hypoventilation, pneumothorax, atelectasis)
Self- or inadvertent extubation
Endotracheal tube dislodgment
Endotracheal tube cuff leak
Injury to pharynx, larynx, trachea
Complications of tracheotomy (pneumothorax, bleeding, tube dislodgment, tracheoinnominate fistula, tracheoesophageal fistula, tracheal stenosis)
Gastrointestinal
Hemorrhage (including "stress" ulceration)
Ileus
Diarrhea
Cardiovascular
Hypotension
Arrhythmias
Decreased cardiac output
Myocardial infarction
Pulmonary hypertension
Renal
Acute renal failure
Fluid retention
Infectious
Nosocomial pneumonia
Bacteremia
Sepsis
Paranasal sinusitis
Nutritional
Complications of underlying malnutrition (decreased respiratory muscle strength, immune suppression, others)
Complications of enteral feeding (pneumothorax, pleural effusion, sinusitis, aspiration, diarrhea)
Complications of parenteral feeding (pneumothorax, sepsis, hyperglycemia, hyperosmolar coma, hypophosphatemia, liver function test abnormalities)
Complications of refeeding (hypercapnia)
Other
Psychiatric (anxiety, depression, confusion, sleep dysfunction, psychosis)
Hematologic (anemia, thrombocytopenia)

GASTROINTESTINAL

A variety of gastrointestinal complications of acute respiratory failure, particularly during mechanical ventilation, have been well described.[69] The major ones include hemorrhage, gastric distention, ileus, diarrhea, and pneumoperitoneum. "Stress" ulceration is extremely common in patients with acute respiratory failure. Associated risk factors include trauma, shock due to a variety of causes, sepsis, renal failure, and liver disease.

INFECTIOUS

Nosocomial infections are a frequent complication of acute respiratory failure. Principal among these are pneumonia, sepsis, and urinary tract infections. Each typically occurs with the use of mechanical devices, including endotracheal and tracheotomy tubes, indwelling central venous and pulmonary artery catheters, and urinary bladder catheters.

The incidences of VAP and ventilator-associated tracheobronchitis (VAT)[46,70–73] in the critically ill are significant. The incidence of VAP is estimated to be as high as 5.8 cases per 1000 ventilator days and is particularly prevalent in those with ARDS. The need for prolonged mechanical ventilation is a harbinger for development of VAP. Not unexpectedly, VAP occurring in the medical intensive care unit is associated with a significantly increased length of stay and higher mortality. Guidelines have been developed for treatment of patients with VAP.[74,75]

RENAL

Acute kidney injury, previously referred to as acute renal failure, and abnormalities in electrolyte and water homeostasis are not uncommon in critically ill patients with acute respiratory failure; the former may be seen in up to 60% of patients in intensive care units. Development of acute kidney injury in a patient with acute respiratory failure carries a poor prognosis and a high mortality. The causes of acute kidney injury are numerous and include sepsis or septic shock, cardiogenic shock, hypovolemia, cardiac or extensive gastrointestinal surgery, administration of nephrotoxic drugs, hepatorenal syndrome, and urinary obstruction, among others.[76]

NUTRITIONAL

Nutritional complications of acute respiratory failure include the effects of malnutrition on respiratory performance and complications related to the administration of enteral or parenteral nutrition.[77–79] Complications of enteral nutritional support relate to initial insertion of the catheter (e.g., tracheal or pleural space penetration, pneumomediastinum, pneumothorax, and pleural effusion) and its maintenance (e.g., paranasal sinusitis and aspiration). In addition, vomiting, abdominal distention, and diarrhea are common. Complications of parenteral nutrition are mechanical (e.g., pneumothorax during catheter insertion), infectious (e.g., catheter-related sepsis), or metabolic (e.g., metabolic acidosis, hyperglycemia and hyperosmolar coma, and hypophosphatemia). Hypercapnia, induced by enteral as well as parenteral nutrition, can complicate management of patients who have limited ventilatory reserve.

PROGNOSIS

Interpretation of studies addressing the prognosis of patients with acute respiratory failure is subject to a number of constraints, including marked clinical variability in the patients studied, predominance of studies from intensive care units in large university teaching hospitals, and variability in treatment methods employed over the time span of studies performed. In addition, many studies report only hospital mortality, not long-term survival or quality of life. Finally, findings from large-population studies are difficult to extrapolate to prediction of outcome in a single patient. Nonetheless, several generalizations can be made regarding the prognosis of patients hospitalized with acute respiratory failure.

MORBIDITY AND MORTALITY IN ACUTE HYPOXEMIC RESPIRATORY FAILURE

As expected, mortality in hypoxemic respiratory failure depends on the underlying cause. A number of studies have addressed outcome in patients with ARDS.

Mortality in ARDS appears to have improved in recent years, but it remains high in the elderly; for those 85 years of age or older, mortality is 60%.[80] Patients who develop sepsis after trauma have a lower mortality than do patients with sepsis that complicates medical disorders. Notably, patients with pre-existing lung disease, higher $F_{I_{O_2}}$ or PEEP requirements, or a lower Pa_{O_2} may not necessarily have a poorer chance of survival.

Although earlier studies indicated that many patients who survived an episode of ARDS manifested some impairment of pulmonary function, including obstructive and restrictive defects and reduction in diffusing capacity, one or more years after recovery,[81] more recent data show good preservation of lung function 5 years following survival from ARDS. In fact lung function is usually normal or near normal, especially in young patients.[82]

Despite recovery of pulmonary function, many survivors of ARDS have persistent functional disabilities after discharge, largely related to muscle wasting and weakness.[82] Many survivors of ARDS have neurocognitive findings at hospital discharge, and in a significant number, the deficits persist long term.[82–86]

MORBIDITY AND MORTALITY IN ACUTE HYPERCAPNIC RESPIRATORY FAILURE

In general, several parameters presage a higher mortality in patients admitted with hypercapnic respiratory failure: (1) the patient's "physiological reserve," as determined by concurrent cardiopulmonary, renal, hepatic, or neurologic disease and the patient's age; (2) the underlying cause of the acute deterioration; (3) the severity of the respiratory failure, as defined by arterial pH and P_{CO_2}; and (4) development of complications after onset of acute respiratory failure—for example, sepsis, pneumonia, renal failure, or gastrointestinal bleeding.

For patients hospitalized with an acute exacerbation of COPD, overall mortality is 8% to 12%, but it may be as high as 28% for those with significant comorbidities;[87,88] mortality for this group at 1 year is 43%.[88] For patients with an acute exacerbation of COPD who require mechanical ventilation, in-hospital mortality is high; 1-year mortality approaches 25%, and 5-year mortality 70%.[28,82–86]

POST-ACUTE CARE OPTIONS FOR SURVIVORS WITH CHRONIC CRITICAL ILLNESS

With increasing numbers of patients surviving acute, catastrophic illness or complications of advanced surgical procedures, long-term ventilator dependency and "chronic critical illness" have become challenging clinical issues. This group of patients requires complex medical management and generates considerable debate over medical ethics and healthcare costs. One relatively recent development related to management of chronically critically ill patients is the growth of long-term acute care hospitals—LTACHs (see Chapter 152, Organization of Intensive Care Units and Long-term Acute Care Hospitals).

LTACHs are either free-standing facilities or are based on the concept of a "hospital within a hospital." They focus on management of a wide variety of medically complex patients and typically include a significant cohort of those who are ventilator-dependent. Medicare provides a DRG payment to the LTACH that is separate from that to the acute care facility from which the patient is transferred. Fairly precise rules constitute admission and discharge criteria and, thereby, determine the average length of stay at the LTACH (25 days or greater).[90]

Data on long-term survival and functional status for ventilator-dependent patients discharged from LTACHs are striking. For those who are admitted and subsequently discharged with ventilator dependency (i.e., patients who are not successfully liberated), mean survival post-discharge is 100 days.[91] Furthermore, overall 1-year survival is 56%, with only 9% of patients reporting independent functioning 1 year after discharge.[92]

CHAPTER 140

Acute Respiratory Distress Syndrome: Pathogenesis

Asha N. Chesnutt
Michael A. Matthay

This chapter focuses on the pathogenesis of acute lung injury (ALI) and the acute respiratory distress syndrome (ARDS). Chapter 141 discusses clinical features and management of these disorders.

A 1994 consensus conference defined the spectrum of ALI/ARDS as follows: (1) ALI, defined as arterial hypoxemia with a Pa_{O_2}/FI_{O_2} <300, and ARDS, defined as a Pa_{O_2}/FI_{O_2} <200, accompanied by (2) bilateral pulmonary infiltrates, and (3) absence of left atrial hypertension.[1] A more recent report, based on the so-called, "Berlin definition," recommends identification of three categories of ARDS, based upon the degree of hypoxemia alone: (1) mild ARDS (200 <Pa_{O_2}/FI_{O_2} ≤300 mm Hg); (2) moderate ARDS (100 <Pa_{O_2}/FI_{O_2} ≤200 mm Hg); or (3) severe ARDS (Pa_{O_2}/FI_{O_2} ≤100 mm Hg).[2] For the purposes of this chapter, both ALI and ARDS will be referred to as ARDS.

PATHOPHYSIOLOGY OF PULMONARY EDEMA IN ACUTE RESPIRATORY DISTRESS SYNDROME

Pulmonary edema occurs when fluid is filtered into the lungs faster than it can be removed. Accumulation of fluid may have major consequences on lung function because efficient gas exchange cannot occur in fluid-filled alveoli. Lung structure relevant to edema formation and the forces governing fluid and protein movement in the lungs have been the subject of classic and more recent reviews.[3]

VASCULAR FLUID AND PROTEIN EXCHANGE

The essential factors that govern fluid exchange in the lungs are expressed in the Starling equation for the microvascular barrier:

$$Jv = LpS[(Pc - Pi) - \sigma d(\pi c - \pi i)]$$

where

- Jv = the net fluid-filtration rate (volume flow) across the microvascular barrier
- Lp = the hydraulic conductivity (permeability) of the microvascular barrier to fluid filtration (a measure of how easy it is for water to cross the barrier)
- S = the surface area of the barrier
- Pc = the pulmonary capillary (microvascular) hydrostatic pressure
- Pi = the interstitial (perimicrovascular) hydrostatic pressure
- πc = the capillary (microvascular) plasma colloid osmotic (or oncotic) pressure
- πi = the interstitial (perimicrovascular) fluid osmotic pressure
- σd = the average osmotic reflection coefficient of the barrier (a measure of the effectiveness of the barrier in hindering the passage of solutes from one side of the barrier to the other)

The Starling equation predicts the development of two different kinds of pulmonary edema. *Increased pressure pulmonary edema* occurs when the balance of the driving forces increases, forcing fluid across the barrier at a rate that can no longer be accommodated by lymphatic drainage. *Increased permeability pulmonary edema* occurs in the presence of ARDS that damages the normal barriers to fluid filtration and allows increased flux of liquid and protein into the extravascular compartments of the lungs. Congestion, atelectasis, and pulmonary edema were features of the original description of the syndrome.[4]

Thus, pulmonary edema results from increases in either hydrostatic driving pressures (increased pressure edema) or barrier conductance (increased permeability edema), or both. What distinguishes the two types is barrier permeability, which is normal in increased pressure edema, but abnormal in increased permeability edema. Fluid flow into the lungs is driven across the barrier in both types of edema by the balance of pressures. ARDS results primarily from an increase in lung vascular permeability, although some cases may be made worse by the presence of elevated lung vascular hydrostatic pressures.

INCREASED PERMEABILITY PULMONARY EDEMA

Increased permeability pulmonary edema is caused by an increase in liquid and protein conductance across the barriers in the lungs. The essential feature is that the integrity of the barrier to fluid and protein flow into the lung interstitium and alveoli is altered. Increased permeability edema is sometimes called *noncardiogenic pulmonary edema*, and the resulting clinical syndromes in humans are commonly lumped together as *ALI* or *ARDS*.

Accumulation of fluid and protein increases when the lung endothelial and epithelial barriers are injured. If the rate of fluid accumulation exceeds the rate at which it can be removed, increased permeability edema occurs. Large animal models employing measurements of hemodynamics and lung lymph flow demonstrate that clinically relevant causes of ARDS, including live bacteria, endotoxin, and microemboli, induce an increase in lung vascular permeability that causes protein-rich lung edema.[5–7] Because the barriers limiting fluid and protein flow into the lungs do not function normally when the lungs are injured, the lungs are not protected against edema by the usual safety factors. Although increases in fluid and protein filtration across the lung endothelium can be removed by lymphatics and drained away from the alveolar walls as in increased pressure edema, much more fluid and protein are filtered at any given sum of driving pressures, since the barriers to flow are much less restrictive than normal.

Edema formation in injured lungs is sensitive to hydrostatic driving pressures. Driving pressures are often increased when the lungs are injured because of the vasoconstrictive effects of inflammatory mediators, such as thromboxanes. Thromboxanes may shift the main site of vascular resistance to postcapillary venules, thus increasing hydrostatic pressure at the microvascular fluid exchange sites, or may exert cardiac effects. For example, elevated left atrial pressure, pulmonary venoconstriction, or an increase in cardiac output in sepsis may increase hydrostatic pressure at the microvascular fluid exchange sites. Although a primary event in ARDS is an increase in lung vascular permeability, the magnitude of lung edema formation in ARDS may be substantially increased when lung vascular pressures and volume are elevated, consistent with the effects of elevated hydrostatic pressure on transvascular flux of fluid and protein.

Because the lung endothelial and epithelial barriers are injured in ARDS, the protective effects of protein osmotic pressure differences across them are lost; driving pressure is unopposed by protein osmotic pressure, and even normal hydrostatic pressure results in significant fluid and protein extravasation into the interstitial and alveolar spaces. The ability of the lymphatics to pump the excess filtrate away is increased when the lungs are injured. If the alveolar epithelial barrier is damaged, edema may accumulate readily in alveoli, since most of the resistance to fluid and protein flow into the alveoli is in the epithelial barrier.

To summarize, the majority of patients with ARDS have normal or low hydrostatic pressures and increased alveolar-capillary permeability. However, up to 30% of patients with ARDS may have an elevated left atrial pressure.[8] Lung fluid balance is a dynamic concept that incorporates both formation and removal of edema fluid in the interstitium and airspaces.

LUNG PHYSIOLOGY

The effects of increased permeability edema on lung mechanics and gas exchange depend, in part, on the magnitude of edema accumulation. As with increased pressure edema, the major effects on pulmonary mechanics occur with alveolar flooding.

About 20% to 30% of the extravascular water of the lungs is in the extravascular interstitial tissue. This volume can more than double before alveolar flooding occurs. In experimental lung injury, functional residual capacity (FRC) is decreased as a consequence of alveolar flooding; the loss of units that can be ventilated accounts for most of the decrease in static lung compliance.[9] Computed tomography has provided new insights into structure–function relationships in human ARDS. In the early stage of lung injury, when alveolar edema predominates, the lungs are characterized by a more homogeneous alteration of vascular permeability, and edema may accumulate evenly in all lung regions, with a nongravitational distribution. Later in the exudative phase of ARDS, the consolidation is more gravity-dependent. In the organizing phase, lung reticulation appears.

Measurements of pulmonary mechanics in mechanically ventilated patients with ARDS show a decrease in static lung compliance as a consequence of loss of ventilated lung units. In addition, airflow resistance is increased as a result of decreased lung volume.[10] Bronchospasm may add to the increase in airflow resistance and may be partially reversed in some patients by administration of inhaled bronchodilators. Chest wall compliance is reduced, probably because of alterations in the intrinsic mechanical properties of the chest wall by abdominal distention, chest wall edema, and pleural effusion. Respiratory mechanics and responses to positive end-expiratory pressure (PEEP) during mechanical ventilation in patients with ARDS originating from pulmonary disease (e.g., pneumonia and associated lung consolidation) and that arising from extrapulmonary disease may differ.[11]

The injured lung in ARDS may release biologically active substances that can interfere with the normal state of low surface tension in the alveoli. In addition, activated neutrophils may reduce surfactant function in vitro and degrade major surfactant apoproteins through a combination of proteolysis and oxidant radical–mediated mechanisms. Human lung surfactant obtained from bronchoalveolar lavage (BAL) fluid in patients at risk for ARDS and from those with established ARDS are abnormal in chemical composition and functional activity.[12] Abnormalities may also be caused by interactions between surfactant and edema proteins, since plasma proteins interfere with surfactant function.

Gas exchange is severely compromised in increased permeability edema, because of both intrapulmonary shunting of blood and ventilation–perfusion inequalities. Clinical evidence indicates that patients with early ARDS have a marked increase in pulmonary dead space fraction.[13] This finding indicates that many ventilated lung units are not well perfused, although intrapulmonary shunting may also contribute to the elevated dead space. Minute ventilation is typically twice normal (approximately 12 L/min) at the onset of ARDS.

PATHOLOGIC FINDINGS

Based on several studies that included a preponderance of postmortem pathology, the light and electron microscopic appearances of human and animal lung tissue in ARDS have been described.[14] The earliest changes are marked by widespread alveolar and interstitial edema, inflammation, and hemorrhage. Hyaline membranes, composed of precipitated plasma proteins, fibrin, and necrotic debris, are frequently found and constitute the footprint of a pathologic finding termed diffuse alveolar damage (DAD), which pathologists use to define ARDS microscopically (Fig. 140-1).[15]

The alveolar epithelium may be more extensively damaged than is the vascular endothelium. Alveoli that demonstrate widespread destruction of type I alveolar epithelial cells may appear adjacent to normal alveoli. The injured alveolar epithelium is swollen, disorganized, and, frequently, detached from basement membranes. The alveolar surface may be covered by hyaline membranes. Type I cells are more severely damaged than type II cells. The thin cytoplasmic extensions of cells far from the nucleus, which cover the thin side of the alveolar-capillary barrier, may be most severely affected. The interstitium is widened by edema (especially in peribronchovascular cuffs) and may be filled with leukocytes, platelets, red blood cells, fibrin, and debris (especially near the alveolar walls). The microvascular endothelium may show cytoplasmic swelling or vacuoles and greater numbers of intraluminal leukocytes.

After about 5 to 10 days, the exudative phase of ARDS is followed by a proliferative phase. The relative contributions of the original insult, repair processes, and effects of therapies on this and subsequent phases are not well known. Some abnormalities occurring after the initial exudative phase are related to effects of traditional modes of mechanical ventilation that used tidal volumes between 12 and 15 mL/kg predicted body weight.

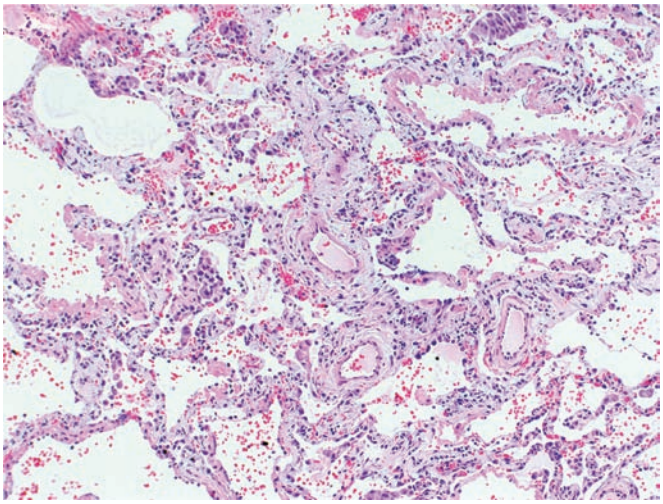
Reabsorption of some of the edema fluid characterizes the proliferative phase. Fibrin may be prominent in alveoli and interstitium, and infiltration with inflammatory cells and fibroblasts, which may have been activated very early in the course of lung injury, may be seen. The alveolar epithelium is often cuboidal and made up largely of proliferating type II cells. The air–blood barrier may be thickened by interstitial and epithelial enlargement. The pulmonary vascular bed may be partially or completely disrupted, and structural alterations may reduce its surface area.

In a study addressing the clinicopathologic correlation of the new Berlin definition of ARDS severity with historical autopsy data, a greater proportion of patients with severe ARDS demonstrated histopathologic findings of DAD compared with those with mild or moderate disease.[16]

EXPERIMENTAL STUDIES

The most common clinical disorders associated with the development of ARDS are pneumonia, sepsis, gastric aspiration, and major trauma. Other, less common causes include transfusion-associated lung injury, drug overdose, severe acute pancreatitis, and near drowning. The initiating insult to the lungs occurs either via the airways or the bloodstream.

The exact mechanisms by which the lungs are injured have been studied in humans, animals, and cellular systems. Human studies have provided descriptive data regarding the events that occur in the airspaces before and after the onset of lung injury. Studies using BAL or collection of pulmonary edema fluid in patients following the onset of ARDS have demonstrated a major acute inflammatory response, which begins prior to clinical



A

recognition of ARDS.[17] The response peaks during the first 1 to 3 days of clinically defined ARDS and resolves slowly over 7 to 14 days in patients who remain intubated. These studies have shown the complexity of the evolving inflammatory responses, characterized by accumulation of acute response cytokines and their naturally occurring inhibitors, oxidants, proteinases and antiproteinases, lipid mediators, growth factors, and the collagen precursors involved in the repair process.

Hypotheses regarding the mechanisms of lung injury have been tested in animal models and in vitro studies, and several reviews have summarized the findings.[3,7] The existing animal models do not completely reproduce all of the aspects of ARDS in humans, in part because human ARDS evolves over a longer period of time than can be studied in the laboratory. In addition, the lungs of humans are exposed not only to the initial injurious insult, but also to the therapies that are used to treat ARDS, such as mechanical ventilation, fluid resuscitation, and antibiotics. Experiments using isolated cells have been helpful in testing specific concepts, but the complexity and redundancy of intact biologic systems is not reproduced in simplified experimental systems. By design, most experimental work limits study to one causative agent, thereby reducing actual clinical complexity to the simplicity of a single experimental pathway. Increased permeability edema in humans is likely to be caused by interactions among a number of different pathways acting in parallel or series, and modulated by process of care variables such as mechanical ventilation, fluid management, vasopressor use, and several comorbidities, including diabetes mellitus, alcohol and cigarette exposure, and renal and liver disease.[7]

Studies in isolated organs and small animals in which hemodynamic variables are not measured can be difficult to evaluate. Indices of lung injury, usually measured by the appearance of markers in lungs, lavage fluid, or perfusate, are not determined solely by the barrier function of the microvasculature. Indeed, when vascular endothelium is injured, fluid and protein movement from the vascular space into the lungs is sensitive to hydrostatic driving pressures and filtration surface area. Hence, the effects of experimental interventions may be caused by changes in these parameters and not by changes in microvascular barrier function.

The effects of microvascular driving pressures and surface area can be difficult to evaluate, even in large, instrumented animals. In

sheep and goats, interpretation of lung lymph fluid and protein flow changes are further complicated by contributions of extrapulmonary lymphatics, physical forces acting on lymphatics, and possible intranodal modification of lymph. Data from experimental animal models suggest that at least two broad categories of mechanisms of ARDS are operative: (1) those that are *indirect* (i.e., require the participation of intermediary mechanisms, e.g., host defenses); and (2) those that are *direct* (i.e., do not require intermediary mechanisms; injury probably occurs as a result of contact between an offending substance and lung tissue). These categories overlap, since once the lungs are injured, inflammatory responses occur, which may compound the primary mechanism of injury.

MECHANISMS OF ACUTE RESPIRATORY DISTRESS SYNDROME

The following themes regarding the mechanisms of ARDS are discussed below: infection, inflammation, and direct toxicity. Although discussed separately, they are all interrelated.

ROLE OF INFECTION

ARDS develops in 20% to 45% of patients with severe sepsis. Increased microvascular permeability to albumin has been shown to accompany human sepsis, and infection and the sepsis syndrome are major causes of ARDS in humans. Patients who develop shock in response to known or suspected infection have a particularly high incidence of ARDS, and the mortality of patients with ARDS associated with infection (i.e., sepsis syndrome) is increased. ARDS also appears to predispose the lungs to infection, and delayed infection is an important cause of morbidity in patients who survive the initial lung insult.

The mechanisms by which infection and sepsis syndrome injure the lungs are only partially understood. The lung injury is likely related to factors other than direct damage by bacteria or other microorganisms, since the prognosis appears unrelated to documented bacteremia or pneumonia. In experimental animals, intravenous infusions of live *Pseudomonas aeruginosa*, or endotoxins from *Escherichia coli*, or surgically induced peritonitis result in increased permeability pulmonary edema.[18] ARDS caused by endotoxin in sheep is thought to be an inflammatory response mediated, at least in part, by neutrophils and tumor necrosis factor (TNF). Endotoxin may also affect the clotting system and metabolic functions of the lungs, as well as predispose the lungs to the development of pulmonary infections by increasing adherence of bacteria to injured endothelium. Exoproducts of bacteria, such as elastase and *Pseudomonas* exoenzyme U, also have been shown to injure the lungs.[7]

Bacterial products may also play a role in pathogenesis of ARDS by sensitizing the lungs to the effects of mechanical stretch. Gram-negative lipopolysaccharide causes an acute inflammatory response in the lungs of humans. Bacterial endotoxin enhances the responses of human alveolar macrophages to positive pressure ventilation; pretreatment of rats with intravenous endotoxin enhances cytokine production in the lungs during mechanical ventilation ex vivo. Furthermore, mechanical ventilation using moderate or large tidal volumes increases the sensitivity of lung macrophages to endotoxin in vitro and the expression of the endotoxin recognition molecule, CD14, on lung cells in vivo. Endotoxin recognition pathways are increased in the lungs of patients with ARDS, and the biologic effects of endotoxin are amplified in the lungs of patients with lung injury. The synergism between bacterial products and mechanical stretch suggests that interrupting these pathways might limit some forms of ARDS in humans.[19]

Increased permeability edema is associated with impaired antibacterial defenses. In animal models, bacterial infections worsen ARDS. The cause of impaired bacterial defenses in ARDS is not known. Genetic polymorphisms that predispose individuals to the injurious effects of specific bacteria or viruses may influence the development of ARDS. Several polymorphisms are associated with more severe pneumococcal, Legionella, and viral lung infections.[20] The genetic factors that regulate the virulence of infecting pathogens also require more research to relate the severity of clinical lung injury to specific microbiologic variables that contribute to severe pneumonia and ARDS.[21]

ROLE OF INFLAMMATION

Substantial evidence implicates host defenses and inflammatory responses in the underlying mechanism of ARDS. The balance between protective and injurious innate and adaptive immune responses and hemostatic pathways may determine whether alveolar injury can be repaired and resolved. For example, in lung infection, acute inflammatory responses to pathogens and their toxins cause ARDS through leukocyte protease release, generation of reactive oxygen species, synthesis of chemokines and cytokines, Toll-like receptor engagement, and actions of lipid mediators. However, these same inflammatory mechanisms, when controlled, rather than excessive, are requisite in pathogen containment and clearance.[22–24]

Normally, the pulmonary circulation contains a large pool of marginated neutrophils that change shape in order to squeeze through the lung capillaries. When neutrophils are activated, they stiffen and become less distensible. These neutrophils are retained for longer periods of time in the pulmonary microcirculation. Endothelial activation leads to increased expression of leukocyte adhesion molecules, providing a second mechanism to slow the transit of neutrophils. Trapped neutrophils respond to chemotactic gradients generated by chemokines produced by alveolar macrophages and mesenchymal cells and migrate into the airspaces. Activated neutrophils generate and release toxic substances (e.g., oxygen metabolites and granular constituents, such as proteases, and cationic lysosomal enzymes) that disrupt the function of the microvascular and epithelial barriers. Normally, these barriers limit liquid and protein flow out of the vascular space and into the alveolar spaces, mitigating the development of permeability edema.[19]

Inflammatory responses also have the potential to induce lung cell injury by activating cell death pathways, leading to apoptosis. Bacterial products, such as *Pseudomonas* Exoenzyme U and mechanical stretch, may lead to direct cellular necrosis. Apoptosis is mediated by a family of death receptors, including TNF and Fas receptors. The Fas ligand (FasL) is a 45-kD peptide that is shed from the cell surface by the action of metalloproteinases.[25] Biologically active soluble FasL (sFasL) accumulates in the lungs of patients with ARDS, inducing apoptotic death of human lung epithelial cells in vitro. Human sFasL induces epithelial cell death in the lungs of rabbits; a monoclonal antibody that activates membrane Fas causes alveolar wall apoptosis and fibrosis in the lungs of mice.[25]

Apoptosis and inflammation pathways intersect, as stimulation of membrane Fas induces cytokine production in human macrophages and inflammation in the lungs of rabbits and mice. In addition, lung injury may be able to trigger apoptosis pathways in distant organs, such as the kidney, perhaps by increasing the concentrations of circulating sFasL. Thus, inflammatory responses may trigger cell death pathways, and cell death pathways triggered by sFasL may induce inflammation in the lung alveolar environment. Recent human studies implicate apoptosis as an important mechanism in human lung injury.[26]

ROLE OF DIRECT TOXICITY

Inflammation is not required for all forms of ARDS. ARDS may develop in neutropenic patients. A clinical trial using granulocyte

colony–stimulating factor to increase the number and activation state of circulating neutrophils in patients with severe pneumonia did not reveal an increased incidence of ARDS.[27] Lung injuries that do not require the participation of neutrophils have been described in animal models.

Direct lung injury is also thought to occur in humans. Putative agents that directly injure the lungs include mechanical forces during mechanical ventilation, toxic and corrosive chemicals and gases (e.g., hydrochloric acid, chlorine gas, phosgene), and aspiration of fresh or salt water (near-drowning). Many of these injuries develop rapidly, supporting the idea that injury is caused directly by contact with the respiratory epithelium in the airways or alveolar walls.

Inflammatory pathways are likely to be rapidly activated following many types of direct lung injury, as probably occurs following aspiration of gastric secretions – one of the most common clinical causes of ARDS. Lung injury occurs rapidly, especially to the epithelium. The injury is probably related, in part, to the low pH of the aspirated stomach contents. Aspirated acid is almost immediately neutralized. However, within hours, proinflammatory mediators are released, the injured lung is infiltrated with neutrophils, fibrin accumulates in the alveolar spaces, and further structural damage is seen on histologic examination. Thus, even direct toxic injuries damage the lung in part through activation of inflammatory pathways.

BIOLOGIC MARKERS

Considerable interest exists in finding a simple test of blood, urine, or BAL fluid that would identify patients at risk for, or in the earliest stages of, ARDS, or that might predict clinical outcome.

Although products of complement activation have been proposed as markers, their serum levels correlate poorly with lung injury. Measurement of circulating endotoxin is not appropriately sensitive or specific for the presence or risk of developing lung injury. The same is true for measurements of release or activity of angiotensin-converting enzyme.[28] Von Willebrand factor (VWF) antigen may be useful as a plasma marker of impending ARDS in patients with nonpulmonary sepsis.[29] VWF levels are elevated in the edema fluid and plasma of patients with ARDS and correlate with poor clinical outcomes.[30] Also, new work indicates that elevated levels of plasma angiopoietin-2 predict the development of ALI in patients with sepsis identified in the emergency department.[31] While increases in other biochemical and inflammatory markers, including surfactant protein D and interleukin-6, correlate somewhat with lung injury and mortality, no simple biologic marker currently serves in the same diagnostic capacity, as do cardiac enzymes in evaluation of suspected acute myocardial infarction.[32]

Other mediators of inflammation in ARDS have been studied. For example, increased levels of TNF are detected in blood and BAL fluid in lung injury, but an association between TNF levels and the development of ARDS has not been found. Furthermore, elevated TNF levels are found in patients with severe congestive heart failure. Lipoxygenase products of arachidonic acid metabolism have been detected in pulmonary edema fluid, BAL fluid, plasma, and urine, and elastase has been detected in BAL fluid in the setting of lung injury.

ARDS follows a wide variety of insults of varying severity. In a study of injured patients with ARDS, investigators found increased levels of IL-6 and thrombomodulin in those who had fewer ventilator-free days.[33] However, since ARDS is such a heterogeneous disorder, with so many possible mechanisms, it is unlikely that any single marker that unequivocally identifies the risk or the presence of ARDS will be found. An investigative focus on particular subgroups of patients with common causes of lung injury, coupled with study of much larger groups of more precisely diagnosed patients, may be a better pathway for future research.

Figure 140-2 depicts multiple pathways involved in the pathogenesis of ARDS in the context of normal and injured alveoli. The depictions place emphasis on potential pathways for injury across the vascular endothelium and alveolar epithelium.

VENTILATOR-INDUCED LUNG INJURY

The most important development of the last 10 years in our understanding of the pathogenesis and treatment of ARDS is recognition that the long-standing practice of mechanically ventilating affected patients using high tidal volumes and airway pressures worsens the injury. Animal studies first suggested the potential contributory role of high tidal volumes and elevated airway pressures in the pathogenesis of lung injury; subsequently, clinical trials confirmed the findings.[3]

ANIMAL STUDIES

Experimental studies have shown that ventilation using high tidal volumes may increase vascular filtration pressures; produce stress fractures of microvascular endothelium, alveolar epithelium, and basement membranes; and cause lung rupture (so-called ventilation-induced lung injury).[34] The injury appears to be due to increased lung excursions at high volumes (volutrauma), rather than the high-airway pressure, per se, since it can be prevented by limiting thoracic motion (e.g., by placing the chest in a cast).

The concept of volutrauma was first established in 1974 when investigators found that modestly elevated tidal volumes, especially in the absence of PEEP, caused lung edema in rats.[35] Several years later, additional animal studies further demonstrated the potential injurious role of high tidal volumes and elevated airway pressures, an effect termed *ventilator-induced lung injury* (VILI).[36] Subsequent experiments demonstrated that VILI could also induce release of several proinflammatory cytokines, injuring the lung and other organs – a process referred to as "biotrauma."[37] These animal studies stimulated clinical investigation that revolutionized the care of patients with ARDS.[36]

CLINICAL STUDIES

The compelling evidence from animal experiments and small clinical trials prompted clinical studies aimed at testing the potential benefit of lower tidal volumes and reduced airway pressures during mechanical ventilation in management of ARDS. In a large, multicenter, National Heart Lung and Blood–sponsored trial of 861 patients, mortality was reduced from 40% to 31% using a tidal volume of 6 mL/kg/ideal body weight and a limited plateau airway pressure of less than 30 cmH_2O.[38] In this trial, use of small tidal volumes was associated with a lower incidence of nonpulmonary organ failure. The protocol for carrying out the lung protective ventilatory strategy is described in detail in Table 140-1. The results of the trial transformed the management of patients with ARDS. Notably, a follow-up clinical trial demonstrated that ventilation using the limited tidal volumes and plateau pressure of the original study is associated with an overall reduction of mortality to 26%. In the follow-up trial, although elevated levels of PEEP did not decrease mortality, the basic lung protective strategy was validated as effective.

The beneficial mechanism underlying the low tidal volume strategy has been well studied. An Italian study reported that use of low tidal volumes in patients with ARDS attenuates the inflammatory response in both lungs and bloodstream, as measured by reductions in neutrophil and cytokine concentrations in BAL and cytokines in circulating blood.[39] Other studies have confirmed a number of these findings. In addition, a reduction in alveolar epithelial injury appears likely, based on a decline in plasma surfactant

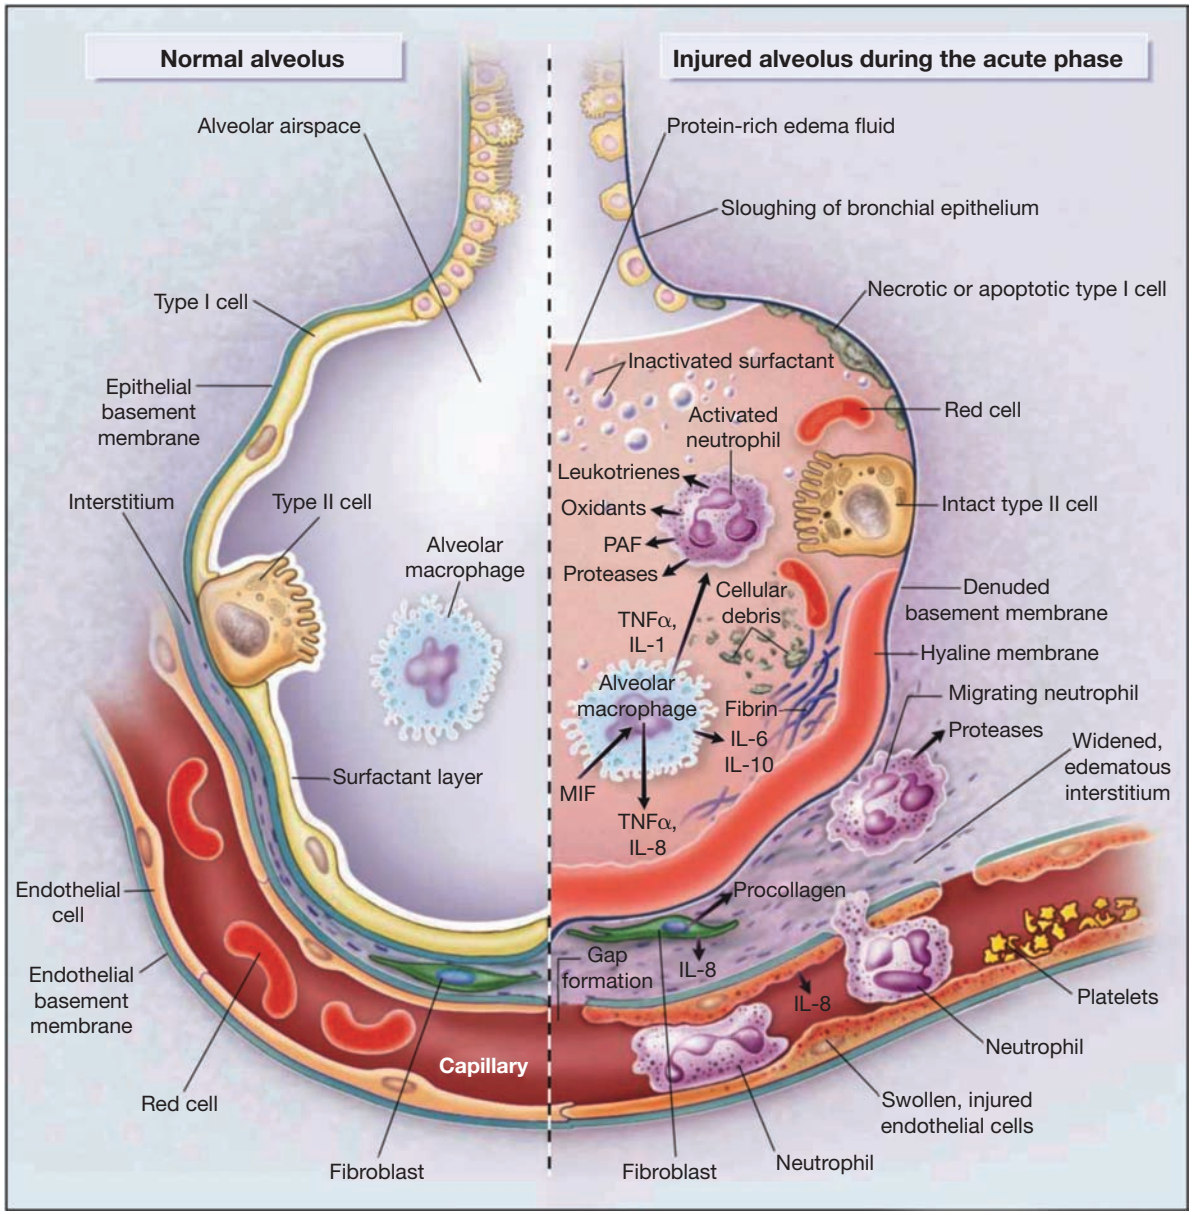

Figure 140-2 Multiple cellular responses and mediators contribute to alveolar-capillary membrane injury *(right-hand side)* and the transition from normal alveolar structure and function *(left-hand side)* in the acute phase of ALI/ARDS. Original investigations of the pathogenesis of ALI/ARDS searched for single mediators that provided final common pathways to inflammation and alveolar edema. Current concepts of pathogenesis involve multiple molecular factors of several classes, a variety of responding cells, and an imbalance between injurious and reparative signals and pathways. See text and Ware & Matthay (2000). *(Reproduced with permission from Ware LB, Matthay MA. The acute respiratory distress syndrome. N Engl J Med. 2000;342(18):1334–1349.)*

protein D levels. Additional clinical and experimental studies are underway. A reduction in lung endothelial and epithelial injury, attenuated inflammatory responses, reduced edema formation, and more rapid resolution of lung edema are likely part of the mechanism(s).[3] Figure 140-3 summarizes current knowledge of the mechanisms of VILI.

■ RESOLUTION OF ACUTE LUNG INJURY

In the last two decades, notable progress has occurred in elucidating the mechanisms responsible for resolution of lung edema. More limited progress characterizes our understanding of the resolution of lung inflammation.

Considerable advances have been made in our understanding of the clearance of fluid and solute from alveoli. Edema can be cleared via five routes: lymphatics, airways, blood vessels, the pleural space, and the mediastinum. Active sodium and chloride transport across the alveolar and distal airway epithelial barriers into the interstitium drives edema fluid removal from the airspaces.[40] The uninjured alveolar epithelium has a remarkable ability to rapidly clear fluid from the airspaces. Even when mild-to-moderate alveolar injury occurs, salt and water transport capacity is often preserved. In severe injury, when the barrier is disrupted, the capacity to clear edema is lost. The vascular endothelium becomes the limiting barrier between the vascular space and airspace. Clinically, the capacity to remove some alveolar edema fluid in the first 4 to 12 hours following ARDS is a favorable prognostic finding; the associated mortality rate is only 20%. In contrast, an inability to resorb alveolar edema fluid early in the course of injury

TABLE 140-1 National Institute of Heart, Lung, and Blood, ARDS Network: Lung Protective Ventilatory Strategy

Ventilator mode	Volume assist-control
Tidal volume	≤6 mL/kg PBW
Plateau pressure	≤30 cmH_2O
Ventilation set rate, pH goal	6–35, adjusted to achieve arterial pH ≥7.30, if possible
Inspiratory flow, I:E	Adjust flow to achieve I:E = 1:1–1:3
Oxygenation goal	$55 \le Pa_{O_2} \le 80$ mm Hg or $88 \le Sp_{O_2} \le 95\%$

$F_{I_{O_2}}$/PEEP Combinations

$F_{I_{O_2}}$	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7	0.7	0.8	0.9	0.9	0.9	1.0
PEEP, cmH_2O	5	5	8	8	10	10	10	12	14	14	14	16	18	18, 22, 24

(further increases in PEEP to 34 cmH_2O allowed, but not required)

Weaning	Attempts to wean by pressure support required when $F_{I_{O_2}}$/PEEP ≤0.40/8

PBW, predicted body weight

Male PBW = 50 + 2.3 [height (inches) − 60] *or*
50 + 0.91 [height (cm) − 152.4]
Female PBW = 45.5 + 2.3 [height (inches) − 60] *or*
45.5 + 0.91 [height (cm) − 152.4]

I:E, ratio of inspiratory to expiratory duration; Pa_{O_2}, partial pressure of oxygen in arterial blood; Sp_{O_2}, oxyhemoglobin saturation measured by pulse oximetry.

is associated with a mortality of nearly 80%. Thus, the function of the alveolar epithelial barrier early in the course of ARDS may be a useful prognostic index, serving as a marker of the severity and extent of injury.[41]

Resolution of ARDS requires effective: (1) reabsorption of alveolar edema, (2) repair of the epithelial and endothelial barriers, and (3) removal of inflammatory cells and exudates from the distal airspaces. Reabsorption of alveolar edema occurs through vectorial transport of sodium and chloride across alveolar epithelial type I and II cells to create a mini-osmotic gradient to reabsorb water.[42–44] This process is impaired in ARDS, in part because of apoptosis and necrosis of alveolar epithelium and defects in transcellular ion transport induced by proinflammatory cytokines, oxidants, and hypoxia.[26,42,45–48]

In uninjured, ex vivo human lungs, alveolar fluid clearance (AFC) is increased by administration of the beta-2 agonist, salmeterol.[49] However, the beta-adrenergic mediated effect by augmentation of intracellular cAMP works primarily when the alveolar epithelium is not injured, as in hydrostatic edema. Aerosolized or intravenous beta-2 agonist therapy does not appear to improve clinical outcomes.[50,51]

Clearance of protein from flooded alveoli is much slower (1%–2% per hour) than clearance of fluid (10%–20% per hour), resulting in an increased concentration of protein in the airspaces. If alveolar edema formed during increased lung vascular permeability clots, its removal from flooded alveoli may be slowed. Clotting may occur because extravasation of plasma into airspaces may lead to clotting system activation by surfactant or macrophage-derived procoagulants.

Most of the interstitial water in pulmonary edema lies in the peribronchovascular loose connective-tissue spaces, rather than in alveolar walls. Because the lymphatic capillaries are arranged to drain only the alveolar wall interstitium, this route for edema removal is not significant for most interstitial edema. Some fluid from the loose peribronchovascular interstitium may drain directly into the bloodstream by crossing the walls of blood vessels in the lungs. Edema may also drain into the pleural space.

Pleural effusions are more common in increased pressure pulmonary edema (25%–50% of patients; if unilateral, usually on the right). However, pleural effusions occur in ARDS as well (35% of patients). As much as 25% to 30% of edema fluid may leave the lungs through the pleural space. A significant portion of interstitial edema probably follows the prevailing pressure gradient in the lungs to drain into the mediastinum, where it may be picked up by the lymphatics.

Short-term alveolar protein clearance appears to proceed primarily by paracellular diffusion. The process depends on the size of the proteins. Most proteins are cleared intact, rather than as degraded, smaller fragments. However, a few specific proteins (e.g., vasoactive intestinal peptide and gastrin) are degraded before being cleared.

Finally, the general consensus is that transcytosis (transport via vesicles) is not a major mechanism for clearing bulk quantities of albumin or other proteins from the alveolar space. Over the long term, phagocytosis and catabolism by macrophages account for most protein clearance from the alveolar spaces. All insoluble, precipitated proteins are removed in this way. Macrophages are also ultimately responsible for removing senescent and dead neutrophils and other debris. The presence of a small, ciliated surface area of the distal airspaces suggests that the mucociliary route accounts for only a minor fraction of alveolar protein clearance. Complete clearance of alveolar protein from pulmonary edema by any route is slow.

AFC appears to be clinically important. In a study of 116 patients with ARDS, the rate of AFC in patients with shock was significantly slower than in those without shock. AFC also decreased significantly as the number of vasopressors required increased. The findings suggest that vasopressor use may be a marker for impaired alveolar epithelial barrier integrity in patients with ARDS and shock.[52]

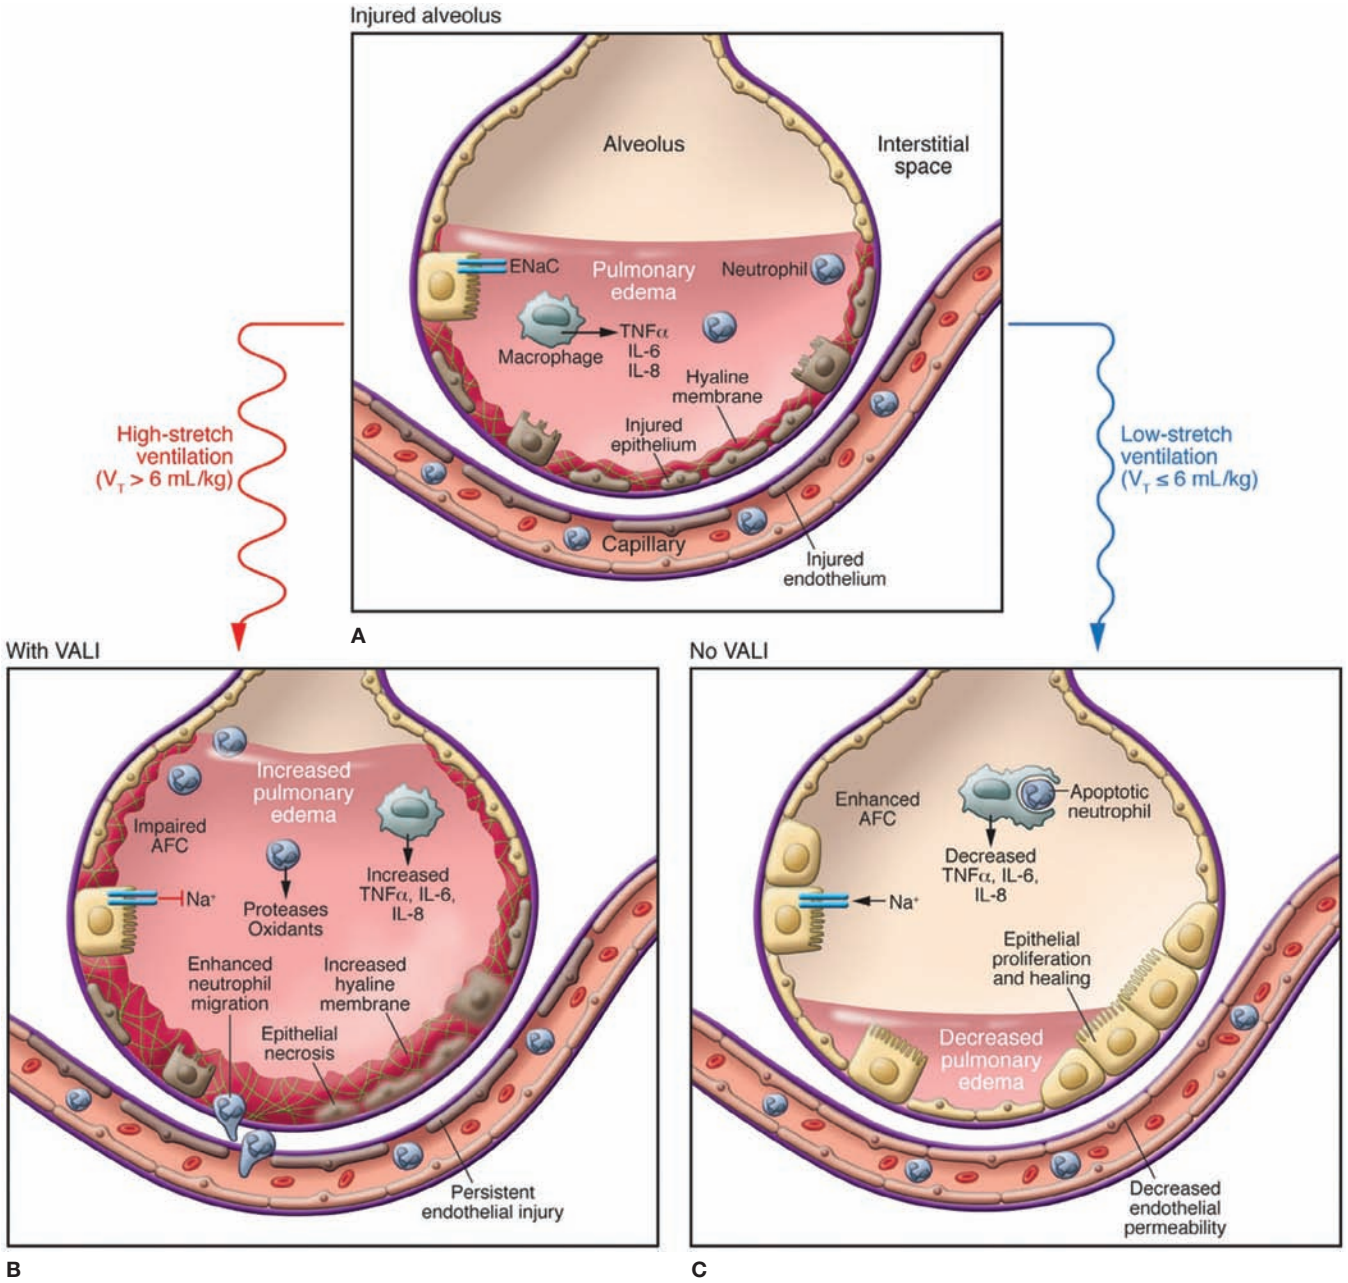

Figure 140-3 Mechanisms of ventilator-associated lung injury (VALI). **A.** Acute lung injury leads to lung endothelial and epithelial injury, increased permeability of the alveolar-capillary barrier, flooding of the airspace with protein-rich pulmonary edema fluid, activation of alveolar macrophages with release of proinflammatory chemokines and cytokines, neutrophil margination and activation, and fibrin deposition (hyaline membranes). **B.** If the injured lung is ventilated with high tidal volumes and high inflation pressures (high-stretch ventilation), then lung injury is exacerbated, with increased lung endothelial and epithelial injury and/or necrosis, enhanced neutrophil margination, release of injurious neutrophil products such as proteases and oxidants, increased release of proinflammatory cytokines from alveolar macrophages and the lung epithelium, increased fibrin deposition, and increased hyaline membrane formation. Injurious mechanical ventilation can also impair alveolar fluid clearance (AFC) mechanisms. **C.** In contrast, a protective ventilatory strategy (low-stretch ventilation) can limit further lung endothelial and epithelial injury, reduce the release of proinflammatory cytokines, and enhance AFC through the active transport of sodium and chloride across the alveolar epithelium, thereby reducing the quantity of pulmonary edema and allowing endothelial and epithelial repair to occur. Epithelial repair occurs through migration, proliferation, and differentiation of alveolar epithelial type II cells to repopulate the denuded basement membrane. *(Reproduced with permission from Matthay MA, Ware LB, Zimmerman GA. CONCLUSIONS

Among the major advances in respiratory medicine and physiology over the last three decades has been the acquisition of important new knowledge on the physiology of fluid, solute, and protein transport in healthy and diseased lungs. Pulmonary edema, defined as the abnormal accumulation of extravascular lung fluid, is a pathologic state that occurs when fluid is filtered into the lungs faster than it can be removed.

The many causes of pulmonary edema are grouped into two main pathophysiologic categories: (1) increased pressure edema, which results from an increase in hydrostatic or protein osmotic forces (or

both) that act across the barriers that normally restrict movement of fluid and solutes in the lungs; and (2) increased permeability edema, which is seen in ARDS, and in which a breakdown of the normal barrier properties of lung endothelium or epithelium develops. Although these two different types of pulmonary edema share many features, usually they can be distinguished by careful clinical, radiologic, and physiologic evaluation. They also differ in treatment and prognosis.

Major advances in the treatment of ARDS have occurred because of the successful application of lung protective ventilatory strategies early in the course of the illness (Table 140-1). Use of a low tidal volume (6 mL/kg/ideal body weight), coupled with a plateau pressure limit (less than 30 cmH_2O) has resulted in the first therapy demonstrated to reduce mortality in patients with ARDS.[38]

Another major advance in the treatment of ARDS was triggered by findings from the Fluid and Catheter Treatment Trial (FACTT), a large randomized trial comparing liberal and conservative fluid management strategies in affected patients.[8] A marked difference in outcome was reported, with patients in the conservative fluid management arm having 2.5 more ventilator-free days (and improved physiology) than those in the liberal fluid management arm. In addition, although not statistically significant, a 2.9% reduction in the 60-day mortality rate was noted in the conservative fluid management arm. Patients were also randomized to receive either a pulmonary arterial catheter or a central venous catheter for monitoring and fluid management. No differences were noted in clinical outcomes between the two groups.[53]

New insights into the pathogenesis of ARDS suggest that other therapies may also prove efficacious in reducing mortality in this common form of severe acute respiratory failure. A major development has been the ability to conduct large, prospective, randomized, clinical trials (e.g., those sponsored by the National Heart, Lung, and Blood Institute) to test a variety of therapies important in supportive patient care, including use of mechanical ventilation, intravenous fluids, and a variety of pharmacologic agents.

Interest exists in the possibility that cell-based therapy using bone-marrow–derived mesenchymal stem cells may be effective for more severe ARDS.[3] Such trials have led to a better understanding of the pathogenesis of human ARDS and have confirmed the importance of VILI. In addition, ancillary pathogenetic studies carried out on biologic samples from clinical trials have advanced our understanding of underlying mechanisms.

In the future, human studies will be needed to explore new therapeutic strategies suggested by basic investigation conducted in animal models of ALI, including efforts to treat patients at an early phase of acute respiratory failure, prior to the need for positive pressure ventilation.[3]

CHAPTER 141

Acute Lung Injury and the Acute Respiratory Distress Syndrome: Clinical Features, Management, and Outcomes

John P. Reilly
Jason D. Christie

DESCRIPTION AND DEFINITIONS

In 1967, Ashbaugh et al.[1] described a syndrome characterized by the acute onset of dyspnea, severe hypoxemia, diffuse lung infiltrates, and decreased respiratory system compliance in the absence of evidence for congestive heart failure (CHF). The syndrome, initially called acute respiratory distress in adults (to contrast it with acute respiratory distress in neonates), is now known as the acute respiratory distress syndrome (ARDS). Following the initial report, other authors utilized various definitions that incorporated elements related to time of onset, presence of hypoxemia and radiographic infiltrates, and absence of overt CHF.

In 1988, Murray and others introduced the Lung Injury Score (LIS), an assessment tool for ARDS that reflects the extent of radiographic infiltrates, severity of hypoxemia and reduced respiratory system compliance, and level of positive end expiratory pressure (PEEP) used in mechanically ventilating affected patients.[2] The LIS incorporates four parameters that are graded on a scale of 0 to 4: (1) ratio of Pa_{O_2} to FI_{O_2}(Pa_{O_2}/FI_{O_2}); (2) total respiratory compliance; (3) level of PEEP; and (4) extent of radiographic infiltrates (assessed by noting the number of quadrants in the chest radiograph demonstrating infiltrates). The LIS equals the sum of the scores for the four variables divided by four. In clinical studies, a score of 2.5 or more is generally used as a threshold for severe disease.

CONSENSUS DEFINITIONS OF ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME

Prior to 1994, published studies used nonuniform definitions of ARDS, prompting an American European Consensus Conference (AECC) to develop standardized definitions for ARDS and acute lung injury (ALI)—a broader category that encompasses ARDS.[3] The AECC definitions included the acute onset of illness, bilateral chest radiographic infiltrates consistent with pulmonary edema, poor systemic oxygenation, and absence of evidence for left atrial hypertension (Table 141-1A). The syndrome was referred to as ALI when the ratio of Pa_{O_2} to FI_{O_2} (Pa_{O_2}/FI_{O_2}); was ≤300, and ARDS when the ratio was ≤200. The AECC definitions of ALI and ARDS were intentionally broad in order to encompass different types of acute hypoxemic respiratory failure occurring in a wide variety of settings.

DEVELOPMENT OF THE BERLIN DEFINITION OF ARDS

The standardization of definitions of ALI and ARDS lead to significant advances in the understanding of the syndrome and allowed researchers and clinicians to communicate findings using common criteria. The AECC definitions were widely used in clinical trials, including those that demonstrated therapeutic benefit.[4,5] In addition, they added important validity to the definition, allowing clinicians to generalize trial results to clinical decisions involving their own patients. Despite this standardization, little data were available to support the reliability and validity of ARDS definitions. In fact, several components of the AECC definition have been recognized as problematic: (1) Acute onset is not defined within a specific time frame. (2) The chest radiograph is subject to variability in interpretation.[6,7] (3) Pa_{O_2}/FI_{O_2} may vary according to ventilator parameters, for example, PEEP, and at extremes of FI_{O_2}. (4) Accuracy in excluding the presence of heart failure may be influenced by measurement methodology and timing, as discussed below.[8]

Given these limitations, an international expert panel was convened in Berlin in 2012 to revise the definition of ARDS. The resultant "Berlin definition" of ARDS addresses ambiguities in the prior AECC definition. The authors of the Berlin definition also applied proposed criteria for the syndrome to existing databases of patients with ARDS to specifically address the predictive validity of a new ARDS definition.[9] According to the Berlin definition, ARDS is defined as a syndrome characterized by (1) onset within 1 week of a known clinical insult, (2) bilateral radiographic opacities, not fully explained by pleural effusions, atelectasis, or nodules, (3) respiratory failure not fully explained by cardiac failure or fluid overload, and (4) poor systemic oxygenation, with a Pa_{O_2}/FI_{O_2} ≤300 and a PEEP or CPAP ≥5 cm H_2O. The definition also categorizes syndrome severity as mild, moderate, or severe, based on Pa_{O_2}/FI_{O_2}. According to the Berlin definition, patients who previously were diagnosed with ALI, but not ARDS (i.e., Pa_{O_2}/FI_{O_2} ≤300, but >200), are referred to as having mild ARDS, with ALI now an obsolete term. Moderate ARDS is defined as Pa_{O_2}/FI_{O_2} ≤200, but >100, and severe ARDS is defined as Pa_{O_2}/FI_{O_2} ≤100 (Table 141-1B).

While the Berlin definition leaves the AECC definition of ARDS largely unchanged, the new definition addresses several specific ambiguities of the prior diagnostic criteria. First, the definition

TABLE 141-1A American European Consensus Conference Criteria for Acute Lung Injury (ALI) and the Acute Respiratory Distress Syndrome (ARDS)

Clinical Variable	Acute Lung Injury	Acute Respiratory Distress Syndrome
Onset	Acute	Acute
Hypoxemia	Pa_{O_2}/FI_{O_2} ≤300 mm Hg	Pa_{O_2}/FI_{O_2} ≤200 mm Hg
Chest radiograph	Bilateral infiltrates consistent with pulmonary edema	Bilateral infiltrates consistent with pulmonary edema
Noncardiac etiology	No clinical evidence of left atrial hypertension or, if measured, pulmonary artery wedge pressure ≤18 mm Hg	No clinical evidence of left atrial hypertension or, if measured, pulmonary artery wedge pressure ≤18 mm Hg

TABLE 141-1B Berlin Definition of Mild, Moderate, and Severe Acute Respiratory Distress Syndrome (ARDS)

Clinical Variable	Mild ARDS	Moderate ARDS	Severe ARDS
Onset	Onset within 1 week of clinical insult known to result in ARDS		
Hypoxemia	Pa_{O_2}/FI_{O_2} ≤300 mm Hg PEEP or CPAP ≥5 cm H_2O	Pa_{O_2}/FI_{O_2} ≤200 mm Hg PEEP ≥5 cm H_2O	Pa_{O_2}/FI_{O_2} ≤100 mm Hg PEEP ≥5 cm H_2O
Chest radiograph	Bilateral opacities, not explained by effusions, atelectasis, or nodules		
Noncardiac etiology	Reparatory failure, not fully explained by cardiogenic pulmonary edema. Exclude hydrostatic edema if no clinical risk factor present.		

Source: Data from ARDS Definition Task Force, Ranieri VM, Rubenfeld GD, et al. Acute respiratory distress syndrome: the Berlin Definition. JAMA. 2012;307(23):2526–2533.

defines "acute onset" and attempts to clarify chest radiograph criteria. In addition, the Pa_{O_2}/FI_{O_2} criterion is influenced by the level of PEEP and other transient factors, including the presence or absence of airway secretions or inadequate sedation. Increasing PEEP generally increases Pa_{O_2} at a given FI_{O_2}. The consequent increase in Pa_{O_2}/FI_{O_2} may result in a value that no longer meets criteria for ARDS. Conversely, without any PEEP, values of Pa_{O_2}/FI_{O_2} <300 may reflect simple atelectasis, rather than ARDS. Adding PEEP may recruit sufficient atelectatic lung to raise Pa_{O_2}/FI_{O_2} >300, thereby excluding such patients from meeting this criterion for ARDS. The Berlin definition addresses this concern directly by requiring a minimum level of PEEP when a determination of Pa_{O_2}/FI_{O_2} ratio is made.

Finally, given the declining use of pulmonary artery catheters (PACs),[10] potential inaccuracies of pulmonary artery occlusion pressure (PAOP) measurements, and the now recognized possibility of concomitant hydrostatic edema and ARDS, the Berlin definition no longer specifies PAOP requirements.[11,12] PAOP in ARDS may be higher than 18 mm Hg due to intravascular volume loading, particularly in the setting of application of goal-directed management paradigms for sepsis. Conversely, some patients with pulmonary edema due to CHF and high left atrial pressures have a normal PAOP by the time the catheter is inserted and PAOP is measured. The Berlin definition specifies that the respiratory failure of ARDS is not fully explained by cardiac failure or fluid overload and requires objective assessment to exclude hydrostatic edema (e.g., an echocardiogram) if no risk factor for ARDS is present.

The predictive validity of the new ARDS definition was assessed in several large cohorts of patients with ALI, as defined by AECC. Compared with the AECC definition, the Berlin definition had marginally better predictive validity for mortality. The identified categories of mild, moderate, and severe ARDS corresponded with progressive increases in mortality. Proposed ancillary variables in the definition of severe ARDS, including a chest radiograph with three or four quadrants demonstrating opacities, PEEP ≥10 cm H_2O, and either a respiratory system static compliance ≤40 mL/cm H_2O or a corrected expired volume per minute of at least 10 L/min did not improve the predictive validity of the definition of severe ARDS. Therefore, the final definition did not include any of these ancillary variables.

While the Berlin definition has been accepted by major professional organizations, it is important to note that the majority of the studies referred to in this chapter were performed prior to its development, and, therefore, utilize the older AECC definition of ALI and ARDS. Further refinements in the reliability and validity of definitions of ARDS constitute important future directions for clinical studies. In addition, attempts at understanding the heterogeneity underlying the syndrome may allow for identification of ARDS subgroups with potential diverse risk factors and pathogenesis. More reliable definitions will not only improve estimates of the public health impact of these syndromes, but also will decrease misclassification errors, which can be especially problematic for research aimed at clarifying underlying mechanisms.

EPIDEMIOLOGY

Over the last several decades, the epidemiology of ARDS has become more clearly delineated.

INCIDENCE AND MORTALITY RATE

A landmark epidemiologic study of the incidence of ARDS in the United States between 1999 and 2000 – the King County Lung Injury Project (conducted in King County, Washington) – represents the first broad, population-based epidemiologic study of ARDS in the United States using the standardized AECC definitions.[13] Study results included an estimated incidence of ARDS based on a Pa_{O_2}/FI_{O_2} ≤300 of 78.9 per 100,000 person-years and an age-adjusted incidence of 86.2 per 100,000 person-years. The incidence of what is now called moderate or severe ARDS was estimated as 58.7 per 100,000 person-years, with an age-adjusted incidence of 64.0 per 100,000 person-years. The incidence of ARDS increased dramatically with age, with an incidence of 306 per 100,000 person-years for ages 75 through 84 years. By extrapolation, an estimated 190,600 cases of ARDS occur each year in the United States (Table 141-2).

TABLE 141-2 Estimated Incidence, Hospital Days and Intensive Care Unit (ICU) Days for Acute Lung Injury (ALI) and Acute Respiratory Distress Syndrome (ARDS) in the United States (US) based on American European Consensus Criteria for ALI and ARDS

Variable	ALI	ARDS
Crude incidence, per 100,000 person-years	78.9	58.7
Age-adjusted incidence, per 100,000 person-years	86.2	64.0
Estimated annual Number of cases in US	190,600	141,500
Estimated annual number of hospital days in US	3,622,00	2,746,000
Estimated annual number of days in ICU in US	2,154,000	1,642,000

Source: Adapted with permission from Rubenfeld GD, Caldwell E, Peabody E, et al. Incidence and outcomes of acute lung injury. N Engl J Med. 2005;353(16):1685–1693.

Although prior estimates of the incidence of ARDS had been lower, the studies were limited by incomplete and nonvalidated data, inaccuracies in the definition of the syndrome, and use of administrative coding.[14–19] Thus, the estimates from King County Lung Injury Project serve as the best indicator of the public health impact of ARDS in the United States. More recently, a retrospective cohort study of all patients admitted to the ICU at the Mayo Clinic from 2001 to 2008 has been reported.[20] Since the Mayo Clinic provides all ICU-level care to the population of Olmsted County, Minnesota, the authors could estimate the incidence trends of ARDS over time. The age and sex adjusted incidence of moderate and severe ARDS ($Pa_{O_2}/FI_{O_2} \leq 200$) declined from 81 cases per 100,000 person-years in 2001 to 38.3 cases per 100,000 person years in 2008. This trend appeared to be driven by declining hospital-acquired ARDS, perhaps the result of improvements is overall ICU care and the increasing use of lower tidal volume ventilation (see Approach to Treatment).

During the time of observation in the King County Lung Injury Project study, the mortality from ARDS was 38.5%, translating into an estimated 74,500 annual deaths from ARDS in the United States.[13] Reported mortality estimates have ranged from 26% to 58% [19–23] To put these figures into perspective, more people die annually with ARDS than from AIDS, asthma, and breast cancer combined.[24] Other than lung cancer, ARDS leads to more annual deaths than any type of cancer, including lymphoma, leukemia, and breast, prostate, colon, ovarian, and pancreatic cancers (Table 141-3). The most common causes of death among patients with ARDS arise from the underlying insult or subsequent nosocomial pneumonia and sepsis.[25,26] Only rarely do patients die from progressive hypoxia and respiratory failure.

Several studies have suggested that ARDS mortality has decreased over time.[26–29] In one hospital using the same definition of ARDS throughout the period analyzed, the mortality rate was 68% in 1982, 29% in 1996, and in the mid-30% range in 1997 and 1998.[26] Obviously, the decrease cannot be ascribed to widespread application of low tidal volume ventilation strategies, since the decline was observed prior to publication of the study reporting the value of using a "low stretch" ventilator protocol in 2000.[4] The improvement is likely attributable to enhancements in general ICU care, including prevention of nosocomial pneumonias and other infections, earlier institution of enteral nutrition, routine use of stress ulcer prophylaxis, and improved teamwork in the ICU.

TABLE 141-3 Estimated Annual Number of Deaths in the United States from Selected Causes

Cause	Number of Deaths
ARDS	59,000
Asthma	3311
HIV/AIDS	7638
Breast cancer	41,271
Leukemia	22,982
Lung cancer	156,614
Lymphoma	21,393
Ovarian cancer	14,312
Pancreatic cancer	37,371
Prostate cancer	27,929

Source: Data for ARDS are from Rubenfeld GD, Caldwell E, Peabody E, et al. Incidence and outcomes of acute lung injury. N Engl J Med. 2005;353:1685; all other are from CDC National Center for Health Statistics estimated number of deaths in 2011 (http://www.cdc.gov/nchs/).

Interestingly, the case fatality rate for patients with ARDS due to sepsis remained the same over the same time frame noted earlier, while that for patients with ARDS due to trauma or other causes decreased significantly. Mortality rates among subjects enrolled in ARDS Network trials[4,30–33] appear to have decreased from 35% (1996–1997) to 26% (2004–2005).[27,34] These findings were robust in adjusting for covariates, including severity of illness and use of low tidal volume ventilation. However, these rates were obtained from clinical trials in specialized centers, excluding large numbers of patients with high-risk comorbidities. Recent systematic reviews of clinical trials and more inclusive prospective cohort studies have drawn opposing conclusions.[28,35] Also, the previously noted study from the Mayo Clinic demonstrated a reduction in ARDS incidence, but it failed to show a change in mortality.[20] While it is unclear if survival from ARDS is improving, the mortality rate remains unacceptably high and represents a major public health problem. Furthermore, as the population of the United States becomes older, the incidence of those at risk for ARDS and ARDS-related death can be expected to rise.

Precipitating Causes

The severe, extensive lung inflammation characteristic of ARDS represents the common final pathogenic process in response to a large variety of precipitating causes,[36–39] resulting in either direct or indirect (systemic) lung injury.[40,41] In general, *direct* causes of ARDS include those that originate within the lung, such as aspiration of gastric contents or viral pneumonia. Examples of *indirect* causes include sepsis, ingested toxins, hypotension, and ischemia–reperfusion injury. Although some causes of ARDS may fit into either category (e.g., multilobar pneumonia with septic shock), this simple classification scheme is useful both for considering the many predisposing causes of ARDS and their varying mechanisms of lung injury and for future development of therapies aimed at different categories of ARDS. Table 141-4 lists precipitating causes of ARDS according to this construct.

TABLE 141-4 Common Direct and Indirect (Systemic) Precipitating Causes of ARDS

Direct Precipitating Causes	Indirect (Systemic) Precipitating Causes[a]
Aspiration of gastric fluids	Acute pancreatitis
Bacterial pneumonia (diffuse), e.g., Legionnaires' disease	Blood transfusions with transfusion-related acute lung injury (TRALI)
Chest trauma with lung contusion	Postcardiopulmonary bypass
Near drowning	Primary graft failure of lung transplantation
Pneumonia due to *Pneumocystis carinii*	Severe sepsis and septic shock
Toxic inhalations, e.g., smoke inhalation, inhaled crack cocaine	Toxic ingestions, e.g., aspirin, tricyclic antidepressants
Viral pneumonia, e.g., influenza, severe acute respiratory syndrome (SARS)	Trauma with multiple fractures and the fat-emboli syndrome

[a]*In indirect or systemic mechanism of lung injury, the lung injury results from deleterious effects on the alveolar epithelium by inflammatory or other mediators delivered via the pulmonary circulation.*

FACTORS INFLUENCING RISK OF ARDS

Not all patients with an underlying cause (e.g., sepsis) of ARDS develop the syndrome. In addition to inherent risk differences within at-risk populations, specific clinical variables may be important.

Clinical variables found to be associated with an increased risk of ARDS include chronic alcohol abuse,[42] hypoproteinemia,[43] advanced age,[13] increased severity, and extent of injury or illness as measured by injury severity score (ISS) or APACHE score, hypertransfusion of blood products,[38,44] and possibly, cigarette smoking.[45,46] Diabetes mellitus and prehospitalization antiplatelet therapy appear to decrease the risk of ARDS.[47–49] The role of obesity in modifying ARDS risk is complicated, as excess soft tissue can render chest x-ray interpretation difficult; the potential role of obesity remains the subject of ongoing research. A higher body mass index has been associated with an increased incidence of ARDS; however, obesity has not been associated with a consistent change in mortality.[50–52] Since many studies of risk factors for ARDS are retrospective or based on a single center's experience, the consistency and generalizability of identified risk factors have not been confirmed. Nonetheless, the mechanistic underpinnings and potential therapeutic implications of these probable associations are the subject of ongoing research.

FACTORS INFLUENCING MORTALITY FROM ARDS

Clinical variables at the onset of ARDS that are associated with increased mortality include advanced age, lower Pa_{O_2}/FI_{O_2}, high plateau pressure (i.e., low respiratory system compliance),[53] greater extent of pulmonary infiltrates, sepsis, chronic liver disease, nonpulmonary organ dysfunction, increased global severity of illness, hypoproteinemia, and greater length of hospitalization prior to onset of ARDS.[13,43,53–58] In addition, an increased dead-space fraction has been identified as a risk factor for increased mortality, possibly indicating the importance of early loss of the pulmonary vascular bed as a sign of greater disease severity.[59,60] Although various precipitating causes of ARDS carry somewhat different prognoses, the strategy of low tidal volume ventilation utilized by the National Institutes of Health (NIH), National Heart, Lung, and Blood Institute (NHLBI)–sponsored ARDS Clinical Trials Network (ARDSNet) as part of its clinical trials appears to be equally efficacious in all subgroups.[4]

PREDICTING ARDS

Using the identified precipitating causes and modifying risk factors, investigators have recently developed and validated a lung injury prediction score (LIPS) aimed at identifying those at highest risk of developing ARDS early.[61,62] The LIPS was developed in a multicenter cohort of 5,584 hospitalized patients at risk for ARDS, among whom 7% eventually developed the syndrome. The LIPS is generated from the sum of points assigned for each of six predisposing conditions (shock, aspiration, sepsis, pneumonia, high-risk surgery, and high-risk trauma) and nine risk modifiers (alcohol abuse, obesity, hypoalbuminemia, chemotherapy, need for oxygen, tachypnea, hypoxia, academia, and diabetes mellitus). The negative predictive value for a score <4 was 97%, while the sensitivity and specificity for ARDS of a score >4 were 69% and 78%, respectively. While not perfect, the LIPS allows for the identification of a higher-risk population and may prove useful for studies of preventative interventions. The goal of identifying predictive and early indicators of ARDS is to shift the syndrome's treatment paradigm to strategies aimed at prevention and treatment at the earliest phases of development.

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical presentation and diagnosis of ARDS are fundamentally related to the syndrome's pathophysiologic changes, regardless of the underlying etiology. A brief description of the pathology and pathophysiology is provided before a detailed discussion of clinical aspects of the disorder. The reader is also referred to Chapter 140 for additional details on disease mechanisms.

PATHOLOGY AND PATHOPHYSIOLOGY

A number of interrelated mechanisms contribute to the development and clinical course of ARDS. Inflammatory cytokines, oxygen radicals, activation of coagulation and complement, platelet and immune cell activation, generation of proteases, and abnormal fluid fluxes resulting in edema fluid generation and defective epithelial alveolar fluid clearance have all been hypothesized to play a role in the early stages.[63–68] In addition, factors specific to apoptosis, edema fluid resolution, and fibrosis and repair, as well as the response to mechanical ventilation are likely to play a role in the pathophysiology of the later phases of ARDS.

Pathologically and clinically, ARDS can be divided into *early* and *late phases* of lung injury (Fig. 141-1).[69–72] In the early phase (first few hours or days), light microscopy shows interstitial and alveolar edema, capillary congestion, and intra-alveolar hemorrhage with minimal evidence of cellular injury. Electron microscopy reveals changes of endothelial cell swelling, widening of intercellular junctions, increased numbers of pinocytotic vesicles, and disruption and denudation of the basement membrane. Inflammatory cell infiltration of the lung interstitium may also be seen. Protein-rich pulmonary edema and its clinical effects are most pronounced in the early exudative phase. Hyaline membranes containing condensed fibrin and plasma proteins form over the next several days. Later, in the exudative phase, inflammatory cells become more numerous within the lung interstitium, and extensive necrosis of type I alveolar epithelial cells is present. Pathologists refer to this constellation of findings as *diffuse alveolar damage* (DAD).

Pathophysiologically, in the exudative phase, alveolar edema and alveolar collapse, that is, atelectasis due to loss of normal surfactant-related stabilization of alveoli, interfere with oxygenation.[73,74] Surfactant is washed out of alveoli and inactivated by

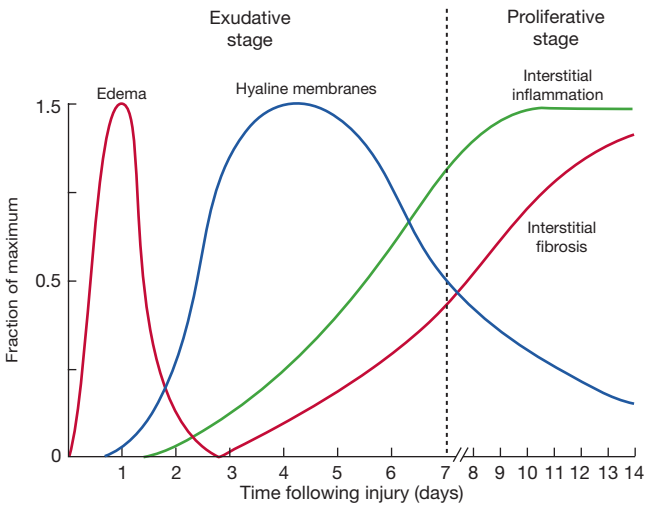

Figure 141-1 Schematic representation showing time course of evolution of the acute respiratory distress syndrome (ARDS). The early or exudative phase is characterized by a pulmonary capillary leak with interstitial and alveolar edema and hemorrhage followed by hyaline membrane formation. Within as short a period of time as 7 to 10 days, a proliferative phase may appear with marked interstitial and alveolar inflammation and cellular proliferation, followed by fibrosis and disordered healing (see text for discussion). *(Reproduced with permission from Katzenstein AA, Askin FB. Surgical Pathology of Non-Neoplastic Lung Diseases. 2nd ed. Philadelphia, PA: Saunders; 1990.)*

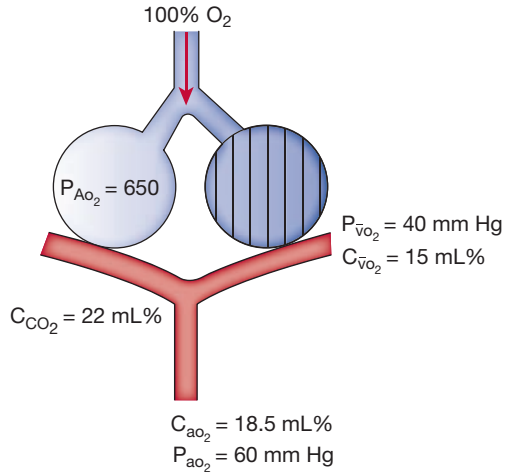

Figure 141-2 Diagram of a two-compartment model of lung perfusion and ventilation demonstrating basis for failure of oxygenation in ARDS. When large portions of the lung are nonventilated due to alveolar collapse or flooding (hatched area), blood flow to these units with mixed venous P_{O_2} ($P\bar{v}_{O_2}$) of 40 mm Hg and content of 15 vol. percent is effectively "shunted" through the lungs without being resaturated. Thus, despite a high concentration of supplemental oxygen (100% in this example) and high alveolar P_{O_2} in ventilated unit, these blood flows mix in accord with their oxygen contents, that is, the resulting left atrial blood has an oxygen content that is the weighted mean of the oxygen content of the shunted and nonshunted blood. In this example of a 50% shunt, the left atrial and systemic arteries have an arterial P_{O_2} of 60 mm Hg. Ca_{O_2}, arterial oxygen content; C_{CO_2}, capillaryoxygen content; $C\bar{v}_{O_2}$, mixed venous oxygen content; P_A, alveolar pressure; Pa_{O_2}, arterial P_{O_2}; $P\bar{v}_{O_2}$, partial pressure of oxygen in the mixed venous blood. *(Reproduced with permission from Christie JD, Lanken PN. Acute lung injury and the acute respiratory distress syndrome. In: Hall JB, Schmidt GA, Wood LDH, eds. Principles of Critical Care. 3rd ed. New York, NY: McGraw-Hill; 2005.)*

the alveolar edema. The hypoxemia in ARDS is typically resistant to supplemental oxygen, reflecting an increased right-to-left shunt (Fig. 141-2). Continued perfusion of alveoli that lack ventilation because of alveolar edema results in ventilation–perfusion ($\dot{V}/\dot{Q}$) ratios of zero, thereby defining physiologic shunt. Furthermore, the effects of this type of shunt are exacerbated by shunt-like contributions from alveoli with very low ventilation–perfusion ratios.

Disordered healing and proliferation of fibrous tissue dominate the late phase of ARDS or persistent ARDS, that is, the *proliferative or fibroproliferative* phase. Type II alveolar cells, fibroblasts, and myofibroblasts proliferate in this phase, which can occur as early as 7 to 10 days after initial injury. The late phase of ARDS is characterized by an increased dead-space fraction, high minute ventilation requirement, pulmonary hypertension, and further reduction in lung compliance.[75,76]

CLINICAL PRESENTATION

The development of ARDS usually follows a rapid course, occurring most often within 12 to 72 hours of the predisposing event.[38] At its onset, patients with ARDS often become anxious, agitated, and dyspneic. Inflammatory changes in the lung decrease lung compliance, which, in turn, leads to an increased work of breathing, small tidal volumes, and tachypnea. If breathing ambient air or low-flow supplementary oxygen, patients with ARDS typically have initial arterial blood gas results showing a Pa_{O_2} less than 50 to 55 mm Hg and pulse oximetry recordings of less than 85% arterial O_2 saturation. The hallmark of ARDS is hypoxemia that is resistant to oxygen therapy because of the large right-to-left shunt (Fig. 141-2). Initially, patients may be able to compensate by hyperventilating, thereby maintaining an acceptable Pa_{O_2} with an acute respiratory alkalosis. Typically, patients deteriorate over several hours, requiring endotracheal intubation and mechanical ventilation.

TABLE 141-5 Differential Diagnosis of Acute Hypoxemic Respiratory Failure (AHRF)

1. ARDS
2. Acute cardiogenic pulmonary edema
3. Bilateral aspiration pneumonia
4. Lobar atelectasis of both lower lobes
5. Severe unilateral lower lobe atelectasis, especially when patient is receiving vasodilators, such as intravenous nitrates, calcium-channel blockers, or sodium nitroprusside, that blunt hypoxic vasoconstriction
6. Acute loss of ventilation to one lung due to complete or near-complete obstruction of its mainstem bronchus, e.g., due to a mucus plug or blood clot
7. Loss of ventilation to one or both lungs due to large pneumothorax/pneumothoraces
8. Loss of ventilation to one or both lungs due to large pleural effusion(s)
9. Diffuse alveolar hemorrhage, especially in patients post–bone marrow transplantation
10. Massive pulmonary embolus
11. Acute opening of a patent foramen ovale in patient with pre-existing pulmonary hypertension

DIFFERENTIAL DIAGNOSIS

The differential diagnoses for acute hypoxemic respiratory failure, in general (Table 141-5), and for ARDS, in particular (Table 141-6), are extensive.[77] Identifying the specific etiology of the diffuse infiltrates in ARDS is important because several causes, for example, acute eosinophilic pneumonia or diffuse alveolar hemorrhage, have specific therapies. Table 141-6 lists the major clinical and diagnostic characteristics of these disorders.

The setting in which respiratory failure occurs usually provides important diagnostic information. ARDS commonly arise following development of a typical predisposing factor (Table 141-4). Sepsis, pneumonia, trauma, transfusion of blood products, and gastric aspiration account for the majority of cases.[38] When an inciting event is obvious and diagnostic criteria (Tables 141-1A and 141-1B) are met, establishment of a clinical diagnosis of ARDS is not difficult. Under such circumstances, management can be instituted immediately. However, in the absence of a clear predisposing event, or when conflicting or ambiguous information exists, the other causes listed in Table 141-6 should be considered, and relevant clues from the history and physical examination sought. For example, cardiogenic edema is most often accompanied by systolic left ventricular or valvular dysfunction, and the appropriate history and physical findings (e.g., a heart murmur or ventricular gallop) are often present. Electrocardiographic and laboratory-based evidence (e.g., serum troponin I levels) of cardiac ischemia suggest cardiogenic edema as

TABLE 141-6 Differential Diagnosis of ARDS

Disorder	Characteristics	Comments
Pulmonary edema due to left heart failure	History of cardiac disease, enlarged heart on chest radiograph, third heart sound.	Rapid improvement with diuresis and/or afterload reduction.
Noncardiogenic pulmonary edema	History of one or more precipitating causes (Table 141-4), crackles absent or not prominent, normal cardiac size on chest radiograph.	Usual etiology for ARDS. Rarely some patients with ARDS have no obvious precipitating cause.
DAH	Often associated with autoimmune diseases (e.g., vasculitis) or following bone marrow transplantation. Often patients do not have bloody sputum. Renal disease or other evidence of systemic vasculitis may be present. Hemosiderin-laden macrophages in bronchoalveolar lavage fluid can confirm diagnosis of DAH. May respond to apheresis, corticosteroids, or cyclophosphamide, depending on etiology.	May meet diagnostic criteria for ARDS (Tables 141-1A and 141-1B), but has different pathophysiology and management.
Acute eosinophilic pneumonia	Cough, fever, pleuritic chest pain, and myalgia are often present. Patients often do not have peripheral blood eosinophilia, but generally have greater than 15% eosinophils in bronchoalveolar lavage fluid. Usually responds rapidly to high-dose corticosteroid therapy.	May meet diagnostic criteria for ARDS (Tables 141-1A and 141-1B), but has different pathophysiology and management.
Lupus pneumonitis	Usually associated with active lupus. May respond to high-dose corticosteroid therapy or cyclophosphamide.	May meet diagnostic criteria for ARDS, but has different pathophysiology and management.
AIP	Slower onset than ARDS (over 4–6 weeks) with progressive course. However it may present in advanced state, mimicking ARDS.	Associated with >90% mortality. AIP includes Hamman–Rich syndrome.
Pulmonary alveolar proteinosis (PAP)	Slower onset than ARDS (over 2–12 months) with progressive course. Can be treated with whole lung lavage.	Characteristic "crazy paving" pattern on high-resolution CT scan of chest.
Bronchiolitis obliterans with organizing pneumonia (BOOP) or cryptogenic organizing pneumonia	May be precipitated by viral syndrome. Slower onset than ARDS (over >2 weeks) with progressive course. However it may present in advanced state, mimicking ARDS. May respond to high-dose corticosteroid therapy.	
Hypersensitivity pneumonitis	Typically slower onset than ARDS (over weeks) with progressive course. However, it may present in advanced state, mimicking ARDS. May respond to high-dose corticosteroid therapy and removal from offending agent.	
Leukemic infiltration	May be rapid in onset during active disease states. Usually leukemia is clinically apparent.	
Drug-induced pulmonary edema and pneumonitis	May follow use of heroin, other opioids, overdose of aspirin, tricyclic antidepressants, or exposure to paraquat.	May progress to overt ARDS.
Acute major pulmonary embolus (PE)	Occurs acutely, occasionally accompanied by severe hypoxemia that may be resistant to O_2 therapy like ARDS, and by hypotension, requiring pressors, mimicking ARDS with sepsis. Patients typically have risk factors for acute PE and may not have common precipitating causes of ARDS.	Chest radiograph in ARDS should have bilateral infiltrates consistent with pulmonary edema. Chest radiograph in acute major PE may have unilateral or no infiltrates. Acute major PE needs a confirmatory study, e.g., CT scan with pulmonary embolism protocol.
Sarcoidosis	The onset is not acute, but its clinical recognition may be. Oxygenation is often impaired and the chest radiograph can be diffusely abnormal.	Historical features and the frequent presence of hilar adenopathy in sarcoidosis usually eliminate confusion with ARDS.
Interstitial pulmonary fibrosis	The onset is not acute, but its clinical recognition may be. Oxygenation is often impaired and the chest radiograph can be diffusely abnormal.	Prior chest radiographs and a history of chronic and progressive dyspnea characterize the collection of diseases causing interstitial pulmonary fibrosis.

AIP, acute interstitial pneumonia; ARDS, acute respiratory distress syndrome; CT, computed tomography; DAH, diffuse alveolar hemorrhage.

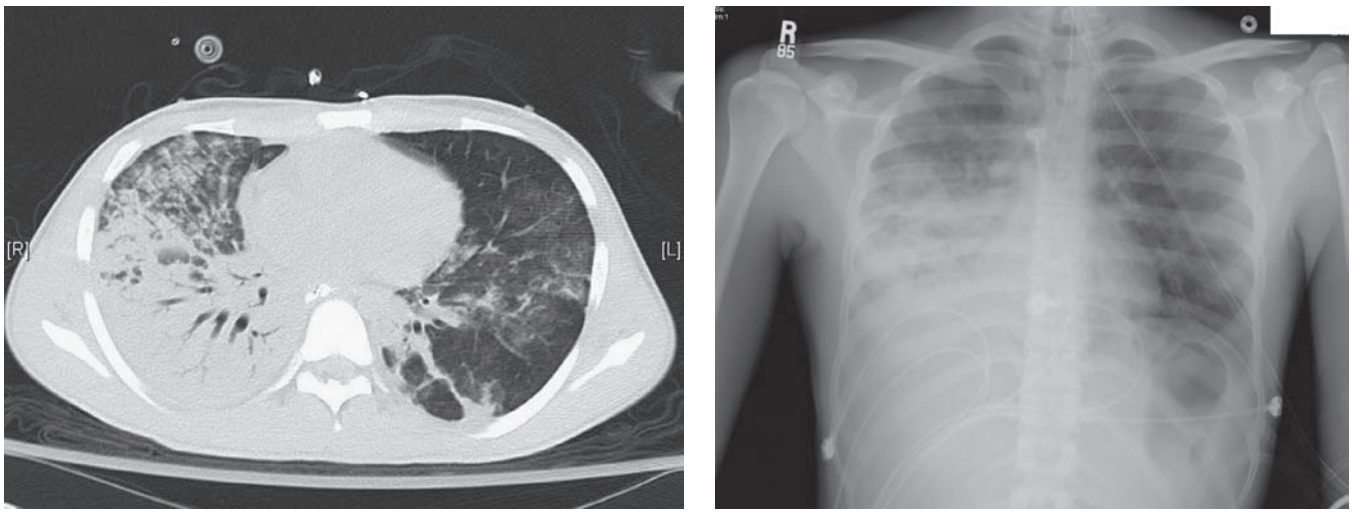
a likely cause. Additional important tests that help to differentiate ARDS from other causes of acute hypoxemic respiratory failure are discussed subsequently.

■ APPROACH TO CLINICAL DIAGNOSIS

A number of diagnostic methods are extremely valuable in evaluating suspected ARDS. Each is briefly described.

Chest Radiograph

The chest radiograph is a simple and widely available test used to assess patients with acute hypoxic respiratory failure. In cases of *established* ARDS, the chest radiograph typically demonstrates findings of diffuse, bilateral alveolar infiltrates consistent with pulmonary edema (Fig. 141-3). However, especially early in the course of the disorder, the infiltrates associated with ARDS may



A B

Figure 141-3 Chest CT and plain radiograph in ARDS. **A.** Chest CT scan reveals asymmetric lung injury, with dense consolidation at the right base, patchy alveolar infiltrates in the right anterior lung field, and patchy ground-glass infiltrates throughout the right lung. **B.** Chest radiograph obtained concurrently with chest CT scan shown in panel (**A**). Dense infiltrates at right base, patchy infiltrates in the right upper lung zone, and more subtle infiltrates in the left lung are demonstrated. The panels illustrate the subtle findings of lung injury that are more apparent on the CT scan than on the chest radiograph.

be variable: mild or dense, interstitial or alveolar, patchy or confluent.[7] In addition, the radiographic infiltrates may not correlate well with the degree of hypoxemia. For example, a patient with early ARDS may have profound hypoxemia in the setting of patchy asymmetrical infiltrates that may be interpreted as pneumonia or segmental atelectasis.

Routine chest radiographs cannot reliably distinguish hydrostatic edema, that is, cardiogenic edema, from ARDS. Nonetheless, several criteria suggest *cardiogenic* edema: increased heart size, increased width of the vascular pedicle, vascular redistribution toward upper lobes, the presence of septal lines, or a perihilar (bat's wing) distribution of the edema.[78] Lack of these findings, in conjunction with patchy peripheral infiltrates that extend to the lateral lung margins, suggests ARDS. In the proper clinical setting, despite a variable radiographic appearance, the presence of bilateral infiltrates and moderate or severe hypoxemia (Pa_{O_2}/FI_{O_2} ≤300 mm Hg) should raise the possibility of ARDS.

Laboratory Studies

Although no laboratory test is specific for the diagnosis of ARDS, arterial blood gas analysis is essential for confirming the diagnosis.[9] Pa_{O_2}/FI_{O_2} is markedly abnormal in patients with ARDS (Tables 141-1A and 141-1B). In addition to the profound oxygen therapy–resistant hypoxemia that is the hallmark of ARDS, acute respiratory alkalosis may also occur in the early stage. If a patient with ARDS then develops respiratory muscle fatigue, hypercapnia results. In late-stage ARDS, patients typically have increased minute ventilation requirements due to an increasing dead-space fraction, despite possible improvement in oxygen exchange.

In addition to arterial blood gas measurements, several other laboratory studies may be helpful in investigating other causes of respiratory failure and evaluating additional aspects of critical illness associated with ARDS. For example, cardiac enzymes (creatine phosphokinase and troponins) are useful for evaluating the presence of myocardial infarction or cardiac ischemia in patients at risk because of increased age or other factors. The results should be interpreted in conjunction with electrocardiographic findings, since elevations in cardiac enzymes, especially troponins, have been reported in patients with sepsis or septic shock in the absence of coronary artery disease.[79,80]

Another cardiac-related laboratory test that may be useful in this clinical context is plasma brain natriuretic peptide (BNP), which is secreted by the cardiac ventricles, and, to a lesser extent, the atria. BNP measurements are often utilized in the evaluation of acute shortness of breath in patients presenting to an emergency department.[81] In this group, a BNP greater than 500 pg/mL indicates that CHF is likely with a positive predictive value greater than 90%. In the same group, a BNP less than 100 pg/mL suggests that congestive heart is unlikely with a negative predictive value greater than 90%. However, interpretation of an elevated BNP in patients who are critically ill is problematic. Reports indicate that BNP increases with renal failure, and that elevations of BNP greater than 500 pg/mL may occur in patients with sepsis and normal left ventricular function.[82] Nonetheless, one can reasonably exclude a cardiac cause for acute pulmonary edema in patients in the intensive care unit if BNP is less than 100 pg/mL.

Echocardiography

Echocardiography is a useful noninvasive method to evaluate potential cardiac causes of acute hypoxemic respiratory failure.[83] Cardiogenic pulmonary edema is suggested by echocardiographic findings of mitral valve stenosis or regurgitation, left ventricular dilatation and systolic dysfunction, or regional left ventricular wall motion abnormalities. Although these findings do not rule out coexisting lung injury, they are helpful in the initial evaluation and management, even in the presence of ARDS.

Invasive Hemodynamic Monitoring

Although pulmonary artery catheterization has been performed often in patients with pulmonary edema, the benefits of the procedure are controversial and the topic of recent investigations (see Chapter 147, Hemodynamic and Respiratory Monitoring in Acute Respiratory Failure).[11,84] Several studies have demonstrated that physician interpretation of data obtained from PACs is inconsistent and often erroneous.[85–87] Previous definitions of ARDS have suggested the measurement of PAOP to distinguish ARDS from cardiogenic

pulmonary edema[3]; however, the recently accepted Berlin definition of ARDS eliminates such suggestions, recognizing the problems inherent in use of PACs.[9] Studies have demonstrated that many patients who originally met AECC criteria for ARDS (i.e., had a PAOP ≤18 mm Hg) often have subsequent measurements with a PAOP >18 mm Hg.[12,88] Furthermore, the Berlin definition recognizes the possibility of concomitant ARDS and cardiogenic edema.

Results of the ARDSNet Fluid and Catheter Treatment Trial (FACCT) support the removal of PAOP criteria from the definition of ARDS, acknowledging that a threshold of 18 mm Hg is arbitrary.[11] FACTT was a large, randomized clinical trial that used a two-by-two factorial design to test a fluid-conservative management strategy against a fluid-liberal management strategy in ARDS. The study also assessed safety and efficacy of a central venous catheter (CVC) or PAC to guide fluid management. In FACTT, 29% of 513 patients enrolled in the PAC arm of the trial were found to have a PAOP greater than 18 mm Hg at the time of initial measurement (following passage of the catheter shortly after enrollment and randomization). Before enrollment, FACTT investigators believed that these patients lacked a primary cardiogenic cause for their pulmonary edema. Approximately one-half of the patients had PAOPs of 19 or 20 mm Hg. Since the vast majority (97%) of this group had a normal cardiac index (≥2.5 L/m^2/min) and a mortality similar to other subjects in FACTT, the elevated PAOP (>18 mm Hg) likely reflected intravascular volume loading, rather than cardiogenic pulmonary edema.

Bronchoalveolar Lavage

Bronchoscopy with bronchoalveolar lavage (BAL) is an important tool in the evaluation of patients who have ARDS of unclear origin. In general, BAL can be performed safely in patients with ARDS, except in those with a very low Pa_{O_2} or those requiring high levels of PEEP. The principal reason for performing bronchoscopy in ARDS is to rule in or rule out acute processes that may have specific therapies.

For example, acute eosinophilic pneumonia is a rare disorder characterized by diffuse eosinophilic infiltrates in the lungs (Table 141-6).[89] When the precipitating cause for ARDS is uncertain, performance of BAL and measurement of the percent of eosinophil count in the lavage fluid is helpful in establishing a diagnosis of this corticosteroid-responsive disorder.

Likewise, BAL may be diagnostic for diffuse alveolar hemorrhage (see Chapter 68, Alveolar Hemorrhage Syndromes).[90] In this case, the bronchoscopy may or may not reveal fresh blood in the trachea and major bronchi. However, BAL generally demonstrates blood-tinged fluid, which contains red blood cells and hemosiderin-laden macrophages. Diffuse alveolar hemorrhage may occur following bone marrow transplantation or as a result of rheumatologic or other immunologic disorders, including Goodpasture syndrome, granulomatosis with polyangiitis (formerly known as Wegener granulomatosis), systemic lupus erythematosus, or antiphospholipid antibody syndrome.

Lung Biopsy

Routine lung biopsy is not recommended in ARDS; however, lung biopsy should be considered if alternative etiologies of respiratory failure cannot be adequately excluded. While many patients with ARDS are not sufficiently stable to undergo a lung biopsy, the safety of a surgical lung biopsy has been demonstrated in a highly selective group of patients with hypoxic respiratory failure.[91,92] In general, lung biopsy should be reserved for a highly selective group of patients where alternative diagnoses are possible and would significantly change management and prognosis.

APPROACH TO TREATMENT

The general approach to treatment of ARDS includes addressing precipitating causes and other concurrent clinical issues, ensuring adequate oxygenation, careful implementation of a lung-protective ventilator strategy, prudent fluid and hemodynamic management, special patient positioning coupled with the so-called "lung recruitment" maneuvers, and a multitude of other measures, including pharmacologic considerations. Each is discussed subsequently.

TABLE 141-7 Goals of Management of Patients with ARDS

Treatment of respiratory system abnormalities
Diagnose and treat the precipitating cause of ARDS, if possible (Table 141-8)
Maintain oxygenation, preferably using nontoxic $F_{I_{O_2}}$ (<0.7), PEEP, or mechanical ventilation
Prevent ventilator-induced lung injury (VILI) by using a low tidal volume ventilatory strategy (Table 141-9) with a limit (≤30 cm H_2O) on static end-inspiratory airway pressure (plateau pressure)
Keep pH in normal range without compromising goal to prevent VILI (but reverse a life-threatening acidosis, even if it prevents meeting goal to prevent VILI)
Enhance patient–ventilator synchrony and patient comfort by use of sedation, amnesia, opioid analgesia, and pharmacologic paralysis, if necessary
Liberate or wean from mechanical ventilation when patient can breathe without assisted ventilation
Treatment of nonrespiratory system abnormalities
Support or treat other organ system dysfunction or failure
General critical care (preventive and homeostatic measures)
Adequate early nutritional support

■ GOALS OF MANAGEMENT

Management of patients with ARDS can be complicated and challenging because clinicians are often faced with simultaneous failure of both respiratory and nonrespiratory organ systems (Table 141-7). Unfortunately, only a limited set of controlled clinical trials are available to support an evidence-based approach. For example, even large, multicenter, randomized clinical trials, such as those done by ARDSNet, are limited in the number of variables that can be tested. As a result, patient management rests on a combination of relevant evidence-based medicine, extrapolations from basic and clinical research, and experience-based approaches.

■ DIAGNOSIS AND TREATMENT OF PRECIPITATING CAUSES AND OTHER COMORBIDITIES

The first step in the therapy of ARDS is identification and treatment of the precipitating cause(s) and any other life-threatening medical or surgical issues (Fig. 141-4).

Since ARDS is a *syndrome* based on nonspecific radiographic and physiologic criteria, establishing a diagnosis of ARDS is *not* equivalent to diagnosing the precipitating cause. The fact that early identification and treatment directed at the inciting cause(s) of ARDS are imperative for the resolution of lung injury and respiratory failure cannot be overemphasized. Treatable inciting causes of ARDS include a variety of infectious and noninfectious disorders (Table 141-8).

■ MANAGEMENT OF RESPIRATORY FAILURE

Management of respiratory failure in ARDS rests on assurance of adequate oxygenation and carefully crafted ventilatory strategies, as outlined in the following sections.

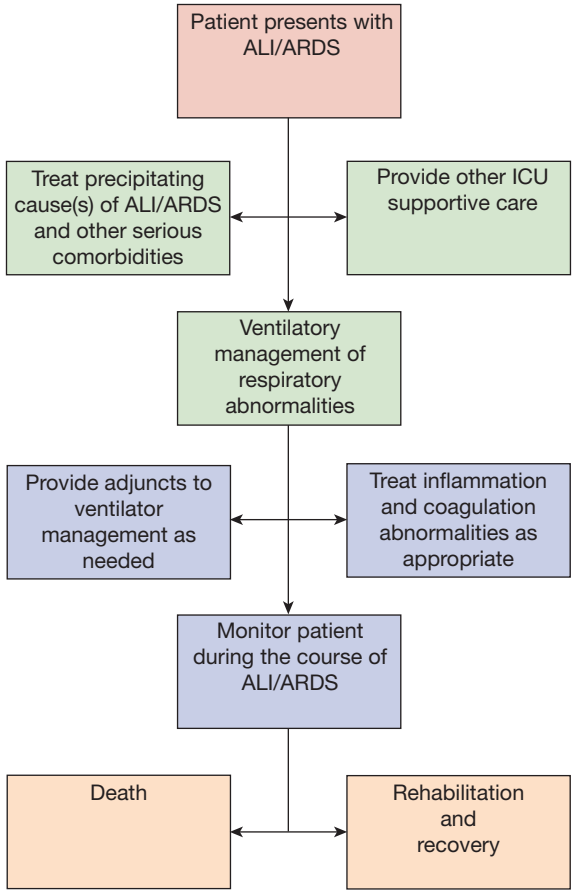


Figure 141-4 Summary of treatment approach to ARDS. Note that, "Treat inflammation and coagulation abnormalities as appropriate," is currently limited. In the ARDSNet "LaSRS" clinical trial, physiologic improvement, but no mortality benefit, was found with high-dose corticosteroid therapy for persistent (late phase) ARDS (see text for details). *(Reproduced with permission from Christie JD, Lanken PN. Acute lung injury and the acute respiratory distress syndrome. In: Hall JB, Schmidt GA, Wood LDH, eds. Principles of Critical Care. 3rd ed. New York, NY: McGraw-Hill; 2004.)*

TABLE 141-8 Treatable Inciting Causes of ARDS

Infectious etiologies
Bacterial or other sepsis, e.g., fungemia, responsive to antimicrobial therapy
Diffuse bacterial pneumonias, e.g., Legionella species
Diffuse viral pneumonias, e.g., cytomegalovirus, influenza A
Diffuse fungal pneumonias, e.g., Candida species, Cryptococcus
Pneumocystis jiroveci pneumonia
Other diffuse lung infections, e.g., military tuberculosis
Noninfectious etiologies
Diffuse alveolar hemorrhage post–bone marrow transplantation
Diffuse alveolar hemorrhage due to vasculitis, e.g., Goodpasture syndrome
Acute eosinophilic pneumonia
Lupus pneumonitis
Toxic drug reactions, e.g., aspirin

Maintaining Adequate Oxygenation

As noted, the pathophysiologic hallmark of ARDS is hypoxemia that is resistant to oxygen therapy. Maintaining adequate arterial oxygenation is the primary goal of both traditional and newer ("lung-protective") approaches to assisted ventilation.

As expected with shunt physiology, administration of supplemental oxygen provided by high-flow oxygenation systems, for example, a nonrebreather face mask, is generally ineffective in reversing the oxygenation deficit. Exceptions to this rule are some patients with mild or transient cases of ARDS that are otherwise uncomplicated by other organ system failures.

Upon intubation, most patients with ARDS require high levels of $F_{I_{O_2}}$ to maintain oxygenation; however, high concentrations of oxygen may potentially be toxic. While not studied adequately in patients with ARDS, studies of animals and healthy humans have demonstrated the toxic effects of oxygen therapy within hours of its initiation.[93,94] Given the theoretical concern for oxygen toxicity, PEEP is employed to improve oxygenation by reducing physiologic shunt. When utilized in sufficient amounts, PEEP generally results in some degree of correction of the hypoxemia in patients with ARDS, thereby allowing $F_{I_{O_2}}$ to be lowered from high, potentially toxic concentrations. Although PEEP is usually used in conjunction with mechanical ventilation, in selected cases of mild ARDS it may be effective when applied by means of a continuous positive airway pressure (CPAP) mask or as the lower level of bilevel noninvasive ventilation. The effect of PEEP-induced improvement in arterial oxygenation is attributed predominantly to recruitment of collapsed alveoli. However, application of PEEP may also mediate a redistribution of alveolar fluid into the interstitium and decrease the absolute magnitude of shunt by reducing cardiac output.

Acutely ill patients in intensive care units typically receive assisted ventilation via an endotracheal tube. In selected non-ARDS disorders, for example, COPD or acute cardiogenic pulmonary edema, noninvasive ventilation has been shown to be as effective as invasive ventilation.[95,96] Although the routine use of noninvasive ventilation for patients with ARDS lacks compelling evidence, the data are limited. In a small randomized trial of 40 patients with mild ARDS (formally referred to as ALI), patients receiving noninvasive ventilation were less likely to require intubation than those receiving supplemental oxygen alone; however, the study was small and not fully blinded.[97] One reason for limited study of noninvasive ventilation in ARDS is the high incidence of concomitant, nonrespiratory organ failure (e.g., multisystem organ failure due to septic shock). Except for select subgroups, for example, immunosuppressed patients with hypercapnic respiratory failure who are hemodynamically stable, use of noninvasive ventilation for patients with ARDS generally should be avoided.

Lung-Protective Mechanical Ventilation

As described in Chapter 140, over the past 30 years investigators have convincingly shown that large tidal volumes delivered during mechanical ventilation can injure lungs of normal animals, producing a pathologic pattern resembling ARDS in humans.[98,99]

In animal models of ALI, use of large tidal volume ventilation has been found to augment pre-existing injury. In addition, repetitive opening and closing of alveoli during inspiration and expiration induces ALI in normal animals.[100,101] The injury can be prevented by application of sufficient PEEP. Finally, overexpansion of alveoli in normal lungs of sheep induces multiorgan failure,[102] with studies in other species showing that lung overexpansion results in systemic

release of proinflammatory cytokines—providing a likely mechanism for these remote deleterious effects.[103–105] These observations support the concept that the lung is an "engine of inflammation."

Concurrent with the previously described observations, clinical investigators studying patients with ARDS using computed tomography observed that, in contrast to the typical diffuse-appearing pattern noted on plain chest radiographs, the pattern of consolidation, atelectasis, and normal alveoli is actually heterogeneous (Fig. 141-3).[106] The key physiologic implication of these observations is that a ventilator-delivered tidal volume is preferentially distributed to the open alveoli, which represent only a small fraction of the entire lung.[107] In referring to this lung fraction as "the baby lung" investigators emphasized the potential danger of delivering traditional tidal volumes of 10 to 15 mL/kg actual body weight and the associated risk for alveolar overexpansion and lung injury. Notably, tidal volumes of 10 to 15 mL/kg actual body weight (equivalent to approximately 12 to greater than 15 mL/kg predicted body weight) were used originally in critically ill patients with ARDS as a complementary strategy to PEEP in recruiting atelectatic alveoli.

These productive lines of basic and clinical research strongly support the hypothesis that mechanical ventilation using limited tidal volumes should be less injurious to the lungs of patients with ARDS and should result in better outcomes (i.e., decreased mortality) compared with use of traditional, large tidal volume ventilation. Several randomized controlled trials have been conducted to address the role of low tidal volume ventilation in ARDS, including the landmark ARDSNet trial, ARMA, discussed in detail below.[4,108] Recent meta-analyses of multiple trials support a low tidal volume ventilation approach to reduce mortality in ARDS.[109,110]

In summary, the goals of lung-protective ventilation are to avoid injury due to overexpansion of alveoli during inspiration (so-called "volu-trauma") and injury due to repetitive opening and closing of alveoli during inspiration and expiration (so-called "atelecta-trauma") (Fig. 141-5). The injurious effects of mechanical

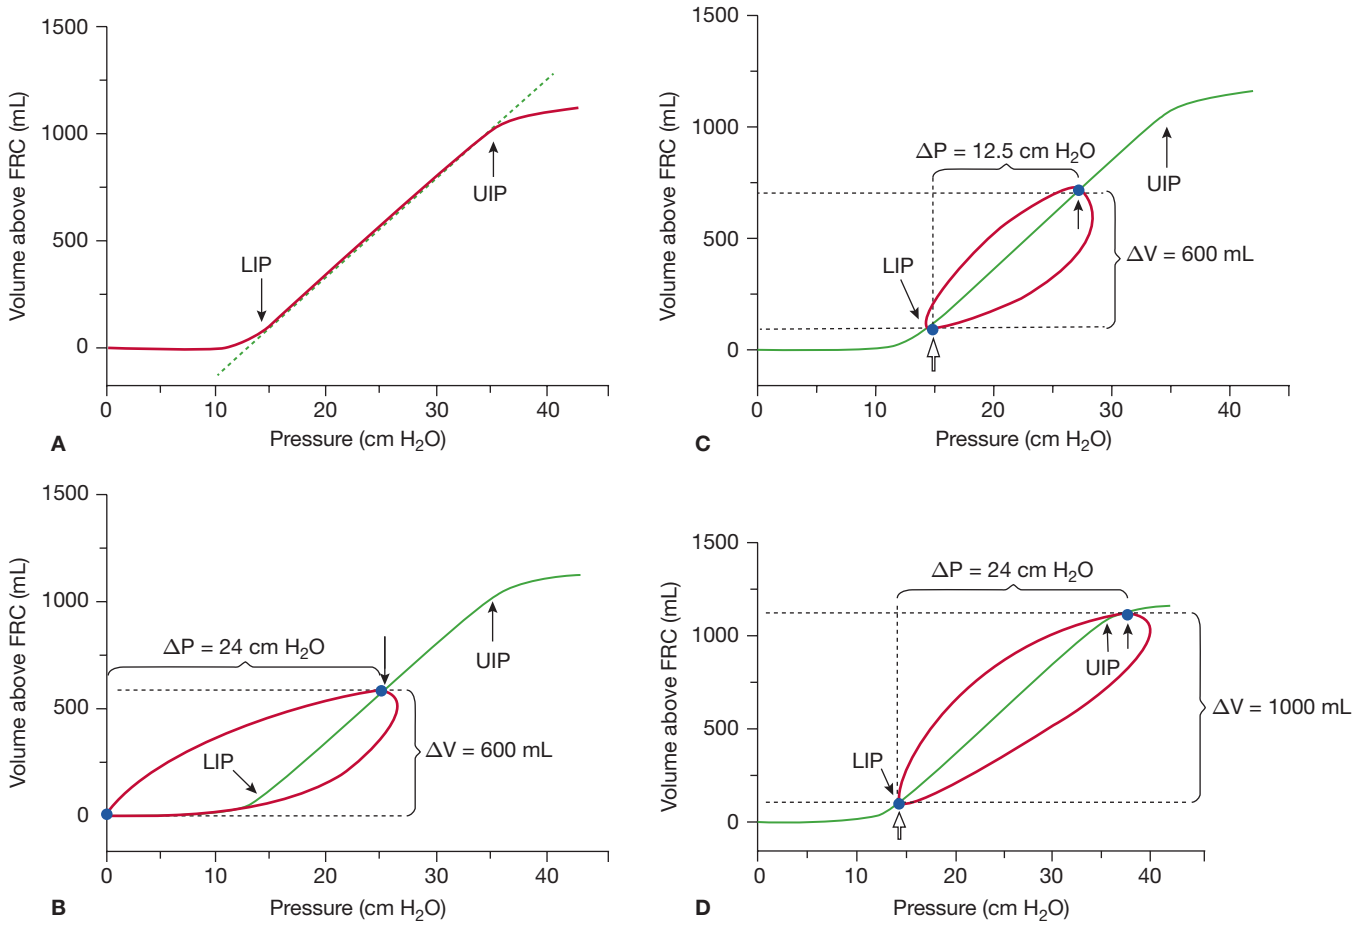

Figure 141-5 **A.** Schematic inspiratory static pressure–volume (P–V) curve of the respiratory system (lung and chest wall combined) in ARDS. Lower inflection point (LIP) is approximately 14 cm H_2O, and upper inflection point (UIP) is approximately 35 cm H_2O. Abscissa is respiratory system recoil pressure; ordinate is lung volume above functional residual capacity (FRC). **B.** Same static P–V curve as (**A**), plus dynamic P–V curve of 600 mL tidal volume starting below the LIP (PEEP = 0). This tidal volume results in a plateau pressure *(closed arrow)* below the UIP (24 cm H_2O). Static compliance (Cstat = $\Delta V/\Delta P$ = 600 mL/24 cm H_2O) is 25 mL/cm H_2O. **C.** PEEP of 15 cm H_2O has moved the starting point for the 600 mL tidal volume up the static P–V curve to a new FRC *(open arrow)*, which is at the LIP. The tidal volume results in a plateau pressure of 27.5 cm H_2O *(closed arrow)*, which is well below the UIP. Cstat ($\Delta V/\Delta P$ = 600 mL/12.5 cm H_2O) is increased to 48 mL/cm H_2O. **D.** Dynamic P–V curve of a 1000 mL tidal volume, starting at 14 cm H_2O PEEP, results in a plateau pressure of 37.5 cm H_2O *(closed arrow)*. Despite an increase in Cstat ($\Delta V/\Delta P$ = 1000 mL/24 cm H_2O = 41.5 mL/cm H_2O), compared with Cstat derived from the 600 mL tidal volume in (**B**), the plateau pressure associated with the 1000 mL tidal volume exceeds the UIP. Delivery of an inflation volume that results in a plateau pressure exceeding the UIP implies alveolar overdistension and is believed to put the lung at risk for ventilator-induced lung injury (see text). *(Reproduced with permission from Lanken PN. Acute respiratory distress syndrome. In: Lanken PN, Hanson CW III, Manaker S, eds. The Intensive Care Unit Manual. Philadelphia, PA: Saunders; 2001.)*

ventilation on the lung have been referred to as ventilator-induced lung injury or "VILI." The term "bio-trauma" encompasses the direct lung injury and the concomitant release of inflammatory cytokines that produce remote cell death or organ injury.[111] Clinical strategies underlying contemporary applications of mechanical ventilation in treatment of ARDS are described subsequently.

ARDSNet Ventilator Strategies: Low Versus Traditional Tidal Volumes Based on the aforementioned considerations, the ARDSNet conducted a randomized trial (ARMA) in the mid-to-late 1990s to test the hypothesis that low tidal volume ventilation, combined with limited end-inspiratory (plateau) pressure, would lower mortality and ventilator days among survivors of ARDS compared with use of traditional tidal volumes.[4] The trial included 861 subjects. The low tidal volume arm consisted of a tidal volume of 6 mL/kg predicted body weight, as long as the end-inspiratory pressure (Pplat) was ≤30 cm H_2O; if Pplat exceeded 30 cm H_2O, the tidal volume could be decreased to as low as 4 mL/kg. The traditional tidal volume arm used a tidal volume of 12 mL/kg predicted body weight, as long as the Pplat remained <50 cm H_2O. Both arms included explicit goals and protocols as the bases for ventilator adjustments and determination of the time and means of weaning (Table 141-9).

Important results of the ARMA trial are summarized in Table 141-10. The difference in actual tidal volumes resulted from protocol-driven target tidal volumes in each study arm. As expected, the mean plateau pressure for the lower tidal volume group was <30 cm H_2O (25 cm H_2O), since the protocol required decreasing the tidal volume from 6 mL/kg predicted body weight to as low as 4 mL/kg if Pplat exceeded 30 cm H_2O. Of note, the traditional tidal volume group had a mean Pplat of 33 cm H_2O on study day 1 – a value less than the threshold of 35 cm H_2O that some clinicians had believed represented a safe threshold.

Despite the fact that the clinical trial used an arbitrary threshold of 30 cm H_2O for Pplat in the lower tidal volume arm, it should not be assumed that any Pplat ≤30 cm H_2O is safe. If a "safe" upper limit of Pplat exists, its value is unknown. Lack of such a safe threshold is supported by the finding of an absence of any significant interaction between differences in mortality and quartiles of static respiratory compliance or quartiles of plateau pressures (Fig. 141-6). These results suggest that the lower tidal volume ventilatory strategy tends to be effective across a wide range of baseline static compliances and plateau pressures. Likewise, a statistical model of mortality proportion versus day 1 Pplat which combined data from both arms of this clinical trial suggests that, in general, the lower the Pplat, the lower the associated mortality (Fig. 141-7).[112]

These considerations are important, since some clinicians may believe that they can achieve the improved mortality rate simply by lowering tidal volumes to the point where Pplat is at or slightly less than 30 cm H_2O, instead of following the ARDSNet low tidal volume strategy of using a tidal volume of 6 mL/kg predicted body weight. In addition, recognition of the need to use predicted, rather than actual, body weight is important, since the latter has been estimated

TABLE 141-9 NIH NHLBI ARDS Clinical Trials Network Low Tidal Volume Ventilation Strategy

Part I: Ventilator Setup and Adjustment

1. Calculate ideal body weight (IBW)[a] (also known as predicted body weight [PBW])
2. Use Assist/Control mode and set initial TV to 8 mL/kg IBW (if baseline TV >8 mL/kg)
3. Reduce TV by 1 mL/kg at intervals ≤2 h until TV = 6 mL/kg IBW
4. Set initial rate to approximate baseline $\dot{V}_E$ (but not >35 bpm)
5. Adjust TV and RR to achieve pH and plateau pressure (Pplat) goals below.
6. Set inspiratory flow rate above patient demand (usually >80 L/min); adjust flow rate to achieve goal of I:E ratio of 1:1.0–1.3

Part II: Oxygenation Goal: Pa_{O_2} = 55–80 mm Hg or Sp_{O_2} = 88–95%

1. Use these incremental $F_{I_{O_2}}$-PEEP combinations to achieve oxygenation goal:

$F_{I_{O_2}}$	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12
$F_{I_{O_2}}$	0.7	0.8	0.9	0.9	0.9	1.0	1.0	1.0
PEEP	14	14	14	16	18	20	22	24

Part III. Plateau Pressure (Pplat) goal: ≤30 cm H_2O

1. Check Pplat (use 0.5-s inspiratory pause), Sp_{O_2}, total RR, TV, and ABG (if available) at least every 4 h and after each change in PEEP or TV.
2. If Pplat >30 cm H_2O, decrease TV by 1 mL/kg steps (minimum 4 mL/kg IBW)
3. If Pplat <25 cm H_2O and TV <6 mL/kg, increase TV by 1 mL/kg until Pplat >25 cm H_2O or TV = 6 mL/kg.
4. If Pplat <20 cm H_2O and breath stacking occurs, one may increase TV in 1 mL/kg increments (to a maximum of 8 mL/kg)

Part IV. pH Goal: 7.30–7.45

Acidosis management: pH <7.30

1. If pH = 7.15–7.30, increase RR until pH >7.30 or Pa_{O_2} <25 mm Hg (maximum RR = 35); if RR = 35 and Pa_{CO_2} <25 mm Hg, may give NaH_{CO_3}
2. If pH <7.15 and NaH_{CO_3} considered or infused, TV may be increased in 1 mL/kg steps until pH >7.15 (Pplat goal may be exceeded)

Alkalosis management: pH >7.45: decrease RR, if possible

ABG, arterial blood gas; RR, respiratory rate on ventilator; Sp_{O_2}, Oxygen saturation by pulse oximetry; TV = tidal volume; $\dot{V}_E$, minute ventilation.

[a]*Male IBW, 50 + 2.3 (height [inches] – 60); female IBW, 45.5 + 2.3 (height [inches] – 60).*

TABLE 141-10 Results of NIH NHLBI ARDS Clinical Trials Network Low Tidal Volume Versus Traditional Tidal Volume Clinical Trial ("ARMA")

Variable or Outcome	Units	Low Tidal Volume Ventilatory Strategy Mean ± SD	Traditional Tidal Volume Ventilatory Strategy Mean ± SD	*p* Value
Tidal volume on day 1	mL/kg PBW	6.2 ± 0.9	11.8 ± 0.8	<0.05
Plateau pressure on day 1	cm H_2O	25 ± 7	33 ± 9	<0.05
PEEP on day 1	cm H_2O	9.4 ± 3.6	8.6 ± 3.6	<0.05
Pa_{CO_2}: $F_{I_{O_2}}$ on day 1		158 ± 73	176 ± 76	<0.05
Pa_{CO_2} on day 1	mm Hg	40 ± 10	35 ± 8	<0.05
Death before discharge or 180 days	%	31.0	39.8	0.007
Breathing without assistance at day 28	%	65.7	55.0	<0.001
No. of ventilator-free days by day 28		12 ± 11	10 ± 11	0.007
No. of days without failure of nonpulmonary systems by day 28		15 ± 11	12 ± 11	0.006

PBW, predicted body weight (see footnote of Table 145-9 for details); PEEP, positive end expiratory pressure; SD, standard deviation; ventilator-free days by day 28, number of days alive and not receiving assisted ventilation between days 1 and 28.
Source: Adapted with permission from Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. The Acute Respiratory Distress Syndrome Network. N Engl J Med. 2000;342(18):1301–1308.

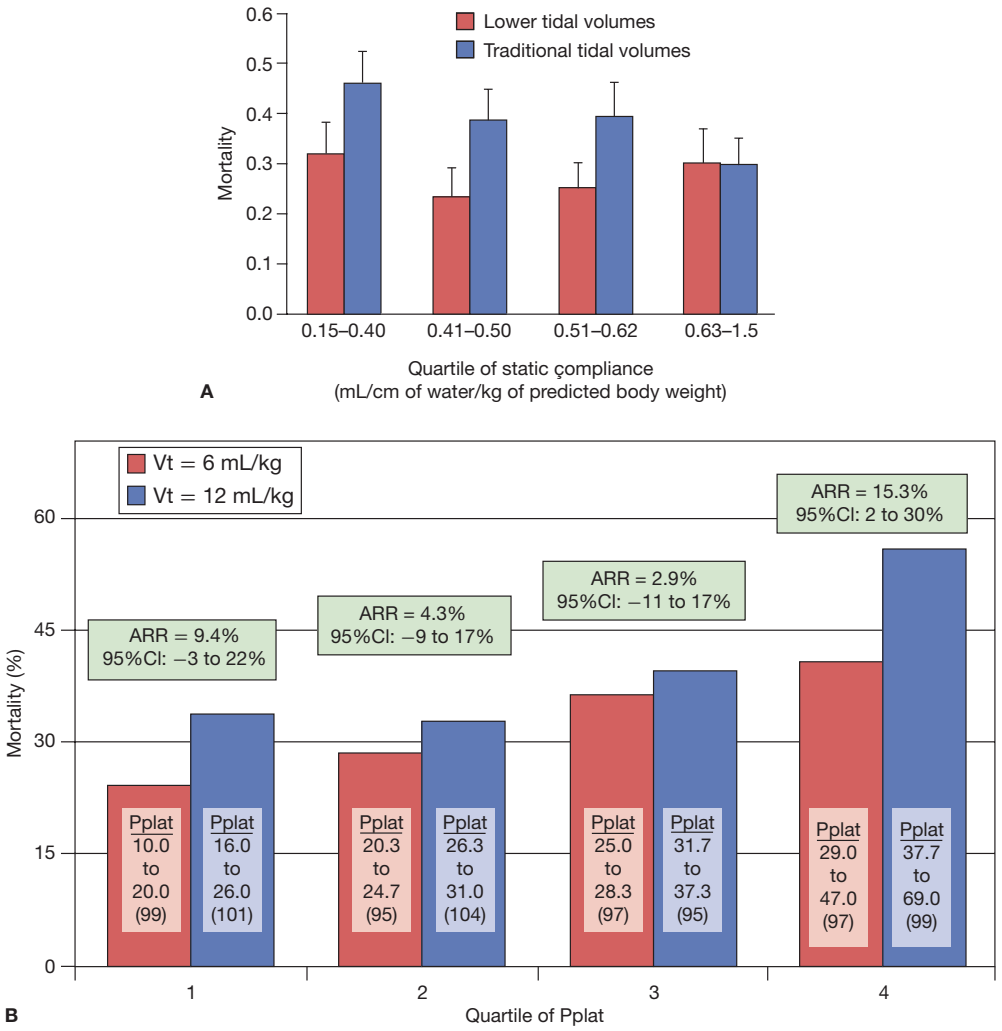

Figure 141-6 ARDSNet ARMA study. Mortality according to quartiles of treatment group (**A**) and end-inspiratory pressure (plateau pressure, Pplat) (**B**) on day 1 in 787 subjects for whom Pplat data are available. Pplat was measured using protocol-dictated tidal volumes. Subjects with the stiffest lungs are likely to have Pplat in the fourth quartile (far right). Range of Pplat (cm H_2O) and number of subjects (parentheses) are shown in each bar of the graph (ARR, (absolute risk reduction; CI, confidence interval). Lower tidal volume ventilation appears to benefit patients with ARDS across a range of Pplat. The hypothesis that a "safe" upper limit exists for Pplat, below which ventilator-induced lung injury does not occur, is *not* supported by the data. *(Reproduced with permission from Hager DN, Krishnan JA, Hayden DL, et al. Tidal volume reduction in patients with acute lung injury when plateau pressures are not high. Am J Respir Crit Care Med. 2005;172(10):1241–1245.)*

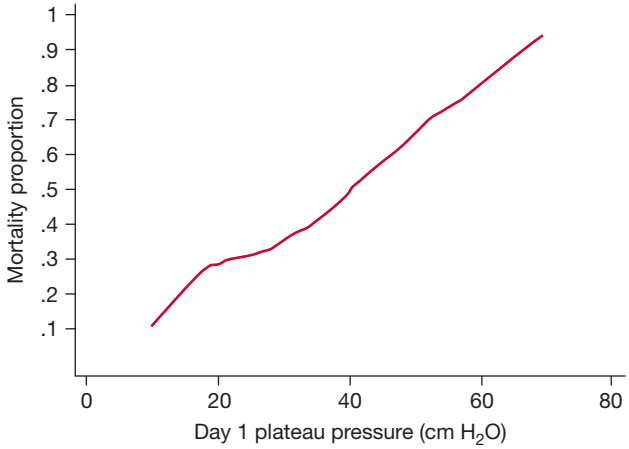

Figure 141-7 Lowess (locally weighted regression and smoothing) plot (bandwidth, 0.4) of mortality proportion and day 1 plateau pressure (Pplat, cm H_2O) for 787 patients enrolled in the ARDSNet ARMA study. Plot includes same subjects and Pplat shown in Figure 141-6. When expressed using this estimating method, the data do not support a safe upper limit for Pplat, the presence of which would be suggested by a leveling in mortality proportion, rather than a further decrease, as the plot demonstrates. The Lowess method is a nonparametric smoother that uses overlapping neighborhoods of data to estimate a local effect. A bandwidth of 0.4 means that 20% of the data on either side of a given Pplat contribute to a local estimate of mortality at that Pplat; data at the high and low ends of the curve represent fewer observations. As data are smoothed using a tricubic weight function, points furthest from the Pplat of interest are assigned the least weight and approach zero. *(Reproduced with permission from Hager DN, Krishnan JA, Hayden DL, et al. Tidal volume reduction in patients with acute lung injury when plateau pressures are not high. Am J Respir Crit Care Med. 2005;172(10):1241–1245.)*

to be about 20% greater than the former (due to fat and extravascular fluid). In summary, clinicians should employ the *entire* ARDSNet protocol (Table 141-9), rather than selected parts in attempting to achieve comparably favorable mortality results.

Lung Protection due to Higher PEEP The initial ARDSNet trial (ARMA) described earlier did not address the question of whether application of higher levels of PEEP than used traditionally is beneficial.[4] The possibility of improved outcomes using higher levels of PEEP was suggested by both basic and clinical studies conducted in the early 1990s.[5] To address whether higher levels of PEEP combined with low tidal volumes decrease mortality, the ARDSNet conducted a second ventilator clinical trial (ALVEOLI) in which each of two groups received the same low tidal volume ventilatory strategy, but one group was treated using an additional 4 to 5 cm H_2O of PEEP.[30] Mortality rates at day 60 were below 30% for both groups and were not significantly different, even after adjustment for imbalances in baseline variables. Similarly, ventilator-free days were not significantly different.

Subsequently, two further trials were conducted to address the role of a high PEEP strategy, the Lung Open Ventilation to Decrease Mortality in ARDS (LOVS) trial and the Expiratory Pressure Study (EXPRESS).[113,114] Neither study demonstrated a difference in the primary mortality outcomes between the control and intervention groups. However, the high PEEP strategy improved secondary endpoints, including use of rescue therapies in LOVS and duration of mechanical ventilation and organ failure in EXPRESS. More recently, a meta-analysis combined the data from AVEOLI, LOVS, and EXPRESS.[115] Treatment with higher levels of PEEP was not associated with an in-hospital mortality benefit, but among patients with a Pa_{O_2}/FI_{O_2} <200 there appeared to be a reduction in mortality. In addition, other studies have demonstrated that while some patients with ARDS have little or no alveolar recruitment (i.e., opening previously collapsed or fluid filled airspaces) with increased levels of PEEP, others PEEP show marked recruitment.[116] This suggests that future clinical trials using higher PEEP be restricted to subjects with ARDS in whom PEEP increments can reliably result in recruitment.

Recommended Core Ventilator Management We recommend that as the core ventilator management in ARDS, clinicians follow the ARDSNet low tidal volume ventilatory strategy (Table 141-9).[4] Because higher levels of PEEP have not yet been found to improve outcomes, unless new evidence arises to the contrary, we also recommend that clinicians follow the same combinations of FI_{O_2} and PEEP used in the first ARDSNet trial, ARMA (Table 141-9). Alternatively, clinicians can consider assessing PEEP responsiveness and increasing PEEP in those that demonstrate significant improvements in oxygenation with the addition of higher levels of PEEP.

Because of constraints of sample size, the ARMA trial tested the low-volume strategy only against use of tidal volumes of 12 mL/kg predicted body weight. Notably, a strategy using 6 mL/kg has not been shown to be superior to a strategy using tidal volumes of 8 to 10 mL/kg. However, based on the previous descriptions of ventilator-induced lung injury (VILI) and biotrauma, we believe it is prudent for clinicians to strictly follow the ARDSNet protocol as their core management strategy in ARDS. Modifications should be considered only in special cases, for example, when contraindications for permissive hypercapnia exist (Table 141-11).

Other Approaches to Ventilator Management

In addition to the low-volume protocol described, several additional approaches may be used in the management of ARDS and are discussed briefly subsequently.

Pressure Control Mode The ARDSNet low tidal volume strategy used the volume-assist-control mode – a familiar device setting and the only ventilator intervention that has been shown thus far to improve long-term survival in patients with ARDS.[4] However, other modes of ventilation can also provide low tidal volume ventilation, including pressure control ventilation (PCV).

TABLE 141-11 Contraindications to Permissive Hypercapnia and Acute Respiratory Acidosis

Increased intracranial pressure from any cause (trauma, mass lesion, malignant hypertension)
Acute cerebrovascular disorders, e.g., stroke
Acute or chronic myocardial ischemia
Severe pulmonary hypertension
Right ventricular failure
Uncorrected severe metabolic acidosis
Sickle cell anemia
Tricyclic antidepressant overdose
Patients taking beta-blockers
Pregnancy (due to potential for decreased fetal blood flow from vasodilation-induced steal syndrome; in addition, shift to the right of the O_2 dissociation curve decreases the maternal-fetal gradient for O_2)

PCV can limit maximal peak airway pressure as well as end-inspiratory pressure (Fig. 141-8A) and, hence, is favored by some clinicians. However, the end-inspiratory pressure in PCV can be underestimated. For example, using PCV with an inspiratory pressure of 30 cm H_2O and a PEEP of 10 cm H_2O, the end-inspiratory pressure is 40 cm H_2O (the sum of the two pressures). Some may misinterpret this combination as equivalent to a Pplat of 30 cm H_2O and assume that it is a "safe" value according to interpretation of ARDSNet results. As discussed previously, however, no Pplat is known to be safe, even when end-inspiratory pressure is calculated correctly. Furthermore, use of PCV to mimic both tidal volume and

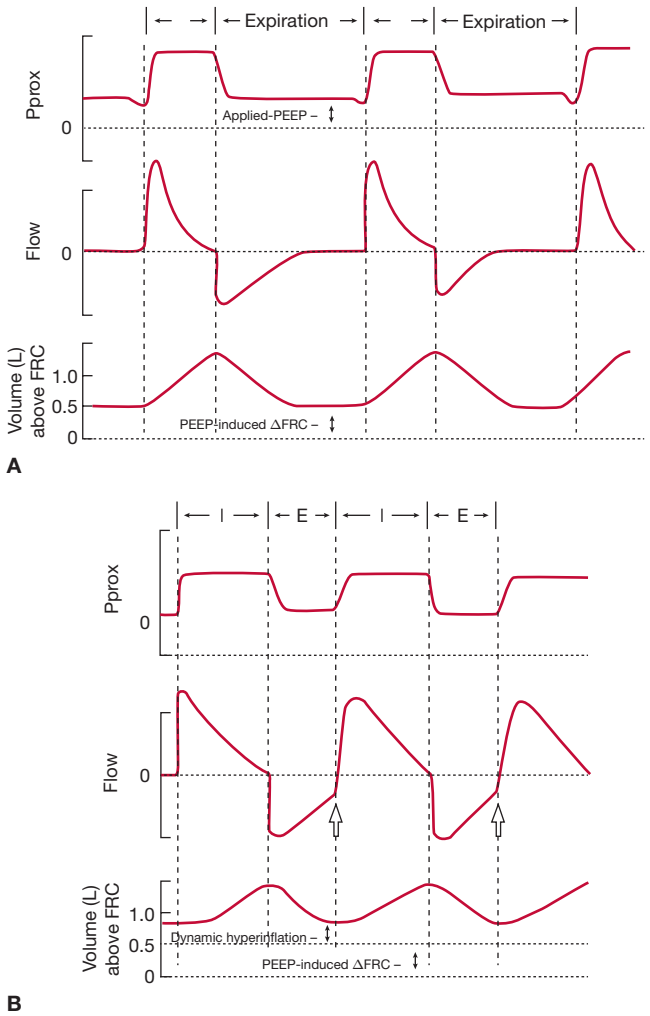

Figure 141-8 Schematic depiction of pressure, flow, and volume waveforms during pressure control ventilation (PCV) with applied PEEP. The x-axis is time and y-axes (from top to bottom) are proximal airway pressure (P_{prose}), inspiratory flow, and volume above functional residual capacity (FRC). Other abbreviations: I, inspiration, ΔFRC, change in FRC. **A.** The inspiratory-to-expiratory (I:E) time is about 1:2. The pressure waveform resembles pressure support ventilation, and the flow pattern is characterized by marked deceleration. Applied PEEP increases FRC (PEEP effect). **B.** I:E time is reversed (I > E), representing pressure-controlled inverse ratio ventilation (PC-IRV). As a result, the next breath starts before expiratory flow has returned to zero (*open arrows*), resulting in auto-PEEP and dynamic hyperinflation. The latter is superimposed on the increased FRC due to the applied PEEP. *(Reproduced with permission from Lanken PN. Acute respiratory distress syndrome. Pressure-controlled inverse ratio ventilation (PC-IRV)
Prone positioning
Recruitment maneuvers
Tracheal gas insufflation (TGI)

Pplat used in the ARDSNet trial remains problematic. The tidal volume delivered at a set pressure in PCV is dependent on the compliance of the respiratory system and is, therefore, variable, particularly in ARDS. The benefit seen from using the ARDSNet strategy may have been due as much to the use of low tidal volume as to lower Pplat. It may be difficult in PCV to ensure tidal volumes are limited, particularly as compliance improves as ARDS improves, which will result in larger tidal volumes at the same set pressure.

Inverse ratio ventilation (IRV) with PCV is based upon an inspiratory time (I) greater than expiratory time (E), that is, I:E >1 (Fig. 141-8B). Lengthening the inspiratory time increases mean airway pressure because more of the respiratory cycle is spent in inspiration, which may translate into improvements in oxygenation. However, IRV also limits the time for exhalation, potentially resulting in dynamic hyperinflation and auto-PEEP. While increasing auto-PEEP may translate to improved oxygenation, it also results in high pulmonary pressures that may not be lung-protective. IRV with auto-PEEP plus applied PEEP may also compromise cardiac output and increase the risk of nonpulmonary organ dysfunction. Clinicians should consider using PCV–IRV only as a "salvage" mode of ventilation (Table 141-12).

Modes that Allow Spontaneous Breathing During Positive Pressure Ventilation Two ventilatory modes of modern, microprocessor-based devices that permit spontaneous breathing to occur at any phase of the respiratory cycle during assisted ventilation include biphasic airway pressure (BIPAP) and airway pressure release ventilation (APRV). In each, airway pressure cycles between higher and lower levels of PEEP at preset time intervals. APRV represents the extreme of BIPAP whereby patients are given a high level of PEEP to promote alveolar recruitment with a brief release to allow for carbon dioxide removal without allowing alveolar derecruitment. Controlled studies using these ventilator modalities are limited. One report found that the use of APRV in patients with ARDS decreased intrathoracic pressure, improved ventilation–perfusion mismatch and cardiac output, and decreased shunt and dead-space fractions compared with pressure support ventilation (matched for the same airway pressure limits or minute ventilation).[117] However, clinically important outcomes were not compared.

BIPAP and APRV can be expected to decrease the use of neuromuscular blocking agents and possibly sedation in patients with ARDS, since both allow spontaneous breathing and potentially less

patient-ventilator dyssynchrony. However, whether such newer modes of ventilation are better than, equal to, or worse than the ARDSNet lower tidal volume ventilatory strategy remains unknown. Until more clinical evidence supports their superiority or equivalency, their routine use cannot be recommended.

High-Frequency Oscillatory Ventilation High-frequency oscillatory ventilation (HFOV) is a mode of ventilation in which patients are supported with rapid pressure oscillations that generate very small tidal volumes. Theoretically, HFOV may be regarded as the ultimate low-tidal volume ventilator, with a capacity to ventilate a patient using a very small tidal volume, which lies midway between the upper and lower inflection points of the pressure–volume curve (Fig. 141-5). While commonly used in respiratory distress of the newborn, the use of HFOV in ARDS has been limited to centers with necessary ventilatory equipment and technical expertise.

Clinically, use of HFOV has previously been shown to be equivalent to "usual" care.[118] However, previous trials comparing HFOV with usual care were conducted at a time when usual care did *not* include low tidal volume ventilation. Since its application generally requires neuromuscular paralysis, HFOV is unlikely to be utilized in patients with mild ARDS because of the risk of paralytic agent–related quadriparesis.

Two large, multicenter, randomized controlled trials of moderate-to-severe ARDS comparing HFOV and traditional care are noteworthy. The trial conducted by the Oscillation in ARDS (OSCAR) study group demonstrated no significant mortality benefit of HFOV compared with usual care, as determined by local practice of participating ICUs.[119] The Oscillation for ARDS Treated Early (OSCILLATE) Trial was stopped early by the Data Safety and Monitoring Committee, as the HFOV group appeared to have a higher in-hospital mortality compared with a low tidal volume, high PEEP control group.[120] While some clinicians may use high-frequency ventilation as a "salvage" mode (Table 141-12), its use, even in those circumstances, is not supported by controlled clinical trials.

Adjuncts to Lung-Protective Mechanical Ventilation

A number of adjunctive measures to mechanical ventilation have assumed importance in the management of patients with ARDS. In some cases, the physiologic or pharmacologic basis for the measure's beneficial effect is apparent; in others, the mechanism is unknown.

Overview Use of adjuncts to lung-protective ventilation is generally based on extrapolations from animal or basic studies, or from clinical studies using physiologic markers as surrogates for clinically meaningful endpoints, for example, mortality or ICU length of stay or ventilator-free days. However, extrapolation from such studies to clinical practice is problematic. For example, the only intervention that, thus far, has been proved to result in increased survival in ARDS – the ARDSNet low tidal volume ventilatory strategy – also resulted in patients in the low-volume group with significantly lower Pa_{O_2}/FI_{O_2} after enrollment compared with those receiving traditional tidal volume ventilation (Table 141-10).[4] If the trial had used improvement in Pa_{O_2}/FI_{O_2} as a surrogate marker for better survival, the results would have been interpreted as showing that low tidal volume ventilation results in *higher*, rather than *lower*, mortality.

In general, both efficacy and safety data supporting use of the following adjunctive therapies in ARDS are lacking. Thus, these interventions should be used cautiously, if at all.

Permissive Hypercapnia Permissive hypercapnia is defined as clinician-allowed hypercapnia during assisted ventilation, despite an ability to achieve a level of minute ventilation sufficient to maintain a normal Pa_{CO_2} (36–44 mm Hg). Because patients may develop hypercapnia during lower tidal volume ventilation, which is recommended as the core ventilator strategy, permissive hypercapnia should no longer be considered an "adjunct."[4] Although, the ARDSNet lower tidal volume strategy did stipulate maintenance of minute ventilation while decreasing tidal volume in order to decrease the secondary rise in Pa_{CO_2}, permissive hypercapnia was allowed as a consequence of the protocol. The response to the resulting respiratory acidosis was left to the local investigator's discretion.

Fluid Management The ARDSNet Fluid and Catheter Treatment Trial (FACTT), noted previously, used a two-by-two factorial design to test the hypothesis that a management strategy of fluid restriction (conservative fluid management) would improve clinically important outcomes in ARDS compared with more generous fluid management strategy (liberal fluid management).[31] Although the strategy of liberal fluid management was based upon a protocol to determine fluid balance, patients' net fluid balance during the first 7 days of the trial resembled that resulting from the nonprotocol-directed care in the first two ARDSNet clinical trials (ARMA and ALVEOLI).[4,30]

FACTT investigators developed a detailed fluid management protocol that, except for patients in shock (mean arterial pressure [MAP] less than 60 mm Hg or on vasopressors for hypotension), used four basic input variables (assessed every 1–4 hours) to determine the fluid management instructions: (1) MAP; (2) urine output; (3) effectiveness of circulation; and (4) intravascular pressure (central venous pressure [CVP] or PAOP). In both arms of the study, the protocol goals were MAP greater than 60 mm Hg (or vasopressor independence); urine output greater than 0.5 mL/kg predicted body weight/hour; and evidence for effective circulation, including a cardiac index $\geq$2.5 L/min/m^2 in patients with PACs or, in those with CVCs, absence of physical examination findings indicating hypoperfusion of extremities. In the group randomized to conservative fluid strategy, the target intravascular pressure was a CVP less than 4 mm Hg or PAOP less than 8 mm Hg. In contrast, for those randomized to the liberal fluid strategy, targets were a CVP of 4 to 8 mm Hg or PAOP of 8 to 12 mm Hg.

Despite marked differences in cumulative net fluid balance between the conservatively and liberally managed groups, the two showed no statistically significant difference in mortality at 60 days, which was the study's primary outcome (Table 141-13). Nonetheless, compared with the liberal strategy, the conservative strategy resulted in statistically significant improvements in several clinically important outcomes, including decreased duration of assisted ventilation and length of stay in the intensive care unit (Table 141-13). Moreover, the conservative strategy did not worsen the incidence of shock, number of days in shock, frequency or extent of other organ system failures, or rate of use of dialysis. These results support the use of a conservative fluid strategy in managing patients with ARDS who are not in shock.

Hemodynamic Management Using the trial's two-by-two factorial design, the ARDSNet FACTT investigators also compared the safety and efficacy of PACs with CVCs in directing fluid and hemodynamic protocols, as described.[11] Mortality and other important clinical outcomes, such as ventilator-free days, ICU-free days, and organ-failure-free days by study day 28 were no different in patients managed with a PAC versus a CVC (Table 141-14). However, use of a PAC was associated with a significantly higher complication rate during catheter insertion – primarily, cardiac arrhythmias. The excess events were attributed principally to the need for passing both a sheath and catheter; none of the adverse events was fatal.

Based on the results, the FACTT investigators recommend using a CVC to guide a hemodynamic and fluid management. The use of the PAC in the United States had been declining, even prior to the publication of the FACTT trial, as evidence had been accumulating against routine use.[10] However, clinicians may elect to use a PAC in selected circumstances, for example, in addressing the response to volume resuscitation, determining the adequacy of cardiac output,

TABLE 141-13 Results of ARDSNet FACTT (Fluids and Catheter Treatment Trial): Conservative Fluid Management Strategy Versus Liberal Fluid Management Strategy

Result	Conservative Strategy ($n = 503$)	Liberal Strategy ($n = 497$)	p Value
Cumulative net fluid balance from day 1 to day 7 (mL)			
All patients	−139 ± 491	6992 ± 502	<0.001
Patients in shock at entry	2904 ± 1008	10, 138 ± 922	<0.001
Patients not in shock at entry	−1576 ± 519	5287 ± 576	<0.001
Death at 60 d (%)	25.5	28.4	0.30
Ventilator-free days from day 1 to day 28[a]	14.6 ± 0.5	12.1 ± 0.5	<0.001
ICU-free days from day 1 to day 28[a]	13.4 ± 0.4	11.2 ± 0.4	<0.001
Organ failure-free days from day 1 to day 7[a,b]

measuring the oxygen saturation of mixed venous blood, calculating the degree of intrapulmonary shunt, or searching for equalization of diastolic pressures during suspected cardiac tamponade.

Prone Positioning About two-thirds of patients with ARDS improve their oxygenation after being placed in a prone position.[121,122] Mechanisms that may explain the improvement include (1) increased functional residual capacity; (2) change in regional diaphragmatic motion; (3) perfusion redistribution; and (4) improved clearance of secretions. Studies of the distribution of ventilation-to-perfusion ratios in animal models suggest that gravity is less influential on the distribution of perfusion in the prone, rather than supine, position.[123] This finding, coupled with the observation that edema fluid migrates to the dependent portions of the lung (as

Source: Data from National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network; Wheeler AP, Bernard GR, Thompson BT, et al. Pulmonary-artery versus central venous catheter to guide treatment of acute lung injury. N Engl J Med. 2006;354(21):2213–2224.

demonstrated on computed tomography) in patients with ARDS who have been turned prone, suggested that ventilation–perfusion relationships might be favorably altered in the prone position.[124]

Patients managed in the prone position need special attention to prevent pressure necrosis of the nose, face, and ears. Extra care is also needed to ensure security and patency of the endotracheal tube. Pressure on the eye may result in retinal ischemia, especially in hypotensive patients. Others may experience cardiac arrhythmias or hemodynamic instability when turned prone.

In a large clinical trial of prone positioning in patients with ARDS, subjects were randomly placed prone for 6 or more hours daily for 10 days or were left in the supine position.[125] Although the investigators found that oxygenation improved transiently with prone positioning, they demonstrated no survival advantage. More recently, a meta-analysis examined the effects of prone positioning on all patients with ARDS and a prespecified subgroup with severe ARDS (Pa_{O_2}/FI_{O_2} <100 mm Hg).[126] Prone positioning failed to demonstrate a mortality benefit among all patients with ARDS, but findings suggested a mortality benefit among those with severe ARDS. In 2013, a prospective, randomized, controlled trial comparing prone positioning for at least 16 hours a day to supine positioning in 466 patients with ARDS and Pa_{O_2}/FI_{O_2} <150 mm Hg treated with low tidal volume ventilation was published.[127] The primary outcome, 28-day mortality, was 16% in the prone group and 32.8% in the control group. This is the first prospective clinical trial to report a mortality benefit with prone positioning in ARDS.

Placing patients prone carries known risk, even in experienced hands, and cannot be recommended for routine use in all patients with ARDS. However, given the previously noted findings from a meta-analysis and the recently published randomized control trial demonstrating a mortality benefit in the subgroup of patients with severe ARDS, experienced clinicians may opt to use prone positioning as a therapy for severe hypoxemia (Table 141-12).

Recruitment Maneuvers Lung recruitment maneuvers are defined as the application of CPAP aimed at "recruiting" or opening totally or partially collapsed alveoli. The alveoli are then kept inflated during expiration using an appropriately high level of PEEP. In one study of a "lung-protective" strategy utilizing low tidal volume ventilation and extra-high PEEP, recruitment maneuvers were performed by maintaining a CPAP level of 35 to 40 cm H_2O for 30 seconds.[113] Others advocate application of equivalent or higher pressures for longer periods.

No controlled clinical trial supports the efficacy of recruitment maneuvers alone to improve clinically important outcomes, such as mortality or ventilator-free days. Studies of recruitment maneuvers have generally used physiologic end points, for example, improvement in oxygenation.[128,129] In a subset of patients treated with high levels of PEEP in the ARDSNet trial comparing high versus low PEEP in ARDS, no clinically relevant improvements in arterial saturation were noted.[130] However, complications, such as transient hypotension and slight drops in arterial saturation during the maneuver, were reported. On the other hand, other clinical studies have reported that recruitment maneuvers improve oxygenation in patients on relatively low levels of PEEP, receiving large tidal volumes, or maintained on paralytics.

Because no controlled clinical trials demonstrate efficacy in clinically relevant end points, and because there are potentially adverse effects, routine use of recruitment maneuvers is not recommended in ARDS. Likewise, in the absence of data showing efficacy, routine use of ventilator "sighs" exceeding peak pressures of 30 cm H_2O (the threshold used in the ARDSNet clinical trial that showed improved survival) is also not recommended. Some clinicians may use recruitment maneuvers with higher pressures as part of salvage therapy for patients with severe refractory hypoxemia (Table 141-12).

Inhaled Nitric Oxide In 1993, Roissant et al.[131] published a study of inhaled nitric oxide (NO) as a novel therapy for ARDS. Given via inhalation, NO selectively vasodilates pulmonary capillaries and arterioles that serve *ventilated* alveoli, diverting blood flow to these alveoli and away from areas of shunt. Lowering of the pulmonary vascular resistance, accompanied by lowering of the pulmonary artery pressure, appears maximal at very low concentrations (0.1 ppm) in patients with ARDS. Beneficial effects on oxygenation take place at somewhat higher inspired concentrations of NO (1–10 ppm). Rapid inactivation of NO by hemoglobin prevents unwanted systemic hemodynamic side effects, but also requires continuous delivery of gas through the ventilator circuit. Thus, if continuous delivery of NO is interrupted (e.g., during patient transport or due to NO supply exhaustion), precipitous and life-threatening hypoxemia and right-sided heart failure may occur.

Inhaled NO has been studied in several controlled clinical trials in patients with ARDS.[132–134] While demonstrating improvements in oxygenation in some patients, inhaled NO did not improve survival in any of the trials. Based on these trials, the routine use of inhaled NO in ARDS is not recommended. Some clinicians may consider using inhaled NO as a salvage intervention (Table 141-12). However, a much less costly alternative, inhaled prostacyclin (epoprostenol/iloprost), is available. The initial daily cost of inhaled NO is several thousands of dollars, while the daily cost of inhaled prostacyclin is several hundreds of dollars. Although less well studied than inhaled NO, inhaled prostacyclin seems to improve oxygenation to the same degree in a majority of patients with ARDS.[135]

Tracheal Gas Insufflation Tracheal gas insufflation (TGI) consists of delivering fresh gas through a modified endotracheal tube at a point just above the carina. The additional gas flow (i.e., flow provided in addition to the standard tidal volumes delivered by the ventilator) tends to remove CO_2-rich gas from the trachea and smaller airways. It has the effect of reducing anatomic dead space. Although ALI decreases the ability of TGI to reduce Pa_{CO_2}, permissive hypercapnia and higher Pa_{CO_2} values increase its relative effectiveness. For example, in one study of patients with ARDS, TGI using 100% humidified oxygen, delivered throughout the respiratory cycle at a flow of 4 L/min, lowered Pa_{CO_2} from 108 to 84 mm Hg.[136]

Because TGI carries a number of potential risks (e.g., tracheal erosion, oxygen toxicity related to an increased FI_{O_2}, and hemodynamic compromise or barotrauma due to TGI-induced auto-PEEP and a larger tidal volume than the ventilator is set to deliver), its routine use is not recommended. However, once again, some clinicians may employ it as a salvage intervention for patients with high levels of Pa_{CO_2} (e.g., >100 mm Hg).

Extracorporeal Life Support Extracorporeal Life Support (ECLS) is a therapy that utilizes an external artificial membrane and a mechanical pump to provide gas exchange and systemic perfusion in patients with failure of lung and/or heart function. The use of extracorporeal gas exchange, such as extracorporeal membrane oxygenation (ECMO) or extracorporeal CO_2 removal ($ECCO_2R$), is based on the hypothesis that more patients will survive if the lung is allowed to recover from its injury by "resting" using extracorporeal gas exchange temporarily. Although this hypothesis was initially stimulated by the desire to decrease the risk of pulmonary oxygen toxicity, its assessment can now be justified in regard to the techniques' potential roles in reducing VILI.

In the 1970s, a large-scale study on use of ECMO in patients with severe ARDS demonstrated that it offered no survival benefit to patients whose mortality was extremely high (approximately 90%).[137] Similarly, a randomized controlled trial in severely ill patients with ARDS reported in 1994 did not find improved survival using $ECCO_2R$.[138] The therapy received renewed attention during the H1N1 influenza pandemic of 2009.[139] Significant technologic advances, along with a population of previously healthy patients

infected with influenza and suffering from severe ARDS, prompted the increased use of ECLS.

Recently, the Conventional Ventilatory Support versus Extracorporeal Membrane Oxygenation for Severe Adult Respiratory Failure (CESAR) Trial randomized 180 patients with severe, but potentially reversible, respiratory failure to conventional therapy or referral to a single, specialized ECMO center for consideration for ECMO.[140] Death or severe disability, the study's primary outcome, occurred in 53% of the conventional arm versus 37% of those referred to the ECMO center. Among those referred to the ECMO center, 76% received ECMO. While the study demonstrated a statistically significant finding, the study design makes it impossible to distinguish the effects of the ECMO therapy from those of a specialized referral center. Current trials aimed at addressing the use of extracorporeal gas exchange in ARDS, utilizing updated technology, are ongoing. Some specialized centers offer ECLS to a highly selective group of adults with severe ARDS and consider the technique as a safe life-saving salvage intervention (Table 141-12).

Corticosteroids The general consensus among intensivists is that corticosteroids have little or no role to play in treating the acute phase of ARDS. However, the role of corticosteroids in later phases of ARDS has been controversial.

A number of small case series suggest that high-dose corticosteroid therapy may be beneficial during the proliferative phase of ARDS, based on the rationale of preventing lung scarring that occurs during this phase of ARDS as a result of alveolar inflammation.[141–143] Potential risks include immunosuppression of debilitated, instrumented patients managed in environments harboring multiple antibiotic-resistant organisms and potential long-term neuromuscular weakness associated with use of high-dose corticosteroids and paralytic agents.

In 2006, the ARDSNet investigators published results of a double blind, randomized, controlled clinical trial (Late Steroid Rescue Study or LaSRS) designed to evaluate benefits and risks of moderately high doses of corticosteroids in 180 patients with persistent ARDS (ARDS lasting 7–21 days) (Tables 141-15 and 141-16).[144] The study revealed no differences in 60- or 180-day mortality rates. Although parameters of respiratory function, including Pa_{O_2}/FI_{O_2}; plateau pressure; respiratory system compliance; and time to, and rate of, liberation from mechanical ventilation improved after corticosteroid administration; the corticosteroid treated group included more patients who returned to assisted ventilation. Furthermore, no statistically significant differences between treated and untreated groups in ICU or hospital days by 180 days were observed. In addition, more adverse events related to weakness occurred in the treated group than in those receiving placebo. Finally, patients treated with corticosteroids after 14 days of persistent ARDS had a significantly increased mortality (Table 141-16). Hence, the results of this study do not support the routine use of steroids for late-phase ARDS in general, and they argue against their use if ARDS has been present for 14 days or longer.

Neuromuscular Blocking Agents Significant controversy exists regarding the role of neuromuscular blocking agents in ARDS. These agents are frequently used to promote ventilator synchrony and improve oxygenation in severe cases of ARDS; however, they have been associated with prolonged neuromuscular weakness in survivors of ARDS.

In one multicenter study, 340 heavily sedated patients with ARDS and a Pa_{O_2}/FI_{O_2} <150 were randomized to 48 hours of cisatracurium or placebo. The 90-day mortality rate was 31.6% in the cisatracurium group and 40.7% in the placebo group, a finding that was only statistically significant after adjustment for baseline Pa_{O_2}/FI_{O_2}, baseline plateau pressure, and the Simplified Acute Physiology II score. Although not powered for this outcome, ICU-acquired neuromuscular weakness was not different between the groups. While further studies addressing the role of neuromuscular blockade in ARDS are needed, current evidence suggest that they may be useful for short-term use in severe ARDS.

Other Therapies Several other therapies have been the subject of ongoing research in ARDS, including statins, beta agonists, and macrolide antibiotics.

Given their effects on inflammatory cytokines, statins are currently undergoing investigation for their role in ARDS. A small trial of 60 patients failed to demonstrate a mortality benefit.[145] The ARDS Network is conducting a larger randomized controlled trial of rosuvastatin in patients with ARDS.

Beta-agonists stimulate removal of fluid from flooded alveoli by stimulating the epithelial sodium pump and promoting active transport of sodium out of the alveoli (with water following passively according to osmotic gradients) and therefore, were considered as a therapy for ARDS. However, two large, randomized controlled trials failed to demonstrate a mortality benefit from beta agonist.[32,146] One

TABLE 141-15 Results of ARDSNet Late Steroid Rescue Study (LaSRS) in Patients with Persistent ARDS: A Priori Protocol-Defined Outcomes and Adverse Events

Variable or Outcome	Methylprednisolone-Treated Group	Placebo-Treated Group	*p* Value

of these trials was actually stopped early for increased mortality among the beta-agonist arm.

Animal studies and an observational cohort study of macrolide antibiotics have suggested they may have a positive effect in ARDS.[147,148] This evidence requires a prospective clinical trial prior to routine use of macrolides in ARDS.

CLINICAL COURSE, OUTCOME, AND LONG-TERM SEQUELAE

The clinical course and outcomes of ARDS have been better delineated in recent years. Both pulmonary and nonpulmonary outcomes have been investigated.

■ CLINICAL COURSE AND DURATION

The course of illness varies considerably in severity and duration among patients. ARDS may last for a few days or even less (e.g., ARDS from opioid exposure, with the patient recovering rapidly after the initial insult). Alternately, ARDS from other causes may last several months and involve a prolonged ICU course. Patients can recover or die at any point in the course of ARDS. Using the new Berlin definition of ARDS, the median duration of mechanical ventilation is approximately 5 days, 7 days, and 9 days for mild, moderate, and severe ARDS, respectively.[9] Up to 25% of patients remain on mechanical ventilation for longer than approximately 2 weeks, many for much longer. Notably, as shown in LaSRS, a longer duration of mechanical ventilation for ARDS does not translate into a higher mortality.[144] Most ARDS-related deaths occur within the first 2 weeks, with one-third occurring by day 7, two-thirds by day 14, and three-fourths to four-fifths by day 28.[26]

The mortality rate of patients on mechanical ventilation after 2 to 4 weeks of persistent ARDS is about 30% over the ensuing 2 to 6 months. These rates are similar to the overall mortality rate (at 180 days) for patients enrolled in ARDSNet clinical trials in which low tidal volume ventilation was used. The findings highlight the importance of continued supportive care in the ICU and vigilance aimed at reducing nosocomial complications.

■ CAUSES OF DEATH

Approximately one-third of ARDS-related deaths occur in the first 7 days.[26] Most are related to the underlying disease or injury, that is, to events occurring before the onset of ARDS. The majority of patients who die succumb after 7 days, with these late deaths also commonly due to the underlying injury or illness. Other causes include complications occurring contemporaneously with, or after the onset of, ARDS. The most common cause of death in this group of patients is sepsis, with associated multiple organ system failure. Of note, only a relatively small fraction of patients – 10% to 20% of all patients with ARDS – die a respiratory death due to irreversible hypoxemia or refractory respiratory acidosis. Therefore, not surprisingly, clinical trials of interventions aimed selectively at improving gas exchange (e.g., use of inhaled nitric oxide or exogenous surfactant) have not demonstrated improved survival.

■ LONG-TERM SEQUELAE

Recent studies indicate that many survivors of ARDS have medical problems and a compromised quality of life, both of which persist well beyond their initial ICU stay.[149–151] Impaired pulmonary, neurologic, musculoskeletal, cognitive, and psychosocial functions have been documented in survivors of ARDS. Furthermore, survivors have a poorer quality-adjusted survival than do critically ill subjects without ARDS.

Research into these disorders is in the early stages; the etiology and pathophysiology of are incompletely understood. Recognition of the problems affecting survivors of ARDS and referral for appropriate evaluation and therapy constitute important components of overall care. With improved therapy of ARDS resulting in greater survival rates, clinicians should anticipate an increase in the prevalence of long-term sequelae.

Health-Related Quality of Life

Health-related quality of life (HRQL) has become increasingly recognized as important in the evaluation of patient-centered outcomes in recovery from a variety of illnesses. A number of studies have evaluated HRQL in ARDS survivors.[149–156] Tools used to assess HRQL include the Medical Outcomes Study 36-Item Short Form Health Survey (SF-36), St. George's Respiratory Questionnaire, Quality of Well-Being Scale, and Sickness Impact Profile. Each has illustrated impaired quality of life in survivors of ARDS compared with various control populations, including critically ill subjects

without ARDS, and patients with chronic diseases (including cystic fibrosis). In general, impairments in HRQL improve over the first 3 months following discharge from the ICU and appear to plateau by 1 year. Studies of interventions to improve HRQL are under way.

Pulmonary Sequelae

Studies of pulmonary function following ARDS are affected by inconsistent disease definitions, methodologic problems due to lack of patient follow-up, and heterogeneity of pre-existing pulmonary diseases. Consequently, a range of lung function impairments has been reported following recovery.[150,151,154,157,158] Although a proportion of survivors of ARDS may have impaired diffusion capacity or restrictive or obstructive abnormalities, restoration of normal lung function occurs in a substantial proportion. In the Toronto ARDS Outcomes study, spirometry and lung volumes improved rapidly among survivors, reaching normal in most subjects by 6 months.[150] Diffusion capacity is mildly impaired in many patients after ARDS, but it may return to normal by 2 to 5 years among survivors.[150,151] Given the severely impaired physical function domains reported in HRQL surveys and the relatively mild pulmonary impairment, investigation has more recently focused on other limitations and causes of symptoms in survivors of ARDS.

Physical and Neuromuscular Sequelae

In the previously noted Toronto ARDS Outcomes study, persistent physical impairment in survivors of ARDS was assessed.[150,151] Despite improvement in pulmonary function at 1 year following their ICU stay, this cohort had low exercise capacity, weakness, and decreased physical quality of life as far as 5 years after their acute illness. Risk factors for these findings included multiorgan dysfunction in the ICU, prolonged duration of ARDS, treatment with corticosteroids during the ICU stay, and increased comorbid disease burden. Although the basis for many of the abnormalities is not clear, a number of patients demonstrated a range of abnormalities, including critical illness polyneuropathy, ICU-acquired myopathy (critical illness myopathy), entrapment neuropathy, and heterotopic ossification.

Cognitive and Psychological Sequelae

Cognitive impairments can cause major limitations in the ability to return to work, affect mood, and lead to increased healthcare expenditures. Study of long-term cognitive function in survivors of ARDS indicates that many have impaired memory, reduced attention, and decreased concentration and processing speed.[149–151,159,160] The abnormalities appear to be associated with the number and severity of hypoxemic episodes in the ICU. Similar to physical abnormalities, cognitive dysfunction appears to be worse in the first 3 months following hospital discharge; it may improve for up to 1 year and then reach a plateau.

Depression and anxiety are frequent following ARDS. Several studies indicate that the prevalence of depression is over 25% following recovery.[161,162] These emotional problems are likely multifactorial, including prior hypoxic brain injury and delirium and subsequent limitation of physical function. In addition, some authors have suggested the presence of a major component of posttraumatic stress disorder (PTSD) in survivors of ARDS.[163] Because these disorders are potentially treatable using pharmacologic, behavioral, and cognitive therapies, clinicians should ask survivors about possible depression and anxiety, which, in turn, may improve HRQL.

Finally, in accord with the concept that the ICU team treats patients, as well as their families, clinicians need to be aware that familial caregivers of patients who are survivors of ARDS experience long-term health effects.[164] In particular, they are at increased risk for emotional distress (associated with various factors, including patient depression) and a lower HRQL over all domains tested on the Medical Outcomes Short Form 36. Clinicians providing long-term follow-up care for patients with ARDS should aim to ensure adequate social and other support for their familial caregivers.

CHAPTER 142

Sepsis, Multiple Organ Dysfunction Syndrome, and Chronic Critical Illness

Emily K. B. Gordon
Clifford S. Deutschman

INTRODUCTION

The past four decades have added greatly to our recognition that *sepsis*, originally defined as a syndrome induced by actively dividing microorganisms in the circulation, is, in fact, a complex and diverse disorder. The term has now come to encompass a constellation of abnormalities that reflect disordered or dysregulated inflammation. As such, sepsis may be initiated by infection; however, it may also occur in the absence of microbial invasion, for example, in response to extensive trauma, uninfected pancreatitis, ruptured aortic aneurysm, or some distinctly unusual entities, such as amniotic fluid embolism. All such patients may develop multiple organ dysfunction syndrome (MODS) and a newly recognized state currently called "chronic critical illness (CCI)." What is now apparent is that our ability to manage shock and to support organ function has unmasked a common family of disorders that have a high mortality and significant morbidity. Familiarity with sepsis is essential for all medical practitioners.

This chapter defines the clinical findings that constitute sepsis, MODS, and CCI. The disorders are described as a function of their position on a continuum of clinical, organ system–specific, cellular, and, indeed, even subcellular, changes that include abnormal biochemistry, metabolism, and energetics. Several pathogenic hypotheses, management strategies, and intriguing new forms of therapy are addressed.

DEFINITIONS, NATURAL HISTORY, AND EPIDEMIOLOGY

The characteristic response to inflammatory stimuli, including surgery and trauma, has been referred to as the *stress response,* the evolutionary importance of which lies in facilitation of survival and tissue repair.[1]

Initially in the stress response, an orchestrated neuro-hormonal-humoral mechanism directs substrate delivery to the most vital organs—the heart and brain. Enabling of the mechanism requires rapid development of vasoconstriction, fluid retention, and translocation of intracellular water into the vasculature. In the absence of exogenous life support, death from shock ensues when these endogenous mechanisms are inadequate.

Resuscitation from the initial phase of shock is followed by a period during which cardiovascular function and global metabolism are markedly enhanced.[2] The driving force behind this second phase is repair of damaged tissue, with white blood cells serving as the primary effectors of the process.[3] To support the increased white blood cell mass, substrate is mobilized from endogenous sources and glucose reserves are rapidly depleted. Because white blood cells are obligate glucose users, muscle (both skeletal and smooth) is broken down to provide precursors for increases in hepatic gluconeogenesis. Nonglucogenic amino acids are used to synthesize structural proteins and enzymes. Energy to support the liver, heart, and other organs is derived from fat and amino acids, since utilization of glucose by tissues other than blood cells and neurons is blocked. Generalized capillary recruitment and leak allow substrate delivery to the avascular area where tissue is damaged. The amount of fluid in the extracellular compartment, particularly in the extracellular, extravascular matrix, increases dramatically. Continued fluid retention and movement of water out of cells fills the dilated, leaky vasculature. Vasodilatation is accompanied by an increase in cardiac output (CO), which further facilitates delivery of substrate. By the fourth day following injury or surgery, neovascularization of damaged tissue results in a sharp increase in substrate delivery to damaged areas. This change is accompanied by a decrease in capillary leak, generalized increase in vascular tone, and mobilization and excretion of fluid in the matrix. Water also returns to cells. In most cases, patients recover uneventfully.

In an unknown fraction of cases, the inflammatory process becomes disordered. Initially the process was defined by the

TABLE 142-1 Diagnostic Criteria for SIRS, Sepsis, Severe Sepsis, Septic Shock, and MODS

SIRS
Temperature >38°C or <36°C
Heart rate >90 beats/min
Respiratory rate >20 breaths/min or P_{CO_2} <32 mm Hg
WBC >12 × 10^9/L or <2 × 10^9/L or >10% immature forms
Sepsis
SIRS + identified or suspected infection
Severe Sepsis
Sepsis + dysfunction of one or more organ systems
Septic Shock
Sepsis + hypotension (BP <90 mm Hg or a reduction of >40 mm Hg from baseline in the absence of other causes) despite adequate fluid resuscitation and perfusion abnormalities (e.g., lactic acidosis, oliguria, altered mental status)
MODS
No current definitions

Source: Data from Levy MM, Fink MP, Marshall JC, et al. 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference. Crit Care Med. 2003;31(4):1250–1256.

presence of two or more of the criteria listed in the original definitions of sepsis (Table 142-1)[4] which indicated enhanced inflammation, a syndrome referred to as the *systemic inflammatory response syndrome* or *SIRS*. Use of SIRS criteria has been very helpful in enabling early recognition of patients for inclusion in epidemiologic and interventional studies on sepsis. However, this approach, even when updated,[5] has been increasingly recognized as problematic because it is too nonspecific and may reflect a view of septic pathophysiology that is too limited. Recent data have shown that disordered inflammation also includes "immunoparalysis," with white blood cell function that is also markedly diminished.[6,7] Thus, virtually all aspects of inflammation are altered in early sepsis.

Previous descriptions of sepsis detailed subsequent development of a state of organ dysfunction or failure.[8–11] This syndrome, MODS, is now considered to begin quite early, perhaps at the very beginning of immune dysregulation. While MODS rarely leads to death, it does progress to a persistent, prolonged, and unchanging state that has come to be known as CCI. Recent studies of CCI indicate that the subset of patients who remain in the ICU for greater than 30 days account for only 8% of total admissions but for 48% of total occupied beds. Six months after hospital discharge, 50% of the cohort is still alive and 80% of the survivors are living in their previous place of residence.[12]

Data on incidence and outcome in sepsis are difficult to determine because the scientific community has used varying definitions of sepsis. In a study published in 2001, sepsis was noted as responsible for 215,000 deaths each year, and overall hospital mortality rate was 28.6%.[13] Expenditures associated with caring for patients with sepsis was estimated at $16.7 billion. More recent work based on examination of the Medicare database from 1996 to 2008 indicated that the number of patients with a diagnosis of sepsis had increased to nearly a million annually.[14] Indeed, the incidence of sepsis in elderly patients has become epidemic: 60% of patients who develop sepsis and 75% of the deaths in sepsis are in patients older than age 65 years. These data are consistent with findings in other industrialized nations.[15–17]

The proportion of patients admitted to ICUs with a diagnosis of sepsis who will progress to developing CCI is difficult to determine. Investigations suggest that, each year, more than 100,000 patients in the United States require prolonged mechanical ventilation.,[18,19] Older studies estimated the annual cost of CCI to exceed $20 billion. This burden has undoubtedly already increased and, in the absence of a change in healthcare policy, will become more pronounced.[20]

Determining the actual mortality from sepsis is equally difficult. Application of evidence-based guidelines for sepsis management indicates a dramatic decline in mortality.[21] Indeed, recent data suggest that mortality may be reduced to <10%.[22] With use of diagnostic and management guidelines for sepsis, patients rarely die of shock. Most develop CCI and expire when exogenous support is discontinued (Deutschman CS, unpublished data). The cause of death in almost all cases is unknown; although patients die *with* CCI, the actual cause of death remains unclear.

PATHOPHYSIOLOGY OF SEPSIS, MODS, AND CHRONIC CRITICAL ILLNESS

As vexing as understanding the pathophysiology of sepsis may be, the mechanisms underlying MODS and CCI are even more problematic.

MODS was once thought to reflect the effects of a sustained activation of the immune system. However, the findings previously cited regarding early immunosuppression cast doubt on this hypothesis.[7] Further, defining "dysfunction" in individual organs is problematic. Although many criteria have been used, none are universally accepted. Some generally used criteria for organ dysfunction are detailed in (Table 142-2).[23] However, these criteria reflect the gaps in our understanding of MODS.

Recent studies suggest that early organ dysfunction differs from the organ failure that becomes evident later in the time course of sepsis. The early changes may represent an adaptive response aimed at preventing further damage from a severe insult.[24–26] The basis for this construct lies in the "mitochondrial hypothesis," which is detailed below. Development of CCI appears to herald the highly lethal state once attributed to MODS. The major factor limiting treatment of MODS is lack of a clear understanding of the underlying pathophysiologic defect. In fact, if not considered carefully, the changes associated with sepsis/MODS may simply resemble an extension of those observed after uncomplicated stress. For example, patients recovering from major surgery undergo increases in metabolic rate, oxygen consumption ($\dot{V}_{O_2}$), and carbon dioxide production, in addition to glucose intolerance and hyperglycemia. The vasculature is dilated, and CO increases to promote oxygen transport. In addition, lactate production may increase, reflecting the overall increase in metabolism rather than tissue hypoxia.

Typically, the septic patient presents with high fever, shock, and respiratory failure. This clinical picture resulted in the prevailing theory that sepsis reflects uncontrolled inflammation. The hypothesis was consistent with demonstration of increased concentrations of TNF, IL-1, IL-6 and, later in the time course, HMGB1 in sepsis.[27] However, a myriad of trials addressing anti-inflammatory approaches to treatment have not demonstrated reduced survival rates.[28,29] Two observations that may contribute to the negative findings have been offered. First, sepsis is characterized by both proinflammatory *and anti-inflammatory* responses. Second, as previously noted, immunosuppression in sepsis has been reported.[6,7] Indeed, in a study of patients whose deaths were attributed to sepsis,[30] 80% had unresolved foci of infection. Hence, a strategy employing *immune enhancement*, rather than anti-inflammation, may be warranted. Further complicating an understanding of pathogenesis is our inability to define the underlying physiologic basis by which sepsis ultimately leads to organ failure or death. Studies[6] have shown that there is very little cell death in most major organs in sepsis, and that histologic damage does not correlate with the degree of organ dysfunction seen prior to death. The exception to this observation lies in the immune system and in the gastrointestinal tract.[31]

TABLE 142-2 General Criteria for Diagnosis of Organ Dysfunction in Sepsis, MODS, and CCI

System	Mild	Severe
Pulmonary	Hypoxia/hypercarbia requiring assisted ventilation for 3–5 d	ARDS requiring PEEP >10 cm H_2O and F_{IO_2} >0.5
Hepatic	Bilirubin 2–3 mg/dL or other LFTs twice normal, PT elevated to twice normal	Jaundice with bilirubin >8–10 mg/dL
Renal	Oliguria (<500 mL/d) or increasing creatinine (2–3 mg/dL)	Dialysis
Gastrointestinal	Intolerance of GI feeding >5 d	Stress ulceration with need for transfusion, acalculous cholecystitis
Hematologic	PTT >125% of normal, platelets <50,000–80,000 per mm^3	DIC
CNS	Confusion	Coma
PNS	Mild sensory neuropathy	Combined motor and sensory deficit
Cardiovascular	Decreased ejection fraction, persistent capillary leak	Hypodynamic state not responsive to pressors

ARDS, acute respiratory distress syndrome; PEEP, positive end-expiratory pressure; LFTs, liver function tests; PT, prothrombin time; PTT, partial thromboplastin time; DIC, disseminated intravascular coagulation; CNS, central nervous system; PNS, peripheral nervous system.

Recent studies also suggest that organ dysfunction develops very early after the diagnosis of septic shock or severe sepsis is made. This finding is not surprising, given that both severe sepsis and septic shock are defined in terms of organ dysfunction.

The 2001 SCCM/ESICM definitions of sepsis were explicit in delineating specific clinical criteria for dysfunction in specific organs.[5] In general, these abnormalities are not manifest for several days. However, when biochemical or histologic criteria are applied, organ dysfunction may be noted once the initial resuscitation is complete. The most common clinical abnormality is respiratory failure requiring mechanical ventilation. In some instances, the need for exogenous support of other organ systems (e.g., dialysis) may develop in short order, while in others deterioration may be slower. In either case, the patient progresses to development of CCI. These patients account for 5% to 10% of the ICU population. Most often, affected patients require prolonged mechanical ventilation, but they also may need continuous hemodialysis, cardiovascular support with vasopressors, prolonged exogenous metabolic/nutritional support, or complex wound management. One key characteristic of CCI is evident in ICU survivors[32]: These individuals suffer from prolonged physical symptoms, such as respiratory insufficiency and muscle weakness. Recovering patients are also often left with long-term neuropsychiatric impairment and reduced quality of life. Indeed, data suggest significant cognitive impairment in this cohort.[33,34] Many suffer from posttraumatic stress disorder (PTSD).[35] Perhaps, most alarming, data from the United States, Canada, and Australia demonstrate that ICU survivors are two to five times more likely to die compared with age- and sex-matched population controls.[36–38] Three-year mortality in sepsis survivors is 70%; 5-year survival is 75%.[14]

A better understanding of these issues has emerged from the Surviving Sepsis Campaign (SSC),[39] a program designed to enhance use of evidence-based approaches to sepsis management. Application of some or all of the elements outlined in SSC has dramatically reduced mortality in this early phase of the disorder.[22] Future examination of the effects of the SSC and correlation with an emerging understanding of pathophysiology may help clarify matters.

UNDERLYING MECHANISMS: NEWER HYPOTHESES

As a result of advances in our understanding of the pathophysiology of sepsis, a number of hypotheses have been abandoned. In particular, those that proposed that sepsis reflected only the effects of excessive, uncontrolled inflammation are difficult to reconcile with recent data demonstrating early immunosuppression. Similarly, it has been difficult to demonstrate translocation of bacteria from the gut or the occurrence of "two hits," that is, a scenario in which a second insult precipitates organ dysfunction. Several contemporary alternative hypotheses have emerged.

THE MICROCIRCULATORY HYPOTHESIS

Characteristic features of CCI are a defect in $\dot{V}_{O_2}$ and an increase in the production of lactate. Two theories have been proposed to account for these observations. The first, termed the *microcirculatory hypothesis*, posits that aberrant oxygen extraction results from a failure of cells or organs to receive adequate levels of oxygen or some important nutrient or substrate.[40] Low blood flow, as is likely to occur in hypotension or shock, contributes to cellular dysfunction. The release of vasoactive mediators and vascular congestion secondary to microthrombi and leukocytes are also thought to play important roles.

Reperfusion of ischemic tissue may be as important a determinant of tissue injury as is decreased flow itself.[41,42] In particular, the generation of oxygen-free radicals and peroxidation of membrane lipids following reperfusion may contribute to tissue injury. Sources of free radicals include the conversion of molecular oxygen to superoxide by xanthine oxidase, activated leukocytes, mitochondria, and prostaglandin synthase.

Circulatory shock, microvascular compromise, and free radical generation likely directly affect the endothelium. Endothelial cells actively generate free radicals, provide a point of attachment for leukocytes, and may be exquisitely sensitive to hypoxia. In addition, they produce and respond to vasoactive mediators.[43] As a result of these interactions, the microvascular hypothesis may be viewed as an extension of the *cytokine hypothesis*.[44] Indeed, cytokines activate endothelial cells to elaborate other vasoactive substances and to express surface proteins that promote leukocyte adhesion. Further, endothelial cells are important participants in the formation of microthrombi.

The microvascular hypothesis is supported by autopsy data documenting the presence of microvascular injury and microthrombi containing platelets, neutrophils, and fibrin in patients dying with CCI. The use of side-stream, dark-field videomicroscopy has demonstrated microcirculatory failure in septic patients, while increased microcirculatory flow during resuscitation is associated

with reduced organ failure at 24 hours, even in the absence of substantial changes in hemodynamics.[45] Conversely, antibodies to CD18, which block leukocyte adhesion and are protective in some forms of ischemia–reperfusion injury,[23,46] do not protect against liver injury or leukocyte adherence in experimental sepsis.[46,47]

While microcirculatory failure is present in sepsis and may contribute to the development of MODS and CCI, it cannot explain many of the clinical and pathologic features of these syndromes.

THE MITOCHONDRIAL HYPOTHESIS

An alternative explanation of the sepsis-induced defect in oxygen extraction is based on studies addressing mitochondrial dysfunction. The central tenet of this process, termed "cytopathic hypoxia," is a defect in oxidative phosphorylation. In support of this concept is demonstration of impairment in several of the five complexes that comprise the mitochondrial respiratory chain in humans during experimental sepsis. A decrease in the so-called "Complex I" (NADH: ubiquinone oxidoreductase) activity is observed in skeletal muscle in patients with sepsis and in liver and muscle in septic rats.[48,49] In addition, sepsis decreased Complexes II–III (succinate dehydrogenase and cytochrome bc1, respectively) activity has been reported in the hearts of septic rats,[50] while attenuated Complex IV (cytochrome c oxidase) activity has been reported in cardiac muscle and liver in septic rats.[25,51,52] Others have suggested that Complex IV functions as a sensor of dysoxia.[53–58] Thus, inhibition of this enzyme complex in response to an insult limits oxidative phosphorylation and protects mitochondria.

THE "FAILED COMMUNICATION" HYPOTHESIS

In the 1980s, investigators[59,60] identified the "proinflammatory" cytokines TNFα and IL-1β as primary mediators of septic shock. Other cytokines have since been added to this list, notably IL-6 and HMGB1.[27] For a time, these disorders were believed to reflect "malignant inflammation." However, two important findings have altered perceptions of severe sepsis/septic shock as inflammatory disorders.

First, as mentioned, immunosuppression, in a sense, the antithesis of "malignant inflammation," is an early and important component of severe sepsis.[6,7] To some degree, immunosuppression may be attributed to enhanced production of "anti-inflammatory" cytokines, such as IL-4 and IL-10, and conversion of T-helper (Th) cells from a Th-1 (proinflammatory) to a Th-2 (anti-inflammatory) phenotype. In addition, recent studies suggest impairment of the receptors and intracellular pathways that transduce cytokine-mediated responses in noninflammatory tissues.[61] In response, the production and release of cytokines increases. This finding explains the dramatically increased levels of TNF, IL-1, and, especially, IL-6.[61] Perhaps, more importantly, therapy designed to limit both pro- and anti-inflammatory activities have failed to improve outcomes in sepsis. Thus, the immune dysfunction of sepsis cannot be simply characterized. Some responses are excessive and some inadequate; most defy a simple approach to classification.

The demonstration that white cell activity becomes depressed over time in sepsis, while coupled with the loss of intracellular activity in nonimmune cells, is suggestive immunosuppression.[7] Along this line of thinking, investigators[62] postulated that sepsis represented a disorder where "connectivity" was lost. Under normal conditions, the functions of the heart, lungs, kidneys, and other organs are tightly coupled and exquisitely responsive to local metabolic demand. In sepsis (and, indeed, in other disorders), the tightly orchestrated fluctuations in activity are lost. This hypothesis is consistent with impaired cytokine production and activity. For example, cytokine-mediated effects may alter activity in the same cell that produces the cytokine (autocrine), as well as that in nearby (paracrine) or distant (endocrine) cells. Loss of the endocrine activity of cytokines limits the ability of organ systems to act in concert. However, there are two other mechanisms by which cells and organs interact and by which metabolic interaction between organs may be coupled: the endocrine and central nervous systems.

Sepsis-induced endocrine abnormalities have been studied and abnormalities defined in the activity of a number of hormones that are similar to those described for cytokines.[63,64] In the early stages of sepsis, peripheral effector cells become increasingly unresponsive to endocrine stimulation. These abnormalities reflect changes in the target cells themselves. For example, the conversion of thyroxine (T4) to triiodothyronine (T3) becomes limited. In response, release of T4 by the thyroid and of TSH by the pituitary increases to compensate for decreased peripheral T3 activity. In the later stages of sepsis, the hormonal output of the pituitary and the peripheral glands themselves decrease. Levels of TSH and T4 decline, and both the effects and levels of T3 become even more depressed. Indeed, sepsis-induced dysfunction occurs in the endocrine system.

Abnormalities in the CNS are less well defined. It has long been known that sepsis alters consciousness. More recent data indicate that sepsis may cause cognitive impairment, encephalopathy, delirium, PTSD, and a host of other abnormalities. Until recently, the only pathologic change demonstrated in the CNS was a loss of blood–brain barrier integrity. However, two recent studies have added key information. Animal studies[65] have demonstrated cognitive impairment in mice surviving cecal ligation and puncture (CLP) sepsis. This effect is paralleled by a loss of synaptic plasticity in hippocampal neurons. In the same model, loss of activity in the orexinergic nervous system (ONS) has been demonstrated.[66] The ONS comprises 3000 to 6000 neurons in the lateral hypothalamus that secrete the neurotransmitter orexin (also known as hypocretin). These neurons receive input from throughout the CNS and, in turn, project to multiple different loci. Of key importance, however, is the known ability of the ONS to modulate activity, level of consciousness, hemodynamics, respiration, thermoregulation, and metabolism—all processes that are impaired in sepsis. In addition, the ONS connects with the pituitary and modulates the release of pituitary hormones. Thus, dysfunction in the ONS may explain a number of sepsis-associated abnormalities.

To further elucidate the failed communication hypothesis, two additional pieces of data are required: Demonstration of (1) interactions between the inflammatory system, the endocrine system, and the CNS, and (2) that reversal of the observed abnormalities in the three systems alters septic pathophysiology. Recent studies have demonstrated an interaction between the CNS and inflammatory cells.[67] This "inflammatory reflex" is a nicotinic, vagally mediated reflex that is impaired in sepsis. Vagal stimulation or administration of compounds with nicotinic activity may restore these lost anti-inflammatory effects. In addition, persistently elevated levels of HMGB-1 in animals that survived sepsis have been demonstrated.[65] Neutralization with an anti-HMBG1 antibody reversed the histologic changes in the hippocampus and attenuated cognitive impairment. Similarly, administration of orexin into the cerebrospinal fluid of septic mice reversed sepsis-induced changes in temperature, heart rate, respiratory rate, motor activity, and arousal.[66] Thus, the inflammatory, endocrine, and central nervous systems are linked and impaired in sepsis. Restoration of activity or of interactions improves sepsis-induced pathophysiology.

Hypothyroidism may contribute to excessive fluid retention and edema, relative hypothermia, decreased ventilatory drive, and malabsorption.[68] Attempts at repletion have not proven successful. Cortisol levels are capricious, but they are often elevated. Whether or not cortisol administration is appropriate in septic patients remains controversial.[69,70] Growth hormone (GH) is reported to increase in the acute setting, but in later stages of sepsis, production is suppressed. One trial indicated that supplementing GH in septic patients increased mortality[71]; however, the study has been criticized on methodologic grounds. Finally, although use of intensive insulin therapy in critically ill patients was initially viewed as highly promising,[72] the results could not be duplicated, and a large randomized trial that included 5000 patients suggests that the hypoglycemia accompanying the therapy causes harm.[73]

MANAGEMENT OF SEPSIS, MODS, AND CHRONIC CRITICAL ILLNESS

Management of patients with sepsis is challenging and focuses on support of major end-organ damage. Support modalities have been compiled into treatment "bundles" by the SSC. This group released revised guidelines in 2012.[39] Importantly, the guidelines were evaluated using the "GRADE" (**G**rading of **R**ecommendations **A**ssessment, **D**evelopment, and **E**valuation) system.[74] According to the GRADE system, each guideline is evaluated on the basis of the strength of the supporting evidence (A through D, or UG for ungraded) and on the strength of the recommendation itself (1, strong, with the intervention designated as "recommended"; or 2, weak, with the intervention designated as "suggested"). For additional information, the reader is referred to the GRADE Working Group website (http://www.gradeworkinggroup.org/index.htm).

Key recommendations and suggestions from the SSC are detailed below. For a more complete discussion, the reader is referred to the guidelines themselves.[39] Ungraded recommendations have not been included.

INITIAL RESUSCITATION

Initial resuscitation of patients with sepsis-induced tissue hypoperfusion (defined in the SSC document as hypotension persisting after initial fluid challenge or a blood lactate concentration ≥4 mmol/L) is quantitative and protocol-driven. Goals during the first 6 hours of resuscitation include: (1) central venous pressure of 8 to 12 mm Hg; (2) mean arterial pressure (MAP) ≥65 mm Hg; (3) urine output ≥0.5 mL/kg/h; and (4) central venous (superior vena cava) or mixed venous oxygen saturation of 70% or 65%, respectively (grade 1C).

In patients with elevated lactate levels, resuscitation is targeted to normalize the lactate level (grade for entire recommendation, 2C).

The imperative for early resuscitation aimed at achieving specific goals that are thought to correlate with tissue perfusion arises from the seminal work of Rivers et al.[75] Rivers and colleagues compared standard management to quantitative resuscitation aimed at explicit physiologic endpoints over a 6-hour period immediately following initial suspicion of sepsis. The approach is known as "early goal-directed therapy" or EGDT. This single-center study of 263 patients demonstrated that EGDT led to a 15.9% absolute reduction in 30-day mortality. A second, multicenter trial of 314 patients in eight centers in China confirmed these results.[76] Multicenter trials are underway to further evaluate EGDT, as some of the specific endpoints, especially the CVP, are quite controversial.

EARLY DIAGNOSIS

Cultures should be obtained, as clinically appropriate, before antimicrobial therapy if there is no significant delay (>45 minutes) in the start of antimicrobial(s) (grade 1C). At least two sets of blood cultures (both aerobic and anaerobic) should be obtained before antimicrobial therapy, with at least one set drawn percutaneously and one drawn through each vascular access device, unless the device was recently (<48 hours) inserted (grade 1C).

Perhaps the most important part of this recommendation is that, under no circumstances, should diagnostic testing delay initiation of antimicrobial therapy.

INITIATION OF ANTIMICROBIAL THERAPY

The goal of therapy is administration of effective intravenous antimicrobials within the first hour of recognition of septic shock (grade 1B) and severe sepsis without septic shock (grade 1C).

Initial, empiric, anti-infective therapy is based on use of one or more drugs that have activity against all likely pathogens (bacterial and/or fungal or viral) and that penetrate in adequate concentrations into tissues presumed to be the source of sepsis (grade 1B).

The antimicrobial regimen should be reassessed daily for potential de-escalation (grade 1B).

Empiric combination therapy should not be administered for more than 3 to 5 days. De-escalation to the most appropriate single therapy should be performed as soon as the susceptibility profile is known (grade 2B).

The duration of therapy is typically 7 to 10 days. Longer courses may be appropriate in patients who have a slow clinical response, undrainable foci of infection, bacteremia with *Staphylococcus aureus*, or in some fungal and viral infections or immunologic deficiencies, including neutropenia (grade 2C).

Antiviral therapy is initiated as early as possible in patients with severe sepsis or septic shock of viral origin (grade 2C).

The recommendation that antimicrobials be started within 1 hour arises from a study published by Kumar et al.[77] and is substantiated by data in the SSC database (Mitchell M. Levy, personal communication). These data show that, in septic shock, mortality rises measurably with each hour that therapy is delayed. Data supporting a similar approach for severe sepsis are less robust.

SOURCE CONTROL

A specific anatomical diagnosis of infection requiring consideration for emergent source control should be investigated and diagnosed or excluded as rapidly as possible, and intervention should be undertaken for source control within the first 12 hours after the diagnosis is made, if feasible (grade 1C).

Despite a paucity of evidence, early control of anatomically accessible sources is strongly recommended.

HEMODYNAMIC SUPPORT

The important tenets of fluid therapy include: (1) use of crystalloids as the initial fluid of choice in the resuscitation of severe sepsis and septic shock (grade 1B); (2) avoiding use of hydroxyethyl starches for fluid resuscitation of severe sepsis and septic shock (grade 1B); (3) administration of albumin in the fluid resuscitation of severe sepsis and septic shock when patients require substantial amounts of crystalloids (grade 2C); and (4) administration of an initial fluid challenge in patients with sepsis-induced tissue hypoperfusion in whom there is suspicion of hypovolemia, aiming to achieve a minimum infusion of 30 mL/kg of crystalloids (a portion of this may be albumin equivalent). More rapid administration and greater amounts of fluid may be needed in some patients (grade 1C).

The high-grade recommendation to use crystalloid solutions reflects the absence of any demonstrable benefit to use of colloid. While albumin may be administered as an adjunct,[78] three clinical trials indicate that use of hydroxyethyl starch in critically ill patients is associated with enhanced renal impairment and increased requirement for renal replacement therapy.[79–81]

Important to note is that it is nearly impossible to restore the body to preinsult hemodynamic status until the inflammatory response has run its course.

RATIONAL USE OF VASOPRESSORS AND INOTROPES

Animal and human studies indicate that SIRS/MODS renders the cardiovascular system relatively resistant to the effects of native and synthetic catecholamines. Therefore, the choice of vasopressor agent may be of great importance.

Vasopressors

Vasopressor therapy is initially aimed at targeting a MAP of 65 mm Hg (grade 1C).

Norepinephrine (NE) is the first-choice vasopressor (grade 1B).

Epinephrine should be added to and, potentially, substituted for, NE when an additional agent is needed to maintain adequate blood pressure (grade 2B).

Vasopressin, 0.03 units/min, can be added to NE with intent of either raising MAP or decreasing NE dosage (UG).

Dopamine should be considered as an alternative agent to NE only in highly selected patients (e.g., patients with a low risk of tachyarrhythmias or absolute or relative bradycardia) (grade 2C).

Phenylephrine is not recommended in the treatment of septic shock except in circumstances where (a) NE is associated with serious arrhythmias, (b) CO is known to be high and blood pressure persistently low, or (c) as salvage therapy when combined inotrope/vasopressor drugs and low-dose vasopressin have failed to achieve MAP target (grade 1C).

Low-dose dopamine should not be used for renal protection (grade 1A).

The target mean blood pressure of 65 mm Hg, while strongly recommended, is based on grade C data. The primary study supporting this blood pressure goal is based on study of 10 patients with septic shock using indices of perfusion that have since proved to be less than reliable.[82] More importantly, the study assessed mean blood pressures between 65 and 85 mm Hg and demonstrated that perfusion did not change. However, pressures below 65 mm Hg were not evaluated.

A number of studies comparing NE to other agents clearly demonstrate this agent's superiority for septic shock. In particular, NE is a superior vasoconstrictor, primarily because it is a less potent β_2-agonist and has less vasodilatory effects. Importantly, catecholamines exert their major effects on vessels of the somatic circulation (supplying skin and skeletal muscle) and largely spare the visceral beds. Thus, NE, even in high doses, is unlikely to directly alter renal, hepatic, or gut blood flow. In fact, splanchnic flow may be improved when fluid is translocated from the periphery to the central, visceral compartment. Five randomized trials that included nearly 2000 patients have demonstrated that NE is superior to dopamine, at least in the short term.[83–87] A meta-analysis confirms this conclusion.[88]

While epinephrine is recommended as a second-line agent, β_2-stimulation increases lactate production in skeletal muscle and may limit use of lactate clearance as a parameter of perfusion.

Use of vasopressin is not graded. While vasopressin may effectively increase blood pressure, it may also impair splanchnic blood flow, even at low doses. Importantly, doses above 0.03 units/min are suggested only as salvage therapy in truly refractory shock.

Finally, the recommendation against use of low-dose dopamine for renal protection may signal the end of that dubious practice. The recommendation, one of the few given grade 1A status, is based on a large randomized trial and a meta-analysis.[89,90]

Inotropes

A trial of dobutamine infusion, up to 20 μg/kg/min, may be administered or added to a vasopressor (if in use) in the presence of (1) myocardial dysfunction, as suggested by elevated cardiac filling pressures and low CO, or (2) ongoing signs of hypoperfusion despite achieving adequate intravascular volume and adequate MAP (grade 1C).

A strategy to increase cardiac index to predetermined supranormal levels should not be employed (grade 1B).

The use of inotropes to achieve supranormal levels of CO and $\dot{V}_{O_2}$ is based on a study demonstrating that patients with critical illness who achieve these levels survive, while those failing to do so do not survive.[91] However, intervention to boost CO and $\dot{V}_{O_2}$ does not improve outcomes.[92]

Corticosteroids

Intravenous hydrocortisone should not be used to treat adult septic shock if adequate fluid resuscitation and vasopressor therapy restore hemodynamic stability. If fluid and vasopressor therapy fail to restore hemodynamic stability, intravenous hydrocortisone at a dose of 200 mg/d should be given (grade 2C).

The ACTH stimulation test should not be used to identify adults with septic shock with regard to hydrocortisone administration (grade 2B).

In patients given hydrocortisone, the drug should be tapered when vasopressors are no longer required (grade 2D).

Corticosteroids should not be administered for treatment of sepsis in the absence of shock (grade 1D).

When hydrocortisone is given for shock, a continuous infusion, rather than intermittent boluses, should be used (grade 2D).

The value of corticosteroids in sepsis remains controversial primarily because of the contrasting results of the two most definitive studies done to date.[69,70] Even meta-analyses show disparate results.[93,94] It is clear, however, that corticosteroids improve blood pressure and reduce catecholamine doses. These effects are not surprising, given that corticosteroids exert a "permissive" effect on catecholamine activity, making a given dose of catecholamine more potent.

CONCLUSION

Sepsis, MODS, and CCI represent major causes of mortality and morbidity. The nature of the underlying pathologic defect is unknown. Current treatment is supportive and centers on standard critical care management, an intensive search for an excisable or drainable inflammatory site, and avoidance of secondary organ injury.

CHAPTER 143

Pump Failure: The Pathogenesis of Hypercapnic Respiratory Failure in Patients with Lung and Chest Wall Disease

Steven G. Kelsen

The ventilatory pump accomplishes bulk transfer of air to and from the alveoli. Accordingly, diseases that perturb the mechanical properties of any component of the ventilatory pump (i.e., the bony rib cage, the extra- and intrathoracic conducting airways, and the respiratory muscles) may interfere with CO_2 elimination and O_2 uptake. If disturbances in the function of the ventilatory pump are sufficiently severe, alveolar hypoventilation and respiratory acidosis may ensue. Hypercapnic respiratory failure is defined as a steady-state Pa_{CO_2} while awake at more than 45 mm Hg, the upper limit of normal. This definition is somewhat arbitrary but has proved clinically useful.

Conceptually, diseases that cause hypercapnic respiratory failure do so by deranging respiratory mechanics and lung dead space volume (e.g., chronic obstructive pulmonary disease [COPD], asthma, or kyphoscoliosis) or by impairing the contractile properties of the respiratory muscles (e.g., neuromuscular disease). Diseases that impair respiratory mechanics increase the elastic or resistive load against which the respiratory muscles must contract. On the other hand, neuromuscular diseases impair the strength or endurance properties of the respiratory muscles and impair their ability to generate swings in intrathoracic pressure sufficient to maintain ventilation.

The rhythmic act of breathing results from the activity of a central respiratory pattern generator (CRPG) comprises interacting networks of excitatory and inhibitory neurons in the pons and medulla oblongata.[1,2] In turn, projections from the CRPG to bulbospinal motor neurons activate the respiratory skeletal muscles in the chest wall, abdomen, and upper airway and, hence, shape the neuromuscular drive to breathe. A variety of compensatory neural mechanisms located in the periphery that sense alterations in blood-gas tensions or ventilatory performance which project to the CRPG elicit increases in the neuromuscular drive to breathe and, in turn, help preserve alveolar ventilation.[3–7] In fact, in most patients, rather marked abnormalities in ventilatory pump performance are required before hypercapnic respiratory failure ensues. Conceptually, the susceptibility to develop CO_2 retention in the setting of lung, chest wall, or respiratory muscle dysfunction, therefore, depends on the balance between the severity of the derangement in ventilatory pump function and the intensity of the respiratory neuromuscular drive to breathe.[5]

This chapter deals with the pathogenic mechanisms at work in the development of CO_2 retention in lung and chest wall diseases. The compensatory/adaptive mechanisms that help preserve ventilation (e.g., respiratory chemosensitivity, motor responses to alterations in the mechanics of breathing, and intrinsic changes in respiratory muscle strength and endurance) and the decompensating/maladaptive responses that predispose to CO_2 retention (e.g., respiratory muscle wasting and fatigue and a rapid, shallow pattern of breathing) will be discussed.

COMPENSATORY/ADAPTIVE MECHANISMS

The roles of compensatory or adaptive mechanisms in hypercapnic respiratory failure are considered with respect to respiratory chemosensitivity, blunted chemosensitivity, and alterations in respiratory structure.

RESPIRATORY CHEMOSENSITIVITY

Below is a discussion of normal respiratory chemosensitivity and measures of respiratory motor output.

Overview—Regulation of Ventilation

Hypoxia and hypercapnia stimulate chemoreceptors in the arterial circulation (peripheral chemoreceptors) and ventrolateral medulla (central chemoreceptors) that reflexively increase motor activity to the respiratory skeletal muscles of the chest wall and upper airway.[8] Contraction of the muscles of the chest wall (e.g., diaphragm, intercostals, abdominals, and neck muscles) deforms the ventilatory pump and moves air.[5] Contraction of the muscles of the upper airway (genioglossus, alae nasi, posterior arytenoids, pharyngeal dilators, sternohyoid, etc.) increases the caliber of the upper airway and diminishes its susceptibility to collapse during inspiration.[6]

Chemoreceptor-induced increases in inspiratory and expiratory muscle activity are proportional to the severity of abnormalities in blood-gas tensions and represent a feedback control loop that restores blood-gas tensions toward normal by enhancing alveolar ventilation. The magnitude of the swings in intrathoracic pressure and resistance and compliance of the upper airway are determined by these changes in respiratory motor activity. The maintenance of blood-gas tensions within a relatively narrow, normal range from neonatal life to senescence attests to the power of this homeostatic mechanism.

Hypoxic and hypercapnic chemical drives to breathe exert the following stereotypic effects on the activity of chest wall and upper airway muscles.[6,8,9] Peak respiratory muscle electrical activity and its rate of rise are increased. For the inspiratory muscles, these changes in muscle electrical activity increase the rate of change and peak inspiratory intrathoracic pressure, inspiratory airflow, and tidal volume. For the expiratory muscles, increased electrical activity enhances the rate of expiratory airflow. For the upper airway muscles, the resistance to inspiratory airflow decreases.

Chemosensitivity-induced increases in respiratory activity also affect the timing of respiratory motor activity as reflected in the duration of inspiration (T_I) and expiration (T_E).[10,11] Hypoxia and hypercapnia lead to decreased T_I and T_E, allowing the frequency of breathing to increase. Reductions in T_E are generally out of proportion to T_I, thereby increasing the fraction of the respiratory cycle spent in inspiration. This partitioning of the respiratory cycle is reflected in the T_I/T_T ratio, where T_T is the total breath cycle duration (i.e., the sum of T_I and T_E).

Hypoxia and hypercapnia differ in their effects on the activity of the inspiratory muscles after the cessation of inspiratory airflow, the so-called postinspiratory inspiratory activity (PIIA).[1] Hypoxia increases PIIA in both chest wall inspiratory muscles and muscles that constrict the laryngeal aperture. Accordingly, hypoxia has a

braking effect on the rate of expiratory airflow. As T_E decreases with increasing hypoxic drive, end-expiratory lung volume increases. PIIA-induced increases in lung volume increase the caliber of the intrathoracic airways and the O_2 content of the lung. Hypoxia-induced PIIA affects the load on the respiratory muscles in complex fashion; that is, PIIA reduces inspiratory resistive work of breathing but increases the inspiratory elastic and expiratory resistive work of breathing. It has been suggested, however, that the net effect of hypoxia-induced PIIA is a reduction in overall energy expenditure during breathing. In contrast, hypercapnia diminishes the duration of PIIA.

Indices of Respiratory Motor Output

Ventilation is a well-accepted index of respiratory motor output.[8,10–12] Traditionally, ventilation was viewed as the product of tidal volume (V_T) and respiratory rate (which is equal to $60/T_T$). More recently, ventilation has been viewed as the product of separate "drive" and "timing" components.[10] The average rate of inspiratory airflow, V_T/T_I – which reflects the rate of rise of inspiratory muscle activity and intrathoracic pressure – is increased when blood-gas tensions are deranged. Accordingly, V_T/T_I has been taken as a reflection of the activity of mechanisms that regulate the drive to breathe. Of note, V_T/T_I may also be increased by excitatory inputs arising from respiratory mechanoreceptor afferents (e.g., vagal irritant receptors) and higher central nervous system (CNS) structures engaged in thermoregulation and emotion (i.e., hypothalamic and limbic areas). Conversely, the T_I/T_T ratio has been taken as a reflection of the activity of mechanisms that regulate respiratory timing. The T_I/T_T ratio is strongly affected by afferent input from mechanoreceptors in the lungs, airways, and respiratory muscles, as well as increasing chemical drive. For example, T_I/T_T increases in anesthetized animals when vagal stretch receptors are stimulated by increases in lung volume and is decreased by bronchoconstriction-induced activation of vagal irritant receptors.

In subjects with normal lung function, V_T/T_I and ventilation are accurate reflections of inspiratory muscle electrical activity and the rate of rise of intrathoracic pressure. On the other hand, diseases that adversely affect the mechanical properties of the ventilatory pump (e.g., obstructive lung disease, kyphoscoliosis) interfere with the translation of changes in intrathoracic pressure into ventilation and airflow. Conversely, conditions that impair respiratory muscle contractility (e.g., neuromuscular diseases, respiratory muscle fatigue) interfere with the translation of inspiratory muscle electrical activity into intrathoracic pressure changes. Accordingly, V_T/T_I reflects the intensity of motor outflow to the inspiratory muscles produced by increasing chemical drive only when the mechanical properties of the ventilatory pump and inspiratory muscle strength are normal. When the ventilatory pump function is abnormal, respiratory motor outflow is best assessed from respiratory muscle electrical activity (i.e., diaphragm electromyography [EMG] activity), a complicated measurement largely confined to the research laboratory.

A simpler, clinically useful measurement that reflects the neuromuscular drive to breathe and the driving pressure to inspiratory airflow is the airway occlusion pressure.[10,13–15] The occlusion pressure is the pressure generated at the airway opening 100 ms after the onset of an occluded inspiratory effort (i.e., P_{100} or $P_{0.1}$) initiated at end-expiratory lung volume. Since the airway is occluded, the inspiratory muscles contract quasi-isometrically, a condition in which muscle force correlates closely with muscle electrical activity. Measurements are made early in inspiration (100 ms) to prevent behavioral responses elicited in response to airway occlusion from altering the shape/trajectory of the pressure waveform. The lack of flow or volume change during the measurement means that the occlusion pressure is unaffected by abnormalities in the flow-resistive or compliance properties of the ventilatory pump. The occlusion pressure, therefore, has been used to assess the drive to breathe in patients with lung diseases (e.g., COPD and asthma) and chest wall diseases (e.g., kyphoscoliosis) during resting and chemically stimulated breathing. On the other hand, the occlusion pressure depends on the ability of the inspiratory muscles to convert neural activity into force and pressure. Accordingly, like ventilation, occlusion pressure may not reflect respiratory motor neuron activity when the inspiratory muscles are weak (e.g., neuromuscular disease) or fatigued.

Hypoxic Response Under isocapnic conditions, ventilation (or occlusion pressure) increases in curvilinear fashion as P_{O_2} falls.[8] However, hypoxic responses depend importantly on the prevailing level of Pa_{CO_2} (i.e., the O_2–CO_2 interaction). When Pa_{CO_2} is in the hypocapnic range, arterial P_{O_2} must fall considerably (to approximately 55–60 mm Hg or less) before respiratory activity increases. Hypercapnia profoundly increases the response to hypoxia by shifting the threshold of the response toward higher levels of P_{O_2} and augmenting the change in ventilation elicited for a given reduction in P_{O_2}.

Although the physiological stimulus for the hypoxic response is the Pa_{O_2} of the blood perfusing the peripheral chemoreceptors, for convenience the oxyhemoglobin saturation assessed with a pulse oximeter has been taken as a reflection of the stimulus. Use of the oxyhemoglobin saturation linearizes the relationship between the hypoxic stimulus, ventilation, and occlusion pressure. The intensity of the hypoxic response has been assessed from the slope of the change in ventilation (or occlusion pressure) relative to the change in O_2 saturation (i.e., $\Delta V_E/\Delta\%\ O_2$ sat) and from the intercept of the relationship (e.g., ventilation at O_2 saturation of 85%).

Hypercapnic Response In contrast to the response to hypoxia, the ventilatory and occlusion pressure responses to hypercapnia under iso-oxic conditions are linear over a relatively wide range of Pa_{CO_2} above and below the resting level of 40 mm Hg.[8] The intensity of the ventilatory and occlusion pressure response to CO_2 has been assessed from the slope of the relationship of V_E to Pa_{CO_2} (i.e., $\Delta V_E/\Delta Pa_{CO_2}$) and from the intercept of the relationship (i.e., V_E at Pa_{CO_2} 50 mm Hg).

The ventilatory response to hypercapnia is strongly affected by the prevailing level of Pa_{O_2} and is heightened as Pa_{O_2} decreases. In fact, hypoxemic and hypercapnic stimuli interact multiplicatively to enhance inspiratory and expiratory motor activities. Worsening hypoxemia enhances the ventilatory response to hypercapnia in accordance with the O_2–CO_2 interaction. The strength of a subject's chemosensitivity to O_2 and CO_2 and, in particular, to the O_2–CO_2 interaction is a powerful feedback mechanism opposing the tendency to retain CO_2 in patients with ventilatory pump dysfunction.

Consequently, treatment of the hypercapnic, hypoxemic patient with supplemental O_2 may decrease V_T/T_I and T_I/T_T and, hence, worsen hypercapnia in accordance with O_2–CO_2 interaction. Increases in Pa_{O_2} in hypoxic, hypercapnic subjects move the O_2 response to the right (less stimulus) and decrease the slope and shift the intercept of the ventilatory response to *hypercapnia* to the right (Fig. 143-1). Shifts in the CO_2 response with increases in the prevailing Pa_{O_2} mean that a higher CO_2 stimulus is required to maintain ventilation at the baseline level. Accordingly, ventilation falls and Pa_{CO_2} rises. The magnitude of the rise in Pa_{CO_2} in patients with COPD in acute respiratory failure produced by supplemental O_2 varies widely among subjects as determined by their chemosensitivity.

Of note, hypercapnia induced by supplemental O_2 in patients with COPD is multifactorial and reflects increases in lung dead space volume as well as reductions in alveolar ventilation. Hypoxemia causes bronchoconstriction via increases in parasympathetic outflow to airway smooth muscle. Accordingly, relief of hypoxemia causes bronchodilation and increased dead space volume.

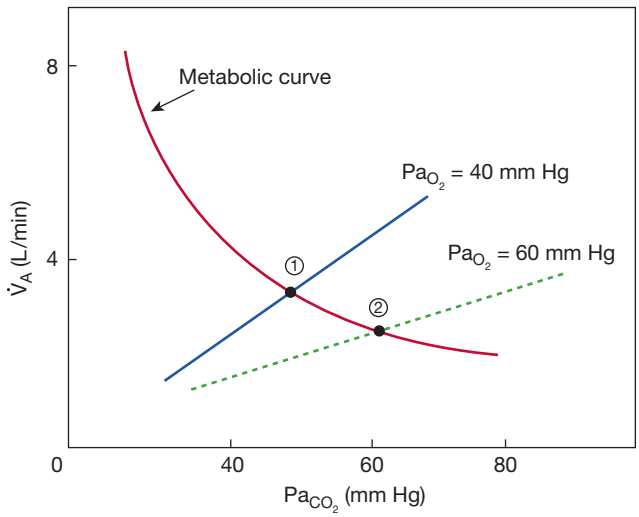

Figure 143-1 Theoretical effects of supplemental O_2 on the ventilatory response to CO_2 and steady-state arterial Pa_{O_2} in subjects with COPD in hypercapnic respiratory failure. Increasing Pa_{O_2} decreases alveolar ventilation and increases Pa_{CO_2} as dictated by effects of O_2 on the CO_2 ventilatory response. The two *straight lines* represent hypercapnic ventilatory response curves at Pa_{O_2} of 40 and 60 mm Hg. As may be seen, increasing Pa_{O_2} produces a downward, rightward shift of the ventilatory response. In contrast, the *hyperbolic line* intersecting the ventilatory response lines is the metabolic CO_2–ventilation curve, which represents the effect of increasing alveolar ventilation (independent variable) on Pa_{CO_2} (the dependent variable) when CO_2 production is normal (~200 mL/min). Steady-state alveolar ventilation and Pa_{CO_2} at rest are dictated by intersection of the ventilatory response curves with the metabolic curve (points 1 and 2). Note the increase in Pa_{CO_2} as the ventilatory response with Pa_{O_2} 60 mm Hg intersects at a lower alveolar ventilation and higher Pa_{CO_2} (point 2) compared to the higher ventilatory response when Pa_{O_2} was 40 mm Hg (point 1).

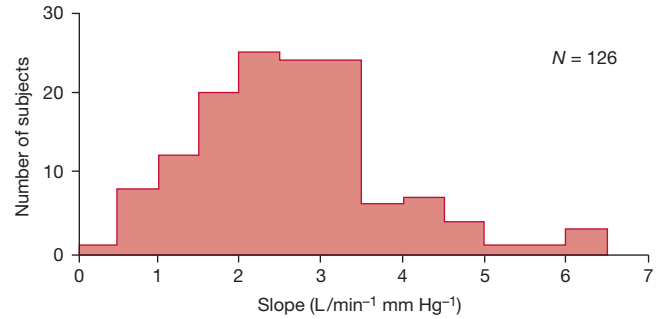

Figure 143-2 Variability of the slopes of the ventilatory responses to progressive hypercapnia (i.e., P_E/P_{CO_2}) in a normal population. Shown is the frequency distribution histogram of the slopes in 126 normal South African medical students. Note the considerable interindividual variation in CO_2 responsiveness. In some healthy subjects, the ventilatory response is blunted to less than 1 L/min/mm Hg P_{CO_2}. *(Data from Irsigler GB. Carbon dioxide response lines in young adults: The limits of the normal response. Am Rev Respir Dis. 1976;114:529–536.)*

ROLE OF BLUNTED CHEMOSENSITIVITY IN DEVELOPMENT OF RESPIRATORY FAILURE

Chemosensitivities to hypoxemia and hypercapnia are heredofamilial and ethnic traits that vary widely interindividually (Fig. 143-2).[16,17] In a given subject, responses to hypoxemia and hypercapnia correlate weakly, so that subjects with strong responses to hypercapnia also tend to have strong responses to hypoxia. Respiratory chemosensitivity to both hypoxemia and hypercapnia declines with age.[18] The decline in chemosensitivity with aging may explain why elderly subjects with lung disease (e.g., COPD) or chest wall disease (e.g., kyphoscoliosis) develop hypercapnic respiratory failure more frequently than young adults. When chemosensitivity is low, subjects with diseases of the ventilatory pump are predisposed to develop hypercapnic respiratory failure.[16,17,19]

In patients with advanced COPD, the severity of airway obstruction required to cause CO_2 retention varies widely from subject to subject (Fig. 143-3).[20,21] Subjects with the greatest respiratory effort responses to changes in Pa_{CO_2} – as measured by diaphragm EMG, respiratory work of breathing, or occlusion pressure – have arterial Pa_{CO_2} values closer to normal than subjects with blunted responses to CO_2 but the same severity of lung dysfunction. Accordingly, when chemosensitivity is low, subjects with diseases of the ventilatory pump are predisposed to develop hypercapnic respiratory failure. However, since CO_2 retention per se may blunt the response to acute hypercapnia, studies in patients in respiratory failure have not been able to determine whether blunted CO_2 responses are a cause or consequence of respiratory failure.[22]

The tendency for chemosensitivity to be inherited has been used in a number of subsequent studies to assess the role of hypoxic and hypercapnic responses in the pathogenesis of CO_2 retention in the setting of obstructive lung disease. Study of relatives with normal lung function and blood gases has been employed to circumvent the effects of CO_2 retention on respiratory chemosensitivity in patients with COPD.

In general, normal relatives of hypercapnic patients with COPD have lower ventilatory responses to hypoxia and hypercapnia than

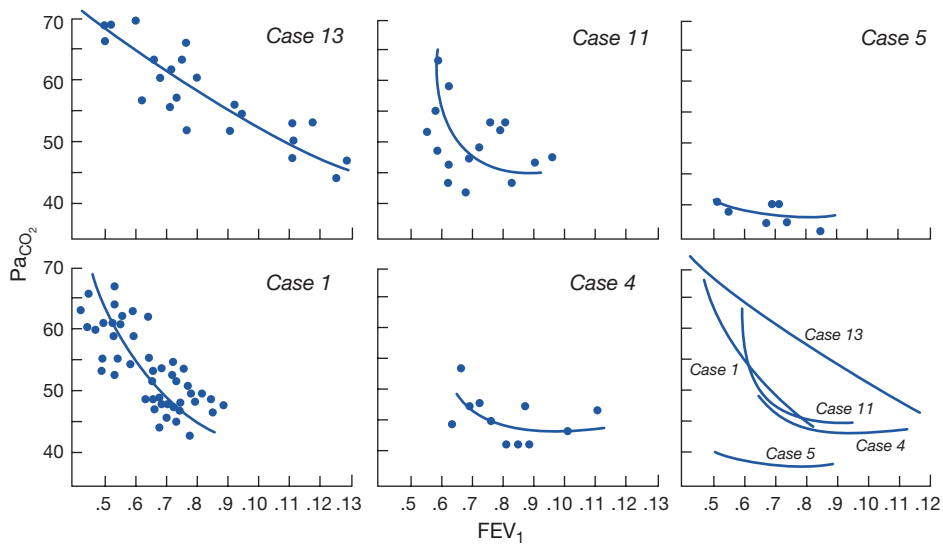

Figure 143-3 Results of repeated measurements of arterial P_{CO_2} and FEV_1 (liters) in five patients with advanced COPD. Free-hand curves of the data are shown plotted together in the lower right graph. Note that cases 1, 11, and 13 show marked increases in P_{CO_2}, with relatively small changes in FEV_1, whereas cases 4 and 5 do not. *(Data from Lane DJ, Howell JBL, Giblin B. Relation between airways obstruction and CO_2 tension in obstructive airways disease. Br Med J. 1968;3:707–709.)*

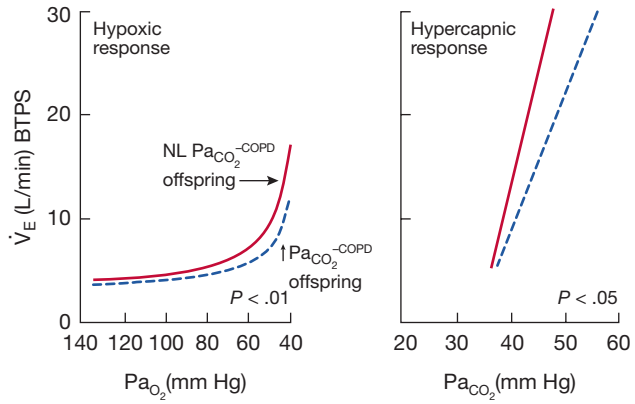

Figure 143-4 Mean isocapnic hypoxia and hyperoxic hypercapnic ventilatory response curves of 12 offspring of hypoventilating patients with COPD *(solid line)* and 10 offspring of eucapnic COPD patients *(dashed line)*. Ventilatory responses to hypoxia and hypercapnia are significantly lower in the offspring of hypercapnic COPD than in the offspring of eucapnic COPD patients. *(Data from Mountain R, Zwillich CW, Weil JV. Hypoventilation in obstructive lung disease: The role of familial factors. N Engl J Med. 1978;297:521–525.)*

relatives of eucapnic patients with COPD (Fig. 143-4).[17] The slopes of the ventilatory responses to isocapnic hypoxemia and hyperoxic hypercapnia are 30% to 40% lower in the offspring of hypercapnic patients than in the offspring of eucapnic patients. Similarly, the slopes of the ventilatory and airway occlusion pressure responses to isocapnic hypoxia are approximately 40% lower in the offspring of hypercapnic patients than in the offspring of normocapnic patients. In one study, the Pa_{O_2} of COPD patients while in a stable state and the Pa_{O_2} and Pa_{CO_2} during COPD exacerbations correlated with the hypoxic ventilatory response of their sons. It appears that blunted chemosensitivities[23] to hypoxia and hypercapnia are likely to be premorbid characteristics of hypercapnic patients with COPD, which contribute to the development of respiratory failure.

A number of reports describe patients with asthma and respiratory failure who had blunted ventilatory responses to hypoxia and hypercapnia and whose healthy immediate family members also showed blunted hypoxic and hypercapnic responses. Respiratory responses to hypoxia and hypercapnia in patients with asthma who have near-fatal attacks differ from those of asthmatics who did not have near-fatal attacks and age-matched, normal subjects.[19] The slopes of the ventilatory and occlusion pressure responses to hypoxia in the patients with a history of near-fatal asthma are approximately 33% similar. Hypercapnic responses tend to be lower in the near-fatal asthmatic groups than in the other two groups, but the differences are smaller in magnitude. Of interest, recent studies indicate that hereditary loss of function mutations in the neuronal transcription factor, paired-like homeobox 2B (Phox2b), which are required for normal development of the retrotrapezoid nucleus, a chemosensitive region, are associated with impaired chemosensitivity to hypercapnia, resting hypercapnia and central hypoventilation in man.[23,24]

Responses to Heightened Respiratory Load

A complex array of mechanoreceptors and proprioceptors whose afferents project to respiratory neurons in the brain stem and higher CNS structures provides the respiratory controller with information about the mechanics of breathing and performance of the ventilatory pump.[6] The sensory receptors providing this afferent feedback and the CNS structures that integrate this feedback into a coordinated respiratory response are not perfectly understood. However, mechanoreceptors in the intercostal muscles that sense muscle tension and length (Golgi tendon receptors and spindle organs, respectively) and pressure and flow sensors in the lower (vagal irritant receptors) and upper airway (larynx and mouth) clearly play a role in shaping the neuromuscular response to alterations in the mechanics of breathing.

Diseases of the airways (COPD and asthma) or chest wall (kyphoscoliosis) change the resistance and compliance properties of the ventilatory pump and, hence, stimulate mechanoreceptors in the ventilatory pump. In normal subjects and those with COPD, mechanoreceptor afferent inputs increase inspiratory neuromuscular output as reflected in airway occlusion pressure in response to bronchoconstriction or external resistances or elastance. Changes in ventilation during acute increases in airway resistance are inversely related to changes in occlusion pressure. Thus, the magnitude of the motor response to increases in respiratory load determines the ventilatory response.

External ventilatory loads that can be consciously detected and alter the intensity of the sensations associated with breathing elicit increases in respiratory effort as reflected by the diaphragm EMG and occlusion pressure.[3,25] Increases in effort occur abruptly within the first loaded breath and in feed-forward fashion; that is, the experience of the previous breath elicits a response in anticipation that the load will still be present. These responses are eliminated by general anesthesia and dulled if not absent in stages III and IV and REM sleep. The afferent input to the CNS elicited by external ventilatory loads probably arises from spindle and tendon organs in the respiratory muscles that project to the sensorimotor cortex and medullary respiratory neurons. The motor response to external ventilatory loads is thought to be behavioral.

The magnitude of the respiratory motor response to external loads varies widely from subject to subject and may be a heredofamilial trait. Of considerable importance, some subjects with COPD demonstrate lesser occlusion pressure responses to acutely applied external resistive loads than age-matched normal subjects.[22] It has been suggested that the blunted respiratory motor response to external loads may be a form of sensory adaptation to chronic increases in respiratory resistance. The fact that occlusion pressure responses of patients with COPD to external elastic loads and patients with asthma to external resistive loads are normal supports this concept. Of interest, the blunted motor response to external loads in some patients with COPD may reflect an increase in endogenous opiates within the CNS, since naloxone administration immediately enhances the response.

In subjects with COPD, bronchoconstriction increases airway occlusion pressure in proportion to increases in airway resistance and to a greater extent than external flow–resistive loads.[26] Bronchoconstriction increases the activity of vagal "irritant" receptors in the airway, which exert an inspiratory augmenting effect on breathing. Irritant receptors may also be excited chemically by inflammatory mediators (e.g., histamine, prostaglandin $F_{2\alpha}$) and, in contrast to external loads, elicit simple monosynaptic reflexes not abolished by sleep or anesthesia.

Mechanoreceptor inputs modify the respiratory motor responses to chemical stimuli to breathing. Increases in the elastic or resistive load to inspiration augment inspiratory muscle electrical activity and the airway occlusion pressures to hypoxia and hypercapnia. Subjects with asthma show heightened occlusion pressure responses to hypoxia and hypercapnia for this reason. Increases in the inspiratory neuromuscular drive to breathe allow ventilation to be maintained in the face of abnormalities in respiratory mechanics. Respiratory motor activity (i.e., occlusion pressure) also tends to be increased when the respiratory muscles are weak. In all likelihood, this reflects the fact that the maintenance of force output by a weakened muscle requires an increase in activation by the CNS.

Increased ventilatory loads also alter the pattern of breathing in load-dependent fashion.[3] Subjects breathing against resistive loads

breathe slowly and deeply, with an increase in tidal volume and prolongation of T_I and T_E. In contrast, subjects breathing against elastic loads tend to breathe with smaller tidal volumes and a reduced T_I and T_E; that is, they demonstrate a rapid and shallow pattern of breathing. Slow, deep breathing during resistive loading and rapid, shallow breathing during elastic loading diminish the resistive and elastic work of breathing, respectively. Alterations in breathing pattern when the mechanics of breathing are deranged are believed to be attempts to minimize the work of breathing, muscle tension, or energy expended.

Integrated Motor Responses

Respiratory motor responses to heightened chemical or mechanoreceptor drives to breathe elicit highly coordinated patterns of muscle activity that optimize the mechanical output of the respiratory musculature contracting in concert.[5,6,27,28] These responses may take the following forms[1]: Simple reflex-mediated recruitment of additional agonists, which exert similar mechanical effects on the chest wall[2]; sequential activation of inspiratory and expiratory muscles, which exert opposing effects on chest wall structures; and[3] complex behavioral acts that use nonrespiratory muscles to effect changes in body posture and expiratory airflow, minimizing dyspnea.

For example, hypercapnia and hypoxia recruit the external intercostal and parasternal muscles during inspiration in a stereotypic rostral-to-caudal direction, and the internal intercostals and triangularis sterni during expiration in the opposite direction. Preferential activation of the inspiratory external intercostal and parasternal muscles in the rostral-most interspaces decreases the impedance of the rib cage to rostral movement and, hence, facilitates thoracic expansion. Conversely, recruitment of the expiratory internal intercostals and triangularis sterni in the most caudal interspaces decreases the impedance to caudal movement and facilitates thoracic deflation. In addition, recruitment of the parasternal intercostal muscles facilitates inspiratory pressure as tidal volume increases. The parasternal intercostal muscle fiber length, which is optimum for tension development, is shorter than that of the diaphragm and occurs at higher lung volume. Accordingly, the parasternal muscles become mechanically more effective than the diaphragm as lung volume increases above functional residual capacity (FRC).

Moreover, hypercapnia and hypoxia increase phasic and tonic inspiratory activities in the dilator muscles of the upper airway (e.g., posterior arytenoid, alae nasi, genioglossus). Increases in activity of the dilator muscles of the upper airway decrease the load on the chest wall pumping muscles by decreasing the resistance to inspiratory airflow through the upper airway. Increased activity of these muscles also diminishes the susceptibility of the upper airway to collapse as inspiratory efforts become greater and subpharyngeal pressure becomes more subatmospheric.

In addition, phasic increases in abdominal expiratory muscle electrical activity during expiratory airflow accelerate lung emptying, thereby allowing the time of expiration to decrease. When sufficiently intense, activation of the abdominal muscles reduces end-expiratory lung volume and improves the ability of the diaphragm to generate pressure by favorably affecting its precontraction length, radius of curvature, and alignment with the rib cage. Reductions in end-expiratory lung volume achieved by the expiratory muscles also allow elastic work to be stored in the passive recoil of the chest wall and released suddenly at the onset of inspiration. Sudden release of the recoil pressure of the chest wall thereby "assists" the inspiratory muscles by contributing to the driving pressure to inspiratory airflow. A portion of the inspiratory load is thus assumed by the expiratory muscles.

Finally, hyperinflated, dyspneic patients with COPD often assume a stereotypic body posture that improves diaphragm, neck accessory, and pectoral girdle muscle mechanical advantage. This posture is forward flexion of the trunk, extension of the head and neck, bracing of the pectoral girdle by rounding of the shoulders, and grasping of the thighs with the arms. The effect of this posture is to increase abdominal pressure (thus increasing diaphragm precontraction length and radius of curvature); provide more favorable alignment of the scalenes and sternomastoid with the upper rib cage; and anchor the pectoral girdle muscles, allowing them to apply an inspiratory action on the rib cage. In this posture, transdiaphragmatic pressure is increased and diaphragm and sternomastoid muscle EMG activity is decreased. Patients with advanced COPD also spontaneously adopt pursed-lip breathing to slow expiratory airflow, thus minimizing dynamic airway compression.

Effects of Sleep

Responses to chemical stimuli to breathing are powerfully influenced by CNS state (e.g., sleep vs. waking).[16,29,30] Slow-wave and REM sleep depress O_2 and CO_2 chemosensitivity, with greatest depression occurring in REM sleep. While the subject is awake, apnea does not occur in the presence of even marked hypocapnia, and ventilation is largely independent of changes in P_{CO_2}. Rather, ventilation persists even when Pa_{CO_2} is less than about 30 to 35 mm Hg. Persistence of ventilation in the setting of hypocapnia (the so-called wakefulness drive to breathe) probably represents the effects on medullary neurons of inputs activated by auditory, visual, and tactile stimuli. In contrast, in the sleeping or anesthetized state, the ventilatory response to CO_2 extrapolates to zero ventilation in the hypocapnic range. In fact, apnea occurs when P_{CO_2} falls only 4 to 6 mm Hg below waking eucapnic levels. Sleep-related changes in chemosensitivity, therefore, underlie the recurrent periods of apnea and hyperpnea and exaggerated hypercapnia that occur in some patients with diseases of the lung and chest wall.

The increase in respiratory motor activity induced by derangements in respiratory mechanics is also state dependent; that is, heightened activity in awake subjects is absent in sleeping or anesthetized subjects. REM sleep, in particular, impairs the "load" response and causes collapse of the upper rib cage during inspiration, which adversely affects the level of ventilation as well as its distribution. Descending inhibitory drives to spinal α– and spindle γ–motor neurons in REM sleep cause atonia of all the respiratory muscles except the diaphragm. Muscle spindle γ–efferent activity determines spindle sensitivity by progressively contracting the intrafusal fiber. Accordingly, reductions in muscle spindle γ–efferent activity diminish spindle organ sensitivity and interfere with a mechanism for augmenting respiratory muscle spinal α–motor neuron activity. The diminished or absent load response during sleep and anesthesia probably explains the exaggerated increases in Pa_{CO_2} that occur during these periods in patients with lung and chest wall disease. In fact, REM sleep is the period in which Pa_{CO_2} is highest and Pa_{O_2} lowest in patients with stable COPD (Fig. 143-5).[31]

■ CHANGES IN RESPIRATORY STRUCTURE

Alterations in respiratory muscles and chest wall anatomy are important to consider in development of hypercapnic respiratory failure.

Respiratory Muscles

The respiratory muscles are highly plastic and undergo changes in structure, biochemistry, and contractile properties in response to chronic increases in load or changes in precontraction length.[32–38] Chronic increases in inspiratory muscle activity enhance their strength and endurance.[37,38] In animal models, chronic increases in inspiratory load produced by emphysema or inspiratory resistive loading increase diaphragm endurance and the content of oxidant enzymes (e.g., succinate dehydrogenase and citrate synthase) essential for high-energy phosphate synthesis. In patients with COPD, the percentage of slow twitch, fatigue-resistant muscle fibers in the diaphragm and parasternal intercostals is increased.[39,40] In chronic asthma, inspiratory and expiratory muscle endurance assessed from the time course of the

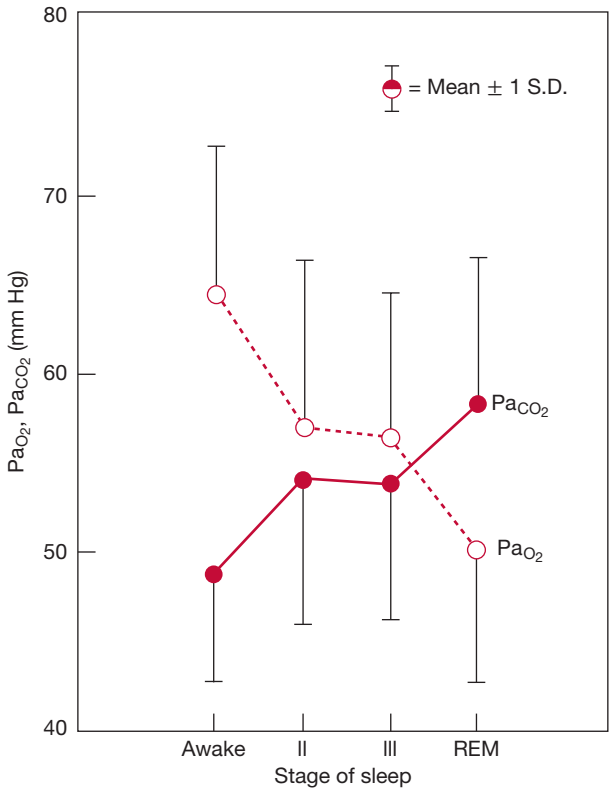

Figure 143-5 Changes in steady-state arterial P_{CO_2} during sleep in eight patients with stable COPD. Note that arterial P_{CO_2} increases and arterial P_{O_2} decreases during sleep. Greatest changes occur during REM sleep. For Pa_{CO_2}, average increase is 10 mm Hg. *(Data from Koo KW, Sax DS, Snider GL. Arterial blood gases and pH during sleep in chronic obstructive pulmonary disease. Am J Med. 1975;58:663–670.)*

fall in maximum static pressure is about 40% greater than in normal controls. The effect of COPD per se on inspiratory muscle endurance has not been assessed. In subjects with COPD, however, daily training with inspiratory resistive ventilatory loads increases inspiratory muscle strength by about 40% as reflected by maximum static inspiratory pressure (PI_{max}) over an 8- to 10-week period.

Hyperinflation impairs the force- and pressure-generating ability of the inspiratory muscles by decreasing muscle precontraction length and unfavorably changing muscle alignment with the chest wall.[5,27,41,42] In particular, severe hyperinflation alters diaphragm shape (i.e., flattening) and decreases the zone of apposition with the rib cage. Flattening of the diaphragm displaces the vector of contraction force from a rostral–caudal direction to a medial–lateral direction and diminishes the ability of the diaphragm to increase abdominal pressure. Reductions in the zone of apposition diminish the inflationary effects on the lower rib cage produced by increases in abdominal pressure induced by the diaphragm. In extreme cases of hyperinflation, the diaphragm may exert an expiratory action on the lower rib cage and retract the lower rib cage on inspiration (Hoover sign).

In part, hyperinflation-induced impairment in the action of the diaphragm is compensated for by adaptive changes in the intrinsic muscle length–tension characteristic. In emphysematous animals, the active and passive length–tension curve of the costal diaphragm is displaced toward shorter lengths, thereby allowing maximum tension to be developed at significantly shorter lengths and higher lung volumes (Fig. 143-6). The shift in the length–tension curve appears to be the reverse of normal growth, in which muscle length is increased by addition of sarcomeres in series. A similar adaptation in the diaphragm seems to occur in chronically hyperinflated, stable outpatients with COPD.[43,44]

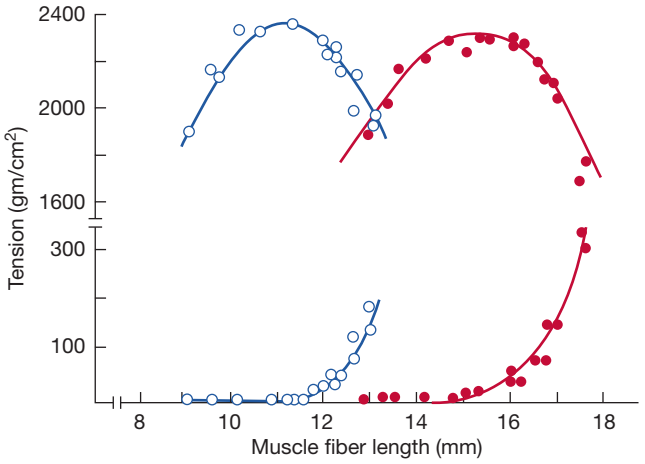

Figure 143-6 Active (upper trace) and passive (lower trace) length–tension (L-T) relationship of costal diaphragm of emphysematous *(open circles)* and normal hamsters *(solid circles)*, assessed in vitro during electrical stimulation. Note that in emphysematous animals, the L-T curve is displaced toward shorter fiber lengths. This adaptive change in emphysematous animals allows the diaphragm to generate maximal tension (force) at shorter fiber lengths and helps preserve diaphragm contractile performance in the face of considerable hyperinflation. *(Reproduced with permission from Supinski GS, Kelsen SG. Effect of elastase-induced emphysema on the force-generating ability of the diaphragm. J Clin Invest. 1982;70(5):978–988.)*

Chest Wall Anatomy

Chronic hyperinflation elicits adaptive changes in the pressure–volume (P-V) characteristic of the passive chest wall.[36] In animal models of emphysema, the static deflation, chest wall P-V curve is shifted up and to the left, so there is a decrease in elastic recoil at any given lung volume. Shifts in the passive P-V curve are accomplished by a structural remodeling of the rigid structures in the chest wall. The length of the sternum and the lengths of the ribs in anteroposterior and transverse dimensions are increased. This displacement of the chest wall P-V curve diminishes the inspiratory elastic work of breathing during hyperinflation and preserves the zone of apposition of the diaphragm. An increase in the zone of apposition of the diaphragm in hyperinflation preserves the appositional force exerted by the diaphragm on the lower rib cage by virtue of changes in abdominal pressure. If present in patients with COPD, the process is reversible, since recent observations of the thorax after volume reduction surgery or lung transplantation for COPD indicate that the shape of the chest wall can quickly revert to normal.

DECOMPENSATING/MALADAPTIVE RESPONSES

Important maladaptive responses must be considered in the setting of hypercapnic respiratory failure.

■ RESPIRATORY MUSCLE FATIGUE

The pathogenesis and clinical manifestations of respiratory muscle fatigue are considered below.

Overview/Definition

Studies in the laboratory and in the clinic indicate that the respiratory skeletal muscles, like muscles in the limbs, fatigue under conditions of intense activity, lead to respiratory failure.[45–50] Conditions that increase the level of phasic inspiratory muscle activity, or the duty cycle of breathing, or that decrease the maximal pressure-generating capacity of the muscle, make fatigue more likely. For example, derangements in the mechanical properties of the lung or chest wall or increases in ventilatory drive increase inspiratory muscle contractile activity. Of

TABLE 143-1 Classification of Respiratory Muscle Fatigue

Central
Refers to decreases in phrenic motor output mediated by spinal or supraspinal mechanisms
Peripheral
Refers to fatigue occurring at the level of the muscle itself
Transmission
Failure of mechanisms operative in muscle excitation ("high-frequency" fatigue)
Contractile
Failure of mechanisms involved in excitation–contraction coupling or contractile protein function ("low-frequency" fatigue)

note, increases in ventilatory drive increase both the peak inspiratory pressure and T_I/T_T ratio, the latter by causing greater reductions in the duration of expiration than in that of inspiration.

Decreases in inspiratory muscle strength caused by aging, protein–calorie malnutrition, or electrolyte imbalances predispose to fatigue at any given level of inspiratory impedance or ventilation by decreasing $P_{I_{max}}$. Finally, on the basis of data from animal models, reductions in diaphragm blood flow are likely to decrease the level of muscle activity that leads to fatigue.[50,51]

Respiratory muscle fatigue has been defined as a loss in muscle capacity to develop force or shorten, resulting from muscle fiber activity under load; which is reversible by rest. In contrast, respiratory muscle weakness has been defined as impairment in the capacity of a fully rested muscle to generate force.

Fatigue is viewed as developing when the muscle is highly active and generating appreciable levels of force. Recovery from fatigue is generally observed over a short time (e.g., minutes to hours). On the other hand, muscle weakness is commonly caused by muscle fiber atrophy, metabolic derangements that impair the ability of actomyosin crossbridges to generate force (e.g., acidosis or electrolyte abnormalities that affect intracellular calcium flux), or chronic reductions in muscle precontraction length that impose a mechanical disadvantage (e.g., hyperinflation of the thorax and its effects on the inspiratory muscles). Implied in the definition of weakness is the idea that alterations in inspiratory muscle function are secondary to alterations in muscle structure or lung volume and hence induce changes in muscle function that are more slowly reversible than fatigue (e.g., days to weeks). In the clinical setting, however, the distinction between muscle weakness and fatigue is difficult and not easily accomplished. Moreover, a close association exists between respiratory muscle weakness and respiratory muscle fatigue. In fact, weak muscles are predisposed to fatigue (see below Pathogenesis of Respiratory Muscle Fatigue).

Fatigue produces complex effects on muscle mechanical output. Fatigue prolongs contraction and relaxation time and depresses the force generated at a given stimulus frequency and fiber length, and reduces the velocity of shortening against a given load.

Depending on the cause of the fatigue, depression of force output can occur at primarily subtetanizing frequencies of muscle stimulation (e.g., <15 to 20 Hz), a condition called low-frequency fatigue, or at frequencies above 50 Hz, a condition called high-frequency fatigue (Table 143-1, Fig. 143-7).[47,52] The biochemical and biophysical processes that underlie low-frequency and high-frequency fatigue differ. Muscle force responses to tetanizing frequencies of stimulation (i.e., >50 Hz) are primarily determined by the processes of neuromuscular transmission and muscle excitation. In contrast, muscle mechanical output at subtetanizing frequencies is determined primarily by the processes of excitation–contraction coupling (e.g., calcium release from the sarcoplasmic reticulum, calcium–troponin interactions), perhaps caused, in part, by O_2 free radical–induced injury.

Of interest, recovery from high-frequency fatigue is more rapid (minutes) than recovery from low-frequency fatigue (hours) (Fig. 143-8). Moreover, the two forms of fatigue have different physiological consequences. High-frequency fatigue impairs muscle force output under conditions in which the muscle is maximally driven by the CNS (i.e., when muscle strength is being evaluated). Low-frequency fatigue, on the other hand, impairs force generation during resting breathing, when phrenic motor unit discharge rates are typically about 15 Hz. Since low- and high-frequency fatigue

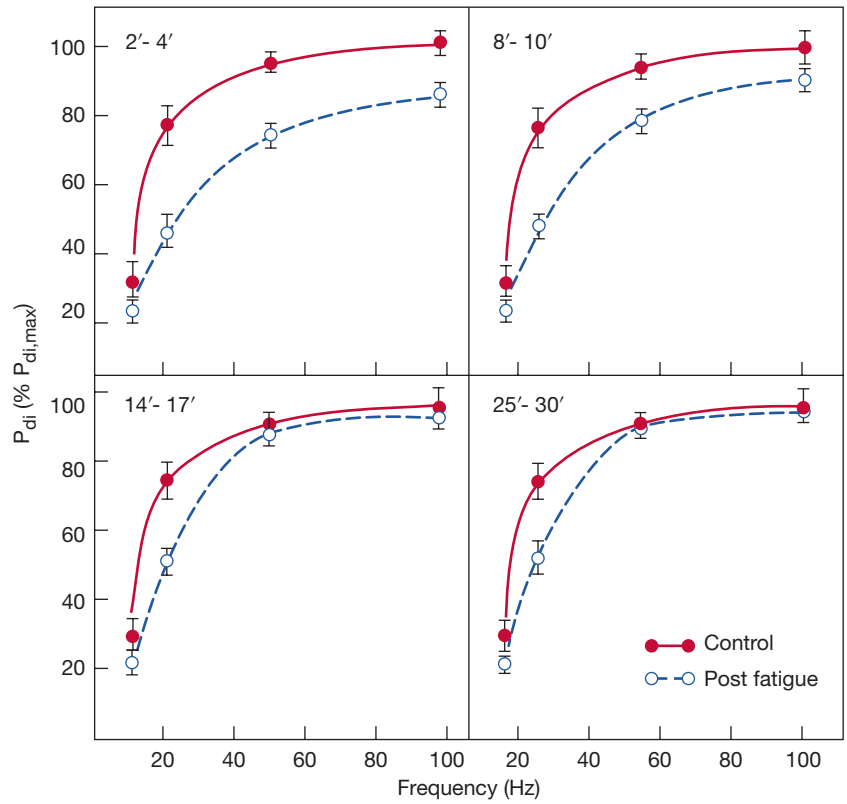

Figure 143-7 Force–frequency relationship of the human diaphragm during electrophrenic stimulation showing rate of recovery from high- and low-frequency fatigue. Data obtained in four subjects before and after a period of inspiratory resistive loading to exhaustion. At the point of exhaustion, the subject was unable to generate targeted values of transdiaphragmatic pressure (P_{di}). Note the decrease in P_{di} in response to low (20 Hz) and high (50 Hz) electrical stimulation immediately after loading, indicating the presence of both high- and low-frequency fatigue. Note also that high-frequency fatigue disappears within 14 to 17 minutes. In contrast, low-frequency fatigue persists beyond the period of observation (>30 minutes). *(Data from Aubier M, Farkas A, De Troyer RT, et al. Detection of diaphragmatic fatigue in man by phrenic stimulation. J Appl Physiol. 1981;50:538–544.)*

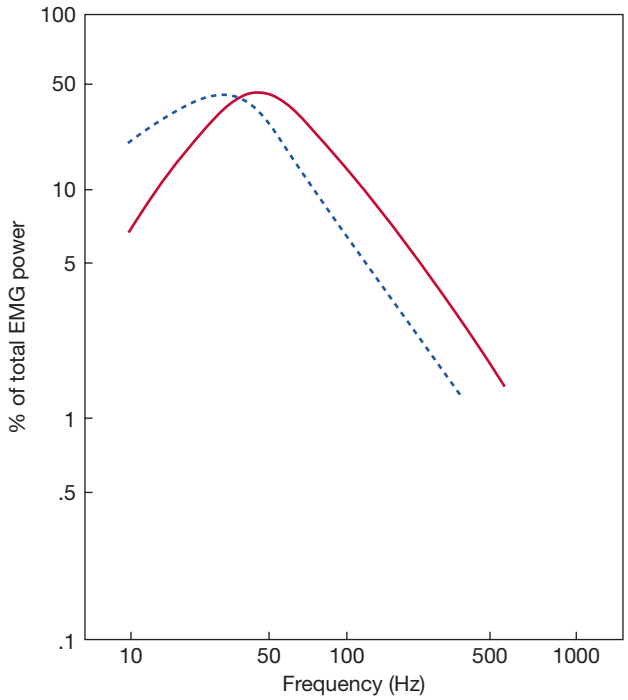

Figure 143-8 Schematic representation of the power spectral density of a respiratory muscle EMG determined by fast Fourier transform. Note the concave appearance of the relationship. Note that fatigue *(dashed line)* decreases and increases power in the high- and low-frequency domains, respectively, thereby shifting the relationship toward the left. *(Data from Moxham J, Edwards RHT, Aubier M, et al. Changes in EMG power spectrum (high-to-low ratio) with force fatigue in humans. J Appl Physiol.1982;53:1094–1099.)*

reflect impairments occurring at the level of the muscle, they have been termed *peripheral fatigue.*

Performance of strenuous ventilatory tasks may also elicit an additional, qualitatively different response—that is, a reduction in central motor output and failure of the CNS to fully activate the respiratory muscles.[47] That is, the diaphragm EMG or phrenic neurogram may decrease late in the performance of strenuous respiratory efforts before the point of exhaustion. This reduction in motor activity may limit task performance. The failure of CNS mechanisms to fully activate the muscle near the point of exhaustion has been termed *central fatigue.* The mechanisms underlying central fatigue are poorly understood. It is not clear whether central fatigue represents a behavioral response elicited by the unpleasant sensations present during ventilatory loading or is mediated reflexively or by changes in brain neurotransmitter levels.

Detection of Respiratory Muscle Fatigue

Diaphragm muscle fatigue has been diagnosed in humans from changes in the response of the muscle to electrical stimulation (i.e., the force–frequency relationship), the power spectral content of the EMG, and $P_{I_{max}}$.[45–47,52,53] As will be seen, the force–frequency relationship and EMG power spectrum analyses are complex and require sophisticated electronics and instrumentation. Consequently, their use has been confined to the research laboratory. On the other hand, $P_{I_{max}}$ is convenient and easily performed at the bedside but suffers from relative nonspecificity.

Electrical Stimulation The force–frequency relationship represents a way of assessing muscle mechanical output over a wide range of stimulus intensities. Since fatigue shifts the force–frequency curve downward (and possibly to the left), the magnitude of the shift in the force–frequency relationship can be used to assess the severity of low- and high-frequency fatigue and the time course of recovery.

Electrical stimulation of the muscle of interest has several advantages. It allows the muscle to be activated in response to a standard stimulus without the cooperation of the subject. Hence, neurological deficits, decreased effort, and central fatigue, which may diminish muscle activation, are circumvented and peripheral fatigue can be detected.

EMG Power Spectrum Fatigue alters the power-EMG spectral content of the raw EMG of the respiratory muscles analyzed by fast Fourier transform (Fig. 143-8). In the fresh diaphragm, the power (or voltage) contained in the EMG waveform reaches a maximum between approximately 85 and 105 Hz, and thereafter declines. (Maximum power in the EMG of the diaphragm, parasternal intercostal, and sternocleidomastoid occurs at somewhat different frequencies, however.) Fatigue-inducing contractions cause a leftward shift of the power spectral density, so that more of the power in the EMG is contained in a lower-frequency domain. The power spectral density of the contracting diaphragm changes almost immediately with fatiguing contractions and considerably before the mechanical output of the muscle fails. The diaphragmatic EMG power spectrum can be obtained from the raw EMG of the muscle, recorded from surface electrodes on the chest wall or within the esophagus. It is, therefore, relatively noninvasive and well tolerated. Moreover, the EMG power spectrum, unlike maximal static pressure, can be measured continuously – that is, breath by breath – and does not require subject cooperation. Accordingly, the EMG power spectrum has proved to be a useful tool to study the pathophysiological mechanisms of human respiratory muscle fatigue. A significant caveat in the use of the power spectrum is the suggestion that it may be unable to detect low-frequency fatigue.

Pathogenesis of Respiratory Muscle Fatigue

Studies designed to examine the pathogenetic mechanisms that led to respiratory muscle fatigue have largely focused on the diaphragm. The diaphragm has been the primary focus of attention for several reasons. First, it is the major respiratory muscle. Second, anatomic considerations allow the mechanical output of the diaphragm (i.e., transdiaphragmatic pressure) and its EMG, an index of phrenic motor outflow and fatigue state, to be assessed relatively easily. Finally, the cervical phrenic nerves can be electrically stimulated, thereby allowing the mechanical output of the muscle to be assessed under standard conditions as well as during volitional contractions.

Muscle Activity In seminal studies, Roussos and Macklem[46] observed that the time of onset of diaphragm fatigue was *not* related to the magnitude of the phasic inspiratory swings in P_{di} during loading alone or to $P_{di,max}$ alone. Rather, the time of onset of mechanical failure of the diaphragm was a unique curvilinear function of the ratio of P_{di} generated on each breath over $P_{di,max}$ ($P_{di}/P_{di,max}$) (Fig. 143-9). Values of $P_{di}/P_{di,max}$ less than 40% to 50% could be maintained indefinitely; values greater than this threshold were associated with progressively more rapid exhaustion. These results made several important points. First, diaphragm fatigue depended on the relative intensity of contraction (i.e., muscle force output as a percentage of its strength). Second, contractions below some critical threshold could be sustained indefinitely and did not lead to fatigue.

Subsequent studies demonstrated that the timing as well as the intensity of diaphragmatic contractions determined the time of onset of mechanical failure of that muscle.[48] Increases in the ratio of the T_I over the T_T increased the rapidity of onset of fatigue at any given $P_{di}/P_{di,max}$ ratio. That is, increasing the duration of diaphragm contraction relative to the period during which the diaphragm is relaxed, the duty cycle of breathing, predisposes to fatigue. In fact, diaphragm fatigue appears to be largely a function of the product of $P_{di}/P_{di,max} \times T_I/T_T$,

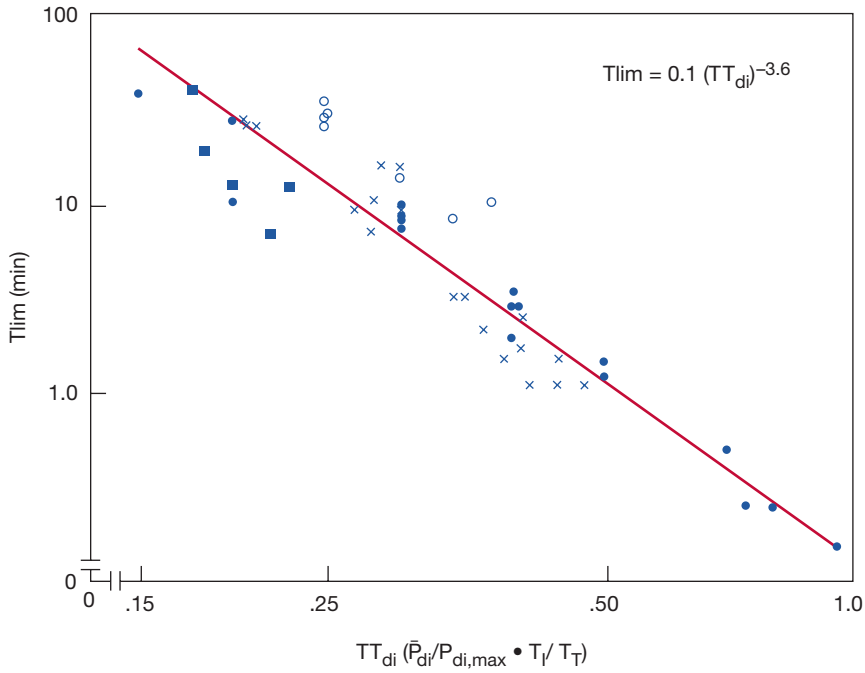

Figure 143-9 Relationship between the intensity of diaphragm contractile activity reflected in the diaphragm tension–time index (TTdi)—that is, the product of $P_{di}/P_{di,max} \times T_I/T_T$ and the time of onset of mechanical failure of the diaphragm, Tlim. The two scales are logarithmic. Data obtained in normal subjects during strenuous volitional contractions during inspiratory resistive ventilatory loading. Note that above approximately 15% TTdi, Tlim decreases progressively with increasing TTdi. These data indicate that a fatigue threshold exists for the human diaphragm above TTdi 15% to 20% and that above this threshold, diaphragm endurance is a unique function of the TTdi. *(Data from Bellemare F, Grassino A. Evaluation of human diaphragm fatigue. J Appl Physiol. 1982;53:1196–1206.)*

which has been termed the *diaphragm tension–time index* (TTI) (Fig. 143-10). The TTI is, in essence, the integrated area under the pressure waveform over time. The TTI is usually expressed not in absolute terms of pressure per unit of time but, rather, in relative terms as a dimensionless value (i.e., as a percentage of the maximum) to reflect the importance of relative changes in pressure and timing of contraction. The TTI determines muscle energy use as reflected in the O_2 consumption.

A threshold for the onset of fatigue occurs at a TTI of approximately 15% to 20% of maximum (Fig. 143-10).[47,48] The greater the TTI above this value, the more rapidly fatigue ensues.

Subsequent studies in normal subjects demonstrated that mechanical failure of the inspiratory muscles as pressure generators can be accelerated at a given TTI by increasing the V_T/T_I. Increases in V_T/T_I reflect an increase in the velocity of inspiratory muscle shortening. Since the greater the velocity of shortening and the more rapid actomyosin crossbridge cycling, the greater the rate of adenosine triphosphate splitting, this is not surprising. Also of interest, respiratory maneuvers associated with high levels of ventilation appear to selectively fatigue the diaphragm, whereas maneuvers that produce high levels of pressure primarily fatigue the intercostal and neck muscles.

Muscle Blood Flow Diaphragm fatigue may relate, in part, to a compromise of muscle blood flow during intense contractions. The relationship of diaphragm blood flow to muscle contractile activity is complex and depends, like fatigue itself, on both the intensity and timing of contractions. The level and pattern of diaphragm activation, therefore, determine not only muscle energy use but also the availability of metabolic fuel (i.e., glucose, free fatty acids, and other nutrients).

Contractions of low intensity increase blood flow.[50,51] In contrast, contractions in excess of 20% to 30% of $P_{di,max}$ mechanically compromise blood flow and cause postcontraction hyperemia. When the diaphragm contracts rhythmically, the T_I/T_T also affects diaphragm blood flow. At $P_{di}/P_{di,max}$ values that compromise blood flow during contraction (i.e., above 20% –30%), blood flow occurs solely during the phase of muscle relaxation. Consequently, increases in the T_I/T_T ratio decrease overall blood flow by encroaching on relaxation time. Diaphragm blood flow is, therefore, a function of the TTI rather than $P_{di}/P_{di,max}$ or the T_I/T_T alone. Blood flow increases up to a TTI of 20% to 30% and thereafter falls progressively with further increases in TTI. Compromise of

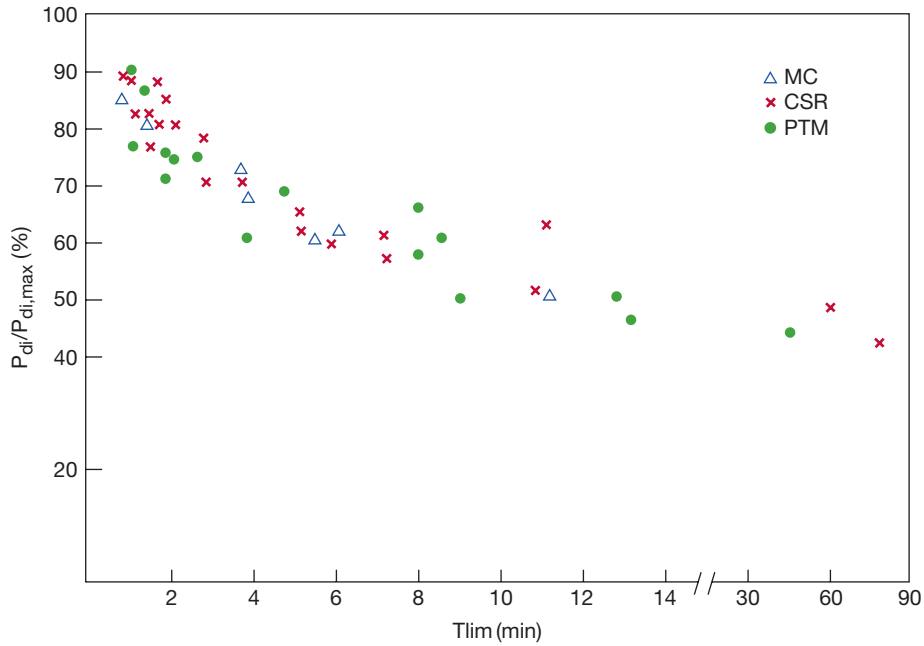

Figure 143-10 Effect of increasing $P_{di}/P_{di,max}$ (i.e., the ratio of peak inspiratory P_{di}) during resistance breathing over maximum static P_{di} (ordinate) at the time of onset of mechanical failure of the diaphragm, Tlim (abscissa). Data from three normal subjects (shown as separate symbols). Note that progressive increases in $P_{di}/P_{di,max}$ are associated with more rapid onset of diaphragm fatigue. Note also the curvilinear nature of the relationship, with apparent asymptote between 40% and 50% $P_{di}/P_{di,max}$, which represents a fatigue threshold. *(Data from Roussos CS, Macklem PT. Inspiratory muscle fatigue, in Macklem PT, Mead J (eds). Handbook of Physiology, section 3: The Respiratory System, vol III: Mechanics of Breathing, part 2. Bethesda, MD, American Physiological Society.1986.)*

diaphragm blood flow when TTI is greater than 20% to 30% of maximum may lead to a condition in which the metabolic needs of the muscle outstrip the availability of energy supply. Alternatively, the importance of blood flow may lie in washing out toxic metabolites (e.g., hydrogen and phosphate ions) from the muscle. The diaphragmatic TTI associated with limitation of blood flow is also a complex function of the level of systemic arterial pressure. Reductions in arterial pressure produced in animal models by bleeding decrease blood flow at any given level of TTI and reduce the P_{di} value at which blood flow is mechanically impeded.

Of considerable importance, diaphragm blood flow may also be a determinant of steady-state diaphragm contractile function in COPD patients in acute respiratory failure.[54] In small numbers of COPD patients, 30% to 50% increases in diaphragm blood flow with intravenous dopamine (8 μg/kg/min) caused rapid, approximately 40% increases in P_{di} during electrophrenic twitch contractions. These findings require confirmation before vasodilator therapy to improve diaphragm function can be advocated. However, they suggest the possibility that diaphragm blood flow may be compromised by intense contractile activity in patients with severe lung disease.

Rapid, Shallow Breathing

Patients with abnormalities in ventilatory pump function breathe rapidly and shallowly in respiratory failure.[55] Respiratory rate is increased and tidal volume is decreased. Reductions in T_I are out of proportion to reductions in T_E, so the duty cycle of breathing (T_I/T_T) is reduced to less than normal values (below 40%). Average inspiratory airflow (V_T/T_I) tends to be normal, despite abnormalities in mechanics, because of increases in the neuromuscular drive to breathe as reflected in the airway occlusion pressure. Reductions in T_I have the effect of increasing the dead space-to-tidal-volume ratio (V_D/V_T) and predisposing to alveolar hypoventilation.

A rapid, shallow pattern of breathing with an abnormally low T_I/T_T ratio and reduced tidal volume is extremely common in patients with COPD during acute exacerbations and tends to get better with improvements in clinical condition.[55] Rapid, shallow breathing appears to cause CO_2 retention rather than result from it. It can be produced in patients with COPD by histamine-induced bronchoconstriction and reversed by topical airway anesthesia. Patients with neuromuscular disease in whom the ability to generate inspiratory pressure is impaired require more intense motor outflow to the respiratory muscles to maintain tidal volume. Patients with respiratory muscle weakness also tend to breathe rapidly and shallowly.

The pattern of breathing has been quantified in adults receiving ventilatory support for acute respiratory failure from the ratio of respiratory rate (breaths per minute) divided by tidal volume (liters). This useful parameter has been termed the *rapid shallow breathing index* (RSBI). It has proved to be an extremely powerful way of assessing weanability in adults with a variety of medical and surgical conditions. The greater the value, the more rapid and shallow is the pattern of breathing. Values for the RSBI exceeding 100 are associated with a high probability of failure to wean from mechanical ventilation. The RSBI lends itself to a more general use in patients with disorders of the ventilatory pump not requiring mechanical ventilation.

Rapid, shallow breathing leading to CO_2 retention exerts a number of deleterious effects. First, CO_2 retention decreases Pa_{O_2} and arterial pH. Decreases in Pa_{O_2} result in accordance with the alveolar air equation. In general, a 1 mm Hg increase in Pa_{O_2} causes a 1.25 mm Hg reduction in Pa_{O_2} (assuming a respiratory quotient of 0.8; larger respiratory quotient values are associated with smaller changes in Pa_{O_2}). Second, renal compensation for hypercapnia-induced respiratory acidosis stimulates bicarbonate resorption. Increases in body fluid bicarbonate restore pH toward normal values but blunt the ventilatory response to further increases in CO_2. Third, hypercapnia depresses diaphragm contractility; that is, P_{di} is decreased at a given level of diaphragm electrical activity in proportion to the increase in P_{CO_2}.

However, rapid, shallow breathing may also confer beneficial effects to subjects with severe ventilatory pump dysfunction. First, CO_2 retention increases the CO_2 partial pressure gradient between the alveolus and atmosphere. Accordingly, during hypercapnia the same volume of metabolically produced CO_2 can be excreted at a lower level of alveolar and minute ventilation and O_2 cost of breathing than during eucapnia. As such, CO_2 retention affords a mechanism to diminish the activity level of the inspiratory muscles and their propensity to fatigue. Normal humans and animal models fatigued by inspiratory resistive loads in the laboratory spontaneously minimize the diaphragm TTI after fatigue by adopting a shallow, rapid pattern of breathing. In fact, a large study of stable outpatients with advanced COPD indicates that the inspiratory muscle TTI is below the fatigue threshold even in markedly hypercapnic (above 60 mm Hg) subjects (see below Pathogenesis of Rapid, Shallow Breathing).[49] Second, rapid, shallow breathing minimizes the magnitude of dynamic hyperinflation in patients with severe COPD who breathe on the envelope of the maximum expiratory flow–volume loop; that is, reductions in tidal volume and decreases in the T_I/T_T ratio diminish the volume to be exhaled and prolong the expiratory time available to reach FRC.

The balance between the beneficial and deleterious effects of CO_2 retention is difficult to define with precision; however, the balance probably is determined by the magnitude and rapidity of the changes in Pa_{CO} and pH and their effect on the cardiovascular and CNSs. Relatively small (5–15 mm Hg) changes in Pa_{CO_2}, produced gradually over days to weeks and leaving pH at levels of 7.25 to 7.30, are likely to be well tolerated and, on balance, beneficial. On the other hand, Pa_{CO_2} changes that occur rapidly and reduce pH to less than 7.25 are likely to exert net negative effects. In fact, respiratory acidosis to pH values under 7.25 is life-threatening and generally considered an indication for intubation and mechanical ventilation. Cardiac function and sympathetic regulation of peripheral vascular resistance are impaired at this level of pH. Patients become encephalopathic (i.e., somnolent and unable to care for themselves and control their airway secretions). Obviously, hypercapnia of such magnitude is to be avoided.

Pathogenesis of Rapid, Shallow Breathing

The neurophysiological mechanisms driving the altered pattern of breathing are obscure. Moreover, whether changes in breathing pattern in animal models and humans are reflexively induced or behaviorally mediated, or reflect changes in brain neurotransmitter levels (e.g., endorphins), are unclear. However, chemosensitivity-induced alterations in respiratory activity do *not* appear to be the explanation. Hypoxia- and hypercapnia-induced reductions in T_E are disproportionately greater than reductions in T_I, so the T_I/T_T ratio increases. Moreover, V_T/T_I and the tidal volume are increasing rather than decreasing.

Reflexes originating from mechanoreceptors in the contracting rib cage muscles and diaphragm (i.e., Golgi tendon organs, spindle organs, and type III and type IV endings) probably play a role in shaping the rapid, shallow pattern of breathing.[7] In deeply anesthetized animals, stretch of the intercostal muscles or an increase in diaphragm tension may abruptly terminate inspiration. Activation of vagal irritant receptors in the airway may also produce rapid, shallow breathing.[4] In animal models, rapid, shallow breathing produced acutely by inhalation of allergen or inflammatory mediators (e.g., histamine, bradykinin) can be prevented by vagal blockade. These observations suggest that rapid, shallow breathing in bronchoconstriction may be mediated by vagal sensory endings in the airways.

Finally, changes in the pattern of breathing may represent a behavioral response to minimize the sense of dyspnea. The sense of dyspnea is a complex perceptual construct that is not fully understood but is probably multifactorial.[56,57] In fact, an important determinant of the sense of dyspnea is the magnitude of the CNS motor command to the inspiratory muscles as reflected in the peak inspiratory intrathoracic pressure. Studies indicate that the sense of breathlessness increases for any set of respiratory mechanical conditions with increases in peak inspiratory pressure, the duration of inspiration, or respiratory rate. In particular, the magnitude of the sense of dyspnea depends on inspiratory pressure (P) swings as a percent of maximum (P/P_{max}), the duration of inspiration relative to the total breath cycle (T_I/T_T), and the respiratory rate (freq). However, the relative importance of these three terms is quite different. The peak inspiratory pressure has a far greater effect than the duration of inspiration, which in turn has a greater effect than breathing frequency. The sensation of dyspnea can be expressed quantitatively by each of these parameters raised to a power:

$$\text{Dyspnea} = P^{1.3} \times T_I / T_T^{1.14} \times \text{freq}^{-0.97}$$

Increases in intrathoracic pressure required to maintain airflow and tidal volume in patients with abnormalities in ventilatory pump function increase the sense of dyspnea. Given the greater exponential value for P than for the timing variables, it can be seen that the magnitude of the swing in inspiratory pressure is the predominant determinant of dyspnea. Thus, at a given level of minute ventilation and set of respiratory mechanics, the pattern of breathing determines the intensity of breathlessness. When the mechanics of breathing are deranged by COPD or kyphoscoliosis, diminishing peak inspiratory intrathoracic pressure (i.e., tidal volume) and increasing respiratory rate (i.e., a rapid, shallow pattern of breathing) tend to minimize the sense of breathlessness.

At equivalent levels of airway resistance and inspiratory effort, the sense of dyspnea is greater during bronchoconstriction than during external resistive loading, probably because of the activation of vagal irritant receptors. Differences in the intensity of dyspnea at any given level of airway obstruction, therefore, may depend on the site of airway obstruction (i.e., intra- vs. extrathoracic). Also, the sense of dyspnea at a given level of peak intrathoracic pressure, T_I/T_T ratio, and frequency of breathing are increased in the setting of inspiratory muscle fatigue, probably because a greater motor command is required to generate a given level of intrathoracic pressure. Finally, it should be apparent from the previous equation that the sense of dyspnea depends on the same variables that determine respiratory muscle fatigability. However, respiratory muscle fatigue, in contrast to dyspnea, does not appear to depend on the pattern in which TTI is developed; that is, whether a given TTI is arrived at by a higher P/P_{max} or a higher T_I/T_T is irrelevant in the development of fatigue, but it *is* important in the generation of respiratory sensations.

Perceptual acuity of the respiratory sensations elicited when the mechanical properties of the ventilatory pump are deranged is a major determinant of the pattern of breathing and tendency to develop CO_2 retention in subjects with COPD.[58,59] For example, when airway resistance is increased experimentally, patients with COPD who retain CO_2 are those with the greatest perceptual acuity for changes in intrathoracic pressure. That is, spontaneous tidal volume and T_I are smallest in patients with COPD who have the highest perceptual acuity for changes in intrathoracic pressure.

On the other hand, when airway resistance was increased experimentally by external resistive loads, asthmatics with near-fatal attacks experienced less dyspnea at any level of resistance than normal subjects (Fig. 143-11).[19] Accordingly, in patients with COPD the acuity of respiratory perception plays an important role in the pathogenesis of respiratory failure. The mechanism by which respiratory perception contributes to respiratory failure awaits clarification.

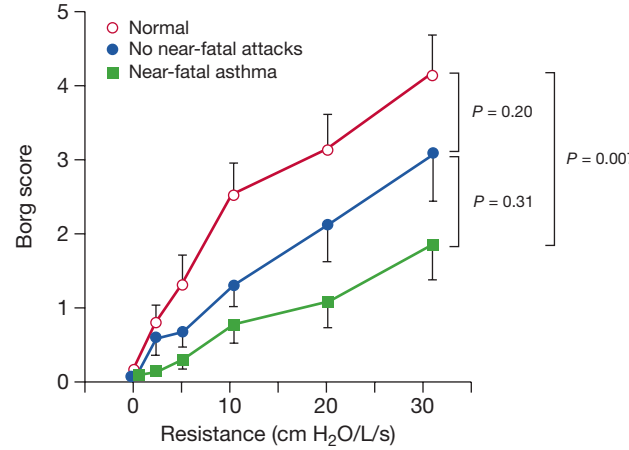

Figure 143-11 Severity of dyspnea experienced during breathing against external resistive ventilatory loads in normal subjects, patients with asthma but no near-fatal attacks, and patients with near-fatal asthma. Y axis indicates the intensity of dyspnea (i.e., Borg score). Increasing numerical values on the Borg score indicate increasing dyspnea. Note that at any given level of external resistance, dyspnea was significantly less in patients with near-fatal asthma than in the normal group. *(Data from Kikuchi Y, Okabe S, Tamura G, et al. Chemosensitivity and perception of dyspnea in patients with a history of near-fatal asthma. N Engl J Med.1994;330:1229–1234.)*

UNDERNUTRITION

Undernutrition, defined as a body weight less than 90% of the ideal, is extremely common in patients with COPD, occurring in about 25% of stable outpatients and about 40% of hospitalized patients. Undernutrition is an independent risk factor for mortality. For a given level of lung function, undernourished patients with COPD have a greater 5-year mortality than normally nourished subjects. The respiratory muscles, like skeletal muscles in other parts of the body, atrophy under conditions of chronic protein–calorie deficiency.[60] In patients without lung disease, PI_{max} is significantly smaller in those who are undernourished than in those who are well nourished. In those with COPD at autopsy, the mass (i.e., weight and thickness) of the diaphragm is diminished in undernourished compared to well-nourished subjects. Both slow and fast fibers in respiratory muscles (e.g., the diaphragm and intercostals) atrophy in subjects with advanced COPD. In patients with COPD, resting Pa_{CO_2} is inversely related to PI_{max}. The weaker the subject, the greater the Pa_{CO_2}. Reductions in PI_{max} predispose to inspiratory muscle fatigue by increasing the $P_{di}/P_{di,max}$ ratio and, hence, the TTI during breathing against a given set of lung mechanics. Of practical importance, aggressive nutritional repletion, which increases body weight, augments PI_{max} and $P_{di,max}$. Thus, respiratory muscle wasting and atrophy are reversible in undernourished patients with COPD.

The pathogenesis of body wasting in subjects with chronic diseases like COPD is unclear. However, increases in the work of breathing and respiratory muscle activity increase resting energy expenditure by as much as 50% to 100% above normal. In normal subjects in whom basal energy requirements are similarly increased by heavy physical labor (e.g., lumberjacks), caloric intake is increased appropriately to meet metabolic demands and body weight is preserved. Accordingly, the root of the problem in undernourished patients with COPD may be "relative anorexia," so that increases in basal caloric requirements are not accompanied by adequate caloric intake. Undernourished patients with COPD have higher blood levels of the cachexia factor tumor necrosis factor-α than well-nourished COPD subjects.

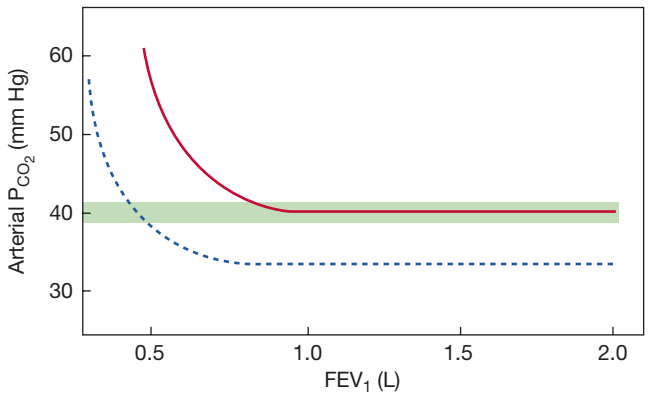

Figure 143-12 Relationship between the severity of airway obstruction reflected in the FEV_1 and steady-state arterial P_{CO_2} in COPD and asthma. *Shaded area* represents normal range of arterial P_{CO_2}. The relationship is curvilinear, so CO_2 retention occurs only after FEV_1 is considerably reduced. The asthmatic curve *(dashed line)* lies below and to the left of the curve for COPD, indicating that much greater levels of obstruction are necessary before arterial P_{CO_2} rises. *(Reproduced with permission from Fishman AP. Pulmonary Diseases and Disorders, vol 1. New York, McGraw-Hill; 1980.)*

SPECIFIC DISEASES

Hypercapnic respiratory failure may complicate a number of specific disorders, as discussed below.

■ CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients with advanced COPD develop CO_2 retention because of abnormalities in the gas exchange and mechanical properties of the lung. The relationship between the severity of COPD as reflected by the forced expiratory volume in 1 second (FEV_1) and steady-state resting P_{CO_2} is curvilinear (Fig. 143-12).[61] In general, Pa_{CO_2} does not increase above normal until the FEV_1 decreases to about 20% to 25% of predicted normal values.

The effects of COPD on lung gas exchange are complex. Simply put, increases in lung dead space and abnormalities in ventilation/perfusion relationships impair CO_2 elimination and O_2 uptake. Increases in physiological dead space require greater than normal levels of ventilation and tidal volume to maintain eucapnia. Maintenance of "normal tidal volume" in the setting of increased dead space predisposes to CO_2 retention because of an unfavorable V_D/V_T. Normally, during resting breathing, ventilation is 4 to 5 L/min, of which alveolar ventilation is approximately 70% to 80%. In COPD, abnormalities in lung gas exchange for O_2 and CO_2 (i.e., increased dead space volume and alveolar–arterial O_2 gradient) require greater than normal levels of ventilation to maintain eucapnia and euoxia. Consequently, in subjects with advanced COPD, minute ventilation is typically two to three times the normal value (i.e., 10–15 L/min). Minute ventilation is increased still further in hypoxemia. Increases in ventilation require increases in airflow, tidal volume, and the duty cycle of breathing.

Hyperinflation and heightened airway resistance are common in patients with advanced COPD. Hyperinflation and increases in FRC in patients with COPD are multifactorial. First, emphysema decreases lung (and possibly chest wall) elastic recoil pressure. Second, tonic activation of chest wall inspiratory muscles throughout the respiratory cycle enhances transpulmonary pressure. Third, activation of laryngeal constrictor muscles and pursed-lip breathing during expiration slow the rate of expiratory airflow. Fourth, severely obstructed patients breathing on the envelope of the maximum expiratory flow–volume curve may have insufficient time during expiration to exhale to passively determined FRC.

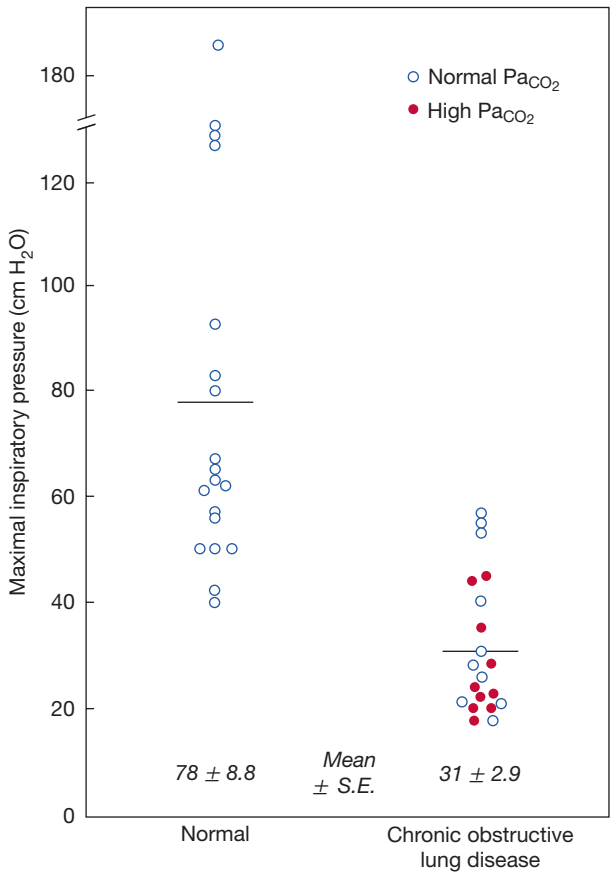

Figure 143-13 Inspiratory muscle strength as reflected in the maximum static inspiratory pressure ($P_{I_{max}}$) at functional residual capacity (FRC) in subjects with advanced COPD and age-matched normal subjects. Each symbol represents a single subject. Note that in COPD subjects, because of hyperinflation and muscle wasting, $P_{I_{max}}$ is reduced to approximately 40% of the value in normal subjects. Note the tendency for hypercapnic subjects to have even lower values of $P_{I_{max}}$ than eucapnic COPD subjects. *(Data from Sharp JT, van Lith P, Nuchprayoon C, et al. The thorax in chronic obstructive lung disease. Am J Med. 1968;44:39–46.)*

In advanced COPD, increases in airway resistance and hyperinflation require greater than normal swings in intrathoracic pressure to generate normal levels of airflow and tidal volume.[38] In consequence, the respiratory neuromuscular drive to breathe, peak inspiratory intrathoracic pressure, and the TTI of the inspiratory muscles are increased considerably.[49,62] Normally, at rest, respiratory muscle O_2 consumption is less than 2% of total body O_2 consumption (i.e., about 5 mL/min or less). In contrast, patients with advanced cardiopulmonary disease may have levels of respiratory muscle O_2 uptake greater than 50% of total body O_2 uptake (i.e., in excess of 125 mL/min).

In subjects with severe COPD, hyperinflation reduces inspiratory muscle mechanical advantage, which decreases the capacity of the inspiratory muscles to generate pressure (P_{max}). P_{max} values in patients with COPD may be as low as one-third to one-half that of age-matched normal subjects (Fig. 143-13). Moreover, aging- and malnutrition-associated changes in the diaphragm may further impair $P_{di,max}$ in subjects with COPD. COPD typically becomes disabling in the sixth and seventh decades of life, a period of life at which P_{di} normally falls. For example, $P_{di,max}$ is about 25% less in healthy men over 65 years of age than in healthy men under 35 years of age.

RESPIRATORY MUSCLE FATIGUE IN COPD

Severe COPD is arguably the clinical condition most likely to cause inspiratory muscle fatigue. The combined effects of increases in

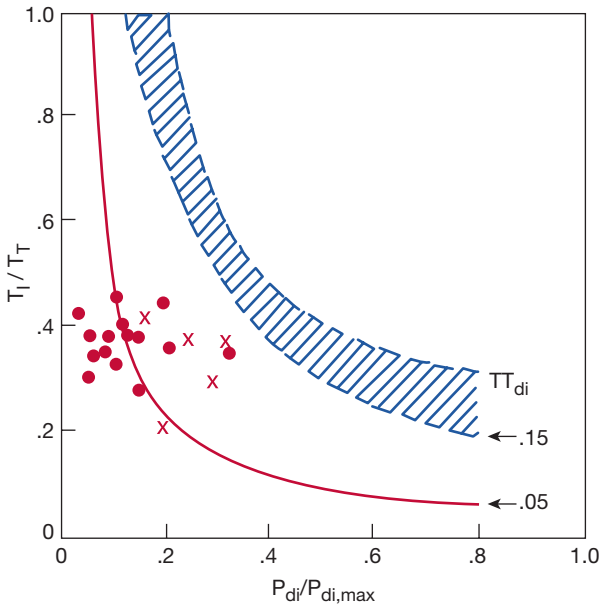

Figure 143-14 Diaphragmatic tension–time index (TTdi) in 20 stable outpatients with COPD breathing room air at rest. Each symbol represents a separate COPD subject. *Shaded area* represents the fatigue threshold in normal subjects. Most COPD subjects breathe well below the fatigue threshold and cluster around 0.05 TTdi. *(Data from Bellemare F, Bigland-Ritchie B. Central components of diaphragmatic fatigue assessed by phrenic nerve stimulation. J Appl Physiol. 1987; 62:1307–1316.)*

inspiratory muscle activity and decreases in muscle strength in severe COPD increase the diaphragm TTI during resting breathing in elderly COPD patients considerably above the normal value of 1% to 2%.[49] The TTI may, in fact, approach the fatigue threshold (i.e., 15%–20%) in patients with COPD (Fig. 143-14). These and similar data indicate that diaphragm activity is increased in patients with advanced COPD, and that the diaphragm is highly susceptible to fatigue when breathing is increased above spontaneous levels by minor increases in tidal volume or T_I/T_T. The diaphragm TTI is higher in hypercapnic than in eucapnic COPD subjects, but even in hypercapnic subjects it does not exceed the fatigue threshold. Mean TTI, even for hypercapnic subjects, is approximately 10%. Therefore, hypercapnia per se does not indicate the presence of diaphragm fatigue even in patients with severe COPD. Rather, hypercapnia may be a manifestation of a breathing strategy (i.e., rapid, shallow breathing) that minimizes inspiratory muscle activity and, hence, prevents fatigue.

On the other hand, inspiratory muscle fatigue may be a relatively common occurrence during the hyperpnea of exercise and could contribute to exercise limitation in COPD subjects. A high percentage (about 50%) of subjects with moderate to severe COPD demonstrate EMG evidence of scalene or diaphragm (or both) fatigue during exercise. Of interest, improvement in exercise performance and elimination of the EMG signs of fatigue can be achieved following inspiratory resistance training.

Subjects with COPD in acute respiratory failure requiring mechanical ventilation are more likely to show evidence of inspiratory muscle fatigue.[53,54] During weaning from mechanical ventilation, diaphragm EMG changes indicative of fatigue precede the increases in Pa_{CO_2}. These findings suggest that diaphragm fatigue contributes to ventilator dependence after the onset of hypercapnic respiratory failure in at least some critically ill subjects.

In COPD patients being weaned from mechanical ventilation during a bout of acute respiratory failure, the tracheal occlusion pressure is usually greater than 6 cm H_2O and EMG evidence of diaphragm fatigue is present during spontaneous breathing.[53] Patients with persistently elevated tracheal occlusion pressure values (>6 cm H_2O) and EMG evidence of diaphragm fatigue generally cannot be successfully weaned from mechanical ventilation. In contrast, sternomastoid muscle fatigue is evident in fewer than 10% of COPD patients hospitalized for worsening respiratory distress.

In summary, most subjects with stable COPD adopt a pattern of breathing that minimizes the diaphragm TTI and prevents inspiratory muscle fatigue. Behavioral mechanisms may be operative in an attempt to minimize the sensation of dyspnea. On the other hand, inspiratory muscle fatigue contributes to the morbidity of a subgroup of patients with COPD by preventing weaning from mechanical ventilation, and possibly by impairing exercise performance. The reported number of COPD subjects with respiratory muscle fatigue is small, however, and may represent a highly select population. Further studies are needed to define the extent of this problem.

■ ASTHMA

The pathophysiology of CO_2 retention appears to be generally similar in patients with asthma and COPD, but the likelihood of developing CO_2 retention is less in asthma than in COPD. That is, the level of expiratory airway obstruction required to produce CO_2 retention in subjects with acute asthma is greater than that required in subjects with COPD (Fig. 143-14).[61] Several possibilities may explain this tendency. First, it appears that inspiratory drive is higher in patients with asthma than in those with COPD. The airway occlusion pressure is considerably higher at any given level of Pa_{CO_2} in patients with asthma than in normal subjects or patients with COPD. The heightened inspiratory drive in patients with asthma may in part arise from irritant receptors within the airway, which have an augmenting effect on inspiratory motor neuron activity. Furthermore, the inspiratory muscles are stronger, and ventilatory responses to CO_2 and hypoxia are greater, in the younger asthmatic than in COPD subjects. These differences are not simply due to age, as the endurance of the inspiratory and expiratory muscles is greater in asthmatic than in age-matched normal subjects. The increased respiratory muscle endurance in subjects with asthma may be a response to chronic increases in inspiratory muscle load. Finally, greater lung elastic recoil in asthma than in COPD tends to preserve maximal expiratory airflow.

■ NEUROMUSCULAR DISEASE

Subjects with neuromuscular disease and weak inspiratory muscles tend to breathe rapidly and shallowly.[63] Despite this breathing pattern, these subjects tend to have hypocapnia at rest, and hyperventilate at any given level of CO_2 during progressive hypercapnia. Increases in ventilation are associated with increases in airway occlusion pressure. Heightened occlusion pressure in the setting of weak inspiratory muscles suggests that the drive to the inspiratory muscles early in inspiration is greater than normal.

The pathogenesis of hypercapnic respiratory failure is very different in patients with neuromuscular disease than in patients with COPD. Patients with neuromuscular disease demonstrate an impaired ability to sigh (i.e., a greater than twofold increase in the tidal volume) because of inspiratory muscle weakness. Inability to sigh decreases lung compliance by interfering with the redistribution of surfactant within the alveolar space. Progressive stiffening of the lung leads to microatelectasis and ultimately lobar atelectasis. Breathing high concentrations of O_2 accelerates this process. In addition, expiratory muscle weakness impairs the cough mechanism and causes retention of secretions.

The best indicators of a tendency to develop CO_2 retention in patients with neuromuscular disease are reductions in inspiratory muscle strength (PI_{max}) and forced vital capacity (FVC). Reductions in PI_{max} and FVC to less than 30% and 25% of predicted, respectively,

are associated with CO_2 retention. Suffice it to say, hypercapnia is a late manifestation of neuromuscular disease and requires marked impairment in inspiratory and expiratory muscle function. With diaphragm dysfunction, hypercapnia may occur during sleep (especially REM sleep) even when the subject is eucapnic while awake.

OBESITY

Obesity imposes a stress on the respiratory system both by altering lung mechanics and the work of breathing (see Chapter 83). The mass loads applied to the thorax and abdomen by excess fatty tissue decrease chest wall compliance and end-expiratory lung volume resulting in increases in the elastic and resistive work of breathing. Furthermore, by diminishing airway caliber, obesity predisposes to premature airway closure and even atelectasis. The resultant low ventilation–perfusion ratios of these lung regions increase alveolar–arterial O_2 gradient and cause arterial hypoxemia. In fact, hypoxemia is the most common respiratory abnormality in the morbidly obese.

In addition, the excessive body mass results in increased CO_2 production and O_2 consumption. Increases in metabolism may be two to three times normal in morbidly obese subjects.[64] These metabolic changes require significant increases in minute and alveolar ventilation to maintain eucapnia and hence, increasing ventilatory demands. For example, a doubling in CO_2 production requires a doubling in alveolar ventilation to maintain eucapnia. Finally, arterial hypoxemia, which is common, induces a further increase in ventilation.

Given these stresses, the maintenance of normal blood-gas tensions requires a considerable increase in respiratory motor output and the work of breathing. Increased work of breathing appears to explain the common occurrence of dyspnea in the morbidly obese person.

Not all morbidly obese subjects develop hypercapnic respiratory failure, however. Although body weight alone does not predict the development of hypercapnia, approximately 30% of severely obese subjects with a body mass index (BMI) of more than 35 kg/m^2 and almost 50% with a BMI of 50 kg/m^2 or greater have unexplained daytime hypercapnia. Observations of eucapnic and hypercapnic obese subjects demonstrate that eucapnic subjects have greater increases in diaphragm electrical activity with increases in CO_2 than hypercapnic subjects. Obese subjects with hypercapnic respiratory failure may have impaired chemosensitivity to hypercapnia and hypoxemia.

A subset of obese subjects with hypercapnia also have daytime hypersomnolence, polycythemia, pulmonary hypertension, and cor pulmonale. This constellation of signs and symptoms has been termed the *obesity hypoventilation syndrome* (see Chapter 92.) Of interest, leptin may be involved in the pathogenesis of hypercapnic respiratory failure in obese individuals. Leptin stimulates ventilation and a deficiency of leptin has been associated with hypoventilation. Clearly excessive body weight is the primary pathogenetic factor, since weight reduction into the normal range, however difficult this may be to accomplish, corrects the problem.

KYPHOSCOLIOSIS

Kyphoscoliosis decreases chest wall and lung compliance, presumably as a result of atelectasis and deformation of the lungs (see Chapter 92). The elastic work of breathing is markedly increased. In addition, the mechanical action of the respiratory muscles may be impaired by changes in configuration of the bony structures on which the respiratory muscles insert. Ventilation–perfusion mismatch and increase in the alveolar–arterial O_2 gradient are common. As expected in patients with diminished respiratory compliance, subjects with kyphoscoliosis breathe rapidly and shallowly. The tendency to develop CO_2 retention is a function of the severity of the restrictive process in kyphoscoliosis, as reflected in the Cobb angles, and is predicted separately for the magnitude of scoliosis and kyphosis.

Hypercapnic respiratory failure tends to develop late in life, even if the severity of the spinal deformity has not changed since childhood; that is, stability of the Cobb angles of kyphosis and scoliosis does not preclude development of hypercapnic respiratory failure. It is not clear why respiratory failure ensues late in life. However, several possibilities exist. Aging adversely affects compliance of the chest wall, leading to an increase in the elastic work of breathing. In addition, aging diminishes respiratory muscle strength. Finally, chemosensitivity to O_2 and CO_2 declines with advancing age, and it seems likely that the subject's ability to compensate for derangements in blood-gas tensions is progressively impaired.

ASSESSMENT OF PATIENTS WITH ABNORMALITIES OF THE VENTILATORY PUMP

Clinical assessment of patients with known or suspected abnormalities of the ventilatory pump is discussed below.

SYMPTOMS

Dyspnea appears to be an early manifestation of respiratory muscle impairment in neuromuscular disease and typically occurs before the development of CO_2 retention. Breathlessness in the supine position is characteristic of isolated diaphragm dysfunction. In the supine position, the increased hydrostatic pressure imposed by the abdominal viscera represents an increased inertial load on the diaphragm.

PHYSICAL FINDINGS

Physical signs of ventilatory pump dysfunction revolve around evidence of accessory respiratory muscle recruitment, abnormal thoracoabdominal movement, and rapid, shallow breathing.[46]

USE OF ACCESSORY MUSCLES

Inspection and palpation demonstrate accessory respiratory muscle use. Intense respiratory efforts are associated with visible activation of the neck accessory muscles, interosseous intercostals, and abdominal expiratory muscles and flaring of the alae nasi.

ABNORMAL THORACOABDOMINAL MOVEMENT

Normally, in the supine position, the anterior abdominal wall displays a prominent outward movement during inspiration. With impaired diaphragm function, as occurs in diaphragm weakness or fatigue, the abdominal wall may move inward on inspiration. This is called *abdominal paradox.* Abdominal paradox reflects cephalad movement of the contracting diaphragm in response to the negative intrathoracic pressure generated by the inspiratory action of the neck and intercostal muscles. Abdominal paradox may also be present in patients with marked derangements in lung mechanics, in whom inspiratory intrathoracic pressure swings exceed 30% of maximum. Abdominal paradox, therefore, is not specific for diaphragm weakness or fatigue.

Abdominal paradox, resulting from ineffectual contractions of the diaphragm, should be distinguished from *pseudoabdominal paradox,* resulting from strong contractions of the expiratory muscles during expiration, with rapid relaxation during early inspiration. For example, intense contraction of the transverse abdominis muscles causes inward movement of the lateral abdominal wall and outward movement of the anterior abdominal wall during expiration. Subsequent relaxation of the abdominal muscles with the onset of inspiration causes outward movement of the lateral abdominal wall and inward movement of the anterior abdominal wall. Tenseness of the lateral abdominal wall during expiration easily distinguishes *pseudo-* from true *abdominal paradox.*

MAXIMUM STATIC INSPIRATORY PRESSURE

Perhaps the most practical method of assessing the function of the inspiratory muscles contracting in aggregate is from the pressure generated during maximal volitional contractions against an

occluded airway at FRC. This parameter is discussed in greater detail in Chapter 84. In brief, however, reductions in $P_{I_{max}}$ indicate inspiratory muscle weakness or high-frequency fatigue. Improvements in $P_{I_{max}}$ occurring over several hours to several days in a patient with COPD suggest that lung volume is improving toward normal and that the mechanical disadvantage imposed on the inspiratory muscles is disappearing. More rapid improvements (occurring over hours) may indicate resolution of high-frequency fatigue or elimination of the metabolic disturbances (e.g., hypercapnia or hypophosphatemia) that depress inspiratory muscle function. Of note, $P_{I_{max}}$ is not affected by low-frequency fatigue.

$P_{I_{max}}$ depends on patient cooperation and motivation. With training, however, patients can provide reproducible values. Performance of the maneuver at FRC, where respiratory system recoil is zero, is preferred; that is, at FRC, changes in airway pressure during inspiratory efforts equal the pressure generated by the inspiratory muscles (P_{mus}).

Maximum static expiratory pressure at FRC ($P_{E_{max}}$) has been used in the laboratory setting to assess the endurance properties of the expiratory muscles. The $P_{E_{max}}$ has not been used extensively in the clinical setting, however, because of the perception that it is more difficult to obtain consistent values than $P_{I_{max}}$ with breathless subjects.

TREATMENT

Abnormalities in respiratory mechanics and gas exchange are the most important pathogenetic factors in the development of respiratory failure. Accordingly, therapy should be directed toward achieving maximum improvement in airway, lung, and respiratory muscle function. For example, in patients with COPD or asthma, an intensive regimen of bronchodilators (e.g., β_2-adrenergic agonists, anticholinergics, and theophylline) and anti-inflammatory therapy (e.g., corticosteroids) can correct respiratory failure by diminishing airway resistance, FRC, lung dead space volume, the alveolar–arterial O_2 partial pressure gradient, and the work of breathing. Improvements in lung function in certain patients with advanced COPD and emphysema may also be accomplished by lung volume reduction surgery (volume reduction pneumectomy) or lung transplantation. Lung volume reduction surgery removes 20% to 30% of the most emphysematous regions of lung and appears to improve FRC, FEV_1, ventilatory capacity, inspiratory muscle function, and elastic recoil pressure of the lung. In patients with myasthenia gravis, cholinesterase inhibitors can improve inspiratory muscle strength and vital capacity and reverse atelectasis, which causes hypercapnia. In addition, noninvasive positive-pressure ventilation (NIPPV) has become one of the most important modalities for treating hypercapnic respiratory failure (see below Chronic Ventilatory Support/Nasal Positive-Pressure Ventilation).

ABNORMALITIES IN CHEMOSENSITIVITY

Respiratory failure caused by impaired chemosensitivity is difficult to treat, since drug treatments to improve chemosensitivity to hypoxia or hypercapnia are not very effective. Since it was observed that women exhibit alveolar hypoventilation during pregnancy and the luteal phase of the menstrual cycle, progestational agents have been used for many years to treat idiopathic hypoventilation syndromes. In some subjects, medroxyprogesterone acetate, given orally in a dose of 20 mg three times a day, acts centrally to augment the ventilatory responses to hypercapnia and hypoxemia and can improve resting arterial blood-gas tensions.[64,65] Medroxyprogesterone is generally well tolerated in women but may produce feminizing side effects in men. The onset of action of the drug is slow. Several weeks may be required before a response is observed. Theophylline, in doses that produce blood levels in the therapeutic range (10–15 μg/mL), also has weak respiratory stimulatory effects, which may contribute to a reduction in Pa_{CO_2} in patients with COPD. Theophylline also produces modest improvements (about 10%–20%) in diaphragm contractile function in this population. Finally, in some patients with hypercapnia, elimination of medications having CNS respiratory depressant effects (e.g., opiate analgesics, benzodiazepine anxiolytics) can lead to improvements in Pa_{CO_2}.

Hypoxemia leading to pulmonary artery hypertension and cor pulmonale may be the most serious complication of chronic hypercapnic respiratory failure. Supplemental O_2 is usually indicated in patients with chronic hypercapnic respiratory failure. Supplemental O_2 may produce exaggerated increases in Pa_{CO_2} in patients with disorders of ventilatory control in whom the ventilatory response to CO_2 is blunted but the O_2 response is preserved. Accordingly, blood-gas tensions should be monitored closely when O_2 is applied initially. During sleep, patients with disorders of the control of breathing typically display exaggerated increases in Pa_{CO_2} (e.g., 15 to >30 mm Hg) with hypoxemia and severe respiratory acidosis. In these subjects, mechanically assisted ventilation (typically with nasal positive-pressure ventilation [NPPV]), with or without O_2, may be required during the sleeping period. NPPV is an effective way of improving blood-gas tensions during sleep. In fact, improvements in blood-gas tensions achieved by nocturnal mechanical ventilation may carry over to the waking period in these patients, perhaps by preventing nocturnal increases in serum bicarbonate or hypoxic depression of CNS function.

RESPIRATORY MUSCLE WEAKNESS OR FATIGUE

The treatment of respiratory muscle weakness depends on pathogenic mechanisms. For example, inspiratory muscle weakness related to the hyperinflation of COPD is best treated by aggressive improvement of airway function. On the other hand, decreases in muscle strength caused by electrolyte abnormalities (e.g., hypophosphatemia) or protein–calorie malnutrition are best dealt with by repletion of the deficits.

The treatment of respiratory muscle fatigue has not been systematically studied. However, several approaches based on theoretical considerations appear to be applicable (Table 143-2). It is clear that diaphragm fatigue is a result of muscle overactivity (i.e., a TTI >20%). Accordingly, attempts should be made to decrease the TTI of the inspiratory muscles to values below the fatigue threshold by improving lung mechanics or reducing ventilatory drive. In

TABLE 143-2 Principles of Therapy for Respiratory Muscle Fatigue

Decrease inspiratory swings in transdiaphragmatic pressure (P_{di})
Improve the mechanics of breathing (i.e., decrease airway resistance, improve thoracic compliance and static lung volume)
Decrease ventilatory drive (i.e., relieve hypoxemia, hypercapnia, metabolic acidosis, fever, pulmonary congestion/inflammation, acute respiratory distress syndrome)
Increase $P_{di,max}$
Correct hyperinflation
Correct muscle atrophy induced by protein–calorie deficiency
Correct electrolyte and blood gas abnormalities (i.e., hypoxemia, hypercapnia, hypophosphatemia, hypokalemia, hypocalcemia, hypomagnesemia)
Optimize muscle blood flow and substrate availability
Correct low cardiac output state (e.g., cardiogenic shock, hypovolemic shock)
Correct hypoxemia, anemia, hypoglycemia

patients with abnormalities in airway resistance and hyperinflation secondary to severe COPD, this can best be accomplished with bronchodilators and corticosteroids. Reductions in ventilatory drive in hypoxic or febrile patients can be accomplished by administration of O_2 or antipyretics.

Unloading the inspiratory muscles by reducing the TTI may be sufficient to prevent or reverse fatigue and allow the muscle to recover. In some cases, however, respiratory muscle fatigue may be sufficiently advanced so that the muscle must be placed at complete rest. Mechanical ventilation and ventilatory muscle rest are certainly indicated when the pH is less than 7.25 or the patient appears unable to maintain ventilation and stable blood-gas tensions. The precise duration of mechanical ventilation to rest the inspiratory muscles in patients with respiratory muscle fatigue is unclear. However, no attempts at weaning should be made until the conditions that initiated fatigue are reversed. Since low-frequency fatigue persists for 24 hours or more, it may not be advisable to wean patients with respiratory muscle fatigue from mechanical ventilation for at least 24 hours, even if the factors that caused fatigue have been corrected.

CHRONIC VENTILATORY SUPPORT/NASAL POSITIVE-PRESSURE VENTILATION

Mechanically assisted ventilation, especially at night, may be helpful in reducing arterial P_{CO_2} and increasing P_{O_2} in the chronically hypercapnic subject.[66] NPPV affords an effective, practical approach to treat selected subjects with chronic hypercapnia secondary to either impaired chemosensitivity or abnormalities in respiratory mechanics. In particular, selected subjects with the obesity hypoventilation syndrome, kyphoscoliosis, or neuromuscular disease have been successfully maintained on NPPV for prolonged periods.[67–70] Its use in neuromuscular disease, particularly for nocturnal hypoventilation or progressive hypercapnic respiratory failure is discussed in Chapter 94.

NPPV obviates the need for airway intubation, provides considerable patient comfort, and is easy to use. The most commonly used masks are oral or oronasal masks with a soft rubber seal. An oronasal mask may be more comfortable for mouth-breathing patients. Small, portable, simple-to-operate bilevel ventilators (BiPAP) that deliver phasic pressure changes are available. Tidal volume is determined by setting the magnitude of the inspiratory positive airway pressure (IPAP) and expiratory positive airway pressure (EPAP). Disadvantages of NPPV include aerophagia and air leaks secondary to poorly fitting masks.

The use of NPPV during acute hypercapnic respiratory failure secondary to COPD has been demonstrated repeatedly to reduce mortality, reduce the need for airway intubation, and rapidly improve Pa_{CO_2} and pH.[71]

DEDICATION

This chapter is dedicated to the memory of my mentor and friend, Neil S. Cherniack, M.D. Neil was a world-class respiratory physiologist who made seminal contributions to our understanding of the regulation of respiration and, in particular, the instabilities in breathing which underlie the development of obstructive sleep apnea. His considerable body of work also contributed much to our understanding of the pathogenesis of hypercapnic respiratory failure which is the subject of this chapter.

CHAPTER 144

Oxygen Therapy and Toxicity

Matthew Wemple
Joshua O. Benditt

INTRODUCTION

Oxygen was discovered in the late 18th century simultaneously by several investigators. Joseph Priestley, a minister in England, made his discovery after attempting to melt mercury oxide using a magnifying glass and the sun's rays. The vapor that was produced by this melting allowed a candle to burn brighter, and Priestley later discovered the vapor could be used in place of air to keep a mouse alive. He first published his findings in 1774. At about the same time, and in a similar way (i.e., by burning mercury oxide), Carl Scheele, a pharmacist in Sweden, described a gas he called "fire air." He may have done his experiments before Priestley, but he did not publish his findings until 1777. Finally, after being told about this new vapor during a 1774 visit by Joseph Priestley, the chemist, Antoine Lavoisier, devised quantitative experiments which he used to prove the existence of this element and its role in combustion. He named the element "oxygen" and published his research in 1777.

Soon after its discovery, oxygen was being utilized as a medicine and cure-all for many respiratory diseases, including "consumption" and asthma. However, suspicions about the safety of oxygen therapy were raised almost as soon as it was discovered and even before the element was named. In 1775, Joseph Priestley wrote of oxygen (which, at that time, he called "dephlogisticated air"): "A moralist, at least, may say that the air which nature has provided for us is as good as we deserve."[1]

Rigorous scientific evaluation of the potential toxicities of oxygen did not occur until the work of James Lorrain Smith, an Edinburgh pathologist, who first published the pulmonary pathologic alterations associated with oxygen exposure in 1899. It was also recognized around this time that under ambient air, the arterial blood was already at near-maximal oxygen-carrying capacity, putting into doubt the utility of further increasing the fraction of inspired oxygen.

Following these observations, the use of therapeutic oxygen fell into some disrepute.

In the early 1920s, supplemental oxygen therapy was reevaluated yet again. This was occurring as the detrimental effects of tissue hypoxia were being recognized, along with their reversibility with supplemental oxygen. Since the mid-20th century, especially with the advent of improved oxygen delivery systems, mechanical ventilation, and the modern intensive care unit, the use of oxygen has become a standard prescribed therapy for a multitude of cardiac and respiratory diseases. Oxygen therapy is now common in the outpatient setting. As of 2005 in the United States, approximately 1 million people receive long-term oxygen therapy (LTOT) from the Medicare Program, with total reimbursement costs related to LTOT exceeding 2 billion dollars per year.[2]

In this chapter, the physiology of hypoxia at the tissue level and mechanisms of arterial hypoxemia are discussed. In addition, various clinical assessments of hypoxemia, indications for acute and LTOT, and available methods of noninvasive oxygen administration are considered. Finally, the pathophysiology and clinical manifestations of pulmonary oxygen toxicity are addressed, along with the potential for oxygen toxicity in other organ systems.

TISSUE OXYGENATION

Important to remember is that the primary goal of supplemental oxygen therapy is to ensure appropriate oxygen delivery to vital end-organ tissues. Therefore, one must understand the mechanisms of tissue hypoxia to understand the indications for using supplemental oxygen.

Tissue hypoxia is governed by the balance between oxygen delivery and oxygen utilization. Generally, failures in oxygen delivery lead to most instances of tissue hypoxia. Oxygen delivery is determined by the cardiac output and the oxygen content of arterial blood, as described by the formula:

$$D_{O_2}\ (\text{oxygen delivery}) = CO\ (\text{cardiac output}) \times Ca_{O_2}\ (\text{oxygen content of arterial blood}) \quad (1)$$

where Ca_{O_2} is calculated by the formula:

$$Ca_{O_2}\ (\text{mL } O_2/\text{dL}) = (1.34 \times \text{hemoglobin concentration} \times Sa_{O_2}) + (0.0031 \times Pa_{O_2}) \quad (2)$$

where Sa_{O_2} is the arterial hemoglobin oxygen saturation and Pa_{O_2} is the oxygen tension or partial pressure of arterial blood.

From this formula, the causes of poor oxygen delivery can be narrowed to three categories: Low cardiac output states (i.e., various forms of shock), low hemoglobin concentration states (i.e., anemia), and low Sa_{O_2} states (i.e., arterial hypoxemia or hemoglobinopathies). Note that a low oxygen tension, although often leading to low arterial hemoglobin saturation, does not contribute appreciably to oxygen delivery. This can be seen numerically in the above formula for Ca_{O_2}, where the Pa_{O_2} is multiplied by 0.0031 and, therefore, contributes little to the final product. It is important to point out that supplemental oxygen therapy addresses only arterial hypoxemia. For other causes of tissue hypoxia, more specific therapies are generally required, such as vasoactive agents or intravenous fluid administration to reverse shock, and blood transfusions for anemia.

Along with the primary basis of poor oxygen delivery, tissue hypoxia can also be caused by inappropriate or excessive utilization of oxygen. One cause of inappropriate oxygen utilization is histotoxic hypoxia, which occurs when cells, for a variety of reasons, are unable to utilize oxygen for aerobic metabolic respiration. This is classically seen in cyanide poisoning, where the cyanide molecule inhibits the enzyme cytochrome c oxidase, and the cell is subsequently unable to use oxygen to produce adenosine triphosphate (ATP) via the mitochondrial electron transport chain. This leads to glycolysis, profound lactic acidosis, and cell and tissue death. Administration of oxygen is indicated in this condition, but it will not, by itself, reverse the toxicity of cyanide; other antidotes must be given (generally, sodium nitrite, amyl nitrite, and sodium thiosulfate).[3]

Another cause of decreased oxygen utilization may occur in the setting of sepsis. In this case, oxygen is not utilized by tissues due to both mitochondrial damage and abnormal shunting of blood from a variety of insults at the endothelial and microcirculatory levels. Finally, oxygen may be excessively utilized by tissues relative to oxygen delivery. This may occur in hypermetabolic states, such as thyrotoxicosis[4] and fever.[5]

ARTERIAL HYPOXEMIA

Important is the distinction between the terms *hypoxia* and *hypoxemia*. Hypoxia may be thought of as the functional equivalent of ischemia and refers to a lack or misuse of oxygen at the tissue level. Hypoxemia refers to the blood's oxygen content and can be more formally defined as a validated deficiency of oxygen tension in the blood. In other words, when a patient's Pa_{O_2} and, therefore, Sa_{O_2} are low, the patient is hypoxemic. Since arterial hypoxemia is a major cause of tissue hypoxia, the cause of which is most likely to be reversed or improved with oxygen therapy, its major etiologies are discussed below.

The driving force of oxygen transport across the alveolar barrier into the blood depends on both the partial pressure of oxygen in the alveolus (PA_{O_2}) and overall respiratory function. Thus, arterial hypoxemia results from either reduction of the inspired oxygen tension or dysfunction of the respiratory system. Along with the reduction of inspired oxygen tension (such as at altitude), there are four other pathophysiologic causes of arterial hypoxemia (Table 144-1).

Alveolar hypoventilation leads to a diminished PA_{O_2} and resultant decrease in Pa_{O_2} and Sa_{O_2}. It may constitute the final common pathophysiologic denominator for a variety of pulmonary and nonpulmonary disorders leading to hypercapnia and hypoxemia. Examples of nonpulmonary disorders leading to these derangements include narcotic overdose, which reduces the central drive to breath; abdominal compartment syndrome, which can mechanically reduce ventilation due to abdominal distension; and obstructive sleep apnea, which is the result of transient loss of the upper airway patency.

Another pathophysiologic cause of hypoxemia arises with defects in diffusion of oxygen across the alveolar–capillary membrane, as, for example, in fibrotic lung diseases and interstitial pneumonias. The increased barrier to oxygen diffusion is detected as a reduced diffusion capacity of carbon monoxide (D_{LCO}). Diffusion limitation generally coexists with ventilation–perfusion mismatch. Its effects on oxygenation often become clinically prominent in states of increased cardiac output (such as exercise) in the setting of fibrotic or interstitial lung disease.[6] These higher output states lead to reduced time for diffusion of oxygen across the diseased alveolar–capillary membrane and subsequent hypoxemia.

Clinically, the most frequently observed pathophysiologic mechanisms of hypoxemia are ventilation–perfusion mismatch and shunt.

Ventilation–perfusion mismatch generally results when focal (or sometimes diffuse) areas of diminished ventilation arise relative to persistent pulmonary capillary blood flow. Clinical examples include cardiogenic pulmonary edema, acute lung injury, and pneumonia—all of which are characterized by alveolar filling, reduced ventilation, and continued perfusion. The hypoxemia resulting from lack of ventilation to these areas can generally be overcome simply by increasing the fraction of inspired oxygen (FI_{O_2}), that is, with the use of supplemental oxygen. In the setting of ventilation–perfusion mismatch, without oxygen supplementation, reflex hypoxic pulmonary vasoconstriction occurs, minimizing the impact on Pa_{O_2}. Hypoxic pulmonary vasoconstriction may ultimately lead to increased pulmonary artery pressure and cor pulmonale.

Shunt occurs when a fraction of pulmonary blood flow effectively bypasses the alveolar compartment. Examples include atelectatic lung in which ventilation is absent but perfusion maintained (at least in part). Other examples include atrial septal defect and pulmonary arteriovenous malformations. Increasing the alveolar concentration of oxygen in the setting of shunt has no effect on arterial oxygenation. The hypoxemia from shunt physiology is refractory to the use of supplemental oxygen.

Finally, when tissue hypoxia is severe, or when increased tissue oxygen utilization is present, the oxygen content of venous blood returning to the right heart may be profoundly reduced—detected as a low oxygen saturation of venous blood (Sv_{O_2}). A low Sv_{O_2}, in combination with ventilation–perfusion mismatch or shunt, leads to worsening arterial hypoxemia. This pathophysiologic constellation may be observed when patients with severe lung disease and poor oxygen delivery are physically active or have high metabolic demands due to critical illness. Hemoglobin desaturation can then be seen.

CLINICAL ASSESSMENT OF TISSUE HYPOXIA

To use oxygen therapy correctly, clinicians must recognize the presence of tissue hypoxia and its etiology. With this knowledge, the clinician can determine who may benefit from supplemental oxygen. Furthermore, the degree of hypoxia must be assessed to determine the optimal dosage of oxygen. In this way, one can balance oxygen's benefits and potential toxicities. Unfortunately, tissue hypoxia is not directly measured by any one test. Instead, a combination of clinical and laboratory parameters is used to determine its severity. In the case of tissue hypoxia caused by isolated arterial hypoxemia, measurement of arterial oxygen saturation can be an excellent guide to appropriate oxygen therapy.

■ CLINICAL MANIFESTATIONS

Clinical manifestations of hypoxia are variable and nonspecific. Whether hypoxia develops acutely or is chronic influences patient presentation: Patients with chronic hypoxia often have minimal symptoms. Symptoms and signs of acute hypoxia are outlined in (Table 144-2). The most prominent findings are dyspnea, tachypnea, and respiratory distress. A frequently observed finding is an acute change in mental status, ranging from agitation to delirium to coma. Cardiac arrhythmias are common. Cyanosis is generally a late finding and is often unreliable in diagnosing hypoxia, as it may be absent in the setting of anemia and with poor peripheral perfusion.

■ LABORATORY ASSESSMENT

Distinction between tissue hypoxia and arterial hypoxemia is important in applying various laboratory studies in clinical evaluation. To determine if tissue hypoxia, that is, hypoxia in end-organs, is present, measures such as serum lactate (elevated in ischemia)

TABLE 144-1 Causes of Arterial Hypoxemia and Response to Oxygen Therapy

Cause	Clinical Examples	Response to Oxygen Therapy
Decreased oxygen intake	Altitude (reduced PI_{O_2})	Rapid increase in Pa_{O_2}
Alveolar hypoventilation	COPD, obesity hypoventilation	Increase in Pa_{O_2}, may depress minute ventilation, however
Diffusion defect	Interstitial pneumonitis	Moderately rapid increase in Pa_{O_2}
Ventilation–perfusion mismatch	COPD	Moderately rapid increase in Pa_{O_2}
Shunt	Atrial septal defect, with right-to-left shunting	Variable increase in Pa_{O_2}, depending on size of shunt

TABLE 144-2 Signs and Symptoms of Acute Hypoxia

System	Signs and Symptoms
Respiratory	Tachypnea, breathlessness, dyspnea, cyanosis, pulmonary hypertension
Cardiovascular	Increased cardiac output, palpitations, tachycardia, bradycardia arrhythmias, hypotension, angina, vasodilation, diaphoresis, shock
Central nervous	Headache, impaired judgment, inappropriate behavior, confusion, euphoria, delirium, restlessness, papilledema, seizures, obtundation, coma
Neuromuscular	Weakness, tremor, asterixis, hyperreflexia, incoordination
Metabolic/renal	Sodium and water retention, lactic acidosis, acute tubular necrosis

and Sv_{O_2} (reduced in ischemia) are generally used. Evaluation for anemia by measuring hemoglobin or hematocrit is also important in this context.

When the cause of tissue hypoxia is isolated arterial hypoxemia, measurements of Pa_{O_2} and Sa_{O_2} provide appropriate surrogates of oxygen delivery and, therefore, tissue hypoxia. Values are derived from arterial blood-gas measurements. Since Sa_{O_2} and Pa_{O_2} have a generally predictable relationship according to the oxygen–hemoglobin dissociation curve, measuring only Sa_{O_2} may be sufficient to assess arterial hypoxemia. This is done noninvasively using pulse oximetry; the estimated Sa_{O_2} is designated as Sp_{O_2}. Importantly, various toxins, such as carbon monoxide and those that result in methemoglobinemia will disrupt the predictable relationship between Sa_{O_2} and Pa_{O_2} as measured by pulse oximetry (see next section). Under these circumstances, cooximetry performed on an arterial blood-gas sample is required, and pulse oximetry cannot be relied upon to evaluate arterial hypoxemia.

PULSE OXIMETRY

Pulse oximetry is an important diagnostic tool which is now widely utilized in hospitals, outpatient settings, and at home. The general principles of this technology are useful to understand, as are its limitations.

First proposed conceptually in the 1930s and developed further in the mid-20th century, the underlying principle of oximetry is Beer's law, which states that concentration of an unknown substance dissolved in a solvent can be determined by its light absorption[7]:

$$L_{out} = (L_{in} \times e) - (D \times C \times a) \quad (3)$$

where

L_{out} is the intensity of transmitted light through the substance
L_{in} is the incident light
D is the distance the light travels
C is the concentration of the substance (in this case, oxyhemoglobin or reduced hemoglobin)
a is the absorption coefficient

When light is passed through a finger, ear lobe, or other tissue, the majority of it is absorbed by connective tissue, skin, bone, and venous blood, and the amount absorbed is constant. However, with each heartbeat, pulsatile flow of arterial blood occurs, allowing the pulse oximeter to detect changes in light absorbance at two wavelengths, 660 nm (red) and 940 nm (infrared). Since reduced hemoglobin and oxyhemoglobin have different absorptions at these two wavelengths, the concentration of oxyhemoglobin relative to total hemoglobin can be deduced.

Several limitations to pulse oximetry exist, which can be inferred from its basic principles. Any substance in the blood with similar absorption at the two wavelengths employed will interfere with accuracy. This is clinically important in the evaluation of two acquired hemoglobinopathies—carboxyhemoglobinemia and methemoglobinemia.

Carboxyhemoglobin has a very similar absorption coefficient at 660 nm as oxyhemoglobin; at 940 nm, it has minimal light absorption. Therefore, no matter what the relative concentrations of hemoglobin molecules saturated with CO versus O_2, Sp_{O_2} will be constant (generally about 90%–95%).

In methemoglobinemia, a condition in which the iron moiety of hemoglobin is reduced to the ferric state, the methemoglobin molecule is characterized by equalization of absorption coefficients at 660 nm and 940 nm. Equal absorption at these two wavelengths translates into an Sa_{O_2} of 85%, which is what the pulse oximeter inevitably reads as methemoglobin concentration increases. Furthermore, an antidote for methemoglobinemia, methylene blue, also affects absorption of light at 660 nm and may falsely lower Sp_{O_2}.

Given that pulse oximetry relies upon pulsatile flow, the technology cannot be used in conditions of low flow, such as cardiac arrest or profound shock. Errors also occur when venous pulsatility is prominent, such as in severe tricuspid regurgitation. In this case, the pulsatility of venous blood, with its higher concentration of reduced hemoglobin, may result in artificially low readings of oxygen saturation. When profound arterial hypoxemia exists, for example, Sa_{O_2} <70%, the accuracy of pulse oximetry declines, as the technology has generally not been calibrated at lower saturations.

OTHER ASSESSMENTS OF HYPOXEMIA

Several other calculated assessments of hypoxemia are useful in assessing the degree of respiratory dysfunction.

Pa_{O_2}/Fi_{O_2}

Pa_{O_2}/Fi_{O_2} (P/F ratio) requires an arterial blood-gas specimen. For example, consider a patient breathing gas with an Fi_{O_2} of 0.80, who has a Pa_{O_2} 240 mm Hg. The P/F ratio is 240/0.8 or 300. The ratio, considered to reflect the magnitude of derangement in O_2 transfer across the lung and thought to be relatively unaffected by differences in Fi_{O_2} among measurements, is most useful in mechanical ventilation, when accurate determination of Fi_{O_2} is possible. In the setting of acute hypoxemia, a P/F ratio of <300 indicates abnormal gas exchange, and a P/F ratio <200 indicates severe hypoxemia.

Alveolar–Arterial (A-a) Difference

The A-a difference (also called the A-a gradient) measures the difference in alveolar oxygen tension and arterial oxygen tension. This measurement, which requires an arterial blood gas, is determined as:

$$\text{A-a difference} = P_{A_{O_2}} - Pa_{O_2} \quad (4)$$

$P_{A_{O_2}}$ is calculated using the alveolar air equation:

$$P_{A_{O_2}} = (Fi_{O_2} \times [P_{atm} - P_{H_2O}]) - (Pa_{CO_2}/R) \quad (5)$$

where,

Fi_{O_2} is the fraction of inspired oxygen
P_{atm} is the atmospheric pressure (760 mm Hg at sea level)

P_{H_2O} is the partial pressure of water (47 mm Hg at room temperature)
Pa_{CO_2} is the arterial carbon dioxide tension
R is the respiratory quotient (which, in the steady state, is usually 0.8, depending on the patient's nutritional intake)

A "normal" A-a difference on room air is often considered to be 10 mm Hg. However, two important factors affect the "normal" value. The first is patient's age, the influence of which can be expressed numerically according to the formula:

$$\text{Normal A-a difference on room air} = 2.5 + 0.21 \times \text{age in years} \quad (6)$$

The second is FI_{O_2}: The higher the FI_{O_2}, the larger the A-a difference, since alveolar oxygen tension increases more than does arterial oxygen tension with increasing FI_{O_2}. Note the distinction in this regard with respect to the P/F ratio described previously.

Oxygenation Index

The oxygenation index (OI) is often used in neonates and children with acute hypoxemic respiratory failure to assess the severity of disease and predict outcome.[8] It can be calculated only for mechanically ventilated patients, where mean airway pressures may be measured.

$$OI = [(\text{mean airway pressure} \times FI_{O_2})/Pa_{O_2}] \times 100 \quad (7)$$

A high OI (e.g., >25) indicates severe hypoxemic respiratory failure.

INDICATIONS FOR OXYGEN THERAPY

Supplemental oxygen is a drug with indications, contraindications, and a therapeutic window. Oxygen dosage should be titrated as precisely as possible and oxygen administration monitored closely with respect to clinical benefits and potential toxicities. Indications for oxygen therapy may be considered in both acute and chronic settings. In addition, special circumstances under which oxygen is used therapeutically warrant special discussion, including hyperbaric administration (oxygen delivered at >1 atmosphere) and oxygen therapy during air travel.

■ ACUTE INDICATIONS FOR OXYGEN THERAPY

Indications for acute, short-term supplemental oxygen therapy, listed in Table 144-3, are based upon guidelines established by the American Association of Respiratory Care and other organizations.[9–11]

Usually, when a patient presents with respiratory distress, supplemental oxygen is administered until an assessment of hypoxemia is made. The clearest indication for oxygen therapy is arterial hypoxemia, and supplemental oxygen is generally administered when the Pa_{O_2} is <60 mm Hg, which normally corresponds to an Sa_{O_2} or Sp_{O_2} of 89% to 90%. When the Pa_{O_2} drops below 60 mm Hg, oxygen saturation may drop precipitously, leading to a much lower arterial oxygen content and resultant tissue hypoxia.

As noted previously, the most common pathophysiologic cause of hypoxemia is ventilation–perfusion mismatch, which responds readily to supplemental oxygen. Hypoxemia secondary to right-to-left shunt is less responsive to supplemental oxygen; when the shunt fraction exceeds 20% to 25%, hypoxemia persists, despite administration of inspired gas with an FI_{O_2} of 100%. In the case of hypoxemia due to alveolar hypoventilation, oxygen therapy often improves Sa_{O_2} and oxygen delivery, but it does not correct the underlying cause of respiratory dysfunction; restoration of ventilation must be pursued.

An oxygen saturation target of 94% to 98% is reasonable for patients at sea level who are hypoxemic and who have normal baseline lung function.[10] In certain circumstances, such as shock states characterized by hypoperfusion, the target may be even higher in an attempt to maximize the oxygen content of arterial blood. Conversely, in patients who have abnormal control of respiration, such as those with chronic hypercapnia, a lower Pa_{O_2} goal may be more appropriate (as discussed later in this chapter).

TABLE 144-3 Guidelines for Acute Oxygen Therapy

Accepted Indications
• Documented hypoxemia, defined as Pa_{O_2} below the normal range. Usually Pa_{O_2} <60 mm Hg or Sa_{O_2} <90%.
• Acute care situation in which hypoxemia is suspected, such as respiratory distress. Requires substantiation of hypoxemia (by Sa_{O_2} or Pa_{O_2}) in a reasonable time.
• Severe trauma
• Acute myocardial infarction with hypoxemia
• Low cardiac output with metabolic acidosis
• Hypotension (systolic blood pressure < 100 mm Hg)
Questionable Indications
• Acute myocardial infarction without hypoxemia
• Dyspnea without hypoxemia (palliative)
• Sickle cell pain crisis
• Pneumothorax

Arch Intern Med. 1984;144(8):1645–1655.

Use of supplemental oxygen may be indicated in a few clinical scenarios other than arterial hypoxemia. As discussed earlier, patients in shock states may benefit from enhanced arterial oxygen content and delivery, as may patients in cardiac and respiratory arrest. Similarly, trauma victims and critically ill surgical patients benefit from early oxygen therapy to improve tissue hypoxia. Use of short-term, postoperative supplemental oxygen has also been shown to reduce wound infection in surgical populations.[12] In patients with carbon monoxide poisoning, in whom pulse oximetry readings are unreliable, supplemental oxygen increases Pa_{O_2}. More importantly, it shortens the half-life of carboxyhemoglobin, thereby increasing the percentage of oxyhemoglobin. With administration of pure oxygen, the half-life of carboxyhemoglobin is 70 to 80 minutes,[13] compared with a half-life of 320 minutes when a patient is breathing room air.[14] Under hyperbaric conditions, when pure oxygen is delivered at higher atmospheric pressure, the half-life is shortened even further. Hyperbaric oxygen is generally employed when carboxyhemoglobin levels are high (>25%) and there is an evidence of end-organ damage, such as cardiac ischemia or alterations in sensorium,[15] although use of hyperbaric oxygen in this setting is currently controversial.

Several other disorders may benefit from administration of supplemental oxygen, although supportive data in these settings are lacking or equivocal. Oxygen therapy is often used in cluster headaches,[16] sickle cell pain crises (although this is falling out of favor),[17] palliative relief of dyspnea without hypoxemia,[18] and pneumothorax in patients who do not have a chest tube (in an effort to facilitate resorption of pleural air).[19,20] Administration of supplemental oxygen has also been proposed to reduce postoperative nausea and vomiting and to alleviate nausea associated with medical transport in ambulances.[21] Use of supplemental oxygen in uncomplicated myocardial infarction is common but controversial; the topic is discussed in more detail below. Finally, hyperbaric oxygen is sometimes used in an effort to accelerate healing of complicated, chronic wounds arising in the setting of peripheral or microvascular disease.[22] Hyperbaric oxygen therapy is widely accepted as the therapy of choice in decompression sickness (see Chapter 93).[23]

TABLE 144-4 Physiologic Indications for Long-Term Oxygen Therapy (LTOT) in COPD[a]

Pa_{O_2}	Sa_{O_2}	LTOT Indication	Qualifier
<55 mm Hg	<88%	Absolute	None needed
55–59 mm Hg	88–90%	Relative with qualifier	Presence of any of the following signs of cor pulmonale: • History of dependent edema • Polycythemia (HCT > 55%) • P pulmonale on EKG (P wave > 3 mm in leads II, III, or aVF)
≥60 mm Hg	≥90%	None unless qualifier	At least one of the following: • Exercise desaturation • Sleep desaturation not corrected by CPAP • Lung disease with dyspnea responding to O_2 therapy

[a]*Generally used in other conditions as well.*

INDICATIONS FOR LONG-TERM OXYGEN THERAPY

The use of LTOT has been growing as our ability to deliver oxygen in outpatient settings has improved. Criteria for administering LTOT have become well established, generally in the context of chronic obstructive pulmonary disease (COPD). Table 144-4 outlines the guidelines of the American Thoracic Society (ATS) for LTOT in COPD.[24] The guidelines are based on the data derived from two major trials.

The first trial, published in 1980, is the Nocturnal Oxygen Therapy Trial (NOTT).[25] In NOTT, 203 hypoxemic patients with COPD were randomized to the treatment with either nocturnal (at least 12 hours) or continuous oxygen. Patients who received nocturnal oxygen therapy alone had a higher mortality at both 12 and 24 months (40.8% at 24 months) compared with those who received continuous oxygen therapy (22.4% at 24 months).

The second trial, published in 1981, is the British Medical Research Council Domiciliary (BMRCD) trial.[26] In this trial, 87 patients with hypoxemia and COPD were randomized to receive either no oxygen therapy or at least 15 h/d of supplemental oxygen. Similar to the NOTT trial, mortality was significantly higher in the no-oxygen group.

From these two trials, in patients with COPD and hypoxemia, we can infer that supplemental oxygen for >15 h/d is better than no oxygen at all, and that continuous supplemental oxygen is better than nocturnal-only therapy. The entry criteria for these trials form the basis of the current Medicare criteria and ATS guidelines for LTOT. Based on the BMRCD trial, most prescriptions for oxygen are written for at least 15 h/d. The data from the two trials have been extrapolated to other conditions complicated by chronic hypoxemia for which data from large trials are lacking, including cystic fibrosis, restrictive lung diseases, and chronic cardiac diseases.

In patients whose hypoxemia does not meet resting criteria for administration of LTOT, evaluation for exercise-related desaturation may be indicated. Some patients may require supplemental oxygen only with exertion; improved exercise performance may be noted,[27] unless cardiac and peripheral circulatory factors are performance-limiting.

Finally, patients with significant desaturation while sleeping may warrant nocturnal supplemental oxygen. Important to note, however, is that in the absence of underlying lung disease, these patients often have obstructive sleep apnea or obesity hypoventilation syndrome, for which noninvasive positive pressure ventilation constitutes primary therapy.[28] Table 144-5 lists the physiologic indications for oxygen therapy during sleep.

INDICATIONS FOR OXYGEN THERAPY IN AIR TRAVEL

An important consideration for clinicians who manage patients with lung disease is determining the need for supplemental oxygen during air travel.

Most commercial aircraft fly at cruising altitudes between 25,000 and 45,000 ft, which would normally result in a very low inspired oxygen tension (PI_{O_2}). Airplane cabins, however, are generally pressurized to an altitude of 8000 ft, which results in an oxygen tension of approximately 108 mm Hg (the PI_{O_2} at sea level is 149 mm Hg). In patients with lung disease, this reduced PI_{O_2} may result in marked reductions in PA_{O_2} and Pa_{O_2}, placing the patient at risk for hypoxemia.

Prior to travel, the patient should have a thorough medical evaluation, with consideration for reevaluating pulmonary function tests, specifically spirometry and D_{LCO}, and obtaining an arterial blood gas. For patients whose Pa_{O_2} ≥70 mm Hg (Sp_{O_2} > 95%) at ground level, their in-flight Pa_{O_2} will likely exceed 50 mm Hg, which is generally considered adequate. For patients with a more marginal Sp_{O_2} or Pa_{O_2} and other risk factors, a 6-minute walk test or other evaluation may be considered.[29]

The 6-minute walk test may be a reliable and practical way of estimating the cardiopulmonary reserve that patients require to deal with the physiologic demands of a reduced PI_{O_2} during flight. Although the entire medical evaluation must be taken into account, if a patient has an abnormally low 6-minute walk distance, has significant dyspnea during the test, or experiences a decline in Sp_{O_2} to

TABLE 144-5 Physiologic Indications for Nocturnal Oxygen Therapy

Pa_{O_2} <55 mm Hg with sleep or Sa_{O_2} <88% with sleep
Or
Pa_{O_2} decreases more than 10 mm Hg with sleep
Or
Sa_{O_2} decreases more than 5% with sleep and signs of nocturnal hypoxemia including: • Pulmonary hypertension • Daytime somnolence • Cardiac arrythmias
Patient should be evaluated for a sleep disorder and need for positive pressure device

<85%, the patient will likely need supplemental oxygen during air travel.

Finally, in anticipation of air travel, a hypoxia altitude simulation test (HAST) may be performed[30] (see Chapter 33). In this test, an arterial blood gas is drawn just prior to administration of a gas mixture with an FI_{O_2} of 15.1%. Another arterial blood gas is drawn 20 minutes later, while the patient breathes the hypoxic gas mixture. If the Pa_{O_2} is <50 mm Hg, administration of supplemental oxygen during flight is recommended. If the Pa_{O_2} is between 50 and 55 mm Hg, further testing should be considered, including a 6-minute walk test. Reviews on oxygen therapy and air travel address the testing options available.[31]

TECHNIQUES OF OXYGEN ADMINISTRATION

When choosing an oxygen delivery device for a given patient, the clinician must consider the degree of hypoxemia, the specificity required with regard to setting the FI_{O_2} (which depends on the patient's respiratory control), and the patient's minute ventilation. The oxygen flow that the device can deliver, the adjustability and precision of that delivery, and the comfort and cost of the device are additional considerations.

Oxygen delivery devices utilized in the acute setting may be divided into low-flow and high-flow delivery systems. The required flow depends on the patient's degree of hypoxemia and minute ventilation. Patients who exhibit a high minute ventilation or are profoundly hypoxemic require high-flow devices (i.e., if they do not require mechanical ventilation). Patients with more moderate degrees of hypoxemia may only need low-flow systems, which are generally more comfortable.

■ LOW-FLOW AND VARIABLE PERFORMANCE OXYGEN DEVICES

Low-flow systems deliver only a fraction of the patient's minute ventilation as pure oxygen. The maximum flow in these systems is 15 L/min. Since a patient's tidal volume usually varies from breath to breath, and the delivered flow of oxygen from the device is constant, the fraction of inspired oxygen for any given breath is impossible to predict. For example, when a patient takes very deep breaths, more room air is entrained, but the flow of pure oxygen is constant, thereby diluting the administered FI_{O_2}. Conversely, when a patient has a reduced minute ventilation or is taking very shallow breaths, the amount of entrained room air is minimal, and the FI_{O_2} inspired is greater than what might be expected. Table 144-6 illustrates this important principle mathematically. The variation in FI_{O_2} with minute ventilation must be considered when administering oxygen to patients with chronic CO_2 retention who are at risk for worsening hypercapnia with excessive oxygen therapy. Because of the uncertainty of the FI_{O_2} delivered by low-flow devices, they are sometimes referred to as "variable performance devices."

Nasal Cannulae

Nasal cannulae allow comfortable delivery of oxygen and unimpeded communication and access to oral intake. The cannula rests just below the nares (Fig. 144-1) and entrains a constant flow of pure oxygen, generally ranging from 2 to 6 L/min. At 6 L/min or higher, the patient may experience discomfort, excessive mucosal dryness, and epistaxis. The continuous flow creates a reservoir of oxygen in the nasopharynx from which the patient draws during inspiration. Contrary to popular belief, even if a patient is a "mouth-breather," the gas inhaled is oxygen enriched because of the effect of the nasopharyngeal reservoir. Although FI_{O_2} varies widely with nasal cannulae (as described above), an approximation of FI_{O_2} based on oxygen flow rate can be derived (Table 144-7). Typically, FI_{O_2} increases by 3% to 4% with each 1 L increment in flow.

Several variations in nasal cannulae design may reduce oxygen waste. The moustache-style reservoir (Fig. 144-1C) contains a soft, inflatable reservoir with a volume of approximately 20 mL. During exhalation, the reservoir fills with oxygen. During inspiration, the patient initially draws from the reservoir and then, when the reservoir is depleted, from the continuous flow of the cannula. This acts to deliver a bolus of oxygen early in the course of the inspiration, while reducing wasted oxygen during expiration. Generally, patients can be maintained at a slightly lower flow rate using the moustache-style cannula compared with a regular nasal cannula.

Another modification is the pendant reservoir cannula (Fig. 144-1B). This device consists of a reservoir worn on the chest like a pendant. The reservoir is attached to a nasal cannula with tubing of slightly greater diameter than normal. The pendant reservoir cannula provides a similar function to the moustache-style cannula.

Simple Oxygen Masks

Oxygen masks can deliver higher oxygen flow rates than nasal cannulae; they entrain less room air and, therefore, can generate a higher FI_{O_2}. In addition, the configuration of simple masks (Fig. 144-2A) enables an enlarged reservoir of oxygen for inhalation. With nasal cannulae, the reservoir comprises anatomic dead space in the airway, such as the nasopharynx. With a well-fitting oxygen mask, the reservoir is expanded to include the volume within the mask. Generally, flow rates for simple masks range from 5 to 12 L/min, which usually requires some room air to be entrained via the side ports of the mask to meet the patient's minute ventilatory needs. Given the higher flow rates delivered using face masks, a humidifier

TABLE 144-6 Effects of Minute Ventilation on FI_{O_2} in Low-Flow Systems

	Respiratory Distress	Relief of Respiratory Distress
Minute ventilation	30 L/min (40 breaths/min × 750 mL/breath)	5 L/min (10 breaths/min × 500 mL/breath)
O_2 flow rate	2 L/min	2 L/min
Calculation of inspired O_2 concentration (FI_{O_2})	2 L/min of 100% oxygen + 28 L/min of 21% oxygen (room air drawn into mask) = 30 L/min minute ventilation Thus, $FI_{O_2} = \frac{(1.0 \times 2) + (0.21 \times 28)}{30} = 0.26$ (**26%** FI_{O2})	2 L/min of 100% oxygen + 3 L/min of 21% oxygen (room air drawn into mask) = 5 L/min minute volume Thus, $FI_{O_2} = \frac{(1.0 \times 2) + (0.21 \times 3)}{5} = 0.53$ (**53%** FI_{O2})

is also often required. The flow rate of a simple mask should never be <5 L/min; below this level, carbon dioxide rebreathing may occur, along with an increased resistance to inspiration.

As is the case with nasal cannulae, predicting the actual $F_{I_{O_2}}$ delivered by simple oxygen masks is difficult, since the $F_{I_{O_2}}$ varies with the size of the patient's tidal volumes and total minute ventilation. Simple masks are also more uncomfortable, making eating and communicating challenging. Because they cover the mouth, aspiration is a risk with any mask.

Reservoir Masks

A reservoir mask is similar to a simple mask but has an attached reservoir of 600 to 800 mL, resting below the patient's chin. Generally, the mask provides flow between 8 and 15 L/min, which keeps the reservoir bag at least half full. Reservoir masks include partial rebreather and nonrebreather types (Fig. 144-3).

When using a partial rebreather mask, the patient exhales approximately the first one-third of the expired tidal volume into the reservoir. That volume is derived predominantly from anatomic

dead space and, consequently, its O_2 content is high and CO_2 content low. The reservoir bag is filled with the exhaled volume and continued oxygen inflow, while the remainder of the patient's tidal volume is exhaled via the mask's side ports and edges. A patient with a high minute ventilation can sometimes deflate the reservoir. As with simple oxygen masks and nasal cannulae, the $F_{I_{O_2}}$ the patient is receiving cannot be determined precisely at any point in time.

The nonrebreathing reservoir mask (Fig. 144-2B) is similar to the partial rebreather, with the exception of a one-way valve at the exit of the reservoir bag. The valve ensures that no exhaled air enters the reservoir (i.e., air can travel only in an inward direction), enabling delivery of 100% oxygen. The mask also incorporates one-way valves on its side ports to minimize the inhalation of room air. When using a nonrebreathing reservoir mask, oxygen flow should be set high enough to prevent deflation of the reservoir bag—usually about 15 L/min. Currently available masks do not fit securely enough to ensure a delivered $F_{I_{O_2}}$ of 100%. Typically, these masks provide a maximum $F_{I_{O_2}}$ of 80% to 90%; the $F_{I_{O_2}}$ may be even lower (60%–80%) in the setting of very high minute ventilation.[32]

■ HIGH-FLOW OR FIXED-PERFORMANCE OXYGEN DEVICES

High-flow oxygen devices deliver a constant $F_{I_{O_2}}$ and are, therefore, sometimes referred to as "fixed performance devices." The devices allow for a fixed $F_{I_{O_2}}$ by providing very high flows of pure oxygen which exceed the patient's minute ventilation, sometimes by a factor of four. Along with very high flow rates, the devices incorporate oxygen reservoirs whose volumes exceed the patient's anatomical dead space. Since the $F_{I_{O_2}}$ is predictable, high-flow devices are ideal for patients who have precise oxygen needs that should be neither exceeded nor unmet. Patients for whom high-flow devices are prescribed may be severely hypoxemic and must be monitored closely for the possible need for noninvasive mechanical ventilation or intubation.

Air-Entrainment Masks (Venturi Masks)

The Venturi mask consists of a mask, a jet nozzle, and entrainment ports (Fig. 144-2D). Oxygen is delivered under pressure via the jet nozzle, which acts to dramatically increase the velocity of the gas. The high-velocity gas entrains ambient air via the entrainment ports. Depending upon the size of entrainment ports, size of the jet nozzle, and flow rate of oxygen, a predictable $F_{I_{O_2}}$ can be delivered.

Typically, the Venturi mask has interchangeable or adjustable valves that enable the clinician or respiratory therapist to better titrate the $F_{I_{O_2}}$ to the patient's needs. Humidification is sometimes difficult to ensure and requires the use of an aerosol-entrainment collar over the jet orifice and entrainment port. Humidification increases the density of the entrained air, slows the speed of entrainment, and thereby reduces the amount of room air entrained, resulting in a higher $F_{I_{O_2}}$. Although described as a high-flow device, air-entrainment masks generally can only ensure a high-flow rate when the $F_{I_{O_2}}$ is <30%.[32] As the $F_{I_{O_2}}$ increases above 30%, the devices are unable to deliver flow rates of 40 L/min (as less room air is entrained) and are considered variable performance devices. However, the ability of these masks to deliver an exact $F_{I_{O_2}}$ at lower levels of $F_{I_{O_2}}$ makes them ideal for patients with chronic lung disease who require a specific $F_{I_{O_2}}$ due to the risk of hypercapnia from hyperoxia. In fact, for treatment of patients with COPD in emergency departments, the British Thoracic Society recommends oxygen administration using a Venturi mask to ensure an appropriate $F_{I_{O_2}}$.[10]

High-Flow Generators

High-flow generators are used to ensure noninvasive delivery of a constant, high concentration of inspired oxygen. High-flow generators are capable of delivering gas in excess of 40 to 60 L/min. From the generator, gas is routed through a heated humidifier, similar to that used for mechanical ventilators. A large reservoir is often placed in line between the humidifier and aerosol face mask. The face mask may incorporate valves which ensure that no rebreathing occurs. Given the high flows delivered, a constant $F_{I_{O_2}}$ is achieved, regardless of the patient's minute ventilation and fit of the mask. When precise oxygen titration is required, air–oxygen blenders are used. The blenders are metering devices which use compressed oxygen and air from a high-pressure wall source (50 psi) to generate a gas mixture which can be delivered at high flow (e.g., 100 L/min) and precise $F_{I_{O_2}}$. The devices are noisy and require specialized personnel to set up and monitor, limiting their usage to intensive care settings.[33]

High-Flow Nasal Cannulae

Recently, nasal cannulae (Fig. 144-2C) that can deliver much higher rates of flow than simple nasal cannulae have been developed (e.g., Vapotherm®) that allow delivery of much higher flows (and therefore, higher $F_{I_{O_2}}$) of humidified oxygen. The devices can deliver between 1 and 60 L/min and may be more comfortable than a facemask.[34] However, particularly in infants, these devices may increase positive end-expiratory pressures (4 cm H_2O or higher). Therefore, the devices' clinical benefits must be weighed against the risk of barotrauma, especially in infants.[35]

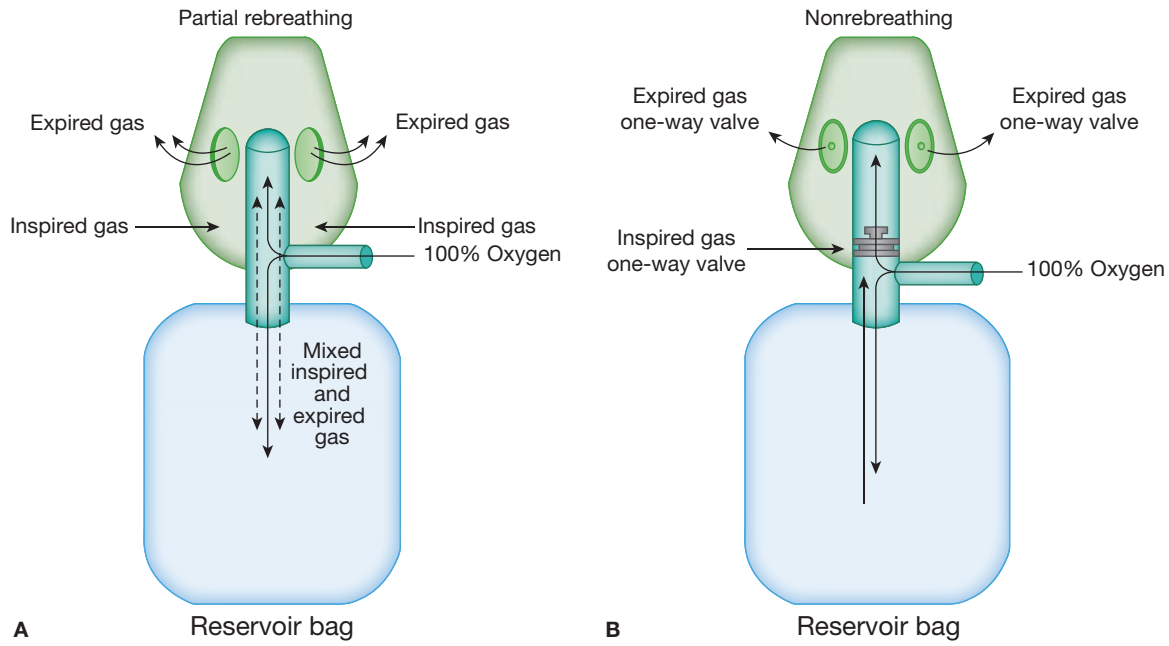

Figure 144-3 Mask reservoir bag systems, illustrating airflows with partial rebreathing (**A**) and nonrebreathing (**B**) masks. *Arrows* indicate direction of airflow.

■ LONG-TERM OXYGEN THERAPY

As noted previously, LTOT has a significant beneficial effect on survival in patients with chronic hypoxemia. However, initiation of chronic home oxygen therapy can be a substantial burden for patients. Like any therapy, LTOT is subject to patient noncompliance. Various studies have noted adherence to LTOT in only 45% to 70% of patients.[36] The barriers to adherence are many and include patient concerns of addiction and dependency, embarrassment from the "stigma" that an oxygen delivery device represents with respect to a smoking-related disease, and the associated limitations on physical activity arising from bulky ambulatory oxygen sources.[36] Therefore, appropriate counseling about the benefits and demands of oxygen therapy is necessary before beginning treatment. Furthermore, the clinician should consider oxygen source portability, social and home support available (e.g., from friends, family, or visiting nurses), and patient attitudes and beliefs when considering LTOT. Finally, the clinical needs to facilitate sufficiently close patient monitoring to ensure long-term benefit from therapy. In the United States, oxygen therapy requires a Certificate of Medical Necessity (CMN). Continued need for LTOT must be recertified annually.

Oxygen Concentrators

Oxygen concentrators use specialized filters to eliminate other gases from room air, thus "concentrating" oxygen for delivery to the patient. Concentrators accomplish this by (1) using a compressor to draw room air into the system, (2) cooling the air (which has been heated up from the compression) using a heat exchanger, and (3) passing the air into molecular sieve beds where oxygen is concentrated. Sieve beds contain granular zeolite crystal composed of an array of small particles which separate gases according to size. Air cycles through two separate sieve beds; the cycling gradually removes nitrogen as waste and isolates oxygen which is diverted to a product tank. The oxygen in the product tank is pressurized at 10 psi and, prior to patient delivery, is passed through a bacteria filter and flow meter. Concentrators usually can produce oxygen concentrations of 95% to 97% at 2 L/min flow; the concentration falls to 86% to 93% at 3 to 5 L/min flow (note that pure oxygen tanks provide 100% oxygen at any flow rate up to 6 L/min).[33] Oxygen concentrators include large devices (weighing about 35 lb) intended for stationary use in the home and smaller portable devices, designed for use outside the home. The larger concentrators can produce high flows (up to 10 L/min) but are often tethered by power cords. High flow rates also demand humidification, which can also be provided by most large concentrators. Portable oxygen concentrators permit patient mobility; their use is increasingly being approved for air travel.[37] They usually weigh between 5 and 10 lb. Battery life is variable, typically of the order of 2.5 hours.

Liquid Oxygen

Although compressed gas oxygen is still utilized, often as an emergency supply in the home environment, liquid oxygen (LOx) has become standard in domiciliary systems. LOx has advantages of being more compact, requiring fewer refills, and operating at lower pressures than gaseous oxygen.

A home system of LOx typically consists of a large stationary reservoir which can hold up to 100 lb of LOx, and a smaller portable system for ambulation. The portable system can be refilled by the patient and may weigh as little as 5 lb. LOx is stored in tanks called dewars, which generally resemble a thermos bottle. The dewar consists of inner and outer containers and interposed insulating material and vacuum to maintain low temperatures.[33] Generally, LOx is more expensive than compressed gas and requires pressure-relief venting. However, LOx delivery systems consume less electricity and enable longer periods of high-flow oxygen administration.

Oxygen-Conserving Devices

LTOT is expensive, and oxygen-conserving devices have been designed to limit oxygen waste. Simple oxygen-conserving devices were discussed earlier. In addition to these simple devices, electronic oxygen-conserving devices are available.

Electronic oxygen-conserving devices are triggered by the onset of inspiration and deliver oxygen in boluses, the volume of which depends on device settings. For *pulse-type devices*, a fixed volume of oxygen is delivered (based on the flow setting) each time a breath is initiated. Some pulse-type devices deliver the volume with alternating breaths, rather than with every breath. For *demand-type devices*, the volume of oxygen is delivered throughout the whole inspiratory cycle; consequently, the volume varies according to the length of the

cycle. For demand-type devices, as respiratory rate decreases, the amount of oxygen conserved also decreases. In fact, demand-type devices commonly deliver an equal or greater volume of oxygen than a continuous-flow device. In the event of an electronic-conserving device malfunction, the delivery system defaults to continuous flow, often without the patient being aware.

Transtracheal Catheters

Transtracheal catheters, also considered oxygen-conserving devices, are considerably more invasive than other forms of LTOT. Transtracheal catheters require insertion directly into the trachea. Usually, this is accomplished percutaneously, using a modified Seldinger technique (similar to that used for placement of a percutaneous tracheostomy), or surgically, using a Lipkin procedure or mini-tracheotomy.[38]

The benefit of a transtracheal catheter is that it delivers oxygen that bypasses much of the anatomical dead space and utilizes the natural oxygen reservoir of the upper airway. Oxygen usage may be reduced by 50% to 75% with the use of a transtracheal catheter. In addition, nasal or facial irritation is minimal. Unfortunately, the catheter can be a nidus for infection and formation of "mucus balls," which rarely are fatal.[39]

PULMONARY OXYGEN TOXICITY

The modern study of pulmonary oxygen toxicity essentially began with J. Lorrain Smith in 1899. Smith described pathologic changes of oxygen toxicity in small animals exposed to the gas at a fractional concentration of 0.4 at 4.5 atmospheres (hyperbaric oxygen).[40] He noted that with high levels of oxygen exposure in mice, "the effect was uniformly fatal, and the immediate cause of death was inflammation of the lungs…and the lungs were found postmortem to be extremely congested…the alveoli were to a great extent filled with an exudate, which was granular and fibrillated in appearance…."

Further studies were conducted in animals to confirm Smith's findings. In the late 1930s, Becker-Freysang et al. studied oxygen exposure in humans and found that with 65 hours of exposure to O_2 at 730 mm Hg, paresthesias, nausea, and significant decreases in vital capacity occurred.[40] In the early 1960s, a healthy volunteer exposed to 110 hours of continuous high oxygen exposure experienced profound alterations in vital capacity, minute ventilation, pH, and Pa_{O_2}.[41] However, in general, the study of oxygen toxicity in humans has proved challenging. Based on animal models, information has been generated on the underlying cellular mechanisms.

■ BIOCHEMICAL BASIS OF PULMONARY OXYGEN TOXICITY

In considering the biochemical basis of pulmonary oxygen toxicity, the roles of free radicals and cellular antioxidant defenses in the production of tissue damage should be noted.

Free Radicals

Descriptions of the mechanisms of oxygen toxicity invariably begin with the concept of highly reactive oxygen-derived free radicals, specifically, superoxide (O_2^-), hydrogen peroxide (H_2O_2) and the hydroxyl radical (OH^-). By definition, free radicals have an unpaired orbital electron which causes either oxidation or reduction of a surrounding molecule. Free radicals are ubiquitously produced during cellular respiration; however, cells normally have the capability of neutralizing them quickly. Invariably, in hyperoxic conditions, generation of free radicals overcomes the cell's natural defenses.[42] Once formed in excess, free radicals are responsible for a cascade of effects, including lipid damage, leading to membrane dysfunction; disruption of enzymatic protein function; and nucleic acids damage.[43] Ultimately, these effects may result in cell death. In the case of nucleic acid damage, mutagenesis may occur.

Cellular Antioxidant Defenses

Various enzymes and cofactors in cells neutralize free radicals produced normally as a by-product of metabolism. These neutralizing enzymes are ubiquitous in eukaryotes.[44] The prototype is the metalloprotein, superoxide dismutase, which converts superoxide to hydrogen peroxide. Hydrogen peroxide so-generated is converted intracellularly to H_2O and O_2 through the actions of catalase (found in peroxisomes) and glutathione peroxidase (found in the cytoplasm). Glutathione peroxidase also repairs damaged lipids. Glutathione reductase and glucose-6-phosphate dehydrogenase regenerate glutathione enabling its recycling as an antioxidant.

Nonenzymatic antioxidants, which are present within cells, include the vitamins, α-tocopherol (vitamin E) and ascorbate (vitamin C). Other antioxidants, such as ceruloplasmin and cysteine, are also normally present in cells and the extracellular fluid. In fact, human lung tissue contains a high concentration of extracellular antioxidants and superoxide dismutase enzymes, which allow exposure to higher-concentration oxygen without development of toxicity.[45–47]

Tissue Damage

The cascade of reactions leading to hyperoxia-induced pulmonary tissue damage can be described in two phases.[48] Three to four days following hyperoxic exposure and generation of free radicals, an *exudative* phase commences, characterized by death of alveolar type 1 and endothelial cells. Interstitial edema is seen along with exudative alveolar filling. Neutrophil recruitment into the capillaries and interstitium is present. Alveolar epithelial damage then occurs, as neutrophils enter the alveoli, as seen in BAL specimens. A second, *proliferative* phase follows, characterized by proliferation of endothelial cells and type 2 pneumocytes. The pneumocytes cover the previously exposed basement membrane. Fibroblast proliferation also occurs in this phase. Recovery from oxygen injury is characterized by interstitial scarring and fairly normal-appearing capillary endothelium and alveolar epithelium.

■ CLINICAL MANIFESTATIONS OF PULMONARY OXYGEN TOXICITY

The exposure level at which oxygen toxicity occurs has not been clearly identified, although a higher $F_{I_{O_2}}$ experienced for a longer period of time is associated with an increased risk.

Clinical oxygen toxicity is manifest in several ways. Normal subjects experience a decrease in vital capacity and fall in $D_{L_{CO}}$.[49] Lung compliance is diminished.[49] Tracheobronchitis, which produces substernal chest pain, may also occur.[50] Clinical toxicity is generally absent when the $F_{I_{O_2}}$ is <50%.

Most clinically relevant concerns over oxygen toxicity center around (1) absorption atelectasis; (2) hypercapnic respiratory failure in at-risk individuals; (3) acute respiratory distress syndrome (ARDS); and (4) hyaline membrane disease, leading to bronchopulmonary dysplasia (BPD) in newborns.[51–53]

Absorption Atelectasis

Absorption atelectasis begins with complete or partial collapse of an alveolar unit's proximal airway. With airway closure, previously inhaled gas is trapped in the distal alveoli. Oxygen passes freely from the alveoli into the capillaries and is bound to hemoglobin or dissolved in plasma. Nitrogen, however, does not diffuse into the blood at nearly the same as oxygen. Hence, alveolar nitrogen "stents" open the alveoli, maintaining patency. For a patient breathing pure oxygen, the absence of nitrogen promotes alveolar collapse.

In a study based on mathematical modeling of alveolar collapse, the time from airway occlusion to alveolar collapse was 37 minutes using 3 minutes of preoxygenation with ambient air, compared with 8.7 minutes using preoxygenation with 100% oxygen (taking into

account hypoxic vasoconstriction).[54] In a clinical context, patients who received 40% oxygen just prior to extubation were shown to have less atelectasis on CT imaging compared with those who received 100% oxygen.[55] Finally, absorption atelectasis is commonly seen with induction of anesthesia. Preoxygenation and resulting nitrogen washout, along with a decrease in FRC from chest wall and diaphragmatic paralysis that occurs with the use of neuromuscular blockade, lead to small airway collapse.[56]

Hypercapnia in the Setting of Chronic CO_2 Retention and Hyperoxia

Patients with chronic CO_2 retention, usually in the setting of COPD, are at risk of worsening hypercapnia when exposed to high levels of oxygen. Classically, this worsening of hypercapnia during excessive supplemental oxygen administration has been attributed to the suppression of hypoxic drive to breathe in the setting of a blunted hypercapnic drive. This formulation was first proposed in a case report published in the middle of the 20th century.[57] However, three other mechanisms have been proposed,[10] as discussed below.

Ventilation–perfusion mismatch is an important cause of hypoxemia in patients with COPD. As discussed previously, hypoxic vasoconstriction (HPV) minimizes the adverse effects of a low $P_{A_{O_2}}$ on Pa_{CO_2}. When $P_{A_{O_2}}$ is increased through administration of supplemental oxygen, HPV is partially reversed, increasing perfusion to alveolar units which are still underventilated and now, oxygen enriched. Alveolar oxygen diffuses across the alveolar–capillary membrane, but because ventilation is still reduced, $P_{A_{CO_2}}$ remains high, reducing the diffusion gradient for CO_2 diffusion out of the blood. As a result, Pa_{CO_2} increases.

An additional consideration is the *Haldane effect*—the increased capacity of deoxygenated blood over oxygenated blood for CO_2 binding. As hemoglobin molecules become deoxygenated (i.e., reduced), they more readily accept protons (H^+). Removal of dissolved protons from plasma drives formation of bicarbonate, which, in turn, is catalyzed by carbonic anhydrase:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+ \quad (8)$$

Bicarbonate is the primary form in which CO_2 is transported and eliminated from the body. Furthermore, deoxygenated hemoglobin binds CO_2 directly, forming carbaminohemoglobin. As $P_{A_{O_2}}$ and, consequently, Pa_{O_2} increase with oxygen therapy, the concentration of oxyhemoglobin increases while that of deoxyhemoglobin decreases. As a result, buffering capacity is depleted, diminishing venous blood's transport capacity for tissue-generated CO_2; Pa_{CO_2} rises.

Finally, since pure oxygen is of higher viscosity than air, the increased viscosity of oxygen-enriched mixtures may contribute to increased work of breathing in an already compromised patient.[58]

Regardless of the underlying mechanism(s), clinicians must be vigilant when administering supplemental oxygen to those with chronic CO_2 retention. Unfortunately, the worsening of hypercapnia with oxygen administration is unpredictable; some patients with COPD do not develop hypercapnia with hyperoxia, while others may develop frank respiratory failure. Use of a high-performance oxygen delivery device (e.g., Venturi mask), and titration of $F_{I_{O_2}}$ to achieve a goal Sa_{O_2} of 88% to 90% in selected populations is the preferred management strategy.

Acute Respiratory Distress Syndrome and Bronchopulmonary Dysplasia

Oxygen toxicity has been implicated in the pathophysiology of the ARDS, although this subject is controversial. In almost all nonhuman mammals, prolonged exposure to 100% oxygen leads to diffuse alveolar damage and, eventually, death. In humans, replicating these findings has been challenging. Conducting human studies on oxygen toxicity presents ethical considerations of testing healthy human subjects. In addition, when oxygen toxicity is studied in the setting of pulmonary disease, differentiation between damage caused by the underlying lung disease and that caused by excessive oxygen exposure may be impossible. Many human studies have failed to show an association between excessive oxygen exposure and development of acute lung injury or ARDS.

In a study of brain-dead patients whose normal lungs were exposed for 24 hours to 100% oxygen delivered via a mechanical ventilator, only mild increases in alveolar capillary permeability were demonstrated; several more days of oxygen exposure failed to produce pathologic evidence of lung injury.[59] Similarly, another trial in postoperative cardiac patients failed to show any clinical differences between those ventilated with 100% oxygen and those ventilated with the minimal amount of oxygen needed (mean $F_{I_{O_2}}$ of 32%).[60] Notably, an acute lung injury pattern due to oxygen toxicity may be seen in humans with prior drug exposure, as discussed below.

Premature newborns often require high levels of oxygen therapy in the setting of hyaline membrane disease—a disorder caused by surfactant deficiency and characterized by alveolar collapse and inflammation.[61] In survivors, chronic lung disease in the form of BPD is often seen.

Oxygen toxicity is considered a major factor in the pathogenesis of BPD. BPD has been described in infants administered a high concentration of oxygen but not mechanically ventilated.[51] Newborns are particularly prone to damage by hyperoxia, as their cellular antioxidant defenses are not fully developed.

The initial pathologic lesions of BPD resemble diffuse alveolar damage. As BPD evolves, pathologic findings include alternating areas of collapse and emphysema, hyaline eosinophilic material lining distended terminal airways, marked epithelial hyperplasia or metaplasia, peribronchial fibrosis, and elastic fibers around air sacs and lobules. Clinically, the condition presents as a persistent requirement for supplemental oxygen or mechanical ventilation following hyaline membrane disease, along with poor lung compliance and pulmonary hypertension. Most infants gradually improve after 2 to 4 months. In more severe cases, infants require prolonged mechanical ventilation and may develop cor pulmonale from severe pulmonary hypertension.

■ POTENTIATION OF PULMONARY OXYGEN TOXICITY

Several drugs have well-known pulmonary toxicity and may potentiate the pulmonary toxicity of oxygen.

Bleomycin, an antibiotic agent first isolated from the fungus *Streptomyces verticillus* in the late 1960s,[62] has been used as a chemotherapeutic agent in the treatment of lymphomas, germ cell tumors, Kaposi sarcoma, cervical cancer, and squamous cell carcinomas of the head and neck. One mechanism by which bleomycin exerts its antitumor effect is through induction of cytotoxicity via generation of free radicals. Bleomycin forms a complex with Fe^{2+}, which is oxidized to Fe^{3+}, resulting in reduction of oxygen to free radicals. Bleomycin is also thought to exert direct effects on DNA. Along with its elimination by the kidneys, bleomycin can be deactivated by the enzyme bleomycin hydrolase, which is found in most tissues (especially the liver). However, two notable organs lack the enzyme: Lung and skin.

In the lungs, bleomycin toxicity is manifest in three ways: Organizing pneumonia, eosinophilic hypersensitivity, and interstitial pneumonitis, which may progress to fibrosis. An experiment in the hamster demonstrated that high doses of oxygen may work synergistically with bleomycin to cause worsening lung injury.[63] In humans, several case reports describe ARDS in patients previously treated with bleomycin who have exposure to a high $F_{I_{O_2}}$ perioperatively.[64,65] However, one prospective trial failed to show an association between high levels of oxygen exposure, past bleomycin exposure, and significant postoperative pulmonary dysfunction.[66]

Another well-known potentiator of pulmonary oxygen toxicity is paraquat. Paraquat is a commercial herbicide commonly used in the United States. It is associated with considerable toxicity and mortality when ingested orally, often in suicide attempts.[67] Like bleomycin, paraquat-induced pulmonary toxicity is the result of oxidative stress arising from the generation of free radicals, leading to pneumonitis and pulmonary fibrosis. Similar to models of bleomycin toxicity, animal studies suggest worsening toxicity in the setting of higher levels of inspired oxygen.[68,69] Therefore, in managing patients with paraquat poisoning, FI_{O_2} should be minimized as much as clinically possible. Use of paraquat is banned in the European Union and in several other countries, but the herbicide is still available for agricultural use in the United States. Fulminant poisonings carry a mortality that well exceeds 50%.[70]

Other drugs studied with regard to potentiation of oxygen toxicity include disulfiram and nitrofurantoin. Disulfiram is converted in vivo to diethyldithiocarbamate, which inhibits cytosolic superoxide dismutase.[71] Metabolism of nitrofurantoin results in the production of superoxide in a similar way to paraquat. The final pathway in both cases is an accumulation of oxygen-free radicals.[72]

Finally, elements of dietary intake are also associated with potentiation of oxygen toxicity, at least in animal models.[73] Protein deficiency leads to hyperoxic damage, possibly through a lack of sulfur-containing amino acids, which are crucial to glutathione synthesis. Deficiencies in the antioxidants vitamin A and vitamin E have also been implicated in the potentiation of oxygen toxicity.[74,75]

OXYGEN TOXICITY IN OTHER ORGAN SYSTEMS

Hyperoxia has the potential for producing toxicity in other organ systems. For example, an association between increased mortality and hyperoxia in the setting of return of spontaneous circulation (ROSC) following cardiac arrest has been reported.[76] In this large, multicenter, retrospective cohort study, patients who had a Pa_{O_2} >300 mm Hg following ROSC had an odds ratio for in-hospital death of 1.8 (95% CI, 1.8–2.2), based on a model controlling for potential confounders. The increased mortality seen in this study was attributed to hyperoxic reperfusion injury leading to oxidative stress—specifically worsening postarrest functioning of the central nervous system. Based on the results of this study, the American Heart Association has adjusted its postarrest guidelines to emphasize titration of FI_{O_2} to maintain an oxygen saturation ≥94%. Prospective data are not currently available to prove causation.

In a retrospective study conducted at a single trauma center, higher mortality was noted in patients with traumatic brain injuries exposed to hyperoxia (Pa_{O_2} > 200 mm Hg) compared to normoxia.[77] Patients with hyperoxic exposure were more likely to have low Glasgow coma scores (3–8) on discharge than those who were normoxic. In the same study, patients with hypoxemia also had worse outcomes compared to those who were normoxic, emphasizing the importance of close and continued monitoring using pulse oximetry.

Finally, in the case of acute myocardial infarction (AMI), controversy exists regarding oxygen therapy. When treating patients with myocardial ischemia who are hypoxemic, oxygen is absolutely indicated, as it can be life-saving. However, when a patient with AMI is not hypoxemic, whether supplemental oxygen is beneficial is unclear.

A double-blind randomized trial conducted in the late 1970s compared oxygen therapy (6 L/min) with no oxygen therapy in 157 patients with uncomplicated AMI.[78] In patients who received oxygen, higher rates of sinus tachycardia and a greater rise in myocardial enzymes were noted, along with no difference in mortality (actually, a trend toward improved mortality was seen in the no-oxygen arm). Several reasons for the potential deleterious effects of hyperoxia in an AMI have been proposed. In healthy humans, hyperoxia has been shown to induce coronary vasoconstriction. Furthermore, in critically ill patients, high-flow oxygen therapy may lead to maldistribution of microcirculatory blood flow, increased functional O_2 shunting, and a reduction in total body oxygen consumption.[79] Although data supporting the use of supplemental oxygen in uncomplicated AMI remain unclear, the practice remains nearly universal.

CONCLUSION

Since its discovery, oxygen has been successfully utilized in medicine, revolutionizing the field in the early half of the 20th century. Supplemental oxygen remains among the most common therapies provided in the inpatient setting. Oxygen therapy may improve oxygen delivery and reverse tissue ischemia. The role of supplemental oxygen in management of outpatients with chronic, severe, pulmonary and cardiac diseases is broad. In the outpatient setting, supplemental oxygen may considerably improve quality of life in those patients willing to adapt to its use. Despite the widespread availability of supplemental oxygen and its relative ease of use, oxygen must be considered a drug with a therapeutic window, above which the potential for significant toxicity exists.

CHAPTER 145

Pulmonary Pharmacotherapy

Karen J. Tietze
Scott Manaker

A wide spectrum of therapeutic agents is currently employed in the treatment of respiratory disorders, including obstructive lung diseases. This chapter reviews the rationale for, and clinical use of, these agents in current clinical practice.

DRUG DELIVERY

Inhaled drug administration is preferred for many medical conditions. Advantages of inhaled drug administration include rapid onset of action and the ability to deliver small drug doses directly to the lungs, minimizing systemic drug exposure. Compressed air nebulizers have been in use for more than 150 years; the first metered-dose inhaler (MDI) became available in the 1950s, followed by the first dry powder inhaler (DPI) in the 1960s.[1] Many new and innovative devices have been marketed as the result of the phase-out of chlorofluorocarbon-containing MDIs.[2]

Device selection depends on drug–device availability, patient characteristics (e.g., age, cognitive function, manual dexterity), and patient preference (Tables 145-1 and 145-2).[3,4] MDIs and nebulizers share universal designs; other drug delivery devices are unique, individually patented devices.

MDIs are small portable devices that protect the medication from contamination; they are difficult to use correctly. Common drug administration errors include improper timing of actuation and inspiration and failure to inspire slowly and deeply. MDI accessory devices (e.g., spacers, valved holding chambers) decrease oropharyngeal drug deposition and reduce the need for precise "press and breathe" timing, but they are bulky, add to the cost of therapy, and must be regularly cleaned to reduce bacterial contamination and electrostatic charges within the chamber. The Respimat device is a unique, multidose liquid inhaler that uses spring-loaded energy to generate a fine aerosol mist.[5]

DPIs are available as premetered devices that contain or accept single doses or as bulk reservoir devices. DPIs are breath actuated, requiring rapid and forcible inhalation to aerosolize and deliver the dose; most require inspiratory flow rates of 30 to 60 L/min. Young children, the elderly, and patients with reduced lung function (e.g., during an acute exacerbation) may be unable to generate adequate inspiratory flow rates.

Nebulizers aerosolize a solution or suspension by one of the three mechanisms: compressed air or oxygen (jet nebulizers), high-frequency ultrasonic energy (ultrasonic nebulizers), and vibrating mesh. Suspensions can only be aerosolized with jet nebulizers. Nebulizers are more expensive, require more dose preparation, and take more time to deliver a dose than other drug delivery devices. However, they require less patient cooperation and may be used by patients of all ages and abilities.

TABLE 145-1 Inhaled Drug–Device Availability

Drug Class	pMDI	BAC MDI	DPI	SMI	Nebulizer
SABA	X	X[a]			X
SAMA	X				X
SABA + SAMA	X[b]			X	X
LABA			X		X
LAMA			X		
ICS	X		X		X

[a]December 31, 2013 was the last date for sale for Maxair (pirbuterol) Autohaler, the only marketed chlorofluorocarbon-containing breath-actuated metered-dose inhaler.
[b]December 31, 2013 was the last date for sale for Combivent (albuterol plus ipratropium bromide), the only marketed chlorofluorocarbon-containing combination SABA + SAMA metered-dose inhaler.

BRONCHODILATORS

Bronchodilation produced by β-Adrenergic agonists, muscarinic antagonists, and methylxanthines is a major component of the pharmacologic management of obstructive airway diseases. Other drugs (e.g., magnesium) have been used clinically for bronchodilation.

β-ADRENERGIC AGONISTS

The β-Adrenergic agonists mimic the actions of norepinephrine at neuroeffector and synaptic junctions. Norepinephrine is the major neurotransmitter in the sympathetic nervous system; therefore, this class of drugs is referred to as *adrenergic agonists* or *sympathomimetics.* The two major types of adrenergic receptors are the α and β receptors; at least two α and three β receptor subtypes have been identified.

β-Adrenoceptor stimulation relaxes smooth muscles via cyclic-3′5′-adenosine monophosphate (cAMP)-dependent and cAMP-independent mechanisms. Adrenergic receptor stimulation catalyzes the conversion of adenosine triphosphate (ATP) to cAMP by activating adenyl cyclase, a cofactor in the production of cAMP. The

TABLE 145-2 Age–Device Guidelines

Device	Age
pMDI	≥5 y
	<5 y, use with spacer or VHC and face mask
DPI	≥4 y
Spacer or VHC	≥4 y
	<4 y, use VHC and face mask
Nebulizer	Infants: SVN with face mask or hood
	≤3 y: SVN with face mask
	≥3 y: SVN with mouthpiece
	≥5 y: breath-actuated nebulizer
	All ages unable to use pMDI with VHC and face mask

pMDI, metered-dose inhaler; DPI, dry powder inhaler; VHC, valved holding chamber; SVN, small volume nebulizer.

increase in cAMP triggers the intracellular events that mediate pulmonary and extrapulmonary responses. β-Adrenoceptor stimulation also activates large-conductance, calcium-activated potassium channels in plasma membranes independent of cAMP.[6]

The β-Adrenergic agonists (Table 145-3) are indicated in the treatment of bronchospasm associated with acute and chronic asthma, bronchitis, emphysema, exercise, and other obstructive pulmonary diseases. Selection of a specific agent and route of administration depends on underlying patient risk factors and the receptor specificity of the drug.

Pharmacology

Adrenergic receptor stimulation produces a wide range of responses, depending on the effector organ and the specific receptor.[7] Although bronchial smooth-muscle relaxation results from β_2-Adrenergic receptor stimulation, none of the currently marketed agonists are completely specific for β_2-Adrenergic receptors. The α-Adrenergic receptor is generally associated with constrictor/contractor responses, including constriction of arteries and veins and contraction of the uterus, radial and sphincter muscles of the iris, urinary bladder, and stomach sphincters. β_1-Adrenergic receptor stimulation increases heart rate, atrial and ventricular contractility, and cardiac conduction velocity. Effects from β_2-Adrenergic receptor stimulation include relaxation of bronchial and uterine smooth muscle, dilatation of arteries and veins, and several metabolic effects, including glycogenolysis, gluconeogenesis, and induction of hepatic pancreatic β-cell secretion.

Structure–Activity Relationships

The parent compound for the adrenergic agonists, phenylethylamine, consists of a benzene ring and an ethylamine side chain. Substituents can be added to the α or β carbons of the ethylamine side chain, the terminal amine group, or one or more of the carbons in the aromatic ring.[8] The addition of hydroxyls at positions 3 and 5 of the aromatic ring (e.g., metaproterenol and terbutaline) promotes oral bioavailability. Large substituents added to the amino group promotes β_2-Adrenergic receptor selectivity and favors a long duration of action (e.g., salmeterol, formoterol, indacaterol, vilanterol).

At least two theories have been proposed to explain the long duration of action of the long-acting and ultra long–acting β_2-Adrenergic agonists (LABAs).[9,10] The *exosite theory* states that a portion of the large side chain on the terminal amine binds to a site separate from, but close to, the β_2-Adrenergic receptor, keeping the active portion of the structure available for binding and rebinding to the β_2-Adrenergic receptor. The *diffusion mucokinetic model* states that the plasma membrane serves as a drug reservoir. However, neither theory fully explains the long duration of action of salmeterol, formoterol, indacaterol, or vilanterol, suggesting additional mechanisms.

Enantiomers

Albuterol and formoterol are 1:1 mixtures of (R)- and (S)-enantiomers. The therapeutic effect of albuterol comes from the (R)-enantiomer; the (R)-enantiomer is marketed separately as levalbuterol. Early in vitro studies suggested that (S)-albuterol might antagonize the effects of (R)-albuterol, but levalbuterol has not been demonstrated to be clinically superior to racemic albuterol.[11] The (R)-formoterol enantiomer, marketed as arformoterol, is 1000-fold more potent in β_2-recetor binding affinity than the (S)-enantiomer.[12] The racemic mixture is marketed as formoterol. Formoterol and arformoterol are equally effective bronchodilators with similar side effect profiles.[13]

Drug Delivery

The β-Adrenergic agonists may be administered systemically or by inhalation; however, not all drugs are marketed in every dosage form (Table 145-1). Systemic dosage forms include oral, subcutaneous, and intravenous preparations. Systemic administration decreases the β_2-Adrenergic receptor selectivity of the drug due to exposure to various metabolic enzymes, including catechol-o-methyl transferase, monoamine oxidase, and sulfatase. These enzymes change the chemical structure of the drug, decreasing the β_2-Adrenergic receptor selectivity.

Inhaled β-Adrenergic agonists are available in several dosage forms, including wet aerosols, aerosols from MDIs, and dry powder forms. Historically, nebulized drug delivery was standard practice for children and for emergency treatment of asthma exacerbations, hospitalized patients, and severely obstructed patients. However, nebulized drug delivery is labor intensive; significant cost savings can be realized, without sacrificing efficacy, by using MDIs coupled with spacer devices.

Clinical Use

The β_2-Adrenergic agonists remain first-line drugs in the treatment of both asthma and chronic obstructive pulmonary disease (COPD).[14,15] In asthma, the short-acting inhaled β_2-Adrenergic agonists are preferred for treating acute symptoms and for preventing exercise-induced bronchospasm. The subcutaneous route of administration is generally reserved for patients unresponsive to frequent, high-dose, inhaled β_2-Adrenergic agonists; uncooperative patients; or patients too severely dyspneic to inhale the dose. Subcutaneous or parenteral administration should not be used in patients with angina or a recent history of myocardial infarction. Oral adrenergic agonists may be appropriate for children too young to cooperate with inhaled drug administration; sustained-release, oral adrenergic agonists decrease nocturnal symptoms, but they are less effective than LABAs.

In COPD, β_2-Adrenergic agonists provide modest symptomatic relief and improvement in pulmonary function. LABAs are standard bronchodilator therapy for patients with moderate and severe COPD. Standard doses of inhaled β_2-Adrenergic agonists appear as effective as inhaled anticholinergic drugs for relief of acute exacerbations of COPD. The value of subcutaneous drugs and high-dose, short-acting bronchodilators in the management of COPD remains indeterminate.

The intensity and duration of response to β_2-Adrenergic agonists is dose and frequency dependent. For patients with asthma, higher doses result in incrementally greater bronchodilation. The dose–response relationships are less well defined for COPD.

The dose–response curve in asthma led to the development of intensive inhaled β_2-Adrenergic agonist drug regimens for the treatment of severe, acute exacerbations. Typically, the nebulized drug is administered every 20 minutes for three to six doses; some patients respond better to continuous nebulized drug delivery. These regimens are generally well tolerated, although cardiac stimulation is common.

The LABAs are add-on agents for patients with moderate or severe asthma when usual doses of inhaled corticosteroids are inadequate and for patients with moderate or severe COPD. The LABAs are also alternate add-on agents for patients with symptoms of nocturnal asthma. The LABAs play no role in the treatment of an acute asthma or COPD exacerbation; all patients should have a short-acting inhaler and should be instructed on how and when to use each type of β_2-Adrenergic agonist.

Tolerance, that is, receptor subsensitivity or tachyphylaxis, is a decreased response to receptor stimulation. Regular use of either short- or long-acting β_2-Adrenergic agonists leads to tolerance of both the nonbronchodilator and bronchodilator effects of the β_2-Adrenergic agonist.[16] Tolerance to the nonbronchodilator effects of the β_2-Adrenergic agonists, including tremor, tachycardia, QT_c prolongation, hypoglycemia, hypokalemia, and vasodilation has been recognized for many years. Tolerance to the bronchodilator effects of the β_2-Adrenergic agonists develop rapidly with quick recovery following discontinuation of the drug.[17] Receptor downregulation likely mediates tolerance to the β_2-Adrenergic agonists.[16]

Safety

The β_2-selective adrenergic agonists produce less cardiovascular toxicity than do the nonselective agents, but β_2-selectivity does not protect from all adverse events. Biochemical abnormalities associated with the β_2-Adrenergic agonists include hyperglycemia, hyperinsulinemia, lipolysis, hypokalemia, hypomagnesemia, and lactic acidosis.[7] These side effects are most pronounced with parenteral and oral drug administration; they are minimal with usual doses of inhaled agents.

β_2-Adrenergic agonists cause dose- and route-dependent hyperglycemia by stimulating glycogenolysis and gluconeogenesis and suppressing glucose clearance.[18] Hyperglycemia may be clinically most important in asthmatic patients with diabetes mellitus or during pregnancy. β_2-Adrenergic agonists increase plasma insulin by directly stimulating pancreatic islet cells; indirect increases occur secondary to the hyperglycemic response. β_2-Adrenergic agonists induce the release of free fatty acids from adipose tissue. Although hyperinsulinemia and high concentrations of free fatty acids have been linked with cardiovascular morbidity and mortality, tolerance minimizes these effects. β_2-Adrenergic receptor stimulation also induces muscle glycogenolysis, increasing lactate production.

The β_2-Adrenergic agonists induce hypokalemia by directly stimulating the uptake of potassium into skeletal muscle cells.[19] β_2-Adrenergic receptor stimulation induces the cellular uptake of magnesium; hypomagnesemia may induce arrhythmias or worsen symptoms of coronary artery disease. Other adverse β_2-Adrenergic agonist effects include (1) an increased baseline tremor by creating an imbalance in fast- and slow-twitch muscle groups; (2) tachycardia by direct chronotropy and through reflex peripheral vasodilatation and decreased venous return; and (3) central nervous symptoms, such as appetite suppression, headache, nausea, and sleep disturbances.[7] The nervousness reported by many patients is probably a response to the peripheral tremors, rather than a result of direct stimulation of the central nervous system.

β-Adrenergic agonist use has increased coincident with the increase in asthma morbidity and mortality in the United States and other countries. The first linkage between β-Adrenergic agonists and asthma mortality was identified during the 1960s when the newly marketed, nonselective β-Adrenergic agonist isoproterenol was associated with an increase in asthma morbidity and mortality in the United Kingdom. More recently, LABA use has been associated with an increased risk of death in patients with asthma.[20,21] The mechanism is unknown, although it may be related to β-receptor downregulation and desensitization. In 2005, the Food and Drug Administration (FDA) began requiring that labeling for all LABAs include a black box warning regarding the increased risk of asthma-related death. In 2010, the FDA released new safe-use requirements for LABAs. The FDA requires that LABAs (1) be used in combination with an asthma controller medication, and only in patients whose asthma is poorly controlled despite controller medications; (2) be used for the shortest duration of time needed to achieve control and then be discontinued, if possible; and (3) that combination inhaled corticosteroid-LABA products be used for children and adolescents.[22] Concurrent corticosteroid use may reduce the risk of death associated with LABAs; FDA-mandated clinical trials designed to answer this question were initiated in 2011.

■ ANTICHOLINERGICS

Atropine, scopolamine, and other naturally occurring antimuscarinic alkaloids from plant extracts have been used for thousands of years to relieve respiratory symptoms in humans with airway diseases. Historically, clinical use of atropine and atropine-like agents has been limited by side effects, including dry mouth and skin, tachycardia, meiosis, and difficulty urinating and mentating. Three synthetic atropine derivatives (ipratropium bromide, tiotropium bromide, and aclidinium bromide), which have more favorable side effect profiles, are available for management of COPD.

Pharmacology

Three of the five known muscarinic receptor subtypes are expressed in the lung (M_1, M_2, and M_3).[23] Activation of airway M_1 and M_3 muscarinic receptors results in bronchial smooth-muscle contraction and mucus secretion. M_2 "autoreceptor" activation decreases acetylcholine (Ach) release; blockade of M_2 receptors increases airway Ach. The ideal anticholinergic drug would selectively block M_1 and M_3 receptors and have no effect on M_2 receptors.

Ipratropium (FDA approved in 1998), tiotropium (FDA approved in 2004), and aclidinium (FDA approved in 2012) are the bromide salts of a different synthetic quaternary ammonium compound. Each does not penetrate the blood–brain barrier, exhibits minimal systemic absorption, and possesses a longer duration of action than atropine; each possesses differing muscarinic receptor binding affinities and receptor–drug complex half-lives.[24]

Ipratropium nonselectively blocks M_1, M_2, and M_3 receptors. Tiotropium has greater muscarinic receptor affinity than ipratropium bromide, but it dissociates rapidly from M_2 receptors, resulting in prolonged M_1- and M_3-drug complex half-lives compared with ipratropium. Aclidinium has a kinetic selectivity for M_3 receptors, with a longer residence time on the receptor than ipratropium or tiotropium.[25]

Ipratropium inhalation produces bronchodilation within 15 minutes, with a peak effect after 1 to 2 hours.[26] Inhalation of tiotropium produces bronchodilation within 30 minutes, with an effect peak after 3 to 4 hours and duration of action for 24 hours.[26] The trough FEV_1 increases after multiple doses, reflecting carryover bronchodilation from the prolonged half-life. Inhalation of aclidinium produces maximal bronchodilation at about 2 hours, with sustained bronchodilation for the 12-hours dosing interval.[27] Tolerance or tachyphylaxis with chronic use has not been reported.

Drug Delivery

Tiotropium bromide and aclidinium bromide are available in the United States as DPIs (HandiHaler™ and Pressair™, respectively). Ipratropium bromide is available in the United States as a HFA MDI, a solution for nebulization, and as a combination product with albuterol in a soft-mist aerosol inhaler (Combivent Respimat™).

Clinical Use

Ipratropium, tiotropium, and aclidinium are most efficacious in patients with COPD, including emphysema and chronic bronchitis, and they are the bronchodilators of choice in the long-term management of moderate-to-severe COPD.[28] In contrast, the role of anticholinergics in the management of asthma has not been established. Compared to the β-Adrenergic agonists, the anticholinergic drugs have a slower onset of action and less effect on lung function.[28] The addition of tiotropium to treatment with inhaled corticosteroids and long-acting β-Adrenergic agonists improves symptoms and lung function and decreases the risk of severe exacerbation in selected patients,[29,30] but these results cannot be generalized to all patients with asthma.

Safety

Consistent with their very low systemic bioavailability, the inhaled anticholinergics are remarkably free of side effects. Transient or mild dry mouth occurs, but it is rarely a reason for halting therapy.[31] Side effects of tiotropium typically appear after 3 to 5 weeks of continued use, reflecting the slow linear tissue accumulation of the drug. Plasma aclidinium is rapidly hydrolyzed to inactive metabolites, reducing systemic exposure to the drug.[32]

The inhaled anticholinergics do not change mucus viscosity or transport, pulmonary hemodynamics, ventilation–perfusion matching, oxyhemoglobin saturation, heart rate, or urinary flow; however, blurred vision and pupillary dilation may occur if any drug inadvertently contacts the eye. All the three drugs should be used with caution in patients with narrow-angle glaucoma, prostatic hyperplasia, or bladder neck obstruction. Ipratropium and tiotropium are renally eliminated; patients with moderate or severe renal insufficiency (Cl_{cr} <30–50 mL/min) should be monitored closely for systemic anticholinergic effects.[33] Less than 0.15% of aclidinium bromide is excreted renally.[34]

Increased mortality in patients with COPD has been reported with long-term (≥30 days) use of tiotropium delivered with the fine-mist Respimat™ inhaler.[35] However, a major recent trial directly comparing tiotropium dry powder and fine-mist inhaler safety revealed no significant differences in either safety or efficacy.[36] Until the risks associated with the fine-mist inhaler are fully described, patients with COPD, patients with hypoxia, cardiac arrhythmias, or ischemic heart disease should use the dry powder form of tiotropium.[37]

Concomitant use of other drugs with anticholinergic properties may increase the risk of side effects with either ipratropium or tiotropium.

METHYLXANTHINES

Methylxanthines have been used to treat pulmonary disease for more than 100 years.[38] General use of methylxanthines became widespread in the 1930s; contemporary use is more limited due to the availability of more effective and safer medications.[39] Theophylline and aminophylline, the ethylenediamine salt of theophylline, are used to treat asthma and COPD. Theophylline may also have a role in therapy of obstructive sleep apnea, apnea of prematurity, and airway obstruction secondary to pulmonary edema.

Pharmacology

Potentially beneficial therapeutic effects of theophylline include bronchial smooth-muscle relaxation, enhanced mucociliary transport, inhibition of mediator release, suppression of permeability edema, decreased pulmonary hypertension, increased right ventricular ejection fraction, improved diaphragmatic contractility, and central stimulation of ventilation.

Methylxanthines have direct bronchodilator and immunomodulatory properties; however, despite having been marketed and studied for decades, the precise molecular mechanism of action is not known. Multiple molecular mechanisms have been proposed, including nonselective phosphodiesterase (PDE) inhibition, nonselective adenosine receptor antagonism (A_1, A_{2A}, $A_{2B,}$ and A_3 receptors), promotion of endogenous catecholamine release, agonist activity at ryanodine receptors, activation of histone deacetylase (HDAC), and induction of peroxisome proliferator-activated receptor gamma (PPAR gamma) expression.[39,40] Nonselective PDE inhibition and adenosine receptor antagonism are the most established of the proposed molecular mechanisms of action.[39]

PDEs hydrolyze cAMP and cyclic guanine monophosphate (cGMP) to inactive 5′ monophosphates; inhibition of PDE increases intracellular concentrations and, therefore, the activity of these secondary messengers, resulting in airway smooth-muscle relaxation and bronchodilation. However, methylxanthine PDE inhibition is concentration dependent, with minimum inhibition seen at clinically relevant serum concentrations.[41] Adenosine is a nucleoside signaling molecule. Adenosine receptor antagonism regulates airway smooth muscle, blocks adenosine-induced mast cell degranulation, and activates HDAC enzymatic activity, inhibiting transcription of proinflammatory cytokines. These anti-inflammatory and immunomodulatory effects are observed at clinically achievable serum drug concentrations.

The anti-inflammatory effect of methylxanthines appears to be qualitatively different than that of corticosteroids. Corticosteroids induce HDAC gene transcription; methylxanthines induce HDAC activity. The combination of corticosteroids and methylxanthines may be synergistic.

Structure–Activity Relationships

Theophylline and aminophylline are 1,3-dimethylxanthines. Other methylxanthines, including theobromine (3,7-dimethylxanthine) and caffeine (1,3,7-trimethylxanthine), differ in the positions of the methyl substituents on the xanthine molecule. Dyphylline is 7-(2,3-dihydroxypropyl)-theophylline. N-1 substituents are important for adenosine antagonism, whereas N-3 substituents augment bronchodilator activity. Substituents at N-7 decrease bronchodilator potency; substituents at N-9 decrease the potency of the xanthine.

Drug Delivery

Three methylxanthines are available in the United States: theophylline, aminophylline, and dyphylline. Dosage forms for theophylline include extended-release tablets and capsules, oral solution, oral elixir, and intravenous solution. Aminophylline, the ethylenediamine salt of theophylline, is only available as an intravenous solution. Dyphylline is available as immediate-release tablets.

Clinical Use

Methylxanthines are FDA approved for the treatment of reversible airway obstruction associated with chronic asthma or other chronic lung disease. Concerns regarding the relative efficacy and safety of the methylxanthines in comparison to other bronchodilators and long-term control medications have relegated methylxanthines to alternative therapy status for both asthma and COPD.

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines recommend oral theophylline as an alternative maintenance treatment choice for all patients with COPD or as combination therapy with any first- or second-line treatment.[15] Intravenous theophylline or aminophylline are second-line choices for treatment of exacerbations of COPD.[15] The current Global Initiative for Asthma guidelines recommend theophylline as an add-on controller medication for patients inadequately controlled on inhaled glucocorticoids alone.[42] The current National Asthma Education and Prevention Program (NAEPP) guidelines recommend theophylline as an alternate medication for patients with mild persistent asthma, or as an alternate adjunctive therapy in combination with inhaled corticosteroids.[14] The NAEPP guidelines do not recommended theophylline for the treatment of acute asthma exacerbations.[14]

In summary, relatively noncontroversial indications for methylxanthines include severe bronchodilator-dependent COPD; severe, systemic, corticosteroid-dependent asthma; nocturnal asthma uncontrolled with adrenergic agonists; and acute, severe asthma progressing to respiratory failure.

The previously accepted therapeutic range for theophylline (10–20 mg/L) was based on early dose–bronchodilator response studies[43] and is no longer considered state of the art.[44] The current NAEPP asthma guidelines recommend a lower target therapeutic range for theophylline (5–15 mg/L).[14] The rationale for lowering the target serum theophylline range includes improved understanding of the dose–bronchodilator response and recognition of the greater risk of adverse drug reactions at serum theophylline concentrations greater than 15 mg/L.[45] The immunomodulatory effects of theophylline occur at lower serum concentrations (1–5 mg/L).[46,47]

Safety

Adverse effects of methylxanthines are generally attributed to PDE inhibition (nausea, vomiting, diarrhea, headache) and adenosine receptor antagonism (cardiac arrhythmias and seizures).[47] Other adverse effects include irritability and insomnia. The caffeine-like adverse effects (nausea, vomiting, diarrhea, nervousness, insomnia, headache) are generally associated with serum theophylline concentrations greater than 15 mg/L.[45] The more life-threatening adverse effects (ventricular arrhythmias and seizures) are generally associated with serum theophylline concentrations greater than 40 mg/L, although these adverse effects may occur at much lower serum concentrations.[45]

Theophylline is metabolized primarily by cytochrome P450 (CYP1A2) enzymes, making it susceptible to numerous drug–disease and drug–drug interactions. Medical conditions that directly impair hepatic function (e.g., cirrhosis, viral hepatitis), cause passive hepatic congestion (e.g., congestive heart failure, cor pulmonale), or induce interferon (e.g., acute viral illness or pneumonia) increase the serum theophylline concentrations.[45]

Hyperthyroidism and cystic fibrosis decrease serum theophylline concentrations by unknown mechanisms. Polycyclic aromatic hydrocarbons in tobacco smoke, and medications, such as rifampin, phenytoin, antivirals, and barbiturates, induce cytochrome P450 enzymes, reducing serum theophylline concentrations. Macrolide and quinolone antibacterials, fluvoxamine, fluconazole, ketoconazole, and cimetidine inhibit cytochrome P450 enzymes, increasing serum theophylline concentrations. Given the narrow therapeutic window, multitude of drug and disease interactions, and wide interpatient variability, it is important to routinely monitor serum theophylline concentrations. The mid-dosing interval serum concentration should be assessed 3 to 5 days after initiating theophylline or modifying the dose and any time theophylline toxicity is suspected.[14]

■ OTHER BRONCHODILATORS

Ancillary drugs sometimes used as bronchodilators include magnesium sulfate and inhaled diuretics.

Magnesium Sulfate

The bronchodilatory mechanism of action of magnesium has not been definitively identified. Several actions have been proposed, including decreasing smooth-muscle intracellular calcium, T-cell stabilization, inhibition of mast cell degranulation and Ach release, and stimulation of nitric oxide and prostacyclin synthesis.[48]

Several systematic reviews of trials of inhaled and intravenous magnesium sulfate in the management of adults and children presenting to emergency departments with severe acute exacerbations of asthma have been published.[48–50] In general, patients with severe exacerbations demonstrate small improvements in pulmonary function following administration of inhaled or intravenous magnesium sulfate. Potential adverse effects include hypotension with rapid infusion, muscle weakness, respiratory depression, and cardiac conduction abnormalities. Despite these limited clinical data, the Global Initiative for Asthma recommends consideration of intravenous magnesium sulfate therapy for acute severe asthma in selected patients (adults with an FEV_1 25%–30% of predicted at presentation, adults and children who do not respond to initial treatment, and children in whom the FEV_1 remains <60% of predicted after 1 hour of standard treatment).[42]

Inhaled Diuretics

Inhaled diuretics (e.g., furosemide) may act upon the airways through a variety of mechanisms to achieve bronchodilation, reduce mucosal inflammation, or interrupt sensory nerve reflex responses to irritants.[51] Data regarding the clinical efficacy of inhaled diuretics in the treatment of acute and chronic asthma are limited. Additional information from well-designed clinical trials is needed before use of inhaled diuretics can be recommended for the treatment of acute exacerbations or chronic management of asthma.

ANTI-INFLAMMATORY AGENTS

Corticosteroids are the mainstay of current anti-inflammatory regimens; other agents in clinical use include mast cell stabilizers, leukotriene receptor antagonists, and leukotriene formation inhibitors.

■ CORTICOSTEROIDS

Corticosteroids are cortisol-like drugs that influence metabolic pathways and have an anti-inflammatory effect. By reducing airway inflammation, corticosteroids have long been known to be useful in the management of asthma; their role in the management of COPD has been increasingly recognized.

Pharmacology

Cortisol is produced by the adrenal cortex and regulated via the hypothalamic–pituitary axis in response to physical and emotional

distress. Although the usual daily secretion of cortisol is approximately 10 mg/m^2/d,[52] up to 500 mg/d can be secreted during periods of severe stress.[53] Corticosteroids stimulate and inhibit DNA transcription in cells with glucocorticoid receptors, which are widespread throughout the body.

Glucocorticoids diffuse across cellular membranes to bind inactive glucocorticoid cytoplasmic receptors; these activated glucocorticoid-receptor complexes translocate to the nucleus and bind to specific glucocorticoid response elements of the gene, influencing gene transcription. Increased gene transcription increases expression of β_2-Adrenergic receptors, increases the production of anti-inflammatory mediators, and decreases the production of inflammatory mediators.[54] The clinical effects of glucocorticosteroids are delayed for several hours following administration, reflecting the time needed to influence gene transcription. In the airways, glucocorticosteroids increase the number and responsiveness of β_2-Adrenergic receptors, decrease mucus production, decrease bronchial hyperresponsiveness, decrease the number of mucosal mast cells, enhance eosinophil apoptosis, and decrease airway edema.[55] Glucocorticosteroids are inactivated by hepatic metabolism, with a clearance rate approximately the same as liver blood flow; beclomethasone dipropionate and ciclesonide and their metabolites are also inactivated by blood esterases.

The inhaled glucocorticoids (beclomethasone dipropionate, budesonide, ciclesonide, flunisolide, fluticasone propionate, mometasone furoate) have different physicochemical properties (potency, receptor-binding affinity, protein binding, lipophilicity, oral bioavailability, pulmonary bioavailability, systemic clearance, volume of distribution, and half-life).[56,57] Physicochemical properties that enhance inhaled glucocorticosteroid efficacy include high receptor-binding affinity, high pulmonary bioavailability, and long pulmonary retention time. Physicochemical properties that enhance safety include low oropharyngeal deposition, high protein binding, rapid systemic clearance, and conversion of inactive prodrug to active drug in the lungs. Since inhaled glucocorticosteroids are marketed and prescribed in relatively equipotent doses, potency is not an important differentiating characteristic as other physicochemical characteristics.

Data regarding the relative clinical benefits of inhaled corticosteroids with different physicochemical characteristics are limited. However, physicochemical characteristics may influence drug safety. For example, oropharyngeal side effects (dysphonia, oral candidiasis) may be minimized by using drug delivery systems that generate a greater proportion of small particles (<5 μm)[58] and with administration of prodrugs that are converted in the lungs to the active drug. DPI particle size depends on the specific device and the patient-generated inhalation flow rate; hydrofluoroalkane MDIs tend to generate a greater proportion of smaller particles. Beclomethasone 17,21-dipropionate is hydrolyzed in the lungs to the more active drug, beclomethasone 17-monopropionate. Ciclesonide is hydrolyzed in the lungs from the inactive parent drug to the active drug, desiosbutyryl-cilcesonide.

The risk of systemic adverse effects may be minimized by using inhaled corticosteroids with low systemic bioavailability, high protein binding, rapid systemic clearance, and increased pulmonary residence time. Ciclesonide, fluticasone, and mometasone undergo rapid first pass hepatic metabolism, resulting in very low (<1%) oral bioavailability. Ciclesonide and mometasone are highly protein bound (99%). Drugs with a higher lipophilicity and drugs that undergo lipid conjugation have a longer pulmonary residence time. Mometasone furoate and fluticasone propionate, with an esterified lipophilic group at the 17-α position, are the most lipophilic of the marketed inhaled corticosteroids; beclomethasone dipropionate, budesonide, triamcinolone acetonide, and flunisolide follow in descending order of lipophilicity.

Clinical Use

Corticosteroids are the cornerstone of therapy in the treatment of asthma. The role of glucocorticoid therapy in COPD is more limited.

Asthma The role of airway inflammation in asthma is well established, and high-dose systemic (parenteral or oral) corticosteroids are standard therapy for patients experiencing severe acute exacerbations of asthma.[14,42] Parenteral administration of corticosteroids is often used preferentially due to the inability of some patients to swallow medications while in respiratory distress or because of lack of oral access after intubation. The time to initial response, as evidenced by augmentation of FEV_1 with bronchodilator administration, begins as early as 1 hour after corticosteroid administration; maximal response is achieved in 8 to 12 hours. Parenteral methylprednisolone is the corticosteroid of choice, due to its lower mineralocorticoid and greater glucocorticoid effects than hydrocortisone.

The combination of an inhaled corticosteroid and a long-acting bronchodilator is better than either agent alone at improving lung function and preventing asthma exacerbations; in patients with moderate-to-severe asthma, such a combination of low-dose inhaled corticosteroid with a LABA appears equieffective as high-dose inhaled corticosteroid alone.[14] Given the concerns regarding the safety of LABAs (see above) as monotherapy in asthma,[20] the FDA recommends that an inhaled corticosteroid always accompany a LABA in asthma therapy.[22]

Beclomethasone dipropionate, budesonide, ciclesonide, flunisolide, and fluticasone propionate are FDA approved for twice-daily administration; only mometasone furoate is FDA approved for once-daily administration. Poor adherence with inhaled corticosteroid regimens is an ongoing issue. Although data are limited, patients with stable, mild persistent asthma might benefit from once-daily inhaled corticosteroids.[14] Twice-daily dosage regimens are more effective for patients with moderate persistent or severe persistent asthma.[14]

Chronic Obstructive Pulmonary Disease The mechanism underlying the beneficial effects of corticosteroids in COPD is not fully known, but changes in inflammatory gene transcription and modulation of β_2-Adrenergic receptor function appear to play a role. For patients with COPD with an FEV_1 <60% (GOLD grades C and D), treatment with inhaled corticosteroids improves quality of life and lung function, decreases exacerbation frequency, but does not alter long-term FEV_1 decline or improve survival.[15] Short courses (5–15 days) of moderate doses (40 mg/d of prednisone) of systemic corticosteroids in combination with standard bronchodilator therapies are effective for treating acute exacerbations of COPD in outpatients, inpatients, and patients in the emergency room who have moderate or severe COPD.[59] However, the role of systemic corticosteroids in the treatment of patients with COPD who are receiving mechanical ventilation is unknown. Definitive data regarding the clinical usefulness of combining inhaled corticosteroids and long-acting bronchodilators are lacking.[15]

Safety

Short-term use (less than 14 days) of systemic corticosteroids is associated with mild glucose intolerance, fluid retention that may progress to edema and hypertension, proximal muscle weakness (especially with large parenteral doses), and mood alteration. Long-term systemic corticosteroids prolong the short-term effects; in addition, peptic ulcer disease, cataracts, increased risk of infection, and impaired wound healing occur. Truncal obesity, hirsutism, acne, moon-shaped facies, striae, and ecchymoses contribute to a cushingoid appearance. Disruption of bone metabolism predisposes patients to osteoporosis and resultant vertebral and long-bone fractures; inhibition of long-bone growth is the major complication

in children receiving systemic corticosteroids. Suppression of the hypothalamic–pituitary–adrenal axis diminishes body cortisol stores, reducing the response to stresses such as trauma, surgery, or infection.

Inhaled corticosteroids are less systemically bioavailable due to poor absorption from the tracheobronchial tree. The most common adverse effect is local irritation of the oropharynx, cough, and bronchospasm. Dysphonia may arise from vocal cord myopathy induced by the corticosteroid, and oral candidiasis (thrush) may occur secondary to suppression of normal oral flora. The risk of dysphonia and thrush are reduced by rinsing the mouth, gargling, and spitting out the rinse water after each use of a corticosteroid inhaler; using a spacer device to decrease deposition of drug particles in the mouth; and keeping the inhaler mouthpiece clean. Limited data suggest inhaled corticosteroids increase the risk of pneumonia in patients with COPD,[60] but not asthma.[61]

Depending on the bioavailability, dose, and duration of use, inhaled corticosteroids may be associated with the systemic adverse effects typically associated with oral corticosteroids, including adrenal suppression, particularly in children. Inhaled corticosteroids slow bone growth velocity in prepubertal children and reduce ultimate adult height[62]; they also increase the risk of bone fracture, with each 500 μg increase in beclomethasone equivalency yielding a 9% increase in fracture risk.[63]

Steroid Resistance

Patients with asthma unresponsive to usually sufficient doses of corticosteroids are described as *steroid resistant.* Varying definitions of steroid resistance exist, such as a <15% increase in FEV_1 after either oral prednisolone administered for 7 days at a dose of 20 mg daily, or 14 days at a dose of 15 mg daily; or a 2-week trial of 40 mg/d prednisone in bronchodilator-responsive asthmatics.[64,65] Steroid resistance must be distinguished from steroid dependency, which is usually defined as the need for systemic corticosteroids to maintain control of asthma.

Steroid resistance may involve reduced metabolism of oral corticosteroids to the active compound or accelerated drug clearance. An impaired cellular response to corticosteroids has been observed in steroid-resistant asthmatics, and altered receptor binding or the presence of anti-lipocortin antibodies may contribute to the phenomenon.

■ CORTICOSTEROID-SPARING AGENTS

Chronic systemic corticosteroid therapy required for the treatment of severe airflow obstruction often results in numerous side effects. Therefore, many anti-inflammatory agents have been evaluated in an effort to identify alternatives to systemic corticosteroid therapy.[66,67] However, wide variability exists between studies in their assurances of proper inhaler technique, dose and frequency of baseline inhaler regimens, and minimization of exposure to known antigens. In addition, most studies did not systematically evaluate and exclude (or otherwise control for) the concomitant presence of disorders known to mimic or exacerbate asthma, including vocal cord dysfunction, gastroesophageal reflux, and rhinosinusitis. These methodological considerations further restrict the limited conclusions to be drawn from these studies.

Methotrexate

From initial observations in patients with rheumatoid arthritis and coexistent asthma, methotrexate therapy appeared to ameliorate both asthmatic and arthritic symptoms. A small number of older studies offer no clear documentation of the clinical efficacy of methotrexate administration in severe, steroid-dependent asthma. Several more recent meta-analyses suggest a small benefit may exist, but use is associated with a significant risk of toxicity. Due to significant side effects, potentially fatal complications, and long-term toxicity concerns, prudency argues for limiting methotrexate administration in severe, steroid-dependent asthmatics to empiric trials in individual patients or investigations in large-scale, controlled clinical trials.

Cyclosporine

Used widely in organ transplantation, cyclosporine inhibits lymphokine synthesis, thereby blocking the activation of T cells. The absence of significant drug interactions with β-Adrenergic agonists, corticosteroids, or theophylline makes cyclosporine particularly attractive as an anti-inflammatory agent for use in asthma. However, only one of the three small, double-blind, placebo-controlled studies suggested that cyclosporine increased peak expiratory flow and FEV_1, reduced exacerbations of airway obstruction, or reduced oral prednisolone dosage by over 60%. Hypertrichosis, hypertension, reversible nephrotoxicity, and a large number of nonspecific side effects limit widespread use of cyclosporine in the management of asthma.

Other Agents

The search continues for anti-inflammatory agents with potential efficacy in asthma. Historically, a broad spectrum of agents have been touted, including gold salts, pooled immunoglobulins, azathioprine, colchicine, dapsone, hydroxychloroquine, ketotifen, nonsteroidal anti-inflammatory agents, inhaled heparin, and anti-tumor necrosis factor agents (both etanercept and infliximab). The original studies purporting the efficacy of these various agents comprise mainly anecdotal reports, small case series, or early phase studies demonstrating little clinical efficacy. Use of these drugs in obstructive airway disease should be restricted to well-designed, controlled clinical trials.

Antibiotic Macrolides

Recently, the role of macrolide antibiotics as anti-inflammatory agents has been recognized and their potential utility in management of a number of pulmonary disorders examined.

Pharmacology

Erythromycin comprises a 14-membered lactone ring, with two attached sugars (cladinose and desosamine). As the first macrolide antibiotic discovered, erythromycin has served as the base compound for this class of drugs.[68,69] Azithromycin (9-deoxo-9 a-aza-9 a-methyl-9 a-homoerythromycin) is formed by substituting a methyl-substituted nitrogen for the position 9a carbonyl group of the aglycone ring, producing an azalide. Substituting a methoxy group for the C-6 hydroxyl group of erythromycin creates clarithromycin (6-O-methylerythromycin). Compared with erythromycin, both of these macrolide derivatives have superior pharmacokinetic and pharmacodynamic properties, including a longer serum half-life, increased tissue penetration and persistence, oral bioavailability, and greater gram-negative antibacterial activity. Tissue concentrations of clarithromycin and azithromycin can exceed serum concentrations by 100-fold.

In the liver, cytochrome P450 3A4 (CYP3A4) metabolizes clarithromycin to an active 14-hydroxy form and six additional products. Clarithromycin and its metabolites are mostly excreted in the bile. However, since about one-third is excreted in the urine, doses should be reduced in patients with creatinine clearances <30 mL/min. In contrast, with hepatic impairment and normal renal function, the consequent reduced metabolism of clarithromycin to the active 14-hydroxy form allows for increased renal excretion of native clarithromycin and obviates dosing modifications. Since azithromycin elimination occurs primarily in the feces as the unchanged drug, with minimal urinary excretion, dosing modifications are unnecessary in renal or hepatic dysfunction.

Traditionally, antibiotic macrolides are prescribed for infections from a variety of gram-positive bacteria (β-hemolytic streptococci, pneumococci, staphylococci, enterococci), *Haemophilus influenzae*, *Legionella pneumophila*, mycoplasma, mycobacteria, chlamydia and some rickettsias. Macrolides rarely cause allergic reactions, and, therefore, are a common alternative for penicillin-allergic patients.

Macrolides reversibly bind to ribosomes, where they inhibit protein synthesis in several ways.[68,69] They block peptidyl transferase from adding the peptidyl attached to transfer-RNA to the next amino acid, analogous to the activity of chloramphenicol. Macrolides accelerate dissociation of peptidyl-transfer-RNA from ribosomes and also inhibit ribosomal translocation. Since macrolides accumulate within cells, in addition to their antibacterial actions, they can exert numerous anti-inflammatory effects within the respiratory tract, including increasing mucus clearance, inhibiting neutrophil recruitment and activation, promoting neutrophil apoptosis, and decreasing the production of reactive oxygen species and elaboration of cytokines, including interleukins (IL-4, IL-5, IL-8, IL-13) and chemokines (C-X-C motif ligand 2 [CXCL2], and ligand 2 [CCL2], 3 [CCL3] and 4 [CCL4]). These anti-inflammatory actions are believed to mediate the efficacy of macrolides in controlling exacerbations of underlying respiratory diseases.

Clinical Use

Since the first clinical use of erythromycin as an anti-infective agent in the 1950s, over the past decade a new role has emerged for macrolide antibiotics as anti-inflammatory agents, mainly in treatment of chronic suppurative respiratory disorders. In randomized, double-blind, placebo-controlled trials in adults with either noncystic fibrosis bronchiectasis or COPD, azithromycin (250 mg daily) or erythromycin (400 mg twice daily in bronchiectasis, 250 mg twice daily in COPD) reduced clinical exacerbations and yielded modest improvements in FEV_1 and quality of life.[70–72]

Retrospective analysis of the Acute Respiratory Distress Syndrome Network dataset revealed increased survival and decreased time to successful discontinuation of mechanical ventilation associated with use of a macrolide early in the clinical course of respiratory failure.[73] However, no randomized trials have expressly tested the efficacy of macrolides in acute lung injury. Azithromycin effectively reduces exacerbations and improves FEV_1 in children with cystic fibrosis,[74] although this effect is attributed to anti-pseudomonal, rather than anti-inflammatory, effects.[75] Macrolides have not been proved effective in infants with viral bronchiolitis.[76,77]

Safety

Since larger macrolide doses produce higher serum concentrations, the incidence of adverse effects increases with increasing doses. Most common are gastrointestinal side effects, specifically abdominal pain and diarrhea, which are usually tolerable. These side effects appear to represent luminal phenomena, while auditory side effects have been attributed to tissue accumulation. Nonetheless, drug-induced, bilateral, sensorineural hearing loss accentuated at the lower frequencies is usually transient and reverses with discontinuation of the macrolide.

Most clinical trials of chronic macrolide therapy that address resistance demonstrate emergence of macrolide-resistant flora. Hepatotoxicity may occur, as manifested by an increase in liver enzymes or cholestasis—findings that should prompt immediate discontinuation of chronic macrolide therapy.

All macrolides may prolong the QT interval, primarily by blocking the outward delayed rectifier potassium channel encoded by the HERG gene. Indirectly, macrolides may also prolong the QT interval by inhibiting the metabolism of other arrhythmogenic drugs metabolized by CYP3A4. The increase in sudden cardiac death associated with erythromycin administration has led to a marked reduction in use of this drug, particularly in the elderly and patients with heart failure. Electrocardiograms to monitor QT prolongation should be considered during chronic macrolide administration.

Clarithromycin, when oxidized by CYP3A4, forms an inactive metabolite/enzyme complex. Clarithromycin is less potent than erythromycin at inhibiting CYP3A4, and azithromycin minimally inhibits CYP3A4. Therefore, dose reductions, clinical assessments, and therapeutic drug level monitoring (when practicable) are necessary with simultaneous administration of drugs metabolized by the CYP3A4, particularly with clarithromycin or erythromycin therapy. The concurrent use of cisapride, pimozide, terfenadine, and astemizole with clarithromycin or erythromycin is contraindicated because of QT prolongation and reported cases of torsades de pointes. Simultaneous therapy with clarithromycin and ergot compounds risks acute ergot toxicity. Numerous other medications metabolized by CYP3A4 (e.g., benzodiazepines, statins, class 1A antiarrhythmic agents, theophylline, carbamazepine, warfarin, sildenafil, colchicine, and cyclosporine) should be used cautiously when given with clarithromycin. Furthermore, although these drug–drug interactions are less likely to occur with azithromycin because of less efficacious inhibition of CYP3A4, high doses may, nonetheless, produce clinically significant side effects. Similarly, respiratory patients with hepatic dysfunction, concurrent congestive heart failure, or cor pulmonale may require dose adjustments. Finally, combination of macrolides with statins has been linked to rhabdomyolysis.[69]

Troleandomycin

Since the 1960s, anecdotal clinical observations suggested that the macrolide antibiotic, troleandomycin, might reduce corticosteroid requirements in patients with severe asthma by decreasing steroid metabolism. However, results from double-blind, randomized trials were mixed, and the weight of evidence suggests that troleandomycin has no clinical effect at relieving airway obstruction or inflammation independent of its effects on corticosteroid metabolism. Troleandomycin has no role in the current therapy of severe, steroid-dependent asthma.

MAST CELL STABILIZERS

Cromolyn sodium and nedocromil exert anti-inflammatory actions by stabilizing mast cells. This blockade of mast cell degranulation prevents inflammatory mediator release, which is partially responsible for the bronchoconstriction and epithelial injury that are characteristic of asthma. However, these agents remain inferior to inhaled steroids for controlling asthma.[78] In addition, limited commercial availability of these agents hampers current usage, largely supplanted by the oral leukotriene formation inhibitors and receptor antagonists.

Cromolyn Sodium

Cromolyn sodium was the first mast cell stabilizer to be approved for clinical use in asthma and remains in use as a nebulized agent in pediatric asthmatics. MDI formulations are no longer available in the United States and Canada.

Pharmacology Cromolyn sodium potently inhibits inflammatory responses. Cromolyn sodium diminishes early phase reactions in asthma by blocking the release of intracellular calcium and inhibiting enzymes responsible for mast cell degranulation; cromolyn reduces late phase reactions in asthma by inhibiting production of the enzymes necessary for superoxide generation. Cromolyn sodium may also exhibit tachykinin antagonism, accounting for some of its anti-inflammatory properties. In vitro, cromolyn sodium potentially inhibits the activation of inflammatory cells, antibody-induced granulocyte cytotoxicity, IgE production by atopic cells, and monocyte IgG production.

Clinical Use Nebulized cromolyn sodium (20-mg dose) is a second-line agent for the management of asthma in children aged 2 to 5 years of age.[14] Cromolyn sodium, alone, or in combination with β_2-Adrenergic agonists, reportedly improved exercise tolerance, enhanced sleep quality, and reduced asthma exacerbations. Cromolyn sodium prophylaxes against exercise-induced asthma in children, although less efficaciously than β_2-agonists alone.

Safety Cromolyn sodium causes few adverse effects, even after long-term use. Although the efficacy of cromolyn sodium in preventing childhood asthma symptoms remains unclear,[78] its safety record leads to continued use as a second-line agent, in conjunction with β_2-Adrenergic agonists, in management of asthma in children.

Nedocromil

Nedocromil also stabilizes mast cells in the bronchial mucosa, but with a broader anti-inflammatory spectrum than cromolyn sodium. Although useful as prophylaxis against asthma exacerbations, nedocromil is not therapeutically efficacious for acute bronchospasm and is currently available only as a DPI in a small number of countries.

■ ANTILEUKOTRIENE AGENTS

Leukotrienes are synthesized from arachidonic acid, a fatty acid stored in phospholipids of cell walls. Numerous stimuli, including IgE receptor activation, antigen–antibody interactions, and activation of phospholipase A_2 induce release of arachidonic acid from phospholipids. Arachidonic acid is converted to a variety of products via several unrelated pathways; the 5-lipoxygenase (5-LO) pathway is the pathway of importance in asthma. Leukotriene A_4 (LTA_4) is metabolized by two different pathways to either the nonpeptide LTB_4 or the cysteinyl leukotrienes (LTC_4, LTD_4, and LTE_4). LTB_4 recruits and activates inflammatory cells but has no effect on bronchial tone or reactivity. The cysteinyl leukotrienes stimulate smooth-muscle contraction, increase vascular permeability, and enhance bronchial hyperresponsiveness; thus, they have a role in the pathogenesis of asthma.

Leukotriene action may be inhibited by either selective receptor blockade or interference with synthesis. Most clinical experience has been with the LTD_4 receptor antagonists, since LTC_4, LTD_4, and LTE_4 interact with a common LTD_4 receptor. Inhibition of 5-LO reduces the generation of all leukotrienes.

Clinical Use

Two LTD4 receptor antagonists (montelukast and zafirlukast) and one 5-LO inhibitor (zileuton) are FDA approved and marketed in the United States. The receptor antagonist pranlukast is available only in Japan; zafirlukast is unavailable in Europe. The antileukotriene agents are alternate anti-inflammatory medications for long-term use in children and adults with mild or moderate asthma, including aspirin- or exercise-induced asthma and asthma associated with concomitant allergic rhinitis.[14] Montelukast is FDA approved for children beginning at age 2 years; zafirlukast for children beginning at age 6 years; and zileuton for teenagers beginning at age 12 years and adults. Although less effective than inhaled steroids or LABAs at improving asthma control, antileukotriene agents have fewer side effects and can provide incremental clinical benefit through bronchodilation and symptom reduction.[79,80] Acute administration of antileukotriene agents has no role in the management of acute asthma exacerbations.[81] Antileukotriene agents have modest salutary effects on airway obstruction, symptoms, and quality of life in patients with COPD,[82] but administration of zileuton does not reduce length of stay in acute exacerbations of COPD.[83]

Safety

Montelukast and zafirlukast are well tolerated. Montelukast chewable tablets contain phenylalanine and, therefore, are contraindicated in patients with phenylketonuria. The leukotriene receptor antagonists have numerous drug interactions.

Hepatotoxicity has been reported with zileuton, which is contraindicated in patients with active liver disease and in patients with serum transaminase levels exceeding three times the upper limit of normal. Baseline liver function tests should be obtained prior to initiating therapy with zileuton, and patients should be monitored closely for the duration of therapy. Zileuton must be discontinued if serum transaminase levels exceed five times the upper limit of normal.

■ IMMUNOGLOBULIN E ANTIBODY

Administration of antibodies directed against immunoglobulin E (IgE) has a role in management of pulmonary disorders with an allergic basis.

Pharmacology

Omalizumab is a recombinant humanized antibody developed for therapy of allergic diseases that has significant efficacy in severe atopic asthmatics.[84] By specifically binding with high affinity to free IgE, but not to other immunoglobulins, omalizumab does not activate mast cells or basophils. Clinical efficacy depends upon near total elimination of circulating IgE; therefore, the role of omalizumab is limited to those asthmatics with elevated serum IgE levels. Subcutaneous administration of omalizumab produces rapid binding of circulating IgE, with serum levels slowly rebounding over the subsequent 4 to 6 weeks.

Randomized, double-blind, placebo-controlled studies of omalizumab have been completed in patients more than 12 years of age who have moderate or severe atopic asthma refractory to high-dose inhaled corticosteroids alone. Studies have also been conducted in patients with severe asthma ages 6 to 12 years and >12 years who were also receiving inhaled, long-acting β-agonists and oral leukotriene antagonists. Use of omalizumab reproducibly decreased the frequency of asthmatic flares, reduced inhaled and oral steroid dosage, and improved quality of life scores.

Clinical Use

Omalizumab therapy is indicated for moderate or severe asthmatics who have serum IgE levels exceeding 30 IU/mL (75 ng/mL) and an allergic basis for their asthma, as demonstrated by positive skin testing or radioallergosorbent tests (RAST) to common antigens.[84] Although several early trials demonstrated efficacy of omalizumab when added to monotherapy with inhaled corticosteroids alone, current guidelines recommend addition of omalizumab to combined therapy using both inhaled corticosteroids and inhaled, long-acting β-agonists.[14] As a chronic therapy, omalizumab treatment should not be initiated in the setting of an acute asthma flare. Subcutaneous administration of omalizumab every 2 to 4 weeks is required to maintain reductions in circulating IgE, with the required dose and frequency dependent upon body weight and initial serum IgE level. Up to three separate subcutaneous injections, each not exceeding 150 mg at a single site, may be required at each administration. When pretreatment serum IgE levels exceed 300 IU/mL, omalizumab should not be administered to patients whose body weight exceeds 90 kg; with high pretreatment serum IgE levels, for example, levels approaching 700 IU/mL, omalizumab should not be administered, even to individuals of normal weight. Subsequent serum IgE measurements are unnecessary, as levels plummet to negligible levels and slowly rebound after each administration of the drug.

The total duration of necessary therapy is unclear, although a review every 6 to 12 months is commonly employed to assess whether improved asthma control has been achieved (as indicated by reduced inhaled and oral steroid usage, fewer emergency medical

encounters and hospitalizations, and decreased overall medical costs).[85] Because of high acquisition costs, the cost effectiveness of omalizumab remains controversial.[86,87]

Safety

Minor local skin reactions at the injection sites occur in almost one-half of patients. A diffuse urticarial rash has been reported, but it is extremely uncommon. Severe hypersensitivity reactions, including anaphylaxis, are rarely observed (rate of 1–2 per 1000 patients receiving omalizumab). Therefore, close observation, including frequent assessment of vital signs, is recommended for at least 2 hours following initial drug administration; similar monitoring is warranted for at least 1 hour following each subsequent administration.[88] Omalizumab should not be self-administered.

NOVEL ANTI-INTERLEUKIN AGENTS

Recognition of the role of interleukins in mediating inflammation has led to development of a variety of anti-interleukin agents, discussed subsequently.

■ MEPOLIZUMAB

Mepolizumab is a humanized, mouse monoclonal antibody directed against human IL-5. Intermittent intravenous of the agent reduces peripheral blood and sputum eosinophil counts.

Pharmacology

Eosinophils play a role in the development of diverse inflammatory responses and have long been thought to play a pathogenetic role in the inflammation of asthma. Eosinophils migrate from the bloodstream to sites of inflammation, including the tracheobronchial epithelium, where they participate in antigen presentation and release of other inflammatory cytokines, as well as disgorge their own cytotoxic granules. Although IL-3 and GM-CSF have important stimulatory effects upon eosinophils, IL-5 is the most specific stimulant of eosinophil growth and activity, mediated through the IL-5 receptor complex expressed on the surface of eosinophils.

Clinical Use

Monoclonal antibodies directed against IL-5 failed to demonstrate efficacy in three clinical trials performed in patients with asthma, in contrast to their clear effectiveness in patients with hypereosinophilic syndromes.[89] However, in a small, double-blind, placebo-controlled trial in asthmatics with persistent sputum eosinophilia despite oral prednisone therapy, patients receiving monthly infusions of mepolizumab (750 mg) achieved significant reductions in their prednisone dose.[90] In contrast, patients receiving placebo experienced a significant number of asthma exacerbations following prednisone tapering. Accompanying significant reductions in sputum and blood eosinophil counts, as well as maintenance of both asthma control and FEV_1, persisted for 8 weeks following the last infusion of mepolizumab.[90]

Subsequently, in a large, international, multicenter, double-blind, placebo-controlled trial, patients with eosinophilic asthma were randomized to receive monthly intravenous mepolizumab (75 mg, 250 mg, or 750 mg) infusions or placebo for 1 year.[91] In a dose-dependent manner, mepolizumab reduced clinically significant asthma exacerbations, along with both blood and sputum eosinophil counts. The efficacious effects of mepolizumab seem to be limited to patients with severe, eosinophilic asthma that remains refractory to high doses of inhaled corticosteroids and, often, requirements for concurrent oral corticosteroids. This limitation may hinder further development of anti–IL-5 therapies for asthma.

Safety

Mepolizumab appears to be well tolerated, with relatively few significant adverse reactions equally reported in both treatment and placebo groups. The most frequently reported adverse events are headache and nasopharyngitis; no serious life-threatening or anaphylactic reactions have been reported.[89–91]

■ DUPILUMAB

IL-4 and IL-13 have been implicated in the pathogenesis of asthma and atopic diseases, with inflammatory activity from these cytokines present in almost half of the patients with asthma. IL-4 and IL-13 signal inflammatory cells through two distinct receptors, although both receptors contain an α subunit of the IL-4 receptor. Dupilumab, a human monoclonal antibody to the IL-4 receptor α subunit, inhibits both IL-4 and IL-13 signaling.

A recent, double-blind, placebo-controlled trial assessed the efficacy and safety of dupilumab in adults with persistent, moderate-to-severe asthma and elevated blood or sputum eosinophil levels,[92] despite appropriate use of LABAs and inhaled corticosteroids. After initiating administration of dupilumab or placebo subcutaneously once weekly, both LABAs and inhaled corticosteroids were withdrawn. Significant improvements were observed in spirometric values and asthma control, and withdrawal of LABAs and inhaled corticosteroids precipitated fewer asthma exacerbations in patients receiving dupilumab. However, only a minority of asthmatics have blood or sputum eosinophilia, and whether dupilumab will add incremental value to standard therapy with LABAs and inhaled corticosteroids remains to be seen.

■ DACLIZUMAB

Airway inflammation in asthma includes activation of T cells and, consequently, increased levels of IL-2 and soluble IL-2 receptor (IL2R), all of which contribute to airway inflammation. Daclizumab is a humanized, monoclonal murine antibody that specifically binds to the α subunit of the high-affinity IL2R, thereby inhibiting IL-2 binding and subsequent activity.[93] Initially, the agent received FDA approval for induction immunosuppression and rejection prophylaxis of patients receiving renal transplantation. Daclizumab has limited availability due to market competition from basiliximab, used for immunosuppression in the setting of renal transplantation.

In a double-blinded, placebo-controlled study, 116 patients with moderate or severe persistent asthma on stable doses of inhaled triamcinolone were randomized to receive intravenous infusions of daclizumab or placebo every 2 weeks for 5 months. Daclizumab improved FEV_1, reduced asthma symptoms, and delayed exacerbations.[93]

In a study of asthmatic patients,[94] an excess number of serious adverse events occurred in those treated with daclizumab, including an episode of severe anaphylaxis. In contrast, prior to withdrawal from the marketplace, daclizumab appeared to be generally well tolerated, in both renal transplant patients and those with inflammatory diseases receiving the drug off-label.

PHOSPHODIESTERASE 4 INHIBITORS

A new area of interest has evolved in the development of phosphodiesterase 4 (PDE4) inhibitors in the management of airways diseases.

■ PHARMACOLOGY

Roflumilast is the first in-class isozyme-selective PDE4 inhibitor to be marketed in the United States. Although nonselective PDE inhibitors (i.e., theophylline, aminophylline) have been used for decades to treat obstructive lung diseases, roflumilast represents a markedly different type of medication.

PDEs hydrolyze cAMP and cGMP to inactive 5' monophosphates; inhibition of PDE increases intracellular concentrations and, therefore, the activity of these secondary messengers.[94] Intracellular cAMP regulates cytokine and chemokine release from inflammatory cells and cell trafficking.

There are 11 known isoenzymes in the PDE superfamily (PDE 1–11).[95] The PDE 4 isoenzyme is expressed in lung inflammatory (neutrophils, monocytes, macrophages, CD4+ and CD8+ T-lymphocytes) and structural (sensory nerves, smooth muscle cells, fibroblasts, endothelial cells, epithelial cells) cells; PDE 4 inhibition reduces lung inflammation and remodeling.[94,95]

Roflumilast is well absorbed following oral administration and has an absolute bioavailability of about 80%.[96] The drug is rapidly metabolized by cytochrome P450 (CYP450) isoenzymes to roflumilast N-oxide, the major active metabolite that accounts for approximately 90% of the PDE 4 inhibitory activity. Roflumilast N-oxide is metabolized by CYP450 isoenzymes to inactive metabolites. Both roflumilast and its metabolites are excreted in the urine. The long plasma half-lives of roflumilast (approximately 20 hours) and roflumilast N-oxide (30 hours) allow the medication to be administered once daily.

■ DRUG DELIVERY

Roflumilast is marketed as a 500 μg tablet. Food does not affect absorption; patients may take it with or without food, although given the pharmacokinetic and pharmacodynamics profile, patients should take the dose at the same time every day.

Clinical Use

Roflumilast is FDA approved for the treatment of patients with severe COPD associated with chronic bronchitis and a history of exacerbations. The current GOLD guidelines recommend roflumilast as a second choice agent in combination with an inhaled corticosteroid and LABA for patients with Group D COPD, and as an alternative choice in patients with Group C COPD.[15] In preapproval, randomized, controlled clinical trials in patients with moderate-to-severe COPD, roflumilast modestly, though significantly, improved prebronchodilator FEV_1 and reduced exacerbation rates.[97] A recent meta-analysis of 26 clinical trials confirmed that roflumilast reduced exacerbation rates in patients with moderate–to-severe COPD.[98] Very limited data from randomized controlled trials of roflumilast in combination with long-acting bronchodilators indicate that roflumilast modestly improves pre-and postbronchodilator FEV_1 and reduces exacerbations.[99,100]

Safety

Concerns regarding the relative risks and small benefits of roflumilast resulted in the FDA's Pulmonary-Allergy Drugs Advisor Committee's vote against (10 to 5) approval of the drug.[101] Although generally well tolerated, roflumilast has PDE 4 inhibitor class-specific gastrointestinal (diarrhea, nausea, decreased appetite) and neuropsychiatric (insomnia, anxiety, depression, mood changes, suicidality) adverse effects.[52] Unexplained weight loss, typically <3% of baseline body weight, has been reported with roflumilast. Patients should be advised of the possibility of these adverse effects and monitored closely during treatment with roflumilast. Roflumilast is contraindicated in Child–Pugh B or C liver impairment.

Many drugs interact with roflumilast.[102] Strong inducers of CYP450 (e.g., carbamazepine, phenobarbital, phenytoin, rifampin) reduce the effect of roflumilast and should be avoided. CYP3A4 or dual CYP3A4/CYP1A2 inhibitors (e.g., cimetidine, enoxacin, erythromycin, fluvoxamine, ketoconazole) increase the effect of roflumilast and also should be avoided.

Clinical experience with roflumilast in patients with immunological disorders and serious infections is limited. Until more data are available, roflumilast should not be used in patients with severe immunological disorders, severe acute infections, or latent infections (e.g., tuberculosis, herpes viral infections, viral hepatitis).[102] Concurrent use of roflumilast with immunosuppressants, including long-term systemic corticosteroids, is not recommended.[102]

MUCOACTIVE AGENTS

Chronic sputum production or inspissated airway secretions trouble most patients with obstructive lung disease. Mucus, which consists of a tangled network of mucin glycoproteins, oligosaccharide side chains, water, and electrolytes is produced by goblet cells and submucosal glands and is cleared by ciliary action; sputum (expectorated mucus) is cleared by cough. Inflammatory-derived substances (neutrophil-derived DNA, filamentous actin, cells and cellular debris, and bacteria) alter the physical characteristics of mucus.

Mucoactive drugs (expectorants, mucolytics, mucoregulators, mucokinetics) modify mucus viscoelastic properties and enhance mucus clearance.[103] Mucoregulator drugs, such as the anticholinergics and glucocorticoids, decrease mucus secretion and improve mucociliary clearance, respectively. Mucokinetic drugs (e.g., β_2-Adrenergic agonists) enhance ciliary activity.

■ EXPECTORANTS

Expectorants increase mucus secretion or increase airway water to facilitate mucus expulsion from the airways. The mechanism of action of guaifenesin (glyceryl guaiacolate) is thought to be mediated through an increase sputum volume and decrease sputum viscosity. A recent in vitro study demonstrated that guaifenesin decreased mucin release, decreased mucus viscoelasticity, and increased mucociliary transport.[104] Guaifenesin, an FDA-approved expectorant, is not recommended in the current evidence-based guidelines for cough or allergic rhinitis.[105,106] Despite a lack of proven efficacy, guaifenesin, with few adverse effects or drug interactions, is a common component in numerous nonprescription cough medications.

Aerosolized hypertonic saline is used to induce sputum for diagnostic and research purposes. Long-term airway surface hydration with aerosolized hypertonic saline may improve mucus clearance; anti-inflammatory and rheological effects have been proposed.[107] In teens and adults with cystic fibrosis, aerosolized hypertonic saline (7% sodium chloride) enhanced mucus clearance and improved lung function[108,109]; no effect was found in children 4 to 60 months of age.[110]

Potassium iodide is an FDA-approved expectorant. The mechanism of action is not known. Efficacy data are limited; potassium iodide is not recommended in the current American College of Chest Physicians (ACCP) cough guidelines.[105] Potassium iodide may cause significant adverse effects (hypersensitivity, dermatitis, hypothyroidism, chronic iodide poisoning) and must be used with caution in patients with Addison's disease, cardiac disease, and renal impairment. Potassium iodide is contraindicated during pregnancy.

■ MUCOLYTICS

Drugs that directly reduce mucus viscosity are classified as classic (e.g., N-acetylcysteine; NAC) or peptide (e.g., dornase alfa) mucolytics. When administered as an aerosol, the free thiol sulfhydryl group hydrolyzes the disulfide bonds that link mucin strands, resulting in less viscid mucus. Aerosolized NAC is acidic (pH 2.2); pretreatment with inhaled bronchodilators is necessary to reduce NAC-associated cough and bronchospasm. Evidence for the efficacy of aerosolized NAC in cystic fibrosis is limited.[111] High-dose oral NAC is under investigation as an oral antioxidant (mucoregulator) in the treatment of cystic fibrosis,[111] idiopathic pulmonary fibrosis,[112] and COPD.[113]

Dornase alfa, purified recombinant human deoxyribonuclease, depolymerizes DNA and F-actin polymers, reducing sputum

adhesiveness. FDA approved for the management of cystic fibrosis, dornase alfa improves lung function and slows the annual rate of decline in FEV_1.[114] Dornase alfa is administered by nebulizer once daily; some patients benefit from twice-daily administration.[115]

ANTITUSSIVES

Antitussives (cough suppressants) are used for the symptomatic treatment of cough associated with a variety of acute and chronic medical conditions. The number of FDA-approved antitussives is limited; no new antitussives have been approved for decades. Data regarding efficacy and comparative efficacy in specific medical conditions are limited.

PHARMACOLOGY

Cough is a complex coordinated neuromuscular response to mechanical and sensory stimuli in the larynx, trachea, and bronchi.[116] The medullary brainstem cough center controls involuntary cough in response to mechanical and chemical stimulation and is interconnected with suprapontine voluntary control of cough.[117]

Antitussives are classified as centrally acting or peripherally acting, depending on the site of action. Centrally acting opioid (codeine, hydrocodone, and morphine) and nonopioid (dextromethorphan, diphenhydramine, and chlophedianol) antitussives suppress cough by acting on the medullary cough center. Benzonatate, a procaine derivative, inhibits peripheral pulmonary stretch receptors. Levodropropizine and moguisteine (neither available in the United States) may modulate peripheral sensory neuropeptide levels throughout the respiratory tract.[118] Guaifenesin may have antitussive effects in acute viral cough, though the evidence is limited and contradictory.[119]

Drug Delivery

Antitussive medications are available in a variety of product-specific formulations, including solutions (liquids, extended-release liquids, syrups, elixirs, and gels) and solid dosage forms (lozenges, capsules, tablets, chewable tablets, and oral disintegrating strips). Alcohol-, sugar-, dye-, and gluten-free and single-ingredient antitussive products are available, although most products contain multiple additional active ingredients (e.g., expectorants, decongestants, analgesics, antihistamines). The majority of states allow codeine-containing antitussives to be sold as nonprescription medications if the products contain one or more noncodeine active ingredients and a maximum of 200 mg of codeine per 100 mL.[120]

Clinical Use

The 2006 ACCP Evidence-Based Clinical Practice Guidelines recommend codeine or dextromethorphan for short-term symptomatic relief of cough associated with acute and chronic bronchitis and postinfectious cough, and centrally acting antitussives, such as dihydrocodone and hydrocodone, for chronic cough associated with lung tumors. Antitussives are not recommended for any other medical condition, including cough due to viral upper respiratory tract infections.[105,121–123]

Safety

Cough and cold medications have not been shown to be safe or effective in children under 2 years of age.[124] Manufacturers have voluntarily restricted labeling to state, "do not use" in children under 4 years of age.[125]

Common side effects associated with opioid antitussives include sedation, constipation, nausea, and vomiting. At antitussive dosages, dextromethorphan has a wide margin of safety; side effects similar to codeine occur infrequently. Side effects of chlophedianol include excitation, hyperirritability, and hallucinations. Benzonatate may cause drowsiness or dizziness; capsules should be swallowed whole to avoid the local anesthetic effect of the liquid capsule contents.

Codeine and dextromethorphan are abused for the CNS effects associated with high doses. Robotripping, that is, abuse of dextromethorphan-containing cough medications for the dissociative hallucinogenic effects, is well known, especially among adolescents.[126] In 2010, an FDA advisory panel considered, but voted against, recommending that dextromethorphan be scheduled in the Controlled Substance Act.[127]

PHYSIOLOGICAL REPLACEMENTS

Replacement therapy comprises a novel class of agents to replace deficient, or augment existing, endogenous substances. To date, replacement therapy has been employed only in adults with α_1-antitrypsin deficiency or neonates with respiratory distress syndrome. However, clinical studies of replacement therapy are ongoing in patients with a wide spectrum of obstructive and other lung diseases.

α_1-ANTITRYPSIN

α_1-Antitrypsin is a glycoprotein synthesized and secreted largely by hepatocytes. A protease inhibitor, α_1-antitrypsin blocks the actions of neutrophil-derived elastase in the lung. Inherited deficiency of α_1-antitrypsin promotes development of emphysema in adulthood; tobacco smoking rapidly accelerates the clinical presentation and severity of the emphysema. Since 1987, α_1-antitrypsin replacement therapy has been available for intravenous administration as a purified product derived from pooled human plasma.

Clinical Use

Weekly or monthly intravenous infusion of α_1-antitrypsin to deficient patients increases α_1-antitrypsin levels in serum and bronchoalveolar lavage specimens and restores antielastase activity in serum and alveolar lining fluid. Numerous case reports and small series dispute whether α_1-antitrypsin replacement reduces the accelerated rate of decline in pulmonary function, CT-measured lung density, or mortality associated with α_1-antitrypsin deficiency.[128–131] The absence of clear efficacy data and high cost have prevented governmental approval for administration of replacement therapy in many countries. Currently, weekly α_1-antitrypsin replacement infusions of 60 mg/kg are recommended for patients with α_1-antitrypsin deficiency who are older than 18 years of age, maintain complete tobacco abstinence, and have both abnormal pulmonary function tests and a serum α_1-antitrypsin level less than 11 mM.[132] Replacement therapy for α_1-antitrypsin deficient patients is not recommended following lung transplantation.

Side Effects

α_1-Antitrypsin replacement therapy is remarkably nontoxic, and current preparations have few side effects, other than mild fever, headache, dyspnea, or dizziness. Repeated administration of α_1-antitrypsin does not shorten the serum half-life, suggesting that α_1-antitrypsin antibodies do not develop, even in patients with complete deficiency.

PULMONARY SURFACTANT

The administration of pulmonary surfactant to premature infants with, or at risk for, respiratory distress syndrome remains standard of care.[133,134] Surfactant administration decreases mortality from respiratory distress syndrome by 30% to 40% and reduces morbidity due to pneumothoraces, interstitial emphysema, bronchopulmonary dysplasia, and intraventricular hemorrhage. Recent studies suggest administration of nasal CPAP may comprise an equally effective alternative, with no difference in long-term neurodevelopmental outcomes.[135] In addition, surfactant administration has an evolving role in neonates with meconium aspiration syndrome and respiratory failure, reducing the need for extracorporeal membrane oxygenation, but not mortality.[136]

Endogenous pulmonary surfactant is an emulsion of phospholipids, cholesterol, and apoproteins that reduces surface tension within alveoli.[137] Natural surfactant is commercially available and is prepared from lung tissue or lavages from a variety of species. Synthetic surfactant is also available from a number of commercial sources, although the optimal composition of the material remains to be determined.

Pulmonary surfactants reduce oxygen toxicity by scavenging free radicals, and the surfactants may be cytoprotective for alveolar cell surfaces. Pulmonary surfactants suppress mediator release by inflammatory cells and may deactivate inflammatory mediators upon release. In vitro studies indicate that surfactant suppresses lymphocyte mitogenic responses, leading to a decrease in inflammatory cell influx. Pulmonary surfactant has both antibacterial and antiviral properties that are mediated by an increase in alveolar macrophage phagocytosis. Surfactant may promote airway clearance by changing the physical properties of mucus, as well as by increasing ciliary beat frequency. Finally, pulmonary surfactant may directly relax airway smooth muscle. This spectrum of putative biologic activities may directly interrupt the pathogenesis of airway inflammation, chronic infection, and bronchoconstriction seen in most obstructive lung diseases.

In adults with respiratory failure, anecdotal case reports and small patient series suggested that surfactant administration produced occasional increases in Pa_{O_2}, although usually no change in radiographic, physiological, or respiratory findings were reported. However, three large, double-blind, randomized, placebo-controlled trials demonstrated administration of synthetic surfactant yielded no demonstrable physiological benefit and no significant decrease in mortality rate.[137,138]

RESPIRATORY STIMULANTS

Respiratory stimulants are a group of pharmacologically unrelated agents used to treat diverse pathophysiological conditions, including COPD, postanesthesia respiratory depression, apnea of prematurity, acute mountain sickness, and obstructive or central sleep apnea.

■ ACETAZOLAMIDE

Acetazolamide is a noncompetitive inhibitor of carbonic anhydrase that induces a weak diuresis and mild metabolic acidosis. FDA-approved indications include acute mountain sickness (prophylaxis and adjunctive treatment), edema, epilepsy, and glaucoma. Unlabeled uses include chronic hypercapnic COPD[139] and weaning from mechanical ventilation. In one small clinical trial, the combination of acetazolamide and auto-continuous positive airway pressure improved nocturnal oxygen saturation and reduced the apnea/hypopnea index in patients with obstructive sleep apnea at altitude.[140]

Acetazolamide may have both indirect and direct respiratory stimulant properties.[141] The increased hydrogen concentration indirectly stimulates respiration via peripheral and medullary chemoreceptor stimulation. Acetazolamide may also directly stimulate respiration by increasing cerebral blood flow through mechanisms unrelated to the metabolic acidosis.[142] Side effects include drowsiness, numbness or tingling of the face and extremities, tinnitus, hypokalemia, and gastrointestinal upset. Long-term safety and efficacy data for use as a respiratory stimulant are unavailable.

■ ALMITRINE

Almitritine bismesyslate increases alveolar ventilation and improves ventilation–perfusion mismatching by stimulating peripheral aortic and carotid chemoreceptors and enhancing hypoxic pulmonary vasoconstriction.[143,144] Small clinical trials of sequential treatment in patients with moderate or severe COPD and hypoxemia demonstrate a small, dose-dependent improvement in oxygenation.[145,146] Investigational in the United States, but approved as a respiratory stimulant in Europe, side effects, including peripheral neuropathy[147] and weight loss, limit the clinical usefulness of the drug.

■ DOXAPRAM

Doxapram is a short-acting, parenterally administered respiratory stimulant. FDA-approved indications include respiratory depression following anesthesia, acute hypercapnia secondary to COPD, and drug-induced respiratory depression; off-label uses include treatment for apnea in premature infants, weaning from mechanical ventilation, and obstructive sleep apnea.[148,149] Doxapram exhibits dose-dependent peripheral chemoreceptor agonist and central respiratory stimulant properties.[148] Limited case reports and small studies describe use of doxapram as a respiratory stimulant in COPD complicated by acute respiratory failure.[150] Benzyl alcohol-containing solutions may cause significant adverse effects in infants, including metabolic acidosis, hypotension, and the "gasping syndrome."[148] Doxapram-associated side effects include flushing, sweating, elevated blood pressure, and muscle spasticity.

■ MEDROXYPROGESTERONE

Medroxyprogesterone acetate is a synthetic progesterone hormone with central and peripheral respiratory stimulant properties.[151,152] Although the mechanism of action is unclear, medroxyprogesterone increases minute ventilation and produces hypocapnia in normal subjects. However, it does not improve breathing disturbances during sleep in patients with obstructive sleep apnea.[153] Limited data show that medroxyprogesterone improves oxygenation and hypercapnia in patients with hypercapnic obstructive lung disease.[140,155] Medroxyprogesterone side effects include thromboembolic disorders, elevated liver function tests, visual disturbances, breast tenderness, reduced bone mineral density, edema, and gastrointestinal upset.

■ METHYLXANTHINES

Caffeine, theophylline, and aminophylline are structurally related methylxanthines with bronchodilatory and respiratory stimulatory properties. Caffeine is FDA approved for the treatment of apnea of prematurity and respiratory depression in adults. The mechanism of respiratory stimulation is not known, but it may include enhanced medullary respiratory center chemoreceptor responsiveness to carbon dioxide, improved diaphragmatic contractility, and competitive adenosine inhibition.[149,155] Caffeine is the most effective methylxanthine for the treatment of apnea of prematurity, with better long-term outcomes and lower toxicity than theophylline.[149,156] Common side effects include tachycardia, jitteriness, and increased gastric aspiration.[157] Caffeine inhibits adenosine receptors, creating a theoretical risk of cerebral damage and impaired neuronal development.[157] No neurodevelopmental disability was reported 18 to 21 months posttreatment in very low–birth-weight infants.[158]

CHAPTER 146

Intubation and Upper Airway Management

C. William Hanson III
Erica R. Thaler

The first known use of positive-pressure ventilation (PPV) as a medical intervention dates back to the 16th century, as described in Vesalius' *de Humani Corporis Fabrica*:

> "But that life may in a manner of speaking be restored to the animal, an opening must be attempted in the trunk of the trachea, into which a tube of reed or cane should be put; you will then blow into this, so that the lung may rise again and the animal take in air. Indeed with the slight breath in the case of the living animal, the lung will swell to the full extent of the thoracic cavity, and the heart become strong. . . . for when the lung, long flaccid, has collapsed, the beat of the heart and arteries appears wavy, creepy, twisting; but when the lung is inflated at intervals, the motion of the heart and arteries does not stop."[1]

Vesalius apparently resuscitated a Spanish nobleman by inflating his lungs through the trachea, resulting in resumption of cardiac activity and nearly in Vesalius' death at the hands of the inquisitors. Vesalius, an excellent anatomist who disproved many of the cherished teachings of Galen that had been accepted as absolute truth for 13 centuries, was viewed as a heretic by his peers. In fact, one described him as "an impious madman who is poisoning all of Europe with his vaporings."

Because of the lack of enthusiasm in response to Vesalius' findings and writings, a 100-year hiatus attended the next attempt at endotracheal ventilation. In 1667, Robert Hooke, a prominent mathematician, geologist, and paleontologist kept a dog alive by intermittently insufflating air into its trachea using a set of bellows. One century later, in 1744, John Fothergill, one of the founders of the British Humane Society, described successful mouth-to-mouth resuscitation.

Because of concerns over development of emphysema and tension pneumothorax as complications of PPV (which was recognized as early as 1827), research on artificial ventilation in the nineteenth and early twentieth centuries focused primarily on negative-pressure ventilation (NPV). Iron lungs, tank ventilators, cuirass ventilators, and a variety of strange and remarkable differential pressure chambers and boxes were developed in the United States and Europe. The devices were powered by hand, water, steam, or electricity, and, in some cases, by the patient himself. However, PPV became incorporated into the resuscitation strategy of the Dutch Humane Society, which advocated mouth-to-mouth ventilation in conjunction with external thoracic and abdominal compression. In 1776, John Hunter described an apparatus that blew fresh air into the lungs with one set of bellows and sucked "bad" air out with a second set.

By the end of the nineteenth century, a surge in the evolution of thoracic surgery led to the use of tracheal intubation and PPV through cuffed tubes as acceptable components of medical care. An American surgeon, Joseph O'Dwyer, designed a series of metal tubes that were inserted between the vocal cords of children afflicted with diphtheria. Rudolph Matas referred to O'Dwyer's devices in describing "intralaryngeal intubation" and "insufflation" and noted that, "the procedure that promises the most benefit in preventing pulmonary collapse in operations is . . . the rhythmic maintenance of artificial respiration by a tube in the glottis." In the early part of the twentieth century, Franz Kuhn, a German surgeon, described techniques for oral and nasal intubation using flexible

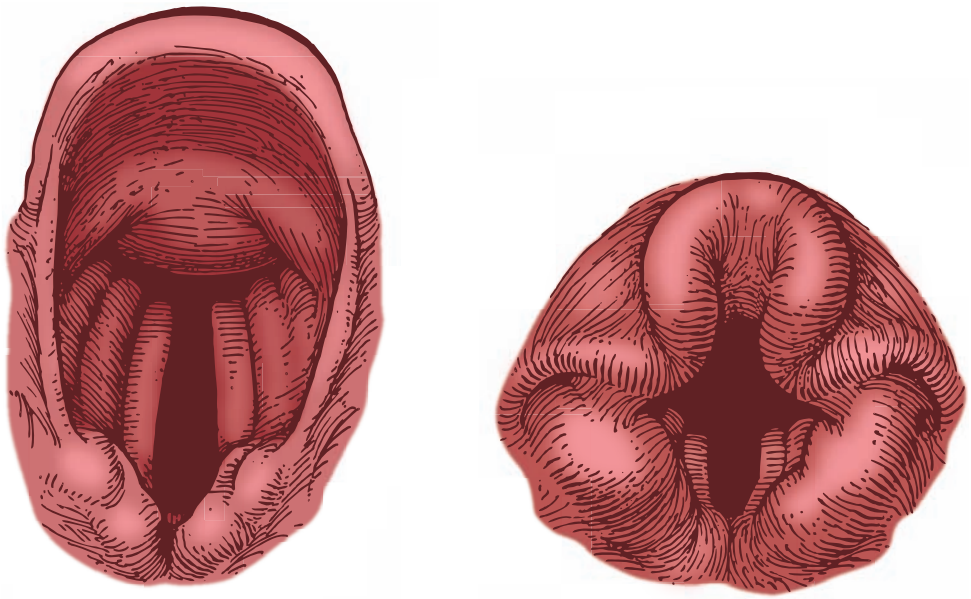

Figure 146-1 Comparative anatomy of adult and infant airways. *(Reproduced with permission from Barash P, et al, eds. Clinical Anesthesia. Philadelphia, PA: Lippincott; 1989:544, D. Factor, illustrator.)*

metal tubes introduced into the trachea with the assistance of the operator's index finger; the procedure was preceded by application of topical anesthesia using cocaine. The airway was then sealed with a supralaryngeal flange and gauze packing.

Among the further advances that followed was the first laryngoscope created by Alfred Kirstein in Berlin. However, his model was never widely accepted. Chevalier Jackson developed a U-shaped laryngoscope that otorhinolaryngologists still use for endoscopy but was never adopted by anesthesiologists. In 1913, Janeway described an endotracheal tube with a removable cuff, an anesthesia ventilator, and a battery-powered laryngoscope. From 1900 to 1920, Dorrance, Elsberg, Löwen, and Sievers published methods for tracheal intubation and PPV.

The most influential figure in the history of endotracheal intubation is Sir Ivan Magill. Along with Stanley Rowbotham, he used anesthetics on Royal Army casualties during World War I (in particular, on patients with disfiguring facial injuries). Their patients were often intubated nasally to allow freer access to the face by the surgeon. Magill's inventions include the Magill forceps, which is still used to facilitate nasal intubation, semirigid endotracheal tubes fashioned from mineralized rubber, and the Magill circuit, an L-shaped laryngoscope. He is also credited with describing the "sniffing position."

Arthur Guedel, an American contemporary of Magill, refined the cuffed endotracheal tube and, by extensive experimentation on animal tracheas, determined that the best position for the cuff was just below the vocal cords. He popularized use of the cuffed endotracheal tube by publicly anesthetizing his pet dog, "Airway," and immersing the animal in a tank of water. Upon awakening, the dog shook itself off and departed the arena.[2]

In current practice, access to the trachea through the nasopharynx or oropharynx takes advantage of laryngoscope blades invented in the 1940s by Robert Miller, a Texas clinician, and Robert Macintosh, an Oxford professor. The Miller blade was an advance over similar straight blades; it was designed to pick up the epiglottis and expose the vocal cords. The curved Macintosh blade differed from previous models and was designed for insertion between the epiglottis and tongue. Although many variants of the two blades are available today, including those with different angulations, prisms, and fiberoptic bundles, the Miller and the Macintosh blades remain the mainstays of the anesthesiologist's armamentarium.

The first departments of anesthesiology were founded in the early 1940s. Thereafter, the skills required for management of the upper airway and endotracheal intubation became widely disseminated in the United States and the United Kingdom.

UPPER AIRWAY ANATOMY AND CLINICAL RELEVANCE

The two functional conduits between the trachea and atmosphere—the oropharynx and the nasopharynx (Fig. 146-1)—join at the level of the base of the skull to form the hypopharynx. The oropharynx includes the base of the tongue, uvula, and tonsils. The nasopharynx is separated from the oropharynx by the mobile soft palate. The hypopharynx includes the vallecula, which is the space posterior to the tongue and anterior to the cervical esophageal inlet. Typically, the adult epiglottis is crescentic, moderately stiff, and thin. Because of its ligamentous attachments, the adult epiglottis can be lifted indirectly using a curved laryngoscope blade applied to the base of the tongue. The U-shaped infant epiglottis is longer and floppier than the epiglottis of the adult. Therefore, a straight blade is typically required to lift the infant epiglottis directly during endotracheal intubation.

The adult and infant airways differ in several other respects. The narrowest portion of the adult airway is the rima glottidis, the area between the vocal cords; in contradistinction, the cricoid is the narrowest portion of the infant's airway. The infant larynx is also situated relatively more cephalad than the larynx of the adult; in addition, the vocal cords of the infant are angled, whereas the vocal cords of the adult are perpendicular to the airway.

In an awake patient, with the head in the neutral position (i.e., neither flexed nor extended), air moves freely through both the oropharynx and nasopharynx. In most normal subjects, the same is true during sleep. Abnormalities of any of the component parts of the upper airway can impede airflow during respiration while awake; alternatively, impeded airflow may only become evident during sleep (e.g., as snoring or obstructive apnea). Consequently, a directed history and physical examination should be performed prior to any procedure on the airway.

A history of nasal polyps or nasal septal deviation mandates caution prior to nasotracheal intubation, transnasal passage of a fiberoptic scope, or insertion of a nasal airway. The patient's sleeping partner is often the best source of information about snoring and apnea, manifestations that may result from a variety of upper airway abnormalities, including soft-tissue redundancy, masses, polyps, stenosis, or lymphoid hypertrophy from the nose to the hypopharynx and larynx. Vocal changes or

abnormalities may suggest abnormalities of the vocal cords and warrant preintubation evaluation.

The physical examination of the airway is preceded by a conversation with the patient. Hoarseness, stridor, tachypnea, and coughing suggest potential upper airway problems. The examination then can be pursued systematically beginning with the nasopharynx. The patient's ability to breathe through a single nostril (when the mouth is closed and the other nostril occluded) indicates that the passage is relatively patent. Asymmetry often exists between the two sides and, whenever possible, instrumentation should be performed on the more patent side.

The ability to open the mouth is limited in patients with temporomandibular joint disease. The temporalis muscle may be scarred or fibrotic (e.g., secondary to prior radiation) resulting in restricted mandibular mobility. Fractures to the mandible produce limited ability to open the mouth that, when the limitation is caused by muscle spasm, disappears with anesthesia. Some fractures functionally affect the mobility of the jaw, irrespective of anesthetic state. Inability to open the mouth more than 40 mm is considered to be clinically significant.

The patient's dentition should also be assessed prior to elective management of the airway. Protruding maxillary incisors ("buck teeth") interfere with direct laryngoscopy by restricting the extent to which the laryngoscope blade can be aligned with the trachea. Dental caps and other prostheses are fragile and easily damaged during laryngoscopy. The laryngoscope may become lodged in gaps between the maxillary teeth during instrumentation and interfere with intubation. Severe dental caries or periodontal diseases make it easier to dislodge teeth during airway instrumentation. The edentulous patient often has an atrophic mandible and large tongue and may be difficult to ventilate by mask because of poor fit of the mask. Intubation of the trachea in such a patient becomes difficult because the tongue, no longer constrained by the teeth, interferes with visualization of the larynx.

Abnormalities of the tongue, hard palate, tonsillar pillars, and hypopharyngeal structures can impede or prevent intubation. Normally the tongue is small and sufficiently flexible to be displaced by a laryngoscope blade during visualization of the vocal cords. However, the tongue is enlarged in obese patients, those with angioedema or impaired lymphatic drainage (e.g., after cervical surgical procedures or trauma), or in the setting of certain neoplasms. Burns, scars, or radiation of the submandibular soft tissue prevent lateral displacement of the tongue into the oropharynx during laryngoscopy. Similarly, in patients with small jaws ("receding chins"), displacement or flattening of the tongue during laryngoscopy is difficult, making intubation a challenge. A hyomental distance (the distance from the hyoid bone to tip of the mandible) of less than 6 cm should raise awareness of potential difficulty with intubation.

A cleft or high, arched palate is seen in a variety of congenital abnormalities of the facial bones, including the Treacher Collins, Pierre Robin, Klippel–Feil, Goldenhar, Beckwith–Wiedemann, and Crouzon syndromes, as well as the mucopolysaccharidosis. Affected patients are difficult or impossible to intubate using standard approaches.[3]

Intraoral, oropharyngeal, hypopharyngeal, and laryngeal lesions, as well as tonsillar hypertrophy, can interfere with both laryngoscopy and ventilation by mask. The epiglottis can be infiltrated, inflamed, floppy, or enlarged by fat. The retropharyngeal and lateral pharyngeal spaces are continuous and therefore subject to expansion by processes that involve the mediastinum (e.g., the presence of edema, blood, pus, or soft-tissue emphysema). Patients with epiglottitis and parapharyngeal swelling often exhibit a characteristic posture, sitting upright in the sniffing position and drooling.

The preferred position for visualization of the vocal cords is the sniffing position (Fig. 146-2). However, this position may be unsuitable in some patients or impossible to achieve in others.

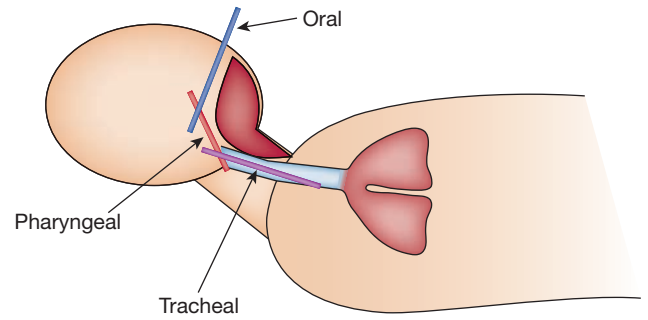

Figure 146-2 The sniffing position with the oral, pharyngeal, and tracheal axes.

The normal range for flexion and extension of the neck ranges from 90 to 165 degrees. A variety of disorders limit this range. Patients with cervical osteophytes or ankylosing spondylitis, who are often fixed in an anteroflexed head position, may be difficult to intubate. Halo fixation imposes similar constraints. Rheumatoid arthritis, which may affect the cervical spine even in asymptomatic patients, may be problematic. By the age of 75 years, the normal aging process results in as much as a 20% reduction in cervical spine mobility. Injury to the cervical spine or the presence of a cervical collar also impairs the ability of the laryngoscopist to position the head. Finally, patients with short, muscular necks have limited neck mobility and redundant soft tissue in the mouth and submandibular space, making airway visualization a challenge.

A variety of other anatomic features, including large breasts or a barrel chest, can complicate airway management by interfering with the excursion of the butt of the laryngoscope blade. During pregnancy, the oral and pharyngeal mucosae are swollen and bleed easily. When associated with a diminished functional residual capacity and increased volume of acidic gastric contents, intubation becomes quite hazardous.

The epidemic of obesity in Western societies has created a new population of patients with airway "abnormalities." Patients with a body mass index greater than 30 may be at increased risk for obstructive sleep apnea and gastroesophageal reflux. On physical examination, these patients often have some combination of macroglossia, a narrower, bulkier oropharynx, decreased neck mobility—all of which can complicate airway management. Some patients have a cervical fat pad, which may prevent optimal head positioning during intubation.[4]

Based upon anatomical considerations, clinicians commonly employ the Mallampati scale (Table 146-1)[5] to evaluate objectively the airway's suitability for placement of the endotracheal tube. The ability to visualize the soft palate, fauces, tonsillar pillars, and uvula is used to predict the degree of difficulty in exposing the larynx. A careful examination of the airway, coupled with attention to difficulties during prior procedures and the physical features described above, permit adequate preparation for instrumentation of the difficult airway.

UPPER AIRWAY MANAGEMENT

Airway management is well suited to the use of algorithms. The American Society of Anesthesiologists has published a "difficult airway" algorithm for use in the operating room.[6] In addition, algorithms for the critical care unit[7] and trauma setting[8] have also been developed. In using an algorithm-based approach, the first decision branch point typically addresses the need for endotracheal intubation, since short-term respiratory insufficiency often can be managed noninvasively.

Factors that must be considered in the care of patients with respiratory compromise include the level of consciousness, clinical context (e.g., the perioperative setting, emergency circumstances, etc.), anticipated duration of respiratory problem, risk of gastric aspiration, airway patency, concurrent medical problems, and anticipated relative ease of noninvasive (i.e., spontaneous or mask ventilation) versus invasive (i.e., endotracheal intubation) management of the airway.

In the patient with neurological depression due to injury of the central nervous system, noninvasive management is usually inappropriate due to the potential for developing hypercarbia or hypoxia and exacerbation of the primary injury. Conversely, in the patient sedated or obtunded by drugs or seizures, the clinical state is often brief in duration, so temporizing measures may be appropriate.

Several factors differentiate elective perioperative airway management from emergency care. During surgery, an anesthesiologist or anesthetist is constantly present; the patient is properly prepared (i.e., the stomach is empty and a drying agent has been administered) and the environment is designed to facilitate airway management (i.e., there is ready access to suction, a ventilator, etc.). Under these circumstances, caregivers may choose to sedate the patient to the point of semi-obtundation. Conversely, in an emergency, the setting is usually less than optimal. Airway management is usually only one component of the care rendered during cardiac or trauma resuscitation, and definitive airway intervention is essential in order to allow care providers to concentrate on other problems.

Potentially quickly reversible processes (e.g., some attacks of asthma or episodes of pulmonary edema) may be appropriately managed without intubation. In other instances (e.g., blunt chest injury), the initial problem can be expected to worsen, and early intubation is warranted.

The volume and acidity of the patient's gastric contents must be factored into any decision about management of the airway. Aspiration of solid food can be catastrophic, as can large volumes of acidic, enzymatically active gastric fluid. Most studies have indicated that aspirated stomach contents with a pH lower than 2.5 or volume greater than 0.5 to 1.0 cc/kg are likely to cause lung damage. The lung damage is manifested by loss of ciliated and nonciliated epithelial cells in the trachea, destruction of type I and II pneumocytes, depletion of surfactant, and increased vascular permeability (see Chapter 141). Pain and narcotics may alter gastric emptying or change gastric pH, as can a number of disease states, such as intestinal obstruction, diabetic gastroparesis, and obesity. Unless the patient has fasted for more than 8 hours and is not subject to the confounding factors noted above, a full stomach should be presumed, and airway management handled accordingly.

The patient's coexisting medical problems and expected course must also be considered in management of the airway. For example, endotracheal intubation can be a dangerous stress to a patient with coronary artery disease and can be performed more safely after suitable preparation than under emergency circumstances. As another example, a patient with Fournier gangrene and normal lungs is appropriately managed by maintaining intubation and sedation between trips to the operating room for debridement, rather than by performing multiple extubations and reintubations. Similarly, elective intubation and mechanical ventilation can prevent aspiration or atelectasis in a patient with hepatic encephalopathy who is awaiting liver transplantation, thereby improving the likelihood of a successful outcome.

TABLE 146-2 Indications for Intubation of the Trachea

Ventilatory failure
Cardiac arrest, primary lung disease, neuromuscular disease or weakness
Airway obstruction
Primary airway process, neurogenic obstruction
Airway protection
Upper airway bleeding or injury (burn), central nervous system depression
Pulmonary toilet
Inability to manage secretions

Some degree of airway obstruction can be managed without intubation by proper positioning of the head, use of an oral or nasal airway, or application of positive airway pressure (PAP) by mask. A rolled towel or small pillow placed behind the neck or occiput reproduces the sniffing position. Oral and nasal airways can alleviate airway obstruction due to redundant airway soft-tissue or muscle relaxation. The application of positive pressure to the mouth and nose (mask continuous positive airway pressure or mask CPAP) distends the soft tissue of the airway. For this reason, nasal mask CPAP is frequently used in the management of obstructive sleep apnea (see Chapter 99). These measures can be used as short-term, temporizing alternatives to intubation in the patient who is ventilating spontaneously in the intensive care unit or operative setting.

Although a growing literature exists on the use of noninvasive ventilation[9–13] in a variety of settings that previously would have mandated endotracheal intubation, anesthesia is frequently administered in the operating room by mask using positive pressure. True mask ventilation is readily accomplished in the anatomically normal patient. However, some anatomic features, such as a beard, flat or sharp nose, or sunken cheeks (in the edentulous patient) can make mask-assisted ventilation difficult or impossible.

Indications for tracheal intubation (Table 146-2) fall broadly under several categories: respiratory failure, airway protection, hemodynamic instability, and perioperative management. If intubation is indicated, the clinician must decide upon the route and technique.

TECHNIQUES AND EQUIPMENT

Although expertise is a function of experience, several principles are generally applicable in any approach to airway management. The first applies to correct head positioning, which facilitates mask management, oral or nasotracheal intubation, and fiberoptic examination of the airway. Incorrect positioning impedes each procedure.

The previously noted sniffing position refers to extension of the head on the neck while the neck is flexed on the thorax (Fig. 146-3). The hypopharynx is at its maximal circumference in this position, and the tongue is farthest from the posterior pharyngeal wall. Anterior displacement of the jaw can be accomplished by pulling it forward or applying pressure on the angle of the mandible (the "jaw thrust" maneuver).

This serves to open further the retrolingual space. Pulling the tongue forward while grasping it with gauze or an instrument accomplishes the same goal. The position is appropriate for spontaneous respiration because it limits soft-tissue obstruction to airflow.

Nasotracheal intubation is easiest in the sniffing position, because the tip of the endotracheal tube is best aligned with the larynx and least likely to be deflected by the walls of the pharynx. Nasal and oral fiberoptic procedures are also easier in this position in which the oral, pharyngeal, and tracheal axes are well aligned. The sniffing

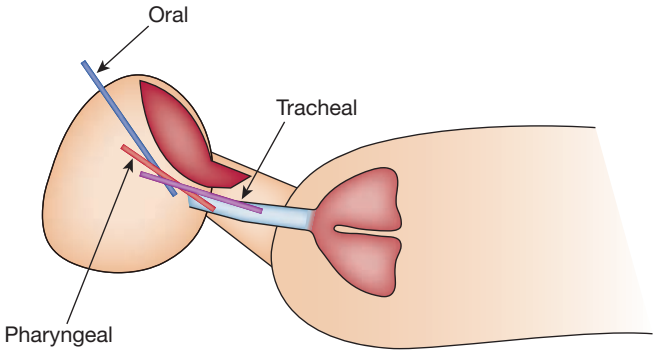

Figure 146-3 The sniffing position modified by additional head extension for oral intubation, with alignment of the oral, pharyngeal, and tracheal axes.

position may be modified by further head extension and flattening of the back of the tongue by the laryngoscope blade during oral intubation (Fig. 146-3).

A second general principle underlining airway management is that saliva and blood interfere with mask ventilation, direct visualization of the airway, and fiberoptic procedures. When circumstances permit, pretreatment with an antisialagogue, such as atropine, glycopyrrolate, or scopolamine, significantly diminishes saliva production. Suction must be available prior to initiation of any elective procedure (as well as on the emergency cart) to clear secretions or deal with regurgitation of gastric contents. A suction tip with a large bore, such as the Yankauer tonsil suction tip, is commonly used; suction should be maximized in order to clear thick, viscous, oral secretions.

A third general principle of airway management refers to preparation of the patient and airway. Small, titrated doses of sedatives, topical anesthesia, and vasoconstrictor agents markedly enhance the ease with which procedures, such as fiberoptic, nasotracheal, or oral intubation, are performed while the patient is awake. Narcotics are more likely to suppress the cough reflex than other agents. Topical cocaine has anesthetic and vasoconstrictor properties, but because of its classification as a controlled agent, the combination of lidocaine and phenylephrine is often used as an alternative. The light source of a laryngoscope or fiberoptic scope should be checked prior to instrumentation, and, with the latter, the focus adjusted. Finally, a backup plan for airway management is essential in case the primary plan should go awry. The American Society of Anesthesiology has published an algorithm, as noted above, with recommended approaches when (1) a difficult airway is identified prior to induction of anesthesia, (2) airway difficulties are encountered after the patient is unconscious, and/or (3) the patient cannot be ventilated nor intubated.[6]

Finally, perhaps the most important principle of airway management is that a source of oxygen and means of ventilation should be available. This implies that the pressure in nearby oxygen tanks should be checked, as should the proximity of a source of wall oxygen. In the absence of an oxygen source, a self-inflating resuscitation bag can provide a method for ventilation, obviously using only room air (see below). Bags used for most anesthesia circuits require a gas source for inflation.

AIRWAYS

A large variety of nasal and oral airways, designed for children and adults of different sizes (Fig. 146-4) are available. Nasal airways are generally made of flexible rubber and have a beveled tip, permitting insertion through narrow nasal passages. Oral airways are curved, designed to lie over and behind the tongue. Some are fashioned with slots for ready passage of a suction catheter, whereas others have a central channel designed to accommodate a fiberoptic scope. Binasal airways are designed to be fitted to a ventilation circuit, permitting ventilation in anesthetized patients without endotracheal intubation.

Figure 146-4 Oral and nasal airways and face masks.

RESUSCITATION BAGS

Resuscitation bags are available in many styles (Fig. 146-5) and are designed with several common features. They are self-inflating, and can, therefore, be used in the absence of a gas source. An internal flap valve system directs inflowing gas to the patient or reservoir, permitting application of positive pressure by mask or endotracheal tube

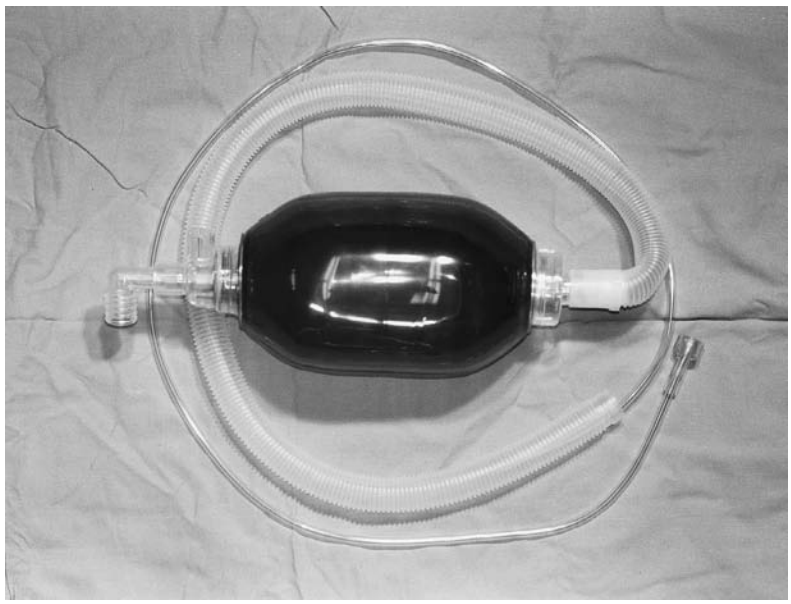

Figure 146-5 Self-inflating resuscitation bag.

and venting exhaled gas to the atmosphere. Inspired oxygen concentration is ordinarily limited to 40% to 60% when oxygen inflow is 10 L/min; bag reinflation is rapid, since room air is entrained with each breath. Addition of an oxygen reservoir, usually in the form of a sleeve or tail at the back of the bag, permits administration of oxygen concentrations of 75% to 90% at 10 to 15 L/min. Some bags are equipped with adjustable valves for application of positive end-expiratory pressure.

MASKS

Although a large variety of masks are available (Fig. 146-4), all have three features in common: the body, seal, and connector. The body is usually made of malleable or moldable material and adjustable to individual facial anatomy. The body of some masks is made of clear plastic to allow diagnosis of regurgitation of gastric contents. The seal is usually a cushioned rim (which can be inflated or deflated) attached to the body, although some are detachable. Some seals are flanged and not cushioned. The connector is designed with a universal fitting (22-mm internal diameter) for attachment to any ventilating circuit. Many are equipped with retaining straps for attachment to mask straps (which pass behind the patient's head, freeing the hand of the operator).

EXTRAGLOTTIC AIRWAY DEVICES

A number of extraglottic or supraglottic airway devices exist,[14,15] and new ones are described every year. Some are cuffed, while others are uncuffed; some are nasally inserted, while others are orally inserted. A few devices are based on cannulation of the esophagus. The most familiar devices are cuffed, orally inserted, hypopharyngeal airways, such as the laryngeal mask airway (LMA)[16,17] and the laryngeal tube airway (LTA).

The LMA (Fig. 146-6) is analogous to the facial mask: It has a compliant cuff that is applied to the dorsal surface of the larynx, isolating the airway from the mouth and esophagus. The LMA came into common intraoperative usage in the early 1990s. While used most extensively in surgical patients, the LMA has also been used for awake, fiberoptic bronchoscopy, in the intensive care unit, and in emergency resuscitation. Variants are specifically designed to be flexible, disposable, or to permit passage of an endotracheal tube through the device's lumen. The LMA is inserted through the mouth into the hypopharynx; its correct positioning is verified by assessment of breath sounds.

The LTA is similar to the LMA. The device has two cuffs, one of which is designed to seal the lower pharynx and esophagus and the other the upper pharynx. A lumen exists between the two.

Figure 146-6 The laryngeal mask airway.

The esophageal obturator airway (EOA) is similar to the LTA in that it also has two cuffs and a single lumen. However, the distal end of the device is designed to lie in the esophagus. A newer device, the Combitube (Armstrong Medical Industries), addresses a concern that the tip of the EOA may inadvertently enter the trachea, making ventilation impossible. The Combitube is designed to permit ventilation and airway isolation regardless of whether its tip lies in the esophagus or trachea.

TRACHEAL INTUBATION

Four approaches are commonly employed in tracheal cannulation: nasal, oral, laryngeal, and tracheal. The first two are noninvasive, whereas the latter two require surgical incisions.

Nasotracheal intubation can be done "blindly" (i.e., without tracheal lumen visualization) or using a laryngoscope and forceps. A blind nasotracheal intubation, when performed by a skilled operator, allows rapid control of the airway in an awake patient and minimal suppression of protective airway reflexes. The technique is used widely by paramedics in prehospital patient care, as a component of many difficult airway algorithms, and as an integral part of Advanced Trauma Life Support algorithms.

In performing blind nasotracheal intubation in a nonemergency setting, the operator examines the nasal passages for patency, septal deviation, or the presence of polyps. If the patient is able to cooperate, the larger nasal passage is selected by alternately occluding each nostril and choosing the one with better airflow. A topical anesthetic and vasoconstrictor agent are sprayed in the nostril or applied with cotton pledgets. Anesthetic is also sprayed into the back of the mouth in order to anesthetize the hypopharynx.

An appropriately sized tube (6–7 mm for women, 7–8 mm for men) is selected and lubricated. Lubrication eases passage of the tube and minimizes abrasion of the nasal mucosa, making bleeding less likely. The patient is placed in the sniffing position and the tube inserted and advanced using slow, firm pressure. The natural slope of the tube is oriented so that the tip initially points toward the occiput and curves in a caudad direction as it is advanced.

During the procedure in an awake patient, the operator listens for breath sounds as the tip approaches the vocal cords. A commercially available whistle attachment (Baam, Great Plains Ballistics, Inc., Lubbock, TX) enhances the operator's ability to hear breath sounds (Fig. 146-7). The tube is advanced into the airway during *inspiration*. Slight clockwise or counterclockwise rotation of the tube at the nose can be used to correct for lateral misalignment. A commercially available endotracheal tube (Endotrol, Mallinckrodt, Athlone, Ireland) allows the operator to anteroflex the tip of the tube with a "trigger" at the connector (Fig. 146-8). This is especially effective in patients with anteriorly positioned vocal cords or those who cannot assume the sniffing position (e.g., due to the presence of a cervical collar).

When nasotracheal intubation is performed in an anesthetized patient, the endotracheal tube tip is advanced into the hypopharynx above the vocal cords, laryngoscopy is performed, and the tube is then advanced into the trachea under direct visualization. Magill forceps (Fig. 146-9) are often used to grasp the tube and direct its tip between the vocal cords. Care must be taken to avoid grasping the tube by the cuff, which is easily perforated.

Correct position of the tube can be verified using a number of methods. Audible or palpable air passage (in the spontaneously breathing patient), a visible vapor trail within the tube, or auscultatory evidence of breath sounds over the lung fields are standard approaches. End-tidal capnometry showing phasic variation in carbon dioxide levels is the gold standard and has become more feasible in nonoperative settings because of the development of portable and disposable devices.

Extensive literature exists on the pros and cons of nasal versus oral intubation in the intensive care environment. Nasal intubation

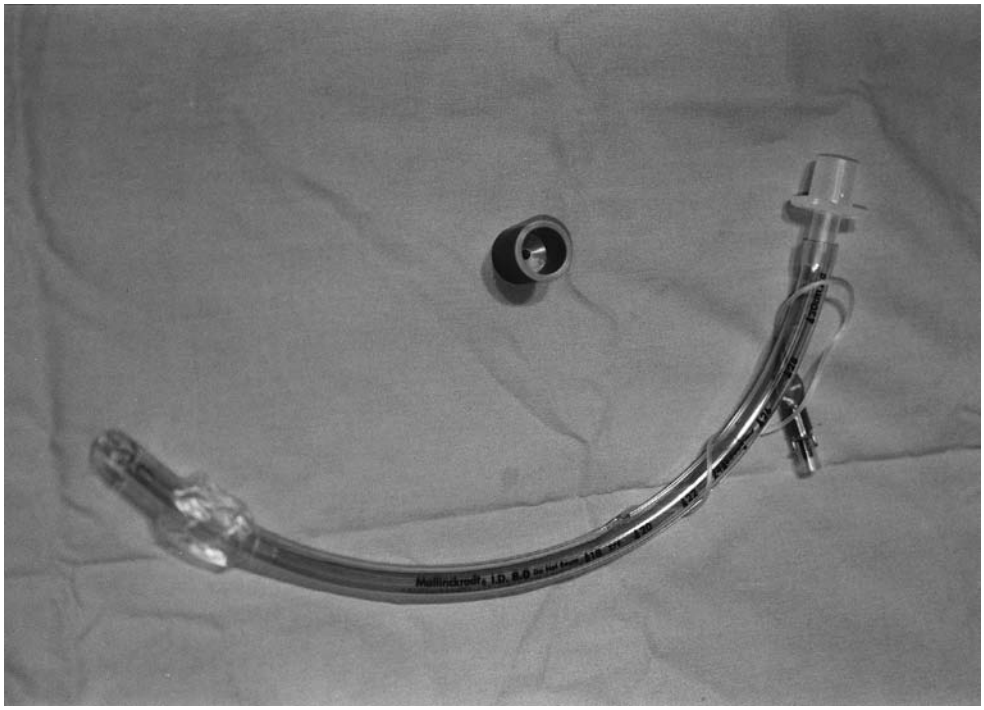

Figure 146-7 Standard endotracheal tube with whistle tip attachment to amplify breath sounds during blind nasal intubation.

is associated with a higher incidence of bleeding, nasal discomfort, and hemodynamic alterations during tube placement. A minimal increase in the dead space of the equipment (less than 10 cc) without significant difference in airflow resistance occurs with nasotracheal intubation compared with the orotracheal route. Literature regarding the incidence of sinusitis and pneumonia as a result of each of the two methods is conflicting; one prospective, randomized trial showed no differences.[18] In general, early tracheostomy is increasingly preferred in critically ill patients who are likely to be intubated for prolonged periods.[19–22]

By far, direct laryngoscopy with orotracheal intubation is the most common approach to secure the airway. With the patient's head in the sniffing position, the operator inserts a Macintosh or Miller blade (Fig. 146-10) into the right side of the mouth using the left hand (regardless of the handedness of the operator). While some anatomic situations make it advantageous to use one blade rather

Figure 146-10 Macintosh and Miller blades.

than the other (e.g., the Miller blade in the setting of an anatomically anterior larynx), most operators become familiar with one blade and use it preferentially.

The blades of both instruments are flanged to keep the tongue to the left and out of the visual field. Larger adult blades (Macintosh no. 4 or Miller no. 3) are used for patients with long mandibles, whereas shorter blades (Macintosh no. 3 or Miller no. 2) are used in normal patients. Smaller blades are used for children.

During the procedure, the operator's right hand pulls the upper and lower lips out of the way, so that they are not caught and injured between the blade and teeth. The tip of the laryngoscope blade is advanced along the tongue until the epiglottis is visible. If the Macintosh blade is used, it is advanced between the tongue and epiglottis; when the Miller blade is used, the epiglottis is elevated directly. The cords should be visible immediately below the epiglottis. Most infants are intubated using a Miller blade. The shape, length, and pliancy of the infant epiglottis are such that it must be "picked up" by the tip of the Miller laryngoscope so that the cords can be seen.

Because some patients are difficult to intubate due to anatomic considerations, a number of alternate approaches have evolved. These include fiberoptic laryngoscopy, by which the trachea is entered using a bronchoscope and an endotracheal tube advanced into the airway over the device. A flexible light wand (see Fig. 146-9) can be used to transilluminate and identify the airway; an endotracheal tube is then advanced into the airway using the wand as a stylet. Retrograde techniques involve percutaneous cannulation of the trachea in the neck and retrograde passage of a wire or catheter into the oropharynx. The wire is grasped and secured to an endotracheal tube and used to guide its passage back into the trachea.

A "bougie" tracheal tube introducer has been designed for difficult airways where only the epiglottis or the most posterior portions of the vocal cords are visible on direct laryngoscopy—the bougie is positioned in the airway and the tube threaded over it. The recent development of a "video laryngoscope" has eliminated the need for alternative approaches in many patients with difficult airways,

showing successful intubation rates greater than 90% after failed direct laryngoscopy attempts. Several variants are now available, all of which use a fiberoptic light source and lens connected to a small video display and a dedicated, specially angled laryngoscopic blade.[23–25]

Percutaneous cricothyrotomy kits are available for emergency access to the airway, as are percutaneous tracheostomy kits. Percutaneous ventilation has been taught in airway management portions of Advanced Cardiac Life Support (ACLS), Advanced Trauma Life Support (ATLS), and Pediatric Advanced Life Support (PALS) courses. The technique requires insertion of a needle or intravenous catheter through the cricothyroid membrane in order to insufflate oxygen during emergency airway management.

Anatomic features indicative of the difficult airway are listed in Table 146-3. While a full discussion of the management of the potentially problematic airway is beyond the scope of this chapter, adequate preparation by the operator can prevent a catastrophe.

Early assessment of the anatomy to determine whether difficulty with intubation alone or intubation and ventilation should be anticipated is important. An anteriorly placed larynx is usually associated with difficulty in intubation alone, whereas an obese patient is more likely to present a challenge with regard to both intubation and ventilation.

TABLE 146-3 Indicators of a Potentially Difficult Airway

Poor mouth opening
Temporomandibular joint disease
Mandibular fracture
Dental problems
"Buck" anterior teeth

An additional important determination is whether interventional airway management is actually necessary. Can the procedure be performed under regional, rather than general, anesthesia? If regional anesthesia cannot be employed, awake intubation using sedation and topical airway anesthesia may be an excellent alternative. Direct laryngoscopy and fiberoptic bronchoscopy are equally appropriate adjuncts in intubating cooperative patients.

If difficulty in airway management is unexpectedly encountered in an already anesthetized patient, ensuring adequate ventilation and oxygenation is critical. A mask or, if necessary, one of the invasive approaches described above, may be used. Establishment of reliable ventilation allows time for alternate approaches, including abandonment of the procedure (allowing the patient to awaken) or tracheostomy.

A large number of endotracheal tubes are commonly employed in a variety of clinical settings.

Single-lumen, reusable, red rubber tubes with separate cuffs were used as recently as the mid-1970s , and red rubber double-lumen tubes were in common use 5 to 10 years ago. Disposable tubes are now widely available, and a host of different design modifications have been made to make the tubes safer and accommodate different surgical procedures.

The cuff of the adult tube has been changed from a low-volume, noncompliant cuff to a higher volume, very compliant cuff; a corresponding decrease in the incidence of tracheal stenosis has been observed. Pediatric tubes are generally uncuffed because children are more vulnerable to development of subglottic stenosis due to tube contact with the trachea. Uncuffed tubes also maximize the cross-sectional area of the airway. Oral and nasal RAE tubes (Fig. 146-11) are preconfigured to permit facial and oral surgery without interference from the proximal portion of the endotracheal tube.

A variety of special tubes are used for laser surgery. These tubes are less likely to burn when contacted by the laser beam. Reinforced or anode tubes have an embedded wire or nylon filament spiral in the wall of the tube that prevents kinking or collapse due to external pressure (see Fig. 146-11). The Hi-Lo Jet endotracheal tube (Mallinckrodt) has four lumens: one for entrained gas, a second for jet ventilation, a third for cuff inflation, and a fourth for pressure monitoring.

All single-lumen tubes have a 15 mm outer diameter and connect to any standard ventilation device. Most also have a radio-opaque stripe that permits tube localization on chest roentgenograms. The

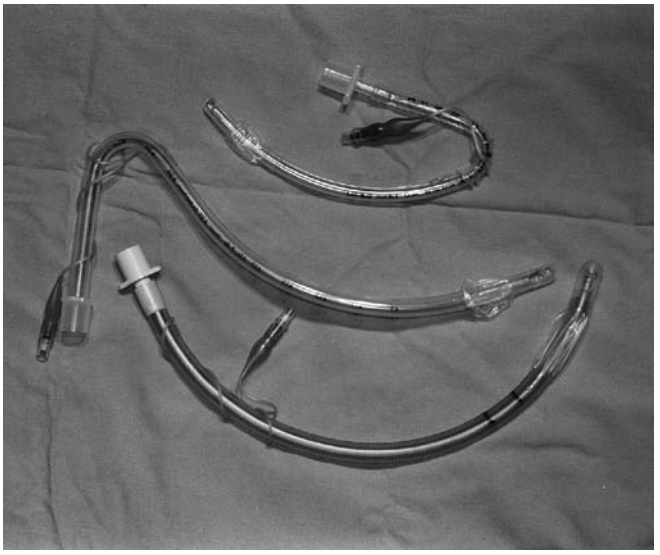

Figure 146-11 Oral and nasal preshaped tubes (RAE tubes). Anode, wire-wrapped tubes to prevent kinking.

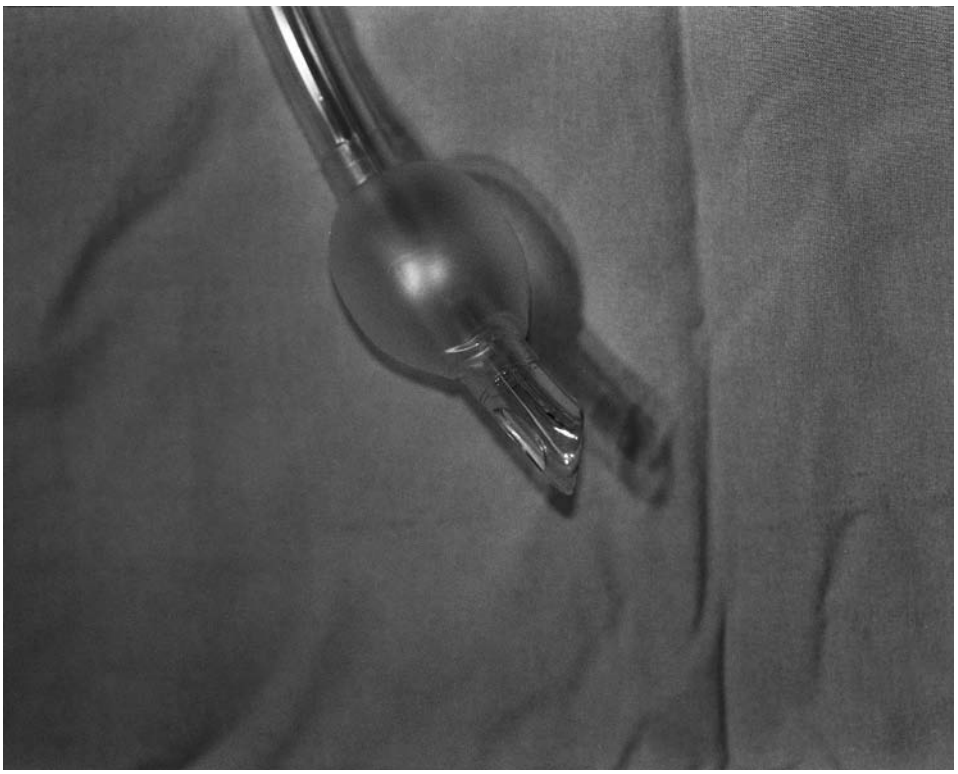

Figure 146-12 Endotracheal tube tip with Murphy eye and bevel (see text).

tip of the tube is beveled (Fig. 146-12); the bevel faces to the left because endotracheal tubes are generally inserted from the right by right-handed operators. An extra hole (Murphy eye) lies opposite to the bevel on many tubes and is designed to permit suctioning or antegrade gas flow if the bevel becomes occluded.

Finally, disposable double-lumen endotracheal tubes are now available. The Carlens and White tubes that were used in the past were equipped with a carinal hook for correct tube placement. These tubes have largely been abandoned in favor of the Robertshaw design, which has tracheal and bronchial cuffs and no hook. The tube is available in four adult sizes (35, 37, 39, and 41 French) in both right- and left-sided designs (Fig. 146-13). The right-sided tube has an oblique bronchial cuff to accommodate the takeoff of the right upper lobe orifice. Correct placement of a double-lumen tube has become easier with development of bronchoscopes small enough to pass through the narrow tube lumens.

An alternative to the double-lumen tube (the Univent tube, introduced in 1982) has a self-contained endobronchial blocker. The tube is inserted in the standard fashion, and the endobronchial blocker is then advanced (blindly or under direct vision) into the right or left main bronchus. A central lumen in the endobronchial blocker allows for inflation or deflation. While the bronchial blocker is integrated into the Univent tube construction, the same functionality can be achieved by using the Arndt wire-guided endobronchial blocker

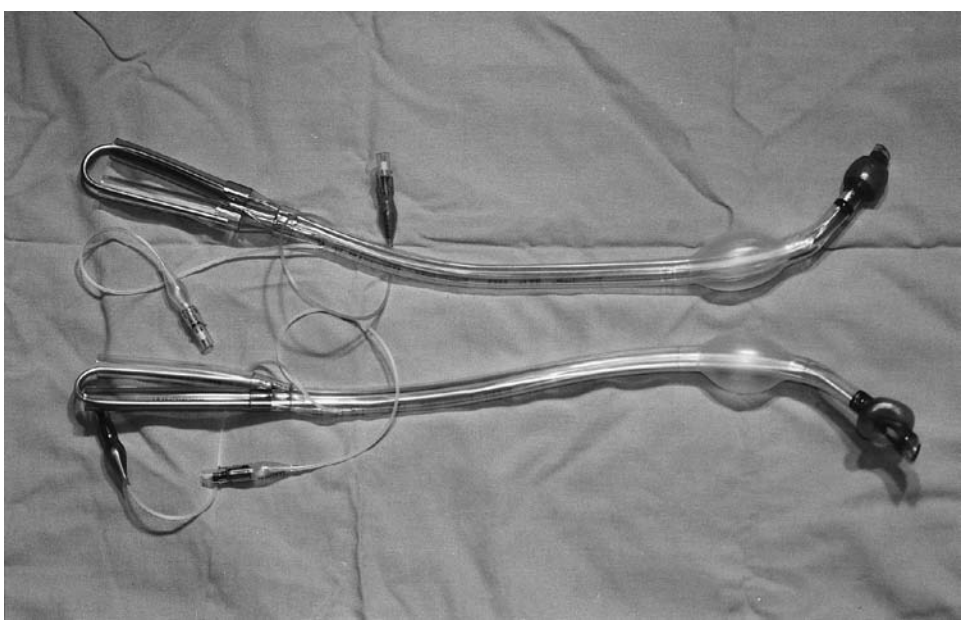

Figure 146-13 Right- and left-sided double-lumen endotracheal tubes. Note oblique bronchial cuff on the right-sided tube to accommodate right upper lobe bronchial orifice.

(Cook Critical Care, Bloomington, IN). The device is a multiport airway adapter, which can be used without a tube change (unlike the Univent tube) and can be "swapped" for a standard Y-piece connector, when desired.

CONCLUSION

While some of the skills developed by the early pioneers may be lost to current practitioners (Fig. 146-14), advances in pharmacology, equipment, and equipment manufacturing standards have greatly facilitated airway management and have made new surgical procedures possible.

CHAPTER 147

Hemodynamic and Respiratory Monitoring in Acute Respiratory Failure

Patrick J. Neligan
Barry D. Fuchs

GENERAL PRINCIPLES

Critical illness associated with acute respiratory failure (ARF) results from direct and indirect injuries to the lungs. Patients are admitted to the intensive care unit (ICU) for organ support, principally mechanical ventilation, and invasive monitoring. It is widely believed, based on dramatic improvements in perioperative outcomes since the 1960s, that monitoring the critically ill patient, invasively and noninvasively, leads to clear therapeutic goals, detects early manifestations of disease, and reduces morbidity and mortality.

A number of important goals of ICU monitoring can be identified. One is to ensure adequacy of respiratory and circulatory function in patients who appear clinically stable. Another is to provide close surveillance for early signs of respiratory and circulatory instability, with the presumption that early detection improves outcome. In addition, measurement of the response to therapeutic interventions, including intravenous fluids and the application of supportive devices, such as endotracheal tubes (ETTs) and mechanical ventilators, are routinely performed in the ICU. Although life-saving, these devices, like all therapeutic interventions, are associated with risks that must be considered. Finally, monitoring respiratory and hemodynamic derangements over hours to days provides valuable insight about prognosis, since the trend in physiological derangements over time predicts outcomes far better than does the severity of abnormalities on admission. Consequently, failure to improve over days, despite full support and appropriate treatment, suggests the need for alternative therapeutic strategies, including patient comfort as the primary goal of care.

Physiological parameters normally vary in critically ill patients. The devices used to measure these parameters are often imprecise and, at times, inaccurate. Therefore, clinical assessment and decision making should not be based, in general, on single data points. Rather, trends in data collectively add reliability to interpretation of measurements. This chapter reviews methods currently available for monitoring hemodynamics and respiratory function in patients with ARF.

HEMODYNAMIC MONITORING

Discussed in the following sections are important aspects of hemodynamic monitoring, which in its many forms, is routinely utilized in critical care settings. Respiratory monitoring is considered later in the chapter.

INDICATIONS FOR HEMODYNAMIC MONITORING

Hemodynamic monitoring is used to provide information that is not readily apparent from clinical examination, or when bedside monitoring is unreliable or equivocal.[1] Such circumstances include: (1) for the patient with pulmonary edema, determining whether the edema is cardiogenic or noncardiogenic in origin; (2) assessing whether hypoperfusion is causing, or contributing to, the patient's end-organ dysfunction; (3) deciding whether the patient with ARF who presents with or develops shock be given intravenous fluids, and, if so, how much; (4) deciding for those patients with volume overload, given the risk of causing or exacerbating organ dysfunction, how much fluid should be removed by using diuretics or dialysis to reduce lung water and improve respiratory function.

The first question requires an estimate of ventricular preload, the second an estimate of cardiac output adequacy, and the third and fourth assessment of the interrelationship of both preload and cardiac output. Regrettably, no monitor can provide consistently accurate answers to these questions. Monitors currently available are discussed in subsequent sections.

BLOOD PRESSURE MONITORING

Considered subsequently are general principles of blood pressure monitoring, as well as various noninvasive and invasive techniques employed in the clinical setting.

General Principles

The mean arterial pressure (MAP) is always monitored with the goal of maintaining it at or above 60 to 65 mm Hg, as cardiac and cerebral organ perfusion may be compromised if it falls below this critical threshold. Exceptions include those patients with pre-existing hypertension, where the MAP goal should be raised proportionately to adjust for the compensatory shift upward in their autoregulatory curve. In contrast, if the baseline MAP is low, for example, as in some patients with end-stage liver disease, a lower goal may be tolerated safely. In early circulatory shock, however, perfusion to other, less vital organs falls well before any reduction in MAP. The importance of understanding, recognizing, and intervening during this early period cannot be underscored. Thus, although essential to monitor, MAP is too insensitive a parameter to use for the detection of circulation dysfunction.

In contrast, in circulatory shock, pulse pressure falls much earlier than MAP. Since pulse pressure changes in proportion to stroke volume (SV), as SV (and cardiac output) declines and compensatory tachycardia ensues, pulse pressure will fall. Consequently, if a patient with shock and tachycardia presents with a preserved or increased pulse pressure, this suggests distributive shock as the cause. Pulse pressure may also vary rhythmically with the phases of mechanical ventilation. This pulse pressure variability (PPV) results, in large part, from the effect of respiratory-associated pleural pressure changes on venous return and occurs exclusively in patients who are hypovolemic. Although only applicable in clinical conditions in which it was validated, this observation can help inform decisions about the value of additional fluid resuscitation, as discussed subsequently.

Noninvasive Blood Pressure Monitoring: Auscultatory Technique

Systolic and diastolic arterial pressures have been measured for over a century based on the auscultatory technique, using a sphygmomanometer, cuff, and stethoscope. The cuff is inflated above the anticipated systolic pressure and, as the cuff is gradually deflated, blood flow returns, generating a series of characteristic turbulent noises (Korotkoff sounds) that can be heard over the artery. The pressure at which the first Korotkoff sound is heard is generally accepted as systolic blood pressure (phase I). The sound character progressively changes (phases II and III), becomes muffled (phase IV), and is finally absent (phase V). Diastolic pressure is recorded at phase IV or V. Phase V may never occur in certain pathophysiological states, such as aortic regurgitation. It is used commonly for BP measurement while patients are managed in general care units.

Although widely used in clinical practice, the auscultation technique is inadequate for critical care. There are considerable interobserver differences based on subjective perception, rate of cuff release, and difficulty in hearing the sounds in shock states. In addition, some inexperienced caregivers have a tendency to "disbelieve" abnormal results, resulting in diagnostic delay. Peripheral edema may artificially inflate the blood pressure reading, as will a cuff that is too narrow for the patient; the width of the cuff should be 20% greater than arm diameter. If the cuff is too small, blood pressure will be overestimated. If the cuff is too loose, blood pressure will be underestimated. Finally, in patients with low output shock, the auscultatory method may underestimate intra-arterial measurements by up to 50 mm Hg.[2]

Noninvasive Blood Pressure Monitoring: Oscillometry

Oscillometers are automated, noninvasive blood pressure (NiBP) monitoring devices that are routinely used in operating rooms, recovery rooms, endoscopy suites, high-dependency wards, and ICUs. NiBP devices measure mean arterial pressure and use an algorithm to estimate the systolic and diastolic blood pressures. They offer significant advantages over auscultation in that they are time saving, reliable, reproducible, and have high- and low-pressure alarms built in.

The oscillometer is a single-cuffed device that occludes the artery and senses restoration of blood flow. The cuff is inflated above systolic pressure and then deflates either continuously, at a rate about 4 mm Hg per second, or in a stepwise manner. The sensor detects oscillation as blood flow returns. The pulse pressure wave and the gauge pressure in the occluding cuff are detected and converted into electronic signals by a transducer. The peak amplitude of pulsations corresponds to MAP. The systolic and diastolic components are calculated using proprietary algorithms. Systolic blood pressure is identified as the pressure at which pulsations are increasing and are at 25% to 50% of maximum. Diastolic blood pressure is the most difficult value to determine by oscillometry and is commonly recorded when the pulse amplitude has declined from the peak value by 80%.

Oscillometers are generally safe and reliable, but care must be taken with cuff location, size, and frequency of measurement. Many complications have been reported, including pain, petechiae, bruising, venous stasis, limb edema, thrombophlebitis, and peripheral neuropathy. The likelihood of these complications is proportional to the duration and frequency of cuff inflation; they result from extremity ischemia and local trauma. The events occur more often after prolonged periods of excessively frequent cuff inflation/deflation cycling.

Invasive Blood Pressure Monitoring Techniques

The insertion of an intra-arterial cannula provides the intensive care clinician with continuous, beat-to-beat blood pressure monitoring and arterial blood sampling for pH and blood gas analysis, as well as for the medley of blood tests that may be performed on the critically ill patient. It is widely believed that this form of continuous invasive blood pressure (IBP) monitoring is more reliable than noninvasive approaches and facilitates earlier diagnosis and resulting interventions.[2,3]

Arterial "lines" are constructed of an intra-arterial cannula, fluid-filled tubing, pressure transducer, and microprocessor with display. The pressure transducer is a low-compliance diaphragm that moves in response to pressure changes transmitted through fluid-filled tubing. This movement is converted to an electrical signal using a strain gauge. A pressure waveform is generated, and the mean arterial pressure is calculated by integrating the area under the waveform. The systolic and diastolic pressures are calculated using an algorithm.

Complications of arterial cannulation include infection, air embolism, bleeding, thrombosis, and infarction. The IBP monitor must be zeroed and leveled in the phlebostatic axis (at the level of the right atrium), regardless of the site of the arterial cannula. Inadequate or incorrect zeroing results in incorrect values and inappropriate therapies. The bedside clinician should always check the "zero" before initiating antihypertensive or vasopressor therapy.

Which is more accurate, NiBP or IBP? Mean arterial pressure measurement correlates well between the two techniques.[4] Oscillometry generally underestimates intra-arterial systolic blood pressure,[5,6] as opposed to diastolic blood pressure, which is overestimated, especially in hypertensive patients.[7] IBP is vulnerable to damping. The presence of air bubbles, blood clot, or kinks in the tubing result in a damped signal. Damping decreases the rate of signal change, leading to low pulse pressure, with low systolic and high diastolic pressure readings. Nevertheless, damping will not impact the accuracy of the mean arterial pressure until it is extreme, and only then will it underestimate the true value. Damping is important to recognize, since interventions may be initiated on the basis of reductions in either systolic or pulse pressure; furthermore, pulse pressure is important for estimating cardiac output by several methods (as discussed subsequently). Routine nursing bedside assessments should enable early identification and troubleshooting, including the performance of the "flush test," which measures the arterial pressure recording systems frequency response to a pulse change in pressure.

■ INVASIVE CENTRAL VENOUS PRESSURE MONITORING

Measurement of central venous pressure (CVP) is a critically important component for monitoring many patients in critical care units. Its assessment, as well as parameters derived from venous blood samples obtained from central venous catheters (CVCs), is discussed in the following chapters.

Central Venous Pressure

CVCs are inserted for a variety of reasons, including for administration of vasopressors and hypertonic dextrose solutions (total parenteral nutrition), for long-term venous access, and for measurement of CVP and venous blood gases. CVP is the downstream pressure that governs the rate of venous return to the right heart; it represents a good approximation of mean right atrial (RA) pressure. CVP may be measured accurately through a variety of catheter types, including triple lumen, tunneled, and percutaneously placed catheters. Commonly employed CVP catheter sites include the internal jugular (IJ), subclavian, and femoral veins.

CVP has been used to assess volume status in the diagnosis and management of shock and to infer the etiology of pulmonary edema. There is no "normal" CVP, and small changes in its magnitude may accompany large changes in circulating blood volume.[2] Although, in some cases, a very low (<5 mm Hg) or a very high (>20 mm Hg) CVP may be helpful in guiding decisions about circulating blood volume, in most patients, a single CVP value is rarely helpful.[8] Numerous studies have failed to show that the CVP value has utility in predicting fluid responsiveness. Nevertheless, the CVP may help in categorizing the pathophysiology of shock and may be a useful parameter to guide protocol-driven resuscitation in an ICU staffed by inexperienced practitioners or trainees. In summary, although CVP has limited utility in volume status assessments, it remains a complementary assessment tool.

One of the most important problems confounding CVP interpretation, which is pertinent to all intravascular pressure measurements taken from within the thorax, is the impact of respiratory-induced intrapleural pressure changes on the interpretation of intravascular pressure. Intravascular pressure is measured relative to atmospheric pressure, providing a zero reference for the transducer. Unless the magnitude of the intrapleural pressure swings are considered, (i.e., referencing intravascular pressure to intrapleural,

rather than atmospheric, pressure) intravascular pressures fluctuate despite constancy in the transmural pressure; if the impact of these intrapleural pressure swings are not considered, spurious readings will arise. Consequently, pressures are recorded at end expiration to minimize this potential error. End expiration is easy to determine in spontaneously breathing patients; in patients on mechanical ventilation who are actively breathing, recording and displaying intraairway pressure and intravascular pressure simultaneously enables accurate timing.

Important clinical questions are whether the CVP or RA pressure is useful in estimating right and left ventricular preload or in determining if pulmonary edema is cardiogenic in origin. Preload is best defined as end-diastolic volume (EDV), which requires an estimate of both the transmural filling pressure (CVP–pericardial pressure) and ventricular compliance, neither of which can be determined reliably at the bedside. Even if CVP correlated with RVEDV, the latter correlates poorly with LVEDV in patients with ARF because of discordance in ventricular afterload and contractility. Indeed, lung disease and the positive end-expiratory pressure (PEEP) used to treat it increase pulmonary vascular resistance and may precipitate right ventricular failure. Furthermore, since the pericardium limits ventricular dilatation, ventricular interdependence further increases the disparity in LVEDV and RVEDV when differential contractility or loading conditions are present. This occurs because ventricular dilatation displaces the septum laterally and compresses the adjacent ventricle. Thus, the CVP is of little or no value in determining ventricular preload or in determining whether pulmonary edema is of cardiogenic or noncardiogenic origin.

The CVP waveform, however, may provide evidence to suggest the presence of specific cardiac or pericardial disorders (Fig. 147-1).

Characteristic findings on the CVP waveform may suggest certain cardiac disorders. For example, a prominent Y descent suggests myocardial restriction; pericardial constriction; or right ventricular ischemia, infarction, or overload. In contrast, the Y descent is greatly attenuated in cardiac tamponade. A large V wave suggests tricuspid regurgitation (TR), which is associated with RV failure. In atrial fibrillation, the A wave disappears. A tall A wave (so-called, "canon A wave") may be seen in atrioventricular dissociation or a junctional rhythm, due to atrial contraction occurs against a closed tricuspid valve. In patients with diastolic dysfunction, these arrhythmias may cause sudden hypotension, and CVP waveform analysis may be diagnostic.

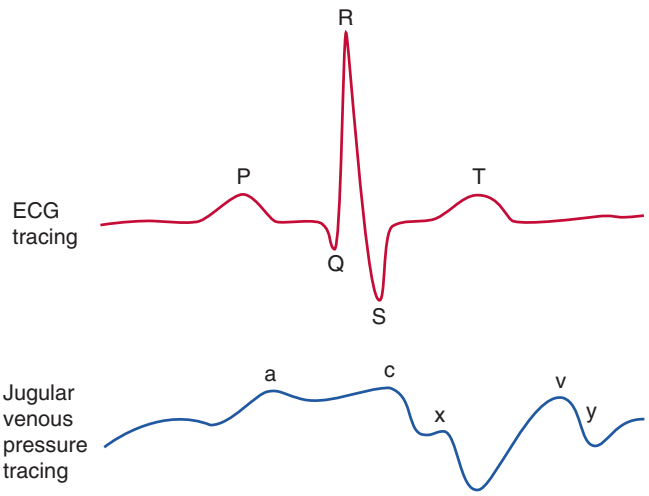

Figure 147-1 **CVP waveforms:** Since there are no valves between the vena cava and the right atrium, central venous pressure waveform reflects the events of cardiac contraction. Simultaneous display of the ECG allows one to identify and time the CVP waveform. **a wave:** Increased atrial pressure during right atrial contraction. It occurs following the P wave on an ECG. **c wave:** During early ventricular contraction the tricuspid valve bulges into the right atrium. It occurs at the end of the QRS segment on an ECG. **x descent:** Atrial relaxation. It occurs before the T wave on an EKG. **v wave:** Atrial filling—the right atrium progressively fills while the tricuspid valve is closed. It occurs at the end of the T wave on an EKG. **y descent:** Following opening of the tricuspid valve in diastole, the atrium empties as blood flows into the right ventricle. It occurs before the P wave on an EKG.

Mixed Venous Oxygen Saturation

Normally, the circulation delivers oxygen to the tissues at a rate sufficient to maintain an intracellular (mitochondrial) oxygen tension above a critical threshold. If oxygen delivery (D_{O_2}) fails to meet tissue oxygen requirements ($\dot{V}_{O_2}$), shock occurs and anaerobic metabolism ensues. If prolonged, cell death may occur.

If D_{O_2} decreases and tissue $\dot{V}_{O_2}$ remains constant, a reduction in the oxygen content is seen. This increase in oxygen extraction results from both an increased capillary transit time and increased gradient for oxygen diffusion, as mitochondrial and tissue P_{O_2} fall. As most of the oxygen in venous blood is attached to hemoglobin, the mixed venous oxygen saturation (Sv_{O_2}), as measured in the pulmonary artery, has traditionally been used as a surrogate for oxygen content.

Since blood flow and metabolic rate vary among organs, so does the venous oxygen content draining from different organs. However, when well mixed in the pulmonary artery, the Sv_{O_2} represents a weighted average of the product of blood flow and oxygen content from every organ and reflects the adequacy of "global" oxygen delivery. Thus, Sv_{O_2} is insensitive to localized tissue ischemia (e.g., bowel ischemia), reflecting an important limitation in its clinical use.

Based on an understanding of the determinants of Sv_{O_2}, the clinician can use the Fick equation (Equation 1) to elucidate the mechanism of shock and to select the most appropriate therapy:

$$\dot{V}_{O_2} = CO \times (\text{arterial } O_2 \text{ content} - \text{venous } O_2 \text{ content}) \quad (1)$$

where CO is cardiac output. Recalling that O_2 content of either arterial or venous blood is the sum of hemoglobin (Hgb)-bound oxygen (1.34 mL O_2/g Hgb × [Hgb]/100 mL blood × % hemoglobin saturation) and dissolved oxygen (0.003 mL O_2/mm Hg), the following expression (Equation 2) for mixed venous O_2 is derived:

$$Sv_{O_2} = (\text{arterial } O_2 \text{ content} \times [\text{Hgb}] \times CO)/\dot{V}_{O_2} \quad (2)$$

Thus, if Sa_{O_2} is stable, Sv_{O_2} will decrease if either CO or [Hgb] decreases or $\dot{V}_{O_2}$ increases. Since Sa_{O_2} and [Hgb] are readily measured and changes in $\dot{V}_{O_2}$ can be grossly estimated, the cause of a decrease in Sv_{O_2} can usually be determined quickly. Compared with alternative methods of monitoring CO, Sv_{O_2} reflects the adequacy of CO relative to oxygen requirements. This is more valuable than the absolute CO, since reference values for CO or body surface area–normalized cardiac indices assume that $\dot{V}_{O_2}$ is normal, which is often not the case in critical illness.

Since Sv_{O_2} is measured from the pulmonary artery, it requires placement of a pulmonary artery catheter (PAC), which is now rarely performed, because randomized control trials have failed to show a benefit on patient outcome. Consequently, since 2001 there has been considerable interest in using the venous oxygen saturation measured from the superior vena cava (SVC) (Scv_{O_2}) as a surrogate for Sv_{O_2}.[9] Since many critically ill patients already have a CVC in place for vasoactive medications, this measurement requires no additional procedures and, therefore, carries no additional risk. To minimize measurement errors, blood should be sampled from the proximal SVC or from within the right atrium via any CVC or device. Importantly, since many hospitalized patients not in critical care units have a CVC or long-term CV access port, Scv_{O_2} may

be used for both diagnostic and therapeutic purposes well before transfer to an ICU.[10,11]

Pulmonary Artery Occlusion (Capillary Wedge) Pressure

The PAC was first introduced into clinical practice in 1970. For many years, the PAC was used widely for hemodynamic measurements in the ICU, particularly in North America. However, more recently, usage has fallen dramatically with the lack of any evidence of meaningful benefit and known complications.[12–14]

The PAC is used to measure CVP and pulmonary artery occlusion or "wedge" pressure (PAOP) for the estimation of right and left ventricular filling pressures and to determine cardiac output. PAOP closely approximates the left ventricular end-diastolic pressure (LVEDP). If "a" and "v" waves are visible in the transduced pressure recording, the mean value of the "a" wave (halfway between the top of the "a" wave and the bottom of x descent) is used to indicate the PAOP. PAOP is also used to estimate pulmonary capillary pressure to determine whether pulmonary edema is due to increased capillary permeability or hydrostatic pressure. In contrast to when the PAOP is used to estimate LVEDP, the mean of the end-expiratory tracing is always used, even if large "v" waves are present, since the systolic pressure spike ('v" wave) is transmitted with an equal contribution to the capillary hydrostatic pressure. If the PAOP never exceeds 18 mm Hg, hydrostatic pulmonary edema can be excluded; however, transient spikes in left atrial pressure that can cause pulmonary edema, may occur between normal PAOP measurements, and may be missed. A PAOP >18 mm Hg is consistent with a hydrostatic cause of pulmonary edema, but high-permeability edema cannot be excluded.

The correct interpretation of PAC-derived hemodynamic data remains a major challenge and may be an important reason for studies having failed to show a benefit on patient outcomes.[15,16]

Does the PAOP provide an estimate of LV preload? Regrettably, this is an equally tenuous proposition, fraught with all the same limitations of those discussed previously regarding CVP as a poor reflection of RV preload.[8,17,18] But even if PAOP provided an accurate estimate of ventricular volume (preload), it should not be used to guide volume resuscitation. EDV does not correlate with fluid responsiveness, the important issue when resuscitating a patient. Fluid responsiveness can only be determined from dynamic indices, which are discussed subsequently. Nevertheless the measurement of pulmonary arterial pressure from the PAC is useful. Right ventricular dysfunction not uncommonly complicates acute respiratory distress syndrome (ARDS) and thromboembolic disease.[19] The presence of high PA pressures should alert the clinician to these diagnoses. Pulmonary artery pressure is also important to follow when titrating pulmonary vasodilators, diuretics, hemofiltration, inotropes, or other therapies.

■ CARDIAC OUTPUT MONITORING

Monitoring cardiac output in critically ill patients has been a central element in clinical management for decades. Underlying principles and techniques are discussed in the following paragraphs.

General Principles

Shock or frank hypotension commonly complicates critical illness and may result from absolute or relative hypovolemia, vasoplegia, or cardiac failure. The ability to measure cardiac output and titrate inotropes, vasopressors, and fluids remains a cornerstone of 21st-century critical care.

In critically ill patients, the history, physical examination, and laboratory testing can help to estimate absolute and relative changes in cardiac output and organ perfusion. In addition, Scv_{O_2} monitoring has become a routine component of hemodynamic monitoring. Although more outcome studies are needed, these routine assessments often provide all the information necessary to categorize the nature of shock and assess the response to early resuscitative interventions. However, in the population of patients who fail to recover fully from shock, these assessments alone may not provide the information necessary for optimal patient management. For instance, additional decisions may need to be made on whether to proceed with more fluid challenges, deciding whether there has been a favorable response to a fluid challenge, or determining when to stop diuresis or ultrafiltration to avoid a reduction in cardiac output. These questions are best addressed by measuring the change in cardiac output in response to an intervention. From a practical standpoint then, accurate determination of *trends* in cardiac output is more important than absolute values.

Traditionally, thermodilution (TD) using a PAC has used to measure cardiac output. Due to the inherent issues with the use of PACs, a variety of less invasive SV/cardiac output monitors have been developed for this purpose.

Thermodilution and Indicator Dilution Techniques

Measurement of CO with a PAC using a TD-based technique is considered the gold standard to which other CO-measuring technologies are compared. CO can also be measured indirectly with the PAC using the Fick method, based on the principle that CO is equal to oxygen consumption ($\dot{V}_{O_2}$) divided by the difference in O_2 content across the circulation (i.e., the arteriovenous O_2 difference). Since $\dot{V}_{O_2}$ is not usually measured directly and may vary considerably in critically ill patients, inaccuracies may result. Hence, in patients with ARF who have a PAC, CO should be measured using TD, unless significant TR is present. If the values obtained by TD are unexpected, then the Fick method should be used for corroboration.

Even if we accept that the CO measurement is accurate, more information is needed to make clinical decisions. Oxygen consumption varies significantly within and between patients with ARF. Since CO usually increases in proportion to $\dot{V}_{O_2}$ and inversely with hemoglobin concentration and O_2 saturation, there is no normal or range of normal values for CO in patients with ARF. Similarly, normalizing CO to body surface area for comparison to reference values is unhelpful. In managing a critically ill patient, the relevant questions are whether the measured CO is adequate for the patient's needs, and if not, whether CO can be improved with intravenous fluids. Alternatively, for the volume-overloaded patient, an important question is how much fluid can be removed by diuresis or dialysis without reducing CO.

Lithium Dilution Technique

Lithium, in low doses, is a nontoxic substance that is not metabolized. When injected, its concentration is easily measured using an ion-selective electrode. Lithium dilution cardiac output (LiDCO) is calculated from the area under the concentration–time curve when lithium is injected into a CVC and measured peripherally in arterial blood. Injection into the antecubital vein appears to be as accurate as injection through a CVC. LiDCO is also used to intermittently calibrate the PulseCO cardiac output monitor.

Dynamic Preload Indices and Pulse Contour Analysis

Positive intrathoracic pressure increases right ventricular (RV) afterload and reduces RV preload. On inspiration, RV stroke volume falls and LV stroke volume increases as a consequence of increased LV filling from enhanced pulmonary venous return, increased LV compliance because of decreased RV dimensions, decreased LV afterload, and external pressure on the LV. The subsequent LV stroke volume is lower, due to the reduction in RV stroke volume. Consequently, blood pressure falls slightly during inspiration and returns to normal during expiration. These cyclic variations are quite sensitive to volume status, such that when the patient is

TABLE 147-1 Devices Used to Measure Cardiac Output

Device	Advantages	Disadvantages
Pulmonary artery catheter	Can be used in extubated patients Accurate cardiac output Can measure pulmonary artery pressures and mixed venous oxygen saturation Continuous monitoring provides core temperature	Inaccurate with tricuspid regurgitation Complications, including arrhythmias, pulmonary artery rupture, infarct Misinterpretation of data
PiCCO	Simple Calibrated cardiac output Can be used to assess fluid responsiveness and extravascular lung water Continuous monitoring	Additional arterial line required
Flotrac-Vigileo	Simple—connected to arterial line Predicts fluid responsiveness Continuous	Patient ideally should be mechanically ventilated Not useful for titrating vasopressors Not responsive to changes in vascular tone
LiDCO	Simple Accurate cardiac output	Requires frequent recalibration Intermittent Not useful for titrating vasopressors Not dynamic enough to titrate fluid responsiveness
Esophageal Doppler	Relatively simple Predicts fluid responsiveness	Patient must be intubated and sedated Intermittent Interuser variability
Echocardiography	Accurate measurement of cardiac output, stroke volume, filling volumes and pressures	Complex High level of skill required Intermittent Requires technician to be present while titrating pressors and fluid
Thoracic bioreactance	Accurate measurement of stroke volume Completely noninvasive Mechanical ventilation, sedation, and regular cardiac rhythm are not required Ease of use	Electrocautery causes interference

relatively hypovolemic and on the steep part of the Frank–Starling curve, SV and, hence, pulse pressure variation (PPV) are greater.[20] Patients on the flat portion of the Frank–Starling curve are insensitive to these cyclic respiratory-related changes in preload.[21]

A PPV >13% appears to be a sensitive indicator of fluid responsiveness.[22] PPV and stroke volume variability (SVV) have become the major focus of current generation cardiac output monitors (Table 147-1).[23] However, these two measurements of fluid responsiveness are only valid under the ideal conditions in which they were validated. These include passive mechanical ventilation with a tidal volume of at least 8 mL/kg IBW, a regular cardiac rhythm, a closed chest, and no evidence of intra-abdominal hypertension or right ventricular failure. Unfortunately, these conditions are met in only a small proportion of patients in ICUs, given their reductions in tidal volume and use of sedation. Thus, for the majority of critically ill patients, alternative approaches to assess fluid responsiveness are required. Most commonly, this involves measuring the change in cardiac output in response to a fluid challenge (bolus) of 250 to 500 cc given rapidly (over 5–10 minutes).

If there is a concern about the safety of giving an additional fluid challenge, measuring the cardiac output response to a passive leg raise (PLR) maneuver should be used. Repositioning from the semirecumbent position (45 degrees) to supine, with the legs raised 45 degrees, provides a rapid endogenous shift of blood volume of approximately 300 cc, mirroring the effect on venous return produced by an exogenous fluid bolus. The technique has been validated under a variety of clinical conditions, albeit in small studies, including those that render other invalid functional hemodynamic assessments, that is, PPV, SVV, and IVC collapsibility.[24] This technique is promising, but large validation and outcome studies are needed.

The Flotrac-Vigileo (F/V) device (Edwards Lifesciences, Irvine, CA) calculates SV and cardiac output, using proprietary algorithms, from a single sensor attached to an arterial line at any site. It does not require external calibration or the presence of a CVC or specialized catheter.

F/V combines rapid analysis in real time of the arterial pressure waveform with demographic data (e.g., gender, age, weight, and height) applied to a continuously evolving algorithm to calculate cardiac output. Arterial pulsatility is directly proportional to SV. As changes in vascular tone and compliance occur dynamically, the device appears capable of correcting the changes by analyzing skewness and kurtosis of the arterial waveform. These correction variables are updated every 60 seconds, and the arterial waveform is analyzed and averaged over 20 seconds, thus eliminating artifacts, jitter, and premature contractions. Cardiac output is calculated utilizing the arterial waveform and the heart rate. F/V also calculates accurately SVV and, hence, provides an assessment of fluid responsiveness.[25]

An increasing number of studies and a meta-analysis[26] on performance of this system have been published. While early studies

demonstrated poor correlation between F/V and TD methods, with application of newer software the correlation has improved.[27] Of note, although TD methods are considered the gold standard for CO measurement, comparison with the F/V device is not ideal, since measurement intervals and averaging times are substantially longer with all TD methods. Hence, F/V may be more sensitive to dynamic changes in cardiovascular function. Obviously, F/V requires an uninterrupted arterial waveform. Thus, in the presence of arterial obstruction, for example, aortic valve disease, aortic coarctation, or use of balloon counterpulsation, the data will be inaccurate and misleading. Care should also be taken in scenarios in which patients are being rewarmed from induced hypothermia (e.g., after cardiac surgery or cardiac arrest) or when intracardiac shunts are present.

Data to date have suggested that F/V is quite accurate at measuring changes in cardiac output associated with volume expansion (i.e., in which there is preload sensitivity),[28] but not changes associated with vasopressor use.[29–31] Accuracy is also likely dependent on the patient having a regular cardiac rhythm and a consistent tidal volume.[25,32]

Pulse Contour Cardiac Output

Systolic ejection results in distension of the arterial tree; if the distension pressure is transduced by an arterial line, a characteristic waveform is observed. This waveform reflects the SV and elastic properties of the arterial wall. The shape of the pulse waveform and the area under the curve (AUC) is proportional to the cardiac output. Measurement of the AOC and pulse contour provides clinicians with a bedside cardiac output. However, arterial compliance is not constant or consistent; there is tremendous inter- and intrapatient variability. Since compliance is mathematically defined as the change in volume divided by the change in pressure, external calibration of the pressure signal with an alternative cardiac output technique is required. Pulse contour devices, for example, Pulse CO, LiDCO (LiDCO plus, LiDCO LTD, Cambridge, UK), and PiCCO (Pulsion, Germany), combine pulse contour analysis to calculate SV, and indicator dilution or TD cardiac output measurements to calibrate the system.

In addition to calculating cardiac output, devices that analyze pulse waveforms also analyze and display PPV that can be used for dynamic preload assessment and fluid responsiveness in mechanically ventilated patients.

PiCCO-plus (Pulsion Medical, Munich, Germany) calculates cardiac output continuously from pulse contour analysis of the aortic waveform via an arterial cannula. The cannula can be placed in the femoral (preferably), brachial, or axillary arteries. The system requires the concurrent placement of a CVC, which is required to perform transpulmonary TD cardiac output measurements, and a thermistor in the arterial catheter to calibrate the system. The major advantage of the system over a PAC is that there is no requirement to cannulate the right heart. Conversely, two separate lines are required, and often this involves the placement of a second arterial line.

The PiCCO device measures the area under the aortic waveform; the systolic area is identified as that part of the waveform proximal to the dicrotic notch, which is proportional to the SV. Although beat-to-beat volumes are measured, they are averaged over 30 seconds to avoid inaccuracy associated with anomalous waveforms, interference, and extrasystoles. The continued accuracy of PiCCO depends on the frequency of calibration using TD. The manufacturer recommends recalibration every 8 hours, but this interval may be insufficient in unstable patients.[33]

In the PiCCO system the temperature differential detected using the arterial thermistor is composed of a series of exponential decay curves as the cold injectate passes through the various compartments of the circulatory system. Unlike the PAC, the receiver is located at a significant distance from the injector. Consequently, a series of exponential decay curves is constructed as the injectate passes along the circulation. Since the injectate is administered centrally and the temperature difference is measured in a proximal artery, the majority of the temperature change occurs in the intrathoracic compartment. As a consequence, it is possible to measure intrathoracic blood volume and extravascular lung water. This provides an advantage of the PiCCO device over the PAC, as the volume of extravascular lung water in patients with ARDS predicts adverse outcomes.[34] Finally, the device also purports to measure global EDV, permitting the construction of Frank–Starling curves and volume titration. To date, the PiCCO system appears to correlate very well with TD techniques.[35–38]

Pulse CO LiDCO (LiDCO plus) combines pulse contour analysis with lithium dilution calibration. The major advantage of LiDCO plus is that no specialized central or arterial catheter is required. The major disadvantage of LiDCO plus is the requirement for lithium injection for the calibration of CO at least every 8 hours. Of note, in patients that are hyponatremic or have recently received neuromuscular blocking agents, the calibration may be inaccurate. As with all of these devices, data are unreliable in the setting of aortic valve disease or balloon counterpulsation therapy. Furthermore, as noted previously, other requirements must be met to mimic the conditions used for validation of the technique.

Esophageal Doppler

While application of esophageal Doppler technology has been widely used in perioperative medicine, it has made little inroads into ICUs.

Given the proximity of the thoracic aorta and esophagus, insertion of an esophageal probe using Doppler ultrasound permits measurement of aortic blood flow parameters that, when entered into an algorithm, allow derivation of SV and cardiac output. There are significant limitations with this technique, particularly in nonoperative venues. Patients must be sedated deeply to tolerate probe positioning, and there is a steep user learning curve and significant interobserver variability. In addition, the technique is contraindicated in the presence of esophageal disease, and it does not provide continuous monitoring, since the probe needs to be refocused for each measurement. Nonetheless, substantial data have been published to support use of the device in the perioperative setting as a component of goal-directed therapy.[39] In the appropriate setting, device insertion is rapid and data can be derived that are clinically useful within seconds.

Other Devices

Noninvasive cardiac output (NiCO, Novametrix, Connecticut, USA), a device that uses partial rebreathing of CO_2 to derive cardiac output using the Fick principle in mechanically ventilated patients, provides data on both respiratory mechanics and cardiac output. However, the device has not found widespread use in intensive care.

Pulse dye densitometry (Nihon, Kohden, Japan) is a technique that uses transpulmonary dye dilution and transcutaneous signal detection to measure cardiac output. The dye is injected intravenously and, although the system is relatively noninvasive, data to date are limited; the approach cannot be currently recommended.

Thoracic electrical bioimpedance is a noninvasive technique that relies on the electrical conductivity of the chest to measure cardiac output. Each cardiac contraction causes a change in transthoracic impedance that is in direct proportion to the additional volume of blood ejected (SV) and its velocity.[40] By placing multiple current-transmitting and voltage-sensing electrodes on the chest, SV can be calculated based on dynamic changes in chest impedance from baseline. The technique has not been shown to be sufficiently accurate in patients in an ICU, in large part due to electrical interference

from other equipment and body motion. Inaccuracy also results from variations in electrode placement and conductivity, operator performance, patient body habitus, and variability in electrode conductivity of skin among patients.[41]

Bioreactance, using the NICOM device (Cheetah Medical, Portland, OR), is a related methodology that has overcome many of the limitations of bioimpedance by processing the data differently. This technique measures the phase shift in voltage across the thorax. The methodology has several advantages over the others, including its noninvasive basis, lack of need for sedation or mechanical ventilation, and applicability in the setting of cardiac arrhythmias; hence, the technique is a promising one for the ICU. Studies performed in the OR, ICU, and ED have shown the technique to be accurate for measuring cardiac output and volume responsiveness, although it cannot be used in the OR while doing electrocautery.[42] Confirmatory studies, as well as outcome studies, are needed.

Echocardiography in the ICU Echocardiography in critically ill patients expands the capabilities of intensivists to more accurately and rapidly diagnose hemodynamic instability. Although expertise in echocardiography requires significant training, commitment, and experience, even basic knowledge may provide life-saving bedside diagnoses in certain conditions, such as profound hypovolemia, systolic heart failure, right heart syndromes, or pericardial tamponade.[43]

Echocardiography plays a key role in the assessment of left and right ventricular function, chamber size, and valvular dysfunction. It may be helpful in preload assessment when intravascular volume determination is difficult. Echocardiography may also be helpful in distinguishing intracardiac from intrapulmonary shunt and for diagnosing cardiac tamponade and aortic dissection.

Transthoracic Versus Transesophageal Echocardiography For the majority of critically ill patients who are hemodynamically unstable, transthoracic echocardiography (TTE) is safe, reliable, and rapidly available.[44] Image quality, due to poor or limited acoustic windows, may be an issue, but new technology, harmonic imaging, and new echo-contrast products, have significantly improved echo signal acquisition.[45] Transesophageal echocardiography (TEE) is used when views on TTE are inadequate or when clear views of the left atrium and aorta are required—such as evaluation for intra-atrial thrombus (prior to cardioversion), aortic dissection, or evaluation of prosthetic valves for evidence of endocarditis. TEE is relatively easy to perform in the ICU, as patients are usually intubated and often sedated.[46] The presence of esophageal varices, recent esophageal or gastric surgery, or an unstable cervical spine are contraindications to TEE.

Uses of Echocardiography in the ICU Application of echocardiography to the ICU setting encompasses a broad array of clinical issues, the most important of which are highlighted below.

Assessment of Ventricular Function Left ventricle (LV) dysfunction in critically ill patients is common and may be caused by ischemia, sepsis, or hyperadrenergic states (i.e., "neurogenic shock"). When the LV becomes dysfunctional, its diameter progressively increases, as does the diastolic volume-to-stroke volume ratio. As the volume of end-diastolic blood that is ejected per cycle is reduced, the "ejection fraction (EF)," expressed as a percentage, falls. EF can be reliably measured by echocardiography. MAP may appear normal despite a severe reduction in ventricular function, which may be impaired further by the use of vasopressors used to restore MAP in septic shock. The size of the ventricle is measured using either M-mode or two-dimensional (2D) techniques. Echocardiography provides an accurate description of global ventricular function and may reveal regional wall motion abnormalities, which are usually associated with myocardial ischemia.

Right ventricle (RV) dysfunction is also very common in critically ill patients. Pulmonary embolism (PE) and ARDS are main causes[47]; however, excessive mean airway pressure, fat embolism, and elevated pulmonary vascular resistance also cause increase RV afterload and RV strain. In patients presenting in shock, identifying this pathophysiology early is very important. Unlike other shock states in which excessive volume resuscitation may result in volume overload and pulmonary edema, neither of which may be life-threatening, inappropriate fluid administration in right heart failure may worsen shock and potentially lead to cardiovascular collapse. This relates directly to ventricular interdependence, wherein RV distension causes a bowing of the interventricular septum into the LV, resulting in LV systolic and diastolic dysfunction. Additional fluid boluses only exacerbate the condition; expeditious volume removal can be life-saving. These pathophysiological circumstances are relatively easy to diagnose with echocardiography and very difficult to diagnose using hemodynamic monitors. The integral parts of complete evaluation of the RV include 2D-echocardiography evaluation of RV size, shape, kinetics of the septum and RV free wall, along with assessment of severity of TR by color Doppler.

RV size is generally compared to LV size. In the four-chamber view, the ratio of RV to LV end-diastolic area is measured. A diastolic ventricular ratio >0.6 suggests moderate dilation and a ratio >1.0 severe dilatation.[48]

Evaluation of Refractory Hypoxemia and Right-to-Left Shunt Commonly seen are patients with hypoxemia despite a clear CXR, or who have pulmonary edema who fail to respond to increasing FI_{O_2} or increases in airway pressure, raising the possibility of a right-to-left shunt. Notably, the incidence of patent foramen ovale is about 30%.

In the setting of right ventricle dysfunction, RA pressure may exceed left atrial pressure, leading to opening of the foramen ovale and significant intracardiac shunt. This can be detected by intravenous injection of agitated saline as a contrast medium during echocardiography. After the injection through a peripheral or central vein, the appearance of microbubbles in the left atrium within three cardiac cycles is diagnostic of a right-to-left shunt. If microbubbles appear in the left atrium after six cardiac cycles, an intrapulmonary right-to-left shunt is suggested, for example, pulmonary AVM or hepatopulmonary syndrome.

Assessment of Cardiac Output (CO) Echocardiography may provide a relatively reliable measure of SV and, hence, CO.[49] The most common technique for measuring CO using echocardiography is Doppler-derived instantaneous blood flow measurement through a conduit (LV outflow tract or pulmonic or mitral valve). SV is equal to the product of cross-sectional area (CSA) of the conduit, determined by 2D echo, and the integral of instantaneous blood flow or velocity–time integral (VTI) through the conduit:

$$\text{CSA} = \text{diameter of conduit (D)}^2 \times (\pi/4)$$
$$\text{SV} = \text{CSA} \times \text{VTI}$$
$$\text{SV} \times \text{HR} = \text{CO}$$
$$\text{CO} = \text{CSA} \times \text{VTI} \times \text{HR}$$

Evaluation of Volume Status Echocardiography may be helpful in estimating volume status or fluid responsiveness. If there is inadequate preload, the left ventricle may appear to collapse during systole ("obliteration"). Echo may also help demonstrate whether inadequate LV filling results from RV dysfunction. Conversely, the finding of acute or chronic ventricular dilatation, defined by LV end-diastolic diameter, does not rule out volume responsiveness.[50] Thus, there are two other echocardiographic techniques that have been used to evaluate fluid responsiveness in mechanically ventilated patients: The *collapsibility index* of the SVC, and respiratory variation in inferior vena cava diameter (i.e., the *distensibility index*).[51–53] Measurement of IVC diameter can be challenging in obese patients,

and its utility is limited in the setting of intra-abdominal hypertension. Accurate SVC measurements require a TEE. In addition neither measurement can be performed continuously.

RESPIRATORY MONITORING

A variety of methods may be employed in monitoring ventilatory and gas exchange functions of the lung, respiratory mechanics, and respiratory muscle strength. Each is described below.

METHODS FOR MONITORING RESPIRATORY FUNCTION

A number of respiratory parameters are routinely monitored in patients with ARF and are discussed subsequently.

Oxygenation

In the ICU, oxygenation is generally monitored using pulse oximetry, arterial blood gas analysis, and, occasionally, transcutaneous methods.

Pulse Oximetry Pulse oximeters are universally deployed in the monitoring of perioperative and critically ill patients. Unique as monitoring devices, they provide useful data regarding oxyhemoglobin saturation (Sp_{O_2}), heart rate, pulse volume, and tissue perfusion.

Pulse oximeters use the spectrophotometric characteristics of pulsatile arterial blood to determine oxygen saturation and heart rate. Oxygenated blood absorbs light at 660 nm (red light), while deoxygenated blood absorbs light preferentially at 940 nm (infrared light). The oximeter consists of two light-emitting diodes (wavelengths, 600 nm and 940 nm) and two light-collecting sensors that measure the amount of red and infrared light emerging from tissues traversed by the light rays. The relative light absorption by oxyhemoglobin and deoxyhemoglobin is analyzed by the device and an oxygen saturation is calculated. The sensing function of the device is directed at pulsatile arterial blood, while local "noise" arising from the tissues is ignored. The result is a continuous qualitative measurement of oxyhemoglobin saturation.

The use of pulse oximetry has not been shown to improve clinical outcomes, but epidemiological data have demonstrated a significant reduction in anesthesia-related morbidity. Although the technique accurately predicts arterial oxygen tension, the relationship between Pa_{O_2} and Sp_{O_2} is nonlinear, as dictated by the oxyhemoglobin dissociation curve. Accuracy falls off substantially at low-oxygen tensions, and saturation readings of less than 80% cannot be used reliably to guide oxygen therapy.

A new generation of rapid oximeters has promised more accurate breath-to-breath analysis of oxygenation and the potential for using the pulse waveform to measure PPV. To date, no positive outcome data have been published.[54]

The use of pulse oximeters is limited by a number of factors. The devices are designed to measure levels of oxygenated and deoxygenated hemoglobin, but no provision is made for measurement error in the presence of dyshemoglobinemias, including carboxyhemoglobinemia and methemoglobinemia. Since carboxyhemoglobin absorbs red light, conventional oximeters cannot distinguish oxy- from carboxyhemoglobin. In clinical situations in which carbon monoxide poisoning is suspected, co-oximetry is essential. Co-oximeters measure reduced hemoglobin, oxyhemoglobin, carboxyhemoglobin, and methemoglobin.

An additional source of error in using oximeters is abnormal patient movement (e.g., due to agitation). Low blood flow, hypotension, vasoconstriction, or hypothermia reduce pulsatility of capillary blood, resulting in underreading or no reading of oxygen saturation. Conversely, increased venous pulsation, such as occurs with TR, may result in an erroneously low reading by the device. Finally, oximetry-determined saturation is inaccurate on the steep part of the oxyhemoglobin dissociation curve. While the *trend* between directly measured arterial saturation and Sp_{O_2} appears accurate, the correlation between the two is not; a drop in Sp_{O_2} below 90% must be considered a potentially significant clinical event.

Arterial Blood Gases Blood gas analyzers have been available for 45 years and provide accurate measurement of Pa_{O_2}, Pa_{CO_2}, and pH. From these primary determinations, a number of parameters are calculated, including serum bicarbonate, base deficit or base excess, and oxyhemoglobin saturation.

Through application of the alveolar gas equation (see Chapters 14 and 33), arterial blood-gas analysis is used commonly in calculating the alveolar–arterial oxygen gradient, a number that reflects the severity of ventilation–perfusion abnormalities. A significant limitation of the alveolar–arterial oxygen gradient is that it varies directly with FI_{O_2}; consequently, changes in the value may not reflect changes in the underlying disease process. An alternative calculation – the ratio of Pa_{O_2} to FI_{O_2}, ("PF ratio"), which does not vary with FI_{O_2} – has been used as a measure permitting comparisons of gas exchange at differing levels of FI_{O_2}.

The PF ratio has been incorporated into consensus definitions of ARDS. A PF ratio ≤200 defines ARDS.[55] Neither the alveolar–arterial oxygen gradient nor the PF ratio takes into account differences in mean airway pressure. Although comparisons using the PF ratio would be more accurate if arterial blood was sampled uniformly at end expiration and in the absence of PEEP, clinical constraints may preclude such sampling conditions.

Ventilation

Clinical assessment of CO_2 metabolism is usually considered with regard to the amount of gas that is dissolved in plasma (Pa_{CO_2}), the amount present in the exhaled tidal volume, and the total extracellular content (total CO_2 or bicarbonate concentration). In the setting of respiratory failure, these measurements provide information on adequacy of ventilation, percentage of physiological dead space, acid–base balance, and nutritional status.

In progressive chronic respiratory failure, as the ability to eliminate CO_2 declines, total body CO_2 stores (bicarbonate) increase. The ratio of total CO_2 to bicarbonate concentration provides an indication of the acuity of the respiratory failure (Table 147-2).

Changes in Pa_{CO_2} may also be related to changes in base deficit or excess[56]:

$$SBEc = (HCO_3^- - 24.4) + ([8.3 \times \text{albumin g/dL} \times 0.15] + [0.29 \times PO_4^{2-}\ \text{mg/dL} \times 0.32]) \times [\text{pH} - 7.4])$$

where SBEc = standardized base excess corrected for weak acids (albumin and phosphate)

Assessment of CO_2 elimination forms the basis of calculating the ratio of dead space to tidal volume—a useful physiological construct in gauging the severity of underlying lung disease in respiratory failure. Through application of the modified Bohr equation (see Chapter 14), the ratio of dead space to tidal volume (V_D/V_T) is calculated in Equation 3 as follows:

$$V_D/V_T = (Pa_{CO_2} - PE_{CO_2})/Pa_{CO_2} \quad (3)$$

Where PE_{CO_2} is mean expired CO_2. PE_{CO_2} can be measured using a metabolic monitor that collects expired gas over 5 minutes. Alternatively, main stream or side stream capnometry can be used to measure PE_{CO_2}.

TABLE 147-2 Changes in Pa_{CO_2} and $[HCO_3^-]$ in Response to Acute and Chronic Acid–Base Disturbances

Disturbance	$[HCO_3^-]$ versus Pa_{CO_2}
Acute respiratory acidosis	$\Delta HCO3^- = 0.2\ \Delta\ Pa_{CO_2}$
Chronic respiratory acidosis	$\Delta HCO3^- = 0.5\ \Delta\ Pa_{CO_2}$

$[HCO_3^-]$, concentration of bicarbonate ion; Pa_{CO_2}, partial pressure of arterial carbon dioxide; Δ, change in value.

In the normal lung, alveolar P_{CO_2} is equivalent to Pa_{CO_2} and can be estimated by sampling expired end-tidal gas. However, in the presence of significant physiological dead space (as in ARF), end-tidal CO_2 ($P_{ET}CO_2$) grossly underestimates Pa_{CO_2}. However, $P_{ET}CO_2$ remains useful in monitoring the adequacy of ventilation, particularly in "spontaneously breathing patients" who are receiving conscious sedation. There is renewed interest in using $P_{ET}CO_2$ as a measure of the adequacy of the circulation during CPR. In addition, recent data suggest that $P_{ET}CO_2$ can be used to assess fluid responsiveness, as indicated by an increase in $P_{ET}CO_2$ following a fluid bolus or straight leg raise.[57]

Endotracheal Tube Placement

For the intubated patient it is important to monitor the position of the ETT. An extremely common complication of intubation is misplacement of the ETT, with passage into the right main bronchus. Ideally, the ETT tip should be located between 2 and 5 cm above the carina. In the case of a tracheostomy, the tube tip should be located about halfway between the tracheotomy stoma and carina.

ETT placement may be confirmed in several ways: (1) By assessing for the presence of bilateral breath sounds during breath delivery, (2) by palpation of the ETT cuff in the jugular notch, (3) using chest radiography, (4) using fiberoptic bronchoscopy, or (5) determining the presence of $P_{ET}CO_2$ using either capnometry or capnography.

The pressure within the ETT cuff should also be measured regularly. The cuff is inflated to create a seal between the side wall of the ETT and the tracheal wall. Since capillary perfusion pressure of the tracheal mucosa is approximately 25 cm H_2O, cuff pressure should be kept below this level to prevent mucosal ischemia, which may lead to ulceration, inflammation, and, if severe, tracheal dilatation. In addition, the injured tracheal segment may develop fibrosis and, ultimately, stenosis. On the other hand, evidence exists that low cuff pressures may increase the risk of pneumonia, presumably by promoting microaspiration. Thus, the current recommendation for optimal tracheal cuff pressure is 20 to 25 cm H_2O.[58]

Following intubation and ETT positioning, the tube cuff should be slowly and progressively inflated just to the point of loss of gas leak occurring with ventilation—the so-called "minimal occluding pressure" technique (some experts advocate use of the "minimal leak" technique). To measure cuff pressure, an aneroid manometer is connected to the cuff's pilot tube (the tube from which the balloon is inflated). If excessive cuff pressure is required to maintain an adequate tracheal seal, the ETT is likely too narrow for the patient's trachea. If cuff pressure increases over time, tracheomalacia should be suspected and the tube changed to a longer one or one with a foam cuff, to alleviate the pressure on the malacic segment.

The presence of a cuff leak may be problematic, particularly in patients who are critically ill. Signs of leak include an audible noise during inspiration, audible patient phonation, frothy mouth secretions with each breath, a difference between set and exhaled tidal volumes, inadequate ventilatory volumes, hypoxemia, and the presence of a thrill over the trachea. Cuff leaks may be caused by rupture or herniation of the cuff, proximal displacement of the ETT, pilot tube valve malfunction, or inadvertent cuff deflation.[59]

■ RESPIRATORY SYSTEM MECHANICS

Assessment of respiratory system mechanics is useful in differentiating the etiology of ARF (e.g., restrictive vs. obstructive disease or upper vs. lower airway obstruction), troubleshooting the cause of new episodes of clinical instability, assessing the effectiveness of therapeutic interventions (e.g., use of bronchodilators or application of PEEP), or minimizing the risk of ventilator-induced lung injury. These measurements are most reliable when patients are being ventilated passively, which is now much less common, as current best practice has shifted to providing the least sedation necessary for comfort and ventilator synchrony. Thus, in addition to their routine and as-needed measurement, mechanics should always be assessed immediately following intubation, while patients are unconscious or paralyzed, to help clarify the underlying initial pathophysiology. If subsequent measurements are thwarted by patient efforts, ventilator adjustments to minimize ventilator drive should be attempted. In addition, in extreme cases in which diagnosis is essential, transient high-dose sedation and even paralysis may be necessary.

Airway Pressure

Airway pressure is an important variable monitored routinely during mechanical ventilation. Respiratory pressures are usually referenced to atmospheric pressure ("single-ended" pressures). Electromechanical transducers (or aneroid manometers), that convert pressure to electrical current, may be located in the patient's ventilator circuit or esophagus. The most common site of pressure transduction is the wye connector (the connector that joins the inspiratory and expiratory limbs of the ventilator circuit), although the distal ETT can also be used. Pressure measured within the ventilator or ventilator circuit is referred to as "airway pressure," P_{AW} (or, more correctly, airway opening pressure, P_{AO}), while that measured at the tip of the ETT is referred to as "tracheal pressure," P_{TR}. Pressure measured within the esophagus is referred to as "esophageal pressure," P_{ES}.

Five different pressure measurements are commonly made during the respiratory cycle: (1) Peak airway pressure (P_{PEAK}), (2) plateau pressure (P_{PLAT}), (3) mean airway pressure (P_{MEAN}), (4) PEEP, and (5) auto-PEEP (also called intrinsic PEEP). Measurement of tracheal pressure at the tip of the distal ETT provides an assessment of pressure in the native airway, as the effect of flow through the ETT is eliminated. Esophageal pressure provides an estimate of pleural pressure. Although not used routinely in clinical practice, esophageal pressure can be used to estimate transpulmonary pressure, which is a more accurate measure of alveolar distending pressure than is plateau pressure.

Accurate measurement of airway resistance requires that airway pressures be determined using constant flow conditions (i.e., a square flow–wave profile) (Fig. 147-2). Most modern ventilators make the flow–wave profile adjustment automatically when the "mechanics function" of the device is selected. In addition, since airway pressures are altered by respiratory muscle contraction, patients must be fully relaxed and exert minimal breathing effort. These conditions may be accomplished by using ventilator settings designed to fully support the patient (e.g., by providing a level of ventilatory support that

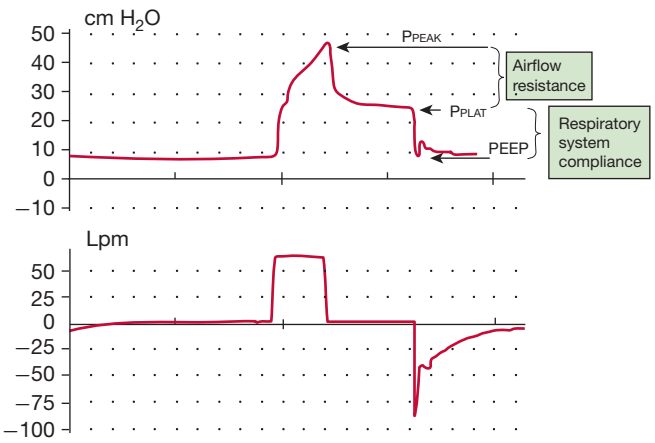

Figure 147-2 Inspiratory hold maneuver during constant flow in a volume-controlled breath. Note the significant difference between the patient's peak airway pressure (48 cm H_2O) and plateau pressure (26 cm H_2O), indicative of increased airway resistance.

exceeds patient demand, or administration of sedation). For quality control, ventilator waveforms should be assessed during the mechanics maneuver to ensure the conditions have been met.

P_{PEAK} represents the total pressure the ventilator must generate to overcome the impedance of the respiratory system, including airflow resistance, elastic load (lung and chest wall distention), and any threshold load due to dynamic hyperinflation (DHI; from auto-PEEP). When interpreting P_{PEAK}, in addition to impedance, several other factors must be considered, including peak flow rate, waveform profile (square or decelerating), and tidal volume. This is a very important point in clinical practice, since P_{PEAK} may erroneously be considered as the primary determinant of barotrauma. When a high P_{PEAK} is observed (as commonly seen in obstructive lung diseases), an attempt to lower P_{PEAK} by reducing inspiratory flow rate may achieve the opposite effect. The risk of barotrauma may be increased by the resulting increment in plateau pressure that occurs as a consequence of reduced expiratory time and increased auto-PEEP.

P_{PLAT} reflects the pressure within the alveoli at end inhalation and is the most important pressure to monitor in preventing barotrauma. The goal P_{PLAT} is ≤30 mm Hg in all cases of ARF, including those due to obstructive airway disease.[60] P_{PLAT} is measured at end inspiration during a period of zero flow, which is achieved by applying an inspiratory "hold" during volume-controlled ventilation (Fig. 147-5). P_{PLAT} is always lower than P_{PEAK} by an amount equal to the pressure required to drive inspiratory flow through the ventilator circuit, ETT, and airways.

For the patient with a high P_{AW}, clinician can determine rapidly whether the problem is resistive (airway) or elastic (lung or chest wall) in nature by assessing the pressure gradient between P_{PEAK} and P_{PLAT} and between P_{PLAT} and total PEEP (set PEEP plus auto-PEEP) (Fig. 147-2). For instance, if the differential between P_{PEAK} and P_{PLAT} increases, airflow resistance must have increased; potential causes include bronchospasm, a kink in the ETT, and increased airway secretions. In contrast, if the rise in P_{AW} is unaccompanied by an increase in the $P_{PEAK} - P_{PLAT}$ pressure gradient (i.e., both P_{PEAK} and P_{PLAT} increase relative to total PEEP), the elastic load must have increased; causes include loss of lung volume (e.g., right main bronchus intubation; lobar atelectasis; or an alveolar filling process, such as pneumonia or CHF) or a stiffer chest wall apparatus (e.g., pleural effusion or intra-abdominal hypertension).[61]

These routinely measured airway pressures are also used to calculate additional important measures of respiratory mechanics, including airway resistance and respiratory compliance. Dividing the $P_{PEAK} - P_{PLAT}$ pressure gradient by inspiratory flow rate yields *airway resistance*. The normal value depends on the size of the ETT, but it is typically about 5 to 15 cm H_2O/L/s.

Respiratory system compliance, expressed as mL/cm H_2O, is calculated as tidal volume divided by the difference between P_{PLAT} and total PEEP. Failure to consider auto-PEEP in the calculation results in overestimation of compliance. Normal respiratory system compliance is >60 mL/cm H_2O.

Auto-PEEP

Auto-PEEP (also known as "intrinsic" PEEP) refers to the positive pressure within alveoli at end expiration that has not been generated by a ventilator.[62] A form of naturally occurring auto-PEEP may be observed with forced exhalation that occurs during heavy exercise. This is also commonly observed in mechanically ventilated patients (Fig. 147-3) with increased respiratory drive. In this case, lung mechanics may be normal, and expiratory muscle force maintains positive intrathoracic and airway pressures throughout expiration; functional residual capacity (FRC) may be normal or decreased.

In contrast, two other types of auto-PEEP are associated with DHI. In one, auto-PEEP results from a high minute ventilatory requirement, as occurs in ARDS, where insufficient expiratory time

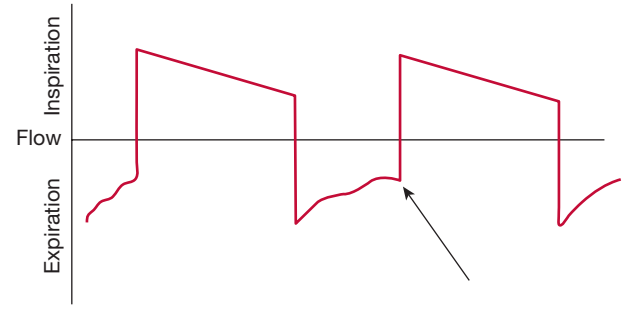

Figure 147-3 The presence of auto-PEEP is identified from the flow waveform. The next breath commences before expiratory flow returns to zero.

promotes incomplete expiration before delivery of the next breath. In the other, more common variety, auto-PEEP results primarily from delayed emptying of alveoli due to expiratory airflow obstruction, as most commonly seen in status asthmaticus or chronic obstructive pulmonary disease (COPD). These two obstructive syndromes have different pathophysiological mechanisms, which impact potential therapeutic interventions. In COPD due to emphysema, DHI results from flow limitation, which is not generally a feature of asthma or other obstructive states.

The development of auto-PEEP is determined by three factors: Tidal volume, expiratory time, and the respiratory system expiratory time constant (the product of resistance and compliance). Auto-PEEP poses significant problems in pressure-targeted mechanical ventilation, where the additional PEEP reduces ventilator-driving pressure, and consequently, tidal volume. In contrast, in volume-targeted ventilation, auto-PEEP causes P_{AW} and P_{PLAT} to increase, which, in turn, increase end-inspiratory lung volumes and alveolar "stretch."

In a mechanically ventilated patient, auto-PEEP is most easily identified by examining the expiratory flow waveform to see if flow fails to return to zero before initiation of the next breath (Fig. 147-3). It is important, however, to first rule out active expiratory effort as the cause (no DHI) as that is treated differently from the other causes of auto-PEEP. Visual inspection or palpation of the abdominal muscles is usually diagnostic. Quantification of the magnitude of auto-PEEP is achieved by implementing an "expiratory hold" maneuver, during which equilibration of pressure is achieved throughout the ventilator circuit (Fig. 147-4). A mechanically

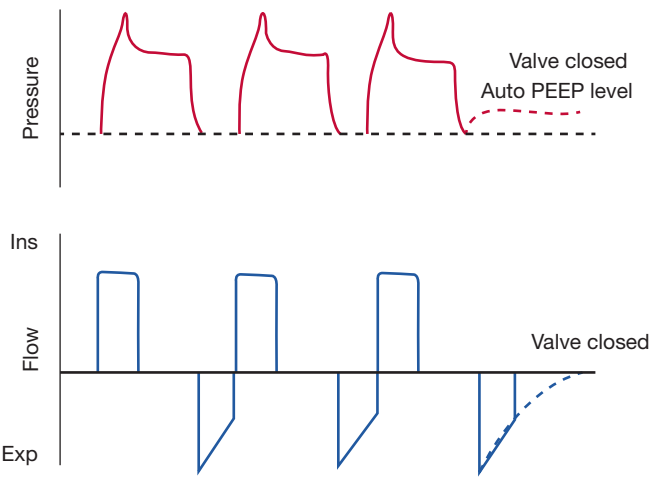

Figure 147-4 Expiratory hold technique to quantify auto-PEEP. The expiratory valve is closed during an expiratory "hold" at the end of a set expiratory time. When flow equals zero, airway pressure rises to the auto-PEEP level.

ventilated patient who is generating spontaneous breaths presents a challenge for measurement of auto-PEEP, as airway occlusion usually incites increased respiratory drive. Under these circumstances, heavy sedation and/or paralysis may be required to obtain accurate recordings.

Esophageal Pressure

Measurement of respiratory system compliance includes the mechanical properties of the lung *and* chest wall. By measuring pleural pressure, the transmural distending pressure of the lung can be calculated. Although regional variation in pleural pressure exists, measurement of lung compliance is based on the *change* in pleural pressure, rather than its absolute value.

Pleural pressure is usually estimated from esophageal pressure, which is recorded using an esophageal catheter. The typical device consists of a latex balloon which is 10 cm long and has several holes. The catheter is inserted into the lower esophagus (usually to a depth of about 40 cm). At this level, artifact from the beating heart is minimized. The adequacy of esophageal balloon positioning is confirmed by having the patient perform inspiratory attempts against an occluded airway. The esophageal pressure changes should be equal (±10%) to airway pressure changes. In the paralyzed patient, external chest compressions are used to create pressure fluctuations. Esophageal pressure has been validated in a small trial of patients with ARDS as a means of determining optimal transpulmonary pressure.[63] Given the complexities involved in employing these catheters, they will likely remain a research tool until more studies show that their use can impact favorably on patient outcomes.

Ventilator Waveforms

Mechanical ventilators all have a spirometer or flow monitor to measure the volume and flow of gas passing through the ventilator circuit with each breath. Data are analyzed by a microprocessor in the ventilator and are graphically represented as waveforms. The most commonly displayed waveforms include pressure, flow, and volume versus time. Plots of flow versus volume (flow–volume loops) and pressure versus volume can be constructed electronically from the measurements, although they do not provide unique information. Monitoring of ventilator waveforms provides useful information about patient–ventilator synchrony, (Fig. 147-5) circuit leaks, patient–ventilator disconnection, development of auto-PEEP, (Fig. 147-3) and airway obstruction.[64]

Pressure versus Time This waveform is usually evaluated first and is most useful in volume-cycled modes, where pressure is the dependent variable. This waveform provides information about whether the patient is initiating breaths (negative deflection prior to inhalation), how much work is required to trigger the ventilator (how negative the trigger deflection is), whether there is sufficient flow during inhalation to meet patient demand (degree of scooping or downward deflection from the usual waveform contour expected during inhalation of a passively breathing patient), and how the prescribed duration of inhalation compares to the patient's neural inspiratory time (airway pressure rise at end exhalation suggests it is too long and "double triggering" suggests it is too short). The inspiratory and expiratory hold maneuvers are evaluated on this waveform to determine resistance and compliance and to quantitate auto-PEEP. Finally, in volume-cycled ventilation, the shape of this curve during inhalation – using a constant flow waveform – may reveal whether the prescribed tidal volume is causing overdistension (concave up), tidal recruitment (concave down), or neither (linear).[65]

Flow versus Time Since flow rate and pattern are set by the clinician in volume-cycled modes, this waveform is most useful in pressure preset modes, for example, pressure control and pressure support, where flow is the dependent variable. In these modes, flow at end inspiration

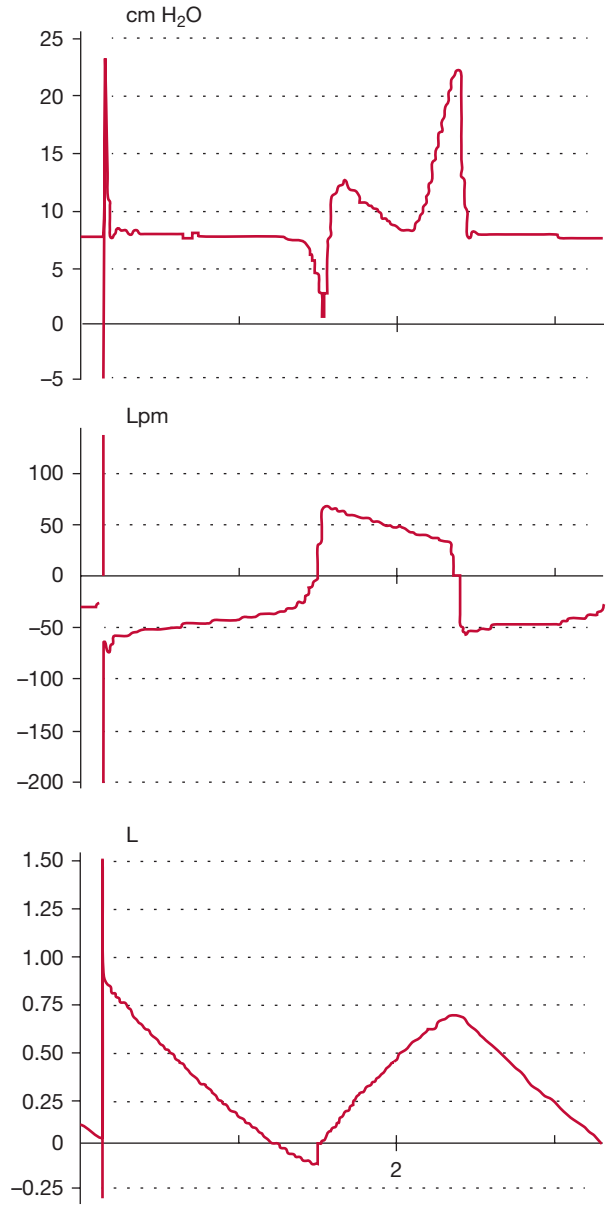

Figure 147-5 Patient-ventilator dyssynchrony during volume-controlled ventilation, secondary to inadequate flow.

helps in determining the most appropriate inspiratory time. In pressure control, where inspiratory time is set, flow should cease immediately prior to exhalation. If not, this can guide subsequent adjustments in inspiratory time. In pressure support, where inspiratory time is variable, flow may fail to fall sufficiently to trigger exhalation, which is typically set at 25% of the peak flow. This is not uncommon in COPD, where inspiratory flow fails to fall sufficiently as alveolar pressure remains low throughout inhalation due to the high lung compliance. To troubleshoot, the expiratory sensitivity setting can be increased to trigger expiration at a much higher end inspiratory flow rate.

For the expiratory limb of the flow versus time waveform, it is important to evaluate whether flow ceases prior to the next inhalation; and if not, auto-PEEP is present. The expiratory hold maneuver will allow quantitation of the auto-PEEP, but it is imperative to first rule out active expiratory effort as the cause.

RESPIRATORY MUSCLE STRENGTH

Respiratory muscle strength may be assessed by measuring maximum inspiratory and expiratory pressures generated against an

occluded airway. This is most easily measured using an aneroid manometer.

Inspiratory strength is measured at FRC, where the length–tension relationship of the inspiratory muscles is optimal. The pressure determined by this maneuver is known as the negative inspiratory force (NIF) or maximal inspiratory pressure (MIP). Clearly, the measurement is dependent on the intensity of the inspiratory effort, which may be suboptimal in uncooperative or unconscious patients. This problem can be circumvented by performing the maneuver off the ventilator, using a one-way valve; the NIF is measured over 10 sequential breaths or 30 seconds. With recurrent efforts over time using the one-way valve, progressively lower lung volumes are reached and the inspiratory drive increases progressively, promoting a maximal effort.[66] Although the utility of the NIF as a predictor of weaning outcome has fallen out of favor, it remains a useful measurement in troubleshooting reasons for ventilator dependence.

Maximal expiratory pressure (MEP) is measured at total lung capacity, where the expiratory muscle length–tension relationship is optimal. Although not routinely employed in clinical practice, MEP may be useful in predicting extubation outcome in selected patient populations.

CHAPTER 148

Principles of Mechanical Ventilation

Martin J. Tobin

The historical evolution of mechanical ventilation is rich and built on advances in many fields, including endeavors by anatomists, chemists, explorers, physiologists, and clinicians.[1] In 1543, Vesalius demonstrated that positive-pressure ventilation could be used to resuscitate a dying animal. Bellows ventilation was advocated by various lay bodies in the resuscitation of near-drowning victims late in the 18th century. In 1827, however, Leroy demonstrated that overzealous bellows inflation could result in pneumothoraces. Official bodies condemned the technique, and, thus, early in its infancy, positive-pressure ventilation was banned from use. Around this time, negative-pressure ventilators were developed and later popularized as a panacea for a wide variety of ailments.

The modern era of mechanical ventilation was ushered in by Bjorn Ibsen in response to epidemic of bulbar poliomyelitis in Copenhagen in 1952. In the first 3 weeks of the epidemic, 31 patients had been treated with negative-pressure respirators, and 27 had died. Ibsen advised immediate tracheostomy and the use of positive-pressure ventilation with manual positive pressure from a rubber bag, as was then customary in the operating room. Hundreds of medical students worked in relays, delivering bag ventilation during the epidemic; shortly thereafter, machines were introduced to deliver positive-pressure ventilation. Over the following 40 years, ventilators changed enormously in appearance, becoming more sophisticated and versatile and having enhanced capabilities for monitoring and alarming.

OBJECTIVES AND INDICATIONS FOR MECHANICAL VENTILATION

The objectives of mechanical ventilation are listed in Table 148-1.[2] In isolation, hypoxemia of mild-to-moderate severity can be managed by administration of oxygen (O_2) through a face mask. With more severe hypoxemia secondary to shunt or ventilation–perfusion $\dot{V}_A/\dot{Q}$ mismatching, it is difficult to guarantee the delivery of a high fractional inspired oxygen concentration ($F_{I_{O_2}}$) through a face mask. Moreover, these patients are commonly in considerable distress. Thus, intubation helps by ensuring delivery of the required $F_{I_{O_2}}$, and positive-pressure ventilation helps by recruiting collapsed lung units, leading to improved matching of ventilation and perfusion.

TABLE 148-1 Objectives of Mechanical Ventilation

Improve pulmonary gas exchange
Reverse hypoxemia
Relieve acute respiratory acidosis
Relieve respiratory distress
Decrease oxygen cost of breathing
Reverse respiratory muscle fatigue
Alter pressure–volume relationships
Prevent or reverse atelectasis
Improve lung compliance
Prevent further lung injury
Permit lung and airway healing
Avoid complications

Source: Reproduced with permission from Tobin MJ. Mechanical ventilation. N Engl J Med. 1994;330(15):1056–1061.

Acute progressive respiratory acidosis is a major indication for mechanical ventilation, although simpler measures can sometimes reverse the process.[3] For example, among patients with acute severe asthma and hypercapnia, hypercapnia resolves with standard bronchodilator therapy, without the need for mechanical ventilation, in more than 90% of patients.[4] If a patient has severe respiratory depression that is expected to be slow in resolving (e.g., certain drug overdoses), intubation and mechanical ventilation should be instituted without delay.

A substantial proportion of patients who require (and benefit from) mechanical ventilation have relatively normal arterial blood gases but have clinical signs of increased work of breathing: nasal flaring; vigorous activity of the sternomastoid muscles; tracheal tug; recession of the suprasternal, supraclavicular, and intercostal spaces; paradoxical motion of the abdomen; and pulsus paradoxus. This picture of a patient "tiring out" is the most common reason for instituting mechanical ventilation. The increase in work of breathing may be the result of increased airway resistance, increased stiffness of the lungs or chest wall, or the presence of a threshold inspiratory load secondary to auto- or intrinsic positive end-expiratory pressure ($PEEP_i$).

Increased respiratory work increases the O_2 cost of breathing to as much as 50% of total O_2 consumption.[5] By decreasing respiratory work, mechanical ventilation allows precious O_2 stores to be rerouted to other vulnerable tissue beds. To substantially reduce patient effort, the ventilator must cycle in unison with the patient's central respiratory rhythm (Fig. 148-1). For perfect synchronization, the period of mechanical inflation must match the period of neural inspiratory time (the duration of inspiratory effort), and the period of mechanical inactivity must match the neural expiratory time.[6] Work of breathing is increased in patients with atelectasis or acute lung injury because breathing occurs on the low, flat portion of the pressure–volume curve. By shifting tidal ventilation to the steep, compliant portion of the curve, mechanical ventilation can decrease respiratory work.

Commonly listed indications for mechanical ventilation include acute respiratory failure, exacerbation of chronic respiratory failure (e.g., secondary to infection, bronchoconstriction, or heart failure), coma, and neuromuscular disease. Many patients with these same conditions, however, do not require ventilator assistance. Indeed, the most common, and honest, reason that mechanical ventilation is instituted is a tautology: A physician thinks that "the patient looks like he (or she) needs to be placed on the ventilator."[7] Mechanical ventilation is most commonly instituted based on a physician's clinical gestalt, formed through assessing a patient's signs and symptoms, rather than because a patient satisfies a certain set of criteria on a checklist. It is important to ground this decision on solid knowledge of pulmonary pathophysiology.

MODES OF MECHANICAL VENTILATION

The term *mode* refers to the relationship among various breath types (mandatory, assisted, supported, and spontaneous), as well as inspiratory phase variables.

CONTROLLED MECHANICAL VENTILATION

In controlled mechanical ventilation, the ventilator delivers all breaths at a preset rate, and the patient cannot trigger the machine.

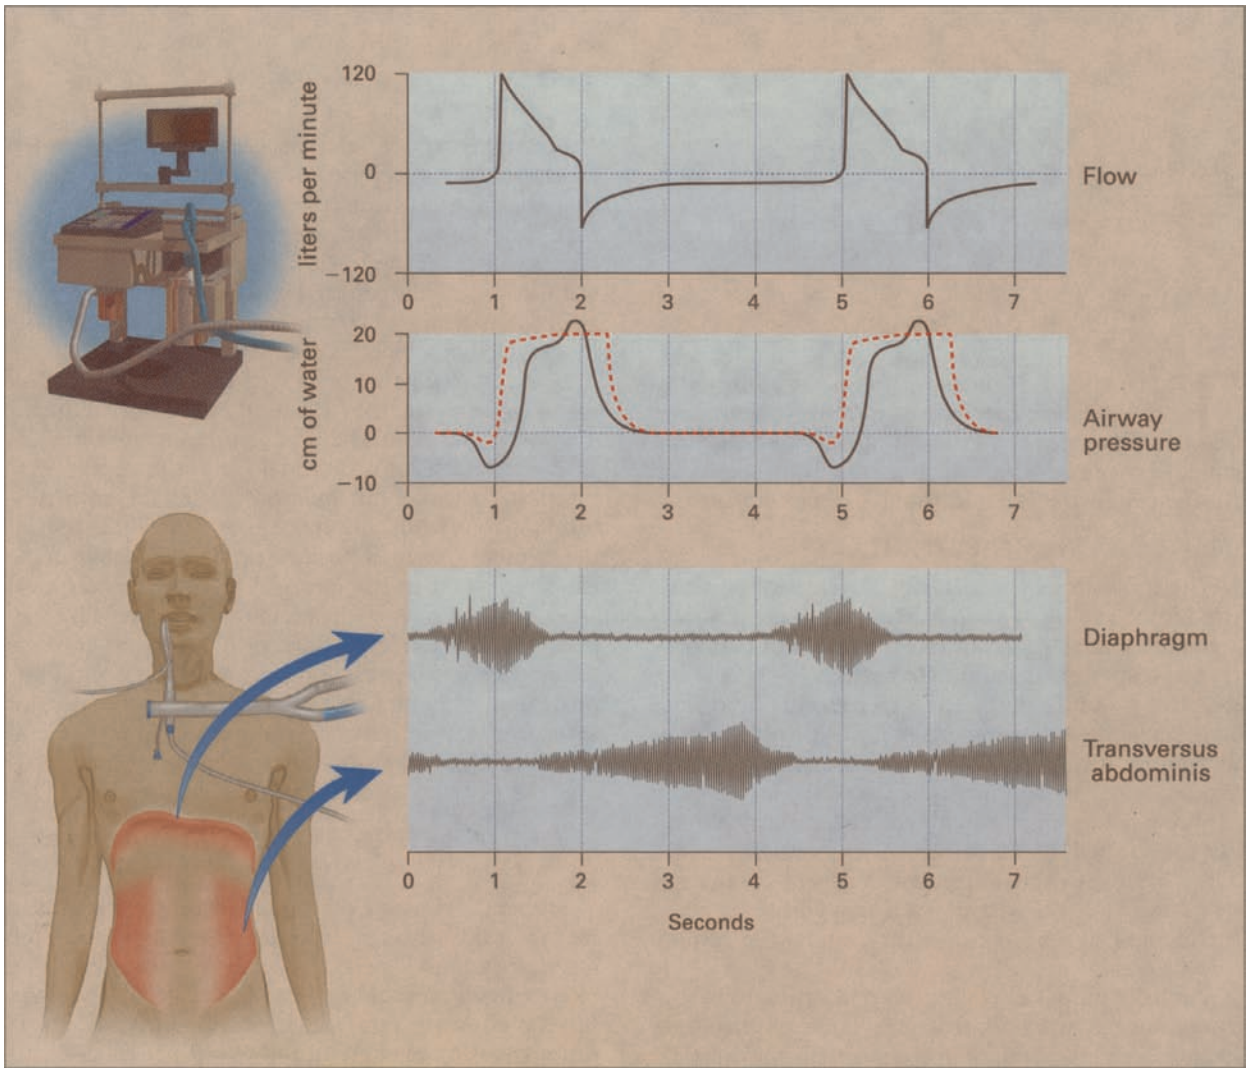

Figure 148-1 Flow, airway pressure, and inspiratory and expiratory muscle activity in a patient with chronic obstructive pulmonary disease who received pressure-support ventilation at an airway pressure of 20 cm H_2O. The electromyograms in the lower portion of the figure show inspiratory muscle activity in the patient's diaphragm and expiratory muscle activity in the transversus abdominis. The patient's increased inspiratory effort caused the airway pressure to fall below the set sensitivity (−2 cm H_2O), and inadequate delivery of flow by the ventilator resulted in a scooped contour on the airway–pressure curve during inspiration. While the ventilator was still pumping gas into the patient, his expiratory muscles were recruited, causing a bump in the airway–pressure curve. That the flow never returned to zero throughout expiration reflected the presence of $PEEP_i$. The broken red line shows airway pressure in another patient, who generated just enough effort to trigger the ventilator and in whom there was adequate delivery of gas by the ventilator. *(Data are from Jubran A, Van de Graaff WB, Tobin MJ. Variability of patient-ventilator interaction with pressure support ventilation in patients with chronic obstructive pulmonary disease. Am J Respir Crit Care Med. 1995;152:129–136; Parthasarathy S, Jubran A, Tobin MJ. Cycling of inspiratory and expiratory muscle groups with the ventilator in airflow limitation. In the volume-targeted mode, the breaths have a preset volume—the so-called volume-controlled ventilation. When the breaths are pressure limited and time cycled, the mode is termed *pressure-controlled* ventilation. Use of volume-controlled ventilation is largely restricted to patients who are apneic as a result of brain damage, sedation, or paralysis.

■ ASSIST–CONTROL VENTILATION

In the assist–control mode, the ventilator delivers a breath either when triggered by the patient's inspiratory effort (pressure or flow triggered) or, independently, if such an effort does not occur within a preselected time period.[8] All breaths are delivered under positive pressure by the machine, but unlike controlled mechanical ventilation, the patient's triggering effort can exceed the preset rate. If the patient's spontaneous rate drops below the preset back-up rate, controlled ventilation is provided. The breath delivered by the ventilator may have a predetermined volume (volume-cycled form of assist–control ventilation) or a predetermined inflation pressure that is applied for a predetermined inflation time (pressure control form of assist–control ventilation). By design, delivered tidal volume is not influenced by patient effort. The greater the inspiratory effort made by the patient, the lower will be the airway pressure during the volume-cycled form of assist–control ventilation, such that the overall airway pressure on the ventilator monitor bears an inverse relationship to patient-generated pressure.

The ventilator cycles off when the preset tidal volume is reached, and machine inspiratory time may be shorter or longer than the patient's intrinsic (neural) inspiratory time.[6] If the set tidal volume

is reached before the end of neural inspiratory time, the machine cycles off while the patient's inspiratory effort continues. If the patient's inspiratory effort ceases before the set tidal volume is reached, the machine increases pressure to provide continued inspiratory flow. The amount of active work performed by a patient ventilated in the assist–control mode is critically dependent on the trigger sensitivity and inspiratory flow settings. Even when these settings are selected appropriately, patients actively perform about one-third of the work performed by the ventilator during passive conditions.[9]

INTERMITTENT MANDATORY VENTILATION

With intermittent mandatory ventilation (IMV), the patient receives periodic positive-pressure breaths from the ventilator at a preset volume and rate, but the patient can also breathe spontaneously between these mandatory breaths.[10] A problem unforeseen at the time IMV was introduced is the difficulty that patients encounter in trying to adapt to the intermittent nature of ventilator assistance. It had been assumed that the degree of respiratory muscle rest achieved by IMV would be proportional to the number of mandatory breaths delivered. Studies, however, have demonstrated that inspiratory effort is equivalent for spontaneous and assisted breaths during IMV (Fig. 148-2).[11,12] Indeed, the tension-time index for both spontaneous and assisted breaths is above the threshold associated with respiratory muscle fatigue at IMV rates of 14 breaths/min or less.[11] At a moderate level of machine assistance (at which the ventilator accounts for 20% to 50% of total ventilation), electromyographic activity of the diaphragm and sternocleidomastoid muscles is equivalent for assisted and spontaneous breaths.[12] These findings suggest that respiratory center output is preprogrammed and does not adjust to breath-to-breath changes in load, as occurs during IMV. As a result, IMV may contribute to development of respiratory muscle fatigue or prevent its recovery.

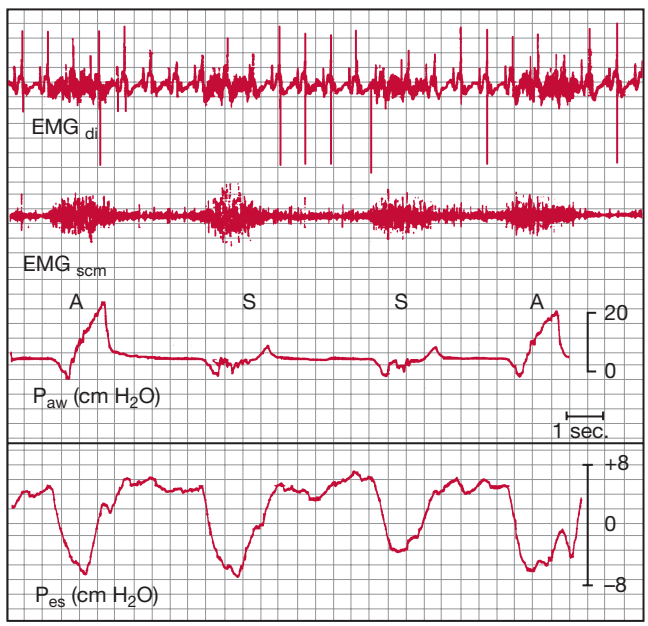

Figure 148-2 Electromyograms of the diaphragm (EMGdi) and sternocleidomastoid muscles (EMGscm) in a patient receiving synchronized intermittent mandatory ventilation. Similar intensity and duration of electrical activity during assisted (A) and spontaneous (S) cycles are demonstrated. P_{aw}, airway pressure; P_{es}, esophageal pressure. *(Reproduced with permission from Imsand C, Feihl F, Perret C, et al. Regulation of inspiratory neuromuscular output during synchronized intermittent mechanical ventilation. Anesthesiology. 1994;80(1):13–22.)*

PRESSURE-SUPPORT VENTILATION

Pressure-support ventilation is patient triggered, like assist–control ventilation and IMV, but it differs in that it is pressure targeted and flow cycled.[13] The physician sets a level of pressure that augments every spontaneous effort, and the patient may alter respiratory frequency, inspiratory time, and tidal volume. Tidal volume is determined by the pressure setting, the patient's effort, and pulmonary mechanics, in contrast to assist–control ventilation and IMV, in which a guaranteed volume is delivered. With volume-targeted ventilation, the inspiratory flow setting is a crucial determinant of patient work. There is no flow setting with pressure-support ventilation, although the initial peak flow determines the speed of pressurization and the initial pressure ramp profile.

Pressure support can be very effective in decreasing the work of inspiration. The degree of inspiratory muscle unloading, however, is variable, with a coefficient of variation of up to 96% among patients.[14] The level of pressure delivered by the ventilator is usually adjusted in accordance with changes in the patient's respiratory frequency. The frequency, however, which signals a satisfactory level of respiratory muscle rest has never been well defined, and recommendations range from 16 to 30 breaths/min.[14]

Cycling to exhalation is triggered by a decrease in inspiratory flow to a preset level, such as 5 L/min or 25% of peak inspiratory flow, depending on the manufacturer's algorithm (Fig. 148-3). The algorithm for "cycling-off" of mechanical inflation causes problems in patients with COPD, because increases in resistance and compliance produce a slow time constant (of the respiratory system). The longer time needed for flow to fall to the threshold value may cause mechanical inflation to persist into neural expiration. In 12 patients with COPD receiving pressure support of 20 cm H_2O, Jubran et al.[14] found that 5 recruited their expiratory muscles while the machine was still inflating the thorax. The patients who recruited their expiratory muscles during mechanical inflation had an average time constant of 0.54 seconds, as compared with an average of 0.38 seconds in patients who did not exhibit expiratory muscle activity.

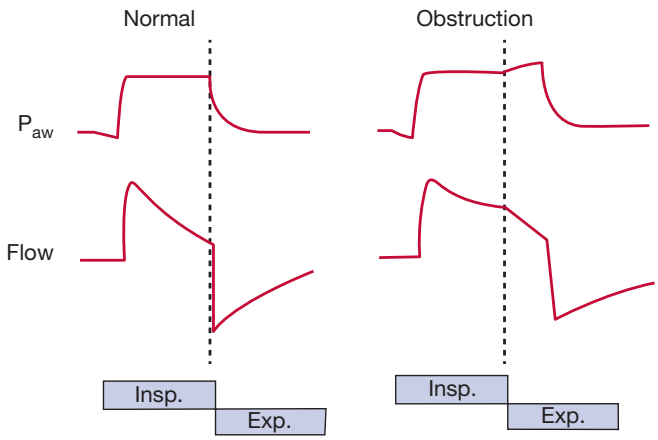

Figure 148-3 Airway pressure (P_{aw}) and inspiratory (Insp) and expiratory (Exp) flow during pressure-support ventilation in patients with normal and obstructed airways. Patient effort triggers the ventilator to deliver a preset pressure, and inspiratory assistance continues until the flow rate falls to 25% of the peak inspiratory flow. In patients with airway obstruction, who have a prolonged time constant, more time is required for flow to decrease to this threshold value, so that neural expiration commences before the termination of mechanical inflation. The resulting activation of the expiratory muscles hastens the fall in flow, but it also results in dyssynchrony between the patient's neuromuscular activity and the mechanical phase of the ventilator—so-called "fighting the ventilator."

The persistence of mechanical inflation into neural expiration is very uncomfortable, as well recognized with use of inverse-ratio ventilation (where, contrary to the normal pattern, inflation lasts longer than exhalation).

■ NEW MODES

New modes of mechanical ventilation are frequently introduced. Each has an acronym, and the jargon is inhibiting to those unfamiliar with it. Yet each new mode involves nothing more than a modification of the manner in which positive pressure is delivered to the airway and of the interplay between mechanical assistance and the patient's respiratory effort.[15] The purpose of a new mode may be to enhance respiratory muscle rest, prevent deconditioning, improve gas exchange, prevent lung damage, enhance coordination between ventilator assistance and patient respiratory effort, and foster lung healing; the priority given to each goal varies.

VENTILATOR SETTINGS

Ventilator settings are based on the patient's size and clinical condition. Determination of the settings is a dynamic process, based on a patient's physiologic response, rather than on a fixed set of numbers.[16] The settings require repeated readjustment over the period of ventilator dependency. Such an iterative process requires careful respiratory monitoring.

■ TRIGGERING

Many ventilators employ pressure triggering, whereby a decrease in circuit pressure is required to initiate ventilator assistance. Patients reach the set sensitivity by activating their inspiratory muscles. When the threshold is reached, however, inspiratory neurons do not simply switch off.[6] Consequently, the patient may expend considerable inspiratory effort throughout a machine-cycled inflation. The level of patient effort during this post-trigger phase is closely related to a patient's respiratory motor output at the point of triggering.[17] As such, measures that decrease respiratory drive may enhance respiratory muscle rest during mechanical ventilation.

If respiratory motor output at the point of triggering is important, one might expect that effort during the time of triggering would determine patient effort during the remainder of inspiration. To elucidate this issue, Leung et al.[17] applied graded levels of pressure support in 11 critically ill patients. They achieved a fourfold reduction in overall patient effort. Yet patient effort during the time of triggering did not change. The constancy of effort during the trigger phase was probably secondary to different factors becoming operational as the level of ventilator assistance was varied (Fig. 148-4). Thus, increases in the level of ventilator assistance do not substantially decrease patient effort during the time of triggering.

The display of airway pressure and flow tracings on ventilator screens has increased awareness that inspiratory effort is frequently insufficient to trigger the ventilator.[6,15] At high levels of mechanical assistance, up to one-third of a patient's inspiratory efforts may fail to trigger the machine (Fig. 148-5). The number of ineffective triggering attempts increases in direct proportion to the level of ventilator assistance. Surprisingly, unsuccessful triggering is not the result of poor inspiratory effort. In a study of factors contributing to ineffective triggering, effort was noted to be more than one-third greater when the threshold for triggering the ventilator was not reached than when it was.[17] Breaths that do not reach the threshold for triggering the ventilator have higher tidal volumes and shorter expiratory times than do breaths that do trigger the ventilator. Consequently, elastic recoil pressure builds up within the thorax in the form of $PEEP_i$. To trigger the ventilator, the patient's inspiratory effort has to first generate a negative intrathoracic pressure in order to counterbalance the elastic recoil; it then must reach the set sensitivity.

The time at which a patient initiates an expiratory effort (in relation to the cycling of the ventilator) partly determines the success of the ensuing inspiratory effort in triggering the machine. The relationship between the onset of expiratory muscle activity and termination of mechanical inflation by the ventilator has been quantified.[18] At a pressure support of 20 cm H_2O, mechanical inflation continues for a longer time into neural expiration in the

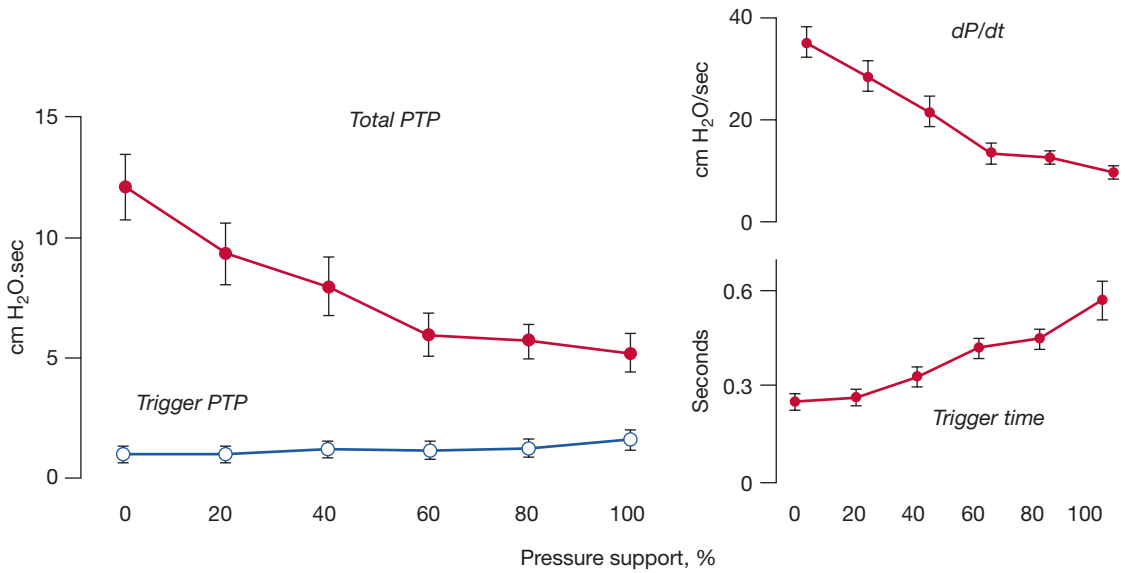

Figure 148-4 Graded increases in pressure support produced a decrease in total pressure–time product (PTP) per breath (*closed symbols*), although PTP during the trigger phase (*open symbols*) did not change (*left panel*). The constancy of PTP during triggering probably resulted from different factors becoming operational at different levels of assistance (*right panel*). At low levels of pressure support, respiratory drive (dP/dt) and $PEEP_i$ were high, but triggering time was short, resulting in a large change in pleural pressure over a brief interval. At high levels of pressure support, dP/dt and $PEEP_i$ were low, but triggering time was long, resulting in a smaller change in pleural pressure over a longer time. *(Data from Leung P, Jubran A, Tobin MJ. Comparison of assisted ventilator modes on triggering, patient effort, and dyspnea. Am J Respir Crit Care Med. 1997;155:1940–1948; Tobin MJ, Jubran A, Laghi F. Patient-ventilator interaction. Am J Respir Crit Care Med. 2001;163:1059–1063.)*

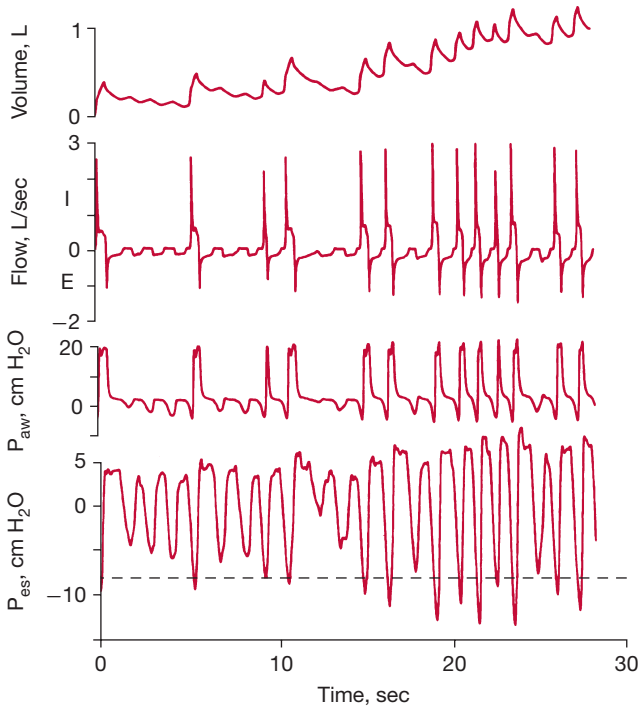

Figure 148-5 Recordings of tidal volume, inspiratory (I) and expiratory (E) flow, airway pressure (P_{aw}), and esophageal pressure (P_{es}) in a patient with COPD receiving pressure-support ventilation. Approximately half of the patient's inspiratory efforts do not succeed in triggering the ventilator. Triggering occurs only when the patient generates P_{es} more negative than −8 cm H_2O (indicated by the interrupted horizontal line), a pressure equal in magnitude to the opposing elastic recoil pressure. Expiratory flow exhibits a biphasic pattern, with momentary braking signaling ineffective inspiratory effort. Thus, monitoring of expiratory flow provides a more accurate measurement of the patient's intrinsic respiratory rate than does the number of machine cycles displayed on the bedside monitor. *(Reproduced with permission from Tobin MJ, Jubran A. Pathophysiology of failure to wean from mechanical ventilation. Schweiz Med Wochenschr. 1994;124:2138–2145.)*

breaths preceding nontriggering attempts. Continuation of mechanical inflation into neural expiration counters expiratory flow, and also decreases the time available for unopposed exhalation. Consequently, elastic recoil increases. In turn, a greater inspiratory effort will be needed to achieve effective triggering. In this way, the time at which a patient commences an expiratory effort (in relation to cycling-off of mechanical inflation) partly determines the success of the ensuing inspiratory effort in triggering the ventilator.

TIDAL VOLUME

In the past, the standard setting for tidal volume was 10 to 15 mL/kg; moreover, every effort was made to ensure that Pa_{CO_2} did not rise above the normal range. This thinking was overturned by a revolutionary study published in 1984 by Darioli and Perret.[19] Analyzing a retrospective dataset collected in patients with status asthmaticus receiving mechanical ventilation, they found that use of lower tidal volumes, with inevitable increase in Pa_{CO_2}, resulted in better survival. A few years later, Hickling et al.[20] applied a similar approach in patients with the acute respiratory distress syndrome (ARDS). A retrospective dataset again revealed better survival with use of permissive hypercapnia. A randomized controlled trial, undertaken by Amato et al.[21] corroborated the Perret–Hickling hypothesis; additional support subsequently came from a randomized trial conducted by the ARDS Network.[22] Three other groups of investigators, however, found that lowering tidal volume tended to increase mortality.[23–25] The only variable that discriminated between the positive and negative studies was the average airway plateau pressure: patients with significantly increased mortality had plateau pressures above 32 cm H_2O. Accordingly, tidal volume should be reduced in patients with ARDS in order to maintain a plateau pressure of no more than 32 cm H_2O.[26,27]

In patients without ARDS, it is usual to use higher tidal volumes, approximately 8 mL/kg, as lower tidal volumes may give rise to considerable dyspnea.[3]

RESPIRATORY RATE

Correct setting of the ventilator rate depends on the mode of ventilation employed.[16] With assist–control ventilation, the ventilator supplies a breath in response to each patient effort. With this mode, physicians commonly pay little attention to the machine rate, which may be set much lower than the patient's spontaneous rate. This gap results in two problems: (1) If the patient has a sudden decrease in respiratory center output, a low machine rate results in serious hypoventilation.[3] (2) A large discrepancy between the patient's spontaneous rate and the machine's back-up rate results in a respiratory cycle with an inverse inspiratory-to-expiratory time (I:E) ratio.

Development of an inverse I:E ratio arises because inspiratory time (T_I) on the machine remains fixed at the initial setting and does not change in response to increases in the patient's spontaneous rate (Fig. 148-6).[16] For example, if the machine rate is initially set at 12 breaths/min (T_{TOT} of 5 seconds) and T_I set at 1.65 seconds (either set directly or indirectly as a consequence of the volume and flow settings), then T_E will be 3.35 seconds. The I:E ratio will be 1:2. If the patient's spontaneous respiratory rate is increased to 25 breaths/min, T_{TOT} will be 2.4 seconds. Because T_I remains fixed at 1.65 seconds, T_E will be 0.75 s, and the I:E ratio will be 2:1. Such inverse-ratio ventilation is very uncomfortable and may lead to increased sedative use, or even to use of neuromuscular blockade, simply because of inappropriate setting of the back-up rate. Based on these considerations, the back-up rate during assist–control ventilation should be set at approximately four breaths less than the patient's spontaneous rate.[2]

With IMV, the ventilator (or mandatory) rate is initially set high and then gradually reduced according to patient tolerance.[10] Unfortunately, titration is often based on data from arterial blood gases, and even a small number of ventilator breaths can result in acceptable values for Pa_{O_2} and Pa_{CO_2} but achieve little or no respiratory muscle rest in patients with increased work of breathing. In

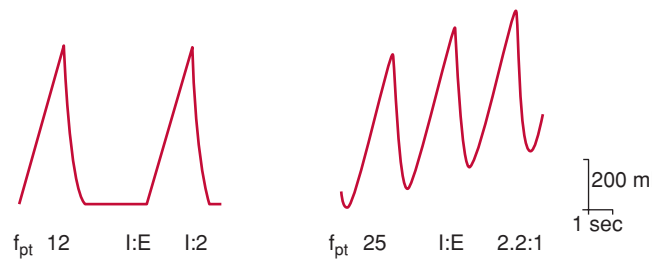

Figure 148-6 Effect of interaction between a patient's respiratory rate and the ventilator back-up rate on inspiratory time—expiratory time ratio (I:E) during assist–control ventilation. Ventilator back-up rate is 12 breaths/min and inspiratory time (T_I) 1.65 seconds. *Left panel.* If the patient's intrinsic respiratory (f_{pt}) rate is also 12 breaths/min, the total respiratory cycle time (T_{TOT}) is 5.0 seconds, the expiratory time (T_E) is 3.35 seconds, and the I:E ratio is 1:2. *Right panel.* If the patient's respiratory rate increases to 25 breaths per minute, the new T_{TOT} is 2.4 seconds, T_E is 0.75 seconds, and I:E is 1:0.45 (or, as more conventionally noted, 2.2:1).

ventilator-dependent patients, work of breathing at IMV rates of 14 breaths/min or less may be sufficient to induce respiratory muscle fatigue.[11,12] With PS ventilation, the ventilator rate is not set.[13]

INSPIRATORY FLOW RATE

Clinicians initially set the inspiratory flow rate at a default value, such as 60 L/min. Many critically ill patients, however, have an elevated respiratory motor output, and the initial flow setting may be insufficient to meet flow demands.[3] As a result, patients will struggle against their own respiratory impedance and that of the ventilator.[9,28] Consequently, work of breathing increases. Clinicians sometimes increase flow in order to shorten the inspiratory time and increase the expiratory time. An increase in flow, however, causes immediate and persistent tachypnea; as a result, expiratory time may be shortened.[29] In a study of healthy subjects, Laghi et al.[30] found that increases in inspiratory flow from 30 L/min to 60 and 90 L/min caused increases in respiratory rate of 20% and 41%, respectively.

One of the main reasons that clinicians increase inspiratory flow is to decrease inspiratory time, in the hope of allowing more time for expiration and, thereby, decreasing $PEEP_i$, especially in patients with COPD. Because increased flow usually leads to an increase in respiratory rate, the expected shortening of expiratory time might actually increase $PEEP_i$.

Laghi et al.[31] investigated this phenomenon in 10 patients with COPD (Fig. 148-7). As with healthy subjects, an increase in flow from 30 to 90 L/min caused respiratory rate to increase from 16 to 21 breaths/min. Despite the increase in rate, $PEEP_i$ fell from 7.0 to 6.4 cm H_2O. The decrease in $PEEP_i$ arose because of an increase in expiratory time (from 2.1 to 2.3 seconds), which allowed more time for lung deflation. Why did expiratory time increase? An increase in inspiratory flow is usually achieved by shortening of mechanical inspiratory time. The shortened inspiratory time, combined with time-constant inhomogeneity of COPD, causes overinflation of some lung units to persist into neural expiration. Continued inflation during neural expiration causes stimulation of the vagus nerve, which prolongs expiratory time.

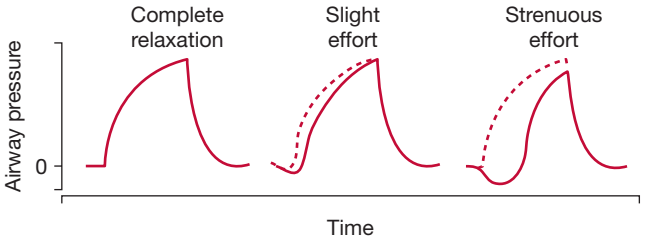

Figure 148-8 Airway-pressure waveforms recorded during assist–control ventilation. The tracings represent changes in airway pressure during inspiration in a completely relaxed patient, and in patients making slight (center tracing) and strenuous efforts (tracing on right) to breathe. The distance between the dashed line (representing controlled ventilation) and the solid line (representing spontaneous breathing) is proportional to the patient's work of breathing. *(Reproduced with permission from Tobin MJ. Mechanical ventilation. N Engl J Med. 1994;330(15):1056–1061.)*

When adjusting the flow rate and trigger sensitivity, examination of the contour of the airway pressure waveform is helpful (Figs. 148-8 and 148-9).[2] Ideally, the waveform should show a smooth rise and convex appearance during inspiration. In contrast, a prolonged negative phase, with excessive scalloping of the tracing, indicates unsatisfactory settings of sensitivity or flow.

FRACTIONAL INSPIRED OXYGEN CONCENTRATION

Correction of hypoxemia and its prevention are major goals in mechanically ventilated patients. Many predictive equations have been published to aid in selecting an appropriate $F_{I_{O_2}}$, but none is

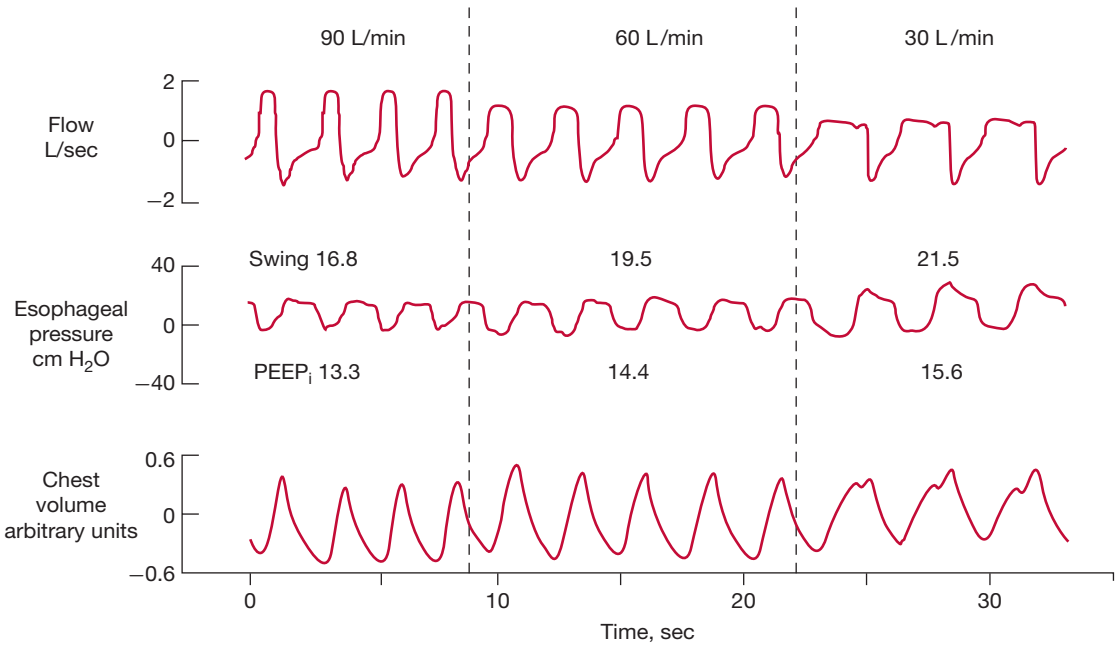

Figure 148-7 Continuous recordings of flow, esophageal pressure (Pes), and the sum of rib cage and abdominal motion, in a patient with chronic obstructive pulmonary disease receiving assist–control ventilation at a constant tidal volume. As flow increased from 30 to 60 and 90 L/min (from right to left), frequency increased (from 18 to 23 and 26 breaths/min, respectively), $PEEP_i$ decreased (from 15.6 to 14.4 and 13.3 cm H_2O, respectively), and end-expiratory lung volume also fell. Increases in flow from 30 L/min to 60 and 90 L/min also led to decreases in the swings in Pes from 21.5 to 19.5 and 16.8 cm H_2O, respectively. *(Reproduced with permission from Laghi F, Segal J, Choe WK, et al. Effect of imposed inflation time on respiratory frequency and hyperinflation in patients with chronic obstructive pulmonary disease. Am J Respir Crit Care Med. 2001;163(6):1365–1370.)*

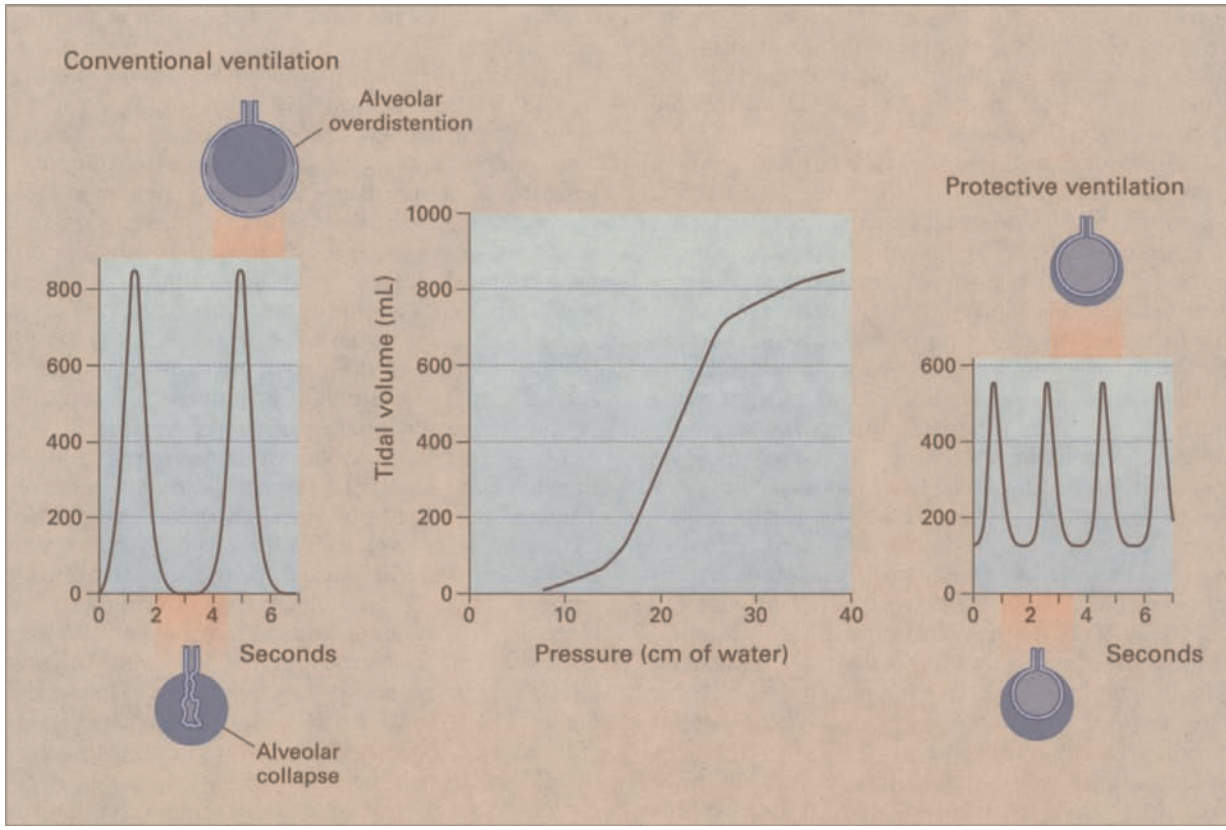

Figure 148-9 Respiratory pressure–volume curve and the effects of traditional versus protective ventilation in a 70-kg patient with acute respiratory distress syndrome. The lower and upper inflection points of the inspiratory pressure–volume curve (center panel) are at 14 and 26 cm H_2O, respectively. With conventional ventilation at a tidal volume of 12 mL/kg and zero end-expiratory pressure (*left panel*), alveoli collapse at the end of expiration. The generation of shear forces during the subsequent mechanical inflation may tear the alveolar lining, and attaining an end-inspiratory volume higher than the upper inflection point causes alveolar overdistention. With protective ventilation at a tidal volume of 6 mL/kg (*right panel*), the end-inspiratory volume remains below the upper inflection point; the addition of PEEP at 2 cm H_2O above the lower inflection point may prevent alveolar collapse at the end of expiration and provide protection against the development of shear forces during mechanical inflation. *(Reproduced with permission from Tobin MJ. Advances in mechanical ventilation. N Engl J Med. 2001;344(26):1986–1996.)*

sufficiently accurate to substitute for a trial-and-error approach.[32] Initially, $F_{I_{O_2}}$ is set at a high value (often 1.0) to ensure adequate oxygenation. Thereafter, the lowest $F_{I_{O_2}}$ that achieves satisfactory arterial oxygenation should be selected. The usual target is a Pa_{O_2} of 60 mm Hg or an arterial saturation (Sa_{O_2}) of 90%; higher values do not substantially enhance tissue oxygenation. Although it is customary to wait 30 minutes to assess the response to a change in $F_{I_{O_2}}$, the effect is usually well defined within 10 minutes. When using arterial blood samples to assess oxygenation, a target of 90% for Sa_{O_2} is appropriate. If pulse oximetry is employed, a Sp_{O_2} target may result in values for Pa_{O_2} as low as 41 mm Hg. In white patients, a target of 92% for Sp_{O_2} indicates satisfactory oxygenation. In black patients, however, this target may still result in significant hypoxemia.[33]

In experimental animals, hyperoxia produces diffuse alveolar damage, with histologic changes that are indistinguishable from ARDS resulting from any other cause. No diagnostic tests distinguish O_2-induced injury from progression of the underlying disease. Thus, the possibility of O_2 toxicity should be considered in any patient receiving an $F_{I_{O_2}}$ of more than 0.50 to 0.60 for 24 to 48 hours or longer. Healthy human subjects who inhale 100% O_2 develop acute tracheobronchitis, manifested as substernal discomfort, cough, sore throat, nasal congestion, eye and ear discomfort, paresthesias, and fatigue. Symptoms begin within 4 hours; bronchoscopic features of tracheal inflammation are evident after 6 hours.[34] Retrosternal discomfort also occurs with an $F_{I_{O_2}}$ of 0.75, but not with an $F_{I_{O_2}}$ of 0.50. Hyperoxia causes absorption atelectasis in lung units with low $\dot{V}_A/\dot{Q}$ ratios, because the rate of absorption of O_2 from the alveoli into the bloodstream is faster than the rate of replenishment from inspired gas. Such atelectasis results in a small shunt (approximately 3%) in healthy elderly subjects and requires only about 6 minutes to develop.

In the face of potential O_2 toxicity, the only possible strategy is to reduce the $F_{I_{O_2}}$ to the lowest level compatible with adequate systemic oxygenation. Thus, excess O_2 demand should be minimized, and measures to enhance systemic oxygenation optimized. Although excessive O_2 administration should be avoided, there is more to fear from severe hypoxemia than from the potential damage that might result from hyperoxia.

■ POSITIVE END-EXPIRATORY PRESSURE

The beneficial effects of positive end-expiratory pressure (PEEP) include improvement in arterial oxygenation, improvement in lung compliance, alleviation of excessive respiratory work secondary to $PEEP_i$ in patients with airflow limitation, and, possibly, a decrease in lung injury resulting from repeated alveolar collapse and reopening.[15] The principal beneficial effect of PEEP is an increase in Pa_{O_2}, which permits a decrease in $F_{I_{O_2}}$ and a reduction in the risk of O_2 toxicity. The major mechanism for the increase in Pa_{O_2} with PEEP is an increase in end-expiratory lung volume (Table 148-2).

Patients with ARDS develop alveolar instability and collapse (see Chapters 140 and 141). Consequently, functional residual capacity falls below closing volume, and small airways close during tidal

TABLE 148-2 Mechanisms of Increased Pa_{CO_2} with PEEP

Increase in end-expiratory lung volume
Distention of patent lung units
Recruitment of collapsed lung units
Redistribution of fluid within the lung
Decrease in shunt
Increase in end-expiratory lung volume
Decrease in cardiac output

breathing, leading to intrapulmonary shunt and hypoxemia. PEEP increases end-inspiratory lung volume by distending lung units that are already open, preventing collapse of unstable alveoli at end expiration, recruiting collapsed lung units, and redistributing liquid within the lung.[35–37] The decrease in venous admixture with PEEP is proportional to alveolar recruitment. It had been thought that the decrease in venous admixture with PEEP resulted largely from a decrease in cardiac output. This view has been shown to be erroneous.[38]

At one time PEEP was thought to decrease extravascular lung water by "pushing" alveolar fluid back into the circulation. On the contrary, PEEP can actually increase lung water.[39] As alveoli expand with application of PEEP, interstitial pressure in the extra-alveolar space decreases, leading to an increase in transmural pressure across the vessel wall. If intravascular pressures remain the same or increase, the filtration of fluid across the vessel wall increases, causing an increase in pulmonary edema; if PEEP causes a decrease in cardiac output and vascular pressures, lung water does not change. The beneficial action of PEEP in pulmonary edema is produced by redistribution of edema fluid from the alveolar space into the perivascular cuffs. This redistribution of lung water, in association with an increase in end-expiratory lung volume, is the major mechanism underlying the increase in Pa_{O_2} with PEEP.

In patients with ARDS, PEEP is often used for the purpose of recruiting previously nonfunctioning lung tissue (see Chapter 141). Selecting the right level of PEEP for a given patient is difficult, however, because the severity of injury varies throughout the lungs. PEEP can recruit atelectatic areas, but it may also overdistend normally aerated areas.[37]

The addition of PEEP also influences lung mechanics. Patients with acute lung injury commonly have a decreased end-expiratory lung volume and, thus, tidal breathing occurs on the low, flat portion of the pressure–volume curve. By shifting tidal breathing to a more compliant portion of the curve, PEEP may reduce the work of breathing.[40] In patients with an airflow limitation and auto-PEEP who have difficulty triggering the ventilator, the addition of external PEEP (to a level not exceeding the level of auto-PEEP) can help to counteract this problem, because to trigger the ventilator the alveolar pressure needs to be decreased only below the level of external PEEP, rather than below zero.[41,42] In addition to the injury induced by high inflation pressures, mechanical ventilation at a low end-expiratory lung volume aggravates lung injury in laboratory animals, possibly because of shear stresses associated with the repeated closing and opening of alveolar units.[43,44]

Overall, about 30% of patients with acute lung injury either do not benefit from PEEP or experience a fall in Pa_{O_2}.[45–47] With the patient in the supine posture, PEEP generally recruits the regions of the lung closest to the apex and sternum. Conversely, PEEP can increase the amount of nonaerated tissue in the regions close to the spine and diaphragm.[47] Among patients in the early stages of ARDS, those with pulmonary causes, such as pneumonia, are less likely to benefit from PEEP than patients with nonpulmonary causes, such as intra-abdominal sepsis or extrathoracic trauma.[48] This distinction may be related to the type of morphologic involvement: Pulmonary causes of ARDS are characterized by alveolar filling, whereas nonpulmonary causes are characterized by interstitial edema and alveolar collapse. In the later stages of ARDS, remodeling and fibrosis may eliminate this distinction between pulmonary and nonpulmonary causes.

Three randomized trials on the effect of PEEP on survival in patients with ARDS have been undertaken: the ALVEOLI trial, the LOV trial, and the Express trial.[49–51] The results of all three trials revealed no improvement in patient survival. Although the subsequent two trials differed in some details from the ALVEOLI trial, the overall design followed the same general principles. The ALVEOLI investigators employed a complex sliding scale for adjusting PEEP and FI_{O_2}.[49] When patients were receiving an FI_{O_2} of 0.60, the design mandated that patients receive either a PEEP of 10 or 20 cm H_2O, with no other options. At an FI_{O_2} of 0.80, patients were mandated to receive either a PEEP of 14 or 22 cm H_2O, with no other options. Of course, physicians do not set PEEP in this manner; hence, this trial design bears no relationship to everyday clinical practice. The investigators of the LOV trial employed the exact same fatal flaw in their study design.[50] The Express investigators adjusted PEEP to achieve a plateau pressure of 28 cm H_2O—a compromise between achieving recruitment and avoiding overdistention.[51] It is well recognized, however, that the response to PEEP is very variable in ARDS. Some patients develop overdistention with PEEP of 10 cm H_2O, whereas other patients show little aeration despite an airway pressure of 45 cm H_2O.[37] The investigators, however, made no attempt to determine the individual characteristics of patients; instead, every patient was treated the same in each arm of the trial.[51]

Rather than setting PEEP on the basis of airway pressure recordings, Talmor et al.[52] investigated whether the selection of PEEP based on transpulmonary pressure might achieve a better physiologic result. They randomized 61 patients with acute lung injury or ARDS to two study arms. In the intervention arm, transpulmonary pressure was measured with an esophageal catheter and PEEP was adjusted to maintain a transpulmonary pressure between 0 and 10 cm H_2O at end expiration. In the control arm, patients were managed according to the protocol employed in the ALVEOLI trial of the ARDS Network.[49] The primary end point was improvement in oxygenation; after 61 patients were enrolled, the stopping criterion was reached. At 72 hours after study entry, Pa_{O_2}:FI_{O_2} ratio was higher in the esophageal-catheter group than in the control group: 280 + 126 versus 191 + 71. A strong, but not statistically significant, trend toward lower mortality at 28 days was observed in the esophageal-catheter group than in the control group: 5/30 (17%) versus 12/31 (39%). A major reservation with this study is that the strategy employed by Talmor et al. depended on making an estimate of absolute pleural pressure; for this step, the investigators employed a correction factor of 5 cm H_2O in all patients. This correction constitutes a major assumption, and it is not clear whether this will prove a stumbling block when investigators attempt to replicate the results of the study.

BRONCHODILATOR THERAPY

Several obstacles are encountered when inhaled drugs are administered to ventilated patients. As a result, drug deposition to the lower respiratory tract is less than that in ambulatory patients. Determinants of aerosol deposition include the configuration of the endotracheal tube and ventilator circuit, ventilator mode and settings, and patient-related factors.[53]

Nebulizers have been used traditionally for the delivery of bronchodilators, but they have a number of disadvantages.[53] Nebulizer

contamination causes aerosolization of bacteria, and lack of attention to this matter by health-care providers has led to epidemics of nosocomial pneumonia. Tidal volume and inspiratory flow must be adjusted to compensate for nebulizer flow. This factor is inconsequential in most adults, but instances of hypoventilation have occurred in patients who are unable to trigger the ventilator. Another shortcoming of nebulizers is the considerable variation in efficiency of different commercial brands, as well as among various batches of the same brand.

In contrast, metered-dose inhalers (MDIs) are easy to administer, involve less personnel time, and provide reliable dosing. Moreover, when MDIs are used with a collapsible cylindrical spacer, it is not necessary to disconnect the ventilator circuit for each treatment. Thus, risk of ventilator-associated pneumonia is decreased. Using MDIs instead of nebulizers results in substantial cost savings. The combination of an MDI and a chamber device achieves a four- to sixfold greater delivery of aerosol than MDI actuation into a connector attached directly to the endotracheal tube or into an in-line device that lacks a chamber.[53] Aerosol delivery is increased with use of a higher tidal volume and longer fractional inspiratory time (T_I/T_{TOT}). Aerosol delivery is decreased by a high inspiratory flow rate; heating and humidification of inhaled gas reduce aerosol deposition by about 40%. When an aerosol is carried by a low-density gas, such as an 80:20 helium–oxygen mixture, aerosol delivery from an MDI is increased by more than 50%.

A dose–response study of 4, 8, and 16 puffs of albuterol (administered with an MDI and cylindrical spacer) conducted in ventilated patients with COPD (Fig. 148-10) demonstrated a decrease in airway resistance after 4 puffs of albuterol; no additional effects were noted after cumulative doses of 12 and 28 puffs.[54] In another study in ventilated patients with COPD, the bronchodilator effect of a single dose of four puffs of albuterol was sustained for at least 60 minutes. The bronchodilator effect obtained with 4 puffs of albuterol from an MDI was comparable to that obtained with 6 to 12 times the same dose given by a nebulizer.

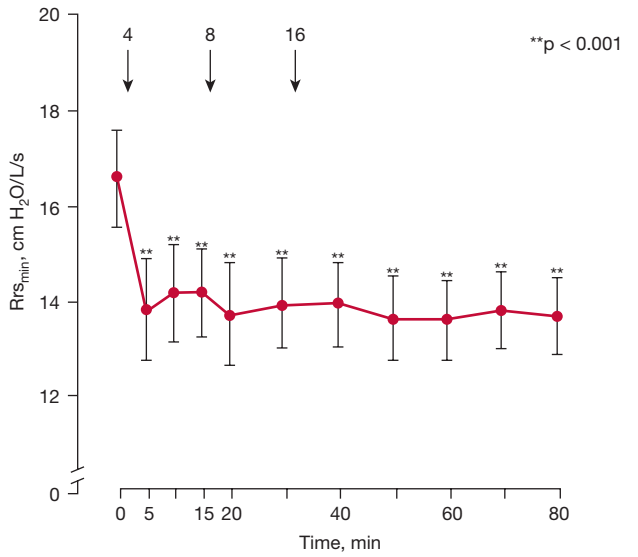

Figure 148-10 Effect of albuterol on minimal inspiratory resistance (Rrs_{min}) in 12 stable mechanically ventilated patients with chronic obstructive pulmonary disease. Significant decreases in resistance occurred within 5 minutes of administration of four puffs of albuterol. The addition of 8 and 16 puffs (cumulative doses of 12 and 28 puffs, respectively) did not achieve a significantly greater effect than that with 4 puffs ($p > 0.05$). Bars represent SE. $^{**}p < 0.001$. *(Modified with permission from Dhand R, Duarte AG, Jubran A, et al. Dose–response to bronchodilator delivered by metered-dose inhaler in ventilator-supported patients. Am J Respir Crit Care Med. 1996;154(2 Pt 1):388–393.)*

TABLE 148-3 Technique for Using Metered-Dose Inhalers in Mechanically Ventilated Patients

1. Assure $V_T > 500$ mL (in adults) during assisted ventilation
2. Aim for an inspiratory time (excluding the inspiratory pause) >0.30 of total breath duration
3. Ensure that the ventilator breath is synchronized with the patient's inspiration
4. Shake the metered-dose inhalers vigorously
5. Place canister in actuator of a cylindrical spacer situated in inspiratory limb of ventilator circuit[a]
6. Actuate metered-dose inhalers to synchronize with precise onset of inspiration by the ventilator[b]
7. Allow a breath hold at end-inspiration for 3–5 s
8. Allow passive exhalation
9. Repeat actuations after 20–30 s until total dose is delivered[c]

[a]With metered-dose inhalers, it is preferable to use a spacer that remains in the ventilator circuit to avoid disconnecting the ventilator circuit for each bronchodilator treatment. Although bypassing the humidifier can increase aerosol delivery, it prolongs each treatment and requires disconnecting the ventilator circuit.
[b]In ambulatory patients with metered-dose inhalers placed inside the mouth, actuation is recommended briefly after initiation of inspiratory airflow. In mechanically ventilated patients using a metered-dose inhaler and spacer combination, actuation should be synchronized with onset of inspiration.
[c]The manufacturer recommends repeating the dose after 1 min.
Metered-dose inhalers' actuation within 20–30 s after the previous dose does not compromise drug delivery.
Source: Modified with permission from Dhand R, Tobin MJ. Inhaled bronchodilator therapy in mechanically ventilated patients. Am J Respir Crit Care Med. 1997;156(1):3–10.

Based on recent research conducted, it is possible to formulate specific steps to achieve maximum bronchodilator effect with use of MDIs in ventilated patients (Table 148-3).[53] Therapy may be given in combination with either controlled or assisted ventilation, provided aerosol administration is synchronized with inspiratory flow. Based on the recommended technique for use of an MDI in ambulatory patients, some authors recommend use of a postinspiratory breath hold; with optimal technique, however, this maneuver does not influence bronchodilator response in ventilated patients. Although humidification of the circuit reduces aerosol deposition, it is advisable not to bypass the humidifier. Even with a humidified circuit, significant bronchodilation can be achieved with as few as four puffs of a bronchodilator aerosol when the MDI technique is carefully executed.

MONITORING AND COMPLICATIONS

Several devices can be used to monitor pulmonary gas exchange, respiratory neuromuscular function, respiratory mechanics, and patient–ventilator interaction. Use of the derived information permits the physician to better tailor ventilator settings to an individual patient's requirements, with the promise of enhancing patient comfort.[55] Monitoring of key variables helps to minimize the risk of iatrogenic complications and alerts the physician to the likelihood of an impending catastrophe, allowing sufficient time for the institution of lifesaving measures. A detailed discussion of techniques used for monitoring of ventilator-supported patients can be found in Chapter 147 and in other textbooks.

Patients receiving mechanical ventilation are at risk for numerous complications, including O_2 toxicity, volutrauma and air leaks,

decreased cardiac output, and endotracheal tube–related issues. These problems are discussed elsewhere in this volume.

WEANING

The term *weaning* literally means a slow, gradual decrease in the amount of ventilator support. The term, however, is used more commonly to refer to all methods of discontinuing mechanical ventilation.[56]

■ CAUSES OF WEANING FAILURE

After discontinuation of mechanical ventilation, up to 25% of patients experience respiratory distress severe enough to necessitate the reinstitution of ventilator support. Our understanding of the basis for weaning failure in patients has advanced considerably in recent years. Among patients who cannot be weaned, disconnection from the ventilator is followed almost immediately by an increase in respiratory frequency and fall in tidal volume, that is, rapid, shallow breathing (Fig. 148-11).[57] As a trial of spontaneous breathing is continued over the next 30 to 60 minutes, respiratory effort increases considerably, reaching more than four times the normal value at the end of this period (Fig. 148-12).[58] The increased effort is caused mainly by worsening respiratory mechanics.[59] Respiratory resistance increases progressively, reaching about seven times the normal value at the end of a failed weaning trial; lung stiffness also increases, reaching five times the normal value; and gas trapping, measured as $PEEP_i$, more than doubles over the course of the trial.[58] Before weaning is started, however, respiratory mechanics in such patients are similar to patients in whom subsequent weaning is successful. Thus, unknown mechanisms associated with the act of spontaneous breathing cause the worsening of respiratory mechanics in patients who are weaning failures.

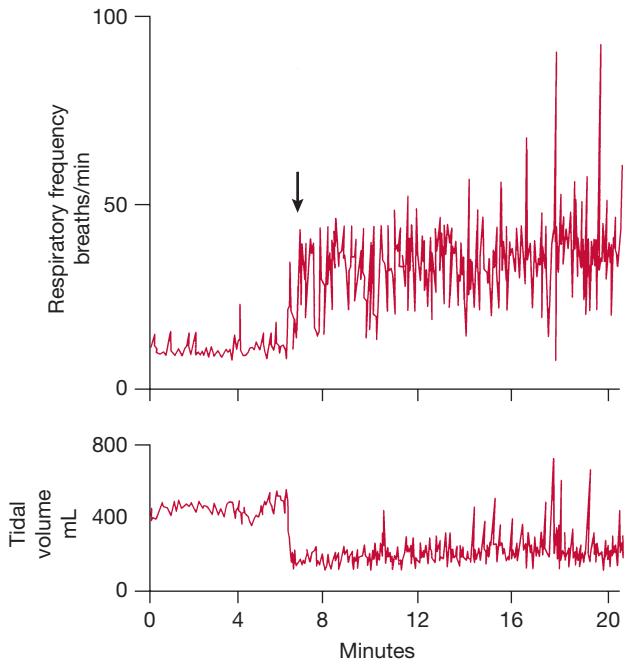

Figure 148-11 A time-series, breath-by-breath plot of respiratory frequency and tidal volume in a patient who failed a weaning trial. The arrow indicates the point of resuming spontaneous breathing. Rapid, shallow breathing developed almost immediately after discontinuation of the ventilator. *(Reproduced with permission from Tobin MJ, Perez W, Guenther SM, et al. The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation. Am Rev Respir Dis. 1986;134(6):1111–1118.)*

In addition to the increase in respiratory effort, an unsuccessful attempt at spontaneous breathing causes considerable cardiovascular stress. Patients may experience substantial increases in right- and left-ventricular afterload during a trial of spontaneous breathing, with increases of 39% and 27% in pulmonary and systemic arterial pressures, respectively.[60] The changes are most likely attributable to the extreme negative swings in intrathoracic pressure. At the completion of a weaning trial, the level of O_2 consumption is equivalent in patients who can be weaned and in those who cannot. How the cardiovascular system meets the O_2 demand differs in the two groups of patients.

In patients who are successfully weaned, O_2 demand is met through an increase in O_2 delivery, mediated by the expected increase in cardiac output on discontinuation of positive-pressure ventilation. In patients who cannot be weaned, O_2 demand is met through an increase in O_2 extraction; these patients have a relative decrease in O_2 delivery. The greater O_2 extraction causes a substantial decrease in mixed venous O_2 saturation, contributing to the arterial hypoxemia that occurs in some patients.[60]

Over the course of a trial of spontaneous breathing, about half of the patients in whom the trial fails have an increase in Pa_{CO_2} of 10 mm Hg or more. The hypercapnia is not usually a consequence of a decrease in minute ventilation. Instead, hypercapnia results from rapid, shallow breathing, which causes an increase in dead-space ventilation.[57] In a small proportion of patients who cannot be weaned, primary depression of respiratory drive may be responsible for the hypercapnia.

■ TIMING OF THE WEANING PROCESS

One of the major challenges in the management of ventilator-supported patients is deciding on the right time to discontinue mechanical ventilation. If the physician is too conservative and postpones weaning onset, the patient is placed at an increased risk of life-threatening, ventilator-induced complications. Conversely, if weaning is begun prematurely, the patient may suffer cardiopulmonary or psychological decompensation of sufficient severity to set back a patient's clinical course.[56]

In randomized trials of different weaning techniques, most patients who had received mechanical ventilation for a week or longer were able to tolerate ventilator discontinuation on the first day that weaning-predictor tests were measured.[61,62] Many of these patients would have tolerated extubation a day or so earlier. As such, one of the main sources of weaning delay is the failure of the physician to *think* that the patient *just might* come off the ventilator. Psychological research suggests that much of this delay in ventilator weaning results from clinicians being overconfident in their intuition that a patient is not ready for a weaning trial.[56] Another source of error is the failure of clinicians to pay close attention to pretest probability—they fail to recognize the importance of Bayesian principles in clinical decision-making. When taking care of a ventilator-supported patient, physicians should be mindful of these cognitive processes and employ compensatory tactics, specifically the use of screening tests, to spot a patient's readiness for weaning. By alerting an unsuspecting physician to a patient's readiness to tolerate unassisted ventilation—hours or days before he or she would otherwise order a spontaneous breathing trial—weaning-predictor tests circumvent the cognitive errors inherent in clinical decision-making.[56]

Physicians commonly view diagnostic testing in monolithic terms: a test is a test is a test. In reality, diagnostic testing has to satisfy two very different tasks: one is screening, the other is confirmation.[63] The characteristics of these test types differ, and a single diagnostic test rarely fulfills both functions.[63]

The fundamental job of a weaning-predictor test is screening. Because the goal is to not miss anyone with the condition under consideration, a good screening test has a very low rate of

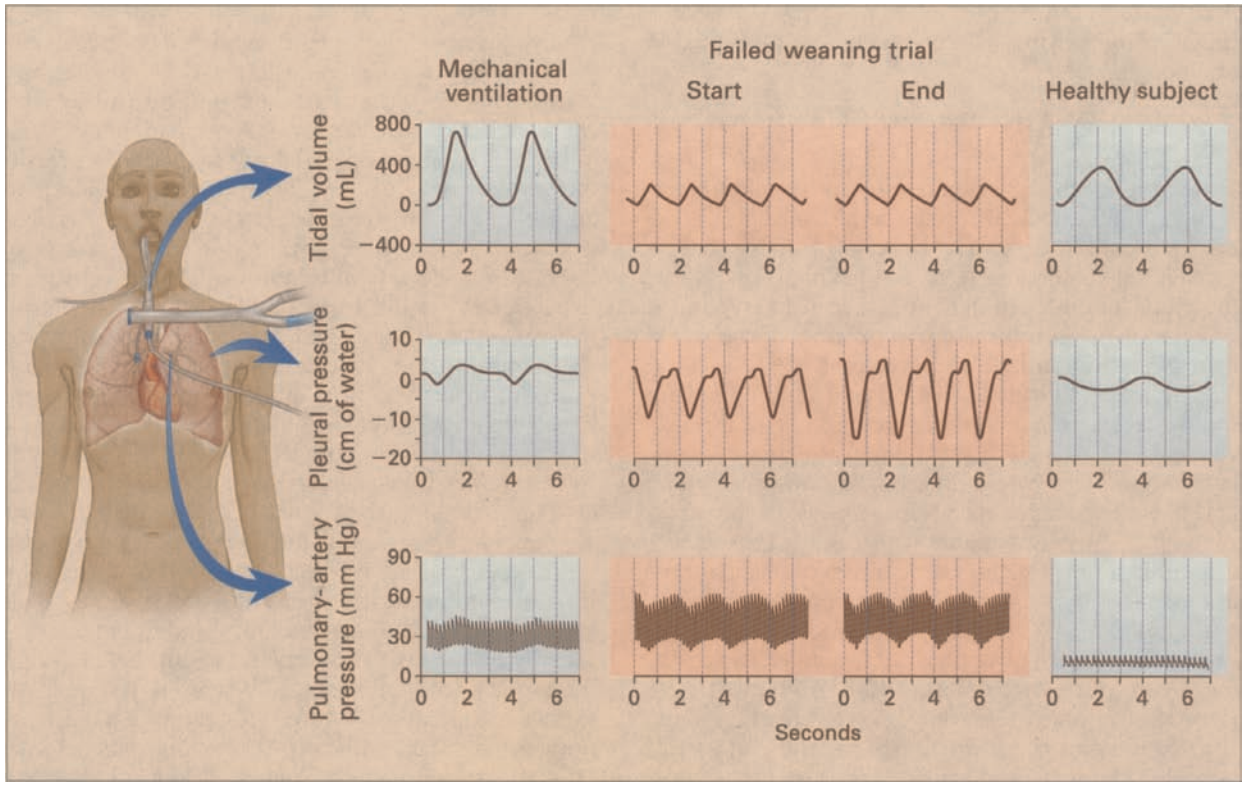

Figure 148-12 Tidal volume, pleural pressure, and pulmonary-artery pressure during assist-control ventilation and at the start and end of a failed weaning trial. During mechanical ventilation, the patient's inspiratory effort is in the normal range, and the pulmonary-artery pressure is 45/22 mm Hg. At the start of the weaning trial, tidal volume falls to 200 mL, respiratory frequency increases to 33 breaths per minute, and a swing of 11 cm H_2O in pleural pressure is noted; the pulmonary-artery pressure at the end of expiration is 60/28 mm Hg. At the end of the trial, 45 minutes later, the tidal volume and respiratory frequency are unchanged, a swing in pleural pressure of 19 cm H_2O is evident, and $PEEP_i$ is 4 cm H_2O; pulmonary artery pressure is 60/31 mm Hg. The values in a healthy subject are tidal volume, 380 mL; respiratory frequency, 17 breaths per minute; pleural-pressure swing, 3 cm H_2O; and pulmonary artery pressure, 18/8 mm Hg. *(Data are from Tobin MJ, Perez W, Guenther SM, et al. The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation. Am Rev Respir Dis. 1986;134:1111–1118; Jubran A, Mathru M, Dries D, et al. Continuous recordings of mixed venous oxygen saturation during weaning from mechanical ventilation and the ramifications thereof. Am J Respir Crit Care Med. 1998;158:1763–1769; Jubran A, Tobin MJ. Pathophysiologic basis of acute respiratory distress in patients who fail a trial of weaning from mechanical ventilation. Am J Respir Crit Care Med. 1997;155:906–915. Reproduced from Tobin MJ. Advances in mechanical ventilation. N Engl J Med. 2001;344:1986–1996.)*

false-negative results; to achieve this goal, a higher false-positive rate is acceptable. Thus, an ideal screening test has a very high sensitivity. The ratio of respiratory frequency to tidal volume (f/V_T) meets this requirement; numerous studies have documented that its sensitivity is 0.90 or higher.[64,65]

The f/V_T ratio must be calculated during spontaneous breathing. Measurements of f/V_T in the presence of pressure support or CPAP will result in inaccurate predictions of weaning outcome.[56] The higher the f/V_T ratio, the more rapid and shallow the breathing and the greater the likelihood of unsuccessful weaning. A ratio of 100 discriminates between successful (less than 100) and unsuccessful (greater than 100) attempts at weaning.[64]

Because the results of screening tests are often negative, an ideal screening test should be simple, expeditious, and safe.[63] Measurement of f/V_T takes a minute or so to perform. In contrast, a trial of spontaneous breathing takes one-half to two hours to perform, during which time attendants commonly leave the patient's room. Accordingly, a spontaneous breathing trial does not satisfy the criteria for a desirable screening test, and commencing weaning with such a trial is likely to prolong the weaning process.[56]

If clinicians obtain weaning-predictor tests at the earliest point that a patient might tolerate extubation, the results will be negative at least half the time. In studies of weaning-predictor tests, however, positive results have been obtained at least 75% of time.[65] Such a high rate of positive test results indicates that clinicians were being too slow in initiating the weaning process.

When a screening test is positive, the diagnostician proceeds to a confirmatory test.[63] A positive confirmatory test result essentially rules in a condition: The likelihood of a patient tolerating a trial of extubation is very high. An ideal confirmatory test has a very low rate of false-positive results, that is, a high specificity. The specificity of a weaning trial is not known and will never be known, since its determination would require an unethical experiment—extubating all patients who fail a weaning trial and noting how many require reintubation.[56]

■ WEANING TRIALS

Four methods can be used for conducting a weaning trial. The oldest is to perform trials of spontaneous breathing several times a day, using a T-tube circuit that contains an enriched supply of O_2.[56] Initially 5 to 10 minutes in duration, T-tube trials are extended and repeated several times a day until the patient can sustain spontaneous ventilation for several hours. This approach has become unpopular because it requires considerable time on the part of ICU staff.

For many years, IMV was the most popular methods of weaning.[56] With IMV, the mandatory rate from the ventilator is reduced in steps of 1 to 2 breaths/min, and an arterial blood gas is obtained about 30 minutes after each rate change.[10] Unfortunately, titrating the number of breaths from the ventilator in accordance with the results of arterial blood gases can produce a false sense of security. As few as two to three positive-pressure breaths per minute can achieve acceptable blood gases, but these values provide no information regarding the patient's work of breathing (which may be excessive). At IMV rates of 14 breaths/min or less, patient inspiratory efforts are increased to a level likely to cause respiratory muscle fatigue.[11,12] Moreover, this occurs not only with the intervening spontaneous breaths, but also with ventilator-assisted breaths. Consequently, use of IMV may actually contribute to the development of respiratory muscle fatigue or prevent its recovery.

When pressure support is used for weaning, the level of pressure is reduced gradually (decrements of 3 to 6 cm H_2O) and titrated on the basis of the patient's respiratory frequency.[13,61] When the patient tolerates a minimal level of pressure support, he or she is extubated. What exactly constitutes a "minimal level of pressure support" has never been defined.[14]

The fourth method of weaning is to perform a single daily T-tube trial, lasting for 30 to 120 minutes.[56,62] If this trial is successful, the patient is extubated. If the trial is unsuccessful, the patient is given at least 24 hours of respiratory muscle rest with full ventilator support before another trial is performed.[59]

Two randomized trials have revealed that weaning time was three times longer with IMV than it was with the use of T-tube trials.[61,62] In a study involving patients with respiratory difficulties on attempted weaning, T-tube trials halved the weaning time as compared with pressure support[62]; in another study, the weaning time was similar with the two methods.[61] Performing trials of spontaneous breathing once a day is as effective as performing such trials several times a day, but much simpler.[62] In patients not expecting to pose any particular difficulty with weaning, a half-hour trial of spontaneous breathing is as effective as a 2-hour trial.[66] In a recent study of patients requiring prolonged mechanical ventilation at a long-term acute care hospital, the rate of successful weaning was more than 40% higher with trials involving unassisted breathing through a tracheostomy than with use of pressure support.[67]

In conclusion, to minimize the likelihood of either delayed weaning or premature extubation, a two-step diagnostic strategy is recommended: measurement of weaning predictors followed by a weaning trial. The critical step is for the physician to contemplate the possibility that a patient *just might* be able to tolerate weaning. Such diagnostic triggering is facilitated through use of a screening test, which is the rationale for measurement of weaning-predictor tests. It is important not to postpone this first step by waiting for a more complex diagnostic test, such as a T-tube trial.

EXTUBATION

Decisions about weaning and extubation are commonly conflated. When a patient tolerates a weaning trial without distress, a clinician feels reasonably confident that the patient will be able to sustain spontaneous ventilation after extubation. Before removing the endotracheal tube, however, the clinician also has to judge whether or not the patient will be able to maintain a patent upper airway after extubation.[68]

Of patients who are expected to tolerate extubation without difficulty, about 10% to 20% fail and require reintubation.[61] Mortality among patients who require reintubation is more than six times as high as mortality among patients who can tolerate extubation.[66] The reason for the higher mortality is unknown. It might be related to the development of new problems after extubation or complications associated with reinsertion of a new tube. A more likely explanation is that the need for reintubation reflects greater severity of the underlying illness.[68]

Because of the high mortality associated with reintubation, clinicians are eager to avoid this problem. The major diagnostic test used to predict the success of an extubation attempt is a weaning trial. In contrast to the many studies that have evaluated the reliability of diagnostic tests that predict the outcome of a trial of weaning, the diagnostic accuracy of weaning trials in predicting the outcome of a trial of extubation is unknown. Moreover, the accuracy is impossible to determine, because the experiments necessary to measure the sensitivity and specificity of a weaning trial (for predicting extubation outcome) are unethical.

Many physicians find it convenient to extubate a patient once he or she can breathe comfortably on a pressure support of about 7 cm H_2O and PEEP 5 cm H_2O based on the belief that such "minimal ventilator settings" are simply overcoming the resistance engendered by an endotracheal tube.[69] This claim ignores the inflammation and edema that develops in the upper airways after an endotracheal tube has been in place for a day or more. On removal of the tube, the mucosal swelling produces an increase in upper airway resistance. Straus et al.[70] demonstrated experimentally that the respiratory work dissipated against the supraglottic airway after extubation is almost identical to the work dissipated against an endotracheal tube before extubation. Thus, applying any level of pressure support causes physicians to underestimate the respiratory resistance a patient will encounter after extubation. The addition of a small amount of pressure support produces surprisingly large reductions in inspiratory work in ventilated patients: 5 cm H_2O decreases inspiratory work by 31% to 38%, and 10 cm H_2O decreases work by 46% to 60%.[14,71] Independently, addition of 5 cm H_2O of PEEP can decrease work of breathing by as much as 40% in ventilated patients.[71] In the case of a patient who might experience cardiorespiratory difficulties after extubation, it is incumbent on a physician to ensure that the patient is able to breathe comfortably for about 30 minutes in the complete absence of pressure support or PEEP before removal of the endotracheal tube.[69]

CONCLUSION

Since the previous edition of this textbook, we have gained a better understanding of the pathophysiology associated with unsuccessful weaning and have learned how to wean patients more efficiently. We have also learned how ventilator settings influence survival in patients with ARDS. Less progress has been made in determining how the ventilator can best be used to achieve maximal respiratory muscle rest, which is the most common reason for providing mechanical ventilation.

CHAPTER 149

Nutrition in Pulmonary Disease

David S. Seres

INTRODUCTION

Clinical nutrition is somewhat complex. Much of clinical practice is based on observation or on flawed, biased, or severely underpowered studies. Furthermore, terminology related to malnutrition is extremely confusing; incorporating terms referring to problems attributable to alterations in nutritional intake intermixed with those secondary to inflammatory illness, which are not responsive to changes in nutrition intake.

Many excellent clinical publications[1,2] review general and specific nutritional concepts. This chapter focuses on newly proposed definitions for malnutrition and on the clinical challenges specific to selected pulmonary diseases and acute respiratory failure and the critical care setting. Chronic obstructive pulmonary disease (COPD) and cystic fibrosis (CF) serve as the prototypes for nutrition-related issues encountered in chronic pulmonary disease.

MALNUTRITION REDEFINED

Malnutrition has long been known to be associated with poor outcomes in medical and surgical patients.[3] However, for decades the terminology describing malnutrition has created great confusion. While new efforts focus on defining malnutrition based on etiology,[4] clinical parameters unrelated and unresponsive to nutrient intake[5,6] remain entrenched.

The new definition of malnutrition (Table 149-1) describes two forms: malnutrition due to nutrient imbalance or malnourishment (e.g., starvation, marasmus, obesity), and that which occurs due to systemic illness (e.g., catabolism, cachexia).[4] Only malnutrition due to nutrient imbalance resulting from alterations in intake or uptake can be treated by alterations in nourishment.

The belief that most traditional markers of malnutrition (e.g., albumin, prealbumin [transthyretin], measures of immune function) reflect adequacy of nourishment has been disproved,[5,6] and some of these elements have been removed from the new definition.[4]

Confusion will likely continue, however, because remaining in the definition are clinical findings, such as loss of lean body mass, which may be caused by starvation, systemic inflammation, or both. The etiology of these signs may be difficult, if not impossible, to distinguish clinically; furthermore, lean body mass loss due to inflammation, for example, does not respond to stand-alone nourishment strategies when inflammation is present. Patients with "malnutrition" may or may not be "malnourished." Well-nourished patients (e.g. receiving tube feeding or eating well) with disease-related muscle wasting are "cachectic."

While it still comes as a "surprise" to many clinicians that so-called nutritional markers are, in truth, markers of systemic inflammation, this is far from a new finding.[7,8] Discussion of alterations in serum albumin and other parameters as arising from systemic inflammation has appeared in physiology and biology texts for decades.[9] By the same token, these "nutritional" markers have long been known to identify patients at high risk for untoward outcomes and to reflect severity of illness.[8] Moreover, nutritional assessments that incorporate the markers, such as the Prognostic Inflammatory and Nutritional Index (PINI),[10] are highly validated to predict poor outcomes. Consequently, the work of nutrition practitioners conducting clinical assessments is very important in identifying high-risk patients.

Insurers have recognized that patients with "malnutrition" are more complex than those who are not and have increased their reimbursement to hospitals for these patients. The author contends that dietitians should be renamed, "riskologists" to acknowledge this added value, and that patients identified as, "at risk for nutritional complications" be relabeled, "very sick and at risk for morbidity and mortality." In addition, patients so identified should receive intensive oversight by a multidisciplinary team of highly qualified clinicians.

Finally, inflammatory markers, such as C-reactive protein, and serum albumin and prealbumin, do not necessarily correlate linearly with the patient's clinical status. New indices that utilize multiple markers, such as the ratio of C-reactive protein to albumin,[11] have shown promise as sensitive outcome predictors.

While weight gain, especially due to increase in lean mass, is considered desirable because of the association between low weight, morbidity, and mortality, weight gain is not, by itself, a nutritional outcome in sick patients. Rather, it is more likely an epiphenomenon and a marker of disease severity.[6] Meaningful outcomes resulting from nutrition support include morbidity, cost of care, and mortality.[5] Moreover, defining ideal nourishment for an individual patient is extraordinarily difficult. Most feeding recommendations arise from studies of surrogate markers, rather than outcomes. In general, meaningful investigations in nutrition require extremely large cohorts and are expensive; few have between conducted in patients with acute or chronic illnesses.

TABLE 149-1 Findings in the New Definition of Malnutrition

	Starvation-Related Malnutrition (Malnourishment)	Disease-Related Malnutrition
Starvation	X	X
Fat wasting	X	+/–
Muscle wasting	X	X
Hypoproteinemia		X
Elevated inflammatory markers		X

ETIOLOGY AND MECHANISMS

Imbalance-related malnutrition is a result of inadequate nutrition; it is treatable by refeeding or nutrition supplementation. On the other hand, disease-related malnutrition is neither due to, nor responsive to, changes in calorie or protein intake.[5] Muscle wasting, decrements in serum proteins, insulin resistance, and immunosuppression are associated with disease-related malnutrition. All of these findings are due to systemic inflammation and, based on our current knowledge, are not due to inadequate nutritional intake.

For example, until systemic inflammation is resolved, serum albumin levels and muscle mass will not normalize, despite protein supplementation. Conversely, normalization of serum albumin may occur despite starvation, once systemic inflammation has resolved.[6] Prealbumin, properly referred to as transthyretin, normalizes more quickly than albumin with resolution of systemic inflammation,

but it is no more reflective of adequacy of nutritional intake than is albumin. Moreover, nutritional supplementation has not proved to slow the decrements seen in these markers.

Traditional nutritional markers, such as serum proteins and muscle mass, should be considered surrogates for systemic inflammation and not markers for adequacy of nourishment. Nor should they be seen as an indication for nutrition support. For example, administration of parenteral nutrition in response to finding a low serum albumin in a patient who is eating and absorbing nutrients normally exposes the patient to potential harm without potential benefit.

The mechanism for inflammation-related muscle wasting that occurs despite adequate or supplemental nutrition is poorly understood, but it is clearly related to production of inflammatory cytokines.[12] One proposed mechanism is that muscle breakdown supports uncontrolled hepatic gluconeogenesis resulting from the insulin resistance observed in this setting. The decrement in serum albumin, as well as in other carrier proteins, is likely due to its extravasation from capillaries, along with other macromolecules, due to increases in capillary permeability arising with inflammation. With maintenance of vascular volume, plasma protein concentrations are diluted. In addition, plasma protein oncotic pressure falls, or becomes nonexistent, once normally semipermeable capillary membranes become permeable, and plays a diminished role in minimizing fluid flux across capillary membranes into soft tissues.

TERMINOLOGY

The two previously noted forms of malnutrition often coexist. Sick patients often exhibit anorexia and decreased nutritional intake. In this instance, loss of muscle mass is due to both systemic inflammation and lack of nutritional intake. Distinguishing between the two forms is difficult. Recognizing a component of caloric deficit provides an opportunity to intervene.

Identifying ongoing inflammation by "nutritional" assessment, may lead to recognition of a medical or surgical condition that may require medical or surgical treatment or help to guide ethical decision-making. Prolonged, untreatable catabolism may predict incurable or fatal illness. Low muscle mass may be hidden in an obese patient with preserved adiposity, but it can be discerned with careful physical examination and may help explain a delay in physical recovery. Muscle mass is an important determinate of serum creatinine concentrations. Physical assessment of muscle mass may also be important in explaining whether a widening of the ratio of blood urea nitrogen (BUN) to creatinine represents hypoperfusion or hypovolemia on the one hand, or severe muscle loss with renal impairment on the other.

Albumin levels require approximately 6 weeks to normalize once inflammation resolves. Consequently, direct markers of inflammation (e.g., C-reactive protein and cytokines) may provide a more accurate measure of inflammation in the presence of persistent hypoalbuminemia. Reversal of hypoalbuminemia is a helpful sign in tracking resolution of inflammation and may indicate a better prognosis; however, trending in albumin levels over weeks is required for the measurements to be useful in this regard.

In distinguishing between the two types of malnutrition, the terminology employed should be very specific. Undernourishment, starvation, nutritional deficiency, nutritional imbalance, obesity, and nutritional excess may be used to describe imbalance-related malnutrition. Conversely, catabolism and disease-related malnutrition are used synonymously with malnutrition due to inflammation. *Marasmus* is an older term that refers to pure starvation. *Kwashiorkor*, an endemic disease in children, is likely due to systemic inflammatory response, but the term is no longer applied to hospitalized patients, especially adults, in nonendemic areas.[13]

Cachexia is the syndrome resulting from severe chronic malnutrition, which contains a component of inflammation-related malnutrition. It results, at least in part, from catabolism. Cachexia may be predominantly due to inflammation, with a smaller component of starvation, or alternatively, from starvation with a smaller component of inflammation.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is an extremely common form of chronic lung disease. Management of COPD is challenging and frequently entails consideration of both starvation and disease-related malnutrition.

MALNUTRITION IN COPD

COPD encompasses a number of systemic manifestations, including malnutrition; hence, it should not be considered solely a pulmonary disease. Cachexia is common in COPD. The underlying mechanisms are difficult to ascertain from existing epidemiological and observational studies. Muscle dysfunction and wasting are common. Fat-free mass predicts mortality.[14] However, muscle wasting and dysfunction may, in part, be related to systemic inflammation or increased oxidative stress.[15] In addition, it has long been known that weight loss in COPD is associated with an increase in inflammatory markers, such as TNFα.[16]

Given the systemic nature of cachexia and muscle dysfunction in COPD, purely nutritional strategies would be expected to have little impact on outcomes. In fact, until recently, whether nutrition support had any clinical outcome benefits was unclear, even though patients given such support gained weight.[17] Notably, however, as discussed previously, weight gain is solely a surrogate marker and not a meaningful clinical outcome. While weight gain may be desirable, it may not be associated with improvement in quality or quantity of life or a decrease in the cost of care.

Recent studies, reassessing data in patients with COPD who received nutrition support compared versus those who did not, demonstrated weight gain in the treated group, as well as improvements in both skeletal and pulmonary muscle function. In addition, improvement in health-related quality of life (HRQoL) was observed when data using the St. George's Respiratory Questionnaire (SGRQ) were analyzed, although not when data from SGRQ were pooled with data from the Chronic Respiratory Questionnaire (CRQ).[18] It is reasonable to continue to recommend that patients with COPD who are undernourished receive nutrition support.

Macronutrient mix in COPD may be far less important than previously thought (see below), but total calories may play an important role. In a nutritional supplementation study, provision of excess calories to subjects with COPD was shown to cause a decrease in exercise performance. This was most profound in patients with more advanced disease and cachexia.[19]

The author's opinion is that as an initial goal, it is reasonable to choose a nutritional prescription based either on an estimate of basal requirements at ideal weight, or calorimetric measurement of basal metabolic rate, and increases aimed at slow (1–2 lb per week or 3600 –7200 kcal excess per week) weight gain. Consultation with a nutrition clinician is recommended, and care should be taken to avoid overfeeding.

MACRONUTRIENTS IN COPD

A great deal of attention has been paid to concerns over the impact of macronutrients in COPD. In particular, because carbohydrates are metabolized to CO_2 and water, concern exists that a diet or tube feeding high in carbohydrate content may result in increases in $PaCO_2$ and adverse outcomes. While initial studies seemed to support this concern, recent investigations suggest the opposite. In one study, nutritional supplementation using a high-fat product resulted in more dyspnea with exercise than did

a high-carbohydrate product.[20] While the respiratory quotient (RQ)—the ratio of carbon dioxide produced to oxygen consumed per minute ($\dot{V}_{CO_2}/\dot{V}_{O_2}$)—increases more with a high-carbohydrate supplement, oxygen consumption is lower than that seen using a high-fat supplement.

These clinical findings are consistent with studies of skeletal muscle in patients with COPD, which suggest impaired fat metabolism and an increase in carbohydrate metabolism. In these patients, studies have shown a decrease in oxidative function[21] and expression of peroxisome proliferator-activated receptors (PPAR),[22] which have an extremely important role in up-regulating lipid uptake and metabolism in cells. In addition, in COPD, a shift from oxidative to glycolytic muscle fibers occurs in skeletal muscle, the degree to which is directly correlated with disease severity.[23]

OTHER NUTRITION-RELATED CONSIDERATIONS IN COPD

Anabolic steroids have been demonstrated to increase fat-free mass in patients with COPD, but have been proved to have minimal benefit in clinical outcomes. In a study of patients with COPD enrolled in a pulmonary rehabilitation program, those who received an anabolic steroid had a higher fat-free mass than those who did not, but improvements in muscle function, exercise capacity, and health status were not different between the two groups. Patients who received corticosteroids demonstrated less response to the rehabilitation. Maximal inspiratory mouth pressure and peak workload were improved in patients receiving both chronic corticosteroids and anabolic steroids compared with those given placebo; this was the only positive outcome.[24]

Appetite stimulants have not proved effective in improving outcomes in COPD. In a study of patients receiving megestrol acetate versus those receiving placebo, the treated group demonstrated a lower 6-minute walk distance, despite having a decreased Pa_{CO_2} and increased Pa_{O_2}. Megestrol increased weight, but it did so by increasing fat mass.[25] No studies on use of cannabinoid appetite stimulants in COPD are available.

RECOMMENDATIONS

Patients with COPD should be screened for malnutrition and referred to a nutrition practitioner when any sign of diminished nutritional intake or weight loss is found. Similarly, obesity or excess weight gain in an individual previously of normal weight should serve as indications for nutritional intervention.

Because of difficulties in distinguishing malnourishment from disease-related changes, along with the inability of nutrition support to impact the latter, failure of nutritional interventions should be viewed as evidence of disease progression and factored into prognostic assessments. Strategies such as appetite stimulation and use of anabolic steroids may impact selected metrics, but they have not been demonstrated to impact outcomes. Measuring and monitoring markers, such as serum albumin, should be considered, but the results should be viewed as reflective of an underlying inflammatory state. In this regard, they may be prognostic, but not reflective of nutritional adequacy.[5,6]

CYSTIC FIBROSIS

Cystic fibrosis (CF) is associated with nutritional issues that are far more complex than in most other pulmonary diseases. Patients with CF are prone to significant chronic inflammation, with acute worsening in the presence of infection. As in other inflammatory disorders, disease-related muscle wasting may be noted, which although not necessarily obvious, may be evident even at an early age.[26]

Patients with CF are at high risk for malnutrition arising from a variety of issues: (1) Inflammation may result in anorexia. (2) Malabsorption may occur due to exocrine pancreatic insufficiency. (3) Patients with longstanding disease may develop gastroparesis severe enough to warrant jejunal tube feeding, which may, itself, be a challenge, given increasing evidence for slowing of small bowel transit in affected patients.[27]

MACRONUTRIENTS AND MICRONUTRIENTS IN CYSTIC FIBROSIS

No properly designed prospective, randomized controlled trials comparing enteral feeding to no intervention have been conducted in CF to determine whether enteral feeding improves outcomes.[28] Such studies are nearly impossible to perform because of the ethical dilemmas posed by not providing supplemental or artificial feeding to patients who are, as best as we can determine, chronically starved.

Multiple approaches have been employed to overcome the complex feeding issues encountered in CF, including use of special, predigested tube feeding mixes and supplementation of nutrients thought to be supportive of immune function. Given difficulties with maldigestion due to pancreatic insufficiency and resulting malabsorption in patients with CF, the concept has arisen that providing partially predigested feedings may enhance absorption. However, in small studies, provision of predigested feedings appears not to improve absorption over use of enzyme replacement therapy.[29] Our approach is to feed patients concentrated, high-fat tube feed products (Altman K. Personal communication. 2013), enabling provision of goal calories in the face of small bowel dysmotility.

Among the micronutrient issues considered in CF—a disorder characterized by immune dysfunction—zinc has long been of interest. Zinc deficiency may cause untoward immunological changes, but zinc supplementation in the setting of normal levels generally has no beneficial effect and may be harmful. Zinc supplementation lowers copper levels,[30] and copper deficiency caused by excessive zinc ingestion may result in mortality.[31,32] Only a few trials, with small number of subjects, have assessed the efficacy of wholesale zinc supplementation for CF. Not surprisingly, zinc supplementation in patients with CF who have normal zinc levels has demonstrated no significant benefit, while supplementation in those with low zinc levels results in fewer days on antibiotics.[33]

STRATEGIES AND RECOMMENDATIONS

In an effort to improve patient education and clinical outcomes, multidisciplinary care, including early involvement by nutrition practitioners, is recommended for all patients with CF.[34]

Nutrition practitioners should have specialized knowledge of CF, as the feeding and nutritional problems can be quite complex.

Malabsorption may be particularly challenging when patients require tube feeding, especially jejunal tube feeding. In recent years, the production of powdered pancreatic enzyme replacements has ceased. Currently, the only available form of pancreatic enzyme replacement is an enteric-coated product. Administration of the product through a gastric tube requires that the outer capsule be opened, exposing coated spherules that require suspension prior to administration. However, the spherules tend to coalesce and may clog the tube. One proposed method to avoid this problem is to mix the spherules into a viscous solution prior to administration,[35] thereby keeping them suspended and preventing settling and coalescence. Others recommend dissolution of the spherules in an alkaline solution, which is then added to the feed product and allowed to sit prior to administration, resulting in feed predigestion. While addition of enzymes to the feed may facilitate predigestion, concern exists that any manipulation of feed products prior to feeding tube installation may increase the risk of bacterial contamination.[36] The data supporting this

concern, however, relate primarily to bacterial counts, rather than clinical outcomes.

ACUTE RESPIRATORY FAILURE

The importance of adequate nutrition in patients with acute respiratory failure who are admitted to critical care units has been recognized for some time. Several practical considerations in administration of nutrition in this setting are outlined subsequently.

SPECIFIC NUTRIENTS

Much has been written about the role of specific macro- and micronutrients in patients with acute respiratory failure. As discussed previously, attempts at manipulating the composition of the feedings administered, for example, the ratio of carbohydrate to fat, have been shown to be without benefit. Use of specific fats, especially oils containing omega-3 fats or their precursors, has been studied in the acute respiratory distress syndrome (ARDS), but the results are still debated.

Three prospective randomized trials were performed comparing a feeding product high in omega-3 fats and supplemented with antioxidant vitamins against a formula similarly high in fat, but with omega-6 fats. Use of the omega-3 formula resulted in decreases in the development of new organ failure, time on mechanical ventilation, and time in the ICU.[37–39] However, in the more recent ARDSNet study, patients were randomized to receive a supplement containing omega-3 fats and antioxidants. The study was terminated early due to no effect, which creates a high risk for inducing bias. Nevertheless, enthusiasm for this nutritional approach has been challenged.

TIMING AND ROUTE OF ADMINISTRATION OF ARTIFICIAL NUTRITION IN ACUTE RESPIRATORY FAILURE

The timing of initiation of enteral or parenteral feeding in critically ill patients appears to be clinically important.[40] Early enteral feeding has become standard of care in the critically ill.[41] However, studies[42] and reviews[43] of this practice have limitations and risks for bias. While early enteral feeding does not stand up to the strictest requirements for evidence-based practice and garners a C grade in evidence-based guidelines,[41] a large body of evidence exists that food in the gut may play an important role in modulating systemic inflammatory response,[44] which theoretically may lead to preservation of immune function, less catabolism, and fewer complications. Indeed, in many cases the physiologic basis for septic shock may be related to interactions between gut pathogens and mucosal cells, with or without actual septicemia.[44]

Enteral nutrition (Tables 149-2–149-4), except in the face of severe prolonged gut failure, is almost always preferred over parenteral nutrition.[45] Early parenteral nutrition, whether the sole source of calories,[46] or as a means of augmenting enteral nutrition,[47] has not proved beneficial in critically ill patients, and may, in fact, be harmful (Table 149-5). The time point at which the risks of starvation exceed the risks of parenteral nutrition is unknown, since most studies have excluded patients already suffering from malnutrition.[48] American guidelines recommend withholding parenteral nutrition during the first week of critical illness when enteral feeding is not possible.[41] Subsequent to publication of the most recent critical care nutrition guidelines, a large randomized trial showed an increase in morbidity when parenteral nutrition was added to early enteral feeding.[47]

TOTAL CALORIES PROVIDED

Whether critically ill patients should receive 100% of estimated or measured calorie needs, especially early in the course of their critical illness, is the subject of great debate. Failure of current practice to deliver "adequate" calories to critically ill patients has also received a great deal of attention. Recent surveys suggest that patients admitted to ICUs receive only about 50% of prescribed calories during their stay.[49] As a consequence, significant efforts have been made to increase calorie delivery through protocol development and quality improvement initiatives,[50] as well as through immediate initiation of parenteral nutrition to "top-off" the calories that early enteral nutrition cannot provide.[51] However, the outcome benefits of these approaches have not been proven.

In the absence of high-quality, prospective, randomized studies, we do not know how to determine the individual caloric needs of critically ill patients. Indirect calorimetry has the potential to lead us completely astray. No currently available marker, assessment tool, or nutritional score can help discern what calorie and protein prescriptions will result in the best clinical outcomes.[5] In addition, high-quality studies in which calorie top-off was achieved enterally[52] or parenterally[47] have showed no benefit. Indeed, a significant increase in gastrointestinal intolerance with early full enteral feeding,[53] and in complications and prolonged length of stay with a parenteral top-off approach have been reported.[47] The findings, from the studies using parenteral nutrition have been criticized by proponents of early achievement of calorie goals on the basis that the investigators used a parenteral nutrition practice different from that employed in North America; in fact, two small studies suggest a benefit.[51,54] However,

TABLE 149-2 Choice of Route for Administration of Enteral Nutrition

Large-bore nasogastric sump tube
Short-term (several days) feeding
Transition from gastric drainage to gastric feeding
Small-bore nasogastric feeding tube
Primary choice for nasal tubes
Short-term (up to 30–90 d)
Small-bore Nasoenteric (nasoduodenal, nasojejunal)[a]
Gastric dysmotility[b]
Very high aspiration risk[c]
Gastrostomy (percutaneous endoscopic, surgical)
Long-term (greater than 30–90 d)
Technical issues with nasal tube[d]
Jejunostomy (percutaneous endoscopic, surgical)
Gastric dysfunction[a]
Long-term access when gastric surgery anticipated[e]
Long-term access when gastric tube not possible[e]

[a]Usually 6–10 French in adults.
[b]Concomitant gastric drainage is likely to be required or vomiting can occur. Short term, a second (nasogastric sump) draining tube or use of a combined dual lumen nasogastrojejunal (draining nasogastric, feeding nasojejunal) tube may be useful. Combined dual tube draining gastrostomy-feeding jejunostomy may be useful longer term.
[c]This recommendation appears in guidelines but is not supported by prospective randomized data. While jejunal placement may result in better calorie delivery, there are no outcome data to support routine choice of jejunal, over gastric, placement of feeding tubes.
[d]With the availability of techniques, such as the nasal bridle for securing nasal tubes, security of the tube is less commonly an indication for percutaneous feeding tubes.
[e]For example, patients with gastric cancer, or esophageal cancer and planned esophagectomy and gastric pull-up.

TABLE 149-3 Usual Characteristics and Indications for Enteral Feeding Formulas

	Standard	Standard Concentrated	Standard High Protein	Renal	Diabetic	Predigested[a]	Pulmonary[b]	Immune/ Inflammation Modulating

Osmolarity[k]	Iso	Up to ~700 mOsm/L	Iso or slightly increased	~700 mOsm/L	Iso or slightly increased	Iso up to ~700 mOsm/L	Increased	Iso or slightly increased

[a]Predigested feeding products may be made up of simple sugars and individual amino acids (e.g., Vivonex™) or of oligosaccharides and oligopeptides (e.g., Vital™, Peptamen™). These are marketed as providing superior tolerance, and better absorption in states such as maldigestion, hypoproteinemia. Most of the data on these is preclinical, and there is no outcome data supporting their superiority. Very low fat feeding has been promoted as an alternative to parenteral nutrition in patients with chyle leakage. Randomized studies are lacking.

[b]These products have not been shown to have any benefit in randomized trials. The principle on which they were created is that dietary fat produces less CO_2 than does carbohydrate. While this effect can be measured on calorimetry, patients are not extubated sooner. Certainly, these products are not indicated for patients on long-term ventilatory support.

[c]Most patients can be fed with a standard feeding product. The cost differential between a standard product and the disease-specific feeds can be as much as 15 fold.

[d]An increase in calorie density, from 1.0 to 1.5 kcal/mL will not substantially increase viscosity and decreases the volume of tube feeding product required to meet calorie goals. The remainder of the volume requirements may be given as water boluses. This decreases overall feeding time and increases convenience for ambulatory patients.

[e]Patients with renal insufficiency and/or on hemodialysis, but not continuous renal replacement, require restriction of dietary sodium, potassium, and phosphorus. In addition, these products are fluid restricted.

[f]Glycemic index is the area under the curve of the rise in blood glucose after a bolus or meal, compared to a standard. This concept does not apply to patients receiving continuous feeding as rate of appearance of glucose will be equal to rate of delivery plus rate of gluconeogenesis in these patients. Glycemic control formulas only improve glycemic control in patients fed intermittently.

[g]Because of the biochemical derangements that occur in critical illness, nutrient levels and consumption are altered. These alterations have led to a great interest in supplementation of specific nutrients to reverse these derangements. There is no strong evidence that these approaches result in improved outcomes. The author believes this may be due to these derangements being adaptive, or epiphenomena.

[h]Insoluble fiber, while favored in long-term tube feeding, should be avoided in critically ill patients, especially while on pressor agents. Bezoar may form when peristalsis is diminished.

[i]Fat content in these products varies. In some, it is highly restricted to 10% of calories (long-chain fat, Vivonex™). In others, fat has been engineered to provide theoretical improvements in absorption and may contain mixtures of medium-chain, long-chain omega-3, and long-chain omega-6 fats.

[j]Fat content in these products varies widely. Products focused on inflammation may have a large amount of omega-3 and other putatively anti-inflammatory fats. Other products provide engineered triglycerides, with a mixture of long-chain omega-3 and omega-6 plus medium-chain fats. Discussed more fully in Acute Respiratory Failure/ Specific Nutrients section in text.

[k]Osmolarity of tube feeds ranges from isotonic to approximately two times isotonic. The osmolarity of many medications and electrolytes is orders of magnitude higher. The latter is a far more important concern when evaluation patients with diarrhea. It is unlikely the osmolarity of current tube feeding products will be the cause.

these smaller studies have significant flaws, and given the rigor of the larger parenteral study, its findings cannot be dismissed.

POSITION AND TIMING OF FEEDING TUBE PLACEMENT

The choice of enteral feeding tube location has been a focus of discussion in the critical care setting: gastric versus duodenal or jejunal. A related center of debate is the incidence of pneumonia with each choice. Overall, studies have shown an increase in calorie delivery using nasoenteric tubes compared with nasogastric tubes.[55] However, current investigations using more stringent feeding protocols do not demonstrate a benefit with nasoenteric tube placement. Neither mortality nor the incidence of pneumonia is affected by tube placement.[55,56] Regardless, postpyloric tube placement is advantageous over gastric placement in the setting of severe gastroparesis or severe pancreatitis, especially when the inflammatory pancreatic phlegmon causes compression of the duodenum.

When artificial feeding is desired, enteral feeding is the standard of care in pancreatitis.[57] Whether the tube should be placed in the stomach or jejunum is still a subject of debate; comparative studies have failed to show any differences in outcomes between these methods.[58]

In recent times, the practice of simultaneous insertion of tracheostomy and PEG tubes (PEG-TRACH) has gained some traction.[59] In certain institutions, interventional pulmonologists or surgeons perform both procedures in the same setting, alone or in collaboration with a gastroenterologist.

Tracheostomy is an important and beneficial adjunct in the management of the critically ill. It is used when clinicians predict that a patient will need a prolonged period of mechanical ventilation. The procedure is well tolerated and may be performed at the bedside. Tracheostomy insertion has been associated with a faster wean from mechanical ventilation, reduced incidence of pneumonia, and ultimately, shorter hospital stay.[60] Timing of tracheostomy insertion

Complications of tube access

[a]Note that while aspiration and pneumonia are associated with use of enteral nutrition, recent studies have demonstrated a lack of relationship between even vomiting and pneumonia in patients receiving enteral nutrition.[76] Furthermore, the incidence of pneumonia does not appear to be decreased by positioning tubes in the jejunum.[57]

has been debated; a move toward earlier performance has been observed because of a suggestion of improved outcomes reported in meta-analysis.[61] However, recent trials have suggested lack of real benefit from early tracheostomy. Consequently, this practice is liable to change.[62,63] Nevertheless, at present, the combination procedure of PEG-TRACH has been advocated by some and has resulted in simultaneous, early PEG insertions (in some cases within 4 days of admission to ICU).[59] Historic observational data on the feasibility of this approach are available, although the effectiveness and safety of this approach have not been studied.[64,65]

TABLE 149-5 Complications of Parenteral Nutrition

Complications of access

Refeeding syndrome
Hyperglycemia
Vitamin and mineral deficiencies due to shortages
Systemic complications
Bacteremia/central-line associated blood stream infections (CLABSI)
Overall increased incidence of infections
Hepatic dysfunction
Prolonged ICU and hospital stays

We postulate, based on discussions with critical care colleagues throughout the country, that a large portion of the drive for simultaneous PEG-TRACH is based on refusal by nursing homes in some parts of the United States to accept patients with nasal feeding tubes, coupled with the push for shorter lengths of stay. In a phone survey of the 127 nursing homes (participation rate, 85%) in New York City, 88 (81.5% of respondents) indicated that they have policies prohibiting nasal feeding tubes. Twenty nursing homes (18.5% of respondents) indicated they would accept nasal tubes, but most had not in the past 6 to 12 months.

Gastroenterologists and interventional radiologists at our institution have estimated that a large percentage of the gastrostomies placed were done solely because of anticipated discharge of the patient to a nursing home. Most nursing homes reported that their refusal of nasal feeding tubes is based on the perception of high risk of aspiration and tube dislodgement.[66] This concern is unsubstantiated in the literature. Indeed, only a total of 686 patients have been randomized in 9 trials comparing nasogastric feeding tube to PEG. PEG has been associated with fewer episodes of feeding interruption, tube blockage, tube leakage, or lack of adherence to treatment in a subset of 7 of these studies, which included only 314 patients. In aggregate, no differences were observed in the incidence of pneumonia or complication rates between the two feeding methods.[67]

Consensus guidelines suggest that PEG should be considered for patients likely to require enteral nutrition >30 days.[68] New York State Department of Health policy allows for nasal feeding tubes for up to 96 days.[69] PEG, while safe and reasonably well tolerated, is not a frivolous procedure. Mortality post-PEG insertion has been reported to be 26% at 30 days,[70] and as high as 43% at *1 week*.[71] These high rates are likely largely driven by poor patient selection. Based on these data, selection of critically ill patients undergoing tracheostomy for concurrent PEG insertion needs to be questioned. By virtue of their complex critical illness, patients undergoing tracheostomy are not at low risk for the procedure. The 30-day mortality posttracheostomy has been variously reported at approximately 30%.[60,62] By extension, one may conclude that selection criteria for combined PEG-TRACH in these series resulted in an excess PEG insertion rate of at least 30%, without demonstrable outcome benefit.

In one series of patients undergoing simultaneous PEG-TRACH, the mortality at 30 days was 11%.[59] In the surviving patients, PEG tubes were removed in 73%, with a median of 76 days (range, 24–611 days). Thus, it seems likely that PEG insertion may have been avoided in many of these patients by deferring simultaneous insertion until the prognosis for resumption of oral diet and prognosis overall were clearer and the patient more medically stable.

In summary, nasogastric feeding tubes are widely regarded as safe and are the preferred option for short-term (30–90 days) delivery of nutrition. While the risks of simultaneous PEG-TRACH insertion appears to be tolerable, based mostly on anecdotal evidence, the procedure has not been proven to be superior to a "watch and wait" approach of continuing with nasogastric feeding. Patients undergoing simultaneous PEG-TRACH should be carefully chosen for procedural risk and likelihood of long-term requirement for a tube feeding.

■ ASPIRATION AND GASTRIC RESIDUAL VOLUMES

Aspiration of gastric contents is a serious concern in the critically ill. But aspiration, by itself, should not be considered an adverse outcome unless it leads to a clinically significant event, such as ventilator-associated pneumonia. Aspiration is common in a variety of settings, such as intubation for routine surgery[72] and during sleep.[73,74] In a study published over 40 years ago, aspiration was

demonstrated in 50% of normal volunteers and in 75% of subjects with depressed consciousness.[74]

Based on the belief that the risk of aspiration is related to the volume of gastric contents, measurement of gastric residual volumes has become common practice in patients receiving enteral feeding. Many protocols and guidelines have been developed for managing tube feedings based on gastric residual volumes. Increasingly, however, this practice has been challenged. High gastric residual volumes are not associated with increases in ventilator-associated pneumonia. In fact, recent studies have questioned the value of checking gastric residuals at all. In a before–after study[75] and in a prospective randomized study,[76] checking gastric residual volumes had no impact on the incidence of pneumonia. In fact, in the randomized trial, vomiting was increased in the group of patients in whom gastric residual volumes were not assessed, but this did not result in an increase in the incidence of pneumonia.[76]

STRATEGIES AND RECOMMENDATIONS

Critically ill patients, whose prognosis warrants the intervention, should receive enteral nutrition early in their course if they are malnourished and are expected to be without nourishment for some time. Parenteral nutrition should only be used for patients with chronic gut failure, and it should not be used early. Our practice is to wait for up to 2 weeks to start parenteral nutrition in patients without preexistent malnourishment who do not respond to efforts at enteral feeding. The practice of routinely measuring gastric residual volumes has been shown to have no clinical benefit and may decrease calorie delivery.

CHAPTER 150

Diagnosis and Treatment of Pain, Agitation, and Delirium in the Intensive Care Unit

Nathan E. Brummel
Timothy D. Girard

INTRODUCTION

The large majority of patients in intensive care units (ICUs) experience pain, agitation, or delirium at some point during their critical illness. During the last two decades, tremendous growth in knowledge regarding the assessment and management of these syndromes in the ICU has prompted important changes in the practice of intensive care medicine. Validated tools now exist that allow clinicians to quickly and reliably evaluate patients for pain, assess their level of consciousness, and detect delirium. These assessments, in turn, guide clinicians as they choose and titrate therapies targeted to best manage a patient's symptoms. Novel strategies to address pain, agitation, and delirium have also recently been investigated. The use of validated tools to diagnose these important clinical issues using evidence-based management strategies has been shown to improve both short- and long-term outcomes in numerous studies. This chapter reviews these assessment tools and presents best practices for management in critically ill patients.

PAIN IN THE CRITICALLY ILL

Critically ill patients frequently suffer from pain.[1,2] Whereas effective treatments for pain are widely available, detecting pain in those critically ill patients who are unable to report it is challenging. Prolonged pain in the critically ill is associated with adverse physiologic effects.[3] Because analgesia is most effective when pain is identified and treated early, clinicians should frequently assess patients for pain and treat it when identified.[4]

■ ASSESSING PAIN IN THE CRITICALLY ILL

Pain is subjective in nature; therefore, a patient's self-report (using numeric scale or visual analog scale) is an easy and reliable method to determine its presence. In fact, the 2013 Society of Critical Care Medicine (SCCM) clinical practice guidelines on the management of pain, agitation, and delirium in the ICU suggest that the numeric rating scale be used to assess pain when patients are able to self-report.[5] Among the critically ill, however, self-reporting is not always possible due to the presence of endotracheal tubes, sedation, or delirium. Therefore, several instruments have been developed and validated to aid clinicians in identifying the presence of pain in critically ill patients.

The two most widely studied pain assessment tools for use in patients in the ICU who are unable to report pain are the Behavioral Pain Scale (BPS) and the Critical Care Pain Observation Tool (CPOT).[6,7] Both the BPS and CPOT utilize nonverbal cues and patient behaviors commonly indicative of the presence of pain; these include facial expressions, body movements, and compliance with mechanical ventilation to establish the presence of pain (Table 150-1A,B). Alternatively, a patient's surrogate may be able to provide description of behaviors indicative of pain in a particular patient, based on the surrogate's prior knowledge of the patient.[8] Finally, in the case where the clinician is unsure if a patient is having pain, a trial of an analgesic medication can be used to assess for a decrease in the suspected pain-related behaviors.[8] Regardless of the assessment method used, it is important to note that assessing for pain among the critically ill is associated with improved clinical outcomes, including optimized analgesic and sedative administration and reduced duration of mechanical ventilation and ICU stay.[9–11]

■ TREATING PAIN IN THE CRITICALLY ILL

Comprehensive pain management in the critically ill consists of pharmacologic therapies (e.g., opioid medications and nonopioid

TABLE 150-1A Critical Illness Pain Observation Tool (CPOT)

Clinical Indicator	Description	Score
Facial expression	Relaxed; no muscular tension observed	0
	Tense; frowning, brow lowering, eye tightening, neck contraction	1
	Grimacing; all previous facial movements plus eye lids tightly closed	2
Body movements	Absence of movements or normal position	0
	Protection; cautious movements, touching/rubbing site of pain, seeking attention through movements	1
	Restlessness/agitation; pulling tube, attempting to sit up, thrashing, not following commands, striking at staff, trying to climb out of bed	2
Muscle tension	Relaxed; no resistance to passive movements	0
	Tense/rigid; resistance to passive movements	1
	Very tense/rigid; strong resistance to passive movements	2
Intubated patients: Compliance with the ventilator	Tolerating vent/movement; alarms not activated, easy ventilation	0
	Cough but tolerating; alarms stop spontaneously	1
	Fighting ventilator; blocking ventilation, alarms frequently activated	2
Nonintubated patients: Verbalization	Talking in normal tone or no sound	0
	Sighing, moaning	1
	Crying out, sobbing	2

Higher scores indicate greater pain.

TABLE 150-1B Behavioral Pain Scale (BPS)

Item	Description	Score
Facial expression	Relaxed	1
	Partially tightened (e.g., brow lowering)	2
	Fully tightened (e.g., eyelid closing)	3
	Grimacing	4
Upper limb movements	No movement	1
	Partially bent	2
	Fully bent with finger flexion	3
	Permanently retracted	4
Compliance with mechanical ventilation	Tolerating movement	1
	Coughing but tolerating ventilation for most of the time	2
	Fighting ventilator	3
	Unable to control ventilation	4

Higher scores indicate greater pain.
Source: Data from Gélinas C1, Fillion L, Puntillo KA, et al. Validation of the critical-care pain observation tool in adult patients. Am J Crit Care. 2006;15(4):420–427 and Payen JF1, Bru O, Bosson JL, et al. Assessing pain in critically ill sedated patients by using a behavioral pain scale. Crit Care Med. 2001;29(12):2258–2263.

medications) in combination with nonpharmacologic approaches to ensure adequate analgesia.[4]

First-line treatment for acute, nonneuropathic pain among the critically ill is intravenous opioid analgesics, such as fentanyl, morphine, hydromorphone, methadone, and remifentanil. The specific drug choice and dose are determined by the severity of the pain, patient characteristics (e.g., age, renal, and hepatic function), the patient's clinical status, and the properties of the drug (e.g., pharmacokinetics and pharmacodynamics) (Table 150-2).

Nonopioid analgesics (e.g., acetaminophen, ibuprofen, ketamine) may be administered as adjuvant therapies to reduce the overall dose of opioids. Nonpharmacologic interventions such as massage, relaxation techniques, heat or ice application, and music therapy may provide additional analgesic effect.[4] For patients experiencing neuropathic pain, use of gabapentin or carbamazepine may be added to opioid and nonopioid analgesics.[5]

AGITATION IN THE CRITICALLY ILL

Agitation in critically ill patients is associated with adverse outcomes, such as the removal of life-support devices and danger to the patient or beside staff. Commonly, agitated patients are given sedatives to reduce agitation and prevent harm.[12] Nevertheless, it is important to remember that agitation does not equate to "sedation deficiency." Rather, the presence of agitation should prompt the clinician to search for and treat an underlying cause, such as pain, hypoxemia, metabolic derangements, developing sepsis, delirium, or withdrawal from alcohol or other drugs. Agitation exists at one extreme of the continuum of consciousness that also includes calm states and states of decreased arousal, such as stupor and coma. This section reviews methods to assess level of consciousness, as well as best practices for the treatment of agitation, primarily through the judicious use of sedative medications.

TABLE 150-2 Pharmacology of Selected Opioid Analgesics

Drug	Equianalgesic Dose	Half-life	Intermittent Dose	Infusion Dose	Adverse Effects/Other Information
Morphine	10 mg	2–3 h	0.01–0.15 mg/kg every 1–2 h	0.07–0.5 mg/kg/h	Accumulates in renal and hepatic failure; hypotension (due to histamine release)
Fentanyl	100 μg	1.5–6 h	0.35–1.5 μg/kg every 0.5–1 h	0.7–10 μg/kg/h	Less hypotension than morphine; accumulates in hepatic failure
Hydromorphone	1.5 mg	3–7 h	10–30 μg/kg every 1–2 h	7–15 μg/kg/h	Accumulates in renal and hepatic failure; use in patients intolerant of morphine or fentanyl
Remifentanil	—	3–10 min	—	Loading dose: 1.5 μg/kg Maintenance dose: 0.6–15 μg/kg/h	No accumulation in hepatic or renal failure

TABLE 150-3 Level of Consciousness Scales: Richmond Agitation–Sedation Scale (RASS) and Riker Sedation–Agitation Scale (SAS)

RASS Level	Label	Description	Label	SAS Score
+4	Combative	Combative, violent, immediate danger to staff, climbing over bedrail, thrashing side to side	Dangerous agitation	7
+3	Very agitated	Pulls to remove tubes or catheters, aggressive, requiring restraint and frequent reminder of limits	Very agitated	6
+2	Agitated	Frequent nonpurposeful movement; fights ventilator	Agitated	5
+1	Restless	Anxious, apprehensive, movements not aggressive; follows commands		
0	Alert and calm	Spontaneously pays attention to caregiver; follows commands	Calm and cooperative	4
−1	Drowsy	Not fully alert, but has sustained awakening to voice (eye opening & contact for more than 10 s)	Sedated	3
−2	Light sedation	Briefly awakens to voice (eyes open and contact for less than 10 s)		
−3	Moderate sedation	Movement or eye opening to voice (no eye contact)		
−4	Deep sedation	No response to voice, but movement or eye opening to physical stimuli	Very sedated	2
−5	Unarousable	No response to voice, physical or noxious stimulation	Unarousable	1

Higher (more positive) scores indicate greater agitation.
RASS, Richmond Agitation–Sedation Scale; SAS, Riker Sedation–Agitation Scale.

Prospective evaluation of the Sedation-Agitation Scale for adult critically ill patients. Crit Care Med. 1999;27(7):1325–1329.

■ ASSESSING AGITATION AND LEVEL OF CONSCIOUSNESS IN THE CRITICALLY ILL

A number of standardized measures can be used to determine level of consciousness in the critically ill. Although these tools are commonly referred to as "sedation-agitation scales," they can be used to evaluate all patients in the ICU, regardless of whether they are receiving sedatives, as they assess patient behaviors and response to verbal or physical stimuli to determine the patient's level of consciousness. The current SCCM guidelines recommend the Richmond Agitation–Sedation Scale (RASS) and Riker Sedation-Agitation Scale (SAS), noting that these scales are the most valid and reliable for determining level of consciousness during critical illness (Table 150-3). Unlike the Glasgow Coma Scale (GCS), the RASS and SAS have been validated for use in the setting of ongoing critical illness, even when patients are sedated or nonverbal due to placement of an endotracheal tube. Regular assessments of level of consciousness can improve detection of changes in neurologic status, as well as facilitate and guide delivery of sedatives and other psychoactive medications.

■ TREATING AGITATION IN THE CRITICALLY ILL

The first step in treating agitation should be to seek out the underlying (and potentially reversible) cause(s). Providing adequate analgesia, treating hypoxemia with supplemental oxygen, correcting electrolyte abnormalities, treating infection, providing reorientation, ensuring an environment conducive to sleep, and treating alcohol and drug withdrawal may eliminate agitation in the appropriate situation. If agitation persists despite measures aimed at addressing the underlying cause, consideration should be given to administration of sedatives.

The past decade has seen a dramatic shift in the strategies used to sedate patients in the ICU. As a result of numerous trials reporting better outcomes among patients managed using protocol-based administration of sedation compared with those managed without the guidance of a protocol,[13–16] an increasing number of ICUs are adopting algorithmic approaches to the delivery of sedatives to critically ill patients. While a multitude of protocols exists, common threads are present in each, including objective assessment of level of consciousness; prioritization of analgesia over administration of sedatives; targeting lighter, rather than moderate or heavy sedation, using intermittent dosing of medications or daily interruption of medications; and relying on benzodiazepine-sparing regimens.

■ PRIORITIZING ANALGESIA

As discussed earlier in this chapter, pain is pervasive among critically ill patients and is a frequent reason for agitation. Thus, evaluation and treatment of pain using the techniques described earlier may be sufficient to restore a patient to a calm and alert state. Several studies of sedation protocols that preferentially treated pain before administering sedatives have demonstrated improved patient outcomes,[13,17,18] and current guidelines recommend treatment of pain prior to administration of sedatives.[5]

A dramatic example of the value of pain management prior to administration of sedatives was provided in a randomized trial comparing a control group (sedated primarily with propofol) with patients managed using a strategy of "no sedation."[19] Patients received morphine for pain first, then haloperidol for agitation, then, if needed, intermittent short-course (i.e., 6-hour) administration of propofol. Only after failing this regimen (as indicated by ongoing agitation) did patients in the intervention group receive sedation using a more conventional propofol- and midazolam-based sedation strategy. Patients managed with the "no sedation" strategy had significantly better outcomes than those in the control group, spending more time off mechanical ventilation and experiencing earlier discharge from the ICU and hospital. Only 18% of patients managed using the "no sedation" strategy required continuous propofol >6 hours, a result that calls into question the still common assumption that endotracheal intubation and mechanical ventilation cannot be tolerated without the use of moderate or heavy sedation.

■ INTERMITTENT VERSUS CONTINUOUS DOSING OF SEDATIVES

As demonstrated in the aforementioned "no sedation" trial, which prioritized use of intermittent morphine and haloperidol, many analgesic and sedative medications can be delivered via intermittent

(bolus), rather than continuous, dosing. The latter has been the most common method used in ICUs,[9] with routine use of continuous infusions reflecting the fact that the majority of early studies of sedation in the ICU utilized continuous infusion strategies. Nevertheless, continuous infusion of analgesics and sedatives can lead to accumulation of the infused drug, resulting in delayed clearance and prolonged effects. Moreover, continuously infused medications are readily titrated to higher doses to treat agitation, but often the infusion may not be rapidly titrated to lower doses once the acute agitation has been controlled. These factors may combine to lead to adverse outcomes, including prolongation of mechanical ventilation and ICU and hospital stays.

One study addressed the association between continuous infusions and outcomes among 242 mechanically ventilated patients in the ICU.[20] Patients who were managed using intermittent doses of benzodiazepines were extubated sooner, were discharged from the ICU and hospital earlier, and had lower rates of reintubation compared with those who received continuous sedation. Based on these findings, the same group developed a sedation protocol that prioritized analgesia first, then intermittent bolus sedatives, before allowing continuous infusions of sedatives. In a randomized controlled trial, this sedation protocol resulted in earlier extubation and discharge from the ICU and hospital compared with management without a sedation protocol.[13] As previously described, the study comparing "no sedation" versus propofol-employed bolus doses of morphine to control pain, and even extended the preference for intermittent treatments to the use of propofol, which was limited, when possible, to only short 6-hour treatment periods—an approach that significantly improved outcomes.[19]

AVOIDING BENZODIAZEPINES

Although early trials of sedation protocols[13] utilized benzodiazepines as the sedative of choice (when an analgesia-only approach did not adequately treat agitation), more recent trials have consistently shown that benzodiazepines lead to worse outcomes than alternative sedative agents. These findings led to the SCCM guidelines suggesting that nonbenzodiazepine sedatives are preferred over sedation using benzodiazepines.

In the late 1980s and 1990s, more than a dozen randomized trials found sedation with propofol led to better outcomes than sedation with benzodiazepines.[21] However, the results did not lead to changes in standard of care, in part because control groups used continuously infused midazolam rather than intermittent boluses. In fact, clinical guidelines published in 2002 recommended lorazepam as the drug of choice for sedating patients in the ICU.[22] Therefore, a randomized trial was conducted to compare intermittent lorazepam with continuous propofol for the sedation of mechanically ventilated patients in the ICU.[23]

Patients in both groups were managed using daily interruption of sedatives. Despite the avoidance of continuous infusions in only the lorazepam group (since propofol generally requires delivery by continuous infusion when used in the ICU), patients sedated with propofol spent fewer days on mechanical ventilation. These findings were consistent with nearly every other trial comparing propofol with benzodiazepines, suggesting that continuous sedation with shorter-acting agents, such as propofol, when interrupted daily, improve outcomes compared with intermittent doses of benzodiazepines.

More recently, benzodiazepine-based sedation has been compared with other sedative agents; the alternatives to benzodiazepines have been found superior. Seven randomized trials compared sedation with benzodiazepines with dexmedetomidine among mechanically ventilated patients in the ICU; all seven found that patients randomized to sedation with dexmedetomidine had better outcomes, for example, less delirium and earlier extubation, than those sedated with benzodiazepines.[24–30] Similarly, in three trials randomizing mechanically ventilated patients to remifentanil-based sedation versus benzodiazepine-based sedation, those sedated with benzodiazepines had worse outcomes.[31–33] The pharmacologic properties of these and other agents commonly used for sedation in the ICU are presented in Table 150-4.

TARGETING LIGHT SEDATION AND DAILY INTERRUPTION OF SEDATIVES

Regardless of which medications are used to provide analgesia and sedation, it should be given in the smallest doses necessary to treat pain and agitation while allowing patients to maintain wakefulness, that is, light, rather than heavy, sedation should be the goal. Sedation protocols not only prioritize analgesics and intermittent sedatives over continuous infusions, they may also target light sedation (measured using a sedation scale) over moderate or heavy sedation.[13] Other studies[34] that randomized mechanically ventilated patients to targeted light versus moderate or heavy sedation also found that those managed with light sedation had shorter periods of ventilator dependency and ICU stays, as well as fewer disturbing memories of the ICU, compared with those managed with heavier sedation.

Whenever given, sedatives should be held each day that basic safety criteria are met, so that the clinician may assess the need for, and optimal dose of, analgesic and sedative medication required to maintain patient comfort and alert mental status. This period of daily interruption of sedatives, also referred to as a daily "wake-up," "sedation holiday," or "spontaneous awakening trial," led to

TABLE 150-4 Selected Sedative Agents

Drug	Mechanism of Action	Half-life	Intermittent Dose	Infusion Dose	Adverse Effects
Propofol	$GABA_a$ agonist	40 min	0.2–0.6 mg/kg	5–80 μg/kg/min	Hypotension, respiratory depression, pancreatitis, hypertriglyceridemia, PRIS
Dexmedetomidine	CNS α-2 agonist	$T_{1/2}$ a = 6 min $T_{1/2}$ b = 2 h	—	0.2–1.5 μg/kg/h	Hypotension and bradycardia (with loading dose); loss of airway reflexes
Haloperidol	CNS D_1 & D_2	18 h	2–10 mg	0.04–0.15 mg/kg/h	QTc prolongation; extrapyramidal symptoms; dystonia
Midazolam	$GABA_a$ agonist	3 h	0.02–0.08 mg/kg	0.04–0.2 mg/kg/h	Respiratory depression; hypotension; accumulates in renal and hepatic failure
Lorazepam	$GABA_a$ agonist	8 h	0.02–0.04 mg/kg	0.01–0.1 mg/kg/h	Respiratory depression; hypotension; propylene glycol–related acidosis; nephrotoxicity

PRIS, propofol-related infusion syndrome; $T_{1/2}$ a, distribution half-life; $T_{1/2}$ b, elimination half-life; QTc, corrected QT interval.

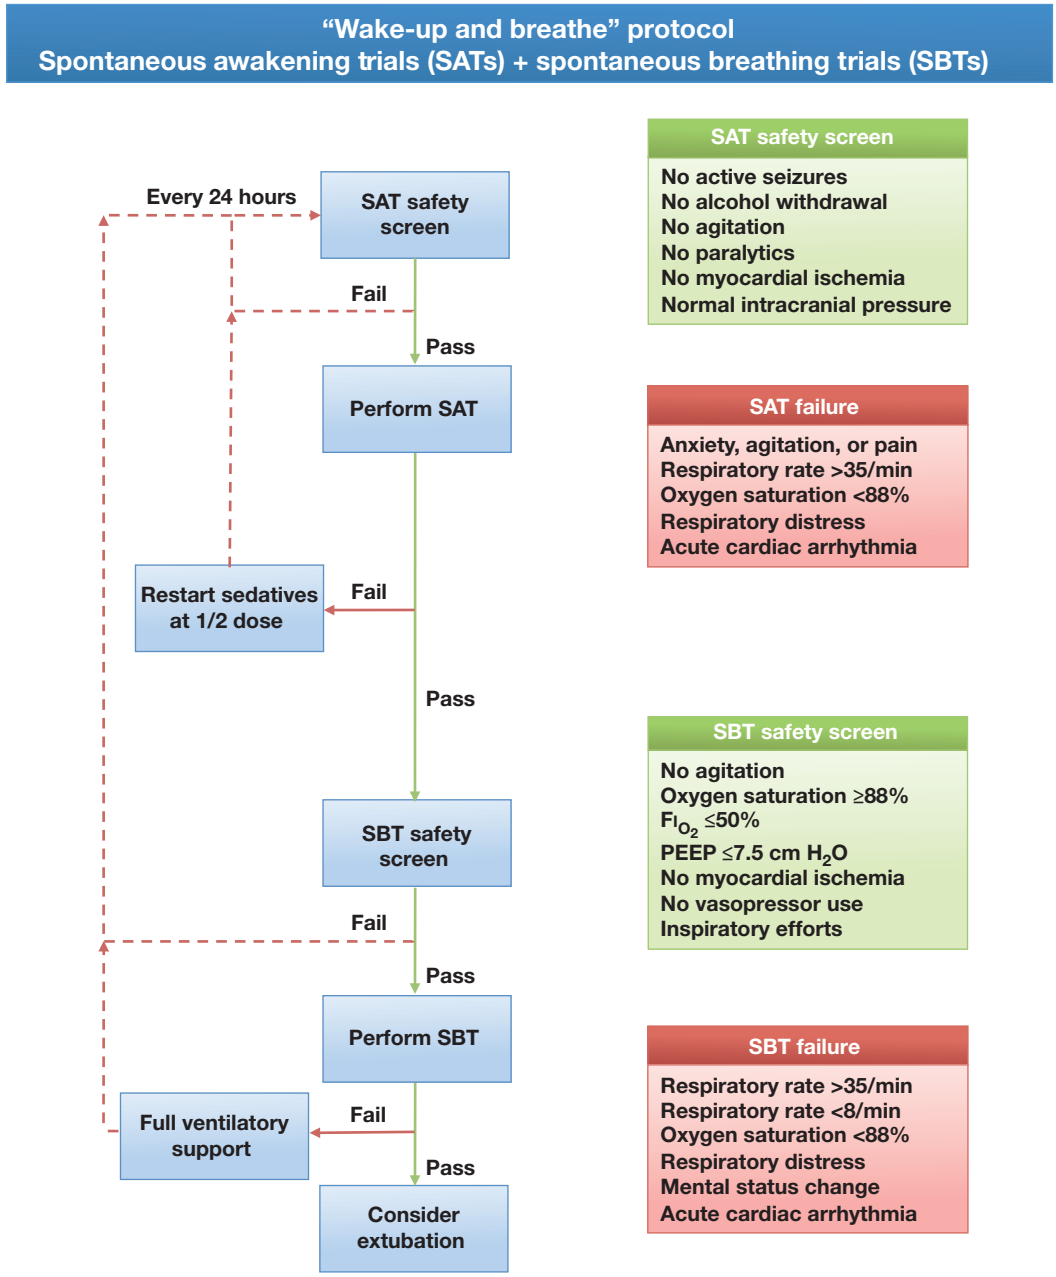

Figure 150-1 Wake-up and breathe flowchart. Each day patients should be assessed for safety criteria to perform a spontaneous awakening trial (SAT), if the safety screen is passed, all sedating medications are held until the patient is RASS-3/SAS 3 or more alert. The patient is then screened for the presence of safety criteria to undergo a spontaneous breathing trial (SBT). As with the SAT, if the SBT safety screen is passed, the patient should undergo an SBT. If the patient meets any of the failure criteria, either sedation or ventilatory support is resumed and the trial begins anew the next day. Combining daily SATs with daily SBTs is associated with shorter duration of mechanical ventilation, ICU length of stay, and a 14% improvement in mortality 1 year following critical illness. *(Reproduced with permission from copyright © icudelirium.org and Vanderbilt University, all rights reserved.)*

significantly better outcomes in two randomized trials. In one,[14] patients managed with daily interruption of sedatives had shorter durations of mechanical ventilation and shorter stays in the ICU, and in another,[15] those managed using this strategy were not only extubated earlier than those in the control group, they also were discharged earlier from the ICU and hospital; furthermore, their 1-year mortality was 14% lower than that observed in the control group. The latter trial paired daily interruption of sedatives or daily spontaneous awakening trials with daily spontaneous breathing trials as part of a strategy referred to as "Wake-up and Breathe" (Fig. 150-1).

Although most sedation trials have examined either targeted light sedation or daily interruption of sedatives, one recent randomized trial attempted to determine whether combining the two strategies yielded improved outcomes over using only targeted light sedation.[35] Patients randomized to targeted light sedation with daily interruption had similar outcomes to those managed without targeted light sedation alone; however, it is unclear whether daily interruption of sedatives was successfully carried out in this trial. Unlike prior studies in which daily interruption of sedatives significantly reduced overall exposure to sedating medications, this approach actually

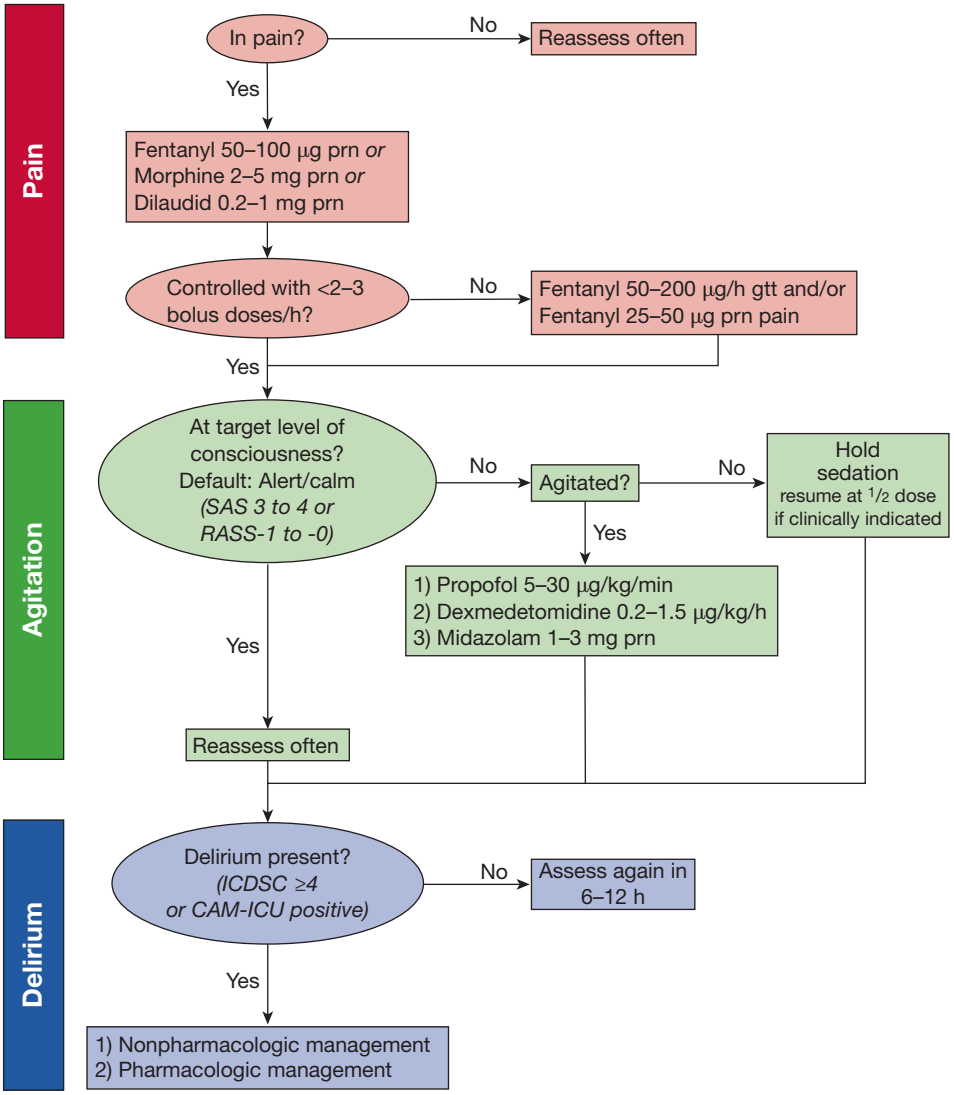

Figure 150-2 Example pain, agitation, and delirium protocol. In this example protocol, pain is first assessed and, if present, IV analgesia is given first with intermittent dosing. If more than three boluses are needed in an hour, an infusion of fentanyl is started. The patient's level of consciousness is monitored using the Richmond Agitation–Sedation Scale (RASS) or the Sedation-Agitation Scale (SAS), with a default of alert/calm or drowsy (RASS-0 to -1 or a SAS 4). If the patient is agitated despite adequate pain control, an infusion of either propofol or dexmedetomidine is preferentially used. Midazolam is begun only if the patient is withdrawing from alcohol, has a propofol intolerance or has received propofol for >96 hours. If the patient is more deeply sedated than RASS-1 or SAS 3, sedatives and analgesics are held until the patient is again alert and calm. If needed, analgesics and sedatives are resumed at half (or less) of the previous infusing dose. Each day patients undergo coordinated spontaneous awakening and breathing trials (SAT+SBT). Finally, patients are screened for delirium using either the Intensive Care Delirium Screening Checklist (ICDSC) or the Confusion Assessment Method for the ICU (CAM-ICU) and if delirium is present a cause is first sought with nonpharmacologic and pharmacologic interventions begun if no reversible cause is identified. *(Reproduced with permission from copyright © icudelirium.org and Vanderbilt University, all rights reserved.)*

increased the doses of benzodiazepines given to patients. Although this trial does not rule out the possibility that daily interruption of sedatives is beneficial when added to targeted light sedation in a way that lowers sedative doses, the study did strongly suggest that the benefit of daily interruption of sedatives is mediated through a reduction in sedative exposure. If overall exposure is not reduced, patients are less likely to benefit.

In summary, modern sedation practices (1) place an emphasis on targeted light sedation, as assessed using a validated tool for determining level of consciousness; (2) prioritize treating pain first using intravenous opiates and then, if the patient requires additional sedation, intermittent and sometimes continuous doses of a nonbenzodiazepine sedative; and (3) routinely incorporate daily interruption of drugs, maintaining a "light" level of sedation (Fig. 150-2).

DELIRIUM IN THE CRITICALLY ILL

Delirium during critical illness represents an acute form of brain dysfunction. Because it is frequently observed in the ICU, this syndrome was previously considered by many to be an expected, inconsequential complication of critical illness, often referred to as "ICU syndrome."[36] Multiple studies have shown, however, that delirium is associated with numerous adverse short- and long-term outcomes. Yet, it often goes unrecognized, in part because the most common presentation is that of hypoactive (quiet) delirium. This section reviews the definition of delirium, key features and differences from other forms of altered mental status, the current understanding of delirium's pathophysiologic basis, risk factors for development, bedside tools specifically designed to assess delirium

in the ICU, the short- and long-term consequences associated with delirium, and methods for preventing and treating delirium.

DEFINITION OF DELIRIUM

The American Psychiatric Association (APA) recently updated their Diagnostic and Statistical Manual of Mental Disorders (DSM).[37] The fifth edition (DSM-5) retained the core diagnostic criteria for delirium while making some changes: What was previously described as a "disturbance of consciousness" is now a "disturbance in attention," and the manual now explicitly states that delirium cannot be diagnosed in the setting of a "severely reduced level of arousal, such as coma." The diagnostic criteria[37] for delirium are (1) a disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment); (2) development of the disturbance over a short period of time (usually hours to a few days), in which the development represents a change from baseline in attention and awareness and which tends to fluctuate in severity during the course of a day; (3) an additional disturbance in cognition (e.g., memory deficit, disorientation, language, visual–spatial ability, or perception); (4) the disturbances in criteria (1) and (2) are not better explained by another pre-existing, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal, such as coma; (5) there is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiologic consequence of another medical condition, substance intoxication or withdrawal (i.e., due to a drug of abuse or to a medication), exposure to a toxin, or is due to multiple etiologies.

Many signs and symptoms commonly observed in delirium, such as disturbance in the sleep–wake cycle, psychomotor agitation or decreased psychomotor activity, hallucinations, delusions and perceptual disturbances, support the diagnosis, but they are neither sufficient nor required to make the diagnosis. Because these symptoms may be caused by other neurocognitive disorders, delirium is sometimes mistaken for other disorders, particularly dementia. Table 150-5 summarizes differences between delirium and dementia.

Historically, a large number of terms have been used to describe delirium in ICU patients, including encephalopathy, ICU psychosis, ICU syndrome, toxic confusional state, brain failure, subacute befuddlement, postoperative psychosis, and septic encephalopathy.[38] Use of these terms can lead to misunderstanding by practitioners, and certain terms, including ICU syndrome and ICU psychosis, can imply that the syndrome is an expected part of an ICU stay.[36,38] Therefore, regardless of the underlying etiology, the standardized term *delirium* should be used to describe a patient who meets the DSM criteria for delirium, with that underlying etiology then used to describe the delirium (e.g., use the term "delirium due to sepsis" rather than, "septic encephalopathy").[36,38]

PREVALENCE AND SUBTYPES OF DELIRIUM

Delirium is highly prevalent among mechanically ventilated patients in ICUs (60%–80% develop delirium at some point during the ICU stay)[15,24,25,39–41] and also commonly affects nonventilated patients in the ICU setting (20%–40%).[42–45] Delirium is often classified into subtypes according to the motor activity of the patient; these subtypes include *hyperactive, hypoactive*, and *mixed delirium*. Patients with hyperactive delirium are agitated, restless, and may show signs of hallucinations or delusions. Those with the hypoactive subtype are calm, lethargic, and may have decreased spontaneous movements. Finally, the mixed delirium subtype presents with features of both hyperactive and hypoactive delirium. The most common subtypes observed in the ICU are mixed and hypoactive, with purely hyperactive delirium comprising only about 1% of cases of delirium.[46–48] Research is needed to determine the clinical outcomes, especially long-term, associated with specific subtypes of delirium in the critically ill. Nonetheless, as data continue to accumulate that the length of time a patient is delirious is associated with worse clinical outcomes, the fact that a majority of delirious patients in the ICU have mixed or hypoactive subtypes is an important point for clinicians, as the presence of delirium is frequently overlooked.[49]

RISK FACTORS FOR DELIRIUM

Delirium during critical illness is typically a multifactorial syndrome that develops when a vulnerable patient encounters a sufficiently strong insult or insults to precipitate onset of the syndrome.[50] Whereas a patient with high baseline vulnerability, such as an elderly patient with underlying dementia, may require only a mild insult, such as pneumonia, a younger patient without pre-existing cognitive impairment, that is, low baseline vulnerability, may require multiple strong insults, such as severe sepsis, sedation with

TABLE 150-5 Distinguishing Delirium From Dementia

Syndrome	Onset	Course	Diagnostic Features	Associated Features	Common Causes
Delirium	Acute (hours to days)	Fluctuating	Disturbance in attention and awareness Memory impairment, disorientation, or language impairment	Sleep/wake disturbances Extremes in psychomotor activity Emotional disturbances (e.g., fear, anxiety, depression, irritability, euphoria, apathy)	Acute medical illnesses Medications Substance intoxication or withdrawal Multifactorial
Dementia	Insidious (months to years)	Progressive	Memory impairment, plus one of the following: – Aphasia – Apraxia – Agnosia – Impaired executive functioning Impairments must be severe enough to cause impairments in social or occupational functioning and represent a decline from baseline	Visuospatial impairment Little/no awareness of memory impairment Gait disturbance Anxiety/mood/sleep disturbances	Dementia of Alzheimer type Vascular dementia Chronic medical conditions (Pick disease, HIV, stroke, head injury)

benzodiazepines, and immobilization. This scenario is not uncommon, given that critically ill patients are exposed on average to 11 risk factors for delirium.[51]

Risk factors for delirium can be thought of as predisposing factors and include baseline patient characteristics and premorbid conditions, as well as precipitating factors, such as those related to critical illness and treatment in an ICU. Baseline risk factors include older age, baseline cognitive impairment or dementia, use of alcohol or tobacco, hypertension, visual or hearing impairment, and APOE4 genotype.[40,52–56] A number of precipitating factors are linked to development of delirium during critical illness, including high severity of illness, admission to an ICU for a medical illness, need for mechanical ventilation, high number of infusing medications, hypotension, acidosis, fevers, sepsis, electrolyte abnormalities, liver function test abnormalities, and anemia.[41,52–55,57,58] Whereas each of these risk factors results from a patient's critical illness, factors associated with treatment may also increase risk. Precipitating risk factors associated with treatment in an ICU include immobility, presence of gastric tubes, bladder catheters, arterial lines, sedative and analgesic medications, particularly benzodiazepines, and those factors related to the overall ICU environment, including lack of daylight, isolation, lack of visitors, and sleep disturbances.[57,59]

PATHOPHYSIOLOGY OF DELIRIUM

Delirium pathophysiology, although incompletely understood, likely represents a final common pathway from many different and, perhaps, interrelated pathophysiologic mechanisms, including neurotransmitter imbalances, inflammatory responses, aberrant stress responses, and impaired cerebral perfusion. It is thought that imbalances in the neurotransmitters that maintain arousal and sleep–wake cycles – acetylcholine and dopamine – are primary drivers of delirium.[60,61] Impaired central cholinergic functioning can result from derangements occurring anywhere along the pathway from acetylcholine production to its release and action of postsynaptic receptors. Acetylcholine deficiency or blockade has been associated with delirium, as has dopamine excess, likely through dopamine receptor regulation of acetylcholine activity.[61–63] Other neurotransmitters, such as gamma-aminobutyric acid (GABA), norepinephrine, serotonin, glutamate, and melatonin have also been hypothesized to play a role in delirium, although the contribution of these neurotransmitters in the development of delirium is less well understood.[60–65]

Alterations in precursor molecules to neurotransmitters, such as dopamine, norepinephrine, serotonin, and melatonin – in particular, the large neutral amino acids (LNAAs) – have also been hypothesized to be involved in the pathogenesis of delirium.[65] LNAAs, which include leucine, valine, tryptophan, tyrosine, and phenylalanine, compete for transfer across the blood–brain barrier via a single transport receptor, such that increased transport of one LNAA results in decreased transport of others. Thus, the concentration of neurotransmitters in the CNS is related to changes in serum concentrations of LNAAs, and changes in these concentrations have been associated with delirium during critical illness.[66–68]

Systemic inflammation, which is very common during critical illness, is also thought to play a role in development of delirium. Inflammatory molecules, such as interleukin-1β, interleukin-6, interleukin-8, tumor necrosis factor-α, prostaglandins, and blood-borne molecules, such as lipopolysaccharide, are released in response to infection, tissue damage, and surgery. These molecules interact with the brain via direct autonomic neural pathways, second-messenger systems, active transport across the blood–brain barrier, and through disruptions in the blood–brain barrier, resulting in neuroinflammation.[69–71] Neuroinflammation triggers CNS production of additional inflammatory cytokines and metalloproteinases, release of reactive oxygen species, and expansion and activation of microglia, resulting in alterations in CNS perfusion, impaired neurotransmitter production, and derangements in oxidative metabolism, ultimately leading to neuronal damage and cell death.[69,71] Neuronal death results in a functional disconnect between neuroanatomical structures, culminating in the neurobehavioral changes observed in delirium.[69]

SCREENING TOOLS FOR DELIRIUM

Since many delirious patients are lethargic or calm, rather than agitated, delirium in the ICU is overlooked nearly 70% of the time.[49] Thus, current expert guidelines recommend that all patients in an ICU be routinely monitored using a well-validated delirium-screening tool.[5] Two screening tools that were developed specifically for assessment of critically ill adult patients, the Confusion Assessment Method for the ICU (CAM-ICU) and the Intensive Care Delirium Screening Checklist (ICDSC), have been the most rigorously validated and widely implemented and, thus, are recommended in expert guidelines.[5] Validated before the recent release of DSM-5[37] criteria, both the CAM-ICU and the ICDSC were compared in validation studies with expert psychiatric examinations applying the DSM-IV[72] criteria for delirium and were found to have high sensitivity and specificity, as well as excellent interrater reliability when performed by ICU physicians and nurses.[39,44,73–77] Both screening tools identify features of delirium that remain part of the DSM-5 definition, such that the tools are considered current and valid in the DSM-5 era.

When using either the CAM-ICU or the ICDSC, the first step in assessing for delirium is to assess the patient's level of arousal/consciousness (see Assessing Agitation and Level of Consciousness in the Critically Ill); as stated in the DSM-5, delirium cannot be assessed in the setting of coma. In validation studies of the CAM-ICU, this was operationalized by determining that patients were arousable to voice (e.g., RASS-3 or more awake) before proceeding with the CAM-ICU assessment. Similarly, the ICDSC excludes patients in coma or stupor from delirium assessment. Once level of consciousness is assessed, the second step in the delirium screen is to assess the content of consciousness using either the ICDSC or the CAM-ICU.

The CAM-ICU was developed based on the full Confusion Assessment Method[78] but tailored to the specific needs of patients in the ICU (e.g., it can be performed in both nonintubated and intubated patients, even in the setting of sedation [as long as the patient is not comatose]). During what is typically a 1- to 2-minute evaluation, the CAM-ICU assesses four key features of delirium: (1) Acute change or fluctuation in mental status, (2) inattention, (3) altered level of consciousness, and (4) disorganized thinking.[39,74] The CAM-ICU is positive, that is, the patient is considered to have delirium, if features 1 and 2 are present and *at least* feature 3 or 4 is present. See Figure 150-3 for instructions on how to assess each feature in the CAM-ICU. This tool has been translated into over 20 different languages, and many of these translated versions have been validated.

The ICDSC is an 8-item checklist of delirium symptoms assessed over an 8- to 24-hour period. Providers monitor patients for the symptoms on the checklist during that period of time (e.g., during a nursing shift) and mark items on the checklist as they are observed. The symptoms include altered level of consciousness, inattention, disorientation, hallucinations/delusions/psychosis, psychomotor agitation or retardation, inappropriate speech or mood, sleep/wake disturbances, and fluctuation of symptoms. One point is given for each symptom observed; a score of four or greater indicates delirium (Table 150-6).

OUTCOMES ASSOCIATED WITH DELIRIUM

In both the short- and long-term, patients who suffer from delirium are at risk for a number of adverse outcomes. Within the context of the acute critical illness, patients who are delirious are more likely to remove catheters and endotracheal tubes, require physical restraints, and have prolonged mechanical ventilation.[52,79,80] In

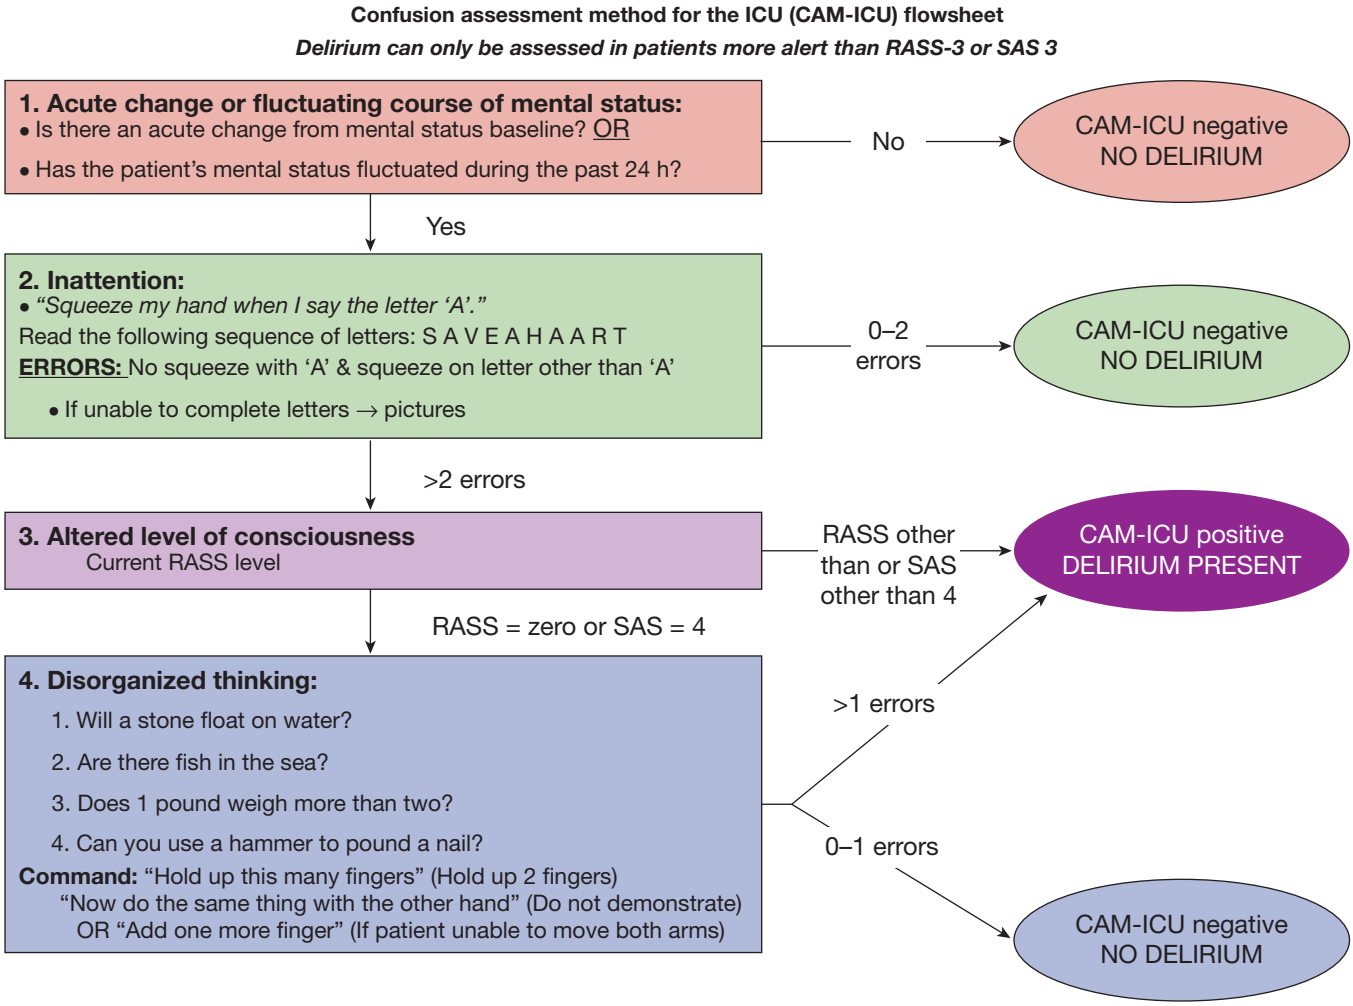

Figure 150-3 The Confusion Assessment Method for the ICU (CAM-ICU). The CAM-ICU assesses for the four features of delirium. Feature 1 is an acute change in mental status or a fluctuating mental status *(orange box)*, feature 2, is inattention, *(green box)*, feature 3, is altered level of consciousness *(purple box)*, and feature 4, is disorganized thinking *(blue box)*. A patient screens positive for delirium if features 1 and 2 and either feature 3 or feature 4 are present. *(Reproduced with permission from copyright © 2002, E. Wesley Ely, MD and Vanderbilt University.)*

addition, compared with those who do not become delirious, these patients are at higher risk for prolonged stays in the ICU and hospital, higher healthcare costs, and discharge to a location other than home.[39,55,80–83]

The adverse outcomes associated with delirium do not end at the time of hospital discharge. In two separate prospective cohort studies, each additional day a patient was delirious in the ICU was associated with a 10% increase in the hazard of death in the 6 to 12 months following hospital discharge.[84,85] In addition, two separate cohort studies have identified duration of delirium as a strong independent predictor of long-term cognitive impairment, with longer delirium durations in the ICU associated with poorer cognitive performance a full year after discharge.[86,87] Finally, one additional study noted that duration of delirium during critical illness was also associated with activities of daily living among survivors of critical illness, with prolonged delirium predicting disability during long-term follow-up.[88]

■ PREVENTING DELIRIUM

Preventing delirium from developing during a patient's ICU stay can be difficult because at the time of the patient's ICU admission, acute organ failures (often including delirium) are already present. Nevertheless, preventative measures may be beneficial, since some patients do not develop delirium until several days into their ICU stay. Additionally, because the duration of delirium is also associated with adverse outcomes, including cognitive impairment, physical disability, and death, measures that may shorten the duration of delirium should be implemented. Although not all risk factors for delirium can be avoided, three risk factors common in the ICU – exposure to sedative and analgesic medications, immobility, and sleep deprivation – have been targeted by interventions designed to prevent delirium; a number of studies have shown that these interventions are associated with reductions in delirium.

Benzodiazepines are consistently associated with the development of delirium in patients in the ICU and, therefore, serve as an easily modifiable risk factor. In studies of medical, surgical, cardiac, trauma, and burn patients, higher doses of benzodiazepines have been independently associated with higher risk for delirium.[41,53,89,90] Based on these data, a number of interventions intended to reduce exposure to benzodiazepines have been investigated. Sedation of mechanically ventilated patients using dexmedetomidine, for example, rather than benzodiazepines, reduced daily risk of delirium in two randomized trials.[24,25] In addition, in one study addressing avoidance of benzodiazepines as one part of a multicomponent quality improvement program designed to reduce delirium risk, a significant increase in days patients spent without delirium was noted.[91]

TABLE 150-6 The Intensive Care Unit Delirium Screening Checklist (ICDSC)

1. **Altered level of consciousness** Choose **ONE** from A–E
Note: May need to reassess patient if recent administration of sedation therapy
A. Exaggerated response to normal stimulation SAS = 5, 6, or 7 Score 1 point
B. Normal wakefulness SAS = 4 Score 0 points
C. Response to mild or moderate stimulation SAS = 3 Score 1 point
(follows commands) **Score 0 if LOC related to recent sedation/analgesia**
D. Response only to intense and repeated stimulation (e.g., loud voice and pain) SAS = 2 **Stop assessment**
E. No response SAS = 1 **Stop assessment**
2. **Inattention** Score 1 point for any of the following abnormalities:
A. Difficulty in following commands OR
B. Easily distracted by external stimuli OR
C. Difficulty in shifting focus
Does the patient follow you with their eyes?
3. **Disorientation** Score 1 point for any one obvious abnormality:
A. Mistake in either time, place, or person
Does the patient recognize ICU caregivers who have cared for him/her and not recognize those that have not? What kind of place are you in? (list examples)
4. **Hallucinations or delusions** Score 1 point for either:
A. Equivocal evidence of hallucinations or a behavior due to hallucinations (Hallucination = perception of something that is not there with NO stimulus) OR
B. Delusions or gross impairment of reality testing (Delusion = false belief that is fixed/unchanging)
Any hallucinations now or over past 24 h? Are you afraid of the people or things around you?
(fear that is inappropriate to clinical situation)
5. **Psychomotor agitation or retardation** Score 1 point for either:
A. Hyperactivity requiring the use of additional sedative drugs or restraints to control potential danger (e.g., pulling IV lines out or hitting staff) OR
B. Hypoactive or clinically noticeable psychomotor slowing or retardation
Based on documentation and observation over shift by primary caregiver
6. **Inappropriate speech or mood Score 1 point for either:**
A. Inappropriate, disorganized, or incoherent speech OR
B. Inappropriate mood related to events or situation
Is the patient apathetic to current clinical situation (i.e., lack of emotion)?
Any gross abnormalities in speech or mood? Is patient inappropriately demanding?
7. **Sleep/wake cycle disturbance Score 1 point for:**
A. Sleeping less than 4 h at night OR
B. Waking frequently at night (do not include wakefulness initiated by medical staff or loud environment) OR
C. Sleep ≥4 h during day based on primary caregiver assessment
8. **Symptom fluctuation Score 1 point for:**
Fluctuation of any of the above items (i.e., 1–7) over 24 h (e.g., from one shift to another) **based on primary caregiver assessment**
TOTAL ICSDC SCORE (Add 1–8)

This 8-item checklist should be completed using clinical information gathered over the last 8 or 24 h. First assess level of consciousness. If level of consciousness is C, D, or E proceed with the remaining items. Patients are given 1 point for having an obvious manifestation of the item. A score of 4 or greater is considered a positive delirium screen.

SAS, Riker Sedation–Agitation Scale; LOC, level of consciousness.

Opioid analgesic medications have also been associated with development of delirium in some studies, but the relationship between opioids and delirium is not as straightforward as the one between benzodiazepines and delirium. This difference likely relates to the dual effects of opioids. For example, when opioids are used to heavily sedate patients (particularly when used to induce coma), the risk of delirium is dramatically increased.[54,55,58] Alternatively, when opioids are used primarily to relieve pain, such as in patients with trauma or burns, the risk of delirium is actually reduced.[41,92,93] Although no delirium prevention trial to date has focused on the role of opioids, treating pain while taking care to not oversedate patients (through use of the principles described earlier in this chapter) may protect patients from developing delirium.

Immobility, particularly due to the use of physical restraints, is a strong risk factor for the development of delirium among both non–ICU-hospitalized and critically ill patients.[50,57,94] Studies in which early mobilization is promoted among critically ill patients have found that it reduced delirium.[95–98] For example, in one study,[95] mechanically ventilated patients in the ICU who were randomized to early physical and occupational therapy, rather than usual care (i.e., delayed physical therapy), on average, spent 2 fewer days in delirium than those in the control group. Similarly, another study noted that a quality improvement program focused on reducing sedation and implementing physical therapy early during the ICU stay resulted in fewer days in delirium.[99]

Critically ill patients frequently suffer sleep deprivation. In fact, studies suggest that normal sleep rarely, if ever, occurs during acute respiratory failure requiring mechanical ventilation in the ICU; in one study, only a small percentage of the sleep observed was restorative (REM) sleep, and nearly half occurred during daytime hours.[100] In light of these data and the known association between sleep deprivation and delirium outside the ICU, investigators studied the effect of earplugs in a randomized trial of patients in ICUs and found significant reductions in incidence of delirium.[101] Using a multicomponent intervention that reduced nocturnal lights and noises and provided eye masks, earplugs, and pharmacologic sleep aids, others were able to increase the number of days that patients were not delirious.[102]

TREATING DELIRIUM

After implementing the preventative measures, practitioners will likely continue to observe delirium in the ICU. Because delirium often serves as the "canary in the coal mine," heralding the onset of a new or exacerbated underlying pathology (e.g., infection, shock, or metabolic abnormality) or a response to a deliriogenic medication, a positive screen for delirium should prompt an immediate search for, and correction of, an underlying etiology and any modifiable risk factors. After addressing potentially modifiable causes of delirium, pharmacologic therapies can be considered. Although antipsychotics are frequently used to treat delirium in the ICU,[103] they are primarily used to treat hyperactive delirium[104]; this practice is primarily supported by results from studies conducted outside the ICU.

Haloperidol, the drug most commonly prescribed for delirium in the ICU,[103] is a "typical" antipsychotic that works primarily as a dopamine receptor antagonist by blocking the D2 receptor, which is believed to treat the "positive" symptoms of delirium (e.g., hallucinations, unstructured thought patterns, etc.). It also may have some sedative effect that does not result in respiratory depression. Outside the ICU, the recommended starting dose of haloperidol is 0.5 to 1.0 mg orally or parenterally, repeated every 20 to 30 minutes until the desired effect is achieved, which is usually resolution of agitation, rather than complete resolution of delirium. In the ICU, higher doses are often used, for example, 2 to 10 mg intravenously, with doses repeated every 20 to 30 minutes until the desired effect is attained. Some practitioners use scheduled haloperidol every 6 to 12 hours (intravenously or orally). Neither of these approaches, however, has been proved to be beneficial to patients in ICUs. Typical antipsychotics, in general, have not yet been extensively studied in the ICU setting. The only randomized trial to compare haloperidol with placebo for the prevention and treatment of delirium during critical illness found no significant improvement among patients treated with an antipsychotic.[105] This pilot study was small, however, and it cannot be interpreted as ruling out a beneficial effect of haloperidol in delirium.

Atypical antipsychotics (e.g., risperidone, ziprasidone, quetiapine, and olanzapine) are also used to treat delirium in the ICU.[105–107] The rationale supporting their use over haloperidol is theoretical and arises from the atypical antipsychotics' effect not only on dopamine, but also on other potentially key neurotransmitters, such as serotonin, acetylcholine, and norepinephrine.[108] Results of prospective studies comparing atypical antipsychotics with placebo or typical antipsychotics in the treatment of delirium have been mixed.[105,107] Although one very small randomized trial found that quetiapine was effective in treating delirium compared with placebo,[106] another small randomized trial found no differences in neurologic outcomes among patients treated with ziprasidone, haloperidol, or placebo.[105] In aggregate, these trials do not provide strong evidence for use of atypical antipsychotics over typical antipsychotics; thus, recent guidelines review the evidence but do not explicitly recommend antipsychotics for the treatment of delirium.

When antipsychotics are used to treat delirium in the ICU, clinicians should monitor for adverse effects, which may include hypotension, acute dystonia, extrapyramidal effects, thrombotic complications, oversedation, laryngeal spasm, neuroleptic malignant syndrome, glucose and lipid dysregulation, and anticholinergic effects, such as dry mouth, constipation, and urinary retention. One of the most immediate life-threatening adverse effects of antipsychotics is torsades de pointes,[109–111] so these agents should be given to patients with prolonged QTc intervals with caution.

CHAPTER 151

Early Mobilization of Patients in the ICU

William D. Schweickert

INTRODUCTION

Improvements in diagnosis and resuscitation of critically ill patients have prompted investigation into the burden of "survivorship."[1–5] Observational research has described substantial morbidity in survivors of critical illness, including general deconditioning, muscle weakness, dyspnea, depression, anxiety, and reduced health-related quality of life.[6] A major catalyst for widespread attention was the comprehensive observations on a cohort of survivors of acute respiratory distress syndrome (ARDS).[7] In this case series, patients were young and generally healthy prior to ARDS, and they experienced severe illness with prolonged critical care. Despite severe acute lung injury, serial follow-up examinations demonstrated that lung function generally normalized during the first year after ICU discharge. In contrast, all patients reported poor function attributed to the loss of muscle bulk, proximal limb weakness, and fatigue. Patients exhibited impaired endurance, and only 49% of patients had returned to work. At 5 years after ICU discharge, subjective weakness and decreased exercise capacity continued.[8] Although 77% of patients were working by the fifth year, patients often required a modified work schedule, gradual transition back to work, or job retraining. In addition, patients were plagued with psychological illness. More than half of survivors experienced at least one episode of depression or anxiety.

Other investigations have reported similar findings of post-ARDS debilitation.[9,10] An observational trial measured a 66% cumulative incidence of physical impairment during 2-year follow-up.[9] The impairment, defined as the acquisition of two or more dependencies in instrumental activities of daily living, had greatest incidence by 3 months after discharge and was associated with longer ICU stay and prior depressive symptoms.

Acquired neuromuscular weaknesses, loss of function, and cognitive impairment have been measured in other critical care settings, such as in severe sepsis and during mechanical ventilation in the elderly. For example, the morbidity of a hospitalization for severe sepsis was evaluated utilizing a registry of Americans over age 50 years who underwent biennial evaluations of cognitive and physical function.[11] Among patients with no functional limitations at baseline, hospitalization for severe sepsis was associated with the development of 1.57 new limitations, as well as a more rapid rate of development of functional limitations after hospitalization. In addition, the incidence of severe sepsis was highly associated with progression to moderate-to-severe cognitive impairment. Similar acquired disability has been observed in a longitudinal study of elderly patients undergoing hospitalizations that included need for mechanical ventilation.[12] In adjusted analyses, mechanical ventilation was associated with a 30% greater disability in activities of daily living and a 14% greater disability in mobility.

These studies show that decrements in physical function occur across the spectrum of critical illness. Although outcomes may be influenced by other factors, such as age, pre-existing comorbidities, acquired psychological and cognitive dysfunction, and social support, it is clear that weakness needs to be recognized early to enable preventive interventions.

ICU-ACQUIRED WEAKNESS

Many patients admitted to the ICU develop a syndrome of neuromuscular dysfunction characterized by generalized muscle weakness and an inability to be liberated from mechanical ventilation. Since this syndrome occurs in the absence of preexisting neuromuscular disease, it is believed to reflect illnesses or treatments occurring in the ICU. Early reports described two categories of acute, acquired neuromuscular dysfunction: polyneuropathy and myopathy.[13–15] Decades of research on this acquired nerve and muscle injury has characterized specific phenotypes with respect to comprehensive physical examination findings, electrophysiologic testing results, and muscle and nerve histopathology. Overall, the spectrum of neuromuscular disorders acquired in the ICU is now collectively referred to as "ICU-acquired weakness" (ICUAW).[16]

Several studies have attempted to establish the prevalence of ICUAW and its associated risk factors. To date, the best summary data are outlined in a systematic review of 24 published studies that included both clinical and electrophysiologic characterizations of the weakness.[17] Of 1421 total patients with sepsis, multiorgan failure, or prolonged mechanical ventilation, 46% had ICUAW. The risk of ICUAW was associated with hyperglycemia (and inversely associated with tight glycemic control), the systemic inflammatory response syndrome (SIRS), sepsis, multiple organ dysfunction, renal replacement therapy, and catecholamine administration. Across studies, there was no consistent relationship between ICUAW and patient age, gender, severity of illness, or medication exposure. Similar findings have been found in a seminal observational study describing ICUAW.[18] In this study of patients undergoing seven or more days of mechanical ventilation, 25% experienced ICUAW. Independent predictors of ICUAW included the number of days with multiple organ dysfunction and the duration of mechanical ventilation. In contrast to the systematic review, female sex and administration of corticosteroids were strong predictors of ICUAW.

Unfortunately, few modifiable risk factors for ICUAW have generated opportunities to improve outcomes. Prospective, randomized trials focusing on exposure to corticosteroids and neuromuscular blocking agents have demonstrated neither consistent nor conclusive results for an association with weakness.[19–21] A Cochrane review identified only one successful preventive intervention for ICUAW: insulin therapy with strict glycemic control.[22] This finding, based on two, single-center, randomized trials, has been challenged by results from subsequent multicenter trials. Specifically, recent trials of intensive insulin therapy have been associated with an increased risk of severe hypoglycemia and either increased or unchanged mortality rates when compared to more permissive blood glucose ranges.[23,24] Accordingly, this treatment option has not been embraced.

For all forms of ICUAW, care is supportive and includes aggressive management of sepsis and underlying medical conditions. Because prolonged immobilization and bed rest have been shown to accelerate muscle loss, early mobilization has emerged as a potential preventive measure. Although no one has systematically measured immobility during ICU care, clinicians acknowledge its occurrence during the earliest days of critical illness, particularly during deep sedation or neuromuscular blockade, specific mechanical ventilation strategies (e.g., prone ventilation), and other advanced support (e.g., continuous hemodialysis).

THE CONSEQUENCES OF BED REST AND INACTIVITY

Rest is necessary for the repair of weak or damaged tissue and muscle remodeling. Prolonging rest has potential benefit, such as avoiding pain in the injured body part and permitting maximal

Figure 151-1 **A.** A patient with cystic fibrosis, pneumonia, and respiratory failure ambulating in ICU on day 5 while receiving invasive mechanical ventilation via an oral endotracheal tube. He is accompanied by his nurse, respiratory therapist, physical therapist, and wife. **B.** Patient with exacerbation of chronic obstructive pulmonary disease and pneumonia marching in place while undergoing noninvasive ventilation under the direction of a physical therapist.

utilization of metabolic resources for healing.[25] Reducing oxygen consumption, minute ventilation needs, and cardiac demand via rest during critical illness may be logical. However, investigations have found few studies that demonstrate even modest benefits from extending bed rest. In contrast, trials of rheumatoid arthritis, low back pain, uncomplicated myocardial infarction, pulmonary tuberculosis, and deep venous thrombosis have demonstrated improved outcomes when bed rest was limited or avoided.[26]

Prolonged physical inactivity has been modeled through investigations of space flight, immobilization of a limb, lower limb suspension, and bed rest.[25,27] Each of these modalities demonstrate that muscle mass, as assessed using computed tomography or magnetic resonance imaging, decreases by approximately 1.5% to 2.0% per day during the first 2 to 3 weeks of enforced rest. Measures of muscle strength demonstrate weakness that parallels the changes in muscle size. For example, individual studies have shown knee extensor strength declined by 22% after 14 days and by 53% after 28 days of limb immobilization.[28,29] Limb casting models of immobilization demonstrate declines in strength as high as 5% to 6% per day.[30,31] The antigravity muscle groups – located in the legs, trunk, and neck – experience the most pronounced muscle atrophy.

Limb injuries of prolonged inactivity also include loss of joint range of motion and muscle contractures. One study of survivors of a 2-week or longer critical illness found that joint contractures occurred in 39% of patients.[32] At the time of discharge from intensive care, 34% of patients had at least one functionally significant contracture, and 23% of patients had functionally significant contractures persisting at the time of discharge. The most commonly affected joints at the time of discharge were the elbow (34%) and ankle (33%).

Other injuries associated with prolonged bed rest and inactivity include pressure ulcers, atelectasis, and thromboembolic disease.[25] Indolent effects, such as endocrinopathy and cardiovascular function, have also been described. For example, healthy volunteers undergoing bed rest demonstrate insulin resistance and increases in total cholesterol and triglycerides.[33] Orthostatic intolerance from baroreceptor dysfunction is commonplace; studies demonstrate increases in systemic vascular resistance following bed rest. For the patient in the ICU, superimposing these developments on existing critical illness may be costly with respect to both survival and survivorship.

MOBILIZATION OF THE CRITICALLY ILL PATIENT

Mobility has long been recognized as a measure to hasten recovery. Given the commonality of ICUAW and the potential for immobility in routine critical care, particularly during mechanical ventilation, investigators have targeted early mobilization as a potential opportunity to improve strength and functional outcomes in survivors (Fig. 151-1). In summary, recent trials highlight that early exercise and mobilization are safe to conduct despite ongoing critical illness, improve patient functional outcomes, and shorten ICU and hospital lengths of stay.[34] Although most investigations have focused selectively on patients undergoing mechanical ventilation, the results are likely generalizable to broader populations of critically ill patients.

PASSIVE RANGE OF MOTION

Passive range of motion exercise is conducted to preserve the range of the joint. Passive range of motion exercise is an expectation of routine care, yet often overlooked. However, evidence to support the isolated use of passive movement is weak. Limited evidence suggests that it may prevent protein degradation, maintain muscle mass, and alter the inflammatory profile in humans. For example, in 20 subjects with severe sepsis or septic shock randomized to 30 minutes of predominantly passive exercise or no intervention, the group receiving passive exercise demonstrated preserved fat-free mass, decreased IL-6 and increased IL-10 levels compared with control patients, who lost 7% of fat-free mass in the first 7 days following admission to the ICU.[35]

One study examined whether muscle wasting in critically ill patients could be prevented with stretching alone.[36] Continuous passive motion was administered by a machine over 7 days to one leg of five separate critically ill adults. In the muscles that received continuous passive stretch, smaller reductions in muscle fiber cross-sectional area and protein per gram of wet muscle weight were noted. However, clinical observation suggests that more than simple passive movement is necessary to help preserve muscle strength.

■ ACTIVE RANGE OF MOTION

"Early mobilization" is defined as the intensification and early application of physical and occupational therapy administered to critically ill patients. The safety and feasibility for early mobilization during mechanical ventilation was first captured in a descriptive cohort study published in 2007.[37] This single-center study in a respiratory ICU tracked the activity levels of 103 patients over an average of 10 days following inception of critical illness. The exercise program began once patients responded to verbal stimulation and exhibited stable respiratory and cardiovascular function (defined as $F_{I_{O_2}} \leq 0.6$, PEEP ≤ 10 cm H_2O, and absence of orthostatic hypotension and catecholamine drips). The exercise team, including physical therapist, respiratory therapist, nurse, and critical care technician, focused training on three activities: sitting on the edge of the bed, sitting in a chair after bed transfer, and ambulation. Maximal activity level was tracked. For this cohort, ICU measurements at discharge showed that 77% of patients were able to ambulate (including 69% able to ambulate >100 ft), 15% of patients were able to sit in a chair, and 5% of patients were only able to sit at the edge of the bed. Most importantly, only 14 of the 1449 activity events resulted in predefined adverse events. Specifically, there were five falls to the knees without injury, four drops in systolic blood pressures to <90 mm Hg, one systolic blood pressure rise to >200 mm Hg, three oxygen desaturations to <80% saturation, and one nasal feeding tube dislodgement.

To emphasize the differences in their practice of early mobilization compared to other ICUs, the same investigators studied the performance levels of mechanically ventilated patients within a 2-day window before and after transfer to the ICU.[38] Within 24 hours of arrival, patients successfully underwent more intense physical activities. For example, ambulation increased from 11% pretransfer to 41% within 48 hours. Multivariable logistic regression demonstrated that transfer to the therapy-dominant ICU was independently associated with the likelihood of ambulation. This study was the first to demonstrate that a unit-based culture of early mobilization could significantly influence patient functional performance.

The first prospective trial comparing early exercise and mobilization with usual care was published in 2008.[39] In this study, a mobility team, including a physical therapist, nurse, and nurse assistant, implemented stepwise increases in therapy based on patient participation and tolerance. Therapy spanned passive range of motion (ROM) to active ROM exercise, sitting, transfers, and ambulation. Therapy practices between groups were strikingly different: 80% of intervention patients underwent at least one therapy session compared with only 47% of patients in the usual care group. Intervention patients were bedridden for a shorter period (8.5 vs. 13.7 days) and had a reduced hospital length of stay (14.9 vs. 17.2 days). Recently, longer-term outcomes of the initial 330 patient cohort were reported.[40] In multivariate analysis, the lack of early ICU mobility was independently associated with readmission(s) or death during the first year. Although the etiology for readmission and death was not specified, these findings suggest early ICU mobility may have a sustained effect.

In 2009, a prospective, dual-center, randomized, clinical trial of very early mobilization was published.[41] One hundred and four patients in medical ICUs were enrolled within 72 hours of the onset of respiratory failure requiring mechanical ventilation. Patients were randomized to an intervention group that received mandated, progressive physical and occupational therapy, or a control group with therapy services ordered by the primary team. The dual therapist team treated patients daily with progressive mobilization, including bed exercises, sitting at the edge of the bed, simulation of activities of daily living, transfer training, and ambulation. In the intervention group, patients underwent therapy on 87% of days, beginning 1.5 days after intubation, compared to 7 days in the control group. Within 4 days, 76% of intervention group were sitting at the edge of the bed, 33% were standing and transferring to a chair, and 15% were ambulating. At hospital discharge, patients in the intervention group had a higher rate of return to independent functional status (59% vs. 35%), greater independent walk distance, and were more likely to be discharged to home (43% vs. 24%). In addition, patients in the intervention group experienced a reduced duration of delirium (2 vs. 4 days) and more ventilator-free days (23.5 vs. 21.1 days), but no significant difference in ICU or hospital length of stay.

Finally, combining the interventions of sedation minimization and early mobilization may yield the most pronounced benefit for patients with respiratory failure. This was demonstrated by a quality improvement project conducted in 2010 in a tertiary academic center.[42] In the preintervention phase, mechanically ventilated patients were deeply sedated during 58% of all patient-days and were either deeply sedated or delirious on more than 85% of all patient-days. Only 24% of patients had consultations for PT or OT while in the medical ICU. Early mobilization stakeholders implemented the following changes: education on sedation and mobilization practices, augmentation of therapist staffing, promotion of physiatry and neurology consultation, and provision of regular feedback to clinicians on these practices. In the postintervention period, patients were more likely to be awake without delirium, receive more therapy services, and exhibit improved functional mobility. In addition, administrative data on all patients in the medical ICU demonstrated reductions in lengths of stay in the ICU (2.1 days) and hospital (3.1 days).

■ USE OF ASSISTIVE TECHNOLOGIES

Assistive technologies offer the opportunity to begin physical activity at the earliest phases in critical illness. So far, two techniques have been studied most extensively: cycle ergometry and neuromuscular electrical stimulation. Both interventions offer the promise of muscle engagement in the noninteractive patient.

The cycle ergometer is a stationary cycle that can be positioned above the foot of the bed (Fig. 151-2). The device can alter the

Figure 151-2 A 58-year-old man with chronic hemiparesis undergoing passive cycling on a cycle ergometer while undergoing invasive mechanical ventilation for acute respiratory distress syndrome complicated by severe sepsis and hypoactive delirium.

amount of work performed by the patient, including passive cycling for the comatose patient. Engaged patients can actively pedal with varying resistance. In healthy subjects undergoing prolonged immobilization, this cycling has been shown to preserve thigh muscle thickness.[43] In addition, the technique has been proved to be both feasible and safe during hemodialysis and for patients with chronic obstructive pulmonary disease.[44,45]

Multimodality mobilization, combining cycle ergometry and standard physical therapy, has been tested in a single-center randomized trial.[46] Ninety patients with ICU stays greater than 5 days were randomized to either multimodality therapy or standard physical therapy alone. Patients receiving the intervention underwent cycling sessions conducted 5 days per week, lasting approximately 30 minutes per session. The study demonstrated safety, feasibility, and efficacy. Of the 425 cycling sessions, no serious adverse events were noted. Only 4% of sessions resulted in early termination due to oxygen desaturation or significant changes in blood pressure. At hospital discharge, patients in the intervention group exhibited a longer 6-minute walk distance, higher survey scores on physical function, and greater increases in quadriceps force.

The second technique, neuromuscular electrical stimulation (NMES), creates nonvolitional contraction of skeletal muscles. Skin surface electrodes deliver low-voltage electrical impulses to underlying muscle. NMES has been studied in outpatients with chronic heart failure and chronic obstructive lung disease to preserve or improve muscle mass, exercise capacity, and function.[47] Despite the promise of the technique, randomized trials in critical illness have reported conflicting results. Six unique ICU trials in patients with acute respiratory failure and sepsis and a trial in patients receiving chronic mechanical ventilation demonstrated mixed, but promising results for potential efficacy.[48] For example, the largest study of critically ill patients randomized 140 patients to NMES versus standard care. Sessions of transcutaneous lower extremity muscle stimulation were conducted daily for 1 hour.[49] Patients in the intervention arm exhibited higher static muscle strength sum scores compared with controls. However, concerns over endpoint selection, measurement

TABLE 151-1 Criteria to Guide Physical Therapy Consultation based on Prior Clinical Trials of Exercise and Mobilization

Neurologic	Patient responsive to voice (e.g., RASS ≥ -3)[40]
Respiratory	PEEP ≤ 10 cm H_2O
	F_{IO_2} ≤ 0.6
Circulation	Minimal vasopressor(s)
	No increase in dose of any vasopressor for ≥ 2 h
	No evidence of active myocardial ischemia
	Stable heart rate and cardiac rhythm

F_{IO_2}, Fraction of inspired oxygen; PEEP, Positive end-expiratory pressure; RASS, Richmond Agitation-Sedation Scale.

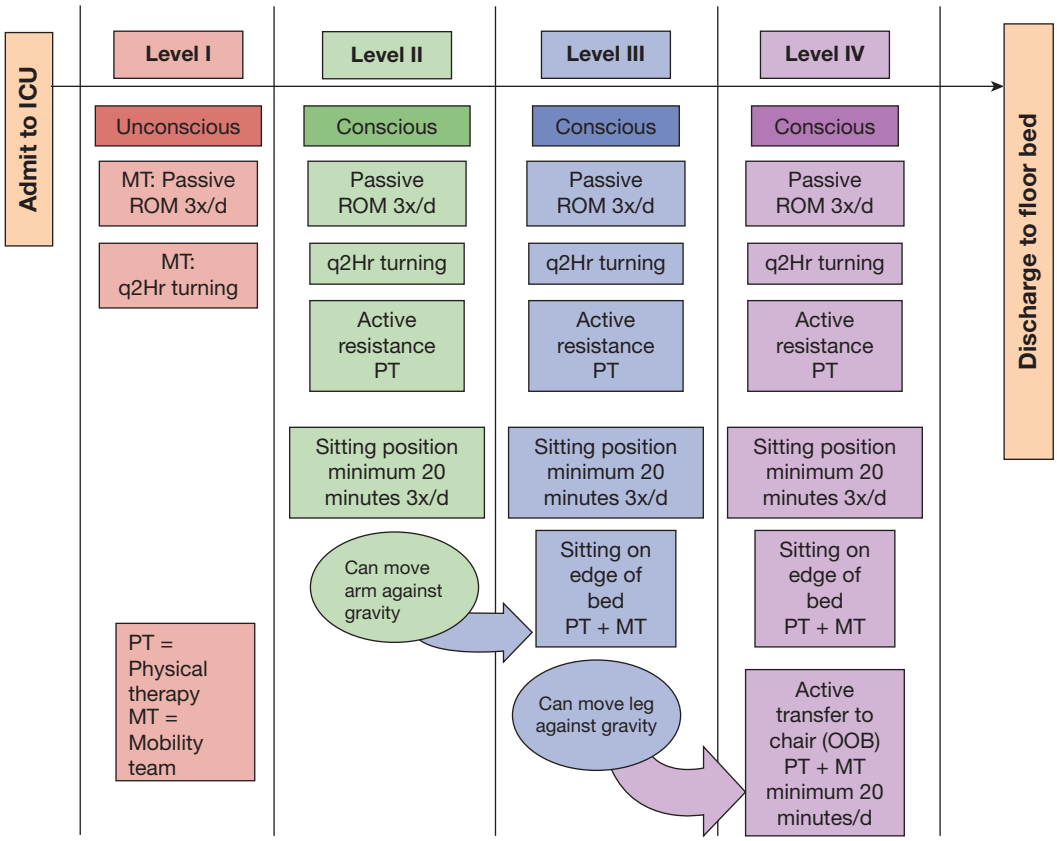

Figure 151-3 Passive range of motion therapy started on day 1 of protocol (level I). As patients demonstrated consciousness and increased strength, they were moved to the next higher level. Physical therapy would first be attempted at level II. The protocol's intervention ceased as a patient was transferred to a floor bed and the patient within both "protocol" and "usual care" groups would receive usual care mobility therapy as dictated by the floor physician teams. *(Reproduced with permission from Morris PE, Goad A, Thompson C, et al. Early intensive care unit mobility therapy in the treatment of acute respiratory failure. Crit Care Med. 2008;36(8):2238–2243.)*

bias, and the need to assess patient tolerance have generated a call for further investigation prior to widespread implementation.

PRACTICAL IMPLEMENTATION OF AN EXERCISE AND MOBILIZATION PROGRAM IN AN ICU

To translate early exercise and mobilization to the acute care ICU, programs must adapt to balancing unpredictable acute care management with the desire to keep rehabilitation a priority. Competing challenges include patient factors (such as delirium and pain), critical care procedures (such as dialysis and bedside procedures like vascular catheter insertion), and clinician factors (such as biases about safety and rehabilitation).

Maximal patient engagement requires optimal management of pain, agitation, and delirium. Protocols to guide drug sedative and analgesic administration may be a necessary prerequisite. In accordance with guidelines, hallmarks of such programs include the utilization of a reproducible, validated scale (e.g., Richmond Agitation and Sedation Scale), an established sedation target prescribed daily, and nurse-led titration of drug administration.[50] Although recent research has questioned the necessity of daily interruption of continuous sedative and analgesic infusions, all experts agree that methods to aggressively minimize drug administration to a "least necessary" model are optimal.[51]

For the mechanically ventilated patients, some experts have advocated the bundling of early mobilization with programs that include spontaneous awakening trials, spontaneous breathing trials, and delirium screening. This bundle, termed "ABCDE," stands for Awake and Breathing Coordination, Delirium screening, and Early mobility.[52] The individual components are based upon clinical trials of benefit (excluding delirium screening) with improved outcomes, such as reductions in ICU and hospital lengths of stay and duration of mechanical ventilation, as well as an association with improved mortality at 1 year.[41,53,54] Clinical researchers are now assessing the feasibility of broad implementation of the initiative.[55]

Criteria to guide initiation of therapy are similarly important. Observational and interventional trials to date have used criteria focusing on the cardiovascular, pulmonary, and neurologic systems to identify candidate ICU patients (Table 151-1).[37,39,42] However, these criteria have been developed for patients undergoing mechanical ventilation and may need further additions as broader patient populations are engaged (e.g., patients with recent gastrointestinal bleeding or surgery). In contrast, veteran critical care therapists may find these criteria too conservative. Data has shown that mobilization may occur in contexts of greater ventilator or oxygen dependence, and patients with advanced delirium or coma may engage in exercise through the use of assistive devices.[56]

Finally, therapy should proceed in a logical, stepwise fashion. Activity and exercise should be targeted for the appropriate intensity and modality. Investigators have proposed detailed approaches for the progression of activities, based on levels of patient consciousness, cooperation, and functional status.[39] Figure 151-3 is a general guide for emerging programs. Acutely ill, comatose patients receive passive ROM, muscle stretching, splinting as needed, and body positioning. Once interactive, patients can increase their level of activity, progressing from active ROM to sitting at the edge of the bed, transfers to chair, marching in place, and then ambulation. Standing and walking frames enable the patient to mobilize safely with attachments for bags, lines, and leads that cannot be disconnected. For the patient with advanced weakness, standing aids and tilt tables enhance physiologic responses as a modality to promote early mobilization of those who are critically ill.

CONCLUSIONS

Although early mobilization may be undertaken by physical and occupational therapists, the feasibility of the intervention rests firmly upon the entire ICU team. Clinicians must balance the desire for rest and recovery from the acute illness with the recognition that maintaining some degree of activity will improve patient outcome. Standardized approaches to pain, agitation, mechanical ventilation, and device management may help to safely conduct mobilization during the earliest days of critical illness. This multidisciplinary teamwork – involving physicians, nurses, and respiratory, physical, and occupational therapists – is necessary to maximize both survival and quality of life for survivors.

CHAPTER 152

Organization of Intensive Care Units and Long-Term Acute Care Hospitals

Mark E. Mikkelsen
Barry D. Fuchs
Michael A. Grippi

INTRODUCTION

The birth of modern day critical care is traditionally ascribed to Bjorn Ibsen, a Harvard-trained Danish anesthesiologist, who led the efforts to combat the poliomyelitis epidemic in Copenhagen in 1952.[1] By relying on the manual power of volunteers to ventilate the critically ill for extended periods of time, respiratory failure-related mortality declined precipitously. From these humble beginnings, the growth of critical care medicine over the ensuing years has been exponential.

The tenets of 21st century critical care include the provision of care by professionals with diverse yet complementary experience and expertise that is delivered across the continuum of care. The nexus of critical care is the Intensive Care Unit (ICU), where critically ill patients are brought to be resuscitated and managed. It is estimated that there are in excess of 5.7 million annual ICU admissions in the United States, and the numbers continue to increase.[2,3] The costs attributed to the care of the critically ill continue to increase dramatically and currently exceed $80 billion, 13% of hospital costs, 4% of the United States healthcare expenditures, and approximately 1% of the gross domestic product.[4] Approximately 500,000 patients admitted to an ICU die.[2] However, as a result of advances in the field, mortality is decreasing and the vast majority of critically ill patients survive. The direct result is that coordinated care is required following discharge from the ICU for these complex patients who have often sustained significant morbidity (e.g., postintensive care syndrome).[5,6]

STRUCTURAL ORGANIZATION

The administrative and functional organization of critical care has evolved over decades. Selected aspects of this organization are discussed in the following sections.

THE CONTINUUM OF CRITICAL CARE

The care of the critically ill patient begins at first recognition of physiologic derangement. The opportunity to alter the patient's course begins with the initial encounter with the healthcare system. Across the continuum of care (Fig. 152-1), this encounter may occur in the prehospital environment, outpatient clinic, or emergency department (ED). For the hospitalized patient, deterioration may occur on the medical or surgical inpatient unit. Evidence suggests that outcomes are significantly worse in patients admitted to the ICU from the general inpatient unit, in comparison to patients admitted through the ED or postoperatively.[7] Once critical illness has been recognized, the tenets of care include resuscitation and stabilization and efficient and safe transport to the ICU. Traditionally, efforts to optimize care of the critically ill patient were focused on management provided in the ICU. One of the greatest advances in critical care medicine has been the recognition that the structure and processes of care in locations outside of the ICU (prehospital environment, ED, inpatient unit) are of paramount importance in optimizing care for these vulnerable patients.

THE RAPID RESPONSE TEAM

Over the last 15 years, driven by the observation that many transfers to the ICU were either avoidable or characterized by delayed or

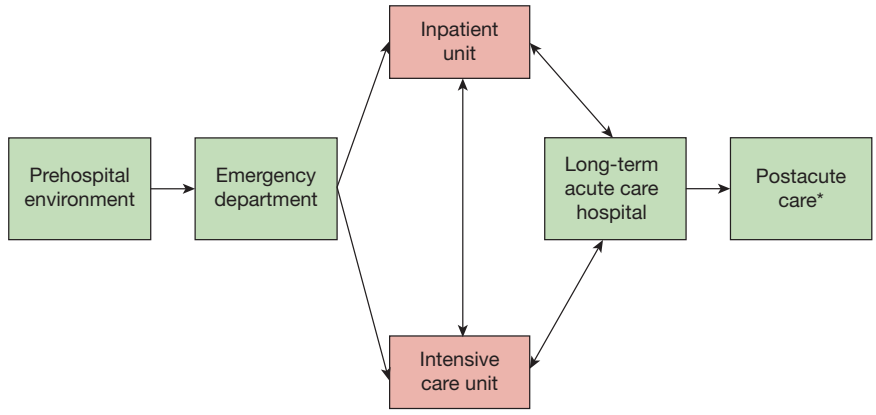

Figure 152-1 The continuum of critical care. *Postacute care includes skilled nursing facility, acute rehabilitation, and home.

suboptimal care,[8,9] substantial growth in the use of rapid response teams (RRTs) has been observed. RRTs, also known as emergency medical teams, serve as the efferent arm of the critical care response in the hospital. Traditionally, primary care providers, including trainees inexperienced in the management of the critically ill, led the resuscitation. However, primary care providers often have competing responsibilities that may impede their ability to assess and manage the deteriorating patient in a timely fashion. Further, based on the concept that a team of experienced critical care providers tasked to respond immediately to the bedside of a deteriorating patient would result in improved outcomes, hospitals have widely adopted the RRT model as a means to improve patient safety.

The success of the RRT is dependent on the ability of the screening method to detect the deteriorating patient ("afferent" limb), as well as the staffing and experience of the efferent arm. Several strategies exist to recognize the deteriorating patient in a timely fashion. The most commonly applied strategy is the modified early warning score (MEWS), a simple and effective tool that trends vital signs and consciousness to identify patients at risk of adverse outcomes, including ICU admission and death.[10] The MEWS has been validated in medical and surgical patients; an important characteristic is that it relies on *serial* measurements, since admission of vital signs is an insensitive marker of subsequent deterioration.[11,12] Future directions aimed at optimizing the strategy include incorporation of clinical data focusing on at-risk patient populations;[13] use of laboratory data and computer programming to incorporate trends in laboratory values, as well as threshold values; and use of automated information technology to improve the efficiency of the system.

Traditionally, the efferent limb or first responders were clinically available staff, who often included inexperienced trainees. The evolution in patient safety has prioritized, appropriately, that the resuscitation efforts for such vulnerable patients are led by practitioners with expertise in managing critically ill patients. It remains unclear whether outcomes differ when the team is led by a critical care certified nurse, advanced practitioner, or intensivist. Further investigation is required to address this important question, given limited resources across the continuum of care. In addition, ancillary personnel (e.g., respiratory therapists, pharmacists) are critical in facilitating delivery of time-sensitive interventions in the deteriorating patient.

Despite a sound rationale, it remains unclear whether an RRT improves patient outcomes.[14] In a large multicenter trial, while more deteriorating patients were managed following implementation of an RRT, no significant decreases in the incidence of cardiac arrest, ICU admissions, or mortality were noted.[15] However, in a more recent meta-analysis, the introduction of an RRT appeared to reduce the rate of non-ICU cardiac arrests.[16] Furthermore, an additional potential benefit of an RRT is that its introduction may facilitate timely end-of-life discussions, preempting ICU admission when such an admission would not align with the patient's preferences and values.[17]

THE INTENSIVE CARE UNIT

Internationally, the availability of resources to care for the critically ill varies significantly, even in developed countries.[3,18] Importantly, evidence suggests that lack of ICU bed availability is associated with increased mortality.[19] In the United States, there has been a rapid increase in the number of ICU beds per capita, with an estimated 5.7 million annual ICU admissions (Table 152-1).[20] The growth in ICU bed availability in the United States is driven by several pressures, including the need to meet the expected demand of critical care services required to care for an aging population, and the demand resulting from high-intensity care elsewhere in the healthcare system (e.g., solid-organ transplantation, intensive chemotherapy, and high-risk surgery).[18,20]

In 2007, 67,357 critical care beds were encompassed in approximately 6000 ICUs.[3,20–22] This equates to 2.80 critical care beds per 10,000 persons,[21,22] an increase from 2.00 beds per 10,000 persons less than a decade earlier.[3] The growth in ICU beds across the United States has been transformative, as ICUs were uncommon prior to the 1970s. At the same time, the growth in ICU beds has been disproportionate at a regional level. As a result of this regional variability, the potential exists that areas with less ICU bed availability may be unable to respond to a disaster or epidemic.[21]

TABLE 152-1 Characteristics of Intensive Care Units in the United States[a]

Variable	Count
Number of ICUs	5980
ICU size (beds)	12 (range, 1–55)
ICU bed to acute care bed ratio	1:9.0
Estimated annual ICU admissions	5,700,000
Type of ICU	(%)
General (mixed medical/surgical)	65
Surgical	12
Medical	12
Other	11

[a]*Data exclude noncoronary ICUs.*

Crit Care Med. 2008;36:2787–2793; Angus DC, Shorr AF, White A, et al. Critical care delivery in the United States: distribution of services and compliance with Leapfrog recommendations. Crit Care Med. 2006;34:1016–1024.

Drawn from a representative sample of hospitals across the nation, the median number of ICUs per hospital is 2, with an interquartile range of 1 to 3 and range of 1 to 8.[22] In general, the number of ICUs per hospital increases in proportion to hospital size, with the smallest hospitals using a single ICU, and the largest hospitals using 3 or more ICUs.[20,23] It has been estimated that approximately half of ICU beds are located in small-to-moderate size hospitals (<300 beds).[20] Importantly, the optimal ratio of ICU beds to hospital beds to ensure safe, efficient, high-quality care remains unclear; furthermore, the ratio is variable from institution to institution and, within institution, from service to service (e.g., medical vs. surgical). Since 1992, the average ICU size (12 beds per ICU) has remained relatively stable, as has the proportion of hospital beds apportioned as ICU beds (8%–9%).[20,23] In general, given evidence that patient admissions to an ICU, when delayed or denied due to bed availability, are at increased risk of adverse outcomes,[22,24,25] a general principle is to apportion 10% to 20% of total beds as ICU beds. Institutions that provide high-intensity care (e.g., intensive chemotherapy) should allot a greater proportion of beds as ICU beds to enable provision of necessary care.

ICU ADMISSION DIAGNOSES AND USE OF LIFE SUPPORT

In general, patients perceived to be at high risk for an adverse outcome are admitted to an ICU; the indication for ICU admission depends largely on the type of ICU. The ED serves as the admitting source for approximately 50% of ICU admissions. Postoperative patients account for an additional 25%, while the remaining patients are admitted from inpatient units or another hospital.[20]

The most common indications for ICU admission include respiratory failure, postoperative care, acute coronary syndrome and congestive heart failure, and severe sepsis.[20–22] On average, the mean length of stay in the ICU is approximately 4 days, with significant variability from hospital to hospital and among ICU types (e.g., length of stay is significantly greater in burn and trauma ICUs than in general medical or surgical ICUs).[20] An additional explanation

for these observed differences is the considerable variation in use of intensive care, as evidenced by the variable rates of ICU admission for a resource-intensive condition associated with a very low rate of mortality—diabetic ketoacidosis.[26] Further investigation is required to better understand the "appropriateness" of ICU admissions and ICU care delivery, given that an increasing proportion of our gross domestic product is allocated to such care.

Life support, including use of noninvasive and invasive mechanical ventilation for respiratory failure, vasoactive agents for cardiovascular failure, and hemodialysis for renal replacement therapy is commonly indicated. These examples of life support highlight the sophisticated technology required to guide resuscitation and support organ failure. Experience with such technology in caring for critically ill patients may explain the observed relationship between patient volume and outcomes.[27,28]

GENERAL VERSUS SPECIALITY ICUS

Two types of ICUs within hospitals in the United States may be generally identified: general and specialty. The general ICU, or mixed medical/surgical ICU, is the care site for patients with diverse diagnoses and is the most common type of ICU (Table 152-1). Usually, these ICUs are located within smaller, community-based hospitals. In contrast, specialty ICUs are located predominantly within larger, urban hospitals. The specialty ICU (e.g., coronary care unit, dedicated medical unit, neurologic unit, cardiothoracic surgery unit) centralizes nursing and physician expertise in a single location to enable efficient, diagnosis-specific care. Interestingly, despite the rationale for specialization, the evidence does not support adopting such an organizational model in efforts to improve outcomes (e.g., mortality, length of stay).[22] However, admission to a specialty ICU of a patient with a diagnosis not typically cared for by that ICU (in which the patient is considered a "boarder") appears to be associated with increased mortality.[22] Consequently, hospitals may elect specialization for a number of reasons distinct from mortality and length of stay (e.g., cost, convenience, staff and family satisfaction). However, these same hospitals should incorporate provisions for optimizing care for "boarders."

ORGANIZATIONAL FACTORS ASSOCIATED WITH PATIENT OUTCOMES

A number of organizational factors have been identified, which, when implemented, are associated with improved outcomes. Broadly, these factors can be categorized as (1) personnel and staffing-related, and (2) processes of care (e.g., multidisciplinary patient and family-centered rounds) that streamline delivery of high-quality critical care. High-quality critical care is delivered by a dedicated critical care team,[29,30] incorporating strong, collaborative physician and nursing leadership,[31] operating within a "closed" unit.[32–34] In an "open" model, care is provided by physicians who have competing responsibilities outside of the ICU (e.g., operating room activities or outpatient practices). In open models, critical care consultation is an option (e.g., consultation for mechanically ventilated patients). In a "closed" model, care is provided exclusively by critical care specialists.

PERSONNEL

Multidisciplinary critical care harnesses the expertise of the entire critical care team. The personnel required to provide critical care include physicians, nurses, respiratory therapists, critical care pharmacists, nutritionists, physical and occupational therapists, speech therapists, social workers, and palliative care experts. The integrated care provided by each of these professionals is essential for optimizing care delivery.[35,36] Given the ever-increasing complexity of critical care,[37] each team member must contribute the necessary expertise to reduce errors, improve communication, and facilitate delivery of safe, efficient, cost-effective care.[38,39] Because of the complexity of the administrative duties required to co-manage an ICU, ensuring that the medical and nursing directors are provided sufficient time to manage and lead effectively is critical.

STAFFING

Physician and nursing staffing models vary across the United States; the optimal approach is unknown. Traditional physician staffing models include coverage by general practitioners (medical and surgical), elective consultation from board-certified critical care physicians (intensivists), or mandatory management by intensivists. The general practitioner model may include physicians trained in Internal Medicine (in the case of medical critical care) or hospitalists. Traditionally, ICU physician staffing is categorized as either low-intensity (staffing by general, nonintensivist practitioners with intensivist consultation) or high-intensity (mandatory intensivist consultation or primary care delivery by an intensivist).[40]

With few exceptions,[41] a high-intensity physician staffing model, which is synonymous with a "closed" ICU is associated with improved outcomes.[40] A systematic review found that high-intensity physician staffing results in lower in-hospital mortality, reduced ICU length of stay, and to a lesser degree, reduced hospital length of stay.[40] While the potential benefits of high-intensity staffing are likely multifactorial, one clear benefit appears to be in use of evidence-based processes of care when care is delivered by practitioners with expertise in critical care. For example, the mortality benefit achieved when intensivists care for patients with ARDS is, in part, mediated by intensivists' increased use of lung protective ventilation.[34] Use of evidence-based protocols (see Process of Care), is one strategy to ensure delivery of evidence-based care that is applicable to ICUs, regardless of their structure and staffing.

In response to the growing costs and use of critical care, and in light of evidence that high-intensity physician staffing is associated with improved outcomes, the Leapfrog Group, a US-based alliance of employers dedicated to improving the safety and quality of healthcare and optimizing purchasing power, identified critical care staffing as one of the principal opportunities to save lives. The Group recommended provision of critical care in metropolitan areas by intensivists on-site during daytime hours and their availability to return in a time-sensitive manner during off-hours. The Group estimated that adoption of these recommendations could save >50,000 lives each year.[42]

A recent analysis of critical care delivery in the United States conducted by the Committee on Manpower for Pulmonary and Critical Care Societies (COMPACCS) estimated that approximately 25% of ICUs provide high-intensity physician staffing.[20] In addition, the majority of ICUs in the United States, in contrast to those in Western Europe, remain "open" units in which patients are managed by nonintensivists who have the option to consult intensivists.[3,41,43]

A legitimate threat to high-intensity staffing is the anticipated intensivist shortage, which will be exacerbated by the anticipated national nursing shortage. Preservation of a limited patient-to-nurse ratio (2:1 or less) and ICU bed-to-intensivist ratio (less than 15:1) is vital to the optimal delivery of critical care.[29,43–45] Until and unless healthcare is able to avoid the pending shortage of intensivists, given the present environment, novel strategies will be necessary for optimizing critical care delivery.

Based on the relationship between volume and outcomes observed across medical and surgical critical care,[27,28,46–48] one potential strategy to improve outcomes is regionalization of critical care.[49] Regionalization has proven beneficial in traumatology and in neonatology, but its effectiveness when applied to adult critical care remains largely speculative. Furthermore, significant barriers to its implementation would exist.[18] Despite these barriers, recent analyses reveal that informal networks already are in place to enable transfer of patients who require a higher level of care.[50]

Given the national shortage of intensivists and expectation of a widening gap between available and necessary critical care providers

over the next several decades as the population ages,[20] it is anticipated that a greater burden of care will be delivered by general practitioners or physician extenders (i.e., nurse practitioners and physician assistants). The optimal approach to meet this growing need is an area of active investigation and inquiry. Potential solutions, beyond regionalization of care[49,50] and use of physician extenders, include expanded use of telemedicine[51] and embracement of the concept of co-management, in which only the most severely ill patients are managed by intensivists.[52]

STAFFING SCHEDULES

The optimal schedule for nursing and physician coverage remains unclear. For attending physicians, models vary from extended rotations (1-, 2-, or 4-week rotations) to traditional shift-work coverage employing a varying mix of day and night schedules, consistent with the model used by most EDs. Whether outcomes or patient or staff satisfaction differ in the different models remain unknown. Of interest, a cluster-randomized trial comparing the effects of 2- and 4-week inpatient attending physician rotations on a general medicine service found that 2-week rotations were not associated with improved outcomes (as measured by readmission rate and length of stay). The shorter rotation was accompanied by less attending physician burnout, a benefit that appeared to be counterbalanced by trainees' perceptions of an inability to be adequately evaluated.[53] Schedules that incorporate a weekend respite appear to result in less burnout, lower job distress, and improved work-life balance.[54] Of import, although continuity of care was disrupted in the model of weekend cross-coverage, outcomes did not appear to differ.[54]

NIGHTTIME COVERAGE

To optimize ICU outcomes, many have advocated for expanding high-intensity staffing to 24 hours per day. The potential benefits of nighttime intensivist coverage are many: improved outcomes; improved efficiency of care delivery; increased adherence to evidence-based care; improved end-of-life care; improved staff, patient, and family satisfaction; and improved trainee satisfaction, given the additional support and educational opportunities afforded by this approach.[55] The potential risks include erosion of trainee autonomy, physician burnout, and incremental cost, although arguments to the contrary have been made for the latter two points.[55,56] Without evidence to guide institutional decisions regarding adoption of nighttime intensivist coverage, as many as one-third of academic ICUs already provide nighttime intensivist staffing,[57] compared with only 6% 20 years ago.[23]

To date, the evidence suggests that the incremental benefit on patient outcomes of nighttime intensivist staffing may be dependent on the daytime staffing model employed. Specifically, nighttime coverage only appears to improve patient outcomes when layered on top of low-intensity physician staffing.[58,59] In observational studies, the theoretical incremental benefit has not been demonstrated in units with high-intensity staffing models,[58–60] an observation confirmed in a recent randomized trial.[61] Distinct from patient-centered outcomes, evidence suggests that intensivists experience less burnout, while trainee autonomy is impacted.[58]

PROCESS OF CARE

The principles of high-quality critical care related to process of care delivery include multidisciplinary rounds, use of evidence-based protocols and guidelines, and use of checklists to ensure that evidence-based care is provided. These principles should be applied to care delivery across the healthcare continuum, as the benefits are not specific to the ICU.

MULTIDISCIPLINARY ROUNDS

The first tenet, multidisciplinary rounds, has been demonstrated to reduce ICU length of stay and ICU mortality.[62,63] In a large population-based cohort study, the highest odds of survival were observed in patients managed in ICUs with high-intensity physician staffing and multidisciplinary rounds.[63] Multidisciplinary care harnesses the expertise of the entire critical care team, including physicians, nurses, and others, in optimizing care delivery and reducing errors.[35,36] Recognizing the importance of effective and timely communication among team members and with patients and their families, multidisciplinary rounds are the forum in which multidisciplinary care takes place. In ICUs that are unable to provide high-intensity physician staffing,[64] (estimated at approximately 50% of ICUs as recently as 2006[63]) implementation of multidisciplinary rounds is one strategy to optimize care delivery.

EVIDENCE-BASED PROTOCOLS

The primary aim of protocols and guidelines is to standardize evidence-based critical care medicine. Protocol adoption is more likely in units that incorporate high-intensity staffing and use multidisciplinary rounds,[65] factors that may account for improved patient outcomes.[63] Importantly, management protocols have been at the core of landmark studies demonstrating benefit in caring for mechanically ventilated patients,[66,67] severe sepsis,[68,69] and following cardiac arrest.[70,71] In addition, protocols are often created to standardize management of complicated, common clinical scenarios (e.g., diabetic ketoacidosis, alcohol withdrawal syndromes) with the goal of improving outcomes and reducing errors in management. Protocols are also a useful means of ensuring that knowledge is effectively translated to patient care. Despite the theoretical threat that use of protocols might erode the education of trainees, evidence does not support the concern.[72]

The science of implementation of evidence-based care is complex and challenging. The initial step required for effective implementation is engaging relevant stakeholders and local experts. This can be accomplished through stand-alone committees or by incorporating the assignment into pre-existing quality committees at the unit or hospital level. After the protocol development phase has been completed, implementation and efforts to ensure compliance are necessary. This iterative process requires a multifaceted approach incorporating academic detailing (e.g., educational efforts by local opinion leaders), reminders (e.g., checklists), prompts (including electronic prompts), and periodic auditing and feedback to ensure compliance. Effective implementation is predicated on a culture of safety, transparency, mutual respect among care providers, and a willingness to learn from one another.

THE CHECKLIST

One of the transformative events in modern day critical care is the incorporation of checklists into multidisciplinary rounds to help ensure that evidence-based care is provided. The checklist has proved to be a simple, effective tool to combat effects of stress and fatigue on memory and provider performance. The benefits, in part, are achieved by reducing errors of omission, reducing unintended complications, and standardizing practice. The benefits derived from checklists have been observed in both surgical and medical critical care settings.[51,73–75] The checklist results in a safer environment by ensuring that important details are not overlooked (e.g., time-out to ensure the correct procedure is being performed on the correct patient, use of deep venous thrombosis and stress ulcer prophylaxis, physical therapy consultation).[73,76] At the conclusion of rounds, a daily goals checklist can be incorporated to ensure that all team members are aware of the plan and goals for the day; "read-back" verification may help facilitate an understanding of the plan.[77] The manner in which a checklist is implemented is not trivial; a strategy employing prompting as a means of ensuring that the checklist is not overlooked improves care delivery and outcomes.[74]

TEAM DYNAMICS

An often overlooked, but vital component of high-quality critical care medicine is effective team dynamics. Effective team dynamics rely on strong team leadership, effective communication among providers, and team composition.[78] Attributes that define positive team dynamics include (1) creating a safe work environment where questions and concerns are encouraged and errors are reported, and (2) recognizing team member skills and attributes, thereby fostering a team-oriented approach to patient care in which "the sum is greater than the parts."[79] Positive team dynamics have been associated with decreased errors and improved patient safety,[80] enhanced staff satisfaction,[81] lower frequency of perceived inappropriateness of care,[82] reduced rates of provider burnout,[83] and improved patient outcomes.[84]

THE LONG-TERM ACUTE CARE HOSPITAL

Advances in critical care over the last several decades have resulted in an expanding population of patients who survive critical illness. These patients, the *chronically critically ill*, remain dependent on higher levels of support than can be provided elsewhere in the healthcare system (i.e., medical or surgical floor, skilled nursing facility, acute rehabilitation). In response to the growth of the chronically critically ill patient population, and as a means to combat the costs associated with extended acute care hospitalization, long-term acute care hospitals (LTACHs) have emerged as a viable option for care delivery.

The origins of the modern day LTACH can be traced to facilities that tended to the chronically ill (e.g., those with tuberculosis) nearly a century ago. The recent growth in the number of LTACHs is attributable to two federal reimbursement decisions in the 1980s. First, the Health Care Financing Administration (HCFA) established that certain facilities, including LTACHs, would be exempted from the traditional, prospective, diagnostic-related group (DRG)-driven reimbursement system used in acute care hospitals. Second, in 1982, the Tax Equitable Fiscal Responsibility Act (TEFRA) created an alternative, cost-based system that incentivized transfer of the chronically critically ill patients from the intermediate care unit or ICU within the acute care hospital to LTACHs.

Over the ensuing 30 years, the LTACH industry has grown exponentially, both in its ability to care for the chronically critically ill and in sheer numbers. In the 1980s, fewer than 100 LTACHs existed. In contrast, by the late 2000s, approximately 400 LTACHs were in operation (representing an annual growth rate approaching 9%), and annual LTACH admissions exceeded 40,000.[85,86] The majority of LTACHs are operated by for-profit companies, are concentrated in the Northeast and Southern United States, and are integrated into the physical structure of an acute care hospital ("hospital within a hospital").

LTACH admissions are more likely to be male and nonwhite. One-year mortality is uniformly poor, remaining at about 50% from 1997 to 2006.[85] Although the setting in which the needs of chronically critically ill patients are met in regions with limited LTACH penetration is not well defined, use of "intermediate care units" is one potential option. Despite introduction in 2003 of a prospective payment system specific for LTACHs (long-term care-diagnosis-related groups [LTC-DRG]) – a system designed to curb costs – Medicare reimbursement for LTACH care approaches $5 billion annually.[87]

The average length of stay for patients in an LTACH approaches 1 month. In fact, as one of the several means to ensure that patients transferred to an LTACH are appropriate admissions, the facility must demonstrate an average length of stay of 25 days or more for Medicare patients during the 6-month demonstration period—a requirement for Medicare certification of the facility. On average, two-thirds of LTACH admissions are Medicare patients. The most common LTC-DRG is respiratory-related (accounting for approximately one-quarter of Medicare-specific discharges), followed by care for complex illness associated with prior intensive care (including postsurgical care, critical illness–associated neuromuscular weakness, infectious disease management, and recovery from multisystem organ failure), chronic neurologic disorders, complicated infectious diseases, and general wound care. As a destination for ICU survivors, LTACHs may provide the necessary care and support, over an extended period of time, to combat the long-term effects of postintensive care syndrome, described as new or worsening impairment in physical function, cognition, or mood.[6]

Evidence to support the LTACH model as an efficient, cost-effective approach for managing the chronically critically ill, as compared with traditional care in an acute care hospital, is lacking. To date, the majority of investigative effort has focused on ventilator liberation rates (estimated at 50%–70%), given the proportion of LTACH admissions requiring prolonged mechanical ventilation.[88] Systematic study reveals that outcomes, in general, do not appear to differ, although a potential benefit may be observed when analyses are extended to include chronically critically ill patients with shorter lengths of stay in the ICU (perhaps, by including patients with overall better outcomes).[89,90] This observation raises the question of whether some patients (e.g., the chronically critically ill patient with reversible disease) may benefit from an LTACH admission, while others (e.g., the moribund, chronically critically ill patient with irreversible organ failure) may not.

When examining management for prolonged mechanical ventilation, care in an LTACH may provide cost savings compared with care provided in traditional acute care hospitals.[89,90] The cost savings, in part, appear to be due to a reduction in subsequent admissions to skilled nursing facilities following the phase of acute care. Yet, from the payer perspective, these apparent cost-savings appear to be counterbalanced by increased overall Medicare payments, equating to increased cost to the public at large.[90]

The potential benefits and costs of LTACH care should be viewed in light of the long-term outcomes of the largest subgroup of patients admitted—those undergoing prolonged mechanical ventilation. In general, outcomes remain poor for this group.[91] At 1 year, approximately 50% of patients who are mechanically ventilated in an LTACH and subsequently discharged are alive; fewer than 10% are living independently at home.[91,92] The clinical trajectory for such patients is often a chaotic one, with a median of four transitions of care postdischarge, including readmission to acute care for the majority.[91] In addition, expectations of patients and their family members often are not congruent with clinical reality, as most surrogates are unrealistically optimistic regarding survival, functional status, and quality of life.[92] Consequently, while outcomes achieved may be optimized through the expertise and experience afforded at an LTACH, studies highlight the importance of identifying patients with the greatest potential for benefit, as well as the importance of educating patients and surrogate decision-makers about the prognosis of the chronically critically ill patient.[92]

CONCLUSION

Modern day, high-quality, critical care medicine requires complex coordination across disciplines and across the continuum of care. Strong leadership and careful planning are required to ensure that the inpatient unit structure and processes of care enable recognition of impending critical illness and facilitate efficient and expert patient management. The ICU remains the hub of critical care, yet coordination between the pre-ICU environment (e.g., ED, general medical or surgical floor) and post-ICU environment (e.g., LTACH) is critical in bridging the continuum from acute injury and illness to rehabilitation and recovery.

CHAPTER 153

Ethics and Palliative Care in Critical Care Units

Joshua B. Kayser
Horace M. DeLisser

Death is common in the intensive care unit (ICU), with approximately 20% of deaths in the United States occurring during or shortly after a stay in an ICU.[1] The majority of these deaths involve the withholding or withdrawal of life-sustaining therapy.[2] Therefore, the ICU represents a particularly distinct clinical setting where the thoughtful and considered application of ethical concepts is required. A proper understanding of the basic principles of bioethics as well as the principles of providing comfort-focused, end-of-life care are essential elements in the competent practice of intensive care medicine.

A number of common ethical themes arise in the ICU. Technological advancements have allowed healthcare providers to keep patients alive for prolonged periods in the context of diseases that, in the past, would have resulted in death. However, the capacity for delivering life-sustaining care has not been matched by efforts to align treatments with the care individual patients wish to receive at end of life, resulting in a discordance between care wanted and care received.[3–5] Compounding this problem is the reality that many patients dying in the ICU, prior to death, lack the capacity to make decisions regarding end-of-life care[6] and have not completed an advance directive that might aid surrogates and physicians in the decision-making process.[7] Many decisions about end-of-life care in the ICU are, therefore, made without the involvement or input of the patient.[6] The resulting uncertainty means that many patients frequently receive far more aggressive interventions than they would have otherwise chosen for themselves, or they receive care that has a low likelihood of restoring health, enabling discharge from the ICU, and having the potential for providing a meaningful quality of life.[5]

Ethical dilemmas that characterize critical care medicine often arise from this interface between the ability to prolong life by expensive and sometimes scarce technology and an inability to cure patients or restore them to their baseline. The relevant ethical question often is whether technology is being used wisely, that is, should the patient's life be prolonged? The question becomes even more complex for practitioners and patients' families when different ethical principles suggest conflicting answers.

Although the practice of critical care medicine encompasses a broad range of bioethical issues, several are particularly common, including palliative and end-of-life care, surrogate decision making, medical futility, communication, and professionalism. These issues are among the most challenging for critical care practitioners and constitute the focus of this chapter.

FUNDAMENTAL PRINCIPLES OF BIOETHICS

Several fundamental principles of bioethics are at the core of the practice of critical care medicine: respect for patient autonomy, beneficence, nonmaleficence, and distributive justice.[8] Ethical dilemmas in the ICU arise when two or more of the principles are in conflict. An understanding of these areas provides a basis for addressing conflict and is imperative in providing high-quality palliative care at the end-of-life.

RESPECT FOR PATIENT AUTONOMY

The principle of patient *autonomy* refers to the concept of self-determination, which asserts that a competent and informed adult patient possessing adequate decision-making capacity has the right to determine what will be done to his or her body.[8] According to this principle, the patient has the ethical right to accept or refuse medical interventions, including those that might sustain life. In addition, the principle of autonomy encompasses the right to privacy and the requirement for informed consent. As such, except in an emergency, a competent adult must give informed consent before receiving medical care, especially interventions that have the potential to cause further harm or death. Under emergency conditions, consent is presumed. Respect for patient autonomy is applicable with respect not only to patients, but also their families and surrogate decision makers or proxies—that is, individuals who speak on behalf of patients who lack the capacity to make medical care decisions.

In the United States, societal and professional consensus, as well as statutory law and judicial precedents, support the principle of patient autonomy. Absent countervailing obligations, healthcare providers are required to respect a competent and informed patient's decision to forgo life-sustaining care. Important to note, however, is that autonomy does not provide patients or their surrogates with the right to demand and receive any desired treatment. Rather, patients or their surrogates are permitted to accept or forgo medical interventions that fall within the standard of medical care.

BENEFICENCE AND NONMALEFICENCE

The principle of *beneficence* obligates healthcare providers to promote the well-being of their patient and provide services that benefit the patient.[8] *Nonmaleficence* is the duty to minimize pain and suffering.[8] The Hippocratic maxim, *primum non nocere,* which can be translated as "First, do no harm," reflects the fundamental importance of this principle for physicians. Both principles relate to the provision of care that maximizes each individual's dignity and worth as a human being. However, a constant tension exists between these two principles: Efforts to cure medical illness often come with substantial suffering. Provided the benefits outweigh the harms, administration of life-sustaining therapies is appropriate. However, once the physician believes the attendant harms may be greater than the foreseen benefits, the physician is obligated to communicate his or her concerns to patients and/or their families. A common example of this tension is provision of cardiopulmonary resuscitation (CPR) to patients who have refractory sepsis despite aggressive medical intervention. The medical literature indicates that offering CPR in this setting is unlikely to restore spontaneous circulation, or at the very best, delay the dying process.[9] Consequently, offering CPR in this context could constitute a harm that outweighs the benefits. Despite this ethical construct, the proportion of patients receiving CPR prior to death continues to rise, particularly among minority groups.[9]

DISTRIBUTIVE JUSTICE

Justice refers to fairness in the distribution of limited resources, that is, *distributive justice*.[8] Ethically, this principle holds that equals should be treated equally and unequals treated unequally. In practice, the principle of distributive justice pertains to defining fairness in allocating resources among individuals when not all can receive the resources. The principle is applicable on two levels in health care: macroallocation and microallocation of resources.

Macroallocation entails the distribution of resources among various goods and services at a governmental or institutional level. In contrast, *microallocation* refers to decision making about an individual patient or small group of patients within, for example, an individual ICU or hospital. A single formulation for the application of this principle in patient care is not available because widely accepted criteria are lacking. Various ethical theories (e.g., deontology, utilitarianism, egalitarianism, among others) define different values as the most relevant criteria for making such judgments. In general, determinations of how to allocate resources and treat patients are best left to institutional or governmental authorities, while physicians provide reasonable and appropriate care on an individual patient basis.

CONSIDERATIONS IN END-OF-LIFE CARE IN THE ICU

A number of considerations comprise the core practice of bioethics in the ICU. Included are the withdrawal and withholding of life-sustaining therapies, surrogate decision making, trust and communication, provision of good palliative care, and medical futility. In this regard, bioethics in the ICU should not be viewed as a fixed body of knowledge, but rather as a continually evolving field, similar to the rest of clinical medicine.

WITHDRAWAL AND WITHHOLDING OF LIFE-SUSTAINING THERAPY

Over the last several decades, a broad societal consensus has developed in addressing the ethics of withholding or withdrawing life-sustaining therapies or "life support." Landmark judicial cases, such as the 1976 New Jersey Supreme Court decision regarding Karen Ann Quinlan[10] and the 1990 US Supreme Court decision regarding Nancy Cruzan,[11] played substantial roles in defining both ethical and legal standards. Based on the principle of autonomy, the current societal and legal standard is that adequately informed adults possessing decision-making capacity have the right to refuse any life-sustaining medical therapy, even if the decision results in death. *Capacity* requires that the patient have the ability to comprehend relevant information, understand their condition, compare and contrast treatment options, and communicate wishes consistently.[12]

In practice, no meaningful legal or ethical difference exists between withdrawing and withholding life-sustaining therapy. In addition, legal precedent has established that artificial nutrition and hydration are considered medical interventions that are no different than CPR or mechanical ventilation. The legal issue of whether artificial nutrition and hydration provided by a feeding tube constitutes medical care was decided when the US Supreme Court deemed it so in its 1990 decision on Nancy Cruzan.[11] This decision established a constitutionally protected legal right to refuse any medical care by a competent adult or appropriate surrogate decision maker acting in accord with the patient's previously expressed preferences or values, including artificial nutrition and hydration. Of note, despite the legal and moral equivalence between withdrawal and withholding of life-sustaining therapy, many patients, families, and healthcare providers often perceive differences between the two.

Morally, controversy continues to exist over the distinction between actions and omissions leading to a patient's death.[13,14] Although the debate is ongoing in the United States, currently, withdrawal and withholding of life-sustaining therapies (sometimes referred to as passive euthanasia) are permissible. In contrast, active euthanasia, where a physician administers an intervention with the intent of hastening death, is neither morally nor legally permissible. This is in direct contradiction to attitudes in many other countries, including parts of Western Europe, where active euthanasia is currently practiced.[15]

RELIEF OF PAIN AND SUFFERING

A key ethical principle in end-of-life care is that physicians are obligated, whenever possible, to provide relief of pain and suffering and ensure a dignified death for the dying patient. *Dignity* can be defined in various ways, but at its core is the idea that patients should be treated respectfully and humanely. This includes efforts to keep the patient clean and comfortable, with as little distress as possible. Control of pain is particularly important in the ICU, where significant doses of sedatives may be required to relieve suffering. For some healthcare providers, fear exists that administration of high doses of sedating medications could suppress respiration or cause hemodynamic instability, thus accelerating the dying process. Consequently, they may underdose patients to prevent potential side effects. Unfortunately, this approach carries the unintended consequence of incompletely or ineffectively controlling pain and suffering, thereby diminishing the quality of the dying experience for both the patient and their loved ones.

The *Doctrine of Double Effect* is a key ethical principle that guides the practice of end-of-life care and informs our understanding of how we can effectively relieve pain and suffering. It holds that if, in the process of treating pain or distress of a dying patient, an intervention has the unintended consequence of hastening death, it is ethically and morally permissible.[8] In other words, as long as the intent is not to hasten death, aggressive treatment of symptoms to achieve comfort for the dying patient is acceptable and encouraged and is consistent with the ethical principle of beneficence. This should not be confused with active euthanasia or assisted suicide. The intention of active euthanasia or physician-assisted suicide is specifically to *cause* the patient's death. Based on current societal norms and judicial precedent, active euthanasia is ethically and legally distinct from withdrawal and withholding of life-sustaining therapies, which are intended to allow patients to die from their underlying disease.

SURROGATE DECISION MAKING

As noted previously, a majority of patients in the ICU lack the capacity to provide either informed consent for, or refusal of, a medical intervention.[6] Many factors may compromise decision-making capacity, including pain, anxiety, disorientation, fear, sleep deprivation, effects of the underlying disease, and the use of sedatives and narcotics. Unfortunately, most patients have not previously discussed their wishes with family and friends or outpatient medical providers, and they often have not completed an advance directive to articulate their wishes.[7]

When patients lack adequate decision-making capacity, surrogate decision makers are often involved in decisions to limit life-sustaining therapy. The current approach for decision making in the ICU is a shared decision-making model, in which providers offer information about medical issues, anticipated benefits, and the patient's prognosis, while families provide an understanding of the patient's values and preferences.[16–18] Some patients may have previously explicitly identified a surrogate decision maker. In the absence of an identified individual, standards for identifying someone to fill that role vary from state to state.

Under ideal circumstances, the surrogate is an individual who knows the patient well and has a good understanding of the patient's values and preferences, allowing them to advocate for the patient based on the *substituted judgment standard*. This standard holds that the surrogate must have knowledge about the patient's wishes, as expressed orally or in writing, or about the patient's values and life goals, from which valid inferences can be made. In situations in which the patient's explicit wishes are unknown, the healthcare team and the patient's loved ones should work collaboratively to make decisions based on the *best interest standard*, taking into consideration the patient's values, preferences, life goals, prior medical decisions, current condition, and prognosis. Under this standard, the surrogate, along with the caregivers, must base their decision on a weighing of the benefits and burdens of life-sustaining therapy—for example, the benefits of life, chance of survival, and chance of full recovery with a high quality of life, compared with the burdens of pain, additional suffering, and poor quality of life.

For a small subset of patients, a surrogate decision maker cannot be identified.[19] Uniform standards for managing patients in this situation are lacking. In general, the manner in which this circumstance is handled varies by institution and may include multiple physician opinions, chief medical officer concurrence, and/or hospital ethics committee review. Institutions are encouraged to establish a written policy for this practice.

MEDICAL FUTILITY

An example of when ethical principles may conflict is in the ongoing debate over the use of medical futility to guide care of critically ill patients. While there are various conceptions of futility in health care, broadly, an intervention may be considered *futile* when it is incapable of accomplishing the result for which it is intended.[20] In the ICU, this goal is typically understood to be meaningful recovery from critical illness, where *meaningful* refers to a survival that the patient can value and appreciate.

An important distinction exists between *physiological futility* and *medical futility.* An intervention that is judged to be *physiologically futile* is one that is not expected to, or does not achieve, the relevant physiological function as an end point. There is both an ethical and professional consensus that healthcare providers are not required to provide such interventions.[21] As described previously, CPR may be judged to be physiologically futile in a patient with refractory septic shock complicated by cardiac arrest after progressively worsening hypotension, despite maximal therapy. Under these circumstances, the conclusion that CPR would have extremely little or no chance of success (beyond, possibly, a brief time period) is well supported by published literature and clinical experience. Further, an attempt at CPR would not only prolong the patient's dying, but could also do physical harm by fracturing ribs and burning the skin. Prolonging dying is not one of the goals of medicine and, under these circumstances, CPR would violate the principle of nonmaleficence. Moreover, an argument has been made that forcing healthcare providers to perform CPR when there is virtually no prospect of success undermines the ethical integrity of the medical profession.[21]

Medical futility is more difficult to define than physiological futility and is, therefore, less well supported in its application. Some of the older literature describes qualitative approaches, in which experience suggests an intervention will not result in a meaningful survival,[22] as well as quantitative approaches, in which the success of interventions is measured in a more standardized way.[23] However, it is important to recognize that physicians may be limited in their ability to accurately determine the prognosis of a patient.[24] Furthermore, what constitutes meaningful survival or good quality of life is inherently unique to a particular individual and, therefore, is difficult to measure. Consequently, employing a medical futility standard, rather than a physiological standard, is more challenging.

Not uncommonly, patients or their families request continuation of treatments that physicians believe are incapable of producing meaningful survival, based on the principle of autonomy. This tension between the rights of patients as autonomous beings and the obligation of physicians to honor the principles of beneficence and nonmaleficence may result in conflict between the parties. In this setting, the current ethical norm is that medical futility should not be used as a means to circumvent patient or surrogate wishes when conflict exists with regard to the value of an intervention. Specifically, in the absence of predetermined, institutionally based criteria, individual physicians should not attempt to unilaterally withhold or withdraw life-sustaining therapies against the wishes of patients and surrogates based on medical futility. Instead, if medical futility is to be invoked, it should be applied based on an explicitly defined institutional policy that is transparent, inclusive of patients and their families, ensures effective communication, and incorporates an appeal process. Ultimately, conflict that is mediated by parties to achieve a mutually agreeable solution is preferable to invoking "futility."

COMMUNICATION AND PROFESSIONALISM

As noted previously, disagreements regarding the plans and goals of care arise at times between medical providers and patients or their surrogates. Frequently, disagreements are a consequence of a breakdown in communication or a loss of trust by the patient or the patient's surrogate for the medical team.

Recognizing the value of good communication and trust in the ICU serves to enhance the quality of care, promote the autonomy of the patient, and increase the likelihood of a patient-centered outcome. Rather than being assumed, trust should be viewed as something that must be earned from each patient and their family. Trust can be earned by providing compassionate care, communicating with patients and their families on a regular basis, encouraging dialogue, and listening empathically.

Good communication starts with a determination to uniquely understand each patient and to engage patients and families in a culturally sensitive and transparent manner. Information should be presented in a language, and at a level of detail, such that patients and their surrogates feel well informed. This is particularly important in light of studies that have found that half of patients and their families are unable to clearly express an understanding of medical facts, diagnoses, and prognosis after meeting with physicians.[25] In addition, the proportion of time families are allowed to speak during family meetings correlates with the degree of their satisfaction with the care.[26] Despite these data, studies have shown that physicians typically do the majority of the talking and rarely initiate discussions about values and goals.[27,28]

The timing and manner of discussions with patients and families may vary, ranging from informal discussions on daily rounds to more formal family meetings to discuss changes in the goals of care. Efforts should be made to engage families initially at the time of admission, followed by a more formal discussion after 24 to 48 hours to review events related to ICU care. This meeting should be less about goals of care or prognosis, and more about providing support for the family, while describing expectations for recovery and establishing benchmarks for recovery or decline. Following the meeting, short daily debriefings should occur to provide updates on the clinical status of the patient and the care being provided. If the patient declines clinically and it becomes clear that chances of recovery are limited, honest and open discussions should occur to provide truthful assessments of the patient's prognosis. Transparent communication enhances patient autonomy and allows families to make more informed decisions about the care of their loved one. This does not mean that all medically available options can, or even should, be discussed with each patient and family. The decision to offer specific treatments should be based on the medical judgment that the treatments in question are beneficial to the patient; they should be informed by a clear understanding of the patient's values and known wishes—what some have referred to as *authentic decisions*.[29]

Each family will vary in its comfort with the responsibilities of being surrogate decision makers and the amount of information needed to make decisions.[30–32] While some families may prefer greater detail and more autonomy to make care decisions, others may lack the ability to process significant amounts of medical information, or they might prefer to take a lesser role in decision making, deferring to the medical judgment of the physician. Evidence suggests that discordance in decision-making roles may substantially increase the incidence of anxiety and posttraumatic stress disorder (PTSD) among surrogates.[33] Consequently, identifying the category into which each family or members of families fit into is essential for successful engagement and provision of adequate support.

Finally, the ICU and critical illness can be potentially overwhelming to patients and families. The ICU experience can evoke powerful emotions, including fear, anger, frustration, guilt, and intense grief—emotions that are as important as physical symptoms and which need to be addressed by clinicians with empathy, patience, and understanding. At times, physicians may need to take time out from direct patient care to actively listen and allow patients and families to express their concerns and discuss the emotional burden of having a loved one in an ICU. These opportunities for empathic discussion provide for not only a catharsis for the patient or family but also a chance for the physician to obtain further insight into the patient's life, goals and wishes, further enhancing trust.

DISCUSSING GOALS OF CARE FOR THE DYING PATIENT

Many patients fail to improve and will die in the ICU. As such, end-of-life discussions have a prominent role in the management of critically ill patients. One of the most difficult and important roles of the ICU physician is to engage in end-of-life discussions with patients and surrogates when it becomes evident the patient will not survive. Included in these discussions are efforts to reach consensus regarding the goals, and the subsequent plan, of care. Agreement is most likely to be reached when trust has been established through good communication. Although each circumstance is unique, basic communication skills and techniques can enhance the quality and success of these meetings.

Critical to the success of these discussions is advance preparation by the medical team, development of a clear understanding of the facts at hand, and establishment of a consensus regarding the best course of action before meeting with the family. Consideration of which team members should be present at the meeting is necessary to facilitate a patient-centered discussion and to reduce the likelihood of overwhelming the family. Ideally, the medical team members should not outnumber the family. At a minimum, the primary ICU physician and bedside nurse should be present. Other participants might include staff from pastoral care, social work, palliative care services, and, when appropriate, the patient's outpatient primary provider. Family members should be made aware of the purpose of the meeting in advance and should be offered the opportunity to meet at a time and place that allows for as many members as appropriate to participate. Determining the size or number of family members should be based on each unique case, but the meeting should incorporate essential members, including those directly involved in decision making. Table 153-1 outlines recommendations for facilitating the goals of care meeting. While these recommendations are not proscriptive, they summarize the current published literature on the best practice for approaching these discussions.[16,29,30,34,35]

The goals of care meeting can be divided into four phases: Preparation, discussion, negotiation, and debriefing. The preparation phase is a premeeting opportunity for the medical team to

TABLE 153-1 A Recommended Approach for Facilitating the Goals of Care Meeting

I. Preparation phase
- (i) Notify family and friends of the time and location of the meeting
- (ii) Hold a premeeting huddle
  - a) Confirm understanding of medical facts, prognosis, and direction of care and ensure team agreement about proposed changes to the goals and plan
  - b) Consider who should be present at the meeting and how to approach potential issues that may arise during conversation
- (iii) Establish conditions for a productive conversation
  - a) Designate a quiet space for the meeting
  - b) Silence pagers and phones
  - c) Provide boxes of tissue
  - d) Disperse team members throughout the room

II. Discussion phase
- (i) Describe the purpose and goal of the meeting
- (ii) Have everyone introduce themselves and state their relationship to the patient
- (iii) Express appreciation for everyone's willingness to participate in the meeting
- (iv) Determine and clarify the family's understanding of medical facts
- (v) Provide additional information about anticipated prognosis and trajectory
- (vi) Elicit fears, concerns, expectations, hopes, etc. from family and friends
- (vii) Ask about the patient's life, values, and goals

III. Negotiation phase
- (i) Recommend treatments and options consistent with the patient's goals
- (ii) Develop explicit consensus about the plan of care
- (iii) Ensure all voices have been heard

IV. Debriefing phase
- (i) Summarize agreed upon plan of care
- (ii) Describe next steps for patient care
- (iii) Respond to unanswered questions
- (iv) Attend to emotions
- (v) Invite the family to share personal stories or experiences about the patient
- (vi) If appropriate, invite prayer by a family member, their clergy, or a hospital chaplain
- (vii) Acknowledge the difficulty of the conversation and decisions made
- (viii) Assure ongoing care for the patient
- (ix) Thank the family for their involvement

assemble and agree on what will be discussed, as described previously. The discussion phase is the early portion of the meeting, during which the medical team has an opportunity to describe current medical facts and prognosis, and the family has an opportunity to express fears, concerns, and expectations. The negotiation phase is an opportunity for the entire group to develop a mutually agreeable plan of care and to establish boundaries and limitations on care based on the patient's values, the family's individual hopes and wishes, and the medical realities of the patient's condition. Finally, the debriefing phase allows the medical team to provide emotional support to the family and to come together after the meeting to prepare to implement the agreed upon plan of care.

PROVIDING PALLIATIVE AND END-OF-LIFE CARE IN THE ICU

Palliative care is an essential component of good patient care in the ICU and has been strongly advocated as a core competency at an international level.[36] Good palliative care matches the care patients desire at end of life with that which they receive and can increase quality of life for patients prior to death. In addition, palliative care can enhance the perception of quality of death among family members and reduce instances of complicated bereavement, including caregiver depression, anxiety, and PTSD.[5] The vast majority of deaths in the ICU are preceded by a change in goals of care toward an approach that emphasizes comfort over cure. As such, a strong foundation and comfort with principles of hospice and palliative medicine is essential to the comprehensive care of critically ill patients. In addition, standardized policies are critical to ensuring effective and efficient relief of pain and suffering in the terminally ill.

The fundamental goal of palliative care is to restore or maintain quality of life and prevent needless physical or emotional suffering for patients and their loved ones. This includes not only administering analgesics and other medications to relieve symptoms of the dying process, but also providing other compassionate care. In fact, it is important to explicitly state that while palliative care encompasses limiting or discontinuing various life-sustaining interventions, it does not mean we are limiting "care" for our patients and their loved ones. In addition to symptom control, "care" also means providing general patient hygiene and attending to the spiritual, emotional, and psychological distress of the patient and the family of a dying patient. As an example of a simple, yet successful, intervention, use of empathic statements about the difficulty of making decisions to withhold or withdraw life-sustaining therapy and losing a loved one have been associated with increased ratings of family satisfaction and bereavement among surrogates.[37]

Once the decision is made to focus exclusively on care that promotes comfort, only treatments and interventions that achieve this goal should be employed. As appropriate, opiates and sedatives should be titrated to prevent pain, dyspnea, or anxiety before withdrawing life-sustaining therapies. When the patient is perceived to be comfortable by the medical staff and family, all life-sustaining interventions should be withdrawn or withheld so as to not prolong the dying process. While care should be tailored to the wishes and values of each family, some basic guidelines should be followed.

First, a clear explanation should be provided to the patient's loved ones before initiating comfort care interventions. Families should understand that comfort care will be provided throughout the dying process, and that time to death is variable. In addition, family should be offered the opportunity to be present at the time of death, understanding that for some, presence is associated with increased incidence of PTSD.[38] Second, withdrawal of all agreed upon life-sustaining therapies should occur at one time, rather than in a sequential fashion, to minimize discomfort to the patient and disruption to the family. Third, any evidence of recurring pain, anxiety, or discomfort, as witnessed by a team member or family, should be aggressively treated. This includes any spiritual or existential suffering, which should be addressed with the support of palliative and pastoral care services. Fourth, when possible, in-room physiological monitoring should be discontinued, as well as unnecessary medications, tests, devices, vascular access, and catheters. Finally, members of the medical team should be in close proximity and readily available to quickly address any issues that arise.

As a general rule, actively dying patients should not be transferred out of the ICU unless the bed is needed for a new critically ill patient. These patients often require high levels of nursing and physician support and typically die relatively quickly after life-sustaining therapies are withdrawn. In addition, leaving the patient in the ICU allows for continuity of care, which can be immensely helpful to grieving families. However, for patients whose needs for palliative care can be met by a less intense level of nursing and medical care, or for patients whose death may not be imminent, consideration should be given to transferring that patient to another room outside of the ICU, where there is more privacy and quiet during the dying process. Some hospitals have hospice units with specially trained nursing and medical staff and pleasant, private surroundings for patients and families. It is customary for hospital visiting hours to be suspended for dying patients.

CONFLICT RESOLUTION IN THE ICU

As a rule, good communication and sustaining of trust in the ICU significantly lessen the likelihood of conflict between healthcare staff and patients and their families. Unfortunately, conflict does arise at times. Although some disagreements may be based on ethical issues (e.g., autonomy vs. beneficence), in most instances conflict occurs due to breakdowns in communication, a loss of trust, or both. At these moments of conflict, it is important to recognize that individuals each have their own sets of values and beliefs that may inform their opinion about a plan of care. This applies not only to patients and their families, but also to medical staff as well. In addition, the ICU is a challenging environment. ICU staff are busy, patient conditions rapidly change, and families suffer from varying degrees of emotional distress. Recognizing and acknowledging these challenges is important in achieving resolution of conflict.

Conflict resolution begins with open communication among all parties. Usually, patient and honest negotiation between parties will result in resolution. In particular, attempting to understand the values and perspective of patients and their families can improve the communication process and diffuse difficult situations. However, at times further discussion may not resolve the dispute. At that point, a number of additional strategies may be considered.

PALLIATIVE CARE CONSULTATION

Palliative care services are an excellent resource for providing additional support in the end-of-life process. In addition to expertise in symptom control, palliative care teams can provide supportive counseling to patients and families, improve communication with the medical team, and aid in conflict resolution. Various studies of the effectiveness of palliative care consultation in the ICU have demonstrated improved quality of death and dying, better family bereavement scores, increased advance directive completion rates and hospice discharge rates, reductions in utilization of nonbeneficial life-sustaining therapies, and reductions in hospital and ICU length of stay.[39,40] In the absence of dedicated palliative care consultative services, social work and pastoral care (two common members of the palliative care multidisciplinary team) may be able to provide support.

ETHICS CONSULTATION AND BIOETHICS MEDIATION

Another potential option for dealing with conflict resolution is the hospital ethics committee. Ethics consultants are excellent resources for clarifying ethical uncertainty when it arises. However, much of the conflict occurring in the ICU is not truly of an ethical nature. In this context, ethics consultation may not necessarily be helpful. In general, use of ethics consultation has produced similar outcomes as the palliative care interventions described earlier.[41]

When not employed appropriately, ethics consults may be viewed as arbitrary and biased in favor of the hospital and medical team. Rendering a decision runs the risk of not meeting the needs of the patient and family and increasing conflict. Given these reservations, it is imperative that hospital ethics committees have sufficient community representation and seek out the involved patients and their families directly to enable a complete understanding of their values, perceptions, and goals when conflict exists.

More recently, bioethics mediation has emerged as another potential approach for resolving conflicts in the ICU. Mediation has been practiced in legal and business settings for decades. Although new to health care, mediation offers an alternative means of handling disputes by focusing on a shared decision-making model, rather than the win–lose scenario of the healthcare team versus the patient and family.

Mediation operates under the premise that mutually agreeable solutions can be negotiated when conflict arises between multiple parties involved in the care of a patient. Unlike legal and business settings, healthcare mediation is nonbinding and, therefore, might be more akin to marriage counseling than true legal mediation. In this sense, it is perhaps better termed "facilitation." The goal of mediation is to create a neutral environment for all parties to come together and share perspectives and concerns. Although promising, bioethics mediation in the healthcare setting remains untested. Furthermore, there are few individuals currently trained in bioethics mediation to make its practice widely applicable at this time. There is, however, a growing sentiment that ICU clinicians should have some knowledge or training in principles of mediation to effectively negotiate conflict.

STRATEGIES FOR WHEN CONFLICTS PERSIST

Even with the previously noted resources, times will arise when the relationship between providers and patient or family is irrevocably damaged, and further communication and negotiation will not successfully resolve the conflict. In these settings, healthcare providers may find themselves providing care they believe to be ineffective or even harmful. This can have unfortunate consequences of burnout and cynicism, both of which can result in erosion of professionalism and poor quality of care for current and future patients.[42] If a provider feels strongly that he or she cannot, in good conscience, offer the care that the patient or family is requesting, the provider may transfer the care to another provider within the same institution or offer to transfer to another hospital. However, if another provider or hospital cannot be identified, it is vital that the medical staff support each other while continuing to provide good care to their patients. One effective approach that is being adopted in many ICUs to minimize emotional and moral distress is "death" or "grief" rounds, during which ICU staff come together to debrief and discuss difficult cases. Grief rounds allow staff to decompress and avoid burnout that could otherwise negatively impact job satisfaction and patient interaction.[43]

CONCLUSION

In today's critical care environment, death in the ICU is common and usually occurs after life-sustaining therapy is withheld or withdrawn. Many ethical considerations arise from the frequency and complexity of this process. Consequently, healthcare providers face challenging ethical dilemmas in weighing these considerations while providing care for their patients.

There is broad legal, ethical, societal, and professional support for limiting life-sustaining therapy at the end of life. As a general rule, the overriding principle is respect for patient autonomy. However, physicians must engage patients and their families to create a shared decision-making environment in which medical facts are matched by a desire to understand the values and wishes of patients with critical illness and terminal disease. Ultimately, effective communication enhances the quality of patient care and family satisfaction and is likely to result in patients getting the care they wish to receive.

Conflicts occur, although they can usually be resolved by good communication and honest, respectful engagement. In situations in which communication strategies fail, additional resources (e.g., palliative care, ethics committees, or bioethics mediation) may prove helpful to resolve conflict. Only in very rare cases should providers find themselves in situations where they are morally distressed by the care they are required to provide. In these situations, the conflict can be resolved by transferring the patient to another provider or hospital and by supporting each other while continuing to provide high-quality critical care.

ACKNOWLEDGMENT

The authors would like to thank Paul N. Lanken for his contributions to this chapter in the previous edition.

APPENDIXES

Appendix A Terms and Symbols in Respiratory Physiology A-2

Appendix B Normal Values for a Healthy 20-Year Old Seated Man A-5

APPENDIX A

Terms and Symbols in Respiratory Physiology

GENERAL SYMBOLS

P	Partial pressure in blood or gas P_{O_2} = partial pressure of O_2
$\bar{X}$	A bar over the symbol indicates a mean value. $\bar{P}$ = mean pressure, as distinct from instantaneous pressure
$\dot{X}$	A time derivative (rate) is indicated by a dot above the symbol $\dot{V}_{O_2}$ = oxygen consumption per minute, mL $\dot{V}_{CO_2}$ = CO_2 production per minute, mL
% X	Percent sign preceding a symbol indicates percentage of the predicted normal value
X/Y%	Percent sign following a symbol indicates a ratio function with the ratio expressed as a percentage. Both components of the ratio must be designated $FEV_1/FVC, \% = 100 \times FEV_1/FVC$
XA, Xa	A small capital letter or a lower-case letter on the same line following a primary symbol is a qualifier to further define the primary symbol. Alternatively, subscript letters may be used $X_A = X_A$, $Xa = X_a$ Additional qualifiers of the primary symbol may be identified as shown $P_{E_{O_2}}$ = Pressure of CO_2 in the expired air, mm Hg

GAS PHASE SYMBOLS

PRIMARY SYMBOLS

V	Volume of gas
$\dot{V}$	Flow of gas
F	Fractional concentration of a gas

QUALIFYING SYMBOLS

I	Inspired V_I = inspired volume
E	Expired V_E = expired volume $\dot{V}_E$ = expired volume per minute
A	Alveolar V_A = alveolar volume $\dot{V}$ = alveolar ventilation per minute
T	Tidal V_T = tidal volume
D	Dead space V_D = volume of dead space $\dot{V}_D$ = dead-space ventilation per minute
B	Barometric P_B = barometric pressure
STPD	Standard conditions: temperature 0°C, pressure 760 mm Hg, and dry (0 mm Hg water vapor)
BTPS	Body conditions: body temperature and ambient pressure, saturated with water vapor at these conditions
ATPD	Ambient temperature and pressure, dry
ATPS	Ambient temperature and pressure, saturated with water vapor at these conditions
an	Anatomic
p	Physiological
f	Respiratory frequency, per minute
max	Maximum
t	Time

BLOOD PHASE SYMBOLS

PRIMARY SYMBOLS

Q	Volume of blood
$\dot{Q}$	Blood flow $\dot{Q}$ = cardiac output, L/min
C	Concentration in the blood phase C_{O_2} = concentration of oxygen in blood, mL of O_2 per 100 mL of blood
S	Saturation in the blood phase S_{O_2} = Saturation of hemoglobin with O_2, percent

QUALIFYING SYMBOLS

a	Arterial Ca_{O_2} = concentration of O_2 in arterial blood, mL of O_2 per 100 mL of blood
c	Capillary Cc_{O_2} = concentration of O_2 in capillary blood, mL of O_2 per 100 mL of blood
C′	Pulmonary end-capillary Pc'_{O_2} = partial pressure of O_2 in end-capillary blood, mm Hg
v	Venous Cv_{O_2} = concentration of O_2 in venous blood, mL of O_2 per 100 mL of blood
$\bar{v}$	Mixed venous $C\bar{v}_{O_2}$ = concentration of O_2 in mixed venous blood, mL of O_2 per 100 mL of blood

VENTILATION AND LUNG MECHANICS TESTS AND SYMBOLS

■ STATIC LUNG VOLUMES*

RV	Residual volume. Volume of air remaining in the lungs after maximum expiration.
CV	Closing volume. Volume of air expired from the onset of airways closure to residual volume. May be expressed as a fraction of VC: CV/VC,%.
ERV	Expiratory reserve volume. Maximum volume of air expired from the resting end-expiratory level.
V_T	Tidal volume. Volume of air inspired or expired with each breath during quiet breathing. When tidal volume is used in gas-exchange formulations, this symbol is used.
IRV	Inspiratory reserve volume. Maximum volume of air inspired from the end-tidal inspiratory level.

■ LUNG CAPACITIES**

IC	Inspiratory capacity. The sum of IRV and TV.
IVC	Inspiratory vital capacity. Maximum volume of air inspired from the point of maximum expiration, i.e., from RV.
VC	Vital capacity. Maximum volume of air expired from the point of maximum inspiration, i.e., from TLC.
FRC	Functional residual capacity. Sum of RV and ERV. FRC is the volume of air remaining in the lungs at the resting end-expiratory position.
TLC	Total lung capacity. Volume of air in the lungs after maximum inspiration. Also, the sum of all volume compartments of the lungs.
RV/TLC,%	Residual volume to total lung capacity ratio, expressed as a percentage.
CC	Closing capacity. Closing volume plus residual volume, may be expressed as a percentage of TLC: CC/TLC, %.

■ FORCED RESPIRATORY MANEUVERS DURING SPIROMETRY†

FVC	Forced vital capacity. The maximum volume of air forcibly expired from total lung capacity
FIVC	Forced inspiratory vital capacity. Maximum volume of air forcibly inspired starting from residual volume.
FEV*t*	Timed forced expiratory volume. Volume of air expired in a specified time in the course of the forced vital capacity maneuver. FEV_1 = volume of air expired during the first second of the FVC.
FEV*t*/FVC,%	Ratio of timed forced expiratory volume to forced vital capacity, expressed in percentage.
FEF*x*	Forced expiratory flow, related to some portion of the FVC curve. Modifiers refer to the amount of the FVC that has been expired at the time of measurement.
$FEF_{200-1200}$	Forced expiratory flow between 200 and 1200 mL of the FVC (formerly called the maximum expiratory flow rate).
FEF_{25-75}	Forced expiratory flow during middle half of the FVC (formerly called the maximum midexpiratory flow rate or MMEF)
PEF	Peak expiratory flow. Highest value for expiratory flow.
$\dot{V}_{max_x}$	Maximum flow when *x* percent of the FVC has been expired. $\dot{V}_{max\,75}$ = flow (instantaneous) when 75% of the FVC has been expired.
FIF*x*	Forced inspiratory flow. As in the case of the FEF, appropriate modifiers designate the volume at which flow is being measured. Unless otherwise specified, the volume qualifiers indicate the volume inspired from RV at the point of measurement. FIF_{25-75} = forced inspiratory flow during the middle half of the FIVC.
MVV	Maximum voluntary ventilation. Volume of air exhaled during maximum breathing efforts within a specified time period. Formerly called the maximum breathing capacity (MBC) MVV_{60} = MVV at a breathing frequency of 60 per minute.
PImax	Maximum inspiratory pressure. The maximum pressure generated during a maximal inspiratory effort made at RV.
PEmax	Maximum expiratory pressure. The maximum pressure generated during a maximal expiratory effort made at TLC.

*Expressed as BTPS.

**Combinations of volumes for practical purposes.

†All values at BTPS.

■ MEASUREMENTS RELATED TO VENTILATION

$\dot{V}_E$	Expired volume per minute (BTPS)
$\dot{V}_I$	Inspired volume per minute (BTPS)
$\dot{V}_{CO_2}$	Carbon dioxide production per minute (STPD)
$\dot{V}_{O_2}$	Oxygen consumption per minute (STPD)
R	Respiratory exchange ratio, the ratio of CO_2 output to O_2 intake in the lungs
$\dot{V}A$	Alveolar ventilation per minute (BTPS)
$\dot{V}_D$	Ventilation per minute of the physiological dead space (BTPS) defined by the equation $\dot{V} = \dot{V}_E \frac{Pa_{CO_2} - PA_{CO_2}}{Pa_{CO_2} - PI_{CO_2}}$
V_D	Volume of the physiological dead space, calculated as $\dot{V}_D/f$.
V_D/V_T	Ratio of dead space to tidal volume. The fraction, usually expressed as a percentage, of each breath that does not contribute to CO_2 elimination.

■ MECHANICS OF BREATHING*

Pressure Terms

Paw	Pressure at any point along the airways
Pao	Pressure at the airway opening
Ppl	Pleural pressure
P_A	Alveolar pressure

*All pressures expressed relative to ambient pressure unless otherwise specified.

Pbs	Pressure at the body surface
Pes	Esophageal pressure: used to estimate Ppl
P_A–Pbs	Transthoracic pressure
P_A–Ppl	Transpulmonary pressure
Ppl–Pbs	Pressure difference across the chest wall
Paw–Ppl	Transbronchial pressure, estimated as difference between airway and pleural pressures.

Flow–Pressure Relationships†

R	General symbol for frictional resistance, defined as the ratio of pressure difference to flow.
Raw	Airway resistance, calculated from pressure difference between airway opening (Pa_o) and alveoli (Pa) divided by the airflow, cm H_2O/L/s.
Rl	Total pulmonary resistance, measured by relating flow-dependent transpulmonary pressure to airflow at the mouth.
Rti	Tissue resistance (viscous resistance of lung tissue), calculated as difference between Rl and Raw.
Rus	Resistance of the airways on the upstream (alveolar) side of the point in the airways where intraluminal pressure equals Ppl, i.e., equal pressure point. Measured during a forced expiration.
Rds	Resistance of the airways on the downstream (mouth) side of the point in the airways where intraluminal pressure equals Ppl, i.e., equal pressure point. Measured during a forced expiration.
Gaw	Airway conductance, reciprocal of Raw.
Gaw/Vl	Specific conductance, airway conductance, expressed per liter of lung volume at which Gaw is measured.

Volume–Pressure Relationships

C	General symbol for compliance of the lungs, chest wall, or total respiratory system. Volume change per unit change in applied pressure. For the lungs, the applied pressure is the pressure difference across the lungs, or transpulmonary pressure, Pao–Ppl; for the chest wall, the applied pressure is the transthoracic pressure, Ppl–Pbs; for the entire respiratory system, the applied pressure is Pao–Pbs.
Cl	Lung compliance. Value for the volume change divided by the transpulmonary pressure.
Cw	Chest wall compliance. Value for the volume change divided by the transthoracic pressure.
Cdyn	Dynamic compliance. Value for compliance determined at time of zero gas flow at the mouth during uninterrupted breathing. The respiratory frequency appears as a qualifier. $Cdyn_{40}$ = dynamic compliance at a respiratory frequency of 40 per minute.
Cst	Static compliance, value for compliance determined on the basis of measurements made during a period of zero airflow.
C/Vl	Specific compliance. Compliance divided by the lung volume at which it is determined, usually FRC.

†Unless otherwise specified, resistance measurements are assumed to be made at FRC.

Pst	Static pulmonary pressure at a specified lung volume. Pst_{TLC} = static recoil pressure of the lung measured at TLC (maximum recoil pressure)

■ DIFFUSING CAPACITY TESTS AND SYMBOLS

D_Lx	Diffusing capacity of the lung expressed as volume (STPD) of gas (x) uptake per minute per unit alveolar-capillary pressure difference for the gas used. A modifier can be used to designate the technique: D_{LCO}/sb = Single-breath CO diffusing capacity; D_{LCO}/ss = Steady-state CO diffusing capacity
D_M	Diffusing capacity of the alveolar-capillary membrane (STPD).
θ	Reaction rate coefficient for red blood cells. Determined as the volume of gas (STPD) that will combine per minute with 1 unit volume of blood per unit of gas tension. If the specific gas is not stated, θ is assumed to refer to CO and is a function of existing O_2 tension.
Vc	Pulmonary capillary blood volume. This should be Qc for consistency with other symbols, but Vc is entrenched in the literature. In the equation that follows for 1/D_L, Vc represents the effective pulmonary capillary blood volume, i.e., capillary blood volume in intimate association with alveolar gas.
1/D_L	Total resistance to diffusion, including resistance to diffusion of test gas across the alveolar-capillary membrane, through plasma in the capillary, and across the red blood cell membrane (1/Dm), with the resistance to diffusion within the red blood cell arising from the chemical reaction of the test gas and hemoglobin (1/θVc), according to the formulation $\frac{1}{D_L} = \frac{1}{D_M} + \frac{1}{\theta Vc}$
D_L/V_A	Diffusing capacity per unit of alveolar volume. D_L is expressed STPD, and V_A is expressed in liters, BTPS.

BLOOD GAS SYMBOLS

Symbols for these values are readily composed by combining general symbols. Some examples include the following:

Pa_{CO_2}	Arterial CO_2 tension, mm Hg
Sa_{O_2}	Arterial O_2 saturation, percent
CcO_2	Oxygen content of pulmonary end-capillary blood, mL of O_2 per 100 mL of blood
$(A\text{-}a)Po_2$	Alveolar–arterial difference in the partial pressure of O_2, mm Hg
$Ca_{O_2} - C\bar{v}_{O_2}$	O_2 content difference between arterial and mixed venous blood (arteriovenous O_2 difference), mL of O_2 per 100 mL of blood

PULMONARY SHUNT SYMBOLS

$\dot{Q}s$	Flow of blood via shunts. This is usually determined as percent of cardiac output ($\dot{Q}$) while breathing 100% O_2, according to the equation $\frac{\dot{Q}s}{\dot{Q}} = \frac{CcO_2 - Ca_{O_2}}{Ca_{O_2} - C\bar{v}_{O_2}} \times 100$ Where CcO_2 = O_2 content of end-capillary blood; CaO_2 = O_2 content of arterial blood; $C\bar{v}_{O_2}$ = O_2 content of mixed venous blood

APPENDIX B

Normal Values for a Healthy 20-Year Old Seated Man

Ventilation (BTPS)	
Tidal volume (V_T), L	0.6
Frequency (f), breaths/min	12
Minute ventilation (V_E), L/min	7.2
Respiratory dead space (V_D), mL	150
Alveolar ventilation, V_A, L/min	5.4
Lung Volumes and Capacities (BTPS)	
Inspiratory capacity (IC), L	3.0
Expiratory reserve volume (ERV), L	1.9
Vital capacity (VC), L	4.9
Residual volume (RV), L	1.4
Functional residual capacity (FRC), L	3.2
Total lung capacity (TLC), L	6.3
Residual volume/total lung capacity × 100 (RV/TLC), %	22
Mechanics of Breathing	
Forced vital capacity (FVC), L	4.9
Forced expiratory volume, first second (FEV_1), L	4.0
Maximum voluntary ventilation (MVV), L/min	170
Forced expiratory volume in 1 s/forced vital capacity × 100 (FEV_1/FVC), %	83
Forced expiratory volume in 3 s/forced vital capacity × 100 (FEV_3/FVC), %	97
Forced expiratory flow during middle half of FVC ($FEF_{25–75}$), L/s	4.7
Forced inspiratory flow at the middle of forced inspiratory capacity (FIF_{50}), L/s	5.0
Static compliance of the lungs (Cst, l), L/cm H_2O	0.2
Compliance of lungs and thoracic cage (CRS, respiratory system compliance) L/cm H_2O	0.1
Airway resistance at FRC (Raw), cm H_2O/L/s	1.5
Pulmonary resistance at FRC, cm H_2O/L/s	2.0
Airway conductance at FRC (G_{aw}), L/s/cm H_2O	0.66
Specific conductance (G_{aw}/V_1)	0.22
Maximum inspiratory pressure, mm Hg	– 75
Maximum expiratory pressure, mm Hg	120
Distribution of Inspired Gas	
Single-breath N_2 test (ΔN_2 from 750 to 1250 mL in expired gas), % N_2	<1.5
Alveolar N_2 after 7 min of breathing O_2, % N_2	<2.5
Closing volume (CV), mL	400
CV/VC × 100, %	8
Closing capacity (CC), mL	1900
CC/TLC × 100,%	30
Slope of phase III in single-breath N_2 test, % N_2/L	<2
Gas Exchange	
O_2 consumption at rest (STPD), mL/min	240
CO_2 output at rest (STPD), mL/min	192
Respiratory exchange ratio (R), CO_2 output/O_2 uptake	0.8
ALVEOLAR GAS	
$P_{A_{O_2}}$, mm Hg	105
$P_{A_{CO_2}}$, mm Hg	40
ARTERIAL BLOOD	
Pa_{O_2}, mm Hg	95
Sa_{O_2}, %	98
pH	7.40
Pa_{CO_2}, mm Hg	40
Pa_{O_2}, while breathing 100% O_2, mm Hg	640
Alveolar Ventilation and Gas Exchange	
Alveolar ventilation, L/min	4.2
Physiological dead space/tidal volume × 100 (V_D/V_T), %	<30
Alveolar–arterial oxygen-gradient, (A-a) P_{O_2}, mm Hg	10
Diffusing Capacity	
Diffusing capacity at rest for CO, single-breath (DL_{COsb}), mL CO/min/mm Hg	29
Diffusing capacity per unit alveolar volume (D_L/V_A)	4.8
Control of Ventilation	
Ventilatory response to hypercapnia, L/min/per ΔPa_{CO_2} mm Hg	>1.5
Pulmonary Hemodynamics	
Pulmonary blood flow (cardiac output), L/min	5.4
Pulmonary artery systolic/diastolic pressure, mm Hg	25/8
Pulmonary capillary blood volume, mL	100
Pulmonary "capillary" (wedge) blood pressure, mm Hg	<10
