CHAPTER 25

T Lymphocytes in the Lung

Lauren E. Cohn

The lung is a major site of exposure to the outside world in air-breathing species. Lung immunity has developed to recognize pathogens and activate appropriate responses, to temper inflammation in response to nonpathogenic exposures and turn off immune responses when danger signals have been eliminated. T lymphocytes play a major role in lung immunity predominantly through the induction of CD4 and CD8 T cells in adaptive immunity. A number of smaller subsets of T lymphocytes also play critical roles in early immune responses to pathogens and stimulating adaptive immune responses. Long-lived memory CD4 and CD8 T cells are crucial for host protection from pathogens, but also may drive chronic disease states, such as asthma. In this chapter the basic biology of T lymphocytes and their relevance in the lung in health and disease will be reviewed.

T LYMPHOCYTE SUBSETS

Lymphocytes make up approximately 10% of leukocytes in the blood and nearly 70% of leukocytes in the normal human lung.[1] In both sites, a majority of lymphocytes are T lymphocytes. Lymphocytes include T and B cells and are small, mononuclear cells with a characteristic large nucleus-to-cytoplasm ratio in the resting state. T lymphocytes have their origin in the thymus. T lymphocytes are essential for adaptive immune responses, the type of immunity that develops over a period of days to weeks that fine-tunes an immune response to limit a specific pathogen or insult. The majority of T lymphocytes express alpha-beta (α/β) T cell antigen receptors (TCRs) on the cell surface. The α/β TCR consists of two polypeptide chains with a variable region that binds to antigen, a constant region, and an anchor to the cell membrane. During development in the thymus, T cells undergo TCR gene rearrangement to generate a receptor that has an antigen-binding structure. Each mature T cell bears only this TCR with its unique specificity for antigen binding. Approximately 10^6 different TCRs develop in an individual, thus allowing the individual to respond to an extraordinary range of antigens throughout life. After exposure to a new antigen, TCRs expressed on T lymphocytes develop even finer antigen-binding capabilities through a process called affinity maturation.

The subsets of T lymphocytes that express receptors with less diversity and ability to recognize antigens include natural killer T (NKT) and mucosal-associated invariant T (MAIT) cells that also express an α/β TCR, and gamma-delta (γ/δ) TCR-expressing cells. These subsets of T lymphocytes are more prominent at sites of pathogen exposure, such as the mucosal surfaces. They express preformed receptors that bind to common pathogen components. This preset ability to bind and react to pathogens allows them to respond quickly, leading to early release of cytokines. NKT, MAIT, and γ/δ T cells are part of the innate immune response to pathogens and other insults that provide signals to initiate and direct CD4 and CD8 T cell activation in the adaptive immune response.

In addition to the α/β TCR, T lymphocytes express coreceptors CD4 or CD8. CD4+ T cells are called T helper (Th) cells because of their ability, through production of cytokines, to stimulate other immune cells. Another subset, CD4 regulatory T cells (Treg), downregulate immune responses. CD8 T cells, traditionally called cytotoxic T cells (Tc), release preformed effector molecules that destroy infected cells. They also produce cytokines that aid in local immunity. TCRs on CD4 T cells recognize peptide antigens that bind to domains on MHC Class II molecules that are present on the surface of antigen-presenting cells (APCs). CD8 T cells recognize endogenously derived antigens bound to MHC Class I molecules. MHC Class I molecules are present on the surface of all nucleated cells, whereas MHC Class II molecules are only present on APCs, including dendritic cells (DCs), B cells, and macrophages. Exogenous protein antigens, such as extracellular pathogens and environmental substances, are taken up by APCs and processed into peptides in endocytic vesicles, which are presented on the cell surface bound to MHC II molecules. Endogenous antigens, such as those of intracellular pathogens, including viruses, are processed and presented by Class I MHC molecules.

CD4+ T CELLS

CD4+ T Cell Activation

Mature, naive CD4+ T cells are released from the thymus into the circulation and enter the lymph node through specialized blood vessels, the high endothelial venules (HEVs). Expression of L-selectin (CD62L) on the naive CD4 T cell along with chemokine signals produced by stromal cells within lymphoid tissues permits attachment and transit through the HEVs into the lymph node.[2,3] In the lung, this occurs in the lymph nodes that drain the trachea, bronchi, and lung parenchyma.

Antigens or pathogens that enter the lung are taken up by APCs in the airways and alveoli. DCs are the major APC of the mucosal surfaces. DC in the airway walls and alveoli form a dense network just beneath the epithelium with processes that extend to the airspaces, designed to catch foreign antigens.[4] Macrophages in the airways and lungs also engulf large particles and pathogens through phagocytosis, but they are typically poor stimulators of adaptive immune responses, and likely eliminate antigens or induce regulatory responses, rather than activate immunity. After antigen uptake, APCs break down antigens into peptide fragments in endocytic vesicles, where the peptides are loaded onto Class II MHC proteins and transported to the cell surface. Concurrent with antigen presentation, the APC increases expression of costimulatory molecules and migrates to the lung-draining lymph nodes.

In the T cell area of the lymph node, naive CD4+ T cells move past antigen-expressing APCs, permitting the interaction of TCR and MHC Class II peptide. When the TCR on a CD4+ T cell interacts with its specific antigen on an APC, it ceases to migrate further. T cell activation is initiated upon (1) TCR recognition of MHC class II peptide (signal 1) and (2) costimulatory signaling from the APC (signal 2) (Fig. 25-1). The principal costimulatory molecules expressed on the surface of APCs are CD80 (B7-1) and CD86 (B7-2), which both interact with CD28 on the T cell.[5] If both signal 1 and signal 2 are received, the T cell goes into G1 phase of the cell cycle, begins to produce interleukin-2 (IL-2) and undergoes clonal expansion. This gives rise to a population of effector cells with the identical TCR specificity to the parental cell.

CD4 Helper T Cell Differentiation

Primary Immune Response Antigen-activated CD4+ T cells differentiate into effector cells of different types. CD4 T cell subsets are defined by the cytokines they secrete, and that pattern of cytokines confers its functional properties (Table 25-1). *T helper type 1* (Th1) cells are a subset of CD4+ T cells that secrete the macrophage activating factor, interferon gamma (IFN-γ), and lymphotoxin (LT or TNF-β). *T helper type 2* (Th2) cells produce interleukin-4 (IL-4), IL-5, and IL-13. *T helper type 17* (Th17) cells produce IL-17A, IL-17F, and IL-22. IL-10, an anti-inflammatory cytokine, was originally defined as a Th2 cytokine, but it is now recognized that it can be synthesized by all Th cell subsets upon appropriate activation.[6] Treg produce IL-10 and/or TGF-β1. Since Treg suppress T cell differentiation and APC activation, they are not considered effector cells. Th1 cells stimulate strong cell-mediated immune responses, particularly against intracellular pathogens. Th2 cells, through the production of IL-4 and IL-13, are potent activators of B cell antibody production, particularly immunoglobulin E (IgE). IL-5 secretion by Th2 cells is critical for eosinophil differentiation and maturation. Th2 cells are elicited in immune responses that require a strong humoral component and in antiparasitic responses. Th17 cells stimulate neutrophil mobilization and recruitment, release of antimicrobial peptides, and serve critical host defense functions at mucosal surfaces. An effective immune response to a pathogen commonly results in the induction of a balance of Th1, Th2, and Th17 cells to provide strong cellular and humoral immunity.

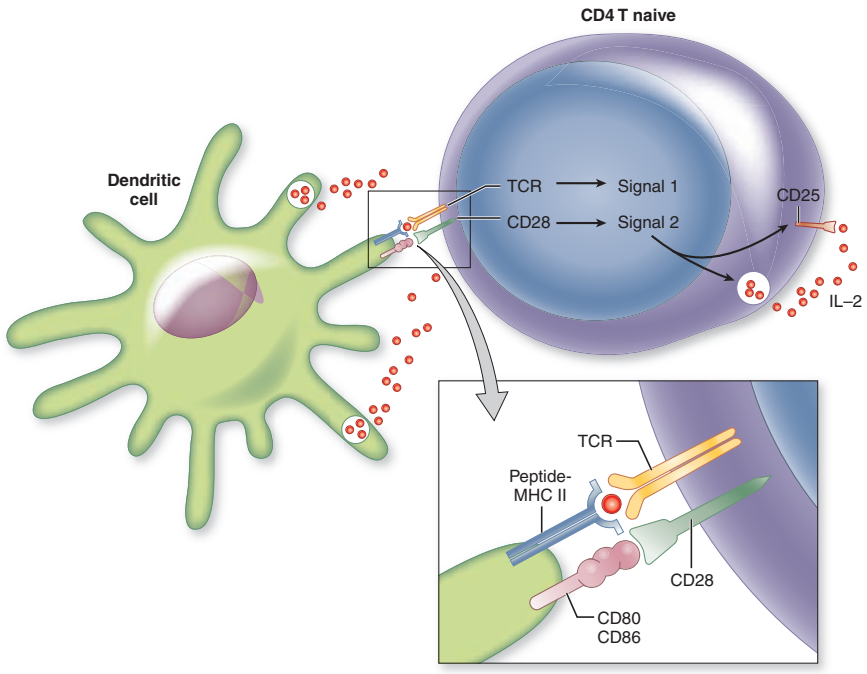

Figure 25-1 Two-signal mechanism of CD4 T cell activation. Antigen-presenting cell (APC) takes up a protein antigen and processes it into peptide fragments that are presented by class II major histocompatibility complex (MHC) molecules. Signal 1 required for CD4 T cell activation is recognized by the T cell antigen receptor (TCR) and engagement of class II MHC-peptide complex. Signal 2 is an interaction of CD28 on the T cell with CD80 or CD86 on the APC, termed costimulation. These signals stimulate interleukin-2 (IL-2) production, IL-2 receptor (IL-2R) expression and induce CD4 T cell proliferation.

CD4+ Treg comprise subsets of cells generated in the thymus (natural Treg) or induced in the secondary lymphoid tissues (inducible (i) Treg) that produce IL-10 and/or TGF-β1 and express the transcription factor Foxp3. They are often identified by their high expression of CD25 and Foxp3.[7] CD4 Treg inhibit the development

TABLE 25-1 T Lymphocyte Subsets and Their Functions

T Lymphocyte		Signals to Activate/Differentiate: Cytokine	Signals to Activate/Differentiate: Transcription Factor	Cytokines and Mediators Produced	Major Functions
CD4 Activated by peptide–MHC Class II	Th1	IFN-γ, IL-12	T-bet	IFN-γ, lymphotoxin	Anti-viral and -mycobacterial effects, activation of macrophages to kill intracellular pathogens
	Th2	IL-4	GATA-3	IL-4, IL-5, IL-13	Antiparasitic responses Stimulation of IgE and other antibody production, increases mucus production, promotes eosinophilia
	Th17	IL-6, TGF-β1, IL-1β (human)	RORγt	IL-17A, IL-17F, IL-22	Antibacterial and anti-fungal effects, recruitment and activation of PMNs
	Treg	TGF-β1, IL-10	Foxp3	TGF-β1, IL-10	Suppression of T cell activation, inhibition of APC function
CD8		Peptide–MHC Class I		IFN-γ, TNF-α Granzyme perforin	Cytotoxicity of cells infected with virus or bacteria
NKT		Glycolipids		Extensive range of preformed cytokines that are rapidly released	Shaping adaptive immunity against pathogens
MAIT		Vitamin B metabolites		IFN-γ, TNF-α, IL-17, granzyme	Antimicrobial responses
γ/δ		Mycobacterial lipids, heat-shock proteins		Extensive range of preformed cytokines that are rapidly released	Antimicrobial responses, immune surveillance

of Th1, Th2, and Th17 subsets through actions on both APCs, naive T cells, and effector T cells.[8] Treg exert their suppressive effects by secreting cytokines, including TGF-β1 and/or IL-10, by cell contact leading to cytotoxicity or metabolic disruption or by suppression of APCs.[9]

Molecular Mechanisms of CD4 Th Differentiation

Differentiation of naive CD4 T cell into Th1, Th2, Th17, or Treg requires the coordinate action of multiple molecular signals induced by stimulation of the TCR, costimulatory molecules, and cytokine receptors (Fig. 25-2). Major factors in these processes are critical lineage-determining molecules important for stimulation of T cell differentiation, simultaneous inhibition of the opposing phenotypes, T cell proliferation, epigenetic remodeling to modify the chromatin structure and cytosine methylation, and expression of key transcription factors.

T-bet is one of the lineage-determining molecules required for Th1 differentiation. It belongs to the T-box family of transcription factors that regulate multiple developmental processes. T-bet is upregulated in Th1 cells, through effects of IL-12 and activation of STAT4, and IFN-γ and activation of STAT1.[10] Induced expression of T-bet in vitro and in vivo led to IFN-γ production.[11] Thus T-bet drives Th1 development. T-bet also promotes Th1 induction through negative regulation of GATA-3.[12]

The transcription factor GATA-3 is an essential regulator of Th2 differentiation.[13,14] Whereas, GATA-3 is expressed at low levels in naive CD4+ T cells,[13] it is markedly upregulated in cells differentiating along the Th2 lineage and is downregulated in cells differentiating along the Th1 pathway.[13] The differentiation of a naive CD4+ T cell along the Th1 or Th2 pathway is accompanied by extensive reorganization of chromatin structure around the IFN-γ or IL-4/IL-5/IL-13 loci, respectively.[15] GATA-3 appears to be the critical downstream regulator of chromatin remodeling around the IL-4 locus.

The orphan nuclear receptor RORγt induces differentiation of naive CD4+ T cells into Th17 cells.[16] RORγt is required for the expression of IL-17 and the related gene IL-17F in response to IL-6 and TGF-β in mice or IL-1β in humans.

Cytokines, by stimulating production of critical lineage-determining molecules, are the primary factors that affect CD4 Th generation.[17,18] Cytokines produced in innate immune responses modulate how the adaptive immune response will develop. IFN-γ and IL-12 cause induction of Th1 cells. IL-4 and IL-13 drive Th2 cell generation. IL-10 enhances Th2 cell development by inhibiting Th1 cell induction. IL-6, IL-1β, IL-23, and TGF-β1 promote Th17 development.

Other factors that influence CD4 differentiation into Th subsets affect the quality of the signal through the TCR. The dose and structure of the antigen affects the APC–TCR interaction and has been shown to drive Th differentiation along distinct pathways.[19] If peptide–MHC Class II complex on the APC has a high-affinity interaction with the TCR, then a Th1-predominant response results, whereas a weaker-affinity interaction leads to a Th2-like response. Very low doses of soluble protein antigen tend to stimulate Th2-predominant responses, and at higher antigen doses, Th1 responses, suggest that the antigen dose affects the APC–T cell interaction. This may have important implications in atopy, since it has been estimated that exposure to common allergens is so small that it does not exceed 1 μg per year. Another line of investigation suggests that high-affinity interactions lead to preferential generation of Th2 cells.[20] More recent studies show that the fate of Th differentiation is an effect of both antigen dose and TCR–MHC Class II binding.[21]

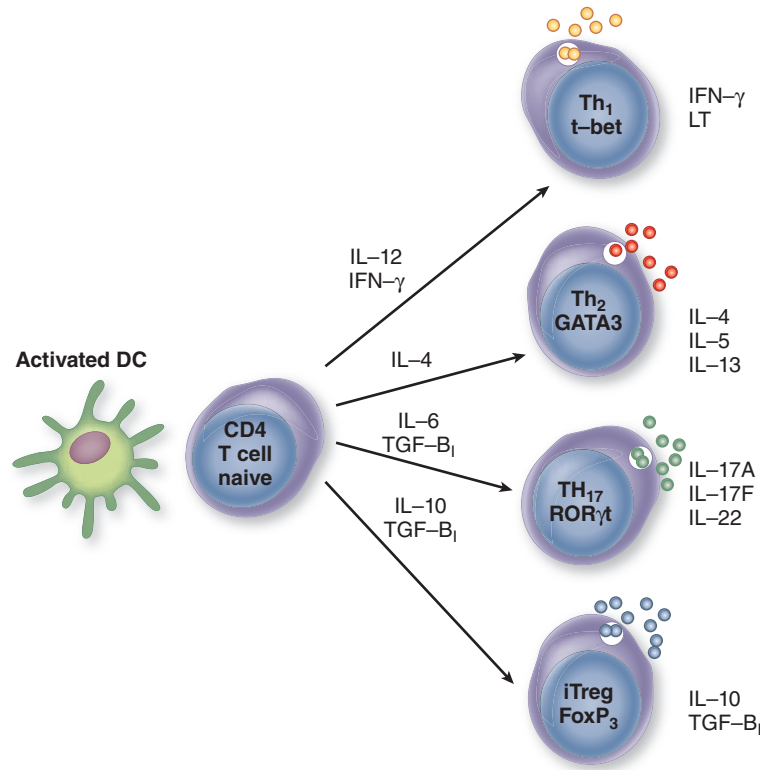

Figure 25-2 Generation of T helper types 1, 2, and 17 (Th1, Th2, Th17) and regulatory T cells (Treg) from a naive CD4+ T cell. A naive CD4+ T cell secretes very low levels of cytokines. Differentiation along the Th1, Th2, Th17, and Treg pathways is triggered when antigen is presented to the T cell receptor in the context of the major histocompatibility complex (MHC) by the appropriate antigen-presenting cell and a second signal imparted by ligation of costimulatory molecules CD80/CD86 and CD28. Dendritic cells (DCs) represent the key APCs for naive T cells. Cytokines produced in innate immune responses activate DC to produce cytokines that direct differentiation of Th subsets leading to induction of critical lineage–determining molecules, T-bet for Th1 cells, GATA-3 for Th2 cells, RORγt for Th17 cells, and Foxp3 for inducible (i)Treg. The cytokines produced by each subset of CD4 T cells are depicted.

Ultimately, the quality of the signals delivered to the T cell through the TCR influences which Th subsets are activated.

Effector/Memory CD4 T Lymphocytes

It takes 4 to 5 days of proliferation in the lymph node for a naive CD4 T cell to differentiate into an effector cell. Associated with differentiation is a change in expression of cell surface of selectins, integrins, and chemoattractant receptors that permit exit from the lymph node and recruitment to sites of inflammation. With differentiation there is loss of expression of the lymph node homing receptor CD62L and gain of function of tissue homing receptors. Whereas skin and gut effector CD4 T cells each have specific ligands that confer their localization to that tissue through binding to vascular endothelial cells (skin, cutaneous lymphocyte-associated antigen [CLA], small intestine, integrin α4β7), such a lung-specific surface marker has not yet been identified. Human lung effector CD4 T cells are enriched for expression of CCR5, CCR6, chemokine (C-X-C motif) receptor 3 (CXCR3) and the integrins VLA1 (α1β1), CD103 (αEβ7), and VLA4 (α4β1).[22] In addition to expression of receptors that respond to specific signals that direct them to the tissue, subsets of effector CD4 Th cells express different panels of chemokine receptors so they can be called to perform specific duties. The type of injury or invading pathogen leads to release of mediators that recruit appropriate, effective populations of CD4 Th cells to manage the specific problem. Th1 cells typically express CCR5 and CXCR3, Th17 cells express

CCR6, and Th2 cells express CCR4 and CCR8, and the prostaglandin D2 chemoattractant receptor DP_2 (CRTH2) in humans.[22]

Effector cells that were activated in the lymph node arrive at an inflammatory site in the lung where they proliferate and produce cytokines. The major function of CD4 T cells is to produce cytokines to recruit other inflammatory cells and modulate local host-protective responses. Following this robust response, most activated effector CD4+ T cells die, either by a process of apoptosis or necrosis. A small population of CD4+ cells persists as memory cells for the life of the host.

CD4 memory T cells, upon reexposure to specific antigen, respond quickly with a strong response of longer duration. Subsets of CD4 memory T cells have been identified based on tissue localization and circulation patterns, cell surface markers, and functional differences. Effector memory cells (T_{EM}) are found in blood and in nonlymphoid tissues, such as liver and lung. Central memory T cells (T_{CM}) circulate through secondary lymphoid organs, lymphatics and blood, produce higher levels of IL-2 and proliferate more than T_{EM}.[23] The third CD4 memory subset, tissue-resident memory T cells make up large pools of cells in the skin and mucosal tissues, including the lung. T_{RM} remain in the tissue compartment to which they were initially called and do not recirculate. T_{RM} are responsible for barrier protection, exhibit the activation marker CD69 and can be activated locally in the tissue, without trafficking to the lymph node, to provide expedient control of infection.[23]

CD4 Regulatory T Cells

CD4 Treg comprise subsets of cells generated in the thymus (natural Treg) or induced in the secondary lymphoid tissues (inducible (i) Treg) that produce IL-10 and/or TGF-β1 and exhibit high expression of CD25 and the transcription factor Foxp3. They make up 5% to 10% of the peripheral CD4 T cell population. Cytokines produced by CD4 Treg inhibit the development of Th1, Th2, and Th17 subsets through actions on APCs, naive and effector T cells.[8] CD4 Treg are critical for suppressing primary immune responses to self, as indicated by mice and humans deficient in a functional Foxp3 protein that develop autoimmune diseases.[24,25] Treg exhibit additional diverse mechanisms to achieve immune suppression in different inflammatory milieu.[26]

■ CD8 T CELLS

Pathogens that enter the lung activate tissue-resident DCs and migrate to lymph nodes where they activate naive CD8 T cells. CD8 T cells are activated to differentiate into effector cells through interactions with DCs and the provision of two required activation signals, antigenic peptide presented by MHC Class I molecules and costimulatory signals. Viruses and intracellular bacteria are classical activators of CD8 T cells. Cytokines secreted by DC drive the proliferation and differentiation of CD8 T cells to acquire the ability to become effector CD8 T cells that most commonly secrete IFN-γ and TNF-α and have cytotoxic capabilities through production of granzyme B and perforin.[27] Effector CD8 T cells may also differentiate into subsets of Tc2 cells that secrete IL-4, IL-5, and IL-13 and Tc17 cells that produce IL-17.[28] CD8 memory cells develop from a small subpopulation of cells activated in a primary immune response. Memory CD8, like CD4, T cells include subsets of T_{CM}, T_{EM}, and T_{RM}. While CD8 and CD4 memory T cells may exhibit different homing patterns, memory functions and surface markers appear to mirror observations in CD4 T cells that were described earlier. For example, CD8 $T_{RM,}$ like CD4 T_{RM}, do not recirculate and confer rapid tissue-specific recall responses in the lung.[23,29]

■ T LYMPHOCYTES WITH RESTRICTED TCR DIVERSITY

T lymphocytes with less diverse arrays of TCRs accumulate in the lung. They respond to different antigens than traditional α/β CD4 and CD8 T cells. Their numbers in tissues are low, but because many respond to the same antigen, they can be activated quickly without further differentiation. Therefore, they participate in innate immunity and some subsets can expand and adapt to exposures. Thus, these T lymphocyte subsets bridge innate and adaptive immunity. There are two small populations of α/β T cells, iNKT cells and MAIT cells that have semi-invariant α chains. Thus, they have undergone somatic mutation in the thymus to generate a TCR, but they have limited diversity due to fewer possible TCR combinations. Both iNKT and MAIT cells are found in high frequencies in mucosal tissues.

Natural Killer T Cells

Type I or invariant (i)NKT cells are a small subpopulation of α/β T cells that express a narrow repertoire of TCRs due to invariant expression of the TCR variable (V)α chain and limited TCR Vβ chains. In humans Vα24-Jα18 pairs almost exclusively with Vβ11, whereas in mice Vα14-Jα18 pair with a limited number of Vβ chains. iNKT cells respond to glycolipid antigens presented on the MHC-like molecule CD-1d, which is a member of a family of nonpolymorphic proteins that bind to lipids, rather than peptide antigens, and is expressed on populations of DCs, B cells, and macrophages.[30]

iNKT cells leave the thymus upon maturation and migrate into tissues. In mice, iNKT cells are enriched in the liver and spleen. In humans iNKT cells are highly enriched in the omentum but have not been well characterized in all tissues.[31] In the bronchoalveolar lavage (BAL) of normal control subjects iNKT cells constituted less than 1% of the lymphocyte population.[32] In mouse, iNKT cells may be 5% to 10% of the lung lymphocytes.[33] Murine studies show that iNKT cells are resident in the lung and, for the most part, do not recirculate to other organs.[34] iNKT cells also reside in the lung microvasculature in the resting state and upon exposure to inhaled lipids, become activated and extravasate into the lung parenchyma where they contribute to lung inflammation.

A hallmark of iNKT cell activation is the rapid elaboration of an extensive array of cytokines and chemokines including IFN-γ, TNF-α, TGF-β, GM-CSF, IL-2, IL-4, IL-5, IL-6, IL-10, IL-13, IL-17, IL-21, RANTES, eotaxin/CCL11, MIP-1α/CCL3, and MIP-1β/CCL4.[30] The early activation of iNKT cells in tissues by specific pathogens is believed to be important in shaping the appropriate adaptive immune response.

MAIT Cells

MAIT cells are another small subpopulation of α/β T lymphocytes that express TCRs with limited diversity. MAIT cells express a semi-invariant α chain, Vα7.2-Jα33, that pairs with a limited number of Vβ chains. MAIT cells are present in humans in the peripheral blood, lamina propria of the intestine, and in the lung.[35] MAIT cell activation requires interaction with the nonpolymorphic MHC I–like molecule MR-1. MR-1 binding of vitamin B metabolites, specifically a precursor of riboflavin synthesis, activates MAIT cells. Since only certain bacteria, fungi, and yeast synthesize this B vitamin, MAIT cells are activated early after exposure to pathogens capable of producing riboflavin.[36,37] Activation of MAIT cells leads to release of cytokines, including IFN-γ, TNF-α, IL-17, granule exocytosis leading to apoptosis, and delivery of antimicrobial peptides.[38,39] MAIT cells help to stimulate effective antipathogen CD4 and CD8 adaptive immune responses. MAIT cells are enriched in the lung in infections, such as tuberculosis, where a fivefold increased frequency, compared to the blood, has been observed.[35]

γ/δ T Cells

Gamma/delta (γ/δ) cells are a subset of T cells that have a TCR composed of γ and δ chains. The γ/δ TCR is generated by VDJ recombination, but unlike the α/β TCR, γ- and δ-chain recombination results in a less diverse repertoire of TCRs. Upon release from the thymus, γ/δ T cells migrate to tissues including lung, skin, intestine, and uterus. γ/δ T cells, like α/β T cells, are found in blood, LN,

and spleen. Within specific tissue compartments all γ/δ T cells may express a monoclonal TCR. γ/δ T cells engage a different group of antigens than α/β T cells. γ/δ TCRs respond to a diverse array of antigens including moieties large and small, self and foreign, and peptide and nonpeptide. This includes mycobacterial lipids and heat-shock proteins.[40] γ/δ T cells do not recognize antigens in the context of class I or II MHC; rather, they may recognize their target antigens directly. The full scope of γ/δ TCR-binding antigens remains unknown.[41] γ/δ T cells secrete a range of cytokines and chemokines, many of which are preformed and quickly produced, to recruit inflammatory cells. Their narrow TCR diversity in a tissue compartment, and ability to respond to their stimuli quickly allows for rapid clonal activation without the need for expansion. This suggests that γ/δ T cells play a role in surveillance and protection from infection, and serve as a bridge between innate and adaptive immune responses.

T LYMPHOCYTES IN THE LUNG

T LYMPHOCYTE DISTRIBUTION IN THE LUNG

In the normal human lung, T lymphocytes are found in the airways and alveolar spaces, in the lung parenchyma/interstitium, the pulmonary intravascular spaces, and in lymph nodes, and their numbers differ in each of these compartments. In adult humans, lymphocytes in the lung are not typically organized into lymphoid structures, such as bronchus-associated lymphoid tissue (BALT), whereas BALT is more common in healthy children, in smokers and those with chronic infections and inflammatory diseases, and in normal animals such as rabbits and rats.[42,43] Recent studies show that lymphocytes are not randomly distributed in each lung compartment, but appear to be organized at sites of pathogen entry.[44] T lymphocytes likely have a multidimensional organization in the lung, including close associations with dendritic, epithelial, and mast cells, but these detailed interactions and their structure is not yet well defined. Until recently, analyses of lung lymphocytes have assessed collections of cells from BAL, which includes cells from the airways and alveolar spaces, or in digested lung tissue. Histopathologic assessments afforded, at best, little more than a two-dimensional analysis. Future studies will define the three-dimensional organization of T lymphocytes in the lung, their detailed interactions with both structural cells, including epithelial, endothelial and neuronal, and hematopoietic cells. Kinetic studies will define how lymphocytes transit between compartments in the lung, to secondary lymphoid and other tissues.

Lymphocytes, including T and B cells, make up about 7% of leukocytes isolated from the human lung. It has been estimated that between 2 and 4 × 10^8 lymphocytes reside in the airways and alveolar spaces. Twentyfold more are estimated to make up the pool of lymphocytes in the lung parenchyma in the normal human lung.[45,46] Lymphocytes isolated from the lung parenchyma consist of large populations within the interstitium and the intravascular space.[47]

In the lung parenchyma, T lymphocytes are the predominant lymphocyte population, a majority of which are CD4 T cells (T:B ratio 15:1, CD4:CD8 2:1).[48] Memory CD4 T cells make up a majority of CD4 T cells in the lung and at other mucosal sites. CD8 memory cells make up half of the CD8 T cell population in the lung. With age, the number of lymphocytes and the proportion of lymphocytes with a memory phenotype increase. In the BAL, CD4 T cells comprise about 4% of leukocytes in young adults and 20% in older adults.[49–51] In lung parenchyma, memory CD4 T cells were 65% in young adults and almost 80% in older adults.[48] Thus, the proportion of antigen-experienced CD4 T cells increases in the lung and likely reflects an individual's accumulated respiratory exposure over time.

T LYMPHOCYTES IN LUNG INFECTION

T lymphocytes play critical roles in host defense against bacteria, viruses, and fungi that enter the host through the respiratory tract. This essential function of T lymphocytes is illustrated in HIV infection, in which individuals lack functional T cell subsets leading to susceptibility to pulmonary infection with bacteria, including *Staphylococcus aureus, Streptococcus pneumonia, Haemophilus influenzae*, and mycobacterial species, viruses such as influenza, and fungi such as histoplasmosis and *Cryptococcus neoformans* and pneumocystis jiroveci pneumonia (PJP).[52]

The immunocompetent individual responds to pathogen invasion through activation of NKT, MAIT, and γ/δ T cells along with other first responders, including macrophages, neutrophils, and epithelial cells. These innate immune cells are rapidly activated to secrete cytokines to help contain the pathogen, and to provide signals to activate CD4 and CD8 T cells. The range of cytokines produced by innate immune cells after activation shape the patterns of CD4 and CD8 T cell subsets induced to differentiate to control the invading pathogen. In a primary response to a pathogen, antigen-specific CD4 and CD8 effector T cells begin to arrive from the secondary lymphoid organs in the lung days after the initial infection.

In lung infection, the primary function of CD4 T lymphocytes is to produce cytokines that ultimately lead to elimination of pathogens. CD8 T cells have the additional capacity to kill infected cells. A primary infection results in the development and recruitment of a range of pathogen-specific T cell subsets, including CD4 Th1, Th2, and Th17, and CD8 T cells. Each subset serves a specific purpose in the complex antimicrobial immune response. Yet, in some infections, one subset is essential for antipathogen immunity. Th1 cells are absolutely required for elimination of a number of pathogens, and this reflects Th1 production of IFN-γ. IFN-γ is essential for immunity to respiratory infections because of its myriad antimicrobial functions including macrophage activation, stimulation of microbicidal effectors, and stimulation of antiviral enzymes.[53] Th1 cells are essential for host defense against all mycobacterial species, other intracellular pathogens such as *Chlamydia pneumonia* and *Francisella tularensis*, virus infections including influenza and RSV, gram-negative bacterial infections with *Klebsiella pneumonia*, and fungal infections including coccidiodes, cryptococcosis, and histoplasma.[54] Th2 cells are required for immunity to helminth parasites, and Th17 cells are essential to eliminate the gram-negative bacteria *K. pneumonia* and *Pseudomonas aeruginosa*, chlamydia, *and Mycoplasma pneumonia* and for immunity to various fungal infections including candida.

After a primary infection, pathogen-specific memory CD4 and CD8 T cells develop. Some are retained in the lung as T_{RM} and are presumed to persist there through the life of an individual. Animal studies show that maintenance of the memory CD4 T cell population in the lung in the first year after primary infection required recruitment of new cells from the circulating pool.[44,55] It remains unknown if memory cells continue to be replaced at this rate further out from infection, but it is likely that a dynamic process sustains the population of memory T cells in the lung long after infection.

The population of memory T_{RM} appears to be retained in the lung by surface expression of tissue-specific homing molecules.[56,57] Animal studies show that in different species memory CD4 and CD8 isolated from the lung returned to the lung when reinjected systemically into another animal. One such localization signal is CD103, which is expressed on antigen-specific T cells.[23,58] In both mice and humans, CD69 expression characterized CD4 and CD8 memory T cells that were retained in the lung, rather than those that recirculated.[44] Influenza-specific CD4 and CD8 T_{RM} were compartmentalized in bronchovascular bundles surrounding the airways.[44] Thus, CD4 T_{RM} may be retained adjacent to the tight web of DCs just below the epithelial surface where they can be quickly activated by specific antigen.[59] Virus-specific memory CD8 T cells were observed in or near capillaries in the lung by chemokines secreted by epithelial cells.[55,60] After reexposure to a pathogen in the lung, CD4 and CD8 T_{RM} are activated locally, rather than recirculating to local lymph nodes.[23,44] In humans, T_{RM} produced IFN-γ and

IL-2 upon activation,[48] thus insuring both antimicrobial and proliferation signals at the site of infection. Therefore, T_{RM} in the lung reside in compartments near key sites of exposure that insure rapid recruitment, reactivation, and proliferation upon pathogen reexposure, and they may be skewed toward a memory type 1 phenotype.

■ T LYMPHOCYTES IN CHRONIC LUNG DISEASES

T lymphocytes serve essential functions in host defense as they respond to specific antigens and are retained in the lung as memory cells, but they may also drive chronic disease when immune responses are generated against nonpathogens such as allergens or self-antigens. The development of immunity against nonpathogenic aeroallergens in allergic asthma is an example of immune dysregulation. While asthma is the most extensively studied T lymphocyte–driven lung disease, many other chronic pulmonary diseases may be caused and/or perpetuated by T lymphocytes, including sarcoidosis, hypersensitivity pneumonitis, autoimmune lung diseases, idiopathic pulmonary fibrosis, pulmonary hypertension and lung cancer, and others.

T Lymphocytes in Allergic Asthma

Long-lived antipathogen responses are protective and reflect useful host immunity. In allergic asthma, the long-lived memory lymphocytes that respond to allergens are deleterious and may remain capable of reactivation throughout the life of the individual. T lymphocytes appear to drive this chronic disease state in the airways. Many T lymphocyte subsets have been implicated in initiating and sustaining asthma.

CD4 T Helper Type 2 Cells in Asthma CD4+ T cells are the predominant lymphocyte population infiltrating the airways and they express markers of activation in asthmatic subjects. CD4+ T cells producing IL-4, IL-5, and IL-13 have been identified in BAL and airway biopsies and are secreted in the airways of patients with mild or asymptomatic asthma.[61] GATA-3 expression was increased in airways of asthmatic patients compared with those in control subjects, indicating the presence of Th2 cells.[62] Antigen challenge in allergic asthmatic patients led to an increase in Th2 lymphocytes in the airways.[63] In asthmatic patients, airway hyperreactivity (AHR) and airway eosinophilia correlated with airway CD4 T cells that produced IL-4 or IL-5 or expressed GATA-3.[62] In conjunction with known effects of IL-4, IL-5, and IL-13, these studies support the hypothesis that Th2 cells drive the characteristic inflammatory response that results in asthma.

Animal studies show that activation of CD4 Th2 cells in the airways leads to pathophysiologic manifestations of asthma. Eosinophilic airway inflammation and AHR have both been shown to be dependent on CD4+ T cells.[64] Studies that employed adoptive transfer of CD4+ T cells from animals with antigen-induced AHR resulted in airway inflammation and hyperresponsiveness in recipient mice, indicating that CD4+ T cells can control many aspects of the disease. CD4+ Th2 cells induced airway eosinophilia, mucus hypersecretion, and AHR, whereas Th1 cells caused a neutrophil-predominant inflammatory response without any of these features of asthma.[64]

Gene association studies also support a role for Th2 cells in asthma. Strong linkages have been identified to flanking markers of the human cytokine gene cluster on chromosomes 5q31 and 16p12, which include genes for IL-4, IL-13, and IL-4Rα.[65] Variants in the IL-4 promoter region are associated with atopy, as are polymorphisms of IL-4Rα, a component of both the IL-4 and IL-13 receptors, and a variant IL-13R.[66] Thus, modifications of IL-4 and/or IL-13 or their signaling, increasing Th2 cell functions, are associated with atopy and asthma.

CD4 T Helper Type 1 Cells in Asthma Th1 cells are also present in the airways of asthmatic patients, but it is still not clear if they serve a protective or pathologic function in asthma. IFN-γ was elevated in the airways of some severe asthmatics, and it was reduced in subsets of other asthmatics[67,68] Some studies show that Th1 cell activation inhibits allergic airway inflammation, whereas other studies suggest that Th1 cells potentiate the inflammatory response in asthma due to the proinflammatory effects of Th1 cytokines.[64]

Human and animal studies suggest that enhancing Th1 cytokines in the lung before or early in the generation of a Th2 response may protect against the development of asthma. IFN-γ–dominated immune responses to viral or mycobacterial infection in childhood are associated with a reduced incidence of asthma.[69] Attendance at day care and exposure to other siblings was protective against wheezing in childhood, which is hypothesized to be from beneficial exposures to respiratory infections. Also, mice immunized in the presence of a Th1-stimulating environment exhibited a reduction in antigen-induced eosinophilic airway inflammation and AHR.[70] Thus, reducing the generation of Th2 cells appears to decrease allergic inflammation. However it is also apparent that a high frequency of virally induced wheezing in early life is a strong predictor for the subsequent development of asthma in children,[71] thus suggesting that timing and nature of infections in early life may be crucial.

Th1 cells can also inhibit the effects of ongoing Th2 cell responses. Th1 cells, through the production of IFN-γ, have been shown to inhibit Th2 cell cytokine production and Th2 cell proliferation in vitro.[72] In mice the Th1 cytokine IFN-γ has inhibitory effects on Th2-induced airway eosinophilia and AHR. When administered before inhaled antigen challenge, IFN-γ reduced the number of CD4+ T cells in the respiratory tract or reduced Th2 cytokine secretion.[73] These effects may result from inhibition of Th2 cell recruitment by IFN-γ. Once Th2 cells are present in the respiratory tract, IFN-γ promotes the resolution of airway eosinophilia and suppresses Th2 cytokine production.[74] Th1 cells, through the production of IFN-γ, can inhibit airway eosinophilia, mucus production, and AHR without an increase in airway inflammation.[75] Although many studies support Th1 cells and IFN-γ as inhibitors of Th2-type responses, other studies show that Th1 cells enhance inflammation and do not ameliorate disease.[76] The proinflammatory effects of Th1 cells are supported by the association of viral respiratory infections, which tend to induce Th1 responses, and exacerbation of symptoms in asthmatic patients. Ultimately, the influence of Th1 cells on allergic airway inflammation may depend on the timing of Th1 relative to Th2 cell activation and the subphenotype of the asthmatic.

CD4 T Helper Type 17 Cells in Asthma Th17 cells, IL-17A and IL-17F are increased in the airways, sputum, and blood of subjects with asthma.[77] Given the heterogeneity of asthmatic airway inflammation and the effects of IL-17A and IL-17F on neutrophil recruitment, it was hypothesized that Th17 cells would be pathogenic in neutrophilic, nonatopic asthma. Yet, there was a positive association of IL-17 and IL-5, and IL-17 with atopic, not with nonatopic asthma.[78] As expected, IL-17A levels were associated with sputum neutrophils and not eosinophils,[79] suggesting that Th17 cells may drive disease in a subset of neutrophilic asthmatics.[80]

Studies to determine the function of Th17 cells have not established a definitive role of Th17 and IL-17A in animal models of asthma. A number of laboratories have shown that Th17 cells, IL-17A and IL-17 receptors are critical for optimal Th2 cell function, AHR, and eosinophilic inflammation. Furthermore, IL-17A was a major determinant in the development of AHR in mice with susceptibility compared to mice with resistance to develop AHR.[81] Yet, other investigators showed neutralization of IL-17 leads to worse disease.[25,82] The complex interplay of Th17 and Th2 cells is highlighted by studies showing that IL-13 inhibits IL-17A production and IL-17A production inhibits IL-25 that drives Th2 function. These studies suggest that disease pathogenesis in asthma may result

from a disruption in a critical balance of cytokines that includes IL-17.

Regulatory T Cells in Asthma Foxp3+ Treg likely determine early sensitization to allergen, as suggested by studies of the rare, immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX), which is caused by mutations in the *Foxp3* gene on the X chromosome. This results in markedly reduced or absent Foxp3+ Treg. Young boys with this condition suffer from both severe autoimmune and allergic symptoms.[24] T cells from these patients show skewing toward a Th2 phenotype. Mice with a mutation in the Foxp3 gene also demonstrate intense multiorgan inflammation, including allergic airway disease, high levels of IgE, eosinophilia, and dysregulated Th1 and Th2 cytokine responses, but they do not exhibit Th2 skewing, as observed in humans with IPEX.[83]

Studies to assess the numbers of CD4+CD25+ T cells in the peripheral blood of healthy, compared to allergic, subjects have not consistently shown differences[8,84] However, some of the methodology used to detect Treg make interpretation of some of these earlier data limited due to the methodologies used to detect Treg. There are data, though, that show impaired $CD4+CD25^{high}$ Foxp3 Treg in allergic disease. In asthmatic children there were reduced numbers of $CD4+CD25^{high}$ T cells in BAL, but not blood, as compared to control children with chronic cough.[85] A lower level of Foxp3 mRNA was reported in asthmatic children. $CD4+CD25^{high}$ T cells in the airways of the asthmatic children correlated with clinical parameters such as lung function, and were restored following corticosteroid treatment. A similar increase in Foxp3 mRNA was reported in the peripheral blood of adult asthma patients following inhaled corticosteroid treatment.[86] Foxp3-expressing Treg are also important negative regulators of asthma and allergic disease in animal models. Treg expressing either IL-10, TGF-β1, or both were required to limit airway inflammation in numerous models of tolerance induction.[87–90] Overall, it appears that impaired Treg responses may contribute to the development of asthma and allergic diseases.

CD8 T Cells in Asthma In atopic asthmatics there were increased CD8 T cells in airway biopsies when compared to biopsies in non-asthmatic, atopic, and normal subjects.[91] Furthermore, the number of CD8 T cells in airway biopsies of atopic asthmatics was associated with a decline in FEV1.[92] During asthma exacerbations and in death from status asthmaticus, there were increased CD8+ T cells in the respiratory tract.[93] These observations suggest that CD8 T cells are detrimental in asthma. Animal studies both support these observations and show that CD8 T cells inhibit allergic airway disease through the production of IFN-γ and induction of IL-12 production. Most likely, CD8 T cells have varying effects in different individuals and under different circumstances.

CD8 T cells recognize endogenous antigens, like viral peptides, rather than allergens. Since asthma exacerbations are most commonly caused by viral respiratory infections, then virus-specific CD8 T cells will be recruited and retained in the lung. Thus, the presence of CD8 T cells in asthmatic lungs may reflect recent infections.

CD8 T cells, like CD4 T cells, can be polarized into subsets. Cytotoxic T cell–type 1 (Tc1) cells are activated in viral infections and generally produce IFN-γ and lymphotoxin. These are classical CD8 T cells. Smaller subsets of CD8 T cells can make other panels of cytokines. For example, when activated in the presence of IL-4, CD8 T cytotoxic–type 2 (Tc2) cells can be induced to produce IL-4, IL-5, and IL-13. Animal studies show that Tc2 cells retain their cytotoxic function, stimulate recruitment of eosinophils, provide B cell help for IgE production, and promote airway hyperresponsiveness.[93] It has been theorized that some respiratory infections may stimulate CD8 Tc2 responses, thus initiating or exacerbating local allergic responses.

CHAPTER 26

Chemokines, Adipokines, and Growth Factors in the Lung

Marcus W. Butler
Paul McLoughlin
Michael P. Keane

Normal development of organ systems, including the lungs, in utero, during subsequent maturation into adulthood, and in health throughout life, requires intricate signals to be exchanged among various tissues, capable of permitting diversity and adaptation in differing cellular and extracellular contexts, while being robust to onslaughts from ever-changing environmental stimuli. Among the mediators involved in such complex cellular signaling, and relevant in the setting of many pulmonary disorders, are chemokines and growth factors. There has been further complexity added with increasing recognition of adipose tissue as a source of systemic bioactive mediators called adipokines, that impact on lung health. While some of these mediators are implicated in the development of disease states, they are more often than not also critical to tissue homeostasis, and are challenging target systems for therapeutic manipulation. Nonetheless, we are now in an era of exciting developments in targeted biologic therapies that offer the potential for substantial progress in the fight against difficult-to-treat pulmonary disorders characterized by pathogenic processes including acute and chronic inflammation, fibrosis, vascular remodeling, and neoplasia.

CHEMOTACTIC CYTOKINES AND THE INFLAMMATORY RESPONSE

The salient feature of inflammation is leukocyte infiltration. These recruited leukocytes contribute to the pathogenesis of chronic inflammation and promote fibrosis via the elaboration of a variety of cytokines. Maintenance of leukocyte recruitment during inflammation requires the expression of cell surface adhesion molecules, and the production of chemotactic molecules, such as chemokines.[1] The chemokines can be divided into four families—CXC, CC, C, and CXXXC—which behave as potent chemotactic factors for neutrophils, eosinophils, basophils, monocytes, mast cells, dendritic cells, NK cells, and T and B lymphocytes (Table 26-1). There is approximately 20% to 40% homology between the members of the four chemokine families.[2] Chemokines are produced by an array of cells, including monocytes, alveolar macrophages, neutrophils, platelets, eosinophils, mast cells, T and B lymphocytes, NK cells, and various structural cells, including keratinocytes, mesangial cells, epithelial cells, hepatocytes, fibroblasts, smooth muscle cells, mesothelial cells, and endothelial cells. Production of chemokines by both immune and nonimmune cells supports the contention that these cytokines may play a pivotal role in orchestrating chronic inflammation.[3]

CXC CHEMOKINES

CXC chemokines can be further divided into two groups on the basis of a structure/function domain consisting of the presence or absence of three amino acid residues (Glu-LeuArg; ELR motif) that precede the first cysteine amino acid residue in the primary structure of these cytokines. ELR+CXC chemokines are chemoattractants for neutrophils and act as potent angiogenic factors. In contrast, ELR−CXC chemokines are highly induced by interferons, are chemoattractants for mononuclear cells, and are potent inhibitors of angiogenesis (Table 26-2).[4]

Chemokine activities are mediated through G-protein–coupled receptors. Seven CXC chemokine receptors have been identified (Table 26-3). The ELR+ chemokines bind to CXCR1 and CXCR2 receptors, which are found on neutrophils, T lymphocytes, monocytes/macrophages, eosinophils, basophils, keratinocytes and mast cells, and endothelial cells.[5] CXCR3 is the receptor for CXCL9, CXCL10, and CXCL11, and is expressed on activated T lymphocytes. CXCR3 is also expressed on human umbilical vein endothelial cells (HUMVECs) in a cell cycle–dependent fashion. CXCR4 is the specific receptor for CXCL12 and is the cofactor for lymphotropic HIV-1. In contrast to CXCR3, CXCR4 appears to be expressed on resting T lymphocytes.[5] Two other chemokine receptors have been identified that bind chemokines without a subsequent signal-coupling event. The DARC receptor is similar to other chemokine receptors and it binds both CXC and CC chemokines without apparent signal coupling. This receptor was originally found on human erythrocytes and was thought to represent a "sink" for chemokines.[6] The second nonsignaling chemokine receptor is the D6 receptor, which binds several CC chemokines with high affinity, including CCL2, CCL4, CCL5, and CCL7.[7]

CXC Chemokines in Pulmonary Inflammation

CXC chemokines play a significant role in mediating neutrophil infiltration in the lung parenchyma and pleural space in response to endotoxin and bacterial challenge. CXCL8 is in the bronchoalveolar lavage of patients with community-acquired pneumonia and nosocomial pneumonia and a variety of animal models of pneumonia. In a model of *Aspergillus fumigatus* pneumonia, neutralization of TNF resulted in marked attenuation of the expression of CXCL1 and CXCL2/3 that was paralleled by a reduction in the infiltration of neutrophils and associated with increased mortality.[8] Administration of a TNF agonist peptide to animals that had been intratracheally inoculated with *Klebsiella pneumoniae* led to markedly elevated levels of CXCL2/3 associated with increased neutrophil infiltration.[9] Studies have shown that ventilator-induced lung injury is secondary to stretch-induced chemokine release with a subsequent inflammatory response and neutrophil recruitment.[10] CXCR2 −/− mice are also protected from hyperoxia-induced lung injury. In other studies, the production of CXCL5 in the lung was correlated with the presence of neutrophil-dependent lung injury, and passive immunization with neutralizing CXCL5 antibodies resulted in significant attenuation of lung injury.[11]

Several studies have demonstrated that CXCL8 levels correlate with the development and mortality of ARDS. Early increases in CXCL8 in bronchoalveolar lavage fluid correlated with an increased risk of subsequent development of ARDS, and also demonstrated that alveolar macrophages were an important source of CXCL8 prior to neutrophil influx.[10] Furthermore, there is an imbalance in the expression of ELR+ (CXCL1, CXCL5, CXCL8) as compared with ELR−CXC (CXCL10, CXCL11) chemokines from bronchoalveolar lavage fluid (BALF) of patients with ARDS as compared with controls. This imbalance correlated with angiogenic activity and both procollagen I and procollagen III levels in BALF.[12] These findings suggest that CXC chemokines have an important role in the fibroproliferative phase of ARDS via the regulation of angiogenesis.

TABLE 26-1 The Human C, CC, CXC, and CXXXC Chemokine Families of Chemotactic Cytokines

Systemic Name	Human Ligand Name
C Chemokines	
XCL1	Lymphotactin
XCL2	SCM-1β
CC Chemokines	
CCL1	I-309
CCL2	Monocyte chemotactic protein-1 (MCP-1)
CCL3	Macrophage inflammatory protein-1 alpha (MIP-1α)
CCL4	Macrophage inflammatory protein-1 beta (MIP-1β)
CCL5	Regulated on activation normal T-cell expressed and secreted (RANTES)
CCL7	Monocyte chemotactic protein-3 (MCP-3)
CCL8	Monocyte chemotactic protein-2 (MCP-2)
CCL9	Macrophage inflammatory protein-1 delta (MIP-1δ)
CCL11	Eotaxin
CCL13	Monocyte chemotactic protein-4 (MCP-4)
CCL14	HCC-1
CCL15	HCC-2
CCL16	HCC-4
CCL17	Thymus and activation-regulated chemokine (TARC)
CCL18	DC-CK-1
CCL19	Macrophage inflammatory protein-3 beta (MIP-3β)
CCL20	Macrophage inflammatory protein-3 alpha (MIP-3α)
CCL21	6Ckine
CCL22	MDC
CCL23	MPIF-1
CCL24	MPIF-2
CCL25	TECK
CCL26	Eotaxin-3
CCL27	CTACK
CCL28	MEC
CXC Chemokines	
CXCL1	Growth-related oncogene alpha (GRO-α)
CXCL2	Growth-related oncogene beta (GRO-β)
CXCL3	Growth-related oncogene gamma (GRO-γ)
CXCL4	Platelet factor-4 (PF4)
CXCL5	Epithelial neutrophil–activating protein-78 (ENA-78)
CXCL6	Granulocyte chemotactic protein-2 (GCP-2)
CXCL7	Neutrophil-activating protein-2 (NAP-2)
CXCL8	Interleukin-8 (IL-8)
CXCL9	Monokine induced by interferon-γ (MIG)
CXCL10	Interferon-γ-inducible protein (IP-10)
CXCL11	Interferon-inducible T cell alpha chemoattractant (ITAC)
CXCL12	Stromal cell–derived factor-1 (SDF-1)
CXCL13	B-cell–attracting chemokine-1 (BCA-1)
CXCL14	BRAK/Bolekine
CXCL16	
CXXXC Chemokine	
CXC3CL1	Fractalkine

TABLE 26-2 The CXC Chemokines that Display Disparate Angiogenic Activity

CXC Chemokines that contain the ELR motif	
CXCL1	Growth-related oncogene alpha (GRO-α)
CXCL2	Growth-related oncogene beta (GRO-β)
CXCL3	Growth-related oncogene gamma (GRO-γ)
CXCL5	Epithelial neutrophil–activating protein-78 (ENA-78)
CXCL6	Granulocyte chemotactic protein-2 (GCP-2)
CXCL7	Neutrophil-activating protein-2 (NAP-2)
CXCL8	Interleukin-8 (IL-8)
CXC Chemokines that lack the ELR motif	
CXCL4	Platelet factor-4 (PF4)
CXCL9	Monokine induced by interferon-γ (MIG)
CXCL10	Interferon-γ-inducible protein (IP-10)
CXCL11	Interferon-inducible T-cell alpha chemoattractant (ITAC)
CXCL12	Stromal cell–derived factor-1 (SDF-1)

The Role of CXC Chemokines in Pulmonary Fibrosis

IPF is characterized by the progressive deposition of collagen within the interstitium and subsequent destruction of lung tissue.[13,14] The mechanisms of cellular injury and the role of classic inflammatory cells remain unclear. CXCL8 is significantly elevated in IPF, as compared with either normal or sarcoidosis patients, and correlates with BALF presence of neutrophils. The alveolar macrophage is an important cellular source of CXCL8 in IPF.[15] In addition, BALF levels of CXCL8 in IPF may correlate with a worse prognosis.[16]

Vascular Remodeling in Pulmonary Fibrosis: The Role of CXC Chemokines

The existence of neovascularization in IPF was originally identified in 1963 by Turner-Warwick, who demonstrated that within areas of pulmonary fibrosis there was extensive neovascularization with anastomoses between the systemic and pulmonary microvasculature.[17] Further evidence of neovascularization during the pathogenesis of pulmonary fibrosis has been demonstrated in a rat model of bleomycin-induced pulmonary fibrosis.[18] An imbalance in the levels of angiogenic chemokines (CXCL5, CXCL8), as compared with angiostatic chemokines (CXCL9, CXCL10, CXCL11), favoring net angiogenesis has been demonstrated in both animal models and tissue specimens from patients with IPF (Fig. 26-1).[19] Renzoni[20] has demonstrated vascular remodeling in both IPF and fibrosing alveolitis associated with systemic sclerosis. Cosgrove et al.[21] provided further support for the concept of vascular remodeling in IPF when they demonstrated a relative absence of vessels in the fibroblastic foci of IPF. This appeared to correlate with increased expression of pigment epithelium–derived factor in the fibroblastic foci. Interestingly, they also noted significant vascularity in the areas of fibrosis around the fibroblastic foci, with numerous abnormal vessels in the regions of severe architectural distortion. These findings are similar to those of Renzoni and support the concept of regional heterogeneity of vascularity in IPF. This heterogeneity is not surprising, as usual interstitial pneumonia, which is the pathologic description of IPF, is defined by its regional and temporal heterogeneity.[14]

CXC Chemokines in Pulmonary Hypertension

The potential role of the CXCL12/CXCR4/CXCR7 axis in pulmonary hypertension was first suspected when it was reported that CXCR7 expression increased in the lungs of hypoxic hypertensive mice and in the lungs of patients with idiopathic pulmonary arterial hypertension (IPAH).[22] Subsequently, CXCL12 was found to be elevated in the peripheral plasma of patients with pulmonary artery hypertension (PAH), although in a separate study this increase was not observed.[23,24] Increased expression of CXCL12 in remodeled vessels and particularly in the plexiform lesions in explanted IPAH lungs has also been shown.[25]

CXR7 was most prominently expressed in the endothelium of the explanted lungs of hypertensive subjects and, in addition to its well-established role in leukocyte chemotaxis, was shown to play a central role in stimulating endothelial proliferation, whereas CXCR4 was required for endothelial cell chemotaxis.[23] Recruitment of progenitor cells to the remodeled pulmonary vessels is a prominent feature in PAH lungs.[25,26] In vivo blockade of CXCR4 in hypoxic mice reduced the recruitment of progenitor cells to the remodeled vasculature of hypertensive lungs, whereas blockade of CXCR7 did not affect this behavior.[24,26,27]

In rodent models inhibition of CXCL12 action using function-blocking antibodies, or separate selective inhibition of CXCR4 signaling or CXCR7 signaling, attenuates the development of hypoxic pulmonary hypertension.[24,27,28] Taken together these data suggest an important role of CXCL12 signaling, requiring both its cognate receptors, in the pathogenesis of pulmonary hypertension.

■ CHEMOKINES AND THE TRAFFICKING OF FIBROCYTES TO THE LUNG

Fibrocytes present in the peripheral circulation were first identified in 1994, comprise a minor component of the circulating pool of leukocytes (less than 1%), and express a characteristic pattern of markers, including collagen (Col) I and CD45.[29] Subsequent studies have revealed that circulating fibrocytes express chemokine receptors such as CXCR4 and CCR7 and extracellular matrix (ECM) proteins, such as procollagen I and procollagen III. Fibrocytes migrate in response to CXCL12 and traffic to the lungs in a model of bleomycin-induced pulmonary fibrosis. Treatment of bleomycin-exposed animals with specific neutralizing anti-CXCL12 antibodies inhibits intrapulmonary recruitment of fibrocytes and attenuated lung fibrosis.[30] Levels of circulating CD45+ Col1+ cells are elevated in stable IPF patients versus controls, are transiently higher during an exacerbation and predicted survival.[31] These findings challenge the dogma that fibroblasts and myofibroblasts arise from an intrapulmonary pool of tissue fibroblasts.[32]

■ THE CC CHEMOKINES

CC chemokines (Table 26-1) are chemoattractants for monocyte, T and B lymphocytes, NK cells, dendritic cells, basophils, mast cells, and eosinophils.[33] The CC chemokines are produced by an array of cells, including monocytes, alveolar macrophages, neutrophils, platelets, eosinophils, mast cells, T cells, B cells, and NK cells, as well as structural cells such as keratinocytes, mesangial cells, epithelial

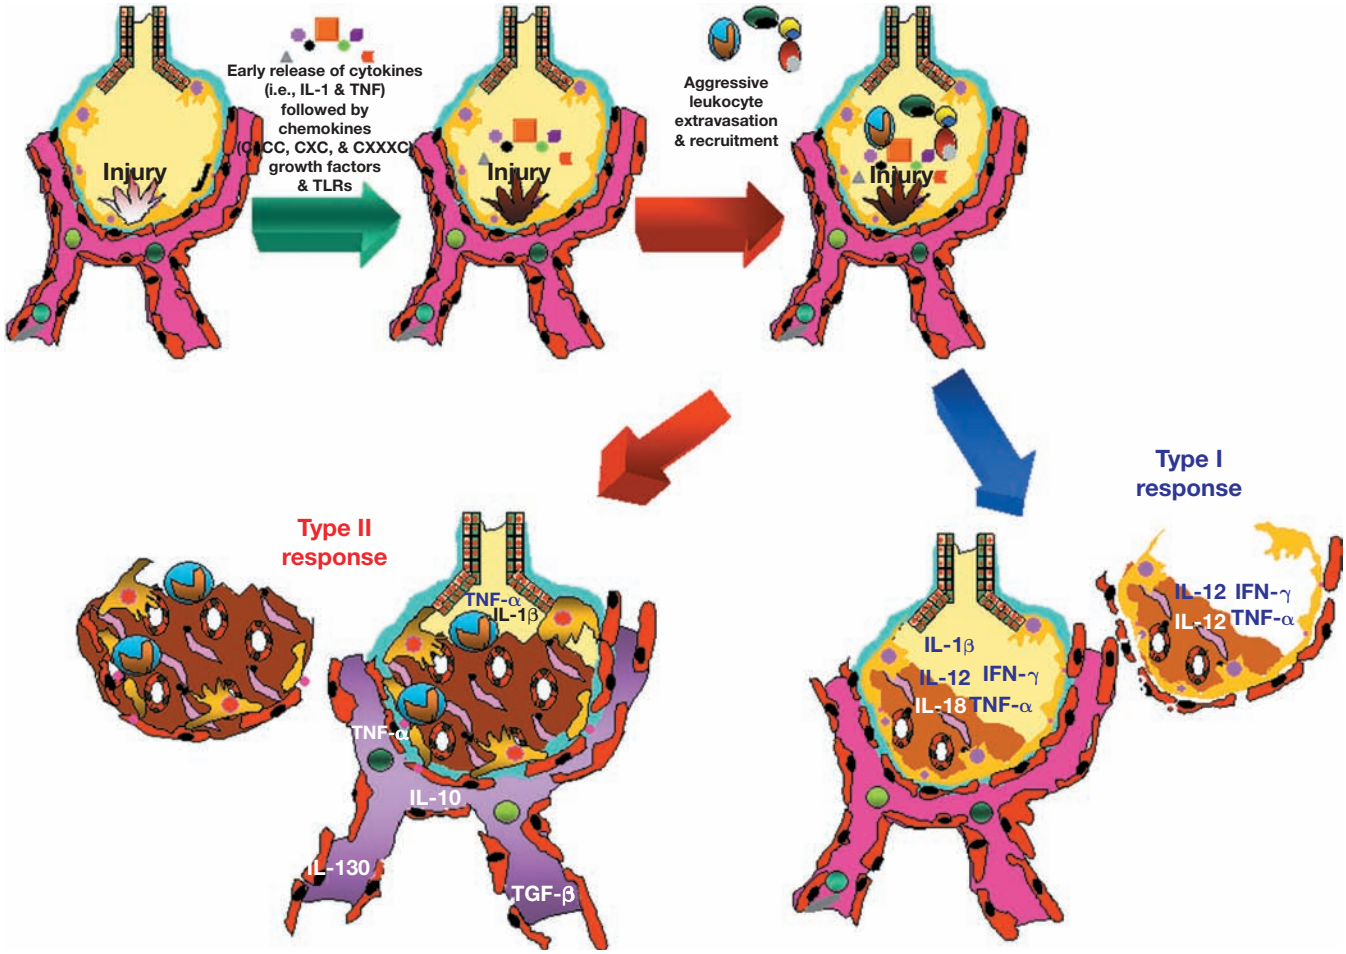

Figure 26-1 The inflammatory response to lung injury. The cytokine profile that is secreted by inflammatory cells during lung injury determines the ultimate outcome following injury. Polarization of the inflammatory response toward a type I response is associated with resolution of lung injury or infection. In contrast chronic infections (e.g., tuberculosis) and chronic inflammatory diseases (e.g., idiopathic pulmonary fibrosis) are associated with a type II profile.

cells, hepatocytes, fibroblasts, smooth muscle cells, mesothelial cells, and endothelial cells.[34]

CC Chemokine Receptors

CC chemokine receptors are structurally homologous and have been identified to have specific ligand-binding profiles (Table 26-4).[34] Naïve T cells express CXCR4 and CCR7 and migrate in response to CXCL12 and CCL19. CXCR3, CXCR6, and CCR5 are expressed at higher levels on type I cells than type II, whereas CCR3, CCR4, and CCR8 are more characteristic of type II cells.[35]

CC Chemokines in Pulmonary Inflammation

The CC chemokines, CCL2, CCL3, CCL4, CCL5 have been implicated in mediating the innate host defense in animal models of pulmonary infection.[36,37] These studies have demonstrated that CC chemokine ligand/receptor biology plays a critical role in innate host defense and development of pulmonary inflammation that is important in eradication of microorganisms.

Mehrad et al. have shown that CCL3 and the recruitment of mononuclear cells play an important role in the eradication of invasive pulmonary aspergillosis. They demonstrated that in both immunocompetent and neutropenic mice CCL3 is induced in the lungs in response to intratracheal inoculation of *A. fumigatus*.[38] These studies indicate that CCL3 and elicitation of mononuclear cells are crucial in mediating host defense against *A. fumigatus* in the setting of neutropenia.[39]

CC Chemokines in Pulmonary Fibrosis

Animal models, such as bleomycin-induced pulmonary fibrosis, have demonstrated the presence and contribution of CC chemokines to the pathogenesis of fibrosis. CCL2 is an important cofactor for the stimulation of fibroblast collagen production and induction of the expression of TGF-β_1. Inhibition of CCL2 or CCL3 resulted in

a reduction of infiltrating cells into the lungs of bleomycin-treated animals.[40,41]

Furthermore, it has been shown that CCL2 can stimulate interleukin-4 (IL-4) production, indicating that it might be involved in type II polarization.[42] IL-13 promotes bleomycin-induced fibrosis through the elaboration of CCL6.[43] Both CCL17 and CCL22 and their receptor, CCR4, are significantly elevated in the bleomycin model and neutralization of CCL17 attenuates pulmonary fibrosis.[44] Thus, chemokines may have an important role in the switch toward a profibrotic type II phenotype.

Both CCR1 and CCR2 have been shown to play an important role in the pathogenesis in the mouse model of bleomycin-induced pulmonary fibrosis. Treatment with antibodies to CCR1 leads to a reduction in both inflammatory cell infiltrates and the development of fibrosis.[45] Similarly, CCR2 −/− mice are protected from pulmonary fibrosis in response to bleomycin.[46] Furthermore, alveolar epithelial cells from CCR2 −/− mice suppress fibroblast proliferation more than AECs from wild-type mice.[47] CCL2 and CCR2 have an important role in suppression of PGE2, thereby promoting fibroproliferation. Similarly, an important role for CCR2 has been seen in murine model of obliterative bronchiolitis, in which the fibrotic response associated with this disorder was attenuated in CCR2 −/− mice.[48] Similarly, CCL2 and CCL3 are elevated in BALF and lung tissue of ILD patients.[49,50] Accordingly, targeting chemokine receptors may be an efficient way to inhibit pulmonary fibrosis.

Choi et al.[51] described enhanced expression of the chemokines CCL7 and CCL22, in lung tissue of patients with IPF as compared with nonspecific interstitial pneumonia, and nonidiopathic interstitial pneumonia. Furthermore, they describe increased expression of CCL5 in nonspecific interstitial pneumonia as compared with usual interstitial pneumonia. Interestingly, CCL5 protein was identified in nonspecific interstitial pneumonia more prominently than usual interstitial pneumonia. This is all the more interesting as CCL5 is a major stimulus for the production of CCL7 through its interactions with CCR5. These findings raise the possibility that there is a continuum from nonspecific interstitial pneumonia to usual interstitial pneumonia with higher levels of CCL5 in nonspecific interstitial pneumonia leading to subsequent increased CCL7 expression as the disease progresses to usual interstitial pneumonia. There is considerable controversy as to whether nonspecific interstitial pneumonia is an earlier lesion of usual interstitial pneumonia.[52] Several studies have demonstrated the presence of usual interstitial pneumonia and nonspecific interstitial pneumonia patterns in the same patients, which suggests that these are overlapping processes.[52–54] The findings of Choi suggest a transition from a predominance of CCL5 to CCL7 and further support this notion. Of further interest is the previous description that CCL7 can act as a natural antagonist at the CCR5 receptor, which raises the possibility that CCL7 may play a role in regulating its own production.[55]

ADIPOKINES AND PULMONARY INFLAMMATION

With the emergence, in the 20th century, of obesity as a major epidemic linked to systemic metabolic dysfunction, concerted efforts have been made to gain a fuller understanding of the varied functions of adipose tissue, beyond that of being an energy storage organ, and leading to the discovery of various factors that are secreted by adipocytes.[56] These mainly proteinaceous endocrine factors were initially termed adipocytokines, and later, adipokines,[57] and possess pro- and anti-inflammatory activities, potentially of relevance in the context of pulmonary disorders associated with body mass index, including asthma, obstructive sleep apnea syndrome, chronic obstructive pulmonary disease (COPD), PAH, various pulmonary infections, and lung cancer.[58] While the main source of adipocytes in the body is from deposits of subcutaneous and visceral adipose tissue, the development of obesity can give rise to collections of adipose tissue in other locations including the heart, kidneys, bone marrow, the adventitia of major blood vessels, and within the lungs. There is evidence that differential adipokine secretion and functional outcomes can occur at different sites of adiposity within the body, following the stimulus of dietary modification.[59] White adipose tissue, the major form in humans, is predominantly composed of lipid-laden adipocytes, but also adipocyte precursor cells, fibroblasts that generate ECM scaffolding, vascular (smooth muscle and endothelial) cells that provide systemic access for secreted adipokines, and macrophages and T cells that influence the immune phenotype.[60] The cellular composition of adipose tissue can vary in conditions of altered body mass, and macrophages in particular, seem to traffic in larger numbers to adipose tissue under conditions of increased obesity with associated capillary rarefaction and adipose tissue hypoxia.[61]

PROINFLAMMATORY ADIPOKINES

Beyond the "pure" effects of uncomplicated obesity upon respiratory mechanics, pulmonary gas exchange, ventilatory drive, and work of breathing, there is increasing evidence of an association among obesity, adipokines, and pulmonary disease states that are characterized by inflammation.[58] Most of the adipokines identified to date are proinflammatory in their effects (Table 26-5). Some important adipokines that are better known for their other roles, such as TNF-α, IL-6, CCL2, and CXCL5, will not be discussed here.

Leptin

Leptin, coded for by the *ob* gene on chromosome 17, is a 16 KDa protein hormone, mainly secreted by adipocytes,[62] and regulated principally by food intake, whereby fasting reduces leptin levels,

TABLE 26-5 Adipokines Linked to Pulmonary Disease States

Adipokine	Pulmonary Source	Receptor	Lung Disease State
Proinflammatory Adipokines			
Leptin	Alveolar type II pneumocytes, alveolar macrophages, bronchial epithelial cells, lung endothelial cells	Leptin receptor	OSAHS, OHS, COPD, asthma, NSCLC, PAH
Apelin	Lung endothelial cells	Apelin receptor	PAH
Nampt	Lung endothelial cells	Unknown	ALI
Resistin	Unknown	Unknown	Asthma
Anti-inflammatory Adipokines			
Adiponectin	Bronchial epithelial cells	Adiponectin receptors 1 and 2, T-cadherin	COPD, asthma, ALI, PAH

OSAHS, obstructive sleep apnea-hypopnea syndrome; OHS, obesity hypoventilation syndrome; COPD, chronic obstructive pulmonary disease; NSCLC, non–small-cell lung cancer; PAH, pulmonary arterial hypertension; ALI, acute lung injury.

and food consumption transiently increases *ob* gene expression, with leptin being initially regarded as a satiety hormone.[63,64] It is also expressed in human peripheral lung tissue, including alveolar type II pneumocytes, alveolar macrophages, and bronchial epithelial cells,[65,66] and is known to be modulated by gender, sepsis, catecholamines, glucocorticoids, and insulin.[67,68] It is now clear that leptin has pleiotropic effects, which include stimulating TNF and IL-6 production by monocytes, stimulating production of CCL3–5 by macrophages, and stimulating reactive oxygen species production, cell proliferation, and migration. In addition, leptin may have a role in lung development,[56] as it is differentially expressed by fetal rat lung fibroblasts during the time of alveolar differentiation,[69] and capable of stimulating fetal rat surfactant protein synthesis in vitro,[70] although contradictory in vivo findings were observed in fetal sheep and mice lungs.[71]

There have been extensive efforts to relate leptin to respiratory disorders, most notably with obstructive sleep apnea-hypopnea syndrome (OSAHS), COPD, asthma, pneumonia, and other pulmonary infections. Some data suggest leptin has a stimulatory effect on ventilation; for example, the mutant *ob/ob* mouse, which lacks functional leptin and has a phenotype of obesity, hyperphagia, and a low-resting metabolic rate, displays an elevated arterial Pa_{CO_2} independent of obesity onset, which is acutely reversible through exogenous leptin replacement.[72] It has been speculated that OSAHS is a leptin-resistant state, but progress in this field has been hampered by conflicting results of leptin and leptin receptor candidate gene association studies[73,74] and trials of nasal continuous positive airway pressure.[75,76]

In COPD, it has been hypothesized that the known link between the cachexia of COPD and increased mortality, might somehow be related to leptin function. There appears to be an absence of the usual circadian rhythm of circulating leptin in cachectic COPD patients, as opposed to normal weight COPD patients, with associated heart rate variability changes that raise the possibility of a role for leptin in the pathophysiology of COPD cachexia,[77] although further data are needed. The reproducible finding of elevated serum leptin levels during acute exacerbations of COPD, that track markers of the systemic inflammatory response, points to disturbance of the normal leptin feedback loop regulating food intake and energy balance, due to the influence of the acute inflammatory response and systemically administered glucocorticoids, as a possible contributing mechanism to cachexia in COPD.[78] Wild-type mice exposed chronically to cigarette smoke have increased leptin expression in bronchial epithelial cells and pneumocytes versus air-exposed controls. *Ob/ob* mice (lacking functional leptin) that are then exposed acutely or chronically to cigarette smoke exhibit higher neutrophils, CD4+, CD8+, and dendritic cells in BAL and lung tissue than smoke-exposed wild-type mice, compatible with modulation of innate and adaptive immune cell recruitment by leptin in response to smoke.[79] Within human airways, leptin expression is increased in bronchial epithelial cells and alveolar macrophages of ex-smokers with or without severe COPD compared to never smokers, and leptin can induce phosphorylation of the transcription factor STAT3 in lung epithelial cells, supporting the notion of a functioning leptin signaling pathway in these cells.[65]

Obesity is believed to be a risk factor for asthma, but some controversy still surrounds whether or not obesity is a central cause or a confounding comorbidity of asthma.[80,81] Notably, unbiased clustering approaches in severe asthma subjects have identified an obesity-related clinical asthma phenotype typified by obese, female patients with late-onset asthma, and lacking in eosinophilic Th2-mediated inflammation.[82] Ob/ob mice, a model of loss of leptin function, appear to have elevated pulmonary resistance, and increased responses to ozone and methacholine, though this could be mechanical bias from the low lung size of these mutant mice.[68] Interestingly, when a cohort of obese asthmatic women and obese female controls were studied in the setting of bariatric surgery, leptin expression and macrophage inflammation were both increased in visceral adipose tissue of asthmatics independent of BMI, and correlated with airway reactivity, but there was no association with airway inflammation measurements even though the airway epithelial cells expressed receptors for leptin, suggesting that leptin exerts a direct effect on airway epithelium (and not indirectly via enhancing airway inflammation) that is important in the pathogenesis of asthma in obesity.[83] These observations run counter to the hypothesis that leptin is merely a marker for airway inflammation in poorly controlled asthma.[84]

Nampt (PBEF/visfatin)

The gene Nampt codes for a cytokine called pre–B cell colony-enhancing factor (PBEF), also known as visfatin. It is now known to be produced by various cell types including adipocytes, and especially by visceral as opposed to subcutaneous fat, and has gained greater interest by the rediscovery of PBEF as Nampt, the rate-limiting enzyme in the biosynthesis of the essential redox cofactor, NAD. Nampt is inducible in neutrophils and lung microvascular endothelial cells by endotoxin, TNF-α and IL-1β, and in monocytes, it induces production of IL-1β, TNF-α, and IL-6, and the surface expression of costimulatory molecules CD54, CD40, and CD80.[85,86] Against this background of catalyzing the respiratory burst, and its proinflammatory and immunomodulatory capabilities, Nampt has been demonstrated to be found at higher concentrations in serum and BAL fluid from patients with acute lung injury.[87] There have also been a number of independent candidate gene association studies that support a role for Nampt promoter genetic variants in ALI pathogenesis.[87–89]

■ ANTI-INFLAMMATORY ADIPOKINES

Adiponectin

The most intensely studied of the anti-inflammatory adipokines, and with notable evidence of a role in inflammatory lung disorders, is adiponectin, which shares some structural similarity with complement factor C1q, and forms trimers that can go on to form stable hexamers or a high molecular weight form, all of which are detectable in blood.[60] Circulating adiponectin levels are decreased in obesity, particularly in visceral obesity, nonalcoholic fatty liver disease, and type 2 diabetes, being inversely related to insulin resistance. The adipokine is inhibited by proinflammatory factors such as TNF, IL-6, hypoxia, and oxidative stress.[56] There has been considerable interest concerning the involvement of adiponectin in pulmonary disease states. Three described adiponectin receptors (AdipoR1, AdipoR2, and T-cadherin) are expressed in the lungs, with AdipoR1 expressed by lung epithelial cells, and importantly, the baseline phenotype of mice following targeted disruption of the adiponectin gene shows evidence of emphysema-like dilated air spaces and activation of alveolar macrophages.[90,91] These same adiponectin-deficient mice develop pulmonary hypertension with evidence of perivascular inflammation,[92] and an exaggerated form of LPS-inducible acute lung injury that is abrogated by adiponectin.[93]

As further evidence of anti-inflammatory functionality, adiponectin can bind to apoptotic cells and facilitate their phagocytosis by macrophages, analogous to other members of the collectin family, such as C1q and surfactant proteins A and D.[94] In keeping with this intuitive role in airways disease pathobiology, a number of groups have reported increased levels of circulating adiponectin in COPD.[91,95] Adiponectin was found to be elevated in BALF of COPD patients, being highly expressed in their airway epithelium, and the adiponectin receptor AdipoR1 on lung epithelial cells was shown to be functional, releasing IL-8 in the presence of adiponectin.[91] Animal and human data suggest that short-term exposure to cigarette smoke downregulates adiponectin whereas the COPD

disease state elevates its expression.[91] In contrast, AdipoR2 is more highly expressed in the airway epithelium of obese asthma patients versus obese control subjects, and the opposite to what is observed for T-cadherin expression.[83] In mice, allergen challenge appears to decrease the pulmonary expression of all three adiponectin receptor types, and T-cadherin may play a role in transporting adiponectin into the lungs.[96] The exact role of adiponectin signaling in asthma will require further study.

■ ADIPOKINES AND PULMONARY HYPERTENSION

The high prevalence of pulmonary hypertension in obese subjects has previously been attributed to hypoxemia resulting from associated obstructive sleep apnea or obesity hypoventilation syndrome.[97–99] However, more recently evidence has been presented that alterations in three specific adipokines (adiponectin, apelin, and leptin) may directly contribute to pulmonary vascular dysfunction.

Adiponectin concentrations are paradoxically reduced in the plasma of obese subjects despite the expansion of adipose tissue.[100] Mice in which adiponectin has been deleted spontaneously develop elevated pulmonary arterial pressure, vascular remodeling, and perivascular inflammation as they grow older.[92] Conversely constitutive overexpression of adiponectin in mice protects against the development of both hypoxia-induced and inflammation-induced (ovalbumin challenge) pulmonary hypertension.[101] These suggest that reduced adiponectin concentrations contribute directly to the development of pulmonary vascular dysfunction in obesity due to a loss of its normal vascular homeostatic action.

Apelin is produced and secreted by adipocytes and acts by binding to the apelin receptor.[102] It is also expressed by a wide variety of other tissues including the pulmonary vasculature.[102] Plasma apelin concentrations are increased in obese individuals.[103] Apelin null mice develop more severe hypoxic pulmonary hypertension than wild-type mice, which is associated with endothelial dysfunction.[104] Leptin concentrations are elevated in patients with both idiopathic PAH and scleroderma-associated PAH and in the pulmonary endothelium from these patients.[105,106] However, the exact role of apelin and leptin in the pulmonary circulation in obese humans remains to be determined.

GROWTH FACTORS

■ TRANSFORMING GROWTH FACTOR-BETA

Mammalian transforming growth factor-beta (TGF-β) belongs to a superfamily of genes and exists as three closely homologous (72%–80%) dimeric isoforms: TGF-β_1, TGF-β_2, and TGF-β_3. Although the three isoforms of TGF-β appear to have overlapping biologic activity, the predominant isoform of TGF-β is TGF-β_1. There are three TGF-β receptors and signal transduction to the nucleus is via the Smad group of proteins. Smad 1, 2, 3, 4, 5, 8, and 9 are activating signals, whereas Smad 6 and 7 are inhibitory signals of TGF-β_1 signaling.[107]

TGF-β is produced by a variety of cells, including platelets, neutrophils, eosinophils, mononuclear leukocytes, fibroblasts, and endothelial cells.[108,109] TGF-β is a pleiotropic cytokine that can modulate inflammatory and immune responses, and orchestrate fibrosis and tissue repair.[110] TGF-β is a potent immunosuppressive agent that inhibits IL-1–dependent lymphocyte proliferation.

TGF-β is chemotactic for fibroblasts and can indirectly induce their proliferation via the expression and autocrine and paracrine activity of PDGF-B. TGF-β is perhaps the most potent and efficacious promoter of ECM production–inducing gene expression and protein production of many of the constituents of ECM. Furthermore, it inhibits the generation of metalloproteinases and augments the expression of tissue inhibitors of metalloproteinases (TIMP).[108,111]

Transient overexpression of active TGF-β_1 results in prolonged and severe interstitial and pleural fibrosis.[112] Transfer of TNF-α or granulocyte macrophage colony–stimulating factor (GM-CSF) to rat lung induces pulmonary fibrosis, due in part to induction of TGF-β_1.[113] Furthermore, transient expression of IL-1β using an adenoviral vector can lead to progressive fibrosis that is associated with a sustained increase in levels of TGF-β_1.[114] Smad 3 −/− mice developed less fibrosis in response to bleomycin compared with wild-type controls.[115] In contrast, IL-7 downregulates TGF-β production and inhibits bleomycin-induced pulmonary fibrosis, and this is mediated via Smad 7 signaling.[116]

In IPF, increased expression of TGF-β has been found in bronchiolar epithelial cells, epithelial cells of honeycomb cysts, and hyperplastic type II pneumocytes. BALF from patients with IPF induces apoptosis in cultured bronchiolar epithelial cells, and this effect is attenuated using anti–TGF-β_1 antibodies.[117] In the bleomycin model, in vivo administration of TGF-β_1 enhanced Fas-mediated epithelial cell apoptosis and lung injury.[117] These studies support the contention that TGF-β is an important mediator of human pulmonary fibrosis.

TGF-beta Superfamily Members and Pulmonary Hypertension

Disturbance of signaling by members of the TGF-β superfamily plays a key role in pulmonary hypertension.[118–121] The bone morphogenetic proteins (BMPs) and their receptors form part of the TGF-β superfamily, whose activities include important proangiogenic and vascular remodeling effects in endothelial and vascular smooth muscle cells.[22,122] The BMPs, like all ligands of the TGF-β superfamily, bind to transmembrane cell surface receptors formed from heterodimerization of a type 1 and type 2 receptor, many of which are expressed in the normal lung and can form a large number of different heteromeric receptor combinations binding with particular BMP ligands. BMP signaling is further modulated by a family of secreted extracellular glycoproteins, accessory proteins that bind directly to BMPs and prevent or enhance their interactions with BMPRs.[123,124]

The requirement for normal BMP function to maintain a healthy pulmonary circulation was first demonstrated by the identification of heterozygote inheritance of mutations in BMPR2 gene as the underlying cause in the rare heritable form of pulmonary arterial hypertension (HPAH) and in a significant proportion (10%–40%) of patients with IPAH without a previous family history.[125–127] These mutations cause attenuation of the normal cellular responses to the BMPs in the lung, where BMP2 and BMP4 signaling through BMP type 1 receptor (BMPR1) and BMPR2 heterodimers play particularly important roles in normal vascular homeostasis, and result in pulmonary hypertension.[121,128–132] Experimentally induced loss of function BMPR2 mutations in mice, or expression of dominant negative BMPR2 constructs, were sufficient to cause the development of pulmonary hypertension alone or increased susceptibility to other well-known causes of PH.[130,132–134] Conversely, overexpression of BMPR2 in the endothelium protected mice against the development of hypoxic pulmonary hypertension.[135] These data show that reduced BMP signaling in the lung either causes pulmonary hypertension or increases susceptibility to other causes of PH.

Later studies reported that reduced BMP signaling was found in many of the common forms of pulmonary hypertension, including hypoxic pulmonary hypertension,[121,131,136] although it was not clear what mechanisms cause reduced BMP signaling in these conditions. More recent work has shown that the glycoprotein BMP antagonist gremlin is markedly and selectively increased in the hypoxic mouse lung and in human lungs with PAH.[22] Genetically manipulated mice with reduced gremlin expression (haplodeficient) are partially protected against the development of hypoxic pulmonary hypertension, suggesting that upregulation of gremlin with a consequent

reduction in BMP signaling is an important contributor to the pathogenesis of pulmonary hypertension.[123,137] Furthermore the basal normoxic expression of gremlin is higher in the lung than in any other organ, potentially rendering it more vulnerable to any loss of BMP signaling and may help to explain why the vascular abnormality in hereditary PAH is restricted to the pulmonary circulation even though the expression of mutant BMPR2 is ubiquitous in all vascular beds.[138]

TGF-β are also expressed in the lung as are their type 1 receptors (TGF-βR1) ALK1 and ALK5, and TGF-β receptor type 2 (TGF-βR2) and increased TGF-β signaling has been observed in some forms of pulmonary hypertension.[118–121] Furthermore, PAH develops in a subset of hereditary hemorrhagic telangiectasia patients who have heterozygous mutations in one of the TGF-β type 1 receptors, the ALK1 (activin receptor-like kinase 1).[139,140] Heterozygous mutations in the endoglin (ENG) gene, which codes for a TGF-β coreceptor, are also associated with the spontaneous development of PAH.[139] $ENG^{+/-}$ mice developed pulmonary hypertension associated with loss of peripheral vasculature in adulthood but not in early postnatal life.[141] Taken together these data indicate a requirement for normal TGF-β signaling to prevent the development of pulmonary hypertension.

EPIDERMAL GROWTH FACTOR

Epidermal growth factor (EGF) is the prototype member of a family of polypeptide ligands that interact with the ERBB family of four tyrosine kinase receptors (ERBB1–4, also known as human epidermal growth factor receptor, HER1–4).[142,143] All 13 of the EGF extracellular ligands described to date, which include transforming growth factor-α (TGF-α), heparin-binding(HB)-EGF, amphiregulin, epiregulin, and betacellulin among others, contain a conserved EGF domain and are made as a transmembrane protein that is then cleaved by cell surface proteases (ectodomain shedding) to release mature growth factors that bind ERBB, such as the case with EGF which binds to HER1/EGFR.[144] EGF motifs are also found in unrelated proteins including ECM and cell adhesion proteins, blood coagulation factors, and immune response proteins.[145] Control of ERBB family signaling occurs at many levels, including specific cellular patterns of ligand and receptor expression, subcellular segregation of ligands and receptors, and the diversity of intracellular receptor binding proteins that can amplify or attenuate receptor signaling and transcription factor activation, leading to varying cellular outputs of cell proliferation, adhesion, migration, differentiation, or apoptosis.[142] Dysfunctional EGF–ERBB signaling in the lung has consequently been implicated in lung tumorigenesis and lung injury.[146]

EGFR (ERBB1/HER1) is overexpressed in a large number of non–small-cell lung cancers (NSCLCs), and its expression has been correlated with a poor prognosis.[147] NSCLCs will also often express EGFR cognate ligands EGF and TGF-α, leading to receptor hyperactivity in an autocrine fashion.[148] The tyrosine kinase inhibitors gefitinib and erlotinib target the EGF–ERBB complex by acting as competitive inhibitors of ATP binding at the active site of the kinase. It became apparent that drug-responsive cases were enriched for somatic activating mutations in the EGFR kinase domain, with these mutations occurring at a greater frequency in nonsmokers, women, those of Asian genetic ancestry, and in adenocarcinoma.[149]

There is overlap between the signaling events that orchestrate the proliferation, migration, and differentiation of the developing lung epithelia, and those events that are active during lung injury and repair. The importance of EGF motif signaling in lung development is apparent from the HB-EGF(−/−) mouse hypoplastic lung phenotype, characterized by fewer alveoli and less surfactant. Similarly, the EGFR knockout mice display alveolar collapse, reduced alveolarization and loss of surfactant expression, resulting in a phenotype similar to the neonatal respiratory distress syndrome,[150] and exogenous EGF can rescue EGFR(−/−) fetal lambs from such a phenotype.[151] Later in life, there is evidence implicating EGFR signaling in an in vitro model of alveolar epithelial wound repair.[152] and bronchial epithelial repair in asthma.[153] A body of evidence has also implicated EGFR signaling in the pathogenesis of pulmonary fibrosis: For example, TGF-α (−/−) mice are protected from bleomycin-induced fibrosis,[154] as are wild-type mice exposed to bleomycin but administered gefitinib.[155] Given that ERBB tyrosine kinase inhibitors can also cause interstitial lung disease in clinical use,[156] it remains to be seen how best the complex ERBB signaling pathways can be therapeutically manipulated in the lung fibrosis arena.

VASCULAR ENDOTHELIAL GROWTH FACTOR

Initially described as a growth factor for endothelial cells, vascular endothelial growth factor (VEGF) is highly expressed in many different lung cell types, and has important roles in lung development and maintenance of lung tissue integrity, through its angiogenic, lymphangiogenic, and hematopoietic roles.[157] VEGF is produced by endothelial cells, fibroblasts, neutrophils, peripheral blood mononuclear cells (PBMCs), and macrophages, and exists as any of five family members, VEGF A, B, C, D, and placenta growth factor (PLGF) and further diversity in biologic activity arises from various alternatively spliced isoforms of family members,[158] including VEGFA121, VEGFA145, VEGFA165, VEGFA189, and VEGFA206, named after the number of coded amino acids. Transcription of VEGF is induced by hypoxia, IL-1β, and by many growth factors including platelet-derived growth factor, TGF-α and -β, insulin growth factor 1, fibrocyte growth factor, and FGF7 (keratinocyte growth factor [KGF]). The VEGF family members have three different VEGF receptors, with VEGFA binding to VEGFR1 and VEGFR2. VEGFR2 −/− mice have lethal defects in vasculogenesis and angiogenesis.[159] The role of VEGF in lung development is complex and can be highlighted by a number of observations. When embryonic murine lungs are cultured, VEGF expression, initially diffuse, is restricted over time and space to subepithelial matrix in the branching tips of the developing airways.[160] Furthermore, aberrant lung morphology has been shown to arise from targeted overexpression or underexpression of VEGF.[161,162] In bronchopulmonary dysplasia, the disease of prematurity and its attending interventions including hyperoxia, there was a demonstrable reduction in lung expression of VEGF, VEGFR1, and Tie-2 associated with disrupted pulmonary vasculature.[163]

There is some evidence to suggest that VEGF may play a protective role in emphysema. Partial and transient inactivation of VEGF gene in murine lungs using an adeno-associated *cre* recombinase virus and conditional VEGF knockout mice, VEGF*loxP*, resulted in apoptosis of alveolar and bronchial cells with ensuing air space enlargement and reduced elastic recoil, reminiscent of emphysema.[164] The low levels of VEGF expressed in human emphysematous lung[165] may be due to upstream factors that cause a reduction in expression of the major controller of VEGF expression, hypoxia-inducible factor (HIF)-1α in COPD lungs.[166]

VEGF and Pulmonary Hypertension

VEGF levels have been variably reported as increased, reduced, or unchanged in pulmonary hypertension with no consistent pattern emerging. However, studies directly examining the effect of inhibiting or stimulating VEGF receptors have produced a coherent picture. Blockade of VEGFR2 using small molecule inhibitors in rats aggravated hypoxic pulmonary hypertension, reduced pulmonary VEGFR2 expression, and increased endothelial cell apoptosis suggesting that VEGFR2 was essential for maintaining and expanding the vascular bed in the hypoxic lung.[167] Moreover, even following return to normoxia and withdrawal of VEGFR2 blockade the pulmonary hypertension was progressive and ultimately fatal. After

extended time periods in this model complex plexiform-like lesions similar to those found in human PAH are observed.[168] Mice also show aggravation of hypoxic pulmonary hypertension in the presence of VEGFR2 blockade.[169] Interestingly, pulmonary hypertension has occasionally been reported in patients receiving VEGF inhibitors as part of a cancer chemotherapy treatment program.[170]

Overexpression of VEGFA in the rat lung using adenoviral vectors protected against the development of pulmonary hypertension although no analysis of the capillaries and small intra-acinar vessels (<50 μm) was carried out so it is not possible to know if this protection was accompanied by angiogenesis.[171] Louzier et al.[172] found that overexpression of VEGFB in the hypoxic rat lung using an adenoviral vector strategy protected against the development of hypertension and increased vessel density within the lung. Thus, it is clear that the balanced actions of agonist and inhibitory members of the VEGF family are essential for normal adaptation of the pulmonary circulation to hypoxia although the precise role of the VEGF pathway in human pulmonary hypertension is at present unclear.

FIBROBLAST GROWTH FACTOR

The fibroblast growth factor (FGF) family consists of 18 secreted polypeptide ligands that bind to one of four target cell surface FGF receptors (FGFR), that are tyrosine kinase receptors (FGFR1–4), and have many isoforms as a result of exon skipping and alternative splicing, the latter being generally tissue specific.[173] FGF subfamilies are grouped for their shared sequence homology and phylogeny. FGFs regulate diverse biologic processes including angiogenesis and organogenesis including proliferation, cell migration, and paracrine effects on tissue patterning. Two of the FGF ligands have particular relevance to the lung, both within the FGF7 subfamily including FGF7 (KGF) and FGF10.[173,174]

FGF7 is expressed specifically by mesenchymal cells including fibroblasts and vascular smooth muscle cells, and binds exclusively to an epithelial receptor FGFR2-IIIb, suggesting a paracrine loop effect in its epithelial–mesenchymal interactions. Using a dominant-negative mutant to inhibit FGFR2-IIIb results in an absence of branching morphogenesis within the developing murine lung,[175] and FGF7 overexpression results in enlarged bronchial air spaces and papillary cystadenomas.[176] A variety of experimental data have indicated that FGF7 expression increases following acute lung injury and that FGF7 is protective, principally when used as a pretreatment, in the face of injury caused by varied insults including hyperoxia, radiation, graft versus host disease following allogeneic bone marrow transplant, acid, and bleomycin,[174,177–179] but FGF7 may also partially prevent loss of barrier function in airway epithelium when given after an inciting exposure, potentially making FGF7 a more attractive therapeutic intervention were it so.[180,181] Notably, recombinant FGF7 (palifermin) which improves wound healing through cellular proliferation, is FDA approved for the treatment of chemoradiation-induced oral mucositis.[182] In addition to FGF7, FGF10 plays a critical role in lung development, given that FGF10(−/−) mice have defects in branching morphogenesis in lungs and other organs.[183] FGF10 overexpression attenuates bleomycin-induced pulmonary fibrosis in mice.[184] Interestingly, the triple angiokinase inhibitor nintedanib (BIBF 1120), inhibits VEGFR(1–3), platelet-derived growth factor receptors α and β, as well as FGFR1–3, and in a recent phase II clinical trial in patients with idiopathic pulmonary fibrosis, produced clinically meaningful reductions in the decline in forced vital capacity.[185]

GRANULOCYTE MACROPHAGE COLONY–STIMULATING FACTOR

GM-CSF is a glycosylated secreted protein produced by a variety of cells including macrophages, endothelial cells, T cells, natural killer cells, mast cells, and fibroblasts. It is defined by its ability to expand in vitro bone marrow precursor cells, via proliferation and differentiation, into colonies of mature myeloid cells, and act as a proinflammatory cytokine.[186–188] Interest from the pulmonary field grew with the initial observation that mice lacking GM-CSF had no major perturbation of hematopoiesis, but had an unexpected finding of compromised maturation of alveolar macrophages resulting in a phenotype of pulmonary alveolar proteinosis (PAP), with defective clearing of surfactant by alveolar macrophages.[189] The major form of human PAP is classified as autoimmune (or primary) PAP, accounting for about 90% of all PAP cases.[190] Autoimmune PAP is characterized by abnormally elevated levels of GM-CSF IgG autoantibodies, that bind GM-CSF with high affinity and neutralize GM-CSF functionality, and results in persistence of dysfunctional alveolar macrophages that are less efficient, with associated neutrophil dysfunction leading to opportunistic infections.[191] While whole lung lavage remains the cornerstone of therapy for PAP, targeted interventions to address the neutralization of GM-CSF are under active study using either (subcutaneous or inhaled) recombinant GM-CSF therapy, rituximab, or plasmapheresis, all with varying success to date.[192]

CONNECTIVE TISSUE GROWTH FACTOR

Connective tissue growth factor (CTGF) is a member of the structurally related CCN (ctgf/cyr61/nov) gene family, which contains six genes: ctgf, cyr61, nov, elm1, cop1, and WISP-3.[193] CTGF is produced by vascular smooth muscle cells, fibroblasts, endothelial cells, and epithelial cells, and is activated by a number of factors, particularly TGF-β.[193] CTGF has in vitro activities that include fibroblast proliferation, fibroplasia, and ECM production.[193–195] Furthermore, its presence has been documented in skin lesions of systemic sclerosis, keloids, scar tissue, and eosinophilic fasciitis and in BALF from patients with IPF and sarcoidosis, and it induces ECM in asthmatic airway smooth muscle.[193–196] Transient overexpression of CTGF in a rat model leads to a moderate but reversible pulmonary fibrosis that is associated with increased levels of TIMP-1.[197] Overexpression of TGF-β leads to a concomitant increase in CTGF and TIMP-1, suggesting that CTGF may be a cofactor for the development of fibrosis.[197] CTGF may be responsible for some of the downstream actions of TGF-β and is a potential therapeutic target for the treatment of interstitial lung disease.

CONCLUSIONS

Chemokines, adipokines, and growth factors are now recognized to play fundamental roles in lung development, the lifelong maintenance of lung health, and the development of pulmonary disorders characterized by inflammation and/or fibrosis, some of which are modulated by body mass. The generation of complex, overlapping signaling networks is necessary for both the pathogenesis and resolution of a variety of acute and chronic lung diseases, as these mediators are fundamental to the initiation, maintenance, and final resolution of the inflammatory response. Studies that illuminate the mechanistic role of chemokines, adipokines, and growth factors in mediating lung inflammation are beginning to lead to novel targeted forms of therapies, which will significantly aid in treating enigmatic lung disease.

CHAPTER 27

Redox Signaling and Oxidative Stress in Lung Diseases

Jessy Deshane
Victor J. Thannickal

INTRODUCTION

Molecular oxygen is a prerequisite to life of all aerobic organisms. The human lung with its large surface area and extensive blood supply is engineered for its primary function in gas exchange. While oxygen is essential for its many roles in human physiology, high concentrations of oxygen or its metabolites, commonly referred to as reactive oxygen species (ROS), have the potential to cause cellular injury and contribute to disease pathogenesis. The most damaging forms of ROS are free radicals. A free radical, by definition, refers to any chemical species containing one or more unpaired electrons in their atomic or molecular orbitals. These unpaired electron(s) give considerable reactivity to free radical species, which can trigger chemical reactions that damage cellular constituents of living organisms. Molecular oxygen (dioxygen) is itself, a radical based on the presence of unpaired electrons in its outermost orbital; however, their parallel spin retrains its reactivity. O_2 can form the superoxide anion radical ($O_2^{\bullet -}$) upon addition of an electron; thus, overcoming this restraint and making $O_2^{\bullet -}$ a highly reactive species.[1,2] The photodynamic activation of oxygen can result in the formation of singlet oxygen, and its reductive activation results in the formation of hydrogen peroxide (H_2O_2) or the highly reactive hydroxyl radical ($^{\bullet}OH$).[3,4] When two free radicals share their unpaired electrons, nonradical species of lower reactivity are generated. Thus, ROS constitute both free radicals and nonradicals.

Nitric oxide ($NO^{\bullet}$) is another small gaseous molecule that serves as an important signaling molecule in diverse physiological processes, including vasorelaxation and immune regulation during chronic inflammation in the lung.[5,6] The regulated production of $NO^{\bullet}$ by lung cells is critical for homeostasis of the lung. However, in some contexts, the reaction of $NO^{\bullet}$ with $O_2^{\bullet -}$ to form reactive nitrogen species (RNS), such as peroxynitrite ($ONOO^-$), may contribute to the pathophysiology of chronic lung diseases.[7–9]

ROS and RNS together play important roles in regulation of cell proliferation, differentiation, and survival.[10–12] ROS/RNS can inactivate enzymes including antiproteases, induce apoptosis, regulate cell proliferation, and modulate the immune-inflammatory system in the lungs and other tissues.[13–16] ROS/RNS have been implicated in initiating inflammatory responses in the lungs through the activation of transcription factors, protein kinase pathways, chromatin remodeling, and gene expression of proinflammatory mediators.[13–16] Under normal physiological conditions, the balance between generation and elimination of ROS/RNS maintains the functional integrity of redox-sensitive signaling cascades regulating cellular phenotypes. In this context, it is important to differentiate the roles of ROS/RNS in "oxidative stress" from "redox signaling." Paradoxically, it appears that nature has co-opted the chemical reactivities of ROS/RNS to function as signaling molecules in homeostasis and normal cellular physiology.

Redox homeostasis of cells/tissues is maintained by the regulated balance of oxidant production and antioxidant systems, both enzymatic and nonenzymatic. However, an increase in oxidant generation in excess of the capacity of cells/tissues to detoxify or scavenge reactive species leads to oxidative stress.[10,17,18] Oxidative stress typically causes damage to cellular components in an indiscriminant manner. Such states are accelerated in the presence of transition metals, such as iron and copper, and/or specific monooxygenases or oxidases.[13,15,16] It is also important to recognize that aberrations in redox signaling or oxidative stress may contribute to the pathogenesis of lung diseases. In this chapter, we review the physiology of ROS and RNS; cellular antioxidant systems; and the role of oxidative stress and redox signaling in the development and progression of selected acute and chronic lung diseases.

METABOLISM OF REACTIVE OXYGEN/NITROGEN SPECIES

ENZYMATIC AND NONENZYMATIC SOURCES OF ROS

The primary ROS include superoxide anion ($O_2^{\bullet -}$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($^{\bullet}OH$), which can be generated from both enzymatic and nonenzymatic sources. The human lung is constantly exposed to ambient air, which may contain environmental toxins capable of inducing ROS generation.[13,19] ROS may also be generated by electron transfer reactions in the mitochondria and endoplasmic reticulum (ER), from xenobiotics, and a range of metabolic enzymes that catalyze oxidation reactions.[19] The major endogenous ROS/RNS and the primary mechanisms for their generation are summarized in Table 27-1.

The highly reactive $O_2^{\bullet -}$ formed by the addition of an electron to molecular oxygen is unstable with a half-life of milliseconds. The major site for producing $O_2^{\bullet -}$ is the mitochondria, which is also the primary site for ATP generation in any cell. During mitochondrial

TABLE 27-1 Key Reactive Oxygen and Nitrogen Species

Reactive Species	Formula	Chemical Reaction		
Superoxide	$O_2^{\bullet -}$	$NADPH + 2O_2$	$\longleftrightarrow$	$NADP+ + 2O_2^{\bullet -} + H^+$
		$2O_2^{\bullet -} + H+$	$\longrightarrow$	$O_2 + H_2O_2$
Hydrogen peroxide	H_2O_2	$Hypoxanthine + H_2O + O_2$	$\rightleftharpoons$	$Xanthine + H_2O_2$
		$Xanthine + H_2O + O_2$	$\rightleftharpoons$	$Uric\ acid + H_2O_2$
Hydroxyl radical	$^{\bullet}OH$	$Fe^2 + H_2O_2$		$Fe^{3+} + OH^- + {}^{\bullet}OH$
Hypochlorous acid	HOCl	$H_2O_2 + Cl^-$	$\longrightarrow$	$HOCl + H_2O$
Peroxyl radicals	$ROO^{\bullet}$	$R^{\bullet} + O_2$	$\longrightarrow$	$ROO^{\bullet}$
Peroxynitrite	$ONOO^-$	$O_2^{\bullet} + NO$	$\longrightarrow$	$ONOO^-$
		$H_2O_2 + NO_2^-$	$\longrightarrow$	$ONOO^- + H_2O$

electron transport, there is an estimated leak of 1% to 3% of electrons to oxygen resulting in the formation of $O_2^{\bullet -}$.[16] $O_2^{\bullet -}$ generated in the mitochondria, due to its negative charge, does not cross membranes and is released into the mitochondrial matrix where it targets proteins with heme moieties or iron–sulfur clusters to cause loss of protein or enzymatic function.[20] The steady-state levels of intramitochondrial $O_2^{\bullet -}$ concentrations are maintained at very low levels by detoxifying enzymes. ER is another intracellular compartment in which enzymes that detoxify lipid-soluble drugs and other toxic metabolites, reduce molecular O_2 to produce $O_2^{\bullet -}$ and/or H_2O_2, while oxidizing unsaturated fatty acids and xenobiotics.[19,20]

The NADPH oxidase (NOX) gene family encompasses enzymes, the primary function of which is the regulated generation of ROS. NOX enzymes form a membrane-bound multicomponent complex that is present in phagocytes and nonphagocytic cells in the lung.[15,16,18] NOX enzymes play crucial roles in host defense, signal transduction, and hormone synthesis in eukaryotes. There are seven mammalian NOX homologs comprising NOX1 to 5 and the DUOX1 and 2.[21–24] The best characterized NOX isoform is NOX2, which is essential for microbicidal-killing activity of phagocytes. NOX2, upon activation, generates ROS by coordinated assembly and activation of the NOX2 enzymatic complex, which comprises the membrane-associated flavocytochrome b558 ($gp91^{phox}$), $p22^{phox}$, and the various cytosolic cofactors ($p47^{phox}$, $p67^{phox}$, and $p40^{phox}$, and the GTPase, Rac1). This complex then mediates the transmembrane electron transfer from the major electron donor, NADPH, to reduce molecular O_2 to $O_2^{\bullet -}$ and H_2O_2.[15,16,18]

Similar to NOX2, activation of NOX1 and NOX3 also requires association with $p22^{phox}$, and assembly with Rac1 and cytosolic cofactors ($p47^{phox}$ and $p67^{phox}$ or their homologs, NOX organizer 1 (NOXO1) and NOX activator 1 (NOXA1). NOX4 also requires $p22^{phox}$, but is constitutively active and functions independently of activation of other cofactors.[16,21–24] Expression of NOX1 and NOX4 in nonphagocytic fibroblasts results in increased levels of both $O_2^{\bullet -}$ and H_2O_2, implying that these, unlike the phagocytic NOX2, possess intrinsic basal activity. NOX5 and DUOX1/2 differ from the other NOX homologs and contain additional intracellular Ca^{2+}-binding EF-hand domain regions, and are regulated by Ca^{2+} signaling, independent of $p22^{phox}$ or other cytosolic factors.[16,21–24] The dual oxidases, DUOXs, are composed of the NOX-like region at the C-terminal half, two EF-hands, a membrane-spanning region, and a peroxidase-like domain at the N-terminus. DUOXs do not require cytosolic regulatory components for their activity.[16,21–24] However, transmembrane maturation factors, DUOXA1 and DUOXA2, are essential for ER-to-Golgi transition, maturation, and targeting DUOXs to the plasma membrane as functional complexes. Although initially identified in the thyroid gland, DUOX1 and DUOX2 are the primary sources of H_2O_2 production in the airway epithelium.[25] The NOX/DUOX isoforms are expressed widely in the lung extending from the proximal trachea and large airways to terminal bronchioles and alveoli (Table 27-2).[16,21–25]

In biological systems, dismutation reaction of $O_2^{\bullet -}$ generates H_2O_2, either spontaneously or by enzymatic catalysis by superoxide

TABLE 27-2 Enzymatic Sources for ROS and RNS

Enzyme	Distribution in Lung	Lung Cell Types
DUOX1, DUOX2, NOX2, NOX4	Trachea and upper airways	Airway epithelial cells
NOX1, NOX2, NOX4	Pulmonary vasculature	Pulmonary artery endothelial cells
NOX4	Pulmonary vasculature	Pulmonary artery smooth muscle cells
DUOX1, DUOX2, NOX2, NOX4	Lower airways/ alveolus	Airway epithelial cells
NOX3	Airway alveolus	Endothelial cells
NOX4	Airway alveolus	Myofibroblasts
NOX2, NOX4	Alveolar space/ blood	Monocytes, Macrophages, Neutrophils, Eosinophils
NOS1 (neuronal)	Trachea, bronchus, airways	Airway epithelial cells Neutrophils Neurons
NOS2 (inducible)	Airways, alveolus, alveolar space/ blood	Airway and vascular smooth muscle cells Type II pneumocytes Fibroblasts Macrophages Monocytes Neutrophils Eosinophils Mast cells
NOS3 (endothelial)	Airways, pulmonary vasculature	Airway epithelial cells Type II pneumocytes Pulmonary artery Smooth muscle cells Endothelial cells Macrophages

dismutases (SODs). $O_2^{\bullet-}$ can be generated by molybdenum hydroxylase reactions involving xanthine, sulfite, and aldehyde oxidases, dihydroorotate and flavoprotein dehydrogenases, tryptophan dioxygenases as well as arachidonic acid metabolism.[26,27] Certain oxidases such as monoamine and amino acid oxidases can generate H_2O_2 directly without the intermediate formation of $O_2^{\bullet-}$.[17] During chronic inflammation in the lung, H_2O_2 is produced by both resident and inflammatory cells of the lung.[26,27] The oxidizing potential of H_2O_2 is amplified by inflammatory cell peroxidases such as myeloperoxidase (MPO) and/or eosinophil peroxidase (EPO).[28–32] The hydroxyl radical, $^{\bullet}OH$, is the neutral form of the hydroxide ion that is highly reactive toward cellular constituents, more so than $O_2^{\bullet-}$ or H_2O_2. This radical contributes to most of the reactivity by $O_2^{\bullet-}$ and H_2O_2 in a series of reactions that are catalyzed by transition metal ions. Excess $O_2^{\bullet-}$ targets Fe–S cluster-containing enzymes and catalyzes production of $^{\bullet}OH$ from H_2O_2 by reducing free iron (Fe^{3+} to Fe^{2+}) for Fenton chemistry (see Table 27-1). MPO and EPO enzymes represent an alternate pathway for $^{\bullet}OH$ formation *in vivo*. MPO uses Cl^- as substrate to generate hypochlorous acid, whereas EPO uses Br^- to generate brominating species. The hypohalous acids then generate $^{\bullet}OH$ by reaction with $O_2^{\bullet-}$.[33–38] Both these enzymes can accelerate oxidative modifications of proteins, in particular bromination and chlorination.

■ ENZYMATIC AND NONENZYMATIC SOURCES OF RNS

An important RNS in the lung is $NO^{\bullet}$, which is endogenously generated by specific nitric oxide synthases (NOSs). These NOS enzymes metabolize L-arginine to $NO^{\bullet}$ and L-citrulline via a five electron oxidation reaction.[6,39–48] This reaction requires a dimeric enzyme, oxygen, NADPH and the cofactors, flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), tetrahydrobiopterin (BH_4), calmodulin, and iron protoporphyrin. Active NOS enzymes exist in the dimeric form with each monomer consisting of an N-terminal oxygenase domain that binds heme, BH_4, and substrate L-arginine. The cofactors FAD, FMN, and NADPH bind the C-terminal end of the NOS monomer. There are three different NOS forms, all of which are expressed in the lung, the inducible form iNOS or NOS2, neuronal NOS or NOS1, and the endothelial NOS enzyme NOS3 (Table 27-2). The NOS1 and NOS3 enzymes are calcium dependent and produce picomolar levels of NO, while nanomolar levels are generated by the calcium-independent iNOS. $NO^{\bullet}$ synthesis by iNOS is regulated by the availability of the substrate L-arginine and cofactor BH_4. Transfer of electrons occur from the carboxyreductase domain to the heme iron of the oxygenase domain, which then binds oxygen and oxidizes L-arginine to generate the end products, $NO^{\bullet}$ and citrulline.[6,39–48] Uncoupling of NOS enzymes can contribute to the formation of the $O_2^{\bullet-}$. In a low arginine condition, NADPH is oxidized by the enzyme to generate $O_2^{\bullet-}$. Arginase, an enzyme that competes with the NOSs for L-arginine decreases the arginine availability for NOS. Arginase is a critical enzyme in the urea cycle and converts arginine to ornithine, and then to urea; it can promote uncoupling of NOSs to generate $O_2^{\bullet-}$.[49,50] About 40% of the highly reactive and highly diffusible $NO^{\bullet}$ is consumed in chemical reactions and, when metabolized, give rise to reactive intermediates. $NO^{\bullet}$ reacts with O_2 yielding nitrite (NO_2^-) and recycling of nitrite causes regeneration of bioactive $NO^{\bullet}$. NO_2^- is also a substrate for the heme peroxidases, MPO and EPO, which oxidize nitrite to nitrogen dioxide radical ($NO_2^{\bullet}$). $NO^{\bullet}$ is also oxidized to methemoglobin and NO_3^- by reaction with oxyhemoglobin. $NO^{\bullet}$ reacts with $O_2^{\bullet-}$ to form peroxynitrite ($ONOO^-$), which can mediate tyrosine nitration that may result in either the loss or gain of function of proteins.[7–9,51] In acidic environments, the protonation of $ONOO^-$ results in the formation of ONOOH (peroxynitrous acid), which is then decomposed to both NO_3^- via intermediate $^{\bullet}OH$ and NO_2.[52] ONOOH can also react with thiol residues to form S-nitrosothiols (SNOs) and the reaction is referred to as S-nitrosation or S-nitrosylation. A wide variety of proteins including kinases, channels, and transcription factors are susceptible to S-nitrosylation. SNOs are important molecules in the signaling of $NO^{\bullet}$ bioactivity in the respiratory system.[53–57] SNOs are present in the airway epithelial lining fluid in μmol concentrations, can influence airway tone, and possess substantially greater half-lives than $NO^{\bullet}$ in the lung. It has also been reported that iNOS can specifically bind to cyclooxgenase-2 (COX-2) and S-nitrosylate COX-2, upregulate its catalytic activity and enhance prostaglandin E2 production. Thus, S-nitrosylation represents an important signaling pathway for $NO^{\bullet}$.[53–57] Under physiological conditions, interaction with metal centers of enzymes and S-nitrosylation are the major mechanisms for biological actions of $NO^{\bullet}$. In biological systems, the levels of $O_2^{\bullet-}$ are 10^{-11} to 10^{-10} M while that of NO is 10^{-9} to 10^{-7} M. Under these conditions, $ONOO^-$ is formed at a low rate by the reaction of $NO^{\bullet}$ with $O_2^{\bullet-}$ with a 1:1 stoichiometry.[7–9,51,53–57] However, under pathophysiological conditions, $ONOO^-$ and its derivatives are formed at high levels and may cause irreversible damage to the respiratory chain, inhibit ATP synthesis, and induce cytochrome c release and caspase-dependent apoptosis. RNS may also mediate lipid peroxidation, protein oxidation and nitration, enzyme inactivation, or even cell necrosis.[7–9,51,53–57]

MECHANISMS TO DETOXIFY ROS/RNS

ROS/RNS play a key role in the initiation, amplification, and persistence of inflammation associated with chronic lung diseases.[15–18,58,59] Similar to the formation of ROS/RNS, the removal or detoxification of these species may involve enzymatic and nonenzymatic mechanisms. Nonenzymatic systems constitute the first line of defense against ROS/RNS. The low–molecular-weight nonenzymatic antioxidants in the lung include glutathione, vitamins C and E, β-carotene, uric acid, thiols, and taurine. The larger–molecular-weight antioxidants include lactoferrin, albumin, ceruloplasmin, and transferrin; these molecules mediate their antioxidant function by binding heavy metals, making them unavailable for participation in the Fenton reaction to produce free radicals such as hydroxyl radical.[15,18,26,59,60] Nonenzymatic antioxidant activities range from the hydrophilic quenching of free radicals, protection of critical sulfhydryl groups on proteins to inhibition of lipid peroxidation.

Although nonenzymatic antioxidants are the first line of defense against different ROS, several enzymatic antioxidants work in concert with nonenzymatic antioxidants to form a tightly regulated antioxidant network. The major components of the pulmonary enzymatic antioxidant defense systems are SODs, catalase, and glutathione peroxidases. Peroxiredoxins (PRXs), thioredoxins (TRXs), glutaredoxins, heme oxygenases, and reductases are also involved in cellular adaptation and protection against oxidative stress in the lung. The enzymatic reactions that catalyze the elimination of ROS/RNS are summarized in Figure 27-1.

Superoxide Dismutases: The $O_2^{\bullet-}$ radical is a primary oxidant in chronic lung inflammation.[15,17,61] It participates in the generation of other reactive metabolites, H_2O_2, $^{\bullet}OH$, and $ONOO^-$. SODs represent a key defense against reactive species generated during normal metabolism or inflammatory states. SODs are ubiquitous enzymes that catalyze the dismutation of $O_2^{\bullet-}$ radical to the weaker oxidant, H_2O_2 (see Fig. 27-1). The function of SOD extends beyond its catalysis of $O_2^{\bullet-}$ dismutation to its participation in the regulation of normal cellular homeostasis. H_2O_2 formed from the SOD-catalyzed reaction may function as a signaling molecule at low concentrations. By reducing steady-state concentrations of $O_2^{\bullet-}$, which reacts with $NO^{\bullet}$ to form $ONOO^-$, SOD may serve to promote vasoreactivity and reduce inflammation.[15,61]

There are three mammalian SOD isozymes: the intracellular copper-zinc SOD (CuZn-SOD), the mitochondrial manganese SOD

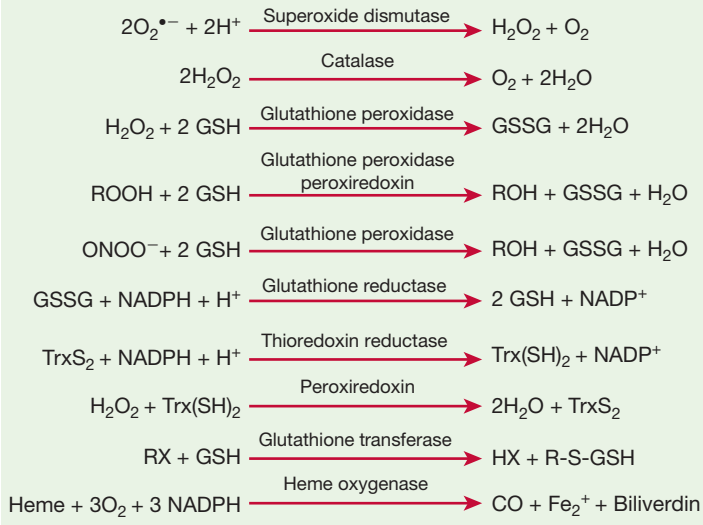

Figure 27-1 Enzymatic mechanisms to detoxify reactive oxygen and nitrogen species.

(Mn-SOD), and extracellular SOD (EC-SOD).[61] The structural and catalytic characteristics of these SOD isozymes are highlighted in Table 27-3.[62–65] Given the complexity of the human lung with its plethora of different cell types, it is conceivable that these isozymes are expressed differentially in specific lung cells with subcellular compartmentalization, as summarized in Table 27-4.[66–79]

Aside from dismutating $O_2^{\bullet-}$ radical by the cyclic oxidation–reduction of its metal ion Cu^{2+}, CuZn-SOD exhibits peroxidase activity.[65] At high levels, H_2O_2 may reduce the Cu^{2+} to either Cu^+-O or Cu^{2+}-OH that may oxidize the histidine residue in the monomer and inactivate or oxidize lung proteins.[80–82] CuZn-SOD also nitrates tyrosine residues in proteins via peroxynitrite,[83–87] and catalyzes the release of NO from nitrosothiols.[88] Although Mn-SOD has similar dismutase activity, it does not elicit peroxidation or nitration, and is inactivated by tyrosine nitration, but not by hydrogen peroxide or cyanide.

EC-SOD is the primary extracellular SOD in the lung[72] containing Cu and Zn ions.[89,90] The EC-SOD has an active site inhibitable by H_2O_2 and cyanide, similar to CuZn-SOD.[74–76] EC-SOD has an arginine- and lysine-rich heparin/matrix-binding domain at its C-terminal region.[91–94] Its extracellular localization is maintained by the interaction of this domain with heparin and heparin sulfate proteoglycans on diverse lung cell types and in the extracellular matrix (ECM) of the lung. This heparin/matrix-binding polybasic region is sensitive to proteolysis, leading to reduced affinity of EC-SOD for ECM and increased release of EC-SOD in plasma.[72,91–97] EC-SOD is abundant in the lung both at the mRNA and protein levels.[91–94] As indicated in Table 27-4, the wide cellular distribution of EC-SOD is consistent with robust EC-SOD activity in the human lung (eightfold > liver, sixfold > brain, two- to threefold > heart, and one- to twofold > kidney)[61]; in comparison, CuZn-SOD and Mn-SOD activities are much lower. The lower activities of CuZn-SOD and Mn-SOD in the lung suggest that cytoplasmic production of $O_2^{\bullet-}$ is lower in lung cells, compared with the metabolically more active cells of the liver and kidney. The dense airway and vascular network in the lung and the higher potential for extracellular inflammatory events resulting from direct exposure of the lung to the external environment may account for high EC-SOD levels in the lung. Even with its high lung localization, EC-SOD is not present at sufficient concentrations to justify its role as the sole scavenger of $O_2^{\bullet-}$ across the entire extracellular space. While CuZn-SOD and Mn-SOD function mainly as bulk scavengers of the $O_2^{\bullet-}$ radicals, the relatively high levels of EC-SOD in the lung and its binding specificity to the ECM components provide protection for the lung matrix.[14,98]

Lack of abnormalities in CuZn-SOD–deficient mice suggest that pathological consequences of mutations are perhaps due to gain of compensatory functions of the enzyme including its peroxidase or nitration reactions and not associated just with the complete loss of SOD activity.[97,99] EC-SOD–overexpressing mice were only partially protected from hyperoxia-induced lung injury, influenza, bleomycin, and hemorrhagic shock,[14,61,98] suggesting that EC-SOD may not be sufficient to attenuate oxidative stress in pathological states in which the EC-SOD system is overwhelmed. Under hyperoxia, mice lacking EC-SOD show shortened survival and extensive lung damage.[14,61,98] Thus, although other antioxidant enzymes may compensate for the loss of EC-SOD under homeostatic conditions, during inflammatory stress, EC-SOD is essential for protecting the lung and limiting injury. Over 90 genetic polymorphisms have been identified in CuZn-SOD, several in association with neurodegenerative diseases.[62] The Arg 213-gly polymorphism in EC-SOD (R213G) is found in 4% to 6% of the human population and influences chronic obstructive pulmonary disease[100,101] and acute lung injury.[102]

Catalase: H_2O_2 is reduced to water by catalase (CAT) and the glutathione peroxidases (see Fig. 27-1). CAT is a metalloprotein oxidoreductase enzyme widely expressed in lung cells (see Table 27-4).[62,103–106] In the presence of excess H_2O_2, CAT undergoes alternate divalent oxidation and reduction at its heme-containing active site. Catalase degrades H_2O_2 to O_2 and water.[62,103–106] Although catalase is the principal scavenger of H_2O_2, it is unable to metabolize large molecular peroxides including lipid peroxides. The gene for catalase is not induced by oxidant stress. However, posttranslational tyrosine phosphorylation of CAT upregulates its activity[107]; whereas, oxidation of tyrosine residues inhibits CAT activity.[8]

Glutathione peroxidases: Glutathione peroxidases (GSH-Pxs) are selenocysteine-containing tetrameric enzymes that utilize reduced glutathione (GSH), a low–molecular-weight tripeptide, as an electron donor and catalyze the biotransformation of various organic and inorganic peroxides, including H_2O_2 and lipid peroxides, to their corresponding alcohols. The detoxification of peroxides by GSH-Pxs occurs via bidirectional second-order kinetics and is a saturation-limited process.[26,108] GSH-Px1, GSH-Px2, GSH-Px3, and GSH-Px4 are the four glutathione peroxidases.[26,108] GSH-Px1 is a ubiquitous intracellular form and is the predominant isoform

TABLE 27-3 Characteristics of Superoxide Dismutases

SOD	Structure	Metal Ions	Type of Enzymatic Activity	Intracellular SOD activity (%)
Mn-SOD	Homotetramer	Mn and Zn	$O_2^{\bullet-}$ Dismutation	10
CuZn-SOD	Homodimer	Cu and Zn	$O_2^{\bullet-}$ Dismutation Peroxidation Nitration	90
EC-SOD	Homotetramer	Cu and Zn	$O_2^{\bullet-}$ Dismutation Peroxidation	0

TABLE 27-4 Enzymatic Mechanisms to Detoxify or Remove ROS/RNS

Antioxidant Enzymes	Acronym	Expression of Antioxidant Enzymes in Lung Cell Types	Cellular Distribution
Superoxide dismutase	SOD		
Mn-SOD		Alveolar type II epithelial cells, septal tip of the alveolar duct, arterioles near the airways, alveolar macrophages	Mitochondria
EC-SOD		Bronchial epithelium, alveolar epithelium, epithelial cells lining intrapulmonary airways, ECM, endothelial cells lining arteries and veins, alveolar macrophages	Plasma membrane
CuZn-SOD		Bronchial epithelium, alveolar epithelium, mesenchymal cells, fibroblasts, arterioles, capillary endothelial cells	Cytosol, nucleus, lysosome, peroxisomes
Catalase	CAT	Airway and alveolar epithelial cells, type II pneumocytes, alveolar macrophages	Peroxisomes, mitochondria
Glutathione peroxidase-1	GSH-Px	Airway epithelial cells, bronchial epithelial cells, alveolar macrophages	Cytosol, mitochondria
Thioredoxin	TRX1 and 2	Bronchial epithelium, alveolar epithelium, macrophages	Cytosol, mitochondria
Thioredoxin peroxidase	TRXPrx	Bronchial epithelial cells, type II pneumocytes, macrophages	Cytosol
Thioredoxin reductase	TRR	Bronchial epithelium, alveolar epithelium, macrophages	Cytosol, mitochondria
Glutaredoxin	Glrx	Bronchial epithelium, alveolar macrophages	Plasma membrane, cytoplasmic vacuoles, nucleus
Glutathione S Transferase	GST	Bronchiolar Clara and alveolar type II cells, bronchial epithelial cells	Plasma membrane, cytosol, microsomes, mitochondria
Peroxiredoxin	PRX	Bronchial epithelium, alveolar epithelium, macrophages	Cytosol, nuclear matrix, peroxisomes, mitochondria
Heme oxygenase	HO	Alveolar type II cells, lung fibroblasts, monocytes, alveolar macrophages	Microsomes, mitochondria, endoplasmic reticulum

that catalyzes the removal of inorganic peroxides, lipid peroxides and hydroperoxides.[26,108–111] GSH-Px2 is localized to the gastrointestinal epithelia with substrate specificities similar to that of GSH-Px1. GSH-Px3 is a secreted form able to reduce lipid hydroperoxides.[110,111] This extracellular isoform accounts for 57% of the GSH-Px activity in the epithelial lining fluid, and GSH-Px1 contributes to 40% activity.[110,111] The fourth isoform, GSH-Px4, is an intracellular peroxidase that preferentially catalyzes the peroxidation of phospholipid hydroperoxides.[109]

Thioredoxins: Thioredoxins (TRXs), which contain an active site cysteine, serve as redox sensors while also reducing H_2O_2.[112,113] H_2O_2 oxidizes the reduced dithiol group (-SH HS-) in TRX to a disulfide bridge (-S-S-). TRXs can reduce protein disulfides (-SH) and protein sulfenic acid intermediates (-SO_3H) by cysteine thiol–disulfide exchanges.[10,11] Two human TRXs are expressed widely in various lung cell types (see Table 27-4). In addition to its direct antioxidant function, TRX, in cooperation with PRXs, augments gene expression of other antioxidant enzymes, including SOD.[114–118] TRXs also participate in refolding of oxidized proteins and activate transcription factors by reducing cysteines present in the DNA-binding site.[119] TRX can be activated by hypoxia, lipopolysaccharide, H_2O_2, microbial infections, and photochemicals. Thus, TRXs are powerful redox modulators, protects cells against oxidative stress, and participates in cell proliferation and survival.[114–118]

Glutaredoxins: Glutaredoxins (GRXs) are thiol–disulfide oxidoreductases with antioxidant capacity in human lung (see Table 27-4).[18,120–123] GRX regulates cellular redox state and redox-dependent signaling pathways via modulation of protein glutathionylation; it regulates the intracellular and extracellular homeostases of glutathionylated proteins and GSH.[18,120–124] These enzymes use glutathione as a cofactor and catalyze the reversible exchange of glutathione with protein thiol groups (see chemical reactions in Fig. 27-1). GRX enzymes are dependent on GSH/GSSG concentrations.[125]

Glutathione-S-Transferases: Glutathione-S-transferases (GSTs) are detoxification enzymes that require intracellular GSH for their catalytic activity. These antioxidant enzymes inactivate secondary metabolites, such as unsaturated aldehydes, epoxides, and hydroperoxides.[126] Three major families of GSTs have been described; the cytosolic GST, mitochondrial GST, and membrane-associated microsomal GST (see Table 27-4).[60] GSTs regulate eicosanoid and glutathione metabolism.[60,127] Under conditions of oxidative stress, cytosolic GST interacts with PRXs.[126] GST family enzymes are expressed in normal lung, mainly in the airways. They protect cells against a number of oxidizing species. GSTs have high genetic variability, and are implicated in the development of smoking-related nonmalignant and malignant diseases.[60,128–131]

Peroxiredoxins: Peroxiredoxins (PRXs) are broad-spectrum peroxidases that detoxify or reduce H_2O_2, peroxynitrite, and organic hydroperoxides (ROOH).[132,133] These are nonseleno-peroxidases whose antioxidant properties are dependent on redox-active cysteines.[133] Six different PRXs have been found in human lung (see Table 27-4).[134,135] These PRXs differ widely in their specificities for H_2O_2, lipid and phospholipid hydroperoxides.[134–138] PRX V and VI function as peroxynitrite reductases, and are protective in ROS/RNS-mediated lung injury.[134–136,139,140] PRXs also regulate peroxide-mediated signaling cascades related to cell proliferation, differentiation, and apoptosis by modulating cytokine-mediated induction of H_2O_2.[18,133,137,138]

Heme oxygenases: Heme oxygenase (HO) catalyzes the breakdown of pro-oxidant heme to generate equimolar amounts of carbon monoxide, ferrous iron, and biliverdin (Fig. 27-1). Biliverdin is then converted by biliverdin reductase to bilirubin, the antioxidant endproduct of the HO reaction.[141–144] CO transported to the lung has vasodilatory and antiapoptotic properties.[145–150] Iron is used for heme synthesis in the cells required for heme-containing proteins or transported to the bone marrow and other tissues.[18,141,144,151,152] There are three isoforms of HO, the inducible HO-1, and the constitutive forms, HO-2 and HO-3. During oxidative stress, transcriptional activation results in rapid induction of HO-1.[141,144,145] This adaptive response of HO-1 confers protection during inflammation and oxidative stress. HO-1 is expressed widely in the lung (see Table 27-4). Consistent with the antioxidant properties of HO-1, mice deficient in HO-1 are more susceptible to oxidative stress.[153,154] Overexpression

or induction of HO-1 suppresses inflammation in several models of chronic lung disease.[18,141,144,151,152]

CELLULAR SOURCES AND REGULATION OF ROS/RNS

IMMUNE CELLS

Inflammation is an adaptive response to infectious and noninfectious tissue injury. Recruited inflammatory cells emigrate from the pulmonary microcirculation into the airspaces where they become activated to generate ROS/RNS.

$NO^{\bullet}$ participates in pathogen killing by macrophages.[155] $NO^{\bullet}$ also delays fusion of phagosomes with lysosomes to form a functional phagolysosome, which enhances antigen processing/presentation of macrophages. Macrophages scavenge endogenous dying cells. Phagocytosis of dying cells requires the secretion of alarmins by dying cells to attract and preactivate phagocytes; these signals by dying cells ensures specific recognition and phagocytosis/efferocytosis, all of which involve redox regulation.[156,157]

Beyond the chemical interactions of $NO^{\bullet}$ and ROS that cooperatively eradicate pathogens, these redox-active biomolecules regulate cellular metabolism, inflammation, and tissue-repair functions. Cellular supply of substrates/cofactors for iNOS activity, including arginine, is required for $NO^{\bullet}$ production. However, in the absence of arginine or BH_4, uncoupled NOS becomes an $O_2^{\bullet-}/H_2O_2$ generator. The flavin-binding sites of the reductase domain of iNOS, eNOS, and nNOS are a source of $O_2^{\bullet-}$ generation in the absence of arginine.[155,158–161] Therefore, metabolic pathways that control arginine and BH_4 play a role in determining $NO^{\bullet}$–$O_2^{\bullet-}$ balance. Cellular arginine levels are dependent on uptake and transport mechanisms and the activation of NOS-arginase enzymatic systems that use arginine. Arginase activation produces ornithine, a starting metabolite for the production of polyamines that are critical molecules supporting DNA stabilization, ion channel transport, and cell proliferation.[155,158–161] Arginase is regulated by NOS and NOX activities; N-hydroxyarginine, a product of NOS, inhibits arginase, while $O_2^{\bullet-}$ increases arginase activity.[155,158–161] High arginase activity is associated with elevated ROS and low $NO^{\bullet}$ fluxes. $NO^{\bullet}$ antagonizes NOX2 assembly through the activation of PPARγ which, in turn, inhibits expression of the p47 subunit required for NOX2 activation.[155,158–161] Thus, $O_2^{\bullet-}$ production is suppressed when NOS activity and $NO^{\bullet}$ levels are high. $NO^{\bullet}$ also inhibits COX2 activity, reducing COX2-dependent ROS production.[162] Thus, as $NO^{\bullet}$ levels decline, ROS generation may increase via multiple mechanisms.

The balance between $NO^{\bullet}$ and ROS may play a key role in the orchestration and resolution of inflammation. RNS and ROS actively control innate and adaptive immune signaling. This aspect of redox function is evident in cells of myeloid lineage, such as monocytes, macrophages, and neutrophils. RNS and ROS produced by these cells participate in induction, maintenance, and/or termination of proinflammatory and anti-inflammatory signaling. Similar to the effect of $NO^{\bullet}$ on pathogen eradication, the temporal and spatial concentration profiles of $NO^{\bullet}$ are key determinants of immune-mediated processes.[155,158–161] A relationship between increasing steady-state levels of $NO^{\bullet}$ has been linked to regulation of expression of tumor suppressor gene p53 and apoptosis in murine and human macrophage cell lines.[163,164] Concentration- and time-dependent changes in the functional profiles of $NO^{\bullet}$ are evident from NO-mediated regulation of cell survival protein signaling cascade[165–169]

Macrophages rely primarily on the NOX2 complex to produce ROS,[5,17,157,168] although the oxidative burst of macrophages is less intense than that of neutrophils. Induction of the proinflammatory phase of an innate immune response is an early response in the immune activation process. This is defined as "classical activation" in macrophages (also called M1 macrophages), and is associated with the production and release of proinflammatory cytokines, proteases including MMP-9, transcription factors such as NF-κB as well as RNS and ROS, including $NO^{\bullet}$ and $O_2^{\bullet-}$. In addition to a role in pathogen eradication, the localized levels of ROS/RNS may dictate integrated signaling and the type of immune activation and determination of cellular phenotypes; ROS/RNS may also regulate crosstalk between proinflammatory and resolution pathways. Classical (proinflammatory) activation of macrophages is followed by an anti-inflammatory healing/tissue-repair phase, which is the ideal outcome of a successful innate immune response. These phases of the innate immune response are initiated by the pathogens or tissue injury, but are rapidly reenforced by the actions of anti-inflammatory cytokines released from macrophages that function in an autocrine manner.[157,158,170–172] These cytokines initiate downregulation of the proinflammatory phase and induction of the repair or tissue remodeling phase.

$NO^{\bullet}$ also affects function of T lymphocytes.[155,173–176] Low $NO^{\bullet}$ concentrations promote differentiation of IFN-γ producing Th1 (T helper 1) in mice and humans, mediated by cGMP activation.[177] During the immune repair/restoration phase, the collective activity of IL-4, IL-13, IL-10, and TGF-β suppress iNOS expression, thereby decreasing $NO^{\bullet}$ and shifting in favor of ROS.[155,173–177] An $NO^{\bullet}$-independent role for arginase has been identified in the differentiation of alternatively activated macrophages. Although arginase expression in macrophages is prominently associated with Th2 responses, part of its function is to sequester arginine away from effector T cells resulting in a reduced Th2 response; reconstitution with exogenous arginine blocks this reduced Th2 response. In general, low $NO^{\bullet}$ favors Th2 responses, and high $NO^{\bullet}$ augments Th1 responses, suggesting that a $NO^{\bullet}$/ROS balance may be a critical determinant of immune polarity.[155,178,179] Naïve lymphocytes exposed to high μmol concentrations of $NO^{\bullet}$, however, regulate the expansion and proliferation of regulatory T cells within lymphoid tissue.[155]

This concentration-dependent regulation by $NO^{\bullet}$ is seen in immunosuppression by heterogeneous immature myeloid cells called myeloid-derived suppressor cells (MDSCs).[180,181] Free radical producing subsets of these MDSCs are critical regulators of allergic airway inflammation.[182,183] $NO^{\bullet}$-producing cells suppress T cell proliferation and airway hyperresponsiveness (AHR), while $O_2^{\bullet-}$ enhance T cell proliferation and exacerbate AHR.[182,183] Immunosuppression by MDSCs also occurs in the tumor microenvironment in which $NO^{\bullet}$-mediated increase in cGMP activation, facilitates their binding to cytotoxic lymphocytes to reduce their proliferation.[184,185] Peroxynitrite and H_2O_2 are produced by the combined and cooperative activities of NADPH oxidase, arginase, and iNOS in different MDSC subsets. These drive several molecular blocks in T cells, ranging from the loss of TCRζ-chain expression, interference with IL-2 receptor–mediated signaling and nitration, and subsequent desensitization of the TCR.[184,185] Signal transducer and activator of transcription 3 (STAT3) is a critical regulator of MDSCs. STAT3-mediated upregulation of the NADPH oxidase and ROS levels enhances the suppressive potential of MDSCs.[155,184,185]

Inflammasome activation is an innate immune response to pathogens, but also accompanies the development of autoimmune and chronic inflammatory diseases. Inflammasomes are multicomponent platforms that sense a variety of danger signals, including bacteria, viruses, pathogenic crystals; aggregates through a family of nod-like receptors and consists of caspase-1 to process proinflammatory cytokines for activation.[186–188] Inflammasome activation starts with a priming signal followed by an activation signal. Studies with ROS scavengers suggest a role of ROS in inflammasome activation.[186–190]

EPITHELIAL CELLS

The epithelium of the airways and the alveoli is exposed to high levels of oxygen and to other environmental oxidizing species. Although inflammatory cells are major producers of RNS/ROS, resident lung cells such as epithelial cells, possess enzymatic systems for regulated production of RNS and ROS. DUOX enzymes are the primary

contributors of H_2O_2 in the airway epithelium.[25,191] DUOXs are expressed in ciliated surface cells, but not in nonciliated cells or basal cells of the upper airway. The levels of expression of DUOX1 and DUOX2 are selectively regulated by cytokines, with Th1 cytokines regulating DUOX2 and Th2 cytokines regulating DUOX1.[19,21,192,193] The highly inducible DUOX2 mediates host responses to infection and inflammation, while DUOX1 is constitutively expressed in noninflamed airways; DUOX2 plays a role in innate immunity, cell signaling, and mucus production.[19,21,193,194] The airway epithelium participates in innate immune response through the secretion of immune effectors such as mucin, antimicrobial peptides, and ROS to entrap or kill invading microbes. Epithelial cells use microbial pattern recognition receptors for innate immune system recognition to discriminate self from nonself.[19,21,192,193] The release of cytokines/chemokines by the epithelium induces neutrophil recruitment and the activation of transcription factors augmenting the inflammatory response. Lactoperoxidase (LPO) a heme-containing peroxidase in concert with DUOX-generated H_2O_2 generates hypohalous acids that kill pathogens.[25,194] A functional difference between the airway DUOX/LPO system and the phagocytic NOX2/MPO system is that the phagocytic system is active only during the respiratory burst, whereas DUOX generates H_2O_2 continuously.[19,21,192,193]

ENDOTHELIAL CELLS

Endothelial cells (ECs) also participate in innate immunity and crosstalk with immune cells. The importance of ECs in inflammation-induced vascular dysfunction is dependent on their ability to produce and respond to ROS and RNS. Inflammation may alter the balance between $NO^{\bullet}$ and $O_2^{\bullet-}$ within (and surrounding) ECs, which is necessary for normal vascular function. ROS produced by the endothelium play an important role in vascular pathology.[195,196] ROS can quench $NO^{\bullet}$ and mediate proinflammatory signaling. Targeting ROS-quenching enzymes catalase and SOD in ECs alleviates toxic effects of excessive ROS and suppresses proinflammatory mechanisms, including endothelial cytokine activation and barrier disruption.[197–199] Pulmonary EC-derived ROS play a pivotal role in EC activation and function. Alterations in EC phenotype contribute to vascular tone, permeability, and inflammatory responses and, thus, have been implicated in lung diseases, including pulmonary hypertension, ischemia-reperfusion (IR) injury, and adult respiratory distress syndrome.[200–202] Contrasting effects of NOS isoforms occur during IR injury, where eNOS appears to be protective and iNOS detrimental. Under homeostatic conditions, the low NO flux generated by eNOS prevents leukocyte recruitment and associated tissue damage through scavenging of ROS. However, when iNOS expression increases, $NO^{\bullet}$ levels rise and induce tissue injury.[200–202] Thus, the beneficial effects of specific NOS isoforms depend on the type of primary damaging event.

FIBROBLASTS

Fibroblasts and fibroblast-like mesenchymal cells participate in innate immunity and in tissue repair. Such cells are typically resident within the adult human lung[203]; however, studies have reported fibroblasts derived from bone marrow cells[204] or epithelial cells, the latter in a process known as epithelial-to-mesenchymal transition (EMT).[205] EMT is a process regulating cell plasticity, which allows epithelial cells to lose their polarity and specialized junctional structures, to undergo cytoskeletal reorganization, and to acquire morphological and functional features of mesenchymal-like cells. Myofibroblasts are the primary "effector" cells in tissue remodeling and pulmonary fibrosis.[206–208] Activation of the NADPH oxidase isoform, NOX4, mediates generation of H_2O_2, myofibroblast differentiation, contractility, and ECM production in response to TGF-β1.[209] In addition, NOX4 may play a profibrotic role by inducing apoptosis of lung epithelial cells, while myofibroblasts themselves acquire an apoptosis-resistant phenotype. Epithelial cell death may also be mediated indirectly by the paracrine secretion of H_2O_2 by activated myofibroblasts, supporting the concept that NOX4 may be responsible for both myofibroblast activation and epithelial cell disrepair.[210]

OXIDATIVE STRESS IN VARIOUS LUNG DISORDERS

Oxidative stress is implicated in the pathogenesis of both acute and chronic inflammatory and fibrotic lung diseases, some of which are discussed here (Fig. 27-2).

ASTHMA

Asthma is a chronic inflammatory airway disease.[211,212] ROS and RNS have been implicated in the pathogenesis of asthma.[20,213–216] Dysregulation in pathways that lead to oxidative stress or its defense may contribute to the initiation and severity of asthma.[8,20,213–218] Recruitment of inflammatory cells and ROS production have been documented in the airways of asthmatic subjects.[20,112,214,219–222] $O_2^{\bullet-}$ generation was observed highest in airspace cells at the sites of antigen challenge.[213] Leukocyte activation with induction of NADPH oxidase and production of $O_2^{\bullet-}$ and H_2O_2 correlate negatively with FEV_1 in asthmatic subjects.[222] Besides airway macrophages and eosinophils, blood eosinophils and monocytes are also major sources of ROS in asthmatic patients.[213,218,223]

Airway inflammation-associated oxidative stress in asthma may induce oxidative modifications of proteins or lipids.[89,90,224] Increased numbers of eosinophils and neutrophils in association with higher

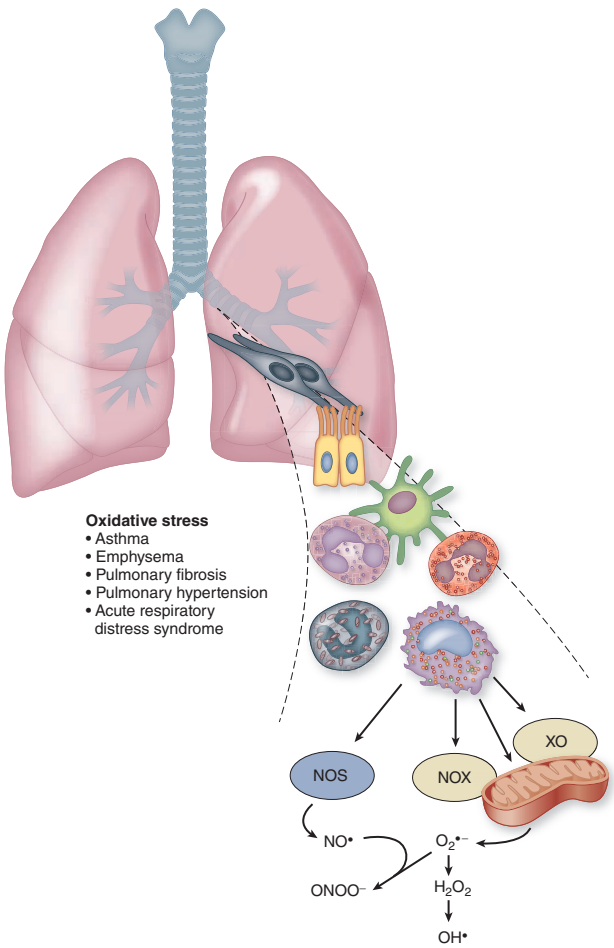

Figure 27-2 Oxidants initiate a number of pathological processes with a multitude of complex mechanisms that contribute to pathogenesis of both acute and chronic inflammatory diseases of the lung. Resident lung cells and recruited inflammatory cells together orchestrate these multilevel processes by regulating enzymatic pathways to balance the generation and metabolism of oxidants.

expression of peroxidases and other markers of eosinophil activation are found in bronchoalveolar lavage fluid (BAL) and bronchial tissues of asthmatics.[225,226] Oxidant products of neutrophil/eosinophil activation, 3-bromotyrosine, and MPO-mediated oxidants, such as chlorotyrosine are increased in asthmatics compared to control subjects; these have been implicated in the pathophysiology of severe asthma.[227,228] Other reactive products including malondialdehyde, thiobarbituric acid-reactive products, and 8-isoprostane, a biomarker of lipid peroxidation are also elevated in exhaled breath condensates of adults and children with asthma.[229–234] The precise mechanisms by which ROS exacerbate asthma is not known, but may involve effects on airway smooth muscle, mucin secretion, and T cell responses.[59,235] ROS can decrease β-adrenergic function in lungs and sensitize airway smooth muscle to acetylcholine-induced contraction.[103,236] H_2O_2 activates mitogen-activated kinases in tracheal myocytes and stimulates contraction of tracheal smooth muscle cells.[235] ROS also stimulates mucin secretion,[103,236] contributes to Th2 cell differentiation,[179] and promotes T cell proliferation via arginase and NADPH oxidase pathways.[182,183] Proinflammatory cytokines are elevated during airway inflammation, which activate oxidases leading to increases in ROS, the targets of which include receptor kinases, phosphatases, phospholipids, or nonreceptor tyrosine kinases.[16,237,238]

Another target of ROS is NO•. NO• metabolism appears to be dysregulated in asthma. Exhaled NO• is increased in asthmatics and is associated with airway inflammation.[54,55,239] Despite the expression and distribution of all three NOS enzymes in the airway, it is primarily iNOS that contributes to exhaled NO•. Induction of iNOS is observed at both transcriptional and translational levels principally in steroid-naïve patients.[41–43] In mild asthmatics, NO•, nitrate, and SNOs are enhanced in the lower airways.[54] Following antigen challenge, levels of NO• decrease, while nitrate increases without perturbing levels of nitrite and SNO.[54] Decreasing NO• levels correlates with increased nitrotyrosine formation from reaction of NO• with $O_2^{\bullet-}$.[54] Peroxynitrite, thus formed during inflammation, is toxic to microbes; however, it can also cause AHR. Nitrate can be generated from peroxidase-mediated RNS production.[54,240] SNOs are primarily formed during the late asthmatic response.[54,240] Thus, persistent increases in ROS and NO• lead to RNS formation and subsequent oxidation and nitration of proteins, which contributes to the dysregulation of airway inflammation in asthma.[15] NO• synthesis can reduce airway resistance mediated by increased production of the bronchodilator S-nitrosoglutathione (GSNO).[241–245] Two mechanisms to co-opt beneficial effects of NO• signaling are (1) shifting NO• to a more stable species, such as GSNO; or (2) reducing the local concentrations of ROS, potentially by augmenting the concentration of antioxidant enzymes in the extracellular space. Elevated NO• has also been attributed to the greater catabolic breakdown of the storage pools of GSNO during changes in the redox state of the lungs.[241–243] GSNOR, a glutathione-dependent formaldehyde dehydrogenase reduces GSNO to hydroxylamine, which is converted to NO by catalase.[245–247] GSNOR-deficient mice are protected from methacholine hyperreactivity following allergen sensitization and challenge, implicating GSNO in controlling airway hyperreactivity.[245–247]

High levels of ROS may overwhelm antioxidant defenses, causing significant loss of antioxidant activity in asthma.[8,67,70,213,217] Global loss of SOD activity, due to SOD deficiency, loss of circulating SOD activity, or inactivation of SOD via oxidative modification reflects the increased oxidative stress in asthmatic patients.[8,67,70,213,217] Oxidative modification-mediated reduction of catalase activity is also observed in asthmatics.[8] Although airway glutathione is increased in asthmatic patients, the ratio of oxidized to reduced glutathione is elevated reflecting an oxidizing microenvironment. Inhalation of exogenous ROS and RNS from exposures to environmental pollutants including ozone, diesel exhaust particles, and oxidant components of tobacco smoke, all contribute to additive oxidative stress, airway hyperreactivity, and inflammation in asthma.

EMPHYSEMA

Emphysema is a dominant phenotype of chronic obstructive pulmonary disease,[248–251] defined pathologically by airspace enlargement and destruction of alveolar septae.[248–251] Important contributing factors to the pathobiology of emphysema include inflammation, alveolar epithelial cell injury/apoptosis, protease–antiprotease and oxidant–antioxidant imbalances.[250–255] Inflammatory cells are recruited to the alveolar environment where they release elastases, cytokines, and oxidants that may then perpetuate the cycle of epithelial injury and inflammation.[250–255] In addition to inflammation, oxidative stress caused by cigarette smoke inhalation contributes to the pathogenesis of emphysema. Cigarette smoke contains $O_2^{\bullet-}$, •OH, and H_2O_2.[256] ROS are also generated by the chronic inflammation, characteristic of emphysema and that persists even after smoking cessation. Activated macrophages and neutrophils present in high numbers in the emphysematous lung are major producers of ROS.[257–262] Oxidative stress originating from constituents of cigarette smoke or products of inflammatory cells can overcome the antioxidative capacity of lung tissues and diminish antiprotease defenses.[263,264] A major consequence of oxidative stress is the activation of the transcription factor nuclear factor-κB (NF-κB), which activates transcription of proinflammatory cytokines.[251,263–265] Cigarette smoke also inhibits histone deacetylase, further promoting the release of proinflammatory cytokines.[266] Therefore, oxidant injury and lung inflammation act in concert to increase alveolar destruction or compromise maintenance and repair of alveolar structure. Antioxidant defenses are determinants of susceptibility to emphysema. A protective role for Nrf2, a transcription factor that regulates multiple critical antioxidant enzymes, has been identified in pulmonary emphysema.[267–270] SOD mimetics abrogate alveolar cell apoptosis and emphysema in mouse models.[271] This blockade of apoptosis prevents oxidative stress and emphysema further supporting the link between oxidative stress and apoptosis.[272,273]

PULMONARY FIBROSIS

Pulmonary fibrosis may result from a number of infectious and noninfectious injuries; by far, the most lethal form is idiopathic pulmonary fibrosis (IPF). IPF is characterized by exuberant ECM deposition, tissue contraction, and apoptosis resistance of (myo) fibroblasts, alongside apoptosis-prone and aberrantly differentiated alveolar type 2 cells.[18,274] This loss of epithelial–mesenchymal homeostasis and communication is central to the pathogenesis of IPF.[206,208] Myofibroblasts are key effector cells in tissue remodeling and fibrosis, typically contained in fibroblastic foci, which are a pathological hallmark of IPF. Chronic inflammation, aberrant wound healing, and degenerative aging processes have all been proposed as contributing to the pathogenesis of IPF.[275] Oxidative stress is common to these processes and is implicated in IPF pathogenesis.[276–278] Lung tissues and bronchoalveolar lavage fluid from IPF patients demonstrate a signature profile of oxidatively damaged proteins.[279–282]

NOX enzymes are a major source of ROS production in pulmonary fibrosis.[207,283–286] Several NOX isoforms, including NOX1,[287–289] NOX2,[290–293] and NOX4[209,285,294] have been implicated in tissue fibrosis. In addition to NOX enzymes, another potential source of ROS implicated in fibrosis is the mitochondria.[295,296] Epithelial cell death is a prominent feature in the IPF lung.[285,297,298] During acute lung injury in mice, NOX1-mediated ROS generation by endothelial and epithelial cells induces cell death.[299,300] NOX4 is expressed in hyperplastic alveolar type II cells in the lungs of IPF patients[294] and may mediate fibrogenic effects by promoting alveolar epithelial cell death.[214] NOX4-deficient mice are protected from bleomycin-induced pulmonary fibrosis through modulation of epithelial cell apoptosis *in vivo*.[214] EMT has been proposed to contribute to the accumulation of myofibroblasts in lung fibrosis.[301,302] ROS has also been shown to promote EMT.[303,304] A role for NOX4 in mediating

myofibroblast differentiation and lung fibrosis has been identified.[227] NOX4 mRNA expression is induced by the profibrotic cytokine, transforming growth factor-β1 (TGF-β1), while other NOX/DUOX isoforms were unaffected. NOX4-dependent generation of ROS, specifically H_2O_2, is required for TGF-β1–induced myofibroblast differentiation, ECM generation, and contractility of lung myofibroblasts.[209] Genetic or pharmacological targeting of NOX4 attenuates lung fibrogenesis in murine models of lung injury. Myofibroblasts from IPF patients also produce high levels of H_2O_2 in response to TGF-β1.[210] NOX4 may also contribute to pulmonary vascular remodeling associated with IPF.[305]

ROS generation from alveolar inflammatory cells, primarily neutrophils, and macrophages, may promote alveolar epithelial cell injury in IPF.[276,306] Mice deficient in NOX2 are protected from bleomycin-induced lung injury and fibrosis suggesting a role for inflammatory injury in this model.[307] The protection in $p47^{phox-/-}$ mice was accompanied by enhanced neutrophilic inflammation and MMP-9 activity.[307] Interestingly, airway neutrophils isolated from IPF patients exhibit elevated expression of $p47^{phox}$ and $p67^{phox}$,[308] supporting roles for the NOX2 isoform and neutrophilic inflammation in IPF. MMPs and tissue inhibitors of matrix metalloproteinases play a role in homeostasis and turnover of the ECM. In IPF, oxidation of the cysteine switch of MMPs by ROS activates the latent forms of MMPs.[210,276,309] ROS also regulates MMPs at the transcriptional level.[210,276,309] Thus, oxidative stress, from exogenous sources and multiple endogenous enzymatic sources, contributes to altered cellular homeostasis, including resident cells, recruited inflammatory cells, and their activated products.

PULMONARY HYPERTENSION

Pulmonary arterial hypertension (PAH) is a disorder of the pulmonary circulation characterized by endothelial dysfunction, intimal and smooth muscle proliferation.[310,311] Increased expression of ROS-generating enzymes, uncoupling of NOS enzymes, and mitochondrial dysfunction all contribute to the oxidative stress in PAH.[310,311] Upstream dysregulation of ROS/$NO^{\bullet}$ redox homeostasis impairs vascular tone, which then triggers the activation of antiapoptotic and mitogenic pathways, leading to cell proliferation and obliteration of the vasculature.[310,311]

ROS derived from the NOX2 and NOX4 isoforms contribute to the long-term responses of the pulmonary vasculature to hypoxia.[312–315] Increased NOX4 expression in pulmonary artery smooth muscle cells (PASMC) has been linked to hypoxia-dependent PAH in mice.[315] Levels of the NOX1 and 2 regulatory proteins, $p47^{phox}$, and Rac1 are increased in both the endothelial and SMC layers of pulmonary arteries[316–318] accompanied by an increase in NOX-derived $O_2^{\bullet-}$.[316–318] NOX-derived ROS is associated with medial thickening, disordered proliferation and migration, impaired angiogenesis, and disturbed fibrinolysis.[316–320] Another source of vascular ROS is xanthine oxidoreductases (XORs), including xanthine dehydrogenase (XD) and xanthine oxidase (XO). In PAH, XO activity dominates over XD activity and is a significant source of ROS production. XO is increased in idiopathic PAH patients compared with healthy controls.[320] In a rat model of chronic hypoxia-induced PAH, lung XO activity was enhanced and inhibition of XO activity with allopurinol reduced the right ventricular hypertrophy and the pulmonary vascular thickening.[316–319,321] Clinical studies have also demonstrated alterations of TGF-β1 expression in adult PAH patients.[322] In hypoxia-dependent PAH in mice, hypoxia increases the expression of TGF-β1 and NOX4 expression.[314,315] TGF-β–induced NOX4 expression and NOX4-mediated ROS production have been implicated in PASMC proliferation.[323,324] TGF-β1 also induces proangiogenic effects by upregulating VEGF.[325] In PASMCs, cyclic stretch induces VEGF expression, both at the mRNA and protein levels[326]; this is preceded by both an increased expression and secretion of TGF-β1 and an increase in ROS generation by the activation of NOX enzymes.[323,324] In models of spontaneously developing PAH, mitochondrial dysfunction and hyperpolarization is associated with reduction in ROS production.[327,328] Decreases in ROS inhibit a $O_2^{\bullet-}$ sensitive K^+ channel leading to pulmonary vascular constriction.[327–329]

Nitrosative stress with increased nitrated eNOS is an early contributor to the development of PAH.[316,330–333] The vasodilatory effects of cGMP are mediated through protein kinase G (PKG).[316,330–333] However, nitration of PKG, attenuates the kinetic activity of PKG, impairs vasodilation, and increases smooth muscle proliferation.[334] This nitration-dependent reduction in PKG activity is observed in lungs of patients with PAH.[334] Nitration of carnitine acetyltransferase, an enzyme that maintains normal mitochondrial function is another indicator of early nitrosative stress in PAH.[335]

Alterations in arginine metabolism have also been noted in models of PAH,[317] where the activity of arginase that catalyzes the hydrolysis of L-arginine to L-ornithine and urea is increased,[158,317,336,337] and the activity of the caveolar enzymes involved in the recycling of L-citrulline and other L-arginine byproducts back to L-arginine are attenuated.[158,317,336,337] Further, increased arginase activity is associated with formation of polyamines and L-proline, which promote smooth muscle cell growth and collagen synthesis. In addition, uncoupling of NOS enzymes occur when L-arginine becomes limited resulting in the production of ROS.[318,338–340] Therefore, high arginase activity may promote aberrant pulmonary vascular remodeling and neointima formation in PAH.[158,336,337]

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute respiratory distress syndrome (ARDS) is a severe form of acute lung injury and a syndrome of acute pulmonary inflammation.[341,342] ARDS is characterized by sudden onset, impaired gas exchange, and an increase in pulmonary capillary permeability.[341–343] Oxidative damage by ROS and RNS has been implicated in the pulmonary vascular endothelial damage that characterizes ARD. Several factors contribute to the intracellular and extracellular oxidant stress in ARDS patients.[341–343] The high inspiratory concentrations of oxygen required to achieve adequate arterial oxygenation, infection, or extrapulmonary inflammation lead to increased ROS production. This, combined with decreased antioxidant capacity of tissues resulting from consumption of the natural antioxidants leads to cellular damage and loss of vasomotor control.[341–343] Measurements of antioxidant concentrations have revealed an oxidant–antioxidant imbalance in ARDS patients. The production of toxic levels of ROS and RNS not only leads to damage of key molecules in cells but can signal changes in cellular responses such as proliferation, apoptosis, and necrosis.[341–343] H_2O_2 has been detected in the exhaled breath, while MPO and oxidized α1-antitrypsin have been detected in BAL of ARDS patients.[341–343] Nitration and oxidation of alveolar space proteins including the surfactants have been identified *ex vivo* in patient samples with ARDS.[341–343] Overabundance of ROS also induces adhesion molecules and cytokines that contribute to endothelial injury.

CONCLUSION

The lungs are exposed to exogenous oxidants from the environment, in addition to endogenous generation of ROS/RNS from resident and recruited inflammatory cells. Several measures of oxidative stress have been used to estimate oxidative stress within the lungs; however, current approaches do not adequately differentiate between different oxidative mechanisms and are used as biomarkers of oxidative damage. Further investigations are needed to discover biomarkers that correlate and differentiate between various types of oxidative injury. While progress has been made to delineate mechanisms through which oxidants initiate and propagate cell and tissue damage, specific signaling pathways and mechanisms of

activation are not well understood. Elucidation of these mechanisms may provide strategies for intervention to prevent or protect from disease pathogenesis or progression. A better understanding of factors that influence individual susceptibility will also be useful in risk stratification of patients. Investigations on how early life exposures to oxidants impact airway morphology, immune function, and the airway epigenome may also aid in determining susceptibility, disease expression, and progression.

CHAPTER 28

Fibroblasts in Lung Homeostasis and Disease

Yong Zhou
Victor J. Thannickal

INTRODUCTION

Fibroblasts are the primary cellular source responsible for synthesis and remodeling of the extracellular matrix (ECM). These cells are in communication with the surrounding microenvironment and play a key role in lung homoeostasis. Following lung injury, fibroblasts are activated and undergo myofibroblast differentiation. Myofibroblasts are key effector cells for lung repair following injury. In addition to fibroblasts, perivascular pericytes and mesenchymal stem cells (MSCs) of bone marrow (BM) origins contribute to myofibroblast population. There is evidence that type II alveolar epithelial cells can differentiate into myofibroblasts in vitro through a process known as epithelial–mesenchymal transition (EMT); however, the role of EMT in fibrogenesis in vivo remains controversial. Myofibroblasts express α-smooth muscle actin (α-SMA), develop robust actin filaments (stress fibers), and acquire contractile activity. The function and behavior of myofibroblasts are regulated by both biochemical and physical cues in the surrounding microenvironment. The fate of myofibroblasts is a key determinant of whether an injury–repair response will resolve or progress into fibrosis. Destruction and aberrant remodeling of the ECM is a common feature of many lung diseases, including pulmonary fibrosis, asthma, chronic obstructive pulmonary disease (COPD), and lung cancer. Targeting myofibroblasts and tissue remodeling may provide a novel and effective strategy for treating a number of chronic lung diseases.

FIBROBLAST BASICS

WHAT ARE FIBROBLASTS?

Fibroblasts were described as early as in the late 19th century, based on their location and their microscopic appearance.[1] These are elongated cells that display a spindle-shaped morphology with extended cell processes.[2] Fibroblasts are ubiquitous in tissues and organs throughout the body and communicate with other cells such as epithelial cells (Fig. 28-1). Despite its discovery over a century, a reliable and specific molecular marker that identifies the fibroblast is currently lacking. Many indicators of fibroblast phenotype have been suggested in the previous studies (e.g., fibroblast-specific protein 1, vimentin, prolyl 4-hydroxylase, procollagen-Iα2, etc.).[3] However, none of them are specific to fibroblasts and/or are present in all fibroblasts. Currently, fibroblasts are identified by their ability to adhere to plastic, and their lack of markers that indicate other cell lineages. Clearly, better cellular markers with absolute specificity for fibroblasts will aid in the study of sources, differentiation, and phenotypic plasticity of fibroblasts.

Tissue-Specific Fibroblasts and Fibroblast Heterogeneity

Fibroblasts isolated from different tissues display a considerable degree of heterogeneity in phenotype and activity.[4] Such diversity is evident by divergent and specific gene expression patterns among fibroblasts isolated from distinct anatomical locations.[5] For example, fetal skin fibroblasts express high levels of collagen types I and V, whereas fetal lung fibroblasts lack collagen I and V expression.[5] Instead, fetal lung fibroblasts exclusively express lung-specific forkhead family transcription factors FOXF1 and FOXP1.[5] Tissue-specific fibroblasts may provide location-specific signaling for a given anatomic origin as well as important positional cues for wound healing and tissue regeneration. Besides the differences in fibroblasts from different anatomical sites, fibroblasts derived from a single tissue are often composed of subsets of different fibroblasts.[6] For example, fibroblast subpopulations isolated from lung differ in expression of surface markers such as Thy-1, cytoskeletal composition, lipid content, and cytokine profile.[7,8] Fibroblasts isolated from lungs with active fibrotic disease such as in the fibroblastic foci of human idiopathic pulmonary fibrosis (IPF) are morphologically and functionally distinct from fibroblasts isolated from normal lungs,[9] suggesting that selective

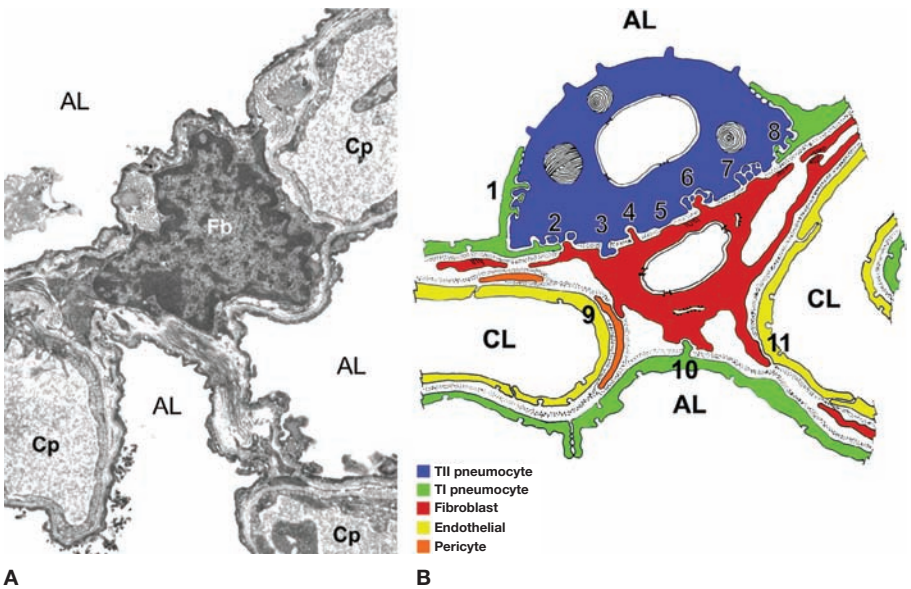

Figure 28-1 An interstitial fibroblast in the alveolar wall. **A.** A transmission electron microscopic image showing the structural organization of the alveolar wall in canine lung. Unique structural features that influence neutrophil emigration into the lung. Physiol Rev. 2003;83(2):309–336.)*

expansion of specific fibroblast subsets is associated with the pathogenesis of this disease.

■ FIBROBLAST FUNCTIONS

The important functions of fibroblasts include deposition of ECM, regulation of inflammation, and wound healing.[10] Fibroblasts produce ECM-degrading proteases such as matrix metalloproteinases (MMPs) and their inhibitors, tissue inhibitors of metalloproteinases (TIMPs), supporting their crucial roles in regulating ECM turnover and homeostasis.[11]

ECM Production

One of the major functions of fibroblasts is the production of ECM. The ECM in the lung provides an essential scaffold on which cells can proliferate and differentiate. It also provides the lung with tensile strength and elasticity that are essential for ventilation. Lung ECM is composed of fibrillar proteins, glycoproteins, proteoglycans (PGs), and polysaccharides, each of which has distinct biochemical and biomechanical properties; these include collagens, elastin, fibronectin, PGs, hyaluronan (HA), laminin, vitronectin, and thrombospondin.[12] Type I and type III collagens are the most abundant collagens in the lung interstitium (ratio 3–6:1). Collagen IV is mainly localized to basement membranes. A fibroblast is estimated to synthesize approximately 3.5 million procollagen molecules/cell/day.[13,14] Depending on tissue type and age, 10% to 90% of synthesized procollagens are intracellularly degraded by lysosomal enzymes (e.g., cathepsins B, D, and L). It is postulated that regulation of procollagen-degrading rate may provide an important mechanism for rapid secretion of collagen in response to injury without de novo synthesis of new proteins.

Secretion of Proteolytic Enzymes and Inhibitors

The ECM is a dynamic structure that undergoes constant remodeling. Remodeling of the ECM is regulated by complex mechanisms including stimulatory and inhibitory mediators derived from resident cells in the local environment.[14] Fibroblasts synthesize a variety of proteolytic enzymes and inhibitors that enable them to control the assembly and turnover of the ECM. MMPs are either secreted by fibroblasts as inactive zymogens or anchored to the cell surface. Activation of MMPs occurs by disruption of interactions between the prodomain and the catalytic domain through either the proteolytic cleavage or the conformational change of the proenzymes.[15] MMPs function as proteinases that degrade most ECM proteins. Proteolysis of the ECM macromolecules by MMPs results in the release of cryptic fragments and neoepitopes that promote angiogenesis and cellular migration.[16,17] MMPs also have critical roles in the posttranslational regulation of other proteins including latent growth factors stored within the ECM, membrane receptors, and other proteases.[18] Hence, MMPs impact cell behavior both through modulation of cell–matrix interactions and through regulation of other signaling molecules. MMPs themselves are regulated by their endogenous inhibitors, TIMPs. TIMPs block MMP activity by noncovalently binding to the MMP active site. A tight balance between MMP proteolysis and TIMP expression is required for maintaining lung homeostasis.[19]

Innate Immune Function

Fibroblasts are capable of synthesizing many inflammatory cytokines that are initially thought to be exclusively produced by inflammatory cells.[20] Fibroblast-derived cytokines play an important role in the amplification and perpetuation of the immune response. Fibroblasts generate constitutive and cytokine-induced C-C and C-X-C chemokines that recruit inflammatory and immune cells to the injured cites.[21] Lung fibroblast–derived granulocyte macrophage colony–stimulating factor promotes the survival of eosinophils, which contributes to the fibrotic response in the lung.[22,23] Direct contacts between fibroblasts and T cells promote the production of adhesion molecules and cytokines by the T cells.[24] Interactions between fibroblasts and mast cells facilitate de novo production of eotaxin, a potent eosinophil chemoattractant.[25] The impact of interactions between fibroblasts and inflammatory cells are bidirectional. Th2 cells produce IL-4 that recognizes specific receptors on fibroblasts and modulates fibroblast proliferation and biosynthetic capacity.[26] Eosinophils release mitogens that augment fibroblast proliferation and collagen production.[27,28] Fibroblasts are the main producers of ECM proteins. Since ECM components affect multiple functions and properties of inflammatory and immune cells,[29,30] it suggests a further regulatory role of fibroblasts in innate immune response by the effects on the ECM.

Regulation of Tissue Interstitial Fluid Pressure and Microhemodynamics

Fibroblasts regulate tissue interstitial fluid volume, pressure, and microcirculation hemodynamics by generation of actomyosin-derived forces and transmission of the forces to the ECM via transmembrane integrins.[31] Such mechanical interactions between fibroblasts and matrix are subjected to modulation by soluble factors, such as PDGF that results in increased interstitial fluid pressure, and TNF-α that leads to decreased interstitial fluid pressure.[32,33] Fibroblasts express ecto-5′-nucleotidase (CD73) and soluble guanylyl cyclase (cGC) that affect hemodynamics,[34] suggesting a role of fibroblasts in the regulation of the microcirculation.

MYOFIBROBLASTS: EFFECTOR CELLS IN TISSUE REPAIR

■ HISTORICAL CONTEXT

Myofibroblasts were first identified as fibroblastic cells with a strong muscle cell–like contractile filamentous apparatus in the granulation tissue of healing wounds.[35] These cells are present in organs with increased remodeling, such as in development, inflammation, fibrosis, cancer invasion, and metastasis.[36] Myofibroblasts display prominent cytoplasmic actin microfilaments (stress fibers) (Fig. 28-2). They are connected to one another with adherens and gap junctions as well as to the ECM with focal adhesion (FA) complexes.[37] Myofibroblasts may be further classified into subtypes based on the presence or absence of vimentin, desmin, and/or α-SMA in cytoskeletal filaments. Expression of these proteins varies upon tissue types and is subjected to the regulation by environmental factors.[38] Alternatively, myofibroblasts can be simply classified into two subpopulations, proto-myofibroblasts and mature myofibroblasts.[39]

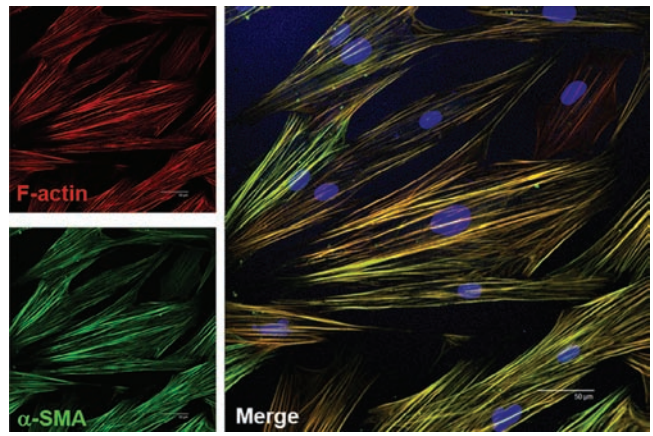

Figure 28-2 Myofibroblasts are characterized by de novo synthesis of α-SMA and incorporation of α-SMA into filamentous actin stress fibers. Scale bar: 50 μm.

TABLE 28-1 Myofibroblast Markers

Marker	Cellular Overlap
Cytoskeletal component	
α-SMA[40]	Smooth muscle cells
Desmin[41]	Hepatic stellate cells, cardiomyocytes
Cofilin[42]	Smooth muscle cells
GB 42-antigen[43]	Smooth muscle cells
Paladin 4Ig[44]	Smooth muscle cells
Tropomyosin-1[45]	Cardiomyocytes
Cell membrane receptor	
Angiotensin II type 1 receptor (AT1R)[46]	Cardiomyocytes, smooth muscle cells
Integrin $a_{11}b_1$[47]	Musculoskeletal cells
Thy-1[48]	Lipofibroblasts
Endosialin[49]	Cardiomyocytes, smooth muscle cells, adipocytes
Cadherin-11[50]	Tenocytes, endothelial cells, mesenchymal cells
Frizzled-2[51]	Smooth muscle cells
Extracellular protein	
Collagen I, III, IV, V, VI[52]	Various cells
Tenascin C[53]	Smooth muscle cells
Fibronectin ED-A[54]	Smooth muscle cells
Osteopontin[55]	Osteoblasts, osteocytes, chondrocytes
Periostin[56]	Preosteoblasts, cardiomyocytes

Proto-myofibroblasts are partly differentiated myofibroblasts that contain α-SMA–negative actin stress fibers, whereas mature myofibroblasts possess extensive network of α-SMA–positive stress fibers and large FAs (termed supermature FAs). α-SMA is the most widely used marker for identification of myofibroblasts (Fig. 28-2). In addition, studies have identified several other markers and modulators of myofibroblasts (Table 28-1). However, a specific and universal myofibroblast marker remains to be identified.

■ ORIGIN OF MYOFIBROBLASTS

The precise origin of myofibroblasts remains unsolved at present. Studies have suggested that local fibroblasts, perivascular pericytes, BM-derived MSCs, tissue MSCs, and epithelial/endothelial cells (through epithelial/endothelial–mesenchymal transition) are among potential cellular sources for myofibroblast population.

Resident Fibroblasts—Mesenchymal Stem Cells

Fibroblasts are the most widely accepted origin for myofibroblasts.[57,58] Fibroblasts influx into injured sites from the surrounding tissue and differentiate into myofibroblasts in response to extracellular stimuli including biochemical and physical cues.[59] These stimuli induce intrinsic changes in gene expression and stress fiber formation that characterizes myofibroblast differentiation.

MSCs that reside in tissues lack hematopoietic and leukocyte markers, but may express α-SMA.[60] Tissue MSCs have been described in the dermal sheath that surrounds the hair follicle facing epithelial stem cells.[61] These MSCs are involved in papilla regeneration and differentiate into myofibroblasts in response to environmental insults. It has been reported that MSCs from subcutaneous fat are responsible for collagen accumulation in scars.[62] Following lung injury, myofibroblasts were found to originate from perivascular and peribronchial sources.[63] It is likely that there are tissue MSCs in the human adult lung,[64] which become activated and undergo myofibroblast differentiation in response to lung injury. In support of this notion, a previous study has provided evidence for isolation of postnatal MSCs from different organs including liver, kidney, and lung.[65]

Pericytes

Pericytes are perivascular cells located on the abluminal side of endothelial cells in microvasculature.[66] These cells share developmental origins with fibroblasts, but differ from fibroblasts by the fact that pericytes anatomically connect with endothelial cells through cell processes within capillary basement membrane, whereas fibroblasts do not directly interact with endothelial cells.[67] The normal function of pericytes includes the regulation of vascular tone and blood flow through expression of contractile microfilaments (actin, myosin) and intermediate filaments (desmin, vimentin).[68] Microvascular pericytes differentiate into myofibroblasts in diffuse cutaneous systemic sclerosis, providing a link between microvascular damage and skin fibrosis.[69] Recent studies using the genetic fate-mapping approach have clearly demonstrated that pericytes are a major cellular source of myofibroblasts in animal models of acute injury to muscle, dermis, and kidney.[70,71] In addition, HSCs, pericyte-like cells in the liver, are the primary myofibroblast progenitors in mouse models of alcoholic and toxic liver fibrosis.[72]

Bone Marrow–Derived Mesenchymal Cells

BM-derived MSCs are self-renewable, multipotent progenitor cells with the capacity to differentiate into lineage-specific cells that form bone, cartilage, fat, tendon, and muscle.[73] Compared with hematopoietic stem cells, MSCs are more radio-resistant and reside mostly in BM stroma. BM-derived MSCs do not express hematopoietic markers and can be isolated as Lin-CD45-CD31-CD34-CD133-Sca-1+Vitamin A-cells.[74] In vitro evidence for a BM origin of myofibroblasts was first presented more than four decades ago. By plating BM cells on culture dishes, colonies consisting of cells exhibiting elongated or polygonal cytoplasm and clear nuclei were formed.[75] Transplantation studies using Y chromosome or green fluorescent protein (GFP) as a marker of donor cells provide in vivo evidence that (myo)fibroblasts in wounded skin, lung fibrosis, and intestinal fibrosis may derive from the BM.[76] There is evidence that monocytes may represent the major BM-derived cell population that contributes to myofibroblasts in fibrotic lesions, at least in some contexts.[77]

Circulating fibrocytes express markers of hematopoietic cells (CD34), leukocytes (CD11b, CD13, and CD45), and fibroblast products (collagens I, III, and fibronectin). These cells are distinguished from monocytes/macrophages, dendritic cells, and B cells by their lack of expression of specific markers for these cell lineages. Circulating fibrocytes migrate into injured tissues and have been identified in a number of fibrotic conditions.[78] Studies have identified the potential for fibrocytes to participate in wound healing and pathological scarring.[78,79] However, the direct contribution of fibrocytes to myofibroblast population during wound healing and fibrosis remains controversial. Evidence for and against fibrocyte-to-myofibroblast differentiation exists.[76,80] It is likely that instead of direct differentiation into myofibroblasts, circulating fibrocytes contribute to fibrosis by production of profibrogenic paracrine mediators that target resident cells.

Epithelial–Mesenchymal Transition

EMT refers to as a process through which fully differentiated epithelial cells lose their epithelial characteristics (e.g., apico-basal polarity, polygonal cell shape, and tight and adherens junctions) and acquire properties of mesenchymal cells (e.g., elongated cell shape, increased motility, and contractility). Epithelial cells undergoing EMT are characterized by downregulation of epithelial markers

(e.g., E-cadherin and ZO-1) and concomitant upregulation of mesenchymal markers (e.g., FSP1 and α-SMA) in the injured epithelium.[81] There is overwhelming evidence that primary epithelial cells cultured in vitro undergo EMT in response to a stimulatory input of soluble growth factors (e.g., TGF-β, EGF, and HGF) and/or ECM components (e.g., collagen).[82] However, the concept of in vivo fibrogenic EMT has been challenged by new epithelial lineage tracking studies in a variety of models of kidney, lung, and liver fibrosis in animals.[83]

FACTORS REGULATING FIBROBLAST ACTIVATION AND MYOFIBROBLAST DIFFERENTIATION

Fibroblasts isolated from the site of a healing wound or from fibrotic tissue secrete higher levels of ECM constituents and proliferate more than their normal counterparts isolated from healthy organs.[84] Such an increased activity is referred to as "fibroblast activation." Activated fibroblasts express α-SMA, leading to the term "myofibroblasts." Fibroblast activation and differentiation into myofibroblasts are regulated by various stimuli, including biochemical factors, biophysical cues from the ECM, and epigenetic modifications.

Growth Factor and Cytokine-Mediated Activation

Fibroblasts become activated by stimulation with cytokines such as TGF-β1, PDGF, and FGF2, which are released from injured epithelial cells, infiltrating mononuclear cells such as monocytes and macrophages as well as the ECM.[85–88] TGF-β1 is a pluripotent cytokine that plays a central role in the development of fibrosis. TGF-β1 is sequestered in a latent form (termed latent TGF-β1) in the ECM.[89] Latent TGF-β1 becomes activated in a spatially and temporally regulated fashion in response to injury.[89] Active TGF-β1 binds to its membrane receptors (TGF-βRI and TGF-βRII) and signals through both Smad-dependent canonical pathway and Smad-independent noncanonical pathway that promote fibrotic gene expression.[39] Active TGF-β1 also increases the assembly of stress fibers and FAs that are required for the development of cellular contractility.[39] In addition, prototypic cytokines produced by CD4+ T cells such as IL-13/IL-4 and IL-17 exert profibrotic effects on fibroblasts and play a crucial role in the development of fibrosis.[90,91]

Components of Vascular/Coagulation System

Coagulation proteases such as factor Xa and thrombin activate fibroblasts through receptor-mediated effects elicited by high-affinity thrombin receptor, proteinase-activated receptor (PAR)-1.[92] PAR-1 signaling promotes fibroblast proliferation via the autocrine production of PDGF and CTGF, and drives fibroblast differentiation into myofibroblasts via αvβ5-dependent TGF-β activation.[93,94] Thrombin upregulates expression of the fibrinolysis inhibitor, plasminogen activator inhibitor (PAI)-1, resulting in increased fibrin matrix.[95] Fibrin matrix inhibits surfactant function and contributes to alveolar collapse and traction of remaining airspaces (honeycombing).[92] Lysophosphatidic acid (LPA), a platelet-derived molecule during blood coagulation, promotes fibroblast activation and pulmonary fibrosis by activation of latent TGF-β1 through LPA receptor.[96] Endothelin-1 (ET-1), an activator of extrinsic coagulation cascade, exerts potent mitogenic and profibrotic effects on fibroblasts.[97] Transgenic mice expressing human ET-1 transgene have been shown to develop progressive pulmonary fibrosis.[97]

Reactive Oxygen Species

Accumulating evidence indicates that oxidative stress and reactive oxygen species (ROS) production, mainly in the form of superoxide and hydrogen peroxide, play a significant role in myofibroblast differentiation.[98] The NAD(P)H oxidases of the Nox family have been identified as the enzyme system that is primarily responsible for ROS generation by fibroblasts in response to injury and are recognized as key mediators of myofibroblast differentiation and matrix accumulation in lung fibrosis.[99] Nox4, the most abundant Nox isoform in the lung, has been characterized as a "constitutively active" enzyme, meaning that the enzymatic activity of Nox4 is primarily regulated at the level of gene expression. TGF-β1 increases Nox4 expression and ROS production in lung fibroblasts, which mediates TGF-β1–dependent myofibroblast differentiation.[99] A similar mechanism for myofibroblast differentiation has been demonstrated in cardiac fibroblasts, renal fibroblasts, and mesangial cells.[100,101] Nox4 is also associated with TGF-β1–induced cellular contractility in lung myofibroblasts and cytoskeletal remodeling in vascular smooth muscle cells as well as endothelial cells.[99,102,103] Together, these results indicate that Nox-derived ROS regulate fibroblast morphology, contractility, and differentiation.

Mechanical Stress

Fibroblasts respond to mechanical cues, including externally applied forces, interstitial fluid flow, and matrix rigidity sensed through internally generated forces. Externally applied forces such as stretch provoke diverse fibroblast signaling responses, including activation of mitogen-activated protein (MAP) kinases, [104]Akt,[105] and focal adhesion kinase (FAK). It has been shown that stretch augments TGF-β release and signaling, and promotes the myofibroblast phenotype.[106,107] The continuous interactions between cell-generated forces and the resistance of matrix to cellular forces strengthen cell–matrix contacts and develop α-SMA–positive stress fibers characterizing myofibroblast differentiation.[39,108] Normal lung fibroblasts grown on polyacrylamide gels with a stiffness grade similar to fibrotic lungs undergo myofibroblast differentiation.[109] The effects of matrix stiffening on myofibroblast differentiation may occur through TGF-β–dependent intrinsic and/or TGF-β–independent extrinsic mechanotransduction (see Section "Mechanotransduction in Myofibroblastsinsser").[109,110] Interstitial fluid flow induces fibroblast proliferation, collagen alignment, and fibroblast-to-myofibroblast differentiation in the absence of exogenous mediators.[111,112] $\alpha_1\beta_1$ integrin appears to play an important role in the specific response to interstitial fluid flow.[111] Taken together, these results suggest that fibroblasts are mechanosensitive and are programmed for matrix production, contraction, and differentiation in the presence of mechanical stimuli.

Epigenetic Regulation

The findings that specific signatures of gene profile in myofibroblasts are "memorized" over passages suggest that epigenetic modifications may be involved in the regulation of myofibroblast differentiation.[113] Epigenetic regulation of myofibroblastic phenotype involves DNA methylation, histone modification, and sequence-specific microRNAs (miRNAs). DNA methylation at CpG islands is associated with expression of myofibroblast marker α-SMA in lung cells. Type II alveolar epithelial cells that do not express α-SMA exhibit high levels of methylation at the three CpG islands in the regulatory regions of ACTA2 gene encoding α-SMA protein, whereas lung (myo)fibroblasts exhibit significantly low levels of DNA methylation at these sites.[114] Inhibition of DNA methyltransferase (DNMT) induces α-SMA expression, whereas overexpression of DNMT suppresses α-SMA expression in lung fibroblasts.[114] Inhibition of DNA methylation activates PPARγ and NF-κB, transcription factors known to suppress ACTA2 gene expression,[115] suggesting that modifications of DNA methylation may also indirectly regulate α-SMA expression by inactivation of PPARγ and NF-κB. Histone acetylation has been shown to regulate myofibroblast differentiation. It has been shown that histone deacetylase (HDAC)4 is an essential epigenetic regulator of TGF-β1–induced skin fibroblast-to-myofibroblast differentiation.[116] HDAC8 binds to α-SMA and the binding is likely to regulate actin cytoskeleton–derived cellular contractility.[117]

miRNAs are single-stranded RNA molecules that target multiple mRNAs and induce silencing of multiple transcripts. It has been shown that miR-21 mediates TGF-β1–induced lung myofibroblast differentiation by targeting Smad7, a major inhibitor of TGF-β signaling.[118] In contrast, downregulation of miRNA let-7d expression by TGF-β results in increased mesenchymal gene expression (e.g., ACTA2) in multiple epithelial cell lines, indicative of EMT.[119] miR-132 inhibits MeCP2 and PPARγ expression, resulting in enhanced α-SMA expression in lung fibroblasts.[115]

Other Factors

Wnt ligands induce fibroblast activation and collagen synthesis.[120] β-catenin, a transcription factor and a downstream signal transducer of Wnt signaling, was found to accumulate in the nuclei of cells located in the fibroblastic foci of IPF lungs.[121] Selective inhibition of β-catenin–mediated transcription attenuates lung fibrosis in bleomycin-induced mouse model.[122] These studies suggest a crucial role of the Wnt/β-catenin signal in fibroblast activation and lung fibrosis. Integrins have been implicated in the differentiation of proto-myofibroblasts into mature myofibroblasts.[123] Integrin $\alpha_5\beta_1$ is associated with α-SMA expression in differentiating myofibroblasts.[123] Large clusters of $\alpha_5\beta_1$ are present in the FAs of mature myofibroblasts.[123]In addition, environmental stimuli including hypoxia and hyperglycemia as well as direct contacts between fibroblasts and leukocytes have been reported to be associated with fibroblast activation.[124,125]

■ MECHANICAL ASPECTS OF MYOFIBROBLASTS

Myofibroblast Contractility

Acquisition of contractility similar to smooth muscle cells is a defining feature of myofibroblasts. Myofibroblasts generate intracellular contractile forces by ATP-powered sliding of actin–myosin filaments.[126] Compared with Ca^{2+}-regulated rapid and reversible contraction in smooth muscle cells, myofibroblast contraction is relatively slow, sustained, and nonreversible.[127] Myofibroblast contractility is primarily regulated by the Rho family of small GTPases (Rho, Rac, and Cdc42) and their downstream targets, primarily myosin light-chain kinase (MLCK) and myosin light-chain phosphatase (MLCP).[39] α-SMA expression and incorporation of α-SMA into stress fibers contribute to myofibroblast contractility.[128] However, the mechanism by which α-SMA regulates myofibroblast contractile force formation is not clear. Myofibroblast contractility facilitates a normal wound healing process by limiting and closing the exposed surface area of the wound. Myofibroblasts disappear from the wound site when a normal repair process is successfully completed. The persistence of myofibroblasts is associated with aberrant wound repair and leads to tissue fibrosis/scarring. Increasing evidence suggests that myofibroblast contractility may provide a feed-forward mechanism (known as mechanotransduction; see Section "Mechanotransduction in Myofibroblasts") that sustains fibrosis. Inhibiting myofibroblast contractility by targeting Rho/Rho kinase (ROCK)/actin cytoskeleton signal pathway selectively activates mitochondria-dependent intrinsic apoptotic pathway in myofibroblasts and ameliorates bleomycin-induced mouse lung fibrosis.[129]

Sensing Matrix Stiffness

The ECM in healthy organs has well-defined mechanical properties that fall within a physiological range.[130] Changes in matrix stiffness that occur in pathological states, such as fibrosis and cancer, have profound effects on cell morphology, proliferation, migration, and gene expression.[130] Characterization of the mechanical properties of normal and fibrotic lung matrix demonstrates increased matrix rigidity in both human IPF and experimental models of lung fibrosis.[131,132] It is believed that protein cross-linking enzymes such as lysyl oxidase (LOXL2) and tissue transglutaminase (TG2) and/or matrix-degrading enzymes such as MMPs regulate the stiffness of ECM, although the precise mechanisms remain to be determined. Fibroblasts sense changes in matrix stiffness by cell–matrix adhesions.[133] Transmembrane integrins at FAs act as direct mechanosensors on the cell membrane by providing a physical link between intracellular actin cytoskeleton and the ECM. The cytoplasmic domain of integrins interacts with signaling molecules at the FA sites (e.g., FAK and c-Src). Thus, integrins also act as indirect mechanosensors to regulate cell function and behavior by modulating FA signals.[134] Matrix stiffness sensing depends largely on cellular contractility and actin cytoskeleton integrity. Fibroblast contractility generates cytoskeletal tension that serves to transmit mechanical information from the ECM. Disruption of actin cytoskeleton–mediated contractility blocks matrix stiffening–induced myofibroblast differentiation.[109]

Mechanotransduction in Myofibroblasts

Mechanotransduction is a process in which cells sense mechanical stimuli and convert mechanical signals into biochemical signals. Recent studies suggest that mechanotransduction in myofibroblasts with prolonged survival/resistance to apoptosis may provide a feed-forward mechanism for progression of fibrosis, as in IPF. It has been reported that lung myofibroblast contraction promotes latent TGF-β activation, the most potent fibrogenic cytokine characterized to date, in the extracellular compartment (Fig. 28-3).[110,135] In this process, the actomyosin apparatus in myofibroblasts generates contractile forces that are transmitted across the cell membrane to the ECM. The force transmission results in a conformational change of the ECM-bound latent TGF-β1 complex, resulting in the release/exposure of active TGF-β1 from the latent complex. The finding suggests an extrinsic mechanotransduction pathway in which mechanical forces derived from intracellular stress fibers are transduced to the ECM and converted into TGF-β1 fibrogenic signal capable of regulating fibrosis.

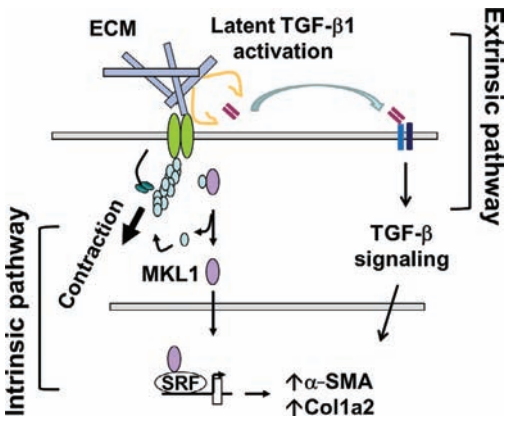

Figure 28-3 Contractile forces promote myofibroblast differentiation via intrinsic and extrinsic mechanotransduction pathways. In the intrinsic mechanotransduction pathway, mechanical stimuli from stiff/fibrotic ECM promote G-actin polymerization into F-actin. This results in the release of MKL1 and its nuclear translocation. MKL1 binds to serum response factor (SRF) in the nucleus to form a transactivation complex and activates fibrotic gene expression that specifies myofibroblast differentiation. In the extrinsic mechanotransduction pathway, actomyosin-generated contractile forces pull against stiff/fibrotic ECM. This results in a conformational change of latent TGF-β1 complex, which releases active TGF-β1 from the latent molecule. Active TGF-β1 then binds to its receptors on the cell membrane and initiates TGF-β signaling that promotes fibrotic gene expression.

In contrast to TGF-β–mediated extrinsic mechanotransduction pathway, an intrinsic mechanotransduction pathway in which the myofibroblast contractile signal is converted into a nuclear signal by transcription factor coactivator megakaryocytic leukemia protein (MKL)1 (also known as MAL/MRTF-A) has also been identified (Fig. 28-3).[109] MKL1 is a serum response factor (SRF) coactivator that constitutively binds to monomeric G-actin in the cytoplasm.[136] In response to matrix stiffening, normal lung fibroblasts undergo extensive actin cytoskeletal remodeling and develop contractile forces. This changes actin cytoskeletal dynamics that favors G-actin polymerization into F-actin. Polymerization of G-actin into F-actin results in the release of MKL1 from G-actin. The liberated MKL1 enters into nucleus, where it binds to SRF and targets to the CArG sequence in the promoter region of ACTA2 gene and col1a2 gene, leading to gene activation.[137] TGF-β neutralizing antibody does not block MKL1-mediated α-SMA expression,[109] suggesting that MKL1-mediated intrinsic mechanotransduction is independent of TGF-β–dependent extrinsic mechanotransduction. In addition to sensing mechanical stimuli, integrins are important mechanotransducers that allow bidirectional transduction and conversion of external forces into intracellular response (outside-in signaling) and internal forces (e.g., stress fiber-derived contractile forces) into extracellular and/or FA signals (inside-out signaling).[39,138] Besides integrins, stretch-activated ion channels, receptor tyrosine kinases (RTKs), CD44, and syndecan-4 are potential mediators of mechanotransduction as well.[139–142] However, mechanical stress may also regulate gene expression in fibroblasts through mechanotransduction-independent mechanisms. It has been shown that cyclic strain increases the mRNA level of tenascin-C within 1 hour in cultured fibroblasts[143] and this induction does not require synthesis of new proteins.[144]

Myofibroblasts in Tissue Homeostasis and Wound Repair

Myofibroblasts play a role in the regulation of differentiation and homeostasis of adjacent epithelia. Such mesenchymal–epithelial interactions are crucial for morphogenesis and organogenesis.[145] Myofibroblasts regulate epithelia by secretion of soluble growth factors and production of basement membrane molecules.[146]

Myofibroblasts play important roles in both normal and aberrant wound repair. As mentioned earlier, myofibroblast contractility facilitates wound closure. During the resolution phase, myofibroblasts produce MMPs and TIMPs that change the local microenvironment from a balance favoring ECM deposition to matrix degradation.[147] Interconnected gap junctions of myofibroblasts allow the electrical signals created by cyclic ion movements to be transmitted through the syncytium and the length of the resident organ.[148] Myofibroblasts sustain their activated state in fibrosis/hypertrophic scarring even when the initial insults have regressed. Myofibroblasts in such a sustained state of activation continue to secrete ECM constituents, growth factors, and cytokines. These result in a self-perpetuating autocrine loop that further stimulates myofibroblast differentiation and prevents normal resolution of tissue injury. In addition to fibrosis/hypertrophic scars, diseases associated with myofibroblastic phenotype include inflammatory pseudotumors, cancer metastasis, and neoplastic transformation of the myofibroblasts themselves.

■ THE FATE OF MYOFIBROBLASTS

The fate of myofibroblasts is a key determinant between normal repair and fibrosis. In normal wound healing, myofibroblasts gradually disappear after wounds are closed. Persistent myofibroblast differentiation is associated with pathological wound healing and fibrosis. Understanding of the physiological clearance of activated fibroblasts is particularly important for developing therapeutic strategies for persistent/progressive fibrosis such as IPF.

Apoptosis

Apoptosis has been suggested as an intriguing possibility for the elimination of myofibroblasts from healing wounds and reversible fibrosis.[149] An earlier study has observed that myofibroblasts undergo apoptosis in granulation tissue on which a vascularized skin flap is grafted.[150] Reduced growth factor and increased MMP expression appear to link to myofibroblast cell death.[151] In addition, disruption of cell–matrix interactions using RGD peptides or soluble fibronectin promotes myofibroblast anoikis, a type of apoptosis that is induced by inadequate or inappropriate cell–matrix interactions.[152] In reversible liver fibrosis, HSC-derived myofibroblasts undergo apoptosis in parallel to the reduction of the total number of HSCs in the recovery phase.[153] Hepatic myofibroblast apoptosis appears to occur by a Fas ligand (APO-1/CD95)–mediated extrinsic pathway.[153] Pharmacological inhibition of ROCK inhibits actin polymerization, downregulates the constitutive expression of antiapoptotic protein, Bcl-2, in IPF lung myofibroblasts; this results in release of cytochrome *c* from mitochondria, triggering mitochondria-dependent intrinsic apoptosis pathway. Furthermore, Fasudil-induced myofibroblast apoptosis ameliorates bleomycin-induced lung fibrosis in mice.[129] This study indicates that targeting mechanosensitive signaling in myofibroblasts may offer an effective approach for treatment of fibrotic disorders (Fig. 28-4).

Dedifferentiation

A recent study showed that HSC-derived myofibroblasts regress to a more quiescent state upon the removal of the fibrogenic stimuli in a carbon tetrachloride–induced mouse model of liver fibrosis.[72] The finding suggests that reversion of myofibroblasts to a more quiescent phenotype may be a second possibility for the clearance of these cells. However, such quiescent HSCs are reactivated more rapidly (in comparison to native HSCs) by subsequent insults, and result in more robust liver fibrosis,[72] suggesting that myofibroblast regression may be an intermediate step toward the resolution of fibrosis. Although regression to an inactive precursor cell may limit the activity of myofibroblasts, this does not appear to completely eliminate the potential for reactivation.

Senescence

Cellular senescence is associated with the loss of the ability of cells to replicate their genome and enter permanent growth arrest in the G1/G0 cell-cycle phase.[154] Although senescent fibroblasts do not respond to mitogens, they remain metabolically active and are resistant to apoptosis. Cellular senescence often occurs by telomere shortening and subsequent activation of p53 and p21 and/or inactivation of pRB and activation of p16.[154] Senescence may also be triggered by other forms of cellular damage, including oxidative stress, DNA damage, and oncogene activation.[154] Myofibroblast senescence has been proposed as an antifibrotic mechanism by limiting the proliferative capacity of fibrogenic fibroblasts and/or by modulating the cellular microenvironment.[155,156] However, this basic assertion is inconsistent with the clinical observation of an increased risk of fibrotic disease with advancing age. This highlights the complexities of cellular senescence in tissue injury repair processes, and supports the concept that the plasticity and fate of senescent cells may be altered with aging which, ultimately, determines the outcome of the tissue repair response.

MYOFIBROBLASTS IN LUNG DEVELOPMENT AND DISEASE

■ ALVEOLOGENESIS

Lung development is a complex process involving reciprocal interactions between mesoderm-derived mesenchyme and endoderm-derived epithelium. Alveolar myofibroblasts are present during alveologenesis, but absent in the adult lung.[157] Myofibroblasts surround

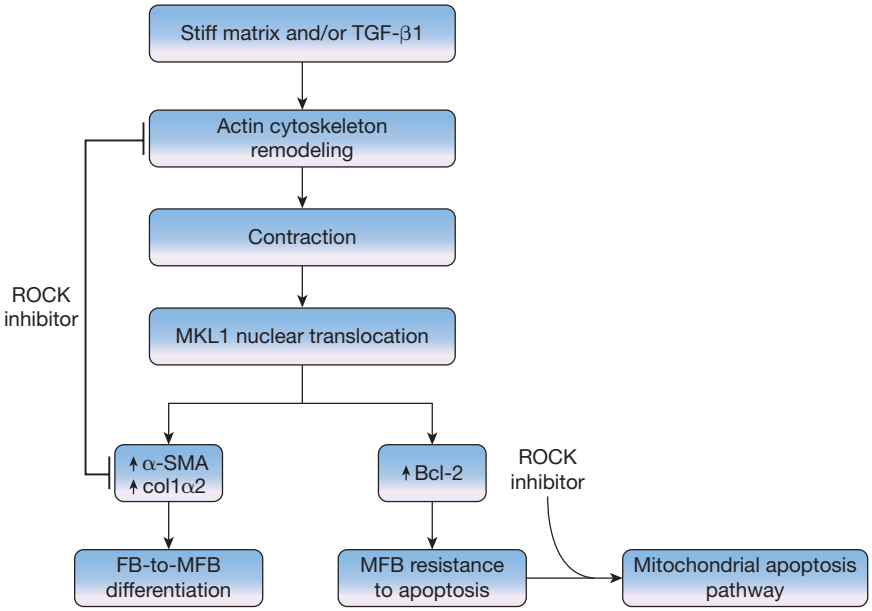

Figure 28-4 Mechanosensitive signaling in myofibroblasts as a target for antifibrotic therapy. In response to extracellular biomechanical and biochemical stimuli, such as matrix stiffness and active TGF-β1, lung fibroblasts undergo actin cytoskeleton remodeling and activation of the actomyosin contractile system, which result in MKL1 translocation from cytoplasm to the nucleus, where it activates fibrogenic genes that specify myofibroblast differentiation. Inhibition of ROCK blocks actin cytoskeletal reorganization, fibroblast acquisition of contractile activity, and MKL1 nuclear translocation, preventing fibroblast-to-myofibroblast differentiation. Inhibition of ROCK activity disrupts the actin cytoskeleton required for myofibroblast contractility. This deactivates constitutively activated MKL1 signaling in myofibroblasts, resulting in downregulation of the antiapoptotic protein, Bcl-2, and activation of the intrinsic apoptotic pathway.

the distal lung epithelial tubules and buds in the pseudoglandular stage of lung development. The absence of alveolar myofibroblasts is associated with deficient secondary septation and the failure of alveolar development.[158] Although alveolar myofibroblasts play an essential role in the morphogenesis of pulmonary alveolar septa, mechanisms involved in the regulation of alveolar myofibroblast survival and clearance in the process of alveologenesis are poorly understood and need further investigation.

■ PULMONARY FIBROSIS

Pulmonary fibrosis is characterized by excessive synthesis and deposition of ECM proteins in the lung parenchyma, resulting in deficient gas exchange. IPF is the most common and lethal diffuse fibrosing lung disease, with a mortality rate that exceeds that of many cancers. Currently, there is no FDA-approved pharmacological therapy for patients with IPF. The pathogenesis of IPF remains elusive. The current paradigm posits that repeated alveolar epithelial injury and persistent myofibroblast activation are central to the progression of IPF.[159] Regardless of the origins, myofibroblasts isolated from IPF lungs have increased migratory activity, ability to deposit ECM, and prolonged survival/resistance to apoptosis compared to their normal counterparts.[159] Abnormal myofibroblast survival is a key determinant of whether fibrosis will progress or resolve.[160] The survival of IPF myofibroblasts has been found to be regulated by multiple antiapoptotic signals.[48] These include enhanced responsiveness to growth factors and fibrotic cytokines; impaired cyclooxygenase-2 expression and consequential reduction in prostaglandin E2 production; decreased caveolin 1 (CAV1) and PTEN expression; and increased antiapoptotic protein expression as well as signals from the extracellular microenvironment. Myofibroblasts isolated from fibrotic lungs induce cytotoxic effects on epithelial cells. Coculturing of myofibroblasts with lung epithelial cells results in epithelial cell apoptosis by FAS–Fas ligand (FAS–FasL)-dependent and -independent mechanisms.[161,162] Epithelial cell apoptosis can cause further lung injury that augments lung fibrosis. Myofibroblasts produce cytokines and growth factors that signal to the epithelium, resulting in damage to the alveolar basement membrane that prevents reepithelialization.[163] Myofibroblast-produced chemokines promote the recruitment of immune cells and fibrocytes that actively participate in fibrotic progression.[164,165]

■ ASTHMA

Airway remodeling in patients with asthma encompasses the structural alterations that lead to persistent airflow limitation. Both smooth muscle cells and (myo)fibroblasts have been implicated in the pathogenesis of airway remodeling in asthmatic airways. In asthmatic patients, susceptibility to injury and aberrant repair responses result in fibroblast activation and myofibroblast differentiation, leading to subepithelial fibrosis.[166] Reduced airway remodeling in antileukotriene therapy is due, in part, to diminished myofibroblasts in asthmatic airways.[167] Viral infections are major triggers of acute asthma exacerbations.[168] The susceptibility to viral infections in asthmatic patients is not limited to epithelial cells. Rhinoviruses have been detected in subepithelial cells including fibroblasts, likely due to the disrupted and inflamed epithelium.[169] Fibroblasts from asthmatic patients have enhanced abilities for replication of rhinoviruses and subsequent production of IL-6 and IL-8, resulting in vigorous proinflammatory responses.[170] TGF-β augments rhinovirus replication in fibroblasts isolated from asthmatic patients.[171]

■ EMPHYSEMA

Emphysema is characterized by the progressive destruction of pulmonary alveoli. A vast majority of cases of pulmonary emphysema is associated with chronic lung injury induced by cigarette smoke. Chronic smoke exposure induces inflammation, protease/antiprotease imbalance, oxidative stress, and death of bronchiolar and alveolar epithelial and endothelial cells.[172] Cigarette smoke reduces lung fibroblast proliferation and migration, and induces fibroblast apoptosis.[173,174] In addition to the cytotoxic effects, cigarette smoke inhibits elastin synthesis and cross-linking in fetal lung fibroblasts.[175,176] Interactions between fibroblasts and alveolar epithelial cells are greatly reduced in the emphysematous lung,[177] suggesting that the repair and regeneration function of fibroblasts are impaired. Emphysema fibroblasts display features of myofibroblast differentiation and senescent phenotype characterized by enlarged morphology and cell-cycle arrest.[178,179]

■ NON–SMALL-CELL LUNG CANCER

Carcinoma-associated fibroblasts (CAFs) constitute a major portion of reactive tumor stroma. CAFs express α-SMA and high levels of collagens and ED-A FN, indicating that these cells are of myofibroblast characteristics.[180] CAFs are responsible for dense ECM deposition around tumors and thus have been considered as a defense mechanism for tumor growth. In established tumors,

CAFs synthesize cytokines/growth factors (e.g., TGF-β1) and ECM-degrading proteases (e.g., MMPs) that promote angiogenesis, recruitment of inflammatory cells, cancer cell proliferation, invasion, and metastasis.[3] CAF-associated prognostic factors have been identified in non–small-cell lung cancer (NSCLC). In adenocarcinomas, carbonic anhydrase IX expression has been found a better prognostic predictor in CAFs than in cancer cells.[181] Expression of podoplanin, a lymphatic endothelial cell marker, in CAFs is associated with shorter survival in patients with NSCLC.[182] In squamous cell carcinomas, MMP-2 expression in CAFs is found to be a significant unfavorable prognostic factor.[183] While expression of PDGF-B, PDGF-C, and PDGFR-α in cancer cells is associated with a negative prognosis, expression of PDGF-A, PDGF-B, PDGF-D, and PDGFR-α in CAFs is favorable prognostic indicators.[184] In addition, it has been found that stromal expression of PDGF-B, PDGF-D, and PDGFR-α is associated with less nodal metastasis.[185] Clinical prognostic values of TGF-β and FGF in NSCLC have been evaluated in the previous studies.[186–189] Due to the conflicting results, the prognostic roles of TGF-β and FGF2 in NSCLC remain uncertain.

TARGETING MYOFIBROBLASTS AND MATRIX REMODELING FOR LUNG DISEASE THERAPIES

Tissue remodeling in response to injury is a common pathological feature observed in many lung diseases including IPF. Dysregulation of fibroblast function and matrix metabolism are crucial to the aberrant injury repair in IPF lungs. Currently, there are no treatments that specifically target myofibroblast-associated pathologies in IPF.

Pirfenidone inhibits fibroblast proliferation and collagen synthesis and attenuates bleomycin-induced lung fibrosis in mice.[190,191] Two randomized, double-blinded placebo-controlled trials for pirfenidone in patients with IPF (CAPACITY) have been recently completed.[192] In one trial, pirfenidone showed a significant reduction in FVC decline at all study timepoints in patients with IPF compared to the placebo control. In the other trial, an apparent pirfenidone effect on predicted FVC change in IPF patients was observed until week 48. However, the difference between groups was not significant at week 72. These data suggest that pirfenidone has a favorable benefit risk profile and represents a potentially effective treatment for IPF.

PDGF is a potent mitogen and chemoattractant for fibroblasts and induces procollagen production by fibroblasts in vitro. Targeting PDGF receptor with imatinib mesylate, a tyrosine kinase inhibitor, has been shown to prevent bleomycin-induced mouse lung fibrosis.[193] However, a randomized, placebo-controlled trial showed that imatinib does not improve survival or lung function in patients with mild to moderate IPF.[194]

TGF-β1 is the most potent inducer of fibroblast ECM production characterized to date and promotes fibroblast to myofibroblast differentiation. Several types of pharmacotherapy to block TGF-β have been developed including antibodies, soluble receptors, intracellular signaling pathway inhibitors and agents that target the cell surface receptors for TGF-β (TGF-βRI/II).[195,196] A phase I clinical trial with TGF-β–neutralizing antibody (Genzyme) has begun in patients with IPF. Orally active TGF-βRI kinase inhibitors have been shown to attenuate bleomycin-induced mouse lung fibrosis.[197] Since TGF-β has important homeostatic functions in the regulation of immune response and tumor suppression, therapeutic strategies that directly blocks TGF-β may yield undesirable side effects. Alternatively, targeting latent TGF-β activation has become a more favorable approach for the antifibrotic therapy. Integrins are important mediators for in vivo activation of latent TGF-β.[198] $\alpha_v\beta_6$ integrin plays the primary role in regulating epithelial latent TGF-β1 activation.[199] Mouse studies have shown that inhibition of $\alpha_v\beta_6$ integrin blocks bleomycin- and radiation-induced lung fibrosis and this integrin is also abnormally regulated in human fibrotic diseases.[199] Stromedix, a humanized monoclonal antibody to integrin $\alpha_v\beta_6$, is currently in phase II clinical trial in IPF. $\alpha_v\beta_5$ integrin regulates mechanical tension–induced latent TGF-β1 activation in lung (myo)fibroblasts.[110] This integrin is coexpressed with α-SMA–positive myofibroblasts, but absent on hyperplastic epithelial cells in the fibroblastic foci in IPF.[200] The GPI-linked Thy-1 blocks mechanical tension–induced latent TGF-β1 activation, presumably by disruption of the binding of latent TGF-β1 with $\alpha_v\beta_5$ integrin.[135]

Inhibition of excess ECM generation, deposition, and stabilization, and increasing matrix degradation has become important targets for pharmacological therapy. Cytokines including CTGF, PDGF, ET-1, and IGF can induce fibroblast/myofibroblast activation and regulate matrix production. Inhibition of all of these cytokines can inhibit pulmonary fibrosis in a variety of in vivo models of fibrosis.[90,201–203] MMPs including MMP-1, 3, 7 among others have been implicated in the pathogenesis of pulmonary fibrosis,[204] although the exact role of the MMPs in the pathogenesis of pulmonary fibrosis remains not known. Matrix cross-linking enzymes are responsible for the regulation of ECM stabilization. Cross-linking makes matrix potentially more resistant to degradation and may favor fibrosis progression. TG2 induces the cross-linking of collagen and fibronectin, resulting in stabilization of the matrix.[205] TG2 is elevated in many forms of human and murine pulmonary fibrosis.[205] Inhibition of the extracellular cross-linking function of TG2 results in inhibition of ECM generation and cross-linking in the lung.[205] Irreversible inhibitors of TG2 have been developed and are available from several commercial sources. LOXL2, another matrix cross-linking protein, catalyzes the first step in the formation of cross-links in collagens and elastin.[206] LOXL2 cross-links fibrillar collagen, making it more resistant to homeostatic turnover. LOXL2 is induced by TGF-β and is upregulated in IPF.[207,208] Administration of a monoclonal anti-LOXL2 antibody (AB0023) in either a prophylactic manner or a therapeutic manner significantly attenuates bleomycin-induced fibrosis in mice.[208] Phase II clinical studies utilizing the LOXL2 inhibitor GS-6624 are currently carrying out for patients with primary sclerosing cholangitis, nonalcoholic steatohepatitis, and cirrhosis secondary to hepatitis C and/or HIV.

CONCLUSION AND PERSPECTIVES

The understanding of the physiology and pathophysiology of fibroblasts has greatly advanced in the past few decades. It has become increasingly clear that fibroblasts and myofibroblasts play important roles in human health and disease. Despite this, many fundamental questions remain to be answered. The origins of myofibroblasts remain to be clarified. It is not known whether myofibroblasts of various origins exhibit different characteristics and functions in the injury and repair process. Identification of specific markers for fibroblasts will allow their specific isolation and more precise characterization, both in vitro and in vivo. In addition, specific markers could facilitate genetic animal studies allowing the specific targeting of these cells. The independent and interactive roles of cytokines, ECM, and mechanical forces in the regulation of the structure and function of fibroblasts and myofibroblasts need to be characterized.

The identification of myofibroblasts as key cells and potential targets in fibrotic diseases such as IPF has led to the concept that targeting these cells may be a promising approach for disease therapy. Interesting approaches that target myofibroblasts and the ECM include termination of myofibroblast persistence by inducing their apoptosis or their reversion to nonfibrogenic cell phenotypes, interference with collagen cross-linking and ECM stiffening by controlling the activities of protein cross-linking enzymes (e.g., LOXL2 and TG2), and the use of miRNAs as potential therapeutic targets. We believe that these novel approaches will eventually lead to more effective treatments for patients with fibrotic lung diseases.

CHAPTER 29

Approach to the Patient with Respiratory Symptoms

Michael A. Grippi
Robert M. Senior
Jeffrey P. Callen

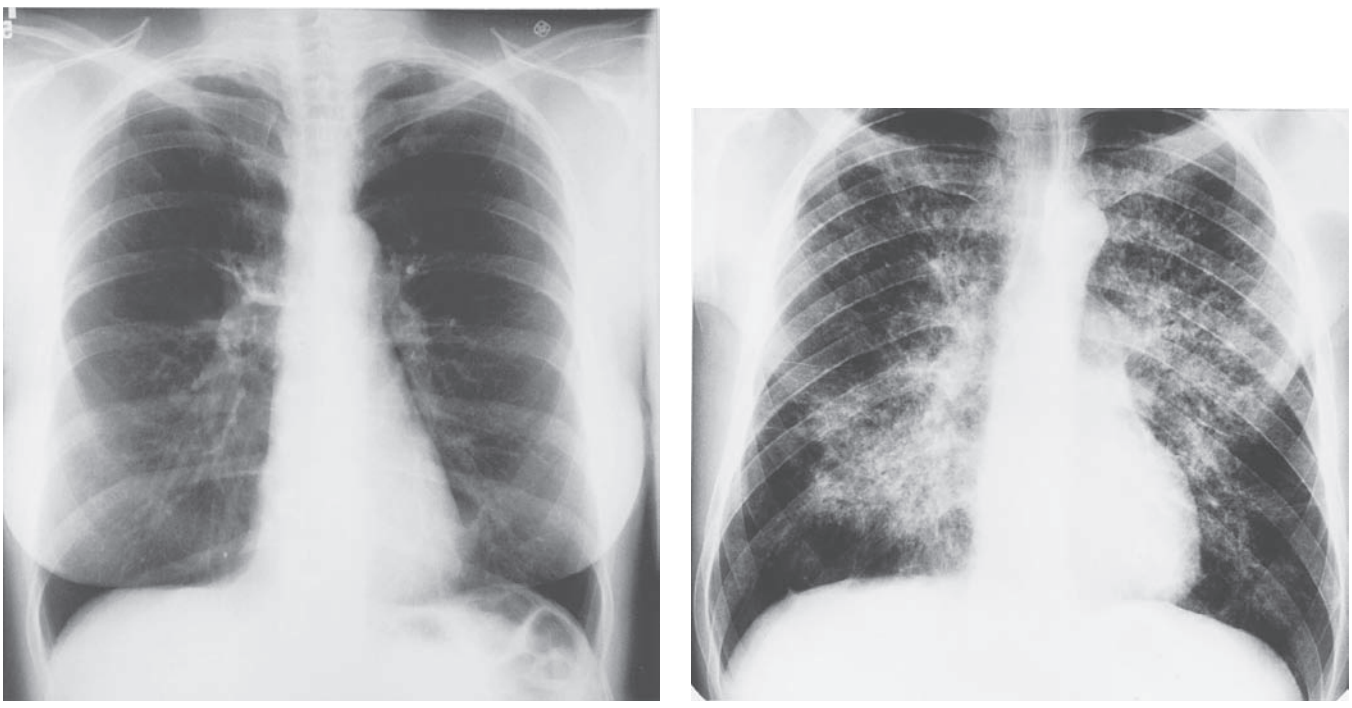
The most common respiratory complaints prompting medical evaluation are shortness of breath and cough. Less frequent are hemoptysis and thoracic pain. As in any medical assessment, a detailed history and thorough physical examination are of paramount importance. Use of plain chest radiography for routine screening, once popular in the hope of uncovering silent disease amenable to therapy, is not routinely employed, as it has not been proven to decrease mortality or to be cost effective. Chest radiography is now usually reserved for patients who have clinical manifestations of thoracic disease; serial chest radiographs often provide invaluable clues regarding the underlying problem. More sophisticated imaging techniques, including computed tomography (CT),[1,2] along with tests of lung function, help complete the clinical picture.

HISTORY

Although seasoned clinicians may be adept at quickly spotting telltale diagnostic clues, a comprehensive medical history is central to patient evaluation. The history should include a detailed inventory of exposure to air-borne substances that may result in lung injury. One of the most common offenders is cigarette smoke. An attempt should be made to quantify the exposure.

Often, the workplace is the site where toxic air is inhaled. An almost forgotten exposure to a toxic inhalant 20 years ago may explain certain types of pulmonary or pleural diseases. Symptoms that appear to improve during weekends or other periods away from work may be a clue to an occupational exposure that causes a respiratory ailment. A newly installed home humidifier or an air conditioning system that incorporates stagnant pools of water can point the way to resolving a mysterious illness. Brief residence in an area where either cryptococcosis (southwestern United States) or histoplasmosis (southern and midwestern United States) is endemic may help clarify the nature of an illness that mimics tuberculosis. A recent visit to a South or Central American country may bring into focus a more remote possibility (e.g., South American blastomycosis) (Fig. 29-1).

The history should include a thorough evaluation of prior and current medical problems. Rheumatologic disorders, such as systemic sclerosis (scleroderma), may be associated with interstitial lung disease, aspiration pneumonia due to esophageal involvement, or pulmonary vascular disease. Certain malignancies often metastasize to the lung (e.g., breast or colon carcinoma), or predispose to development of venous thromboembolism (e.g., pancreatic carcinoma). Infection with the human immunodeficiency virus (HIV) should not be overlooked, since pulmonary complications are often



A B

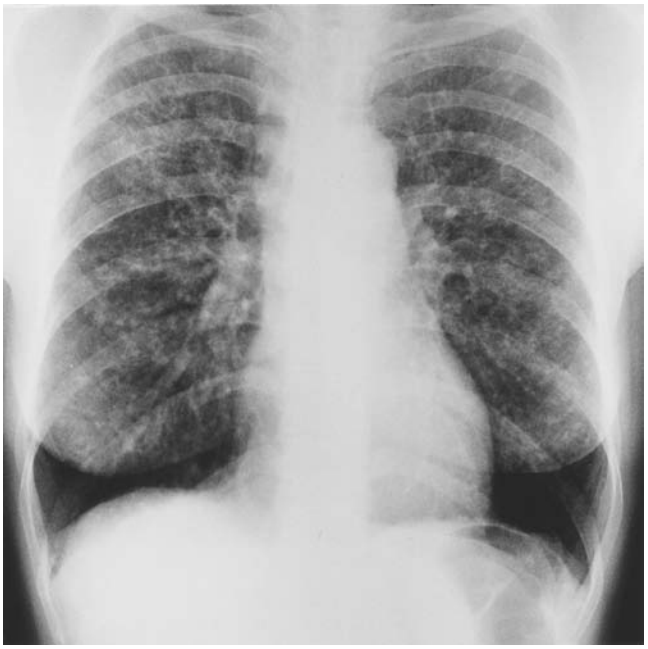

Figure 29-2 Nitrofurantoin hypersensitivity pneumonitis. The ingestion of nitrofurantoin was accompanied by the appearance of patchy interstitial and alveolar changes throughout both lungs.

the initial presentation of acquired immunodeficiency syndrome (AIDS). Other causes of immunodeficiency, such as hematologic malignancy, or prior administration of chemotherapeutic agents, should heighten suspicion of infection as the cause of respiratory symptoms, as well as potential pulmonary drug toxicity.

Indeed, many pharmacologic agents, including chemotherapeutic and nonchemotherapeutic agents, have a propensity for inflicting lung damage (see Chapters 65 and 66). Classic examples include bleomycin, nitrofurantoin, and methotrexate (Fig. 29-2). Beta blockers, administered as part of a cardiac regimen, may evoke bronchoconstriction. Even a common medication, such as aspirin, may, on rare occasion, cause a severe pulmonary disorder (e.g., pulmonary edema).

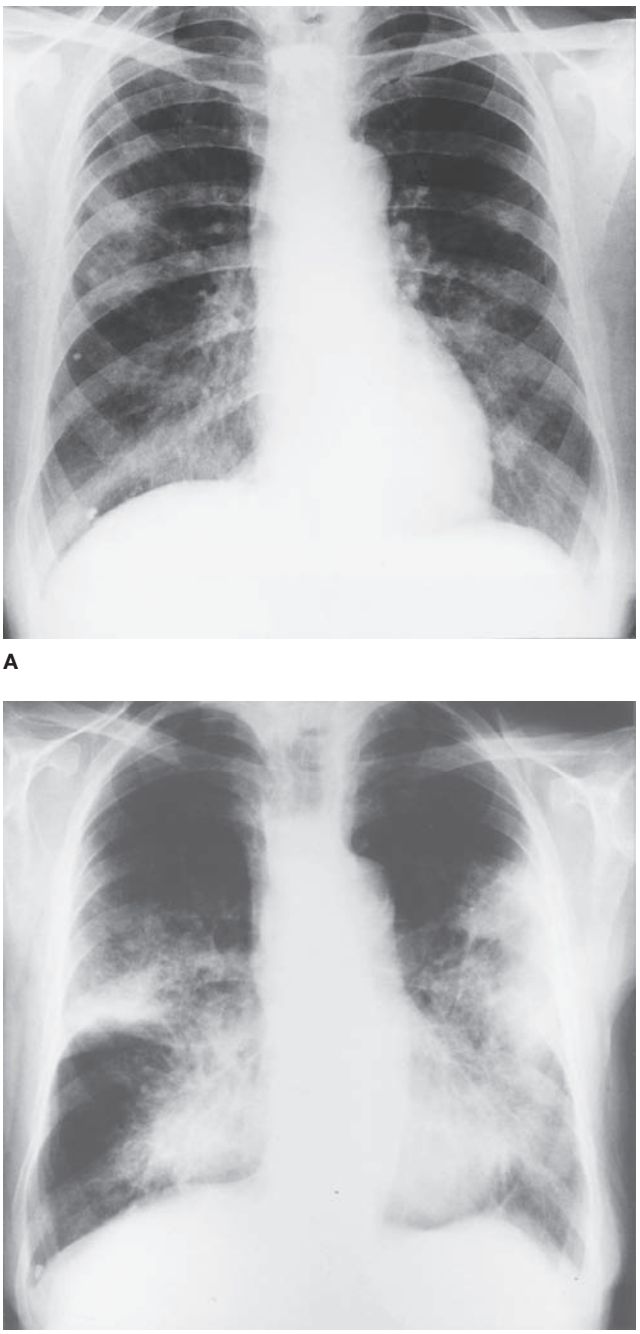
Finally, the family history is an essential ingredient of the medical inventory. This history can uncover a heritable disease of the lungs (e.g., cystic fibrosis [CF], α_1-antitrypsin deficiency, alveolar microlithiasis, and hereditary telangiectasia).

PHYSICAL EXAMINATION

Before the widespread use of chest radiography, physical examination, along with the history, played a pivotal role in the diagnosis of pulmonary disease. The advent of chest radiography and chest CT imaging has de-emphasized the value of the physical examination. Nonetheless, the physical examination remains a valuable diagnostic measure in the appraisal of chest disease.[3,4]

GENERAL ASPECTS

Important clues are often available before examination of the chest. For example, neglected pyorrheal teeth raise the prospect of necrotizing aspiration pneumonia. A lacerated tongue suggests that a convulsive episode may have led to aspiration (Fig. 29-3). Pursing of the lips during expiration ("pursed-lip breathing") may be seen in patients with chronic obstructive pulmonary disease (COPD). Subtle changes in consciousness or coordination may signal that metastasis has occurred to the brain from a primary carcinoma of the lung. In the patient with COPD, a clouded sensorium or a disturbed personality can signify acute elevation in arterial P_{CO_2}.



A

B

Figure 29-3 Chronic aspiration pneumonia. **A.** Chronic aspiration pneumonia in a 72-year-old man hospitalized for repair of hernia. Patchy infiltrates bilaterally. No pulmonary symptoms. Initiating cause was achalasia of esophagus. **B.** Eighteen months later. Persistent cough and breathlessness.

Inspection of the skin often provides clues to diseases of the chest; a more detailed discussion of notable cutaneous manifestations in respiratory disorders is provided later in this chapter. Evidence to support the diagnosis of pulmonary sarcoidosis may be found in the eyes and skin. Petechiae, purpura, necrosis, and/or ulceration of the skin may reflect a systemic vasculitis. The skin lesions of neurofibromatosis type 1 (von Recklinghausen disease) may signify that a solitary pulmonary nodule in the paraspinal region may be a neurofibroma. A minute skin abscess may turn out to be the source of multiple lung abscesses. Distinctive scars over the antecubital veins of a drug addict can help to clarify the etiology of old lesions

TABLE 29-1 Clinical Disorders Commonly Associated with Clubbing of Digits

Subacute bacterial endocarditis
Gastrointestinal and hepatic
Hepatic cirrhosis
Chronic ulcerative colitis
Regional enteritis (Crohn's disease)

in the lungs, as well as of a newly discovered lung abscess. Erythema nodosum (EN) is frequently due to sarcoidosis, but may also occur in patients with tuberculosis, histoplasmosis, or coccidioidomycosis. Skin papules in Birt–Hogg–Dube syndrome (see Pulmonary-Cutaneous Syndromes, below) may antedate the pulmonary manifestations of cystic lung lesions and pneumothorax by decades.[5]

A variety of endocrine syndromes may accompany carcinoma of the lung. An altered mental status may be due to hyponatremia caused by the syndrome of inappropriate antidiuretic hormone (SIADH). Clubbing of the digits may accompany various clinical disorders, including idiopathic pulmonary fibrosis, bronchiectasis, and certain carcinomas of the lung (Table 29-1).[6] A puffy face, neck, and eyelids, coupled with dilated veins of the neck, shoulder, thorax, and upper arm (i.e., superior vena cava syndrome) may constitute the first clinical evidence of obstruction of the superior vena cava by a neoplasm of the lung. Although the causes of superior vena cava syndrome are many and diverse, at least 80% are attributable to a primary carcinoma of the lung (Fig. 29-4). In the patient in whom a neoplasm has evoked acute signs and symptoms of increased systemic venous pressure that progresses rapidly (e.g., to laryngeal edema), early diagnosis and prompt treatment of the neoplasm can be lifesaving. The presence of Horner syndrome – unilateral ptosis, miosis, and anhidrosis – in a patient with a carcinoma of the lung suggests a pulmonary sulcus tumor with involvement of the ipsilateral sympathetic pathway within the thorax (Fig. 29-5).

■ INSPECTION OF THE CHEST

Observation of the chest from the foot of the bed can be informative: a visible lag in expansion of one side of the thorax localizes a pleural effusion, pulmonary infection, or paralyzed diaphragm. The respiratory pattern may be informative: patients with severe airflow obstruction often take slow, deep breaths, whereas rapid and shallow breaths are often seen with restrictive processes, such as interstitial lung disease or kyphoscoliosis. Inspection of the chest and abdomen in the supine position may reveal paradoxical inward movement of the abdomen, indicative of respiratory muscle weakness.[7]

C

Figure 29-4 *(Continued)* **C.** Angiogram showing obstruction and extensive collateral circulation.

PALPATION OF THE CHEST

Over the years, the role of palpation in examination of the chest has been considerably devalued. Nonetheless, palpation may provide helpful diagnostic clues as well as confirmatory evidence for other physical signs. For example, the position of the trachea determined by palpation in the suprasternal notch may be helpful in detecting a lateral displacement of the upper mediastinum. Displacement of the apical impulse and of cardiac dullness may be useful indices in detecting shift of the lower mediastinum.

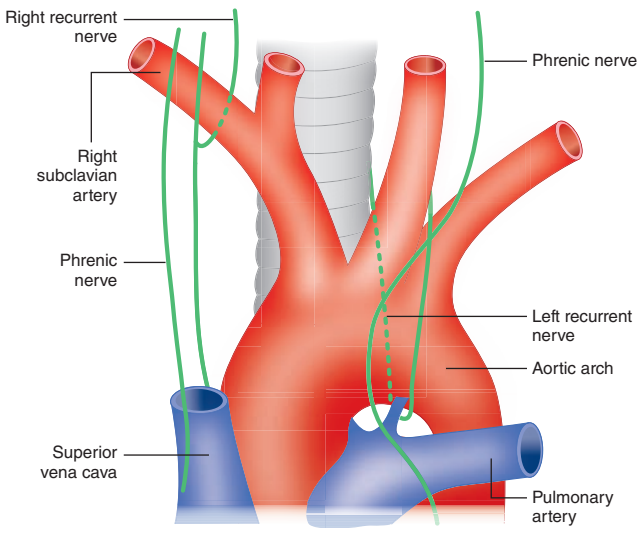

Figure 29-5 Courses of the recurrent laryngeal nerves. Invasion or compression of a nerve by a carcinoma of the lung causes paralysis of the vocal cord.

Tenderness over a rib may reflect a fracture, metastasis, or underlying pleuritis. Enlargement of the right ventricle can be readily detected by palpation in the subxiphoid region. *Hoover sign* may be useful in disclosing a unilateral lag in motion of one side of the chest due to pleuritis or a pleural effusion. The sign is elicited by comparing the displacement from the midline during a patient's deep inspiration of the examiner's hands, each placed lightly over one hemithorax, with thumbs touching beneath the xiphoid at the start of the breath.

An abnormal mass or fullness palpated in the supraclavicular space may be a clue to a neoplasm or an involved lymph node and suggests a convenient location to obtain a biopsy for diagnosis.

Consolidation of the lung, which causes increased transmission of sound, can be detected as fremitus (i.e., as a palpable vibration) over the affected area while the patient repeatedly vocalizes the traditional "one, two, three" as the examiner moves his or her palms systematically over the two hemithoraces. Conversely, impairment of sound transmission, as by a pleural effusion, diminishes vocal fremitus. In some instances, a pleural friction rub is palpable.

PERCUSSION OF THE CHEST

Percussion as part of the physical examination follows Auenbrugger sounding of beer barrels to determine their fluid levels. The response to percussion is impaired whenever something other than air-filled lung lies directly beneath the chest wall. Common causes of dullness to percussion are consolidation or atelectasis of the lung, fluid in the pleural space, pleural thickening, and a large mass at the surface of the lung. Widespread hyperresonance may be elicited in emphysema, and circumscribed hyperresonance over a pneumothorax or large bulla.

AUSCULTATION OF LUNGS

Ever since the time of Laennec, physicians have applied a stethoscope to the chest in search of sounds of disease.[8] Attention is focused on the intensity and quality of the sounds, as well as on the presence of abnormal (often called "adventitious") lung sounds.[9] Other devices have been used to assess sounds generated by breathing.[10,11] Web sites providing access to audio files demonstrating normal and adventitious breath sounds are available (e.g., www.easyauscultation.com/lung-sounds.aspx).[12]

Changes in the Intensity and Duration of Lung Sounds

The generation of lung sounds requires an ability to move air through patent airways. A global decrease in the intensity of breath sounds over the thorax or a hemithorax may be due to a variety of abnormalities: impaired movement of air due to airways disease (e.g., in emphysema), paralysis of a diaphragm, or complete obstruction of a bronchus. A decrease in audible breath sounds may also occur when the transmission of sounds to the chest wall is impaired (e.g., by a pleural effusion, pleural thickening, or a pneumothorax). A bulla gives rise to a more circumscribed diminution in breath sounds. In a patient with COPD, regional variations in breath sounds correspond to the distribution of ventilation. With adequate pressure of the diaphragm of the stethoscope, it is possible to auscultate the lungs as effectively through thin clothing as over bare skin; of course this approach hinders inspection and percussion.[13]

An abnormal increase in intensity of breath sounds is accompanied by a change in their character (the sounds become either harsh or bronchial). The abnormal sounds are heard over consolidated, atelectatic, or compressed lung as long as the airway to the affected portion of the lung remains patent. Consolidated lung is presumed to act as an acoustic conducting medium that, unlike normal lung, does not attenuate transmission of tracheal sounds to the periphery.

Noting the duration of the inspiratory and expiratory phases of breathing may be useful. Inspiration is normally audible for a longer period, with little, if any, expiratory noise. A prolongation of expiration, often longer than inspiration, is found with obstructed airways.

Changes in the Transmission of Lung Sounds

Changes in voice sounds are often easier to appreciate than changes in breath sounds. Large pleural effusions, pneumothorax, and bronchial occlusion produce distant or inaudible breath sounds. Transmission of voice sounds is enhanced by consolidation, infarction, atelectasis, or compressions of lung tissue. Accompanying the increased transmission is a change in the character of the voice sounds that causes them to be higher pitched and less muffled than normal *(bronchophony)*. When bronchophony is extreme, spoken words assume a nasal or bleating quality *(egophony)* and the sound "ee" is heard through the stethoscope as "ay."[14] Egophony is most common when consolidated lung and pleural fluid coexist; sometimes it is heard over an uncomplicated lobar pneumonia or pulmonary infarction. Transmission of whispered voice sounds with abnormal clarity *(whispered pectoriloquy)* has the same significance as bronchophony.

Changes in the Quality of Lung Sounds

Normal breath sounds have a smooth, soft quality and are described as *vesicular*. Abnormal, or adventitious, lung sounds have traditionally been resistant to meaningful clinical classification. However, a rational, clinically useful set of definitions based on acoustic analysis of tape recordings and the nomenclature introduced by Forgacs is commonly employed (Table 29-2). Using this approach, lung sounds are categorized as continuous (*wheezes*, *rhonchi*, or *stridor*) or discontinuous *(crackles)*.

Wheezes, rhonchi, and stridor are musical adventitious sounds. Wheezes originate in airways narrowed by spasm, thickening of the mucosa, or luminal obstruction. Although wheezes are more apt to occur during forced expiration (which further narrows airways), they may occur during both inspiration and expiration in asthma. Wheezes presumably originate through a combination of limitation to airflow and vibrations in the walls of the airways. Rhonchi are due to the presence of liquid or mucus in the airways; the quality and location may be readily changed by asking the patient to cough, thus moving the secretions. Stridor is predominantly inspiratory and best heard over the neck. Common causes of stridor are a foreign body in the upper intrathoracic airway or esophagus, an acquired lesion of the airway (e.g., carcinoma in adults), or a congenital lesion in children.

Crackles are generally attributed to a rapid succession of explosive openings of small airways that closed prematurely during the previous expiration.[15] Crackles have been subdivided according to their timing during inspiration (early or late) and by differences in their quality ("wet" or "dry"); at times they have been termed "*rales*." Noting differences in timing has been advocated as a way of distinguishing between possible causes (e.g., "dry" crackles in the fibrosis of interstitial lung disease vs. "wet" crackles in pulmonary edema).[16] Unfortunately, wide variation in the interpretation of these sounds generally renders such attempts at classification of little value and often a cause of confusion. Crackles may accompany alterations in the elastic recoil of airways (emphysema), the presence of secretions (bronchitis or pneumonia), inflammation or fibrosis (interstitial lung disease), or fluid (pulmonary edema). Crackles may also be due to atelectasis, as noted in bedridden patients, and may clear with sequential deep breaths.

TABLE 29-2 Classification of Common Lung Sounds

Acoustic Characteristics	American Thoracic Society Nomenclature	Common Synonyms
Discontinuous, interrupted explosive sounds; loud, low in pitch	Coarse crackle	Coarse rale
Discontinuous, interrupted explosive sounds; less loud than above and of shorter duration; higher in pitch than coarse crackles or rales	Fine crackle	Fine rale, crepitation
Continuous sounds longer than 250 ms, high-pitched; dominant frequency of 400 Hz or more, hissing sound	Wheeze	Sibilant rhonchus
Continuous sounds longer than 250 ms, low-pitched; dominant frequency about 200 Hz or less, snoring sound	Rhonchus	Sonorous rhonchus

Pleural Rub

A pleural friction rub is a coarse, grating, or leathery sound that is usually heard late in inspiration and early in expiration; most often a pleural friction rub is audible low in the axilla or over the lung base posteriorly. The rub sounds close to the ear and usually is not altered by coughing.

DYSPNEA

Dyspnea is the medical term for breathlessness or shortness of breath.[17] The American Thoracic Society has published a comprehensive discussion of the topic.[18] For the patient, dyspnea involves an experience of discomfort in breathing. It is alarming to most and may arouse great concern about a potential dire cause, making it one of the most frequent complaints prompting patients to seek medical evaluation.

In the extensive medical, physiologic, and psychological literature, dyspnea is used variously to designate a variety of sensations, ranging from awareness of breathing on the one hand to respiratory distress on the other. The wide range of meanings is understandable on several counts: (1) dyspnea is a subjective complaint without consistency in objective signs such as tachypnea; (2) few physicians have experienced the respiratory discomfort associated with chest disease, so that most interpretations of the complaint represent extrapolations from normal breathlessness (e.g., after strenuous exercise); (3) most experimental observations relating to dyspnea are based on the study of normal subjects or animals under artificial circumstances; and (4) most physicians apply the term loosely, based on their experience with the predominant patient population that they serve (e.g., patients with COPD or asthma). Despite this variability, in clinical medicine, the complaint of dyspnea almost invariably implies respiratory discomfort.

Because of its subjective nature, the sensation of dyspnea is an amalgam of two components. The first is the sensory input to the cerebral cortex, which consists of information from specialized receptors, predominantly mechanoreceptors, at various sites in the respiratory apparatus (predominantly the upper airways) and face (Fig. 29-6). The different sites of stimulation may contribute to disparities in the sensation. Furthermore, no specific area in the central nervous system (CNS) has been identified as the sensory locus for dyspnea. The input – from airways, lungs (via the vagus nerves), respiratory muscles, chest wall, and chemoreceptors – is processed at consecutive levels of the nervous system (i.e., spinal cord and supraspinal regions en route to the sensorimotor cortex). Additional sensory input, triggered by inadequate oxygen delivery or utilization, is poorly understood. The second component is the perception

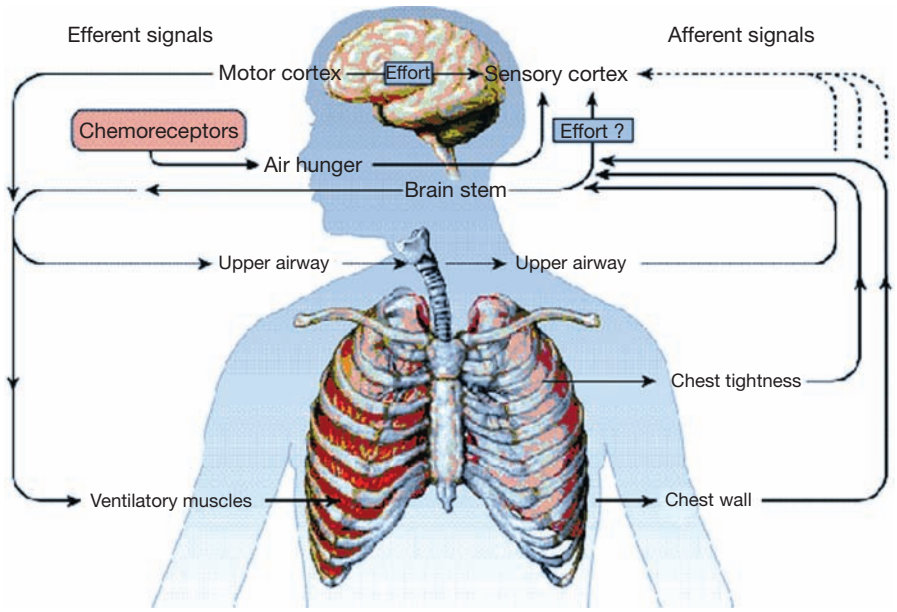

Figure 29-6 Pathways to the sensation of breathlessness. Respiratory effort is believed to originate as a signal transmitted from the motor cortex simultaneously to the sensory cortex and to the motor command to ventilatory muscles. The brain stem may also contribute to the sense of effort. The perception of air hunger is believed to arise, in part, from increased respiratory activity within the brain stem, whereas the sensation of chest tightness probably results from stimulation of vagal irritant receptors. Although afferent information from airway, lung, and chest-wall receptors most likely passes through the brain stem before reaching the sensory cortex, the *dashed lines* indicate uncertainty about whether some afferents bypass the brain stem and project directly to the sensory cortex. *(Reproduced with permission from Manning HL, Schwartzstein RM. Pathophysiology of dyspnea. N Engl J Med. 1995;333(23):1547–1553.)*

of the sensation, which rests heavily on the interpretation of information arriving at the sensorimotor cortex. The interpretation depends greatly on the psychological makeup of the person.

A variety of influences may modify the psychological component of dyspnea. During "Kussmaul breathing" (see below), "air hunger" may seem obvious to the observer, even though the patient does not feel short of breath. In contrast, patients with congestive heart failure or COPD frequently volunteer the complaint of "air hunger." Blunting of the sensorium, as by narcotics or by acute hypercapnia, can eliminate the sensation of breathlessness, even though the abnormal breathing pattern remains. Anxiety may heighten the sense of breathlessness. Indeed, anxiety may be responsible for the clinical syndrome of psychogenic dyspnea, in which the patient experiences "breathing discomfort" that eludes explanation on the basis of a somatic cause. Ill-defined sensations may accompany a full-blown hyperventilation syndrome, consisting of lightheadedness, tingling of the hands and feet, tachycardia, inversion of T waves on the electrocardiogram, and even syncope. Breathing discomfort at rest that decreases with activity is often seen when anxiety or other psychological issues are the cause and is a distinctly unusual pattern for dyspnea due to a cardiopulmonary abnormality.

The quality of dyspnea can vary greatly. In normal persons, as well as in those with chest disease, dyspnea may simply signify the transition from an effortless process that is ordinarily conducted at a subconscious level to the awareness that muscular effort is being expended in breathing.[19] The healthy athlete completing a sprint experiences breathlessness that can be exhilarating, rather than uncomfortable. The asthmatic often interprets breathlessness in terms of "tightness in the chest." The patient with COPD often complains of less severe breathlessness than would be expected from the degree of airway obstruction, possibly reflecting adaptation, either to the chronic obstructive airway disease or to CO_2 retention.

Patients may use different terms to describe breathing discomfort due to various causes.[20–25] In some instances these descriptors may be useful in establishing a differential diagnosis and in assessing the response to therapy.[26] Patients with asthma or myocardial ischemia often refer to "chest tightness."[27] Patients with pulmonary edema may suffer a sensation of "air hunger" or "suffocation."[28] Patients with COPD and hyperinflation of the chest often note an inability to take a deep, satisfying breath. Individuals who are deconditioned may complain of "heavy breathing." Unfortunately, no descriptor has sufficient sensitivity or specificity to be used alone in establishing the cause of a patient's dyspnea. Ethnic and gender differences in the descriptors and perceptions related to dyspnea have been reported.[29,30]

CLINICAL PRESENTATIONS

Dyspnea may be acute, chronic, or paroxysmal (Table 29-3).

TABLE 29-3 Common Causes of Acute and Chronic Dyspnea[a]

Acute
Pulmonary edema
Asthma
Injury to chest wall and intrathoracic structures
Spontaneous pneumothorax
Pulmonary embolism
Pneumonia
Adult respiratory distress syndrome
Pleural effusion
Pulmonary hemorrhage
Foreign body aspiration
Vocal cord dysfunction
Chronic, progressive
Chronic obstructive pulmonary disease
Left ventricular failure
Diffuse interstitial fibrosis
Asthma
Pleural effusions
Pulmonary thromboembolic disease
Pulmonary vascular disease
Psychogenic dyspnea
Anemia, severe
Postintubation tracheal stenosis
Hypersensitivity disorders

[a]Many chronic processes (e.g., left ventricular failure, asthma, and COPD) may have acute exacerbations.

Acute Dyspnea

The usual causes of acute dyspnea in children differ from those in adults. In children, upper airway infection (e.g., epiglottis, laryngitis, or acute laryngotracheobronchitis) is a common cause. In adults, the causes of acute dyspnea are much more varied (Table 29-3). Among the most common are acute left ventricular failure, pulmonary thromboembolism, pneumonia, and spontaneous pneumothorax. Less common, but not unusual, is massive collapse of one lung due to inability to clear the airways of thick, tenacious secretions (e.g., in chronic bronchitis or asthma) or the first attack of asthma.

Chronic Dyspnea

Chronic dyspnea is almost invariably progressive. As a rule, this type of dyspnea begins with breathlessness on exertion—which, in time, progresses to dyspnea at rest. Pulmonologists encounter dyspnea in patients who have COPD; cardiologists more often deal with dyspnea in patients who are in chronic congestive heart failure. Especially in older patients, distinction between the heart and lungs in the etiology of dyspnea, or the relative contributions of each, can be difficult to establish.

Asthma is a common cause of recurrent bouts of dyspnea, which are usually accompanied by cough and wheezing. Cardiac dysfunction is another cause of acute bouts of bronchospasm, especially in middle-aged or elderly persons.

■ PHYSIOLOGIC CORRELATES OF DYSPNEA

Historically, attempts to understand the physiologic bases of dyspnea have evolved along four separate lines: ventilatory performance, the mechanics of breathing, chemoreception, and exercise testing. Exercise testing is presented in Chapter 34.

Ventilatory Performance

Early investigations related the sensation of dyspnea to the level of minute ventilation. Dyspnea was found to correlate with excessive minute ventilation relative to the level of oxygen uptake. Most of the increase in ventilation was accounted for by an increase in respiratory rate, especially in patients with stiff lungs. In patients who continued to ventilate excessively for the level of oxygen uptake (e.g., those with chronic left ventricular failure), the sensation of breathlessness gradually diminished, suggesting adaptation to the continued stimulus.

A second ventilatory measurement that proved to correlate well with dyspnea is the maximum voluntary ventilation (MVV). MVV is decreased by diseases of the lungs, airways, or chest wall. The smaller the MVV, the more likely is dyspnea to occur.

A third time-honored approach to measurement is the "breathing reserve." This value is determined as the difference between the MVV and the actual minute ventilation. In principle, the sensation of breathlessness during the performance of any ventilatory task may be related to the fraction of the maximum breathing capacity (i.e., the MVV) that is used for force generation by the respiratory apparatus. Thus, the closer the minute ventilation is to the maximum breathing capacity, the more likely is the subject to complain of breathlessness. Indeed, when the actual level of ventilation reaches 30% to 40% of the maximum breathing capacity, dyspnea is inevitable. Unfortunately, the breathing reserve correlates better with the dyspnea of normal subjects during exertion than with the dyspnea of chronic bronchitis and COPD or of left ventricular failure. Thus, in COPD the minute ventilation may be a very large fraction of the MVV (>50%) without eliciting dyspnea. In contrast, in acute left ventricular failure, a mild increase in ventilation and a nearly normal MVV may be associated with considerable breathlessness.

Mechanics of Breathing

One teleologic way to regard dyspnea is as a sensation that prompts an unconscious effort to minimize the work, energy cost, or force of breathing. In this light, dyspnea protects the respiratory apparatus from overwork and inefficient operation. This approach has led to exploration of the relationships between dyspnea and the work or oxygen cost of breathing.

Work, Oxygen Cost, and Efficiency of Breathing

It has not been possible to identify a critical level for the work of breathing at which dyspnea will occur. However, a breakdown of the work of breathing into its elastic, resistive, and inertial components has helped to relate physiologic disturbances to particular diseases. For example, in chronic mitral stenosis with pulmonary congestion, the elastic work is greatly increased (Fig. 29-7), whereas in obstructive airway disease, resistive work predominates. Moreover, such observations have reinforced the concept that patterns of breathing are automatically adjusted to minimize the work done by the respiratory muscles in breathing.

The relationship between ventilation and O_2 consumed by the respiratory muscles is curvilinear (Fig. 29-8). This O_2 cost of breathing may increase extraordinarily in patients with COPD or with abnormalities of the chest wall. Indeed, in patients with COPD, the quantity of O_2 delivered to the respiratory muscles during the large ventilatory effort may fail to satisfy their aerobic needs, leading to anaerobic metabolism and lactic acidosis. Although the greater the O_2 cost of breathing the greater the likelihood of dyspnea, the determination of O_2 cost provides no more useful insight into the mechanism of dyspnea than does the work of breathing. Calculation of the efficiency of breathing (i.e., the work of breathing related to energy cost) provides no further clarification.

Length–Tension Inappropriateness

The concept of "length–tension inappropriateness" explains dyspnea as a mismatch between the central motor command to the respiratory muscles (i.e., the motor signal emitted from the brain) and the suboptimal ("inappropriate") shortening of the respiratory muscles elicited by this command (e.g., suboptimal thoracic expansion for any level of central motor command).[31] In essence, this concept pictures a decrease, instead of an increase, in the pressure-generating capacity of the respiratory muscles in the face of the increased need arising from the heightened respiratory drive.

Chemoreception

Chemoreceptors in the medulla respond to changes in pH and Pa_{CO_2} (see Chapter 11). Peripheral receptors in the aortic arch and carotid body also respond to alterations in Pa_{O_2}. Acute hypoxia, hypercapnia, and acidosis are the traditional stimuli for ventilation. For example, upon ascent to altitude, acute hypoxia can stimulate ventilation to the level of awareness that may progress to discomfort during exertion. The effects of these stimuli on breathing decrease if they continue unabated. In addition, side effects, such as blunting of the sensorium during chronic CO_2 retention, diminish the likelihood of dyspnea, even if the level of ventilation is increased. In patients with abnormal pulmonary mechanics, the onset of abnormalities in blood gas composition, as during exercise, may aggravate or contribute to dyspnea. In general, acute hypercapnia is a stronger stimulus for dyspnea than is acute hypoxia.

■ SCALING

A variety of scaling methods have been devised to quantify dyspnea during exercise and various experimental settings. Some, such as the Borg Category Scale (Table 29-4), use numbers and descriptive terms to depict a change in the intensity of the stimulus ("threshold stimulus detection methods"). Others rely on visual analog scales, which are straight lines, usually 10 cm long, that extend from "not breathless" at one end to "extremely breathless" at the other. The

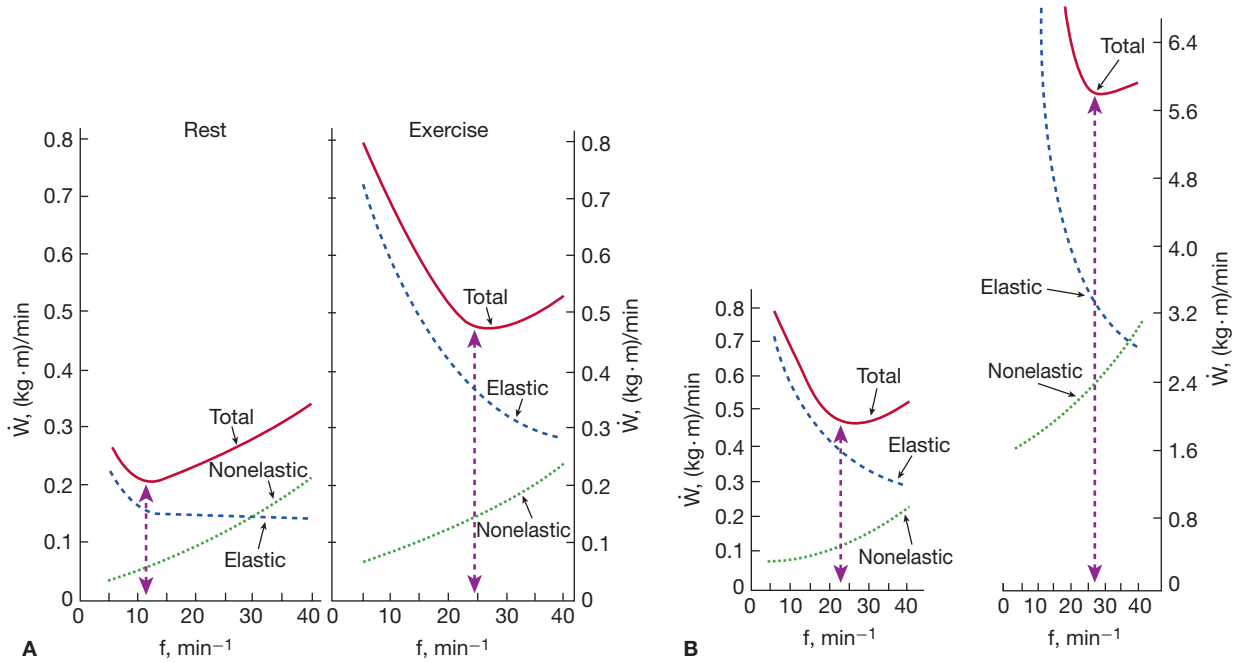

Figure 29-7 Partition of the work of breathing in pulmonary congestion and edema at rest and during exercise. **A.** Normal. The minimal work of breathing at rest was at a respiratory frequency of 12 breaths/min; during exercise, the minimal work was done at a higher frequency (25 breaths/min). **B.** Mitral stenosis. At rest, the frequency for least respiratory work was abnormally high (22 breaths/min); during exercise it increased further (to 28 breaths/min). The *dashed vertical line* (capped by *arrowheads*) in each frame indicates the respiratory frequency at which respiratory work was minimal. f, respiratory frequency. *(Reproduced with permission from Christie RV. Dyspnea in relation to the visco-elastic properties of the lung. Proc R Soc Med. 1953;46(5):381–386.)*

patient marks on the line the intensity of respiratory discomfort elicited by external stimuli, such as resistive loads or exercise testing. The score is measured as the length of the line between "not breathless" and the mark made by the patient. The Shortness of Breath Scale issued by the American Thoracic Society (Table 29-5) has also been used in one form or another, particularly in epidemiologic studies. A recent method of quantifying dyspnea severity that utilizes patient descriptors appears to be applicable and reproducible in a variety of disorders.[32]

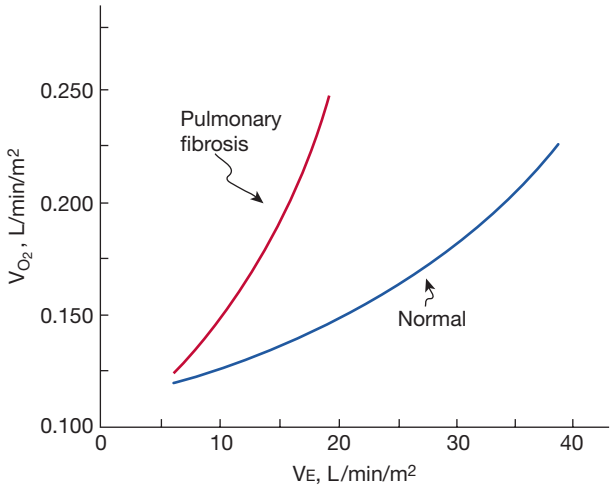

Figure 29-8 Oxygen cost of breathing in restrictive lung disease. Relationship between ventilation and O_2 consumption in pulmonary fibrosis. At each level of ventilation, the patient with pulmonary fibrosis does more work and expends more energy in breathing than does the normal subject.

DYSPNEA IN OBSTRUCTIVE AND RESTRICTIVE PULMONARY DISORDERS

Two common pathophysiologic categories of pulmonary disease in which dyspnea features prominently are chronic obstructive airway disease and restrictive pulmonary disorders.

CHRONIC OBSTRUCTIVE AIRWAY DISEASES

Several chronic obstructive airway diseases associated with dyspnea are well recognized, including COPD and asthma.

COPD

COPD refers to a spectrum of airway diseases in which obstruction to airflow is the common denominator (Chapters 39 and 40).

TABLE 29-4 Modified Borg Category Scale

Rating	Intensity of Sensation
0	Nothing at all
0.5	Very, very slight (just noticeable)
1	Very slight
2	Slight
3	Moderate
4	Somewhat severe
5	Severe
6	
7	Very severe
8	
9	Very, very severe (almost maximal)
10	Maximal

TABLE 29-5 American Thoracic Society Shortness of Breath Scale

Descriptions	Grade	Degree
Not troubled by shortness of breath when hurrying on the level or walking up a slight hill	0	None
Troubled by shortness of breath when hurrying on the level or walking up a slight hill	1	Mild
Walks more slowly than people of the same age on the level because of breathlessness or has to stop for breath when walking at own pace on the level	2	Moderate
Stops for breath after walking about 100 yards or after a few minutes on the level	3	Severe
Too breathless to leave the house; breathless on dressing or undressing	4	Very severe

Cigarette smoking is the leading cause of COPD (Chapter 41). The outer limits of the spectrum are marked by chronic bronchitis at one end and emphysema at the other. Most patients with COPD fall into categories between those limits (i.e., they manifest mixtures of chronic bronchitis and emphysema, which vary in degrees) (Fig. 29-9).

Patients with COPD suffer from disturbances in the mechanics of breathing, abnormal lung volumes, and derangements in gas exchange. The minute ventilation, which may be only slightly increased at rest, constitutes an abnormally large fraction of the maximum breathing capacity (i.e., the "breathing reserve" is low).

Abnormalities in the mechanics of breathing dominate the scene: resistance to airflow is high; the thorax assumes a hyperinflated position, placing the inspiratory muscles at mechanical disadvantage; the work of breathing is greatly increased. The O_2 cost of breathing is correspondingly high. Derangements in dead space ventilation and in alveolar–capillary gas exchange add to the afferent stimuli. As a result of the disturbances in mechanics and gas exchange, swings in pleural pressure (a measure of force applied to the lungs) are large, and a considerable muscular effort is expended in breathing; instead of the normal increase of about 1 mL of O_2 uptake per liter of ventilation per minute, the O_2 uptake increases enormously (up to 25 mL/min). Should O_2 delivery to the overworked respiratory muscles be insufficient, fatigue and exhaustion may send nervous and chemical signals of their own to the brain. Finally, if the patient accumulates excess water in the lungs, the juxtacapillary ("J") receptors provide additional sensory input to the central integrating mechanism. As noted above (see "Length–Tension Inappropriateness"), the convergence of these diverse stimuli upon the sensorimotor cortex may generate an inordinate motor command to the respiratory muscles, which cannot mobilize the thorax sufficiently to generate the pleural pressures needed for adequate ventilation.

One enigma is why patients with COPD maintain different levels of ventilation despite equal abnormalities in conventional pulmonary function tests. The "CO_2 retainer," with respiratory acidosis and arterial hypoxemia, often breathes less than does the non–CO_2 retainer in whom blood gas levels are near normal. One teleologic explanation is that the lower ventilation in the CO_2 retainer causes less dyspnea. However, this explanation affords no insight into the physiologic mechanism.

Treatment of the patient with COPD is directed at diminishing airways resistance and restoring arterial blood gases toward normal. Unfortunately, bronchodilators generally have only modest effects, and the basic abnormalities in the mechanics of the lungs and airways remain. Consequently, the load on the respiratory muscles is not readily alleviated by medical management. Management strategies also include consideration of ways in which the performance of the respiratory muscles can be improved. These have generally taken the form of training exercises to facilitate adaptive changes and to increase both muscle strength and endurance. Exercise reconditioning in patients with COPD has been shown to diminish breathlessness, possibly owing to three interactive mechanisms: (1) increased mechanical efficiency of the exercising muscles, which decrease ventilatory requirements; (2) improved function of the respiratory muscles; and (3) increased tolerance of the "dyspneagenic" sensory input to the brain. Attempts to rest the respiratory muscles have no lasting effect on dyspnea.

Asthma

Asthma constitutes a different entity, not only in its clinical expressions but also because it is usually episodic and is often related to allergic manifestations, and generally affects younger individuals (Chapters 45 to 47).

The mechanisms described previously for COPD apply as well to asthma. However, these mechanisms do not account for the sensation of "tightness in the chest" or the inordinate sense of labored breathing that accompanies the breathlessness in asthma.

■ RESTRICTIVE VENTILATORY DEFECTS

Restrictive ventilatory defects are due to a variety of causes, ranging from lung disorders to diseases that affect the pleural space, as well as neuromuscular diseases that affect the function of the thorax (Table 29-6). Diffuse interstitial disease has many different etiologies and may be either acute or chronic (Table 29-7). Characteristically, in widespread interstitial disease the diffusing capacity is low and is accompanied by a considerable decrease in total lung capacity and in vital capacity, as well as lesser decrements in functional residual capacity and residual volume (see Chapter 33). Similar findings occur in severe kyphoscoliosis or encasement of the lung by pleural thickening (Fig. 29-10). In contrast, in pulmonary vascular disease, such as idiopathic pulmonary arterial hypertension, a low diffusing capacity may be accompanied by normal lung volumes. Neuromuscular disease that affects the inspiratory muscles sufficiently to diminish maximum inspiratory pressures may decrease vital capacity and total lung capacity, leaving functional residual capacity and residual volume increased.

Patients with widespread pulmonary fibrosis breathe faster and maintain a higher minute ventilation than do normal subjects, both at rest and during exercise. The work and oxygen cost of ventilating

TABLE 29-6 Common Causes of Restrictive Ventilatory Defects

Cause	Example
Interstitium	
Interstitial fibrosis and/or infiltration	Usual interstitial pneumonitis/ idiopathic pulmonary fibrosis
Pulmonary edema	Left ventricular failure
Pleura	
Pleural disease	Fibrothorax
Thoracic cage and abdomen	
Neuromuscular disease	Poliomyelitis
Skeletal abnormalities	Severe kyphoscoliosis
Marked obesity	Grossly overweight

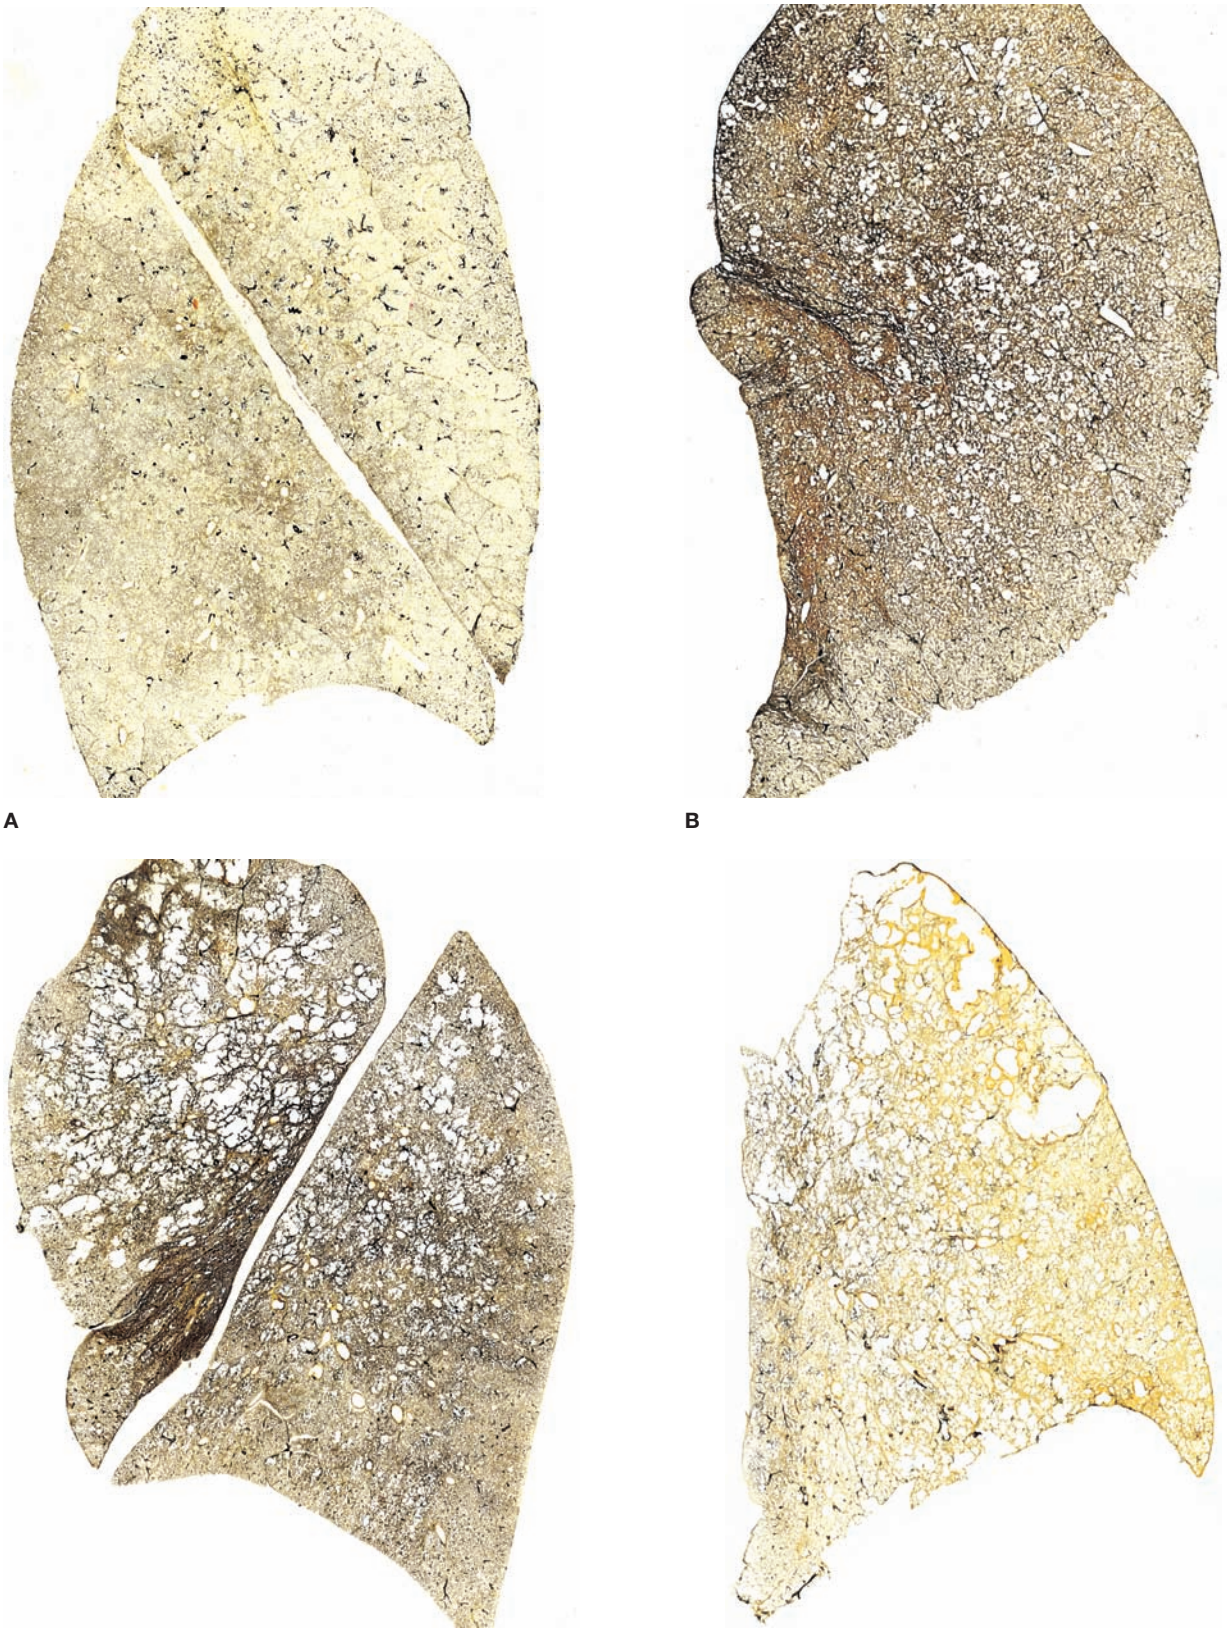

Figure 29-9 Chronic obstructive pulmonary disease (COPD). Sagittal sections showing patterns of emphysema. **A.** Normal lung from a patient who died of unrelated causes. **B.** Predominantly centrilobular emphysema. **C.** Predominantly centrilobular and panlobular emphysema. **D.** Predominantly panlobular emphysema. Centrilobular emphysema is less marked. The three patients with emphysema (**B, C, D**) also had clinical manifestations of chronic bronchitis confirmed by histologic sections.

TABLE 29-7 Some Types of Diffuse Interstitial Diseases

Etiology	Example	Common Features
	Acute	
Infections	Miliary tuberculosis, histoplasmosis	Opportunity for exposure to organism
	Pneumocystis, cytomegalic inclusion virus, fungi	Immunosuppression
Pulmonary edema	Narcotic overdosage, nitrogen dioxide (silo-filler's disease), uremia	Distinctive history
Inhalation	Byssinosis	Monday morning asthma and fever
Aspiration	After loss of consciousness	History of alcoholism or epilepsy
Immunologic	Goodpasture syndrome	Renal and pulmonary involvement
Carcinoma of lung	Adenocarcinoma in situ or minimally invasive adenocarcinoma (previously known as alveolar cell carcinoma)	
	Chronic	
Inhalation	Pneumoconioses	History of exposure to inorganic dust
Radiation therapy	After mastectomy	Gradual evolution after treatment
Lymphangitic spread	Carcinoma of breast, lung, stomach, pancreas	Evidence of primary carcinoma
Medications	Bleomycin, busulfan, cyclophosphamide	History, suggestive chest radiograph
Systemic disorders	Sarcoidosis, connective tissue disorders, eosinophilic granuloma, amyloidosis, tuberous sclerosis	Multiorgan involvement; biopsy
Idiopathic	Idiopathic pulmonary fibrosis	Exclusion of known causes

A

B

Figure 29-10 Restrictive ventilatory disorders. **A.** Asbestosis with markedly thickened pleura that encases and compresses the lungs. In addition, the lungs were afflicted with diffuse interstitial fibrosis. **B.** Compressed, distorted lung in patient with kyphoscoliosis. The lungs were otherwise normal, so that in this instance restriction was imposed by the chest wall rather than by intrapulmonary or pleural disease.

the stiff lungs are increased. Dyspnea is attributable to the considerable effort by the respiratory muscles in ventilating the stiff lungs and in sustaining the high ventilatory rate. During exercise, dyspnea may become intolerable.

DYSPNEA IN CHRONIC CARDIAC DISEASE

The mechanisms responsible for dyspnea in cardiac disease vary with the extent to which the lungs are stiffened.

Dyspnea occurs in many forms of heart disease that are not associated with congestion of the lungs. Uncomplicated pulmonic stenosis is an excellent example. The symptom is probably related to an inadequate cardiac output during exercise. In Tetralogy of Fallot, dyspnea is sometimes severe and often relieved by assuming a squatting position. In this and other forms of cyanotic heart disease, both dyspnea and fatigue appear during exertion when the arterial oxyhemoglobin saturation decreases appreciably below the resting level.

Cardiac dyspnea is associated with an increase in blood and water content of the lungs. It is a common occurrence in left ventricular failure and mitral stenosis, both of which are accompanied by increases in pulmonary venous and capillary pressures. The engorged pulmonary circulatory bed, coupled with interstitial and alveolar edema, stiffens the lungs (i.e., decreases their compliance) and stimulates the ventilation via "J" receptors. In chronic left ventricular failure, pulmonary fibrosis, consequent to long-standing interstitial edema, contributes to the stiff lungs. Edema of the tracheobronchial mucosa increases airway resistance.

As a result of the stiff lungs and increased airway resistance, swings in pleural pressure during the respiratory cycle are large and the work and energy cost of breathing are increased. Arterial hypoxemia, generally mild, may add to the ventilatory drive. Exercise exaggerates the pulmonary congestion and edema, promotes arterial and mixed venous hypoxemia, and increases the dyspnea.

In patients with pulmonary congestion and edema, tachypnea is a regular feature at rest and increases during exercise. Although tachypnea is consistent, its degree is generally modest and probably not entirely responsible for the dyspnea. Fatigue is a common concomitant of low cardiac output and may stem from diminished O_2 delivery to the respiratory muscles, contributing to respiratory discomfort.

■ ORTHOPNEA AND OTHER POSITIONAL FORMS OF BREATHLESSNESS

Orthopnea signifies dyspnea in the recumbent, but not in the upright or semiupright, position; it is usually relieved by two or three pillows under the head and back. *Platypnea* signifies dyspnea induced by assuming the upright position and relieved by recumbency.[33]

Platypnea may be seen when, due to gravity, increased blood flow worsens right to left shunting of blood through arteriovenous malformations at the lung bases; it may be accompanied by *orthodeoxia*—desaturation of arterial blood when the patient is upright.

Orthopnea is a hallmark of pulmonary congestion that stiffens the lungs (i.e., decreases their compliance). The decrease in compliance on lying flat is attributable to the fact that more of the lung is located at or below the level of the heart. During recumbency, the swings in pleural pressure, the work of breathing, and the respiratory frequency increase. The increase in respiratory frequency appears to be automatically adjusted to minimize the work of ventilating the more rigid lungs.

Some patients with chronic lung disease or asthma are also intolerant of lying flat. Their discomfort is attributed to the greater difficulty of performing vigorous movements of the chest bellows in the recumbent position.

Finally, patients with asymmetric lung disease may experience *trepopnea*—dyspnea when the affected side of the chest is in the dependent position, thereby promoting ventilation–perfusion mismatch (Chapter 14) and resultant hypoxemia.

■ PAROXYSMAL NOCTURNAL DYSPNEA

In an episode of paroxysmal nocturnal dyspnea (PND), the patient is aroused from sleep, gasping for air, and must sit up or stand to catch his or her breath; sweating may be profuse. Sometimes the patient opens a room window in an attempt to relieve the oppressive sensation of suffocation. The chest tends to become fixed in the position of forced inspiration. Both inspiratory and expiratory wheezes, often simulating typical asthma, are heard. In some instances, overt pulmonary edema occurs, accompanied by inspiratory crackles. Attacks occasionally recur several times a night, forcing the patient to sleep upright in a chair.

An episode of PND represents precipitous failure of the left ventricle caused by the factors that produce orthopnea (see above), abetted by pulmonary hypervolemia caused by a surge in systemic venous return. Mobilization of peripheral edema from the periphery as the extremities are elevated from the dependent position may contribute to the increase in systemic venous return. The acute increase in pulmonary blood volume increases pulmonary capillary pressures, thereby promoting pulmonary edema, while the surge in venous return imposes an additional burden on the left ventricle.

A variety of factors may trigger an episode of PND: coughing, abdominal distention, the hypercapnic phase of Cheyne–Stokes respiration (see below), a startling noise, or anything that causes a rise in heart rate and further increases the pulmonary capillary and venous pressures. Usually the attack is terminated by assumption of the erect position and a few deep breaths. Cough, an important manifestation of pulmonary congestion, frequently occurs during the attack.

■ CARDIAC ASTHMA

Asthmatic wheezes, often audible in patients with pulmonary congestion, have given rise to the term *cardiac asthma.* The wheezes are a manifestation of tracheobronchial edema and often are accompanied by overt signs of pulmonary edema. In addition to the reduction in the lumen of the airways and thickening of bronchial walls by edema, the high intrathoracic pressures, which are required to overcome the obstruction during expiration, tend to narrow the airways even further. The resistance to airflow is increased during both inspiration and expiration, and the compliance of the lungs is greatly reduced, reaching values as low as one-tenth of normal. Upon recovery from the acute episode of pulmonary edema, airway resistance and pulmonary compliance return toward normal unless previous episodes have left a residue of pulmonary fibrosis.

DYSPNEA IN ANEMIA

Shortness of breath during exercise or excitement is a common complaint in severe anemia (e.g., hemoglobin concentration under 6–7 g/dL). It is more common in acute than in chronic anemia. Often the dyspnea is associated with dizziness or faintness, and invariably the patient manifests signs of a high cardiac output and low peripheral resistance (i.e., bounding pulse, warm skin, and systolic cardiac murmurs). Although the pathogenesis of the dyspnea is not clear, inadequate oxygen delivery to the respiratory muscles has been proposed.

METABOLIC ABNORMALITIES AND DRUGS

Increases in CO_2 production demand a concomitant rise in ventilation to dispose of the metabolic load and, hence, may result in dyspnea. To prevent acidemia, patients with diabetic ketoacidosis may require an enormous increase in minute ventilation in order to reduce Pa_{CO_2}. Thyrotoxicosis, fever, infection, and pregnancy can also cause an increased minute ventilation, as can drugs, such as aspirin and progesterone.

MISCELLANEOUS DISORDERS

Breathlessness is not uncommon in patients with musculoskeletal disorders. The usual explanation is the heightened motor drive that is needed to activate the weakened respiratory muscles. In the intensive care unit, inadequate ventilator settings for flow and tidal volume may fail to satisfy the intrinsic ventilatory drive of the patient, generating the sensation of breathlessness.

ABNORMAL BREATHING PATTERNS

An important clue to the nature of a clinical problem in pulmonary disease is sometimes provided by bedside observation of a patient's breathing pattern. The pertinent features are the rate, regularity, depth, and apparent effort being expended in breathing. A normal person at rest breathes about 12 to 15 times per minute, with a tidal volume of 400 to 800 mL. As a result, minute ventilation is normally greater than 5 L/min. The pattern is quite regular except for an occasional slow, deep breath, and the respiratory movements appear effortless.

Severe skeletal deformity, as well as massive obesity, can limit chest excursions to cause alveolar hypoventilation (Chapter 83). Neuromuscular weakness, as in myasthenia gravis or Guillain–Barré syndrome, may do the same, not only by diminishing ventilatory excursions as a result of generalized weakness of the respiratory muscles, but also by causing overload of respiratory muscles (e.g., residual effects of poliomyelitis) (Chapters 83 and 84). Unilateral involvement of one pleural space by pneumothorax, effusion, or fibrothorax limits excursions on the affected side. Massive chest trauma may cause flail chest.

In COPD, a slow respiratory rate and large tidal volumes are characteristic. This pattern presumably serves to minimize the work of breathing. Pursed-lip breathing, a self-induced type of positive-pressure breathing, is often part of the picture. In contrast, persons with restrictive ventilator disorders adopt a breathing pattern that is characterized by small tidal volumes and a rapid respiratory rate, often with little apparent effort. This pattern is seen in patients with a decrease in the distensibility of the lung or chest wall or with reduction of the vital capacity from any other cause. During exercise, minute ventilation increases inordinately with respect to the level of O_2 uptake, and respiratory frequency increases more than tidal volume.

Fatigue of the diaphragm and intercostal muscles, sufficient to disturb their coordinated contractions, may give rise to paradoxical breathing, which heralds the onset of respiratory failure.

■ CHEYNE–STOKES RESPIRATION

In the fourth century BC, in a preterminally ill person with fever, sweats, and black urine, Hippocrates described a pattern of breathing in which "the respiration throughout [was] like that of a man correcting himself, and rare and large." Presumably he had observed Cheyne–Stokes breathing, which was described more graphically by William Stokes two millennia later (in 1854) as follows:

"The symptom in question (previously described by Dr. Cheyne) consists in the occurrence of a series of inspirating, increasing to a maximum, and then declining in force and length, until a state of apparent apnea is established. In this condition the patient may remain for such a length of time as to make his attendants believe that he is dead, when a low inspiration, followed by one more decided, marks the commencement of a new ascending and descending series of inspirations."

Cheyne–Stokes breathing is characterized by alternating periods of hypoventilation and hyperventilation (Fig. 29-11). In its typical form, an apneic phase, which lasts for 15 to 60 seconds, is followed by a phase during which tidal volume increases with each successive breath to a peak level and then decreases in a progressive fashion to the apneic phase. At the onset of apnea, CO_2 tension in brachial or femoral arterial blood is at its lowest. As apnea persists, CO_2 tension gradually increases, and respiration is stimulated. CO_2 tension continues to increase until maximum hyperventilation is attained, after which ventilation decreases until apnea again occurs. The arterial oxyhemoglobin saturation varies in an inverse manner, being highest at the onset of apnea and lower during midhyperpnea. During the cycle, CO_2 tension varies by as much as 14 mm Hg and oxyhemoglobin saturation by as much as 18%.

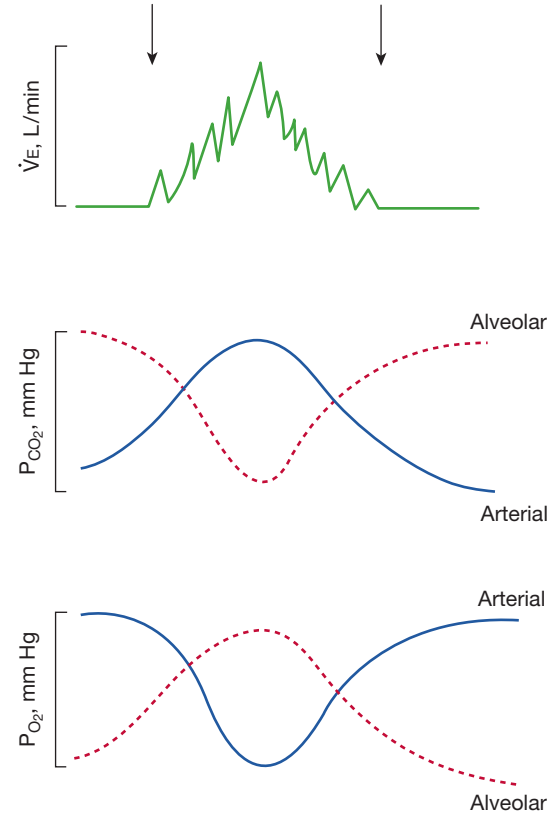

Figure 29-11 Cheyne–Stokes breathing, illustrating the relationship between the ventilation and the blood and alveolar gas tensions during the periods of apnea and hyperpnea. *(Reproduced with permission from Cherniack NS, Fishman AP. Abnormal breathing patterns. Dis Mon. 1975:1–45.)*

In patients with congestive heart failure, the respiratory oscillations are attributable to slowing of the circulation so that the blood gases reaching the respiratory centers in the brain are 180 degrees out of phase with those in pulmonary capillary blood. This mechanism has been verified experimentally by eliciting Cheyne–Stokes breathing in dogs by prolonging the circulation time from heart to brain by way of an extracorporeal circuit.

Fluctuations in mental state and electroencephalographic patterns, and evidence of nervous system dysfunction, may occur during Cheyne–Stokes breathing because of swings in cerebral blood flow. In neurologic disorders, Cheyne–Stokes breathing may be due to supramedullary dysfunction, particularly in patients who have destructive lesions in the tegmentum of the pons.

Less common than in heart failure or neurologic disorders is the occurrence of Cheyne–Stokes respiration in normal infants, in healthy elderly persons, and in normal persons at high altitude. It is also seen occasionally after the administration of respiratory depressants (e.g., morphine), often accompanied by an increase in intracranial pressure, uremia, or coma. At one time, the respiratory center was believed to be depressed in Cheyne–Stokes respiration. This hypothesis has been proved to be in error, since it has been shown that the respiratory response to inhalation of CO_2 is greater than normal in individuals with Cheyne–Stokes respiration. Respiratory alkalosis is common and the arterial P_{CO_2} remains subnormal in both the apneic and hyperpneic phases.

KUSSMAUL BREATHING

In 1874, Kussmaul described three patients with diabetic ketoacidosis who manifested "air hunger": they were breathing with large tidal volumes and so rapidly that there was virtually no pause between breaths. In essence, they were breathing at rest as though they were exercising; breathing was accomplished with little apparent effort. Since then, this pattern of breathing has been observed in other types of severe metabolic acidoses (e.g., alcoholic ketoacidosis). The usual sequence leading to this type of breathing is renal failure with a progressive decrease in plasma bicarbonate and resultant acidosis. The "compensatory" increase in ventilation that Kussmaul described mitigates the fall in systemic pH caused by the fall in plasma bicarbonate (see Chapter 17).

OTHER ABNORMAL PATTERNS

Gasping respirations are characteristic of severe cerebral hypoxia. The pattern consists of irregular, quick inspirations associated with extensions of the neck and followed by a long expiratory pause. It is commonly seen in shock or in other conditions associated with severe reduction in cardiac output.

Hyperventilation is commonly seen in anxious patients without structural disease of the lungs. In some of these patients, striking deep sighs dominate the ventilatory pattern.

DIAGNOSTIC TESTING IN THE EVALUATION OF DYSPNEA

Attention to the history and physical examination findings, as described in the preceding sections, will help to focus the initial approach to diagnosis.[34] In most cases, the initial diagnostic impression can be confirmed or excluded with only a few tests, and appropriate therapy instituted or the hunt for a cause continued (Table 29-8).

A plain chest radiograph is useful in demonstrating changes suggestive of COPD (chest hyperinflation, bullous changes). Vascular engorgement, an enlarged cardiac silhouette, increased interstitial markings, and pleural effusions may indicate left heart failure.

Spirometry is useful in identifying airways obstruction; improvement in values may be noted following administration of a bronchodilator. The measurement of lung volumes or the diffusing capacity may be reserved for when there is suspicion of an interstitial process or other cause of restriction (e.g., muscle weakness). Measurement of arterial oxyhemoglobin saturation both at rest and with exertion is important. While oxyhemoglobin desaturation will not indicate the etiology of the problem, its presence is always an important indicator of the severity of the disease. An echocardiogram can be used to assess ventricular or valvular cardiac function and to estimate pulmonary arterial pressures.

A complete blood count may reveal anemia or suggest an infection. Measurement of serum electrolytes may indicate the presence of an acidosis or renal dysfunction. Measurement of brain natriuretic peptide (BNP) has been useful in helping to exclude heart failure as an acute cause of dyspnea.[35]

Additional testing is usually not required unless the cause of dyspnea remains unclear following basic studies. Further tests often include CT of the chest, which may rarely reveal changes of emphysema or an interstitial process not suggested by plain radiographs or lung function testing. The CT may additionally help to better

TABLE 29-8 Common Tests in the Evaluation of Dyspnea

Test	Some Possible Abnormalities	Some Possible Diagnoses
Plain chest radiograph	Cardiac enlargement	Congestive heart failure
	Vascular enlargement	Pulmonary hypertension
	Abnormal interstitial markings	Pulmonary fibrosis
	Pleural effusions	Malignant pleural effusion
	Hyperinflation	COPD
	Nodules/masses	Neoplastic process
Pulmonary function tests		
Spirometry	Obstructive ventilation defect (decreased FEV_1/FVC, %)	Asthma
		COPD
	Restrictive ventilatory defect	Interstitial lung disease
Diffusing capacity	Decreased	Interstitial lung disease
		Pulmonary vascular disease
	Increased	Alveolar hemorrhage
Inspiratory and expiratory pressures	Decreased values	Respiratory muscle weakness
Computed tomography	Abnormal interstitial markings	Interstitial lung disease
	Cystic changes	Bullous lung disease
	Lymphadenopathy	Sarcoidosis
	Vascular filling defects	Pulmonary embolism
	Ground-glass opacities	Neoplastic disease
Blood tests	Elevated white blood cell count	Infection
	Anemia	Anemia
	BNP	Heart failure
	Cr	Renal failure
		Respiratory or metabolic acidosis
	ABG	Acidoses or alkaloses (respiratory or metabolic)

COPD, chronic obstructive pulmonary disease; FEV_1/FVC, forced expiratory volume in 1 s/forced vital capacity; BNP, brain natriuretic peptide; Cr, creatine; ABG, arterial blood gas.

characterize an interstitial process identified on plain radiographs. Cardiopulmonary exercise testing (Chapter 34) may be helpful in differentiating between cardiac and respiratory causes of dyspnea, or in excluding a significant abnormality of either system and suggesting deconditioning as the culprit. Arterial blood gas measurements may be necessary to characterize the level of blood oxygenation or to identify hyperventilation or hypercapnia. More invasive testing, including cardiac catheterization or lung biopsy (by either bronchoscopy or surgery), is reserved for situations when the diagnosis remains unsettled and the results will be helpful in guiding therapy or discussions of prognosis.

COUGH

Cough is one of the most frequent causes of visits to the doctor's office.[36,37] Patients are frequently anxious about the possibility of a serious underlying cause. They may also be troubled by the complications of cough, including chest pain from intercostal muscle strain or even a fractured rib. They may be embarrassed by cough-induced urinary or fecal incontinence. Social isolation may also arise from the frequent fear of others that the patient's cough is infectious and communicable.

A cough is an explosive expiration that protects the lungs against aspiration and promotes the movement of secretions and other airway constituents upward toward the mouth. It is a critical element in the self-clearing and protective mechanisms of the lungs—a reflex act that usually, but not invariably, arises from stimulation of the bronchial mucosa somewhere between the larynx and the second-order bronchi. On rare occasions the cause is remote: impacted cerumen in the external auditory canal[38] or an inflammatory process of the pleura (see "Mechanism" below) (Fig. 29-12). The stimuli that may elicit a cough are diverse: inhaled particles, mucus that has been elaborated by the lining of the airways, inflammatory exudate in airways or parenchyma, a new growth or foreign body in an airway, or pressure on the external wall of the bronchus.

A cough may be voluntary, involuntary, or a combination of the two if the subject attempts to control an involuntary cough. Three categories of stimuli are commonly at work in producing an involuntary cough: mechanical, inflammatory, and psychogenic. Mechanical and chemical causes range from inhalation of irritants, such as smoke or dust, to distortions of the airways produced by pulmonary fibrosis or atelectasis. Most often, cough is due to tracheobronchial inflammation. The cigarette smoker is particularly vulnerable to exacerbation of cough by inhaled particles and fumes because of underlying chronic pharyngitis, laryngitis, and tracheobronchitis. As a rule, cough represents organic disease. But on occasion, psychogenic influences are responsible for a dry cough that is related to anxiety. Psychogenic stress can aggravate cough due to organic causes.[39]

The site of origin and significance of a cough may sometimes be ascertained from telltale signs and symptoms (Table 29-9). For example, the cough of acute tracheitis is often associated with retrosternal "burning." Acute laryngitis is usually associated with hoarseness and sore throat, as well as cough. Tuberculosis of the larynx is associated not only with painful swallowing but also with unequivocal evidence of pulmonary tuberculosis. In asthma, cough is part of a constellation of airway obstruction.

Interpretation of the significance of a cough depends on the clinical features with which it is associated. It has to be viewed in context: Is it acute or chronic? Is it productive or nonproductive? How long has it lasted? What is the general condition of the patient, and what comorbidities are present? For example, the acute onset of a hacking, nonproductive cough accompanied by coryza, sore throat, malaise, sweating, and fever generally heralds a viral upper respiratory infection. An episode of asthma may begin with cough and wheezing. In contrast, a persistent cough, even if virtually ignored by the patient, may be a harbinger of serious disease (e.g., carcinoma of the lung). In a cigarette smoker, a change in the nature of the cough from nonproductive to productive may signify the onset of a serious tracheobronchial infection or pneumonia.

A cough that is productive of purulent sputum is generally a reliable indication of infection in the tracheobronchial tree or lungs. When this symptom is associated with an acute illness, the characteristics of the sputum can be of considerable diagnostic help. Rust-colored sputum, which has a distinctive coloration from the even dispersion of blood in yellow, purulent sputum, was previously seen often in pneumococcal pneumonia; it is less commonly seen today due to the widespread use of antibiotics. The classic description of sputum in *Klebsiella* pneumonia is a resemblance to currant jelly; it also contains blood, but it is bright red and more translucent and viscid than the sputum of pneumococcal pneumonia. Purulent sputum with a foul odor usually indicates an anaerobic infection, commonly due to streptococci or *Bacteroides* in a lung abscess. A persistent cough that is productive of purulent sputum occurs in chronic bronchitis, bronchiectasis, and a variety of other suppurative disorders. Sputum that is mucoid may be a consequence of any long-standing bronchial irritant. Copious sputum production *(bronchorrhea)* may be a sign of adenocarcinoma in situ (AIS) or minimally invasive adenocarcinoma (MIA), previously known as bronchoalveolar carcinoma.

TABLE 29-9 Some Causes and Characteristics of Cough

Cause	Characteristics
Sinusitis or nasopharyngitis	Cough following an upper respiratory syndrome or sinus symptoms; sensation of a need to clear the throat; postnasal drip
Acute infections of lungs	
Tracheobronchitis	Cough associated with sore throat, running nose, and eyes
Lobar pneumonia	Cough often preceded by symptoms of upper respiratory infection; cough dry, painful at first; later becomes productive
Bronchopneumonia	Cough dry or productive, usually begins as acute bronchitis
Mycoplasma and viral pneumonia	Paroxysmal cough, productive of mucoid or blood-stained sputum associated with flulike syndrome
Exacerbation of chronic bronchitis	Cough productive of mucoid sputum becomes purulent
Chronic infections of lungs	
Bronchitis	Cough productive of sputum on most days for more than 3 consecutive months and for more than 2 y Sputum mucoid until acute exacerbation, when it becomes mucopurulent
Bronchiectasis	Cough copious, foul, purulent, often since childhood; forms layers upon standing
Tuberculosis or fungus	Persistent cough for weeks to months, often with blood-tinged sputum
Parenchymal inflammatory processes	
Interstitial fibrosis and infiltrations	Cough nonproductive, persistent, depends on origin
Smoking and inhalation of irritants	Cough usually associated with injected pharynx; persistent, most marked in morning, usually only slightly productive unless succeeded by chronic bronchitis
Tumors	
Bronchogenic carcinoma	Cough nonproductive to productive for weeks to months; recurrent small hemoptysis common
Adenocarcinoma *in situ* or minimally invasive adenocarcinoma	Cough similar to that with bronchogenic carcinoma except in occasional instances, when large quantities of watery, mucoid sputum are produced
Benign tumors in airways	Cough nonproductive; occasionally hemoptysis
Mediastinal tumors	Cough, often with breathlessness, caused by compression of trachea and bronchi
Aortic aneurysm	Brassy cough
Gastrointestinal	
Gastroesophageal reflux disease (GERD)	Nonproductive cough often following meals or with recumbency; may (or may not) be accompanied by other symptoms of GERD (e.g., heartburn, a bitter oral taste, belching)
Foreign body	
Immediate, while still in upper airway	Cough associated with progressive evidence of asphyxiation
Later, when lodged in lower airway	Nonproductive cough, persistent, associated with localizing wheeze
Cardiovascular	
Left ventricular failure	Cough intensifies while supine, along with aggravation of dyspnea
Pulmonary infarction	Cough associated with hemoptysis, usually with pleural effusion
Medication-induced	
Angiotensin-converting enzyme (ACE) inhibitors	Nonproductive cough, more common in women, may occur at any time (following soon after drug initiation or with years of use)

MECHANISM

A cough begins with a rapid inspiration, followed, in rapid sequence, by closure of the glottis, contraction of the abdominal and thoracic expiratory muscles, abrupt increase in pleural and intrapulmonary pressures, sudden opening of the glottis, and expulsion of a burst of air from the mouth (Fig. 29-13). The high intrathoracic pressures, which often exceed 100 to 200 mm Hg, increase the velocity of airflow through the airways, hastening the propulsion of the offending particles and producing the sound of a cough by setting into vibration airway secretions, the tracheobronchial walls, and the adjacent parenchyma (Fig. 29-14).

Afferent stimuli for a cough originate in irritant receptors and are conveyed centrally by the vagus, glossopharyngeal, trigeminal, and phrenic nerves (Fig. 29-12). In subjects with an idiopathic, persistent, nonproductive cough, increased sensitivity of the afferent nerves of the airways due to neuropeptides stored in them has been proposed.

The vagus nerve carries impulses not only from the larynx, trachea, and bronchi, but also from the pleura and stomach. Receptors in the airways are most concentrated in the larynx, diminish in density in the conducting airways, and are absent from the distal airways, enabling the pooling of secretions in the periphery. The glossopharyngeal nerve carries stimuli from the pharynx; the trigeminal nerve, from the nose and paranasal sinuses; the phrenic nerve, from the pericardium and diaphragm. The motor pathways are even more extensive, comprising not only the cranial and phrenic nerves but also the nerves to the muscles of the rib cage and the accessory muscles. Additional impulses from chemoreceptors are located in the esophagus and carried by the phrenic nerve.

The effectiveness of a cough is strongly influenced by the lung volume at which it occurs. As indicated elsewhere in this volume, cough only removes particles toward the mouth ("downstream"

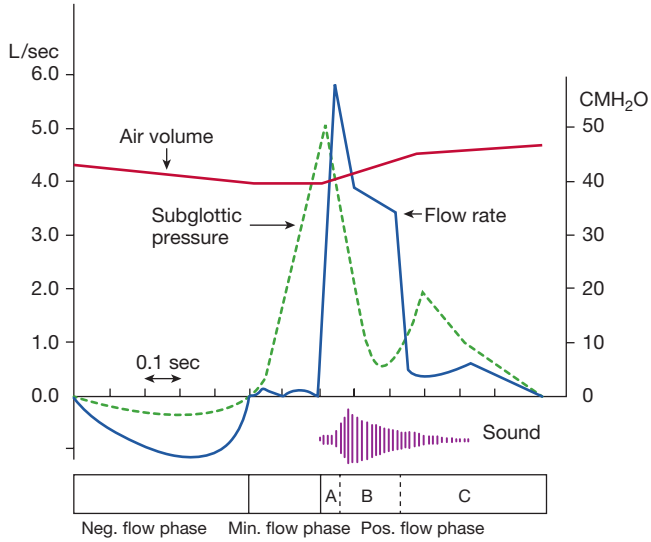

Figure 29-13 Sequence of events during a cough. Simultaneous recordings obtained during a single explosive cough by a normal subject. The three phases of a cough are identified by the boxes at the bottom of the figure. They correspond to (1) a deep initial inspiration, (2) compression of air in the lungs and airways by forceful contraction of the expiratory muscles coupled with tight closure of the glottis and opening of the larynx, and (3) sudden explosive expiration followed by narrowing of the glottis and return of the larynx to its normal inspiratory position. *(Reproduced with permission from Yanagihara N, Von Leden H, Werner-Kukuk E. The physical parameters of cough: the larynx in a normal single cough. Acta Otolaryngol. 1966;61(6):495–510.)*

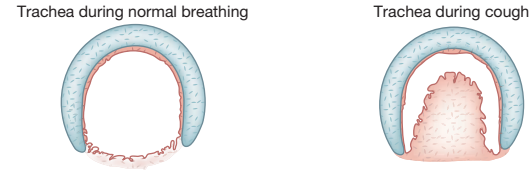

Intrathoracic pressure, cm H_2O	− 4	+ 150
Cross-sectional area, cm^2	1.5	0.25
Volume flow, L/sec	1	7
Linear velocity, cm/sec	667	28,000

Figure 29-14 Effects of tracheal narrowing during a cough. The forced expiratory effort during coughing causes invagination of the noncartilaginous part of the intrathoracic trachea by the high intrathoracic pressure. Air rushing with a high linear velocity through the exceedingly narrow trachea dislodges the material to be dispelled and propels it into the throat. *(Reproduced with permission from Comroe. Physiology of Respiration. St. Louis. Mosby-Year Book; 1965.)*

from the "equal pressure points"). In healthy persons at high lung volumes, the equal pressure points are located in the larger airways; they move toward the alveoli ("upstream") as lung volume decreases. A series of coughs without any intervening inspiration moves the equal pressure points even closer to the small airways, helping to clear the depths of the lungs.

The cough reflex may be impaired by interrupting or blunting any step in the sequence. Irritant receptors can be damaged by a local destructive process (e.g., bronchiectasis), or their sensitivity can be diminished by narcotics or anesthetics.

The reflex pathways may be damaged as part of a neurologic disease. Tracheostomy, which eliminates glottic closure, decreases peak intrapulmonary pressures. Contraction of the respiratory muscles may be impaired by weakness due to illness, age, or neuromuscular disease. In general, as long as the patient can achieve maximum expiratory pressures greater than about 60 cm H_2O, the peak flow will suffice to produce effective coughs.

CIRCULATORY CONSEQUENCES

The increase in intrathoracic pressure that is part of the cough mechanism exerts considerable circulatory effects. However, because the increase in intrathoracic pressure is accompanied by an equal rise in vascular (and cerebrospinal fluid) pressures, distending pressures on the vessels of the heart, lungs, and other vital organs are unaltered, so they are normally spared the ill consequences of marked swings in transmural pressures.

The increase in intrathoracic pressure is accompanied by reflex vasodilation of systemic arteries and veins. Both of these effects contribute to a decrease in cardiac output. In patients with cor pulmonale and right heart failure, cough impedes systemic venous return and may result in syncope.

POSTTUSSIVE SYNCOPE

Over 100 years ago, Charcot recognized the syndrome of posttussive syncope in individuals without underlying cardiopulmonary disease. Originally conceived of as a form of epilepsy or a consequence of a laryngeal reflex, it is now attributed to the same circulatory consequences of raised intrathoracic pressures that coughing evokes in a normal person. However, the patient with cough syncope probably coughs more forcefully and longer than does a normal person.

The syncope usually develops within a few seconds after the onset of a paroxysm of coughing and ends quickly once the coughing has stopped. Return to consciousness is without sequelae unless the subject falls and is injured during the faint. Posttussive syncope nearly always occurs in men, probably because they generate a higher intrathoracic pressure and much more profound decrease in cardiac output than do women. It is not clear why this type of fainting occurs in the supine, as well as the upright, position; this occurrence suggests that the reduction in cerebral blood flow during posttussive syncope reflects more than interference with cardiac output. The extent to which intense reflex vasodilation contributes to posttussive syncope is unclear. It is important to distinguish cough syncope from epilepsy and cataplexy.

ETIOLOGY

The most common causes of chronic cough and sputum (defined as lasting longer than 8 weeks) are postnasal drip, gastroesophageal reflux disease (GERD), and asthma. In one series of 71 patients, the cause was determined in 97%, with one cause noted in 38%, two causes in 36%, and three causes in 26%. The spectrum of conditions included postnasal drip in 40%, asthma in 24%, GERD in 15%, and bronchitis in 11%.[40]

In patients treated with angiotensin-converting enzyme (ACE) inhibitors, the drug is very often the cause of a chronic cough (even one developing after years of uncomplicated use). The association of cough and ACE inhibitors may be different among various ethnic groups.[41]

A deliberate evaluation can identify the cause of cough in the vast majority of patients. Usually, the diagnosis is established only by the resolution of the cough following a specific intervention (Fig. 29-15). For example, cough that disappears after antihistamines and inhaled nasal corticosteroid treatment for allergic rhinitis can logically be attributed to postnasal drip. Similarly, cough may disappear after interventions for GERD (e.g., use of H_2-blockers) or asthma (use of

inhaled bronchodilators and steroids). A cough that resolves after discontinuation of an ACE inhibitor was presumably caused by the drug. Although the causes of chronic cough are usually benign, a chest radiograph is warranted at the beginning of the evaluation of a chronic cough to assess for serious causes.

HEMOPTYSIS

The coughing up of blood is termed *hemoptysis.*[42] The material and amount produced varies from mere blood streaking of expectorated sputum to massive volumes of pure blood. Massive hemoptysis has been variably defined according to the volume, but its presence

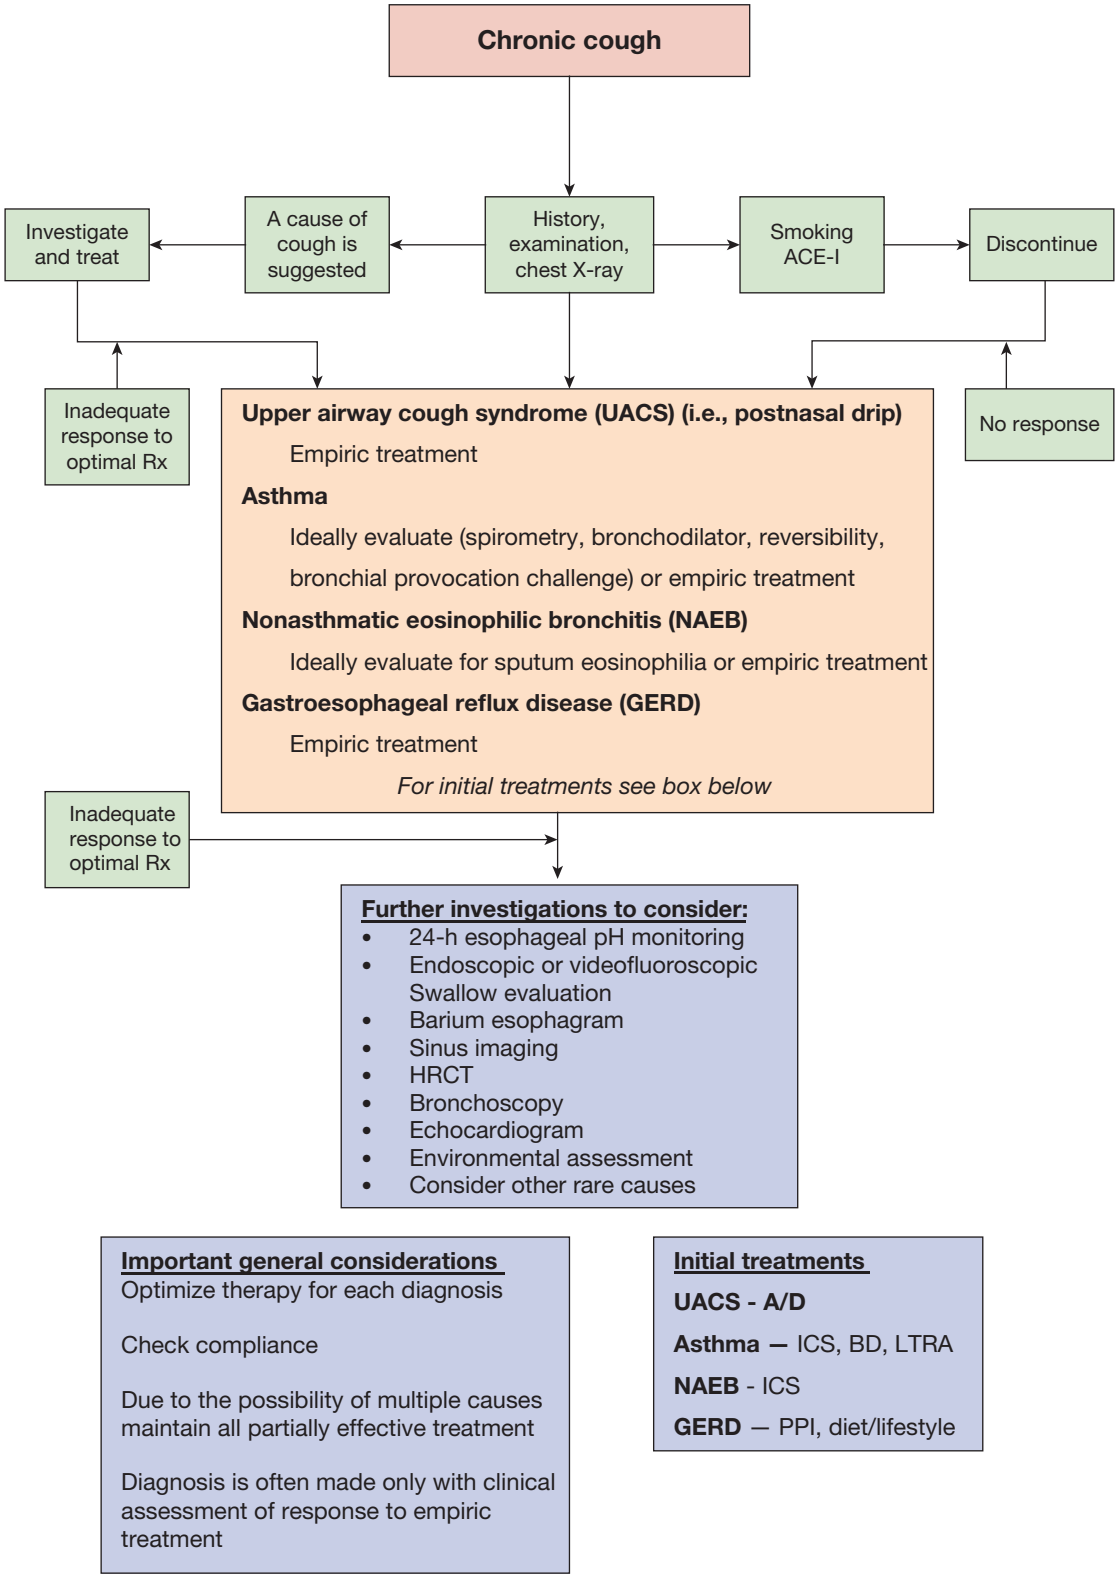

Figure 29-15 Algorithm for the evaluation of chronic cough lasting 8 weeks in adults. ACE-I, ACE inhibitor; BD, bronchodilator; LTRA, leukotrienes receptor antagonist; PPI, proton pump inhibitor; ICS, inhaled corticosteroid; A/D, antihistamine/decongestant; HRCT, high-resolution computed tomography. *(Reproduced with permission from Irwin RS, et al. Diagnosis and management of cough executive summary: ACCP evidence-based clinical practice guidelines. Chest. 2006;129 (1 Suppl):1S–23S.)*

implies a potentially life-threatening process requiring immediate evaluation and treatment.

An initial decision faced by the physician who is told that blood has been coughed up is whether to conclude that the blood is coming from the respiratory tract. Any portion of the respiratory tract can be the source of bleeding including a main bronchus, the lungs, or the nose or throat. On occasion, blood from the nose and throat is inhaled and then expectorated. As long as this possibility is kept in mind, bleeding that originates in the nose, throat, or larynx is not apt to be overlooked.

An additional consideration is distinguishing hemoptysis from hematemesis (vomited blood). Even if the blood is aspirated and then coughed up, the patient can usually tell if the blood originated in the respiratory or alimentary tract. The appearance of the bloody material also helps to distinguish between hemoptysis and hematemesis: blood that originates in the airways is usually bright red, is mixed with frothy sputum, has an alkaline pH, and contains alveolar macrophages that are laden with hemosiderin; in contrast, blood from the stomach usually is dark, has an acid pH, contains food particles, and often occurs in patients with a long history of gastric disease.

Blood arising from the bronchial arteries is more often the source of massive hemoptysis, owing to its higher perfusion pressure, than blood from the pulmonary circulation. The bronchial circulation may be the source of life-threatening bleeding, for example, in patients with bronchiectasis in whom the vessels frequently become distorted and easily ruptured. Dieulafoy's disease of the bronchus, in which there is a submucosal fistula between bronchial and pulmonary arteries, is a rare cause of massive hemoptysis.[43]

The differential diagnosis of hemoptysis includes disorders arising within the airways and the pulmonary parenchyma. Inflammatory processes (e.g., bronchitis and bronchiectasis) and neoplasms are the most common causes of blood arising within the airways. Within the pulmonary parenchyma, common causes are infections, such as tuberculosis, pneumonia, *Aspergillus*, or lung abscess. Inflammatory processes that involve the lung, such as granulomatosis with polyangiitis (formerly known as Wegner's granulomatosis) or Goodpasture syndrome, are also important causes of hemoptysis (Fig. 29-16). Bleeding may be iatrogenic, as for example, after a lung biopsy or when chemotherapy for bone marrow transplantation evokes diffuse alveolar hemorrhage. Vascular disorders, including pulmonary embolism, arteriovenous malfunctions, and mitral stenosis are also to be considered in the differential diagnosis. Unexplained hemoptysis occurs in COPD and usually is not recurrent.[44]

The causes of hemoptysis are numerous and diverse (Table 29-10). The clinical setting is usually helpful in identifying the cause. Hemoptysis before middle age usually brings to mind infections; after 40 to 45 years of age, or if there is a history of smoking, bronchogenic carcinoma heads the list. In patients left with a pulmonary cavity after pulmonary disease that has healed (e.g., tuberculosis), and in regions of the country where pulmonary fungal diseases are prevalent, a bout of hemoptysis is occasionally the first sign of the disease. In patients who have a predisposing cause, such as oral contraceptives or chronic heart failure, pulmonary embolism must be considered.

The evaluation of hemoptysis involves a careful history, physical examination, and a chest radiograph. Initial studies also include a complete blood count. The degree of anemia may influence the rapidity of further testing, and thrombocytopenia may be a contributing factor to hemoptysis. Rapid correction of anemia, thrombocytopenia, or coagulopathy with the transfusion of appropriate blood products may be required promptly depending upon the clinical status and degree of abnormality. Similarly, measurement of coagulation parameters is important. Studies of renal function and a urinalysis may be indicated when a systemic process, which causes a pulmonary-renal syndrome is a possibility. Sputum should be collected and, depending on the circumstance, microbiologic cultures and stains or cytologic examination should be performed. Depending on whether a cause is identified, and the risk factors for a serious cause of bleeding, the evaluation next involves additional studies to search for a source.

TABLE 29-10 Some Causes of Hemoptysis

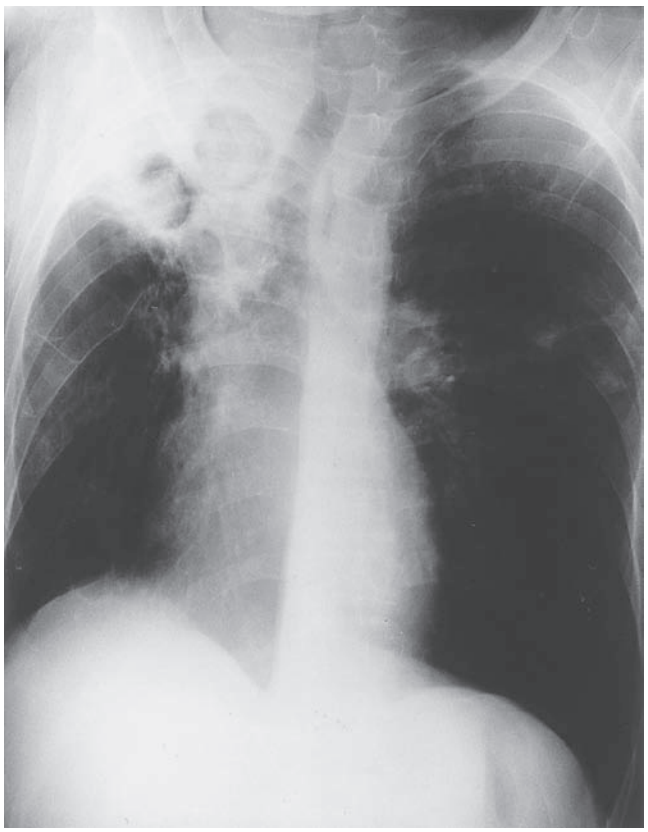
Disorders of hemostasis
Goodpasture syndrome

Because hunting for the cause and the source of bleeding is generally uncomfortable for the patient and often expensive, the intensity of the search depends on the circumstances. For example, rarely is a search for the bleeding site needed in a patient with acute bronchitis, pneumonia, or bronchopulmonary suppuration. But as a rule, unless the cause is evident, a full-scale investigation is mandatory.

Patients with hemoptysis and a history of tobacco smoking, individuals who are more than 40 years of age, or those who experience hemoptysis that lasts for more than 1 week are at greater risk for a worrisome cause and warrant additional studies. A high-resolution computed tomography (HRCT) of the chest is usually the next step if the patient has no history of tobacco use or if the plain chest radiograph suggests a parenchymal abnormality, such as bronchiectasis or arteriovenous malformation. Patients with a history of tobacco use or other risk factors for a malignancy warrant fiberoptic bronchoscopy (Chapter 35). In practice, HRCT and bronchoscopy are often complementary for visualizing abnormalities that are not apparent on plain chest radiographs. Patients with chronic bronchitis and who are at low risk for malignancy, or in whom the chest radiograph is normal or identifies the cause of hemoptysis (e.g., pneumonia) can usually be treated initially for bronchitis with follow-up appraisals to show prompt resolution of hemoptysis. However, should hemoptysis recur, further evaluation is required.

■ NEOPLASMS

Nonmassive hemoptysis (<500 cc/24 h) is common in bronchogenic carcinoma; less frequently carcinoma is the cause of massive hemoptysis. The likelihood of a neoplastic cause of hemoptysis is greatly increased in a cigarette smoker. Usually a troublesome cough and vague chest pain precede and accompany the hemoptysis. For hemoptysis to occur, the lesion must communicate with the airways. Most often the bleeding is a consequence of ulceration caused by an expanding tumor; sometimes it is due to a pneumonic process or to an abscess in the lung behind an obstructive lesion. Hemoptysis



A

Gough.)* **D.** Sagittal section of lung. Fungus ball due to aspergillosis in old tuberculosis cavity. Recurrent hemoptysis was treated with surgical removal of right upper lobe.

rarely complicates metastatic tumors of the lungs (primarily renal and colon carcinomas).

Not only malignant, but also benign, tumors of the lung cause bleeding. The classic example is bronchial carcinoid.

Hemoptysis may accompany a severe infection occurring anywhere from the top to the bottom of the respiratory tract. It is uncommon in the usual viral or bacterial pneumonia. Conversely, it is not uncommon in the pneumonia that complicates bronchogenic carcinoma or in the pneumonia that is caused by staphylococci, influenza virus, or *Klebsiella*.

The infecting organism determines the appearance and composition of the material that is expectorated with the blood. As indicated previously, in pneumococcal lobar pneumonia, the sputum at the onset is characteristically rusty-looking, but sometimes it is faintly or grossly bloody. In staphylococcal pneumonia, the blood is mixed with pus. In *Klebsiella* pneumonia, the bloody sputum may resemble currant jelly. Brisk bleeding is common in lung abscess; the blood is mixed with copious amounts of foul-smelling pus. In lung gangrene, blood is associated with necrotic lung tissue.

Bleeding is common in bronchiectasis. Because it usually originates in a bronchial artery, bleeding is often brisk. While most episodes stop spontaneously, the hemoptysis tends to recur and may be life-threatening.

Fungal infections of the lungs may cause hemoptysis (Fig. 29-16). As in tuberculosis, hemoptysis is generally a consequence of a continuing necrotizing and ulcerating inflammatory process or of bronchiectasis. The most common fungal disorder associated with hemoptysis is a "fungus ball" that resides either in a healed tuberculous or bronchiectatic area or in a cystic residue of sarcoidosis. *Aspergillus* is the usual fungal agent; less often another fungus (e.g., *Mucor*) is the cause.

At one time, the most common source of hemoptysis was an active tuberculosis cavity. Despite the increasing frequency of tuberculosis, hemoptysis is uncommon because of effective antituberculous therapy. If tuberculosis is allowed to progress to the point of extensive fibrosis and cavitation, or becomes complicated by bronchiectasis, hemoptysis can be troublesome and persistent. Hemoptysis may arise from a *Rasmussen aneurysm*, which is an erosion of a small- or medium-sized pulmonary artery into an adjacent tuberculosis cavity.

The "right middle lobe syndrome" is frequently associated with hemoptysis. It is due to a partial or complete obstruction of the right middle lobe bronchus, resulting in atelectasis or pneumonitis in the right middle lobe. The obstruction is more often caused by scarring or inflammation than by physical compression of the lumen by an enlarged lymph node. The cause is usually infectious; the infection may be tuberculosis.

In parts of the world where amebiasis is endemic, hemoptysis follows perforation into the airways of an amebic lung abscess. The sputum resembles anchovy sauce.

CARDIOVASCULAR DISORDERS

Pulmonary congestion and alveolar edema sometimes produce blood-tinged sputum. In chronic pulmonary congestion secondary to left ventricular failure or to mitral valve disease, alveolar macrophages in the sputum are often laden with hemosiderin ("heart failure cells"). In severe congestion and edema, the sputum is often pink and frothy. Usually there is no difficulty in recognizing that inadequate performance of the left ventricle is the cause of the bloody sputum.

Pulmonary thromboembolism may produce hemoptysis when associated with infarction (Fig. 29-17). The hemoptysis of pulmonary infarction is usually associated with pleuritic pain and, often, with a small pleural effusion because of the peripheral location of the infarct.

Tight mitral stenosis is sometimes first manifested by a bout of brisk, bright-red hemoptysis that is difficult to control. The source of the bleeding is the submucosal bronchial veins, which proliferate considerably in this disorder. Massive hemoptysis due to mitral stenosis is a medical emergency and is an indication for surgical intervention to relieve the obstruction at the mitral valve.

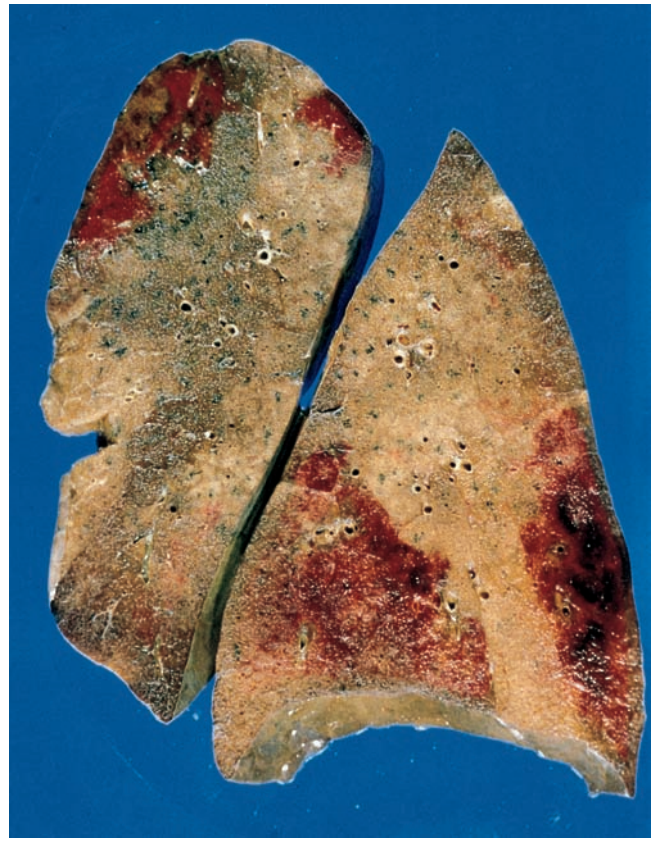

Figure 29-17 Hemorrhagic pulmonary infarcts. Several subpleural areas of infarction are clearly demarcated.

Hemoptysis from other circulatory disorders is much less common. Occasionally, an aortic aneurysm penetrates into the tracheobronchial tree, causing death by exsanguination and asphyxiation. An extraordinary event is the communication of an arteriovenous fistula with a small airway, causing bleeding that is exceedingly difficult to arrest.

TRAUMA

Hemoptysis follows a variety of chest injuries: puncture of a lung by a fractured rib, contusions of a lung by severe blunt trauma to the chest, and necrosis of the lining of the tracheobronchial tree by inhaled fumes or smoke. Blunt trauma from the steering wheel during an automobile collision sometimes lacerates or fractures the tracheobronchial tree. Stab or gunshot wounds often tear the lungs or airways. On occasion, mucosal lacerations in the course of severe coughing evoke hemoptysis.

After lobectomy, or now, less commonly, pneumonectomy, a large hemothorax occasionally empties into the airways. This is an alarming and ominous event. Its imminent occurrence is often heralded by the expectoration of blood-stained sputum after a paroxysm of coughing. The hemothorax must be promptly evacuated and the bronchus surgically repaired. Hemoptysis within a few weeks to months after lung resection has different implications: recurrence of tumor, granulation tissue, or bronchial sutures. Prompt bronchoscopy is necessary for accurate appraisal of the situation.

MISCELLANEOUS

Other causes of hemoptysis are listed in Table 29-10. They vary greatly in severity, urgency, and prognosis. Sometimes the cause is obscure, as in the occasional instance of hemoptysis that

accompanies menstruation (*catamenial hemoptysis*). An aspirated foreign body produces bleeding by damaging the mucosa on impact; if allowed to remain in place, it sometimes causes bronchiectasis, which, in turn, may cause bleeding. Pulmonary calcific foci, either in the pulmonary parenchyma or in lymph nodes, sometimes cause hemoptysis by ulcerating into a bronchus.

Thrombocytopenic purpura and hemophilia and the therapeutic use of anticoagulants are occasional causes of hemoptysis.

Hemoptysis in Goodpasture syndrome (Fig. 29-16) or in idiopathic hemosiderosis is life-threatening.

■ MANAGEMENT OF MASSIVE HEMOPTYSIS

The first priority in the care of a patient with life-threatening hemoptysis is to protect the airway and prevent asphyxiation.[45] Intubation should be contemplated and consideration given to selective intubation of one lung in order to protect it from spillage of blood from the other. When the site of bleeding is known, one simple, initial bedside maneuver is to place the involved side in a dependent position in order to protect the uninvolved lung. Bronchoscopy should be performed promptly in order to identify the source (Chapters 35 and 36). This may also allow bronchoscopic interventions, such as the placement of a balloon catheter to isolate the involved segment, lavage with iced saline, or the application of topical epinephrine (1:20,000). Bronchoscopic localization may help to guide attempts at arresting the bleeding by angiographic embolization. If these modalities fail to stop the bleeding, surgical exploration may be required. Not surprisingly, emergency procedures are accompanied by a high mortality. None of the approaches has been rigorously studied, and the choice is frequently dictated by the urgency, local experience, and availability of bronchoscopy.

CYANOSIS

Cyanosis refers to a bluish discoloration of the skin that is caused by increased amounts of reduced hemoglobin in the subcapillary venous plexus. The discoloration is most apparent in the lobes of the ears, the cutaneous surfaces of the lips, and the nail beds. In patients with dark skin, the mucus membranes and the retina are important sites to examine for cyanosis. Unless flow through the skin is slowed, as in heart failure, cyanosis implies arterial hypoxemia. Cyanosis does not appear in carbon monoxide poisoning or in severe anemia, even though arterial O_2 content is extremely low. This is because there is an insufficient amount of reduced hemoglobin present for the cyanotic discoloration to be visible. The presence of abnormal pigments in blood, such as methemoglobin or bilirubin, complicates the detection of cyanosis.

■ CAPILLARY O_2 CONTENT

An increase in the amount of reduced hemoglobin in the capillaries of the skin, as elsewhere, results from inadequate oxygenation of arterial blood, excessive removal of O_2 from capillary blood (as when the circulation through a region is slowed by vasoconstriction or a very low cardiac output), or from a combination of the two. The concentration of reduced hemoglobin in the skin capillaries must reach about 5 g/dL before cyanosis becomes discernible. Thus, in severe anemia, when hemoglobin concentrations are exceedingly low (on the order of 3–4 g/dL), although virtually all the hemoglobin can be reduced in traversing the skin capillaries, an insufficient amount of reduced hemoglobin remains to produce a visible discoloration. On the other hand, the polycythemic patient develops cyanosis at a higher arterial O_2 saturation than does the normal individual.

■ CAUSES OF CYANOSIS

Several types of cyanosis are usually identified according to the underlying mechanism. They include peripheral cyanosis, cyanosis arising from pulmonary disease, cyanosis from venous admixture, and cyanosis due to abnormal pigments in the blood.

Peripheral Cyanosis

This type of cyanosis is secondary to abnormally large extraction of O_2 from blood flowing through peripheral capillaries. The most common cause is a diminished cardiac output associated with peripheral vasoconstriction. Not only the hands and feet but also the tip of the nose become blue in severe heart failure. Indeed, in patients with intractable heart failure, necrosis occasionally develops at the tip of the nose.

Peripheral vasoconstriction per se, as in Raynaud's disease, also produces cyanosis of the nail beds.

Cyanosis in Pulmonary Disease

Patients with chronic bronchitis and emphysema characteristically manifest derangements in ventilation–perfusion relationships. In some, arterial hypoxemia results. In patients with diffuse interstitial fibrosis, normal arterial oxygenation at rest is succeeded by arterial hypoxemia, and sometimes, by cyanosis, during exercise. Another cause of arterial hypoxemia is the syndrome of alveolar hypoventilation in patients with normal lungs. In any of these situations, cyanosis is intensified if heart failure supervenes and slows blood flow through the skin (i.e., is associated with decreased O_2 delivery).

Cyanosis Due to Venous Admixture

In patients with intracardiac right-to-left shunts, cyanosis arises from a mixture of venous and arterial blood. The effect of venous admixture is particularly striking if the O_2 content of mixed venous blood is inordinately low, as in some types of congenital heart disease and in severe heart failure. Often, secondary polycythemia contributes to the cyanosis. On occasion, regional cyanosis is diagnostic. For example, in patent ductus arteriosus with reversal of blood flow, the lower extremities are deeply cyanotic, whereas the upper extremities are virtually normal in color.

Cyanosis Due to Abnormal Pigments in Blood

Methemoglobinemia is an occasional cause of cyanosis. Methemoglobinemic blood is chocolate brown, and spectrophotometric examination of blood reveals the characteristic pigment. Arterial blood examination discloses a normal P_{O_2}.

The cause of methemoglobinemia may be hereditary (i.e., due to the presence of hemoglobin M or a deficiency in methemoglobin reductase) or, more often, acquired (e.g., by exposure to chemical agents such as aniline dyes, chlorates, nitrates, and nitrites); methemoglobinemia may also result from drugs, such as dapsone, nitroglycerin, phenacetin, or primaquine. Nitrates are a common cause of methemoglobinemia. Nitrates are reduced to nitrites by bacteria in the intestinal tract. Excessive use of nitroglycerin, an organic nitrate, leads to methemoglobinemia.

In methemoglobinemia, the ferrous iron is oxidized to ferric iron, rendering the hemoglobin molecule incapable of binding O_2 or CO_2. Methemoglobin is formed continuously in the normal erythrocyte, but its level within the cell is kept low (<2%) by intracellular reductive mechanisms. High levels of methemoglobin result from hereditary abnormalities (e.g., a deficiency in methemoglobin reductase) or from exposure to drugs or chemicals that increase the rate of oxidation beyond the reductive capacity of the erythrocytes. Clinical manifestations of methemoglobinemia vary with the blood levels. Concentrations of methemoglobin between 10% and 25% usually cause asymptomatic cyanosis. When these levels are exceeded, dizziness, fatigue, and headache appear.

CLUBBING

Clubbing of the digits is a classic finding in medicine that dates back to Hippocrates' awareness of the association between characteristic

changes in the fingertips and empyema. Occasionally, it constitutes a valuable clue to clinically inapparent disease of the lungs and pleura. Clubbing of the fingers designates the selective bulbous enlargement of the distal segments of the digits due to an increase in soft tissue (Fig. 29-18). Although most often it is painless, clubbing remains an important finding, as its presence should signal an evaluation for potential serious causes.

When full-blown, clubbing is easy to recognize: (1) the nails, particularly the index finger, become abnormally curved in the longitudinal and coronal planes; (2) the hyponychial angle, viewed

A

E

Figure 29-18 Clubbing of the digits and hypertrophic osteoarthropathy. A 40-year-old woman developed swelling and tingling of the fingertips in association with painful swelling of both knees. She was a heavy smoker (36 pack-years) and had an 8-month history of a dry cough. **A.** Clubbing of all fingers. **B.** Index finger. **C.** Left hilar mass that proved to be a primary adenocarcinoma of the lung. **D.** Subperiosteal formation of new bone on the medial aspect of the diaphysis of the femur. **E.** Bone scan, using ^{99m}Tc methylene diphosphonate. An abnormal accumulation of isotope is seen in the area of new bone *(arrow)*.

in profile, becomes blunted, often in conjunction with softening and sponginess of the base of the nail; and (3) the undersurface of the terminal digit becomes large and bulbous. Early stages of clubbing are subtle and generally difficult to diagnose. Clubbing often has to be distinguished from simple curvature of the nails and, occasionally, from chronic paronychia and Heberden nodes. A variety of methods have been proposed for quantifying clubbing (e.g., measuring casts of the fingertips), but none has become popular.

Clubbing is generally acquired, but it may be hereditary. Acquired clubbing is seen in a wide variety of disorders, both extrathoracic and thoracic (Table 29-1).

It is important to recognize that clubbing is not caused by all forms of chronic lung disease. COPD, for example, does not cause clubbing. The presence of clubbing in a patient with COPD should alert the clinician to the possibility of a second process, commonly lung cancer. As a rule, clubbing is bilaterally symmetrical, affecting hands and feet; on occasion, local factors, such as injury of a finger or of the median nerve, may cause clubbing that is confined to a single finger. Rarely, clubbing may be confined to the digits of one hand (e.g., in an ipsilateral pulmonary sulcus tumor that has invaded the brachial plexus or following hemiplegia). In certain types of congenital heart disease, a telltale distribution of clubbing is of considerable diagnostic value. For example, in patent ductus arteriosus associated with reversal of shunt through the ductus, clubbing affects only the toes.

■ PATHOGENESIS

The pathogenesis of clubbing is unknown, and no suitable animal model of clubbed fingers has yet been developed, largely because so few species other than primates have fingers. A common denominator in the pathogenesis of clubbing appears to be vasodilation of vessels in the fingertip, including formation of the arteriovenous connections. As a result, hydrostatic pressures increase in the capillaries and venules, promoting the transduction of fluid into the interstitium. The reason for this preferential vasodilation is unclear. A popular notion is that a humoral substance escapes normal deactivation by pulmonary capillaries. This theory could account for clubbing in cyanotic congenital heart disease, in various pulmonary diseases in which proliferation of the bronchial circulation occurs, and in hepatic cirrhosis in which pulmonary arteriovenous anastomoses and right-to-left shunts are common. However, it is difficult to relate this theory to the high incidence of clubbing in subacute bacterial endocarditis.

At present, a single hypothesis that would account for the clubbing that occurs in such diverse disorders as subacute bacterial endocarditis, carcinoma of the lung, hemiplegia, chronic mountain sickness, and purgative abuse is not possible. Indeed, it seems likely that clubbing of the digits is a stereotyped consequence of diverse influences that have in common the capacity to induce marked digital vasodilation and interstitial edema of the soft tissue.

HYPERTROPHIC OSTEOARTHROPATHY

Occasionally, clubbing of the digits is accompanied by hypertrophic osteoarthropathy (HOA), a separate clinical and radiographic entity. Clinically, HOA is manifested by pain and swelling of the soft tissues over the distal ends of the long and tubular bones. Radiographically, the distinctive feature of HOA is the formation of new bone beneath the periosteum of the distal diaphyses of the long bones of the extremities (Fig. 29-18).

The most common disorder associated with HOA is carcinoma of the lung. The incidence is about 5% and is unrelated to the cell type of the cancer, except that small cell carcinoma is rarely implicated; a peripheral carcinoma of the lung is slightly more common than a central one. Joint symptoms precede the local signs of tumor in about one-third of the cases; the interval is sometimes as long as 2 years. Pulmonary metastases rarely cause HOA. Pulmonary tuberculosis is seldom, if ever, associated with HOA. CF and idiopathic pulmonary fibrosis may be accompanied by HOA. Pregnancy may rarely be a cause of HOA, with symptoms resolving promptly with delivery.

As in the case of clubbing of the digits, theories about pathogenesis tend to focus on humoral factors generated elsewhere. However, a neurogenic theory has also been advanced on the basis of two types of observations: (1) in a few patients, vagotomy has relieved the symptoms of inoperable carcinoma of the lung and led to regression of the bony lesions; and (2) in keeping with the observations on the few patients, vagotomy in dogs is usually followed by a decrease in blood flow to the limbs.

In contrast to clubbing of the digits, which is rarely painful, HOA associated with carcinoma of the lung often causes severe rheumatic symptoms. These symptoms vanish after resection of the carcinoma, even though clubbing usually remains. In patients who are treated with radiotherapy for unresectable carcinoma, pain in the vicinity of the joints usually decreases greatly and usually does not recur even if metastases develop in the lungs or elsewhere.

CHEST PAIN

Pain in the chest is a common clinical problem. It may arise from within the thorax (the heart, pericardium, lungs, pleura, chest wall) or be referred from elsewhere (e.g., from below the diaphragm). Characteristic patterns and associations may help to clarify the source of the pain.

First thoughts about chest pain almost invariably turn to the pain of myocardial ischemia. However, cardiac pain is often distinguishable from other types of chest pain because of its viselike nature; its characteristic radiation to the left arm, shoulder, or neck; and its lack of relation to breathing. Extracardiac painful sensations can arise from various sites within the thorax, most often from the pleura, the lungs, or the chest wall. Pain may also be referred to the thorax as a result of GERD.[46–48] In the primary care setting, in stable patients it is usually possible to exclude as the basis for pain cardiac, gastrointestinal, or pulmonary diseases.[49,50]

■ PLEURITIC PAIN

The most characteristic pain associated with the respiratory apparatus is pleural pain. It originates in the parietal pleura and endothoracic fascia; the visceral pleura is insensitive to pain. In contrast to the deep, oppressive substernal pain of myocardial infarction, pleuritic pain is identified by the patient as being close to the thoracic cage. It is predominantly an inspiratory pain, reflecting the stretching of inflamed parietal pleura during movement of the thorax; coughing or laughing is distressing; the patient often clutches the chest to minimize its excursion. The pain is usually local, but sometimes it spreads along the course of the intercostal nerves that supply the affected area. Irritation of the diaphragmatic pleura by an inflammatory process either below or above the diaphragm often causes ipsilateral shoulder pain when the central portion of the diaphragm is involved; sometimes the pain is referred to the abdomen when the outer diaphragmatic pleura is irritated.

As a rule, pleural pain is part of a syndrome of pleural inflammation that includes malaise and fever; an important exception to this generalization is the pleural pain of pulmonary infarction, which is often unassociated with any premonitory signs. In addition to inflammation and malignant etiologies, pleuritic pain occurs with pneumothorax.

■ PULMONARY PAIN

A second distinctive type of respiratory chest pain accompanies a tracheitis or tracheobronchitis. The pain is searing and is most pronounced after cough. Invariably, this central chest pain is associated with evidence of upper respiratory infection. It is aggravated by cough. Cold air may be intolerable.

An uncommon type of chest pain is associated with pulmonary hypertension. It is usually absent at rest and appears during exertion.

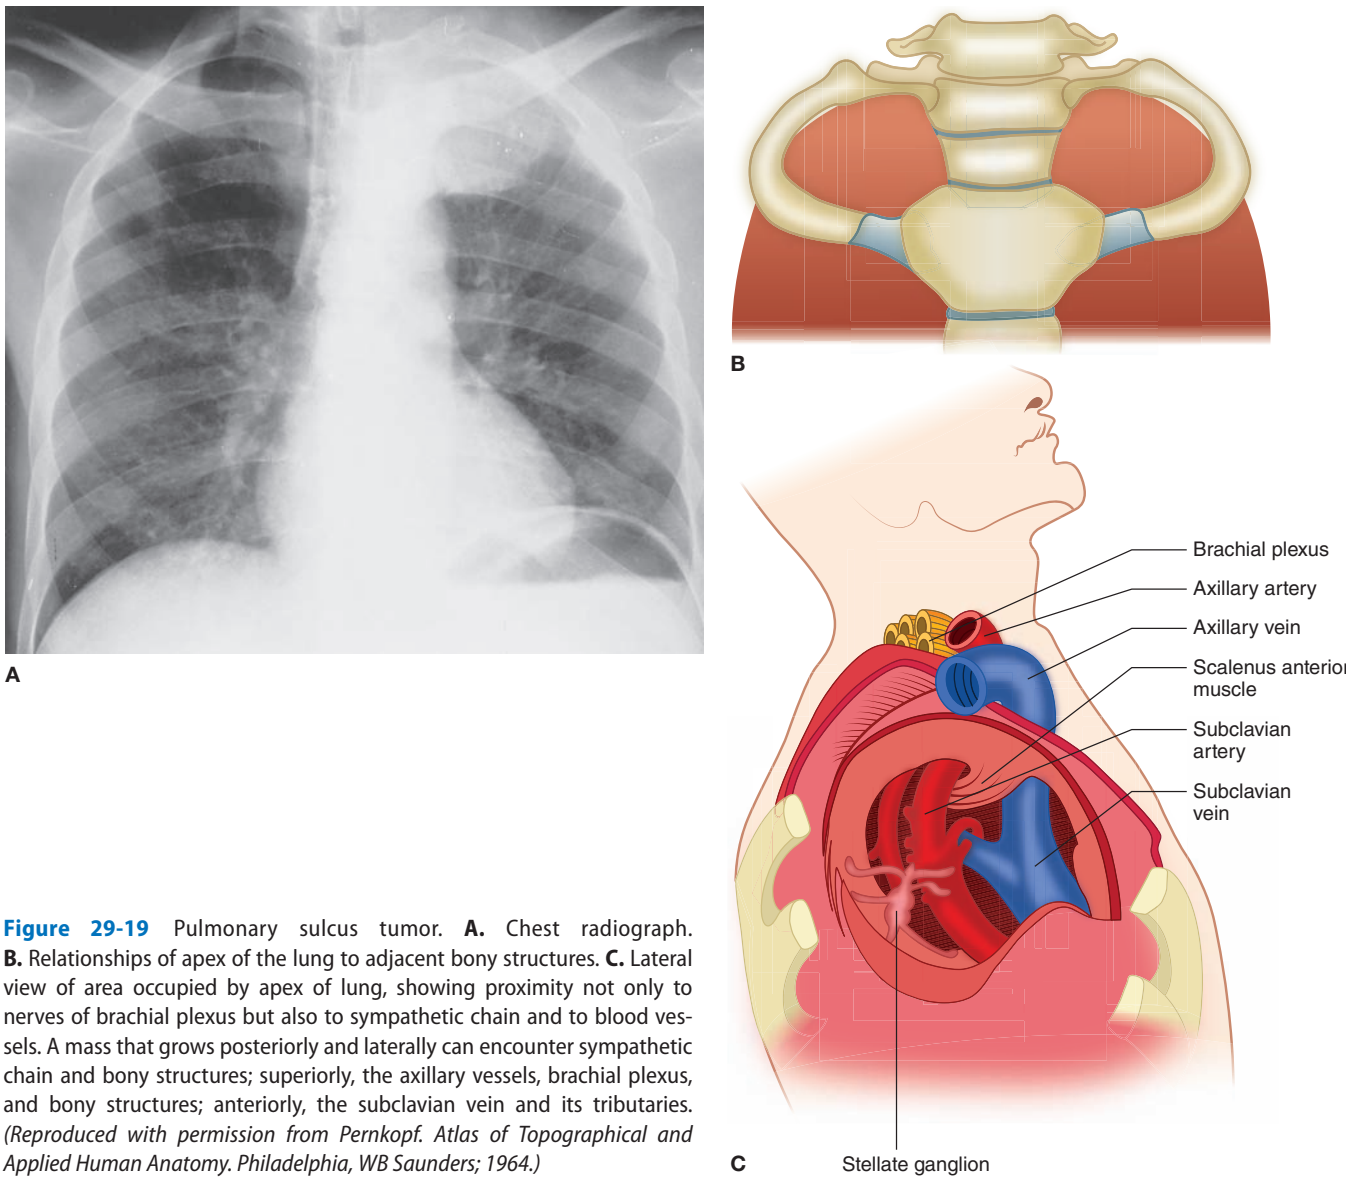

Figure 29-19 Pulmonary sulcus tumor. **A.** Chest radiograph. **B.** Relationships of apex of the lung to adjacent bony structures. **C.** Lateral view of area occupied by apex of lung, showing proximity not only to nerves of brachial plexus but also to sympathetic chain and to blood vessels. A mass that grows posteriorly and laterally can encounter sympathetic chain and bony structures; superiorly, the axillary vessels, brachial plexus, and bony structures; anteriorly, the subclavian vein and its tributaries. *(Reproduced with permission from Pernkopf. Atlas of Topographical and Applied Human Anatomy. Philadelphia, WB Saunders; 1964.)*

The pain is substernal and is associated with dyspnea; it subsides promptly when exercise stops. It is often mistaken for classic angina until the presence of pulmonary hypertension is uncovered. It may be due to right ventricular strain and ischemia.

■ CHEST-WALL PAIN

Musculoskeletal pain arising in the chest that is also aggravated by breathing may be confused with pleuritic pain. It is rarely severe and incapacitating, is often bilateral, and generally is intensified by changes in body position or flexing the thorax. The affected muscles are often tender to gentle pressure. A fractured rib is often identified as the source of pain by a history of a fall, injury, or trauma. Additional clues are point tenderness and crepitus of the affected area, reproduction of the pain upon manual compression of the chest, or radiographic evidence of a broken rib.

The pain of a pulmonary sulcus tumor, or "Pancoast tumor," (Fig. 29-19) is quite distinctive. This unusual location of a carcinoma of the lung was originally described by Pancoast in 1932. Pain due to the tumor occurs along the distribution of the eighth cervical and first and second thoracic nerves. In addition, Horner syndrome, local destruction of bone by the tumor, and atrophy of hand muscles may be observed. The chest radiograph is distinctive in showing a small, sharply defined shadow at one apex. Destruction of one or more of the upper three ribs posteriorly and of their adjacent transverse processes may also be seen.

■ CARDIAC PAIN

Attention was called above to the pain of myocardial ischemia. Another type of cardiac pain is that of pericarditis. Pericardial pain is often aggravated by deep breathing and, almost invariably, is accompanied by a telltale rub that is synchronous with the heartbeat. The discomfort may be relieved by leaning forward.

The *postcommissurotomy* or *postpericardiotomy syndrome* is characterized by chest pain that develops within a few days to weeks after cardiac surgery or pericardiotomy. The pain is usually sudden in onset and substernal, with radiation to the left side of the neck; often it is aggravated by deep breathing. Low-grade fever and a high erythrocyte sedimentation rate are regular concomitants.

Chest pain may also be troublesome in patients who have undergone cardiac transplantation. The diagnosis is usually self-evident when account is taken of the antecedent history of cardiac surgery. Indeed, confusion is more apt to arise with the pain of myocardial infarction than with respiratory causes of chest pain.

MISCELLANEOUS CAUSES OF PAIN

Other structures in the mediastinum may be the source of chest pain. Noteworthy are the types of pain arising from the esophagus (peptic esophagitis) and dissection of the aorta. Their patterns and intensity help to distinguish them from respiratory pain. Esophageal disease is typically accompanied by a burning pain, frequently after eating. Acid reflux may worsen with recumbency. Aortic dissection is often described with a sharp, tearing sensation of acute onset, with radiation to the shoulder; these are often signs of impending cardiovascular collapse.

Arthritis of the cervical spine is a common cause of thoracic pain. Usually the cause is quite clear because of the characteristic distribution of the pain. Cervical spondylosis occasionally causes severe pain in the chest and arms, but it is more apt to mimic myocardial infarction than is respiratory pain. A metastatic tumor to the thoracic spine often causes bilateral symmetric pain; there is often discomfort to palpation over the affected area. Unilateral pain, along the distribution of an intercostal nerve, is characteristic of herpes zoster before the appearance of the skin eruption and is often described as an intense burning sensation.

Anxiety may produce or intensify chest pain. Usually, pain related to anxiety is accompanied by dyspnea and hyperventilation. Manifestations of vasomotor instability, such as excessive palmar sweating, flushing, and tachycardia, may accompany the complaint of chest pain due to anxiety. Rarely does the pain conform to a characteristic or consistent pattern. Anxiety also interferes with the quantification of pain originating in a somatic lesion and with its management.

FEVER

In the patient with lung disease, fever usually, but not invariably, signifies infection. When the lung disease is chronic, as in bronchitis and emphysema, a bout of acute bronchitis usually elicits only a modest fever, even though the sputum turns purulent. In contrast, an acute pneumonia or lung abscess may be associated with high fever.

The possibility that fever is due to infection lends urgency to the situation. The wide range of pulmonary infections is considered elsewhere in this book. Often overlooked at the outset is miliary tuberculosis, which occasionally escapes detection on the initial chest radiograph. Favoring this diagnosis is a history of recent contact with a patient with active tuberculosis, general malaise, easy fatigability, and anorexia during the previous few weeks. This insidious onset differs strikingly from the more sudden onset of acute pneumonia.

Neoplasms are also associated with fever. In certain neoplasms, such as carcinoma within a bronchus, the fever is generally a secondary effect attributable to infection distal to obstruction; necrosis within the tumor is a less common cause. In others, such as hypernephroma, fever and chills are striking, even though evidence of infection is absent. A mesothelioma of the pleura is often associated with fever. Presumably, in patients with neoplasms who have no evidence of infection, necrosis within the tumor leads to the elaboration of fever-producing factors within and around the tumor.

Acute hypersensitivity pneumonitis (extrinsic allergic alveolitis) is sometimes accompanied by fever.

In contrast to the pulmonary disorders in which fever is a characteristic feature, pulmonary sarcoidosis is uncommonly associated with fever unless there is extrapulmonary involvement, such as lymphadenopathy or EN. Nor is pneumoconiosis associated with fever unless complicated by necrosis in the midst of conglomerate fibrosis or by superimposed tuberculosis. Among the other many disorders of the lungs that cause no fever (and few systemic complaints) are idiopathic pulmonary fibrosis, lymphangitic carcinomatosis, multiple pulmonary metastases, alveolar proteinosis, idiopathic pulmonary hemosiderosis, and alveolar microlithiasis.

PULMONARY-CUTANEOUS SYNDROMES

Examination of the skin may provide important clues in the diagnosis and treatment of patients with pulmonary disease. Some skin lesions either accompany pulmonary disease or complicate its treatment; occasionally, systemic diseases that affect both skin and lung first manifest themselves in the skin.

This section focuses on processes in which there is prominence of cutaneous manifestations that might impact the care of the patient with pulmonary disease. The diagnosis and development of a differential diagnosis of cutaneous lesions is beyond the scope of this chapter and can be found in general dermatology textbooks.[51–53]

ATOPIC DERMATITIS

Atopy refers to a group of disorders, including asthma, allergic rhinitis, and atopic dermatitis, in which immune and pharmacologic responses are abnormal. The atopic person usually has a family history of one or more of these disorders. Atopic dermatitis is a common disorder, affecting 1% to 3% of the population in the United States. In 85% of affected subjects, the skin lesions appear before 5 years of age.[54] The dermatitis may resolve as the patient reaches adulthood; in the adult, either the skin lesions or respiratory systems may predominate although there is a wide range of individual variability.

In infants, the skin lesions often begin as dry, erythematous plaques on the cheeks; excoriations and scaling may be prominent. In older children, the lesions localize in flexures; lichenification and excoriated papules are prominent features (Fig. 29-20). In adults, the lesions favor the hands and extremities. Atopic subjects also manifest prominent folds of the lower eyelids, periorbital hyperpigmentation with facial pallor, generalized dry skin, and white dermatographism. At any age, pruritus may be prominent, leading to secondary bacterial infection (bacterial impetigo) within the lesions.

The cause of atopic dermatitis is unknown. In all likelihood, the pathogenesis is multifactorial, probably including disordered immune regulation as a causative factor. Patients with atopic dermatitis often have elevated levels of IgE; may have abnormalities of CD30, macrophage-derived chemoattractant, interleukins (IL)-12, -16, -18, and -31, and thymus and activation-regulated chemokine; and have mutations of the filaggrin gene. The use of any of these biomarkers has not yet been demonstrated to be diagnostic or of prognostic value.[54] In persons with atopic dermatitis, abnormalities in cell-mediated immunity and lymphocyte function increase the risk of disseminated viral disease, particularly herpes simplex. The role of food or environmental antigenic challenge in flares of atopic dermatitis is unsettled, but it is known that asthma can be precipitated by such challenges.

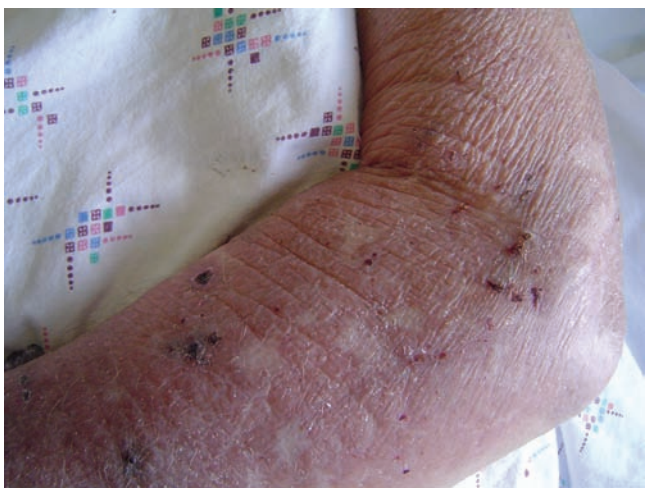

Figure 29-20 Atopic dermatitis is characterized by lichenification, excoriations, and slight scale.

Figure 29-21 Heliotrope eruption of dermatomyositis.

The relationship between atopic dermatitis and lung disease is imperfect. Although hyposensitization is useful for asthma, it is either not helpful or is detrimental in atopic dermatitis. In addition, the use of omalizumab, while beneficial for asthma, has demonstrated mixed results for patients with atopic dermatitis. Recent evidence suggests that the use of dupilumab, an IL-4, IL-13 antagonist might be useful for atopic dermatitis, as well as for the associated asthma[55]

COLLAGEN VASCULAR DISORDERS

Common collagen vascular disorders warrant discussion in relation to possible coexisting pulmonary manifestations, especially dermatomyositis (DM) and scleroderma.

DERMATOMYOSITIS

DM is an idiopathic inflammatory myopathy characterized by proximal, symmetrical, slowly progressive muscle weakness, and characteristic cutaneous lesions.[56,57] The pathognomonic skin lesions include a heliotrope eruption, which consists of erythematous-to-violaceous periorbital changes that may be accompanied by edema (Fig. 29-21), and Gottron papules, which consist of erythematous papules over the bony prominences on the dorsal hands (Fig. 29-22). Patients may also manifest a photodistributed poikiloderma (Fig. 29-23), nail-fold changes, and an erythematous-to-violaceous scaly alopecia. Patients with DM frequently complain of marked itching.

Figure 29-22 Gottron papules in dermatomyositis: Erythematous to violaceous lesions are most prominent over the joints. In addition, this patient demonstrates cuticular and periungual changes that are frequent in dermatomyositis.

Figure 29-23 Photodistributed poikiloderma in a patient with dermatomyositis.

Patients with DM may also have other systemic manifestations, including arthritis, esophageal disease, and cardiopulmonary disease; some have a malignancy. Others with the characteristic cutaneous lesions of DM are not weak and do not have an increase in muscle-derived enzymes. These patients are said to have amyopathic dermatomyositis if they have skin lesions with normal strength, and normal muscle-derived enzyme assessments for a period of 2 or more years without having been treated with systemic immunosuppressives or corticosteroids for more than a month.

Pulmonary disease occurs in classic dermatomyositis and in amyopathic dermatomyositis in approximately 15% to 65% of patients. Interstitial pneumonitis is a primary process in DM/polymyositis. Interstitial lung disease also occurs in patients with amyopathic dermatomyositis; in this subset of patients, survival is poor.

Pulmonary involvement is more frequent in patients with esophageal dysfunction. Lung disease may also occur as a direct complication of the muscle disease, for example, hypoventilation or aspiration in patients with dysphagia, or may be a result of treatment, such as opportunistic infections or drug-induced hypersensitivity pneumonitis.

Pulmonary disease appears to be more prominent in patients in southeast Asia, China, and Japan; however, there are many reports of patients in the United States with varying ethnicities who have developed pulmonary disease, particularly interstitial fibrosis, as well as rapidly progressive and, at times, fatal disease.[58] Patients with polymyositis and lung disease tend to have antisynthetase antibodies, particularly the Jo-1 antibody. However, Jo-1 is rarely found in patients with dermatomyositis. Recently, the anti-melanoma-differentiation gene 5 antibodies appeare to be associated with an increased risk of pulmonary disease.

Treatment of interstitial lung disease in patients with dermatomyositis is often difficult. Several recent studies have suggested that Mycophenolate mofetil is useful for these patients.[59,60]

SCLERODERMA

Scleroderma refers to hard skin. This process may be localized to the skin or may be part of a systemic disease.[61,62] Localized cutaneous scleroderma may occur as limited plaques of morphea, generalized morphea, deep morphea, or linear scleroderma. Interstitial pneumonitis is a rare complication of morphea or linear scleroderma.

Two principal forms of progressive systemic sclerosis (PSS) have been described: limited scleroderma (acrosclerosis) and diffuse scleroderma. Acrosclerosis is the more common of the two and is characterized by sclerosis of the skin of the fingers (sclerodactyly) (Fig. 29-24) and Raynaud's phenomenon (Fig. 29-25).

Figure 29-24 Acrosclerosis characterized by marked contractures and sclerodactyly.

Figure 29-26 Vitiligo-like dyspigmentation associated with progressive systemic sclerosis.

A variant (CREST syndrome) includes calcinosis, Raynaud's syndrome, esophageal dysmotility, sclerodactyly, and telangiectasia.

In contrast, patients with diffuse scleroderma have widespread sclerosis beyond the acral areas of sclerodactyly. The prognosis for diffuse scleroderma is much worse than for acrosclerosis. Both types of scleroderma are often preceded by Raynaud's phenomenon, diffuse arthralgias, or arthritis. The skin manifestations begin with transient, recurrent swelling of the hands, and progress to tapered fingers with shiny, hidebound skin (sclerodactyly). The feet, chest, face, and scalp are often involved in the sclerotic process. In time, the skin becomes taut, leading to contractures of the large and small joints that culminate in a claw-like deformity of the hand.

A variety of pigmentary disturbances may occur in scleroderma, including generalized hyperpigmentation that resembles adrenal insufficiency, focal hyperpigmentation or hypopigmentation, and areas of perifollicular pigmentation that resemble vitiligo (Fig. 29-26). Raynaud's phenomenon leads to small pitted scars at the fingertips or frank ulceration, with or without gangrene of the fingertips, toes, knuckles, and ankles, especially the malleoli.

The face often undergoes distinctive changes, leading to a fixed stare and inability to wrinkle the forehead. As the facial tissues shrink, the nose becomes pinched, the cheeks sunken, the mouth narrowed, and the lips thinned. In diffuse scleroderma, cutaneous sclerosis, accompanied by a yellowish-brown hue, spreads from the chest to the head and extremities. Sharply delineated, broad telangiectatic macules appear on the face, buccal mucosa, lips, and hands.

PSS is associated with interstitial pneumonitis. This is more common in patients with diffuse disease than in patients with limited disease. Pulmonary hypertension has been reported to occur in patients with CREST syndrome (see Chapter 72).

Figure 29-25 Raynaud's phenomenon in this patient was so severe that autoamputation of the distal digits occurred.

■ INFECTIONS

A variety of infections involving the lungs may have cutaneous involvement.[63] Prototypical examples are described below.

Blastomycosis

Skin lesions are as common as pulmonary lesions in patients with blastomycosis. Cutaneous disease usually represents dissemination from a pulmonary focus that is often small and may be inapparent. The typical presentation is as a solitary nodule or multiple papules or nodules on the face, wrists, hands, or feet, which subsequently ulcerate and discharge pus (Fig. 29-27). The lesions grow eccentrically at the periphery and atrophy centrally over a period of months, eventually forming an arciform or serpiginous contour with sharply elevated and verrucous borders. Miliary abscesses occur along the borders of the lesions. In addition to the cutaneous involvement, osteolytic lesions may occur.

Coccidioidomycosis

Coccidioidomycosis is usually manifest as a pulmonary infection. In its acute form, it is often associated with cutaneous symptoms; roughly 20% of patients develop erythema nodosum (EN). EN is often accompanied by fever, arthritis, and eosinophilia. In patients with progressive pulmonary disease and eventual disseminated disease, the skin may be affected; subcutaneous granulomatous eruptions form and undergo necrosis and ulceration. After several months, the lesions tend to become verrucous. A third form is primary cutaneous disease, which occurs in farmers and laboratory workers as a chancriform lesion with sporotrichotic spread. This variant is extremely rare.

Actinomycosis

The thoracic form of this disease presents as a pulmonary parenchymal process that sometimes forms multiple draining sinus tracts.[64] Diagnosis is often difficult, but identification of sulfur granules in the draining exudates is helpful.

A B

Figure 29-27 **A, B.** Blastomycosis: verrucous lesions on the face (**A**) and trunk (**B**).

Tuberculosis

Cutaneous involvement results from direct inoculation with the tubercle bacillus via either the skin or mucus membranes, or as a consequence of widespread organ involvement that begins in the respiratory tract.

When the tubercle is introduced via the skin or mucus membranes by a contaminated syringe or a wound in a previously unexposed host, a nodule usually develops at the site of injury. Within several weeks, the nodule evolves into a chancre, a well-circumscribed ulcer. Particularly if host defenses are impaired, these chancriform lesions, which are typically located on the extremities, develop associated regional lymphadenitis, followed by systemic dissemination of the organism.

A person who was previously infected with *Mycobacterium tuberculosis* is apt to develop *tuberculosis verrucosa cutis* after receiving a cutaneous inoculation. The characteristic lesion in a sensitized person is a papule or a pustule, which becomes verrucous. On occasion, this disorder produces plaque-like lesions of the extremities, consisting of verrucoid–indurated papules surrounded by an erythematous halo.

Lupus vulgaris is the most common form of cutaneous postprimary tuberculosis that follows inoculation or lymphatic or hematogenous spread of *M. tuberculosis.*[65] Patients with this disorder typically present with reddish-brown plaques surrounded peripherally by yellowish nodules, especially on the neck or extremities. The skin lesions tend to spread centrifugally as the center becomes atrophic. Papillary growths also occur in the nasal, buccal, and conjunctival mucosa. Histologically, lupus vulgaris generally shows epithelioid tubercles with caseation necrosis. Chronic cutaneous eruptions tend to involute, leaving considerable scarring. Treatment with antituberculosis drugs is effective in treating these skin manifestations.

Disseminated miliary tuberculosis may result in macules, papules, or vesicles. In children, especially those who are debilitated, subcutaneous nodules or gummas appear, ulcerate, and eventually develop draining sinus tracts, especially in the extremities and trunk. *Scrofuloderma,* which occurs following the necrosis of cervical nodules, is associated with fistula and sinus tract formation in the overlying cutaneous tissues.

Tuberculids are skin lesions that are considered to represent either a hypersensitivity reaction to *M. tuberculosis* or an embolic response to atypical *Mycobacteria.* EN also occurs in association with primary tuberculosis.

HIV Infection

Early in the epidemic of HIV infection, the incidence of Kaposi's sarcoma (KS) increased. However, since the advent of HAART therapy, KS has become less common.[66,67] KS can occur in any immune-suppressed individual, whether the immune dysfunction is due to HIV infection, age, or iatrogenic immunosuppression in transplant recipients.

Human herpesvirus-8 (HHV-8) has been identified and linked to all forms of KS. In addition, HHV-8 viremia is associated with progression on KS in both classic and endemic forms. In the elderly population, KS has an indolent course and occurs primarily on the lower extremities. At the outset, the lesions are dark-blue, purplish, or reddish papules, macules, and nodules (Fig. 29-28). After months to years, plaques evolve in association with thickening of the skin from midtibia to ankle and lymphedema. In patients with immune dysfunction, including AIDS, KS is more aggressive and is often widespread in its cutaneous manifestations.

The respiratory tract is second only to the gastrointestinal tract in frequency of systemic involvement. Tumors may involve the larynx, trachea, bronchi, pulmonary parenchyma, and pleura. Accordingly, local manifestations of respiratory tract involvement range from hoarseness, signs of airway obstruction, cough, and hemoptysis, to dyspnea. When the parenchyma of the lung is affected, chest radiographs usually show many small nodules; occasionally, parenchymal infiltration of the lung is massive. On bronchoscopic examination, bronchial and tracheal lesions appear as small bluish nodules. Bloody pleural effusions are rare.

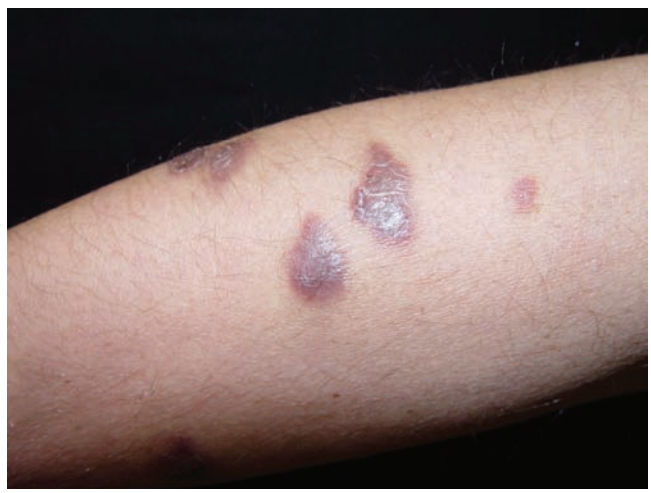

Figure 29-28 Kaposi's sarcoma in an HIV-positive patient.

Figure 29-29 Tripe palms. *(Used with permission of Dr. Jon Dyer.)*

LUNG CANCER

Several paraneoplastic syndromes may occur in patients with lung cancer.[68] In most instances the dermatosis is not specific for lung cancer; other sites may be involved. The following are some of the more ominous manifestations of potential pulmonary malignancy.

Tripe palms is a paraneoplastic condition that is manifest as rugose thickening of the palms and, occasionally, the soles (Fig. 29-29).[69] Patients often have coexistent acanthosis nigricans (AN). Patients with tripe palms and AN usually have adenocarcinomas of the gastrointestinal tract; however, when tripe palms occur in the absence of AN, patients often have squamous cell carcinoma of the lung.

Patients with *Bazex syndrome (acrokeratosis paraneoplastica)* develop an erythematous-to-violaceous psoriasiform eruption primarily on acral surfaces.[70] (Fig. 29-30). The ears, nose, cheeks, hands, feet, and knees are most often affected, but the nails may become dystrophic, and the palms and soles may develop a keratoderma in later stages of the disease. The disorder may develop in stages, and is associated primarily with carcinomas of the upper respiratory and digestive tracts (larynx, pharynx, trachea, bronchus, and/or upper esophagus); the malignancy is often detected concurrently. If the tumor is effectively treated the eruption may resolve, but it may return with tumor recurrence.

Ectopic ACTH-producing tumors cause many of the typical signs and symptoms of Cushing syndrome. Intense hyperpigmentation, present in only 6% to 10% of patients with Cushing disease, is especially common in association with ectopic ACTH production and should alert the clinician to the possibility of a hormone-secreting tumor. Although the cause of the hyperpigmentation is unclear, it may be related to tumor production of the peptide β-lipotropin, which contains within its sequence of 91 amino acids the 22–amino acid sequence of β-MSH. A myasthenia gravis–like syndrome, including profound proximal muscle weakness, may be a striking clinical feature and may reflect either underlying hypokalemia or polymyositis. Small cell carcinoma of the lung is the tumor most often associated with ectopic ACTH production, although other malignancies have been reported.

Figure 29-30 Acrokeratosis paraneoplastica (Bazex syndrome). This patient was thought to have psoriasis prior to the diagnosis of a squamous cell carcinoma of the tonsillar pillar.

The *carcinoid syndrome* is another example of a hormonal syndrome associated with a nonendocrine tumor. The disorder is probably most often caused by the release of the enzyme kallikrein from tumor cells, with subsequent conversion of kininogen to vasoactive kinin peptides, including bradykinin; in addition, increased blood levels of histamine may be important in the rare metastatic gastric carcinoid. The most striking cutaneous manifestations are episodes of flushing, initially lasting 10 to 30 minutes and involving only the upper half of the body; as the flush resolves, gyrate and serpiginous patterns may be noted. With successive attacks more extensive areas may be affected and the redness takes on a cyanotic quality, eventually leading to a more permanent facial cyanotic flush with associated telangiectasia, resembling rosacea. Persistent edema and erythema of the face may result in leonine facies. A pellagra-like picture, which has been noted in some patients, may be due to abnormal tryptophan metabolism. Systemic symptoms associated with the cutaneous flushing include abdominal pain with explosive watery diarrhea, shortness of breath, and hypertension.

Carcinoid tumors are usually found in the appendix or small intestine; extraintestinal carcinoid tumors may arise in the bile ducts, pancreas, stomach, ovaries, or bronchi.[71] The carcinoid syndrome occurs primarily when an intestinal carcinoid tumor metastasizes to the liver or with extraintestinal tumors; flushing attacks can be provoked by palpation of hepatic or abdominal metastases or by alcohol ingestion, enemas, emotional stress, or sudden changes in body temperature. When the syndrome is associated with bronchial adenomas of the carcinoid variety, the flushing is more prolonged and often associated with fever, marked anxiety, disorientation, sweating, salivation, and lacrimation.

Migratory superficial thrombophlebitis and multiple deep venous thromboses have been noted in patients with cancer, especially those with tumors arising in the pancreas, lung, stomach, prostate, or hematopoietic system. The neck, chest, abdominal wall, pelvis, and limbs are most frequently affected.

LYMPHOMATOID GRANULOMATOSIS

Lymphomatoid granulomatosis is classified as a B cell lymphoproliferative disorder of uncertain malignant potential. It has been associated with Epstein–Barr Virus infection and may occur more frequently in patients with immunologic diseases undergoing therapy with immunosuppressive agents, particularly thiopurines and methotrexate. The skin is the most commonly affected extrapulmonary site, occurring in 40% to 50% of patients.[72]

In 10% to 25% of patients, the skin lesions are the first clinical evidence of the disorder; the skin lesions precede involvement of the lungs by 2 weeks to 9 years. Because of the frequent occurrence of skin lesions, ease of performing a skin biopsy, and characteristic histology of the disease, careful dermatologic examination should be carried out in patients suspected of having lymphomatoid granulomatosis.

The characteristic cutaneous lesions are 1- to 4-cm erythematous-to-purplish dermal papules, or subcutaneous nodules, with or without ulceration.[73]

Figure 29-31 Lymphomatoid granulomatosis. This young woman developed the acute onset of multiple erythematous plaques on her face, accompanied by dyspnea and fever. She died within a month from pulmonary disease.

The lesions generally occur over the buttocks, thighs, and lower extremities (Fig. 29-31), but they may occur anywhere. Healing is often accompanied by scarring and hyperpigmentation.

The skin histopathology is similar to that observed in the lungs and is characterized by a marked angiocentric and angiodestructive lymphohistiocytic infiltrate composed predominantly of CD4-positive T cells. EBV-positive B cells are often present.

■ REACTIVE DERMATOSES

Two disorders in this category warrant mention: pachydermoperiostosis and EN.

Pachydermoperiostosis is a syndrome in which HOA is associated with cutaneous changes of the face and extremities that are similar to those that occur in patients with acromegaly. Although this disorder is generally benign, it is occasionally associated with bronchogenic carcinoma.

EN is a relatively common process and is usually acute and self-limited.[74] The typical clinical presentation is the sudden onset of one or more, tender, erythematous nodules on the anterior legs, which are more easily palpated than visualized (Fig. 29-32). The eruption is often preceded by a prodrome of fever, malaise, or arthralgias. As the lesions age, they may develop an ecchymotic appearance. They heal over a 4- to 6-week period, usually without scar formation. Ulceration of the primary process is rare. Although EN is usually acute, patients with chronic or recurrent disease have been described using such terms as "chronic EN," "EN migrans," "subacute nodular migratory panniculitis" (Vilanova's disease), or "septal granulomatous panniculitis." Chronic or recurrent EN most commonly occurs in middle-aged women. The disease is often present for several years and is most common on the legs.

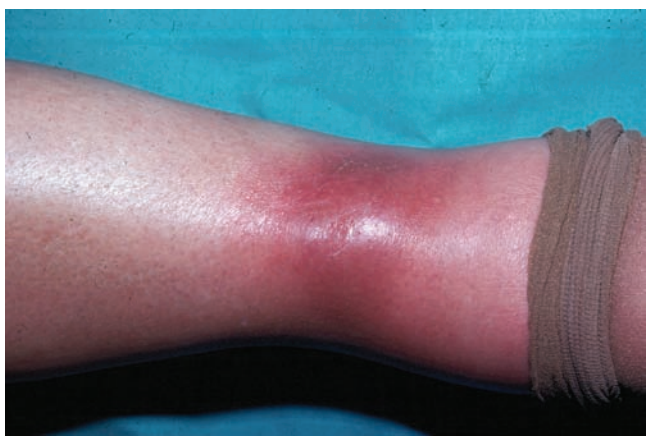

Figure 29-32 Erythema nodosum. Red tender subcutaneous nodule on the leg.

Etiologic or associated conditions are present in about 50% of patients with EN. The associated conditions can be divided into three broad categories: infections, drugs, or systemic diseases (usually inflammatory disorders). The infectious agents associated with EN tend to primarily affect the respiratory or gastrointestinal tract and are most often bacterial or fungal in origin. The most common drugs are antibiotics and oral contraceptives. Pregnancy, particularly in its second trimester, is a known association, and the EN will recur with subsequent pregnancies or with the administration of oral contraceptives. EN-like lesions may occur in Behçet disease and are accompanied by oral and genital ulcerations, pathergy, uveitis, or CNS disease or other systemic manifestations.

A specific variant of sarcoidosis associated with EN is known as Löfgren syndrome.[75] This is an acute, self-resolving process in which EN occurs with bilateral hilar lymphadenopathy, arthritis, and anterior uveitis. Granulomatous colitis (Crohn disease), regional enteritis, and ulcerative colitis have been associated with EN. In patients with inflammatory bowel disease, it appears that the EN parallels the activity of the bowel disease. At least half of the cases of EN are not found to have an associated or underlying process.

■ NEUTROPHILIC DERMATOSES: SWEET SYNDROME AND PYODERMA GANGRENOSUM

Sweet syndrome (Fig. 29-33) and pyoderma gangrenosum (Fig. 29-34) are distinct dermatoses, but they share common associations and are often managed using similar therapies.[76,77] In addition, a condition known as neutrophilic dermatosis of the dorsal hands (Fig. 29-35) often has characteristics that overlap between a superficial variant of pyoderma gangrenosum (also termed atypical pyoderma gangrenosum) and Sweet syndrome.[77] The associated diseases include inflammatory bowel disease, rheumatoid arthritis, and myelogenous malignancy and premalignancy. Extracutaneous neutrophilic inflammation has been reported in multiple organs, but the lungs are most frequently involved. The inflammatory reaction may cause pulmonary infiltrates, including cavitary disease. It is critical that infectious diseases be excluded with appropriate cultures before initiating therapy with corticosteroids or other immunosuppressive therapy.

Figure 29-33 Acute febrile neutrophilic dermatosis (Sweet syndrome): erythematous plaque with what appears to be vesiculation on the surface.

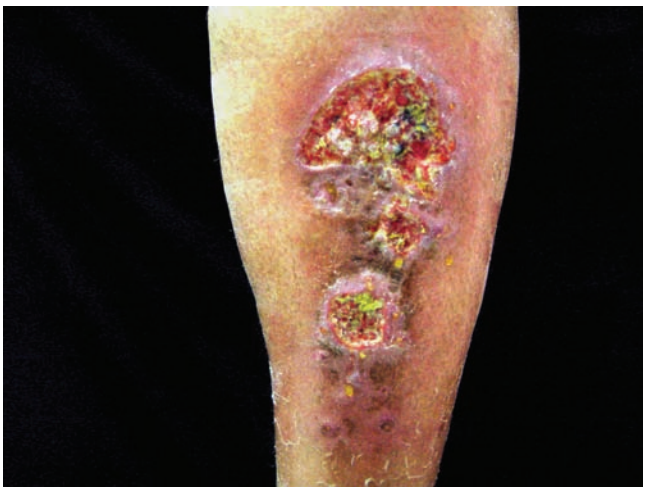

Figure 29-34 Pyoderma gangrenosum: large ulceration on the leg with a violaceous, undermined border. This patient had active Crohn's disease.

■ PRURITUS

Pruritus is a symptom that accompanies many dermatoses, but it may also accompany systemic diseases.[78] Patients without an obvious cause for their itching require a systemic evaluation, which usually includes a chest x-ray. Causes for pruritus are not commonly found, but Hodgkin disease and other malignancies might be uncovered during the evaluation. Effective treatment of an underlying malignancy will result in a disappearance of the pruritus.

■ URTICARIA

Urticaria is a reactive cutaneous disease manifested by transient urticarial skin lesions. Acute urticaria is almost always due to the ingestion of a food or medication and usually subsides within several days. The presence of chronic urticaria requires a thorough evaluation and, at times, pulmonary evaluation may reveal an infectious, inflammatory, or neoplastic cause (<25% of patients).

■ VASCULITIC SYNDROMES

Important vasculitic syndromes with cutaneous and pulmonary (Chapter 60) involvement are discussed below: Churg–Strauss syndrome, granulomatosis with polyangiitis (formerly known as Wegener granulomatosis), polyarteritis nodosa, and urticarial vasculitis.

Figure 29-35 Neutrophilic dermatosis of the dorsal hands (also known as atypical pyoderma gangrenosum). Such patients often have a hematologic malignancy or premalignant process.

Churg–Strauss Syndrome

The clinical picture of allergic rhinitis, asthma, peripheral eosinophilia, and pulmonary infiltrates occurring with systemic vasculitis has been designated the Churg–Strauss syndrome.[79] However, the histologic finding of necrotizing granulomas and tissue eosinophilia is not unique to this clinical syndrome. Indeed, the same histologic appearance may be seen in a wide variety of systemic diseases, including allergic granulomatosis, granulomatosis with polyangiitis (see below), rheumatoid arthritis, and lymphoproliferative disease.

One or more types of skin lesions develop in 70% of patients with Churg–Strauss syndrome. Most common is palpable purpura of the extremities; histologically, the lesions show necrotizing vasculitis without granuloma formation. In one-third of patients, the cutaneous lesions are nonspecific—that is, erythematous and urticarial. In another one-third, however, the skin lesions are distinctive—that is, tender, red-to-violaceous, indurated nodules, measuring 0.5 to 2 cm, which develop central crusting or become infarcted. These nodules occur most often over the scalp or symmetrically over the extensor surfaces of the extremities. These nodules are the ones most likely to have the histologic picture of necrotizing granulomatous vasculitis and eosinophilic infiltration; immunofluorescence staining may show vascular deposition of fibrin and complement.

Granulomatosis with Polyangiitis

About 45% of patients with granulomatosis with polyangiitis have cutaneous manifestations, most often small vessel vasculitis.[80] Occasionally, biopsy of the skin lesions reveals a granulomatous vasculitis. In addition, the presence of cutaneous disease is usually indicative of active systemic involvement; therefore, such patients should be carefully evaluated and aggressively treated.

Polyarteritis Nodosa

Patients with polyarteritis nodosa frequently have cutaneous lesions. The skin disease may represent small vessel vasculitis as in granulomatosis with polyangiitis or may represent medium-sized vessel involvement. In the latter case, the manifestation is livedo reticularis or ulceration.

Urticarial Vasculitis

Urticarial lesions may occur in patients as a manifestation of small vessel vasculitis. Urticarial vasculitis was first described in four patients with recurrent attacks of erythematous urticarial and hemorrhagic skin lesions associated with synovitis and, sometimes, abdominal distress. The patients did not have systemic lupus erythematosus or paraproteinemia, but they did have hypocomplementemia; two had nephritis.

Urticarial lesions may also be an early clinical manifestation of lesions that become typical palpable purpura. The spectrum of urticarial vasculitis has also grown in recent years to include the presence of lung disease, characterized by asthma or obstructive lung disease. Patients with hypocomplementemic urticarial vasculitis often have or develop obstructive pulmonary disease, whereas most patients with normal complement levels, chronic urticarial, and vasculitis have little or no systemic involvement.[81]

Patients are often treated with corticosteroids or other immunosuppressive drugs. Although these agents are useful in controlling the cutaneous lesions, they do not appear to have any impact on progression of the pulmonary disease.

■ TOXIC EPIDERMAL NECROLYSIS

Toxic epidermal necrolysis (TEN) is one of the true dermatologic emergencies.[82] This disorder is most often due to drug administration and develops acutely. Patients often have a prodrome followed shortly by widespread skin involvement with a superficial blistering

Figure 29-36 Stevens–Johnson syndrome/toxic epidermal necrolysis.

(Fig. 29-36). Multiple mucosal surfaces are affected (Fig. 29-37). Prognosis is dependent upon the extent of the blistering, age, and the presence of comorbid diseases.

Lung involvement in TEN is unusual, but affected patients often are treated in an intensive care unit or burn unit and frequently become ventilator-dependent. Infections, particularly pneumonia, are a frequent complication and may result in death.

■ YELLOW NAIL SYNDROME

Thick, yellow discoloration of all 20 nails occurs in the yellow nail syndrome[83] (Fig. 29-38). The nails are thick, but there is no onycholysis and no subungual debris, allowing clinical differentiation from onychomycosis. The nails are not clubbed, and there are no underlying bony abnormalities. This disorder is almost always associated with pulmonary abnormalities, including pleural effusions, lymphoma, and sleep apnea. There is no known therapy for the nail changes in this disorder, but improvement of the associated pulmonary disease may result in improvement of the nails.

■ MISCELLANEOUS DISORDERS

Pulmonary-cutaneous syndromes include a number of inherited congenital and developmental disorders.

Figure 29-37 Mucosal lesions of Stevens–Johnson syndrome/toxic epidermal necrolysis.

Figure 29-38 Yellow nail syndrome. All 20 nails were affected in this patient.

α_1-Antitrypsin Deficiency

α_1-Antitrypsin deficiency is regularly associated with pulmonary (Chapters 39 and 40) or hepatic disease. Cutaneous manifestations may also occur in some patients with this inherited disorder and most commonly manifest as panniculitis or, rarely, as a cutaneous vasculitis.[84,85] Although the panniculitis is a lobular panniculitis, in contrast to the septal panniculitis that is found in EN, the clinical disease is similar except that these patients' lesions may ulcerate.

Cutis Laxa

Cutis laxa is caused by a disorder in the formation of elastin that is transmitted as a dominant hereditary trait.[86] In children with this disorder, skinfolds of the abdomen and face are large and pendulous. The pulmonary manifestations of cutis laxa include emphysema and pulmonary artery stenosis.

Cystic Fibrosis and the Skin

CF is an inherited disorder that frequently affects the lungs and results in premature death (Chapter 50). Some patients with CF have skin disease.[87] Specifically, cutaneous vasculitis seems to be more frequent in CF patients, probably due to the frequent formation of circulating immune complexes.

Ehlers–Danlos Syndrome

The most important disorder of collagen affecting the skin and lungs is Ehlers–Danlos syndrome (cutis hyperelastica), a hereditary disorder of collagen in which the skin and blood vessels are unduly elastic and fragile and the joints are hyperextensible. The skin is smooth, rubbery, and bruisable; the joints are hypermobile. Associated systemic abnormalities include megaesophagus, megacolon, dissecting aortic aneurysm, and diaphragmatic and inguinal hernias. Among the pulmonary disorders are spontaneous pneumothorax, arteriovenous fistulas, megatrachea, and bronchial ectasia.[88]

Birt–Hogg–Dubé Syndrome

Birt, Hogg, and Dubé described an autosomal dominant condition that is manifested by multiple facial flesh-colored papules characterized histologically as trichodiscomas.[89] BHD is due to heterozygous mutations in the folliculin (FLCN) gene located on chromosome 17, which encodes a highly conserved tumor suppressor protein. (Fig. 29-39) Affected patients frequently develop renal cell carcinomas, particularly oncocytomas. In addition, multiple lung cysts and development of spontaneous pneumothorax at a young age are common. Although there is no known therapy, recognition of affected patients may lead to discovery of renal tumors prior to metastasis and assessment of family members.

Figure 29-39 Flesh-colored central facial papules in a patient with Birt–Hogg–Dubé syndrome.

Figure 29-41 Peau 'd orange changes in a patient with nephrogenic systemic fibrosis.

Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT), also known as Osler–Rendu–Weber syndrome, is an autosomal dominant disorder that is manifested by vascular ectasia in various organs, including the skin and mucus membranes (Fig. 29-40). HHT often is first manifested as nosebleeds. Eventually lesions affect the lips, tongue, nasal mucosa, palate, and palms. Patients with HHT may have arteriovenous malformations in the lungs or CNS. Epistaxis, melena, and hemoptysis are common in adults.

Nephrogenic Systemic Fibrosis

Nephrogenic systemic fibrosis is a disorder of the skin in which a rapid onset of skin hardening (Fig. 29-41) occurs in patients with some form of renal disease.[90] Often the onset of the fibrosis is preceded by anasarca. The disease has been linked to gadolinium deposition in tissue following its use for MRI or MRA. Initial descriptions of the disease focused on the cutaneous findings, but it has become evident that patients may also have systemic fibrosis, including pulmonary fibrosis. There is no known effective therapy for these patients, but with time the fibrosis does seem to lessen.

Paraneoplastic Pemphigus

Paraneoplastic pemphigus (PNP) is a severe mucocutaneous disease with a specific pattern of immunofluorescence. It is a rare vesiculobullous disorder. Patients with PNP often present with severe oral erosions and polymorphous cutaneous lesions, including targetoid lesions, bullae, and erosions (Fig. 29-42). Patients with PNP often have a lymphoproliferative disorder with a high prevalence of Castleman disease. In addition to the mucocutaneous disease, these patients frequently have bronchiolitis obliterans.[68]

Sarcoidosis

Sarcoidosis is a multisystem disorder with protean manifestations (Chapter 55). Skin lesions occur in about 25% of patients and may be "histopathologically specific" or "nonspecific." The most common nonspecific manifestation is EN. Histopathologically specific lesions are manifestations of granulomatous inflammation in the skin. Although associated with chronic disease in the past, it now appears that there are many patients with self-limiting granulomatous disease of the skin. Skin lesions are most commonly papules, plaques, or nodules. Rarely is there a great deal of surface change, and ulceration is uncommon.

Several clinical variants are worth noting. Papular lesions on the knees (Fig. 29-43) are commonly associated with EN and are self-limiting. Lesions on the nasal ala (Fig. 29-44) are frequently associated with sarcoidosis of the upper respiratory tract (SURT), and a thorough otolaryngologic evaluation is indicated. Erythematous-to-violaceous plaques on the face are known as lupus pernio (Fig. 29-45); residual scarring in this disorder is possible. In addition, patients tend to have accompanying chronic disease in the lungs. Finally, lesions of sarcoidosis frequently occur within scars or tattoos (Fig. 29-46). In this circumstance it may be difficult to distinguish sarcoidosis from foreign body granulomas.

Figure 29-40 Mucosal telangiectasia in a patient with hereditary hemorrhagic telangiectasia.

Figure 29-42 Paraneoplastic pemphigus.

A B

Figure 29-43 **A, B.** Sarcoidosis: acute onset of papular lesions (**A**) on the knees and feet (**B**) were associated with a self-limited course in these patients.

Tuberous Sclerosis

Tuberous sclerosis is a hereditary disorder characterized by mental retardation, epilepsy, and skin lesions, including adenoma sebaceum, Shagreen patches, and ash leaf macules. Also seen as part of this disorder are retinal phakomas, calcification of basal ganglia, and ungual fibromas. Approximately 9% of patients with visceral tuberous sclerosis have pulmonary manifestations; some of the pulmonary lesions are cystic and may be associated with recurrent spontaneous pneumothorax and hamartomas. Certain poorly understood diseases, such as fibrocystic pulmonary dysplasia, may represent a forme fruste of tuberous sclerosis.

MEDICATION TOXICITY

Cutaneous toxicity may arise from therapy given for pulmonary disease. In addition, pulmonary toxicity may develop in the setting of treatment of dermatologic disorders.

■ DERMATOLOGIC TOXICITY FROM AGENTS USED TO TREAT PULMONARY DISEASE

Two examples of dermatologic injury from agents used to treat lung disease are described below: epidermal growth factor receptor inhibitors and immunosuppressive agents.

Epidermal Growth Factor Receptor Inhibitors

Epidermal growth factor receptor inhibitors are now being used for the treatment of solid tumors, including lung cancers. These agents are regularly associated with development of an acneiform eruption on the face.[91] The presence and severity of the eruption appear to correlate with survival.

Immunosuppressive Therapy in Lung Transplant Recipients

Patients who are organ recipients are regularly treated with corticosteroids in combination with various immunosuppressive agents. Therapy with corticosteroids has well-known dermatologic consequences, including striae, steroid-acne, or folliculitis, and an increased risk of superficial fungal infections. The intensity of the immunosuppression and duration of therapy are associated with increasing risk of cutaneous malignancy, specifically nonmelanoma skin cancer (NMSC) and KS. Squamous cell carcinoma is overrepresented in comparison to basal cell carcinoma; in addition, the tumors appear to be more aggressive in the presence of immunosuppressive therapy. Therefore, in patients who develop multiple squamous cell carcinomas immunosuppressive therapy should be less intense, if possible, or substitution of cyclosporin and azathioprine by other "less" toxic agents should be considered.

Figure 29-44 Sarcoidosis affecting the nasal ala is regularly associated with granulomatous disease in the upper respiratory tract (SURT).

Figure 29-45 Lupus pernio (sarcoidosis).

Figure 29-46 Sarcoidosis within tattoos.

■ PULMONARY TOXICITY FROM DERMATOLOGIC THERAPIES

Two examples of pulmonary toxicity arising from agents used to treat dermatologic disorders are described below: methotrexate and tumor necrosis factor-α inhibitors.

Methotrexate

Methotrexate is a common systemic therapy for patients with psoriasis. In addition, it is regularly used for cutaneous dermatomyositis, cutaneous sarcoidosis, and cutaneous lymphomas. Pulmonary toxicity is not common and is believed to be idiosyncratic. Most of the dermatologic use is for psoriasis vulgaris and psoriatic arthritis; fortunately, pulmonary disease appears to be quite rare in these patients. No specific monitoring is recommended.

Tumor Necrosis Factor-α Inhibitors

A growing number of tumor necrosis factor (TNF) antagonists are available, including infliximab, etanercept, and adalimumab. These therapies have revolutionized our approach to psoriasis, psoriatic arthritis, inflammatory bowel disease, and rheumatoid arthritis. All have been associated with an increased risk of infection, particularly pneumonia and tuberculosis.

SUMMARY

The diagnostic approach to a patient with suspected pulmonary disease begins with a thorough history and physical examination. Elements of the family history, along with determination of work and other environmental exposures, are important components of the history. Many times, characteristic cutaneous findings shed light on an underlying pulmonary diagnosis. The clinical examination is complemented by radiographic studies, assessment of pulmonary and cardiac function, and routine and specialized laboratory studies, as warranted.

CHAPTER 30

Modern Approach to Thoracic Imaging Diagnosis

Eduardo J. Mortani Barbosa Jr.
Warren B. Gefter

INTRODUCTION

This chapter is not intended to provide a comprehensive review of the entire scope of thoracic imaging; dedicated textbooks in radiology serve this purpose well. Moreover, the chapter does not provide a comprehensive guide to the interpretation of thoracic imaging studies. Rather, the focus is on what modern thoracic imaging can provide to empower clinicians to diagnose and manage common clinical scenarios in the second decade of the 21st century. The goal is to present a strategic approach to thoracic imaging, which starts with broad clinical categories of disease and addresses the following central clinical questions: What is the differential diagnosis and how can a specific diagnosis be confirmed? What is the prognosis and how can disease progression and therapeutic effectiveness best be monitored?

In each subsection, organized initially by imaging technique, and subsequently, by broad diagnostic categories, the authors aim to answer these questions by providing a practical, logical, and evidence-based approach that emphasizes which imaging tests to order and what to expect from each test. Oftentimes, imaging findings are either pathognomonic or highly characteristic of a diagnosis in the appropriate clinical context and, therefore, will suffice for clinical diagnosis and management. However, when this is not the case, tissue sampling or additional laboratory tests may be required for diagnostic confirmation; these scenarios are outlined and options discussed for tissue sampling, including image-guided percutaneous biopsy, bronchoscopy, and surgical biopsy. In addition, the ways in which modern functional and quantitative radiographic techniques may impact the field of thoracic imaging in the near future will be considered, and validated clinical applications differentiated from promising research applications that may evolve into useful clinical tools in the next several decades.

Finally, since radiology and, in particular, thoracic imaging, play such a major and central role in modern medicine, our ultimate goal is to enable the practicing pulmonologist to use imaging resources consistently, wisely, efficiently, and effectively.

SUMMARY OF TECHNIQUES: DIAGNOSTIC AND INTERVENTIONAL

The inception of the field of radiology dates back to 1895 with Wilhelm Röentgen's serendipitous discovery of x-rays and subsequent production of the first radiograph. Within only a few years, radiology became established as a new medical field. Chest radiography, although one of the first clinical applications and currently over 100 years old, is still the most frequently performed imaging test worldwide and the cornerstone of initial imaging assessment of most patients with thoracic diseases. Nonetheless, over the last four decades we have witnessed an explosion of technical innovation and developments, with the introduction of ultrasound (US), computed tomography (CT), magnetic resonance imaging (MR), positron emission tomography (PET), and hybrid scanners (PET/CT and PET/MR), which have greatly expanded the ability of modern imaging to accurately diagnose even the smallest or earliest disease processes and revolutionized the practice of medicine.

More recently, the widespread impact that computers have made on the acquisition, distribution, visualization, and postacquisition processing of medical images have consolidated the central role of radiology. In the future, we hypothesize that major trends will include quantitative imaging, functional imaging, molecular diagnosis, and value assessment with regard to generating better patient outcomes. In the following sections we present current clinical applications, advantages, and disadvantages of each modality, as well as appropriateness criteria for ordering each test, according to the clinical scenario.

CHEST RADIOGRAPHY

Two basic types of chest radiographic examinations are available—bedside portable AP (anteroposterior) and the combination of PA (posteroanterior) and lateral projections. Supplementary views include oblique, lordotic, lateral decubitus, and expiratory radiographs. For most clinical scenarios, the evaluation should begin with a chest radiograph, as this study remains the most cost-effective imaging test for diagnosing a variety of common clinical conditions. Moreover, chest radiographs are universally available and can be obtained even in patients who cannot be moved to an advanced scanner (e.g., patients in the ICU setting). Nonetheless, in many clinical scenarios, additional advanced imaging will be required to clarify radiographic findings or obtain more accurate characterization of disease pattern and severity (Figs. 30-1–30-4).

Whereas the basic physical principles of radiography have not changed in over a century, the quality and clinical availability of chest radiographs have been greatly enhanced in recent decades due to the transition from analog to digital technology. Digital imaging provides better image contrast, reduces the number of suboptimal or nondiagnostic examinations, and permits more immediate examination availability using image transfer and display software.

Currently, two standards for digital radiography exist: computed radiography (CR) and digital radiography (DR), which differ in the process of imaging acquisition. CR utilizes a photostimulable phosphor cassette, just as does the film-screen analog technique; however, the latent image is read by a laser and converted from an analog to digital signal, rather than being transferred to film. DR bypasses this step and utilizes flat panel detectors that directly transform the x-ray signal to a digital image via integrated, thin-film, transistor readout systems. From a practical perspective, DR images are often sharper, with better spatial resolution and, consequently, better visualization of detail. In addition, DR streamlines workflow for routine images and offers the possibility of tailoring the radiation dose.

Most modern facilities use a combination of CR and DR units, due to cost considerations. The principal benefit of CR and DR technology is the ability to process the acquired images to emphasize specific anatomical areas (e.g., lung parenchyma, soft tissues, bones), thereby greatly reducing the need to repeat examinations due to over- or underpenetration by the x-ray beam.[1] Digital methods to "remove" the ribs from the image are now available using either postprocessing bone-suppression software or dual-energy

Figure 30-1 Lateral chest radiograph following barium contrast swallow. Not only is this technique very useful for evaluating the esophagus, it is also able to demonstrate left atrial enlargement, with consequent posterior displacement of the contrast column *(arrow)*.

acquisition techniques. These approaches can provide an unobstructed view of the lungs for improved detection of nodules and other pulmonary findings. In addition, computer-aided diagnostic techniques may now assist the radiologist in the detection of subtle lung lesions.

The PA view obtained in the erect position is the standard radiographic examination and demonstrates the anatomy and most thoracic pathologic processes. In particular, the PA view allows evaluation of pulmonary masses and consolidation, diffuse lung disease, pleural effusion, pneumothorax, mediastinal abnormalities, and disorders of the rib cage and scapular girdle.

The lateral view provides additional information by better depicting the posterior diaphragms and posterior lung bases, retrocardiac left lung base, anterior mediastinum, and thoracic spine.

The AP view provides similar information to the PA view, but it is limited by lower spatial and contrast resolution and by magnification of the mediastinal structures. In addition, it is less sensitive for detection of small pneumothoraces and pleural effusions. The AP view is often performed in the supine position in bedridden patients, particularly those who are postoperative or in the ICU. AP portable chest radiographs can be very helpful in assessing the position of support lines, tubes, and medical devices. Medical devices can also be enhanced using newer digital image-processing algorithms.

Supplementary views are not routinely performed, unless there is a specific clinical question. In the past, lordotic views were obtained to better visualize the lung apices by displacing the clavicle and first rib shadows superiorly. However, their role has been largely replaced by CT. Expiratory views may be more sensitive in detecting small pneumothoraces, particularly in the setting of recent lung interventional procedures. Lateral decubitus views, although used less frequently than in the past, may be helpful in determining if a pleural opacity seen on standard views is a freely mobile effusion or a loculated effusion or pleural mass. When the patient is imaged with the pleural opacity on the dependent side, a freely mobile pleural effusion conforms to the most dependent region of the hemithorax and a sharp horizontal level demonstrated due to gravity. If a nondependent lucency is seen in the chest or abdomen, in conjunction with a sharp horizontal level delineating it from normal anatomical structures, the diagnosis of a small pneumothorax or pneumoperitoneum may be made. Finally, oblique views are helpful in determining if a questionable radiographic abnormality seen on the frontal view is real or artifactual, as well as in determining its location in the thorax. Performed properly, supplementary views can increase the diagnostic accuracy and clinical utility of chest radiography, sometimes obviating the need for chest CT with its attendant higher cost and radiation exposure.

Many radiographic techniques that were widely used in the past (e.g., laminography, bronchography, air contrast studies, and fluoroscopy) have been made obsolete by other techniques and are of historical interest only. The exception is focused fluoroscopy for evaluation of diaphragmatic motion ("sniff test"), in which the patient is imaged during quiet breathing, deep breathing, and forceful inspiration ("sniff"). A paralyzed hemidiaphragm moves paradoxically upward with forceful inspiration. Fluoroscopy in conjunction with barium swallow may also be used to assess esophageal diseases.

CHEST CT

CT is the current cornerstone of advanced thoracic imaging. It is a digital cross-sectional imaging technique that utilizes a rotating x-ray source around the patient, coupled to diametrically positioned sodium iodide detectors in a circular configuration. As the scanner gantry rotates, multiple projections are generated at different angles with different x-ray beam attenuations, depending on which part of the patient's anatomy was traversed. Following scan acquisition, through a mathematical procedure (filtered back projection or, more recently, iterative reconstruction), the sum of projections is transformed into an image in which the relative density of each small volume of the patient's anatomy (voxel) is proportional to its x-ray absorption coefficient, and normalized from a scale of −1000 to > +1000 HU (Hounsfield units, zero representing the absorption coefficient of water, −1000 of air). Because it eliminates the main drawback of radiographic techniques, that is, the projection of a three-dimensional (3D) structure into a two-dimensional image, CT allows very accurate localization of pathologic processes. Moreover, the superior contrast resolution of CT allows detailed evaluation of mediastinal and chest wall soft tissue attenuation structures, which are poorly assessed radiographically. CT is also superior to chest radiographs for detection of small pulmonary lesions, as well as for their characterization (Figs. 30-5 and 30-6).

Early CT scanners had a single row of detectors and a single x-ray source, acquiring one axial image at a time before the scanner table was moved to acquire the next image. This process could take more than 30 minutes for a single thoracic CT examination. Most modern scanners have between 64 and 320 rows of detectors, one or two x-ray tubes, extremely fast and continuous gantry rotation, and simultaneous table translation, resulting in helical image acquisition and the ability to scan the entire chest in less than 1 second. Modern CT scanners are able to produce high-quality, submillimeter, isotropic resolution images that can be reconstructed in any arbitrary plane without loss of detail. Postprocessing techniques utilizing computational algorithms also allow 3D reconstructions,

Figure 30-2 Normal bronchogram. The normal bronchial anatomy of the right lung is shown in the PA (**A**), oblique (**B**), and lateral (**C**) projections. The corresponding anatomy of the left lung is demonstrated in the PA (**D**) and oblique (**E**) projections; the latter also illustrates bronchiectasis. Although valuable to demonstrate bronchial anatomy and pathology, the bronchogram is an obsolete examination, having been replaced by CT and airway reconstruction techniques.

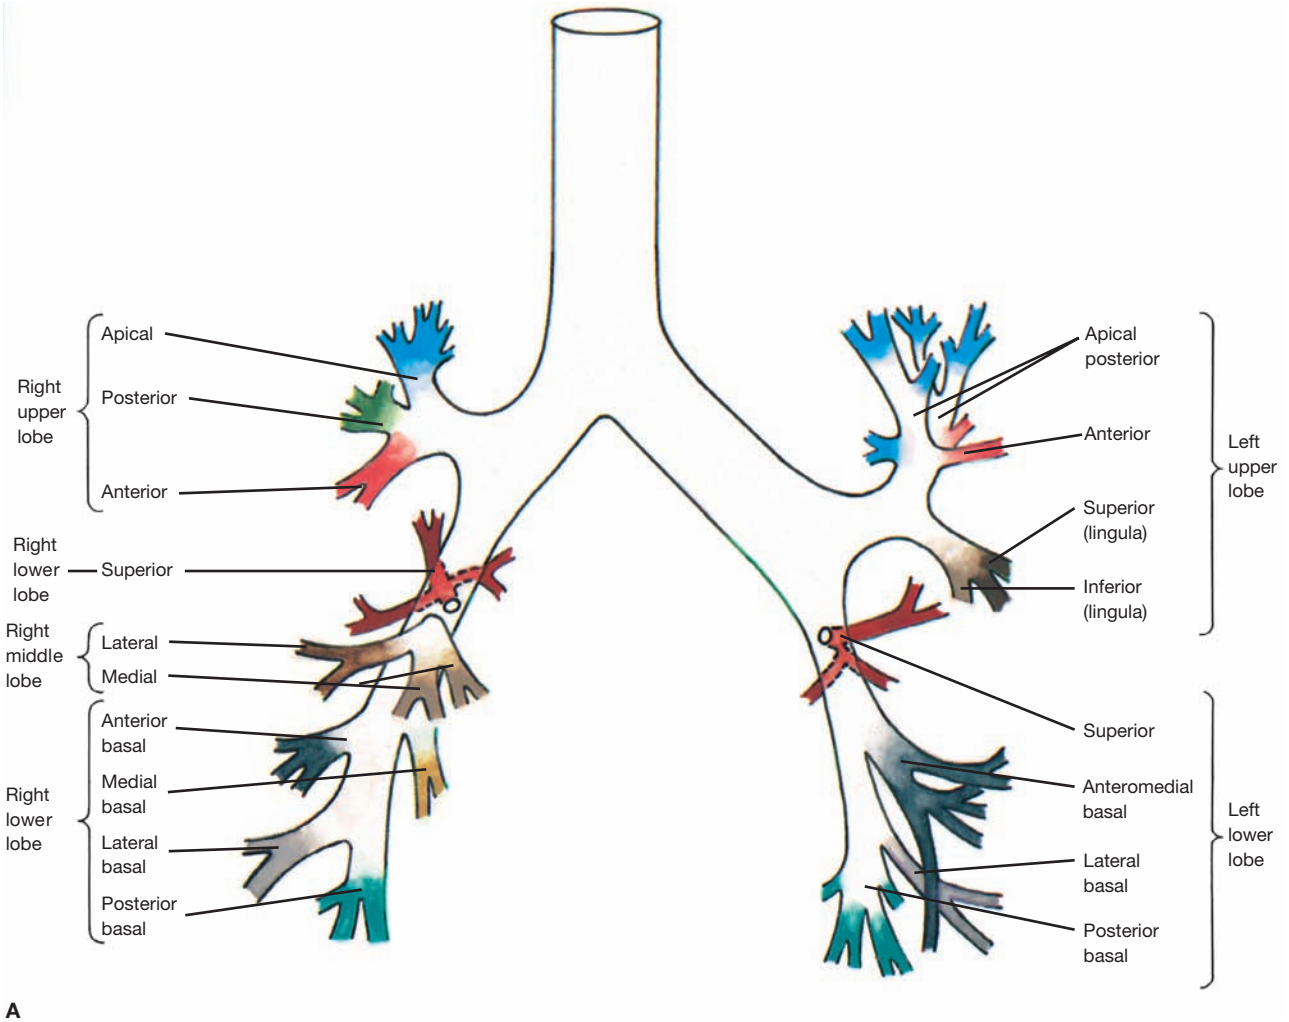

Figure 30-3 Topographic anatomy of the tracheobronchial tree and respective pulmonary subsegments. **A.** Tracheobronchial tree. **B.** Right lung segments. **C.** Left lung segments. Currently, CT is the best modality for accurate anatomical delineation of pulmonary airway segmentation. RUL, right upper lobe; RML, right middle lobe; RLL, right lower lobe; LUL, left upper lobe; LLL, left lower lobe.

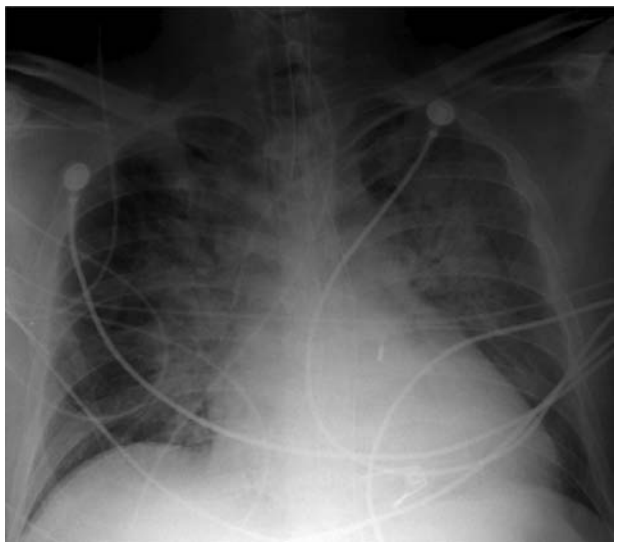

Figure 30-4 Portable AP (anteroposterior) projection chest radiograph, in a patient in the ICU, demonstrating multiple support tubes and lines and the typical configuration of cardiogenic pulmonary edema, with symmetrical bilateral consolidations with perihilar predominance.

such as volume rendering and maximal intensity projection images, which can be utilized to demonstrate complex 3D vascular or airway anatomy and pathology.

An important concept is that of high-resolution CT ("HRCT") of the thorax. Historically, when early CT scanners were limited to the acquisition of relatively thick axial slices (7 to 10 mm) in the thorax, the only way to adequately assess lung parenchymal detail was to acquire serial thin (1 mm) anatomic images utilizing an axial, rather than helical mode; this required noncontiguous (i.e., slices with an interslice gap, typically 20 mm wide), rather than contiguous, slices. These images were also reconstructed using a high spatial frequency algorithm, sharpening edges and allowing improved visualization of fine detail. The result was a set of higher spatial resolution, thin-section images that sampled the lung parenchyma and provided excellent insight into certain pulmonary disorders. This was termed "high-resolution CT" or "HRCT" of the chest, differentiating it from the "standard" chest CT scan, in which thicker sections were acquired through the entire chest in a contiguous helical mode (i.e., without interslice gaps). Generally, a choice had to be made as to which of these two types of scans to perform, since both studies could not be performed simultaneously. Standard CTs were ordered for a general assessment of larger pulmonary lesions, as well as mediastinal, bone, and chest

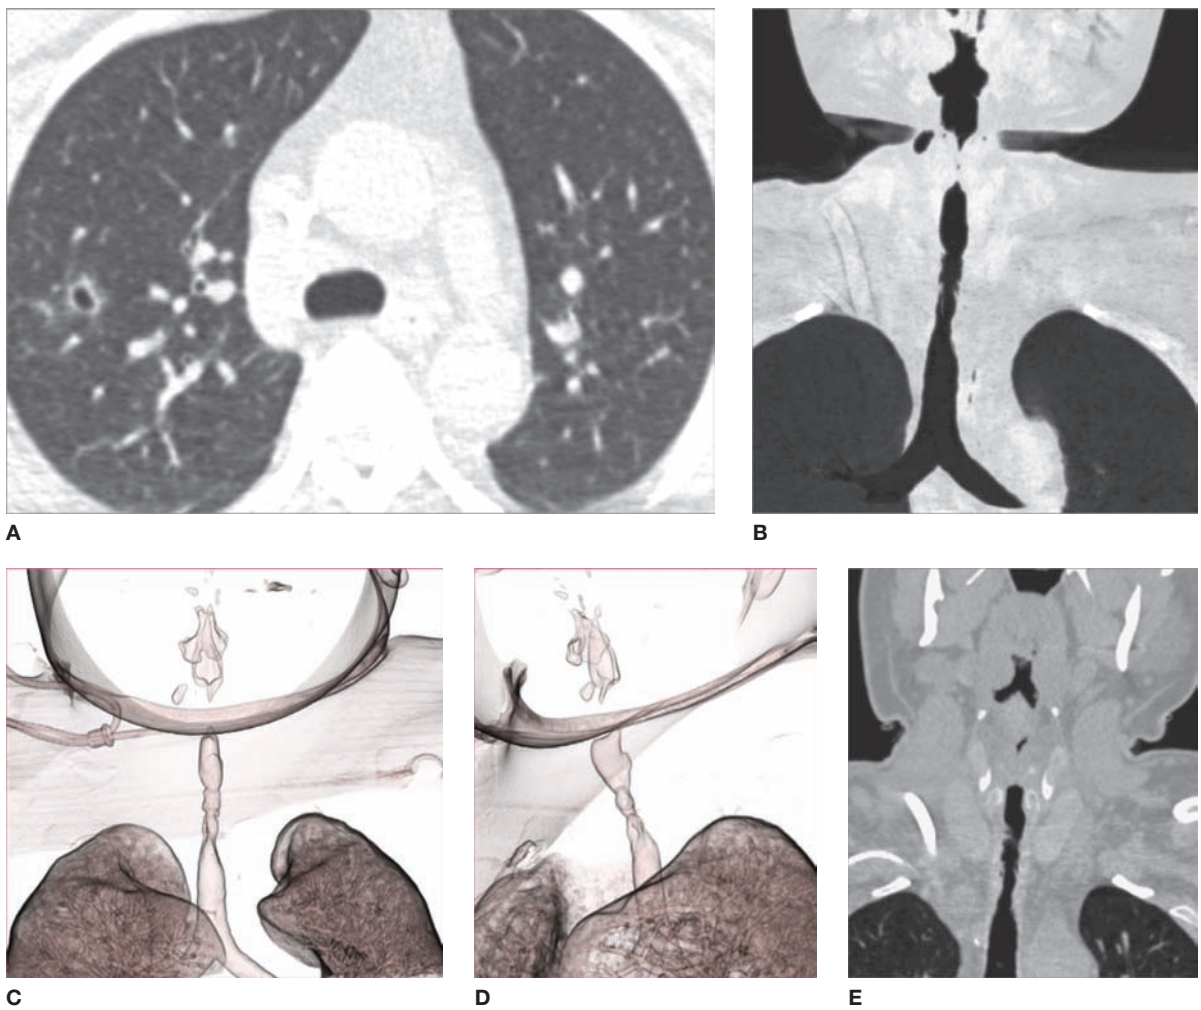

Figure 30-5 CT offers the best imaging evaluation of the pulmonary parenchyma and airways, and advanced postprocessing techniques can provide exquisite views of disease distribution and extension. Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis) affecting the lung and airways. **A.** Cavitary nodule in the right upper lobe; (**B**) minimum intensity projection image demonstrating irregular, long segment narrowing of the upper and middle trachea; (**C**) and (**D**) two different projections of a 3D volume rendering airway reconstruction demonstrating the complex configuration of the stenotic tracheal segment; (**E**) coronal reformatted image depicting tracheal wall thickening associated with stenosis.

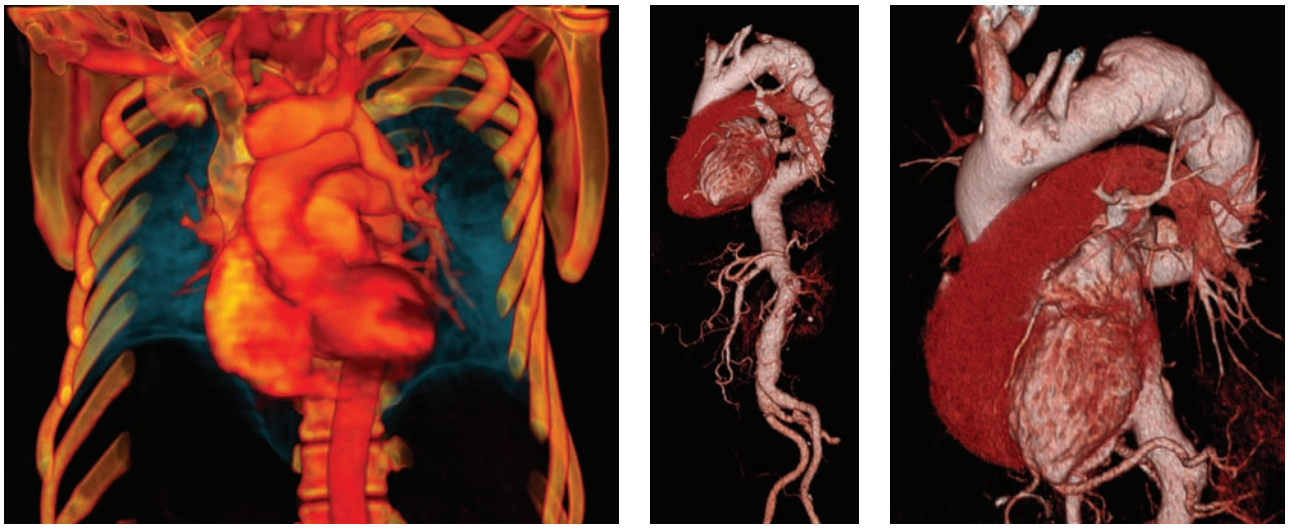


A B C

Figure 30-6 CT allows acquisition of isotropic volumetric images, in which advanced 3D postprocessing can be performed to demonstrate complex disease processes with a high level of detail. **A.** VR (volume rendering) reconstruction demonstrating partial anomalous pulmonary venous connection of the left upper lobe to the left brachiocephalic vein; (**B**) and (**C**) VR reconstructions at different degrees of rotation, demonstrating the complex configuration of a thoracic aortic aneurysm. These images are invaluable for treatment planning.

wall pathology. High-resolution chest CTs were ordered to assess pulmonary parenchymal disease, such as bronchiectasis, interstitial diseases, and micronodular diseases.

With advances in CT technology, however, it is currently feasible to acquire volumetric, isotropic thin-section (1 mm) images throughout the entire thorax in a single breath-hold, and to reconstruct them in any arbitrary plane (typically axial, sagittal, and coronal) using soft tissue and high-resolution algorithms. Consequently, every chest CT is now effectively both a standard, as well as a high-resolution CT, combining the advantages of each in a single study. This simplifies the ordering process for clinicians. Currently, when ordering a chest CT, there are only two decisions that the clinician needs to make: (1) whether to include expiratory imaging; and (2) whether to perform the study with or without intravenous contrast (these are discussed in detail below).

The first important decision is whether to perform expiratory images, noting that normally, a chest CT is acquired in full inspiration. The reason to avoid performing expiratory images for every patient is to decrease medically unnecessary radiation exposure. Typically, an expiratory CT is ordered if there is a clinical concern for an obstructive lung disease (e.g., asthma, COPD, or small airway disease) or if there is a risk of developing bronchiolitis obliterans (e.g., related to lung or bone marrow transplantation) (Video 30-1A,B). Expiratory CT may also be ordered to assess for large airway diseases, such as tracheobronchomalacia. Expiratory CT is currently the best imaging test to demonstrate small airway air trapping and, therefore, it is a very useful tool to evaluate potential causes of a "mosaic attenuation pattern" on CT (as discussed in detail in the following sections addressing specific diseases).

The second important decision is whether to perform the study with or without intravenous contrast administration. For the sake of decreasing medically unnecessary radiation exposure, there are very few indications for combined chest CT (i.e., with and without intravenous contrast); these are discussed below. The vast majority of chest CT is performed either with or without intravenous contrast. Generally, to assess the lung parenchyma and airways, no intravenous contrast is required. Assessment of bone lesions also usually does not benefit from intravenous contrast administration. On the other hand, vascular and cardiac assessment is greatly enhanced by intravenous contrast. Moreover, mediastinal and hilar pathology (including lymphadenopathy) and cervical and chest wall masses are more conspicuous and better evaluated using intravenous contrast. For certain thoracic neoplasms, the enhancement pattern adds information to their diagnostic characterization. Finally, assessment of pleural diseases also is enhanced using intravenous contrast administration.

It is important to emphasize that since iodinated CT intravenous contrast is excreted primarily by the kidneys, substantially impaired renal function may preclude intravenous contrast administration and may increase the risk of nephrotoxicity. Additional risks associated with intravenous contrast administration include local effects related to contrast extravasation at the injection site and anaphylactoid reactions, ranging from clinically insignificant symptoms to life-threatening airway or cardiovascular collapse; the latter is very rare with the low osmolar contrast material currently utilized.

When performing chest CT with intravenous contrast, it is important to inform the radiologist of the clinical indication. Broadly, three different basic protocols can be utilized: (1) standard contrast-enhanced CT; (2) CT angiography (CTA) for visualization of the aorta or coronary arteries; and (3) CTA for visualization of the pulmonary arteries ("pulmonary embolism [PE] protocol").

Video 30-1 **A.** Axial cine images using lung window and inspiratory acquisition. This CT airway examination demonstrates bronchiectasis, mosaic attenuation, and faint peribronchial opacities, compatible with a diagnosis of bronchiolitis obliterans. Inspiratory acquisitions should ideally reflect the lung appearance at TLC (total lung capacity). **B.** Same patient as in Video 30.1A. Axial cine images on lung window/level, expiratory acquisition, in this CT airway examination, demonstrating same findings earlier, plus dynamic partial collapse of the trachea and central bronchi, compatible with tracheobronchomalacia superimposed on bronchiolitis obliterans. Note the value of expiratory imaging to establish the diagnosis of tracheobronchomalacia and to increase the conspicuity of the mosaic attenuation pattern reflecting small airway disease. Expiratory acquisitions should ideally reflect residual volume (RV). *Access at www.fishmansonline.com*

Video 30-2 **A.** Axial cine images using soft tissue window, demonstrating a massive saddle embolus straddling the bifurcation of the main pulmonary artery. Note that the clot extends to the bilateral lower lobes; oligemia of the right lower lobe is demonstrated. Also note right ventricular enlargement and leftward deviation of the interventricular septum, findings compatible with right ventricular strain. **B.** Same patient as in Video 30.2A. Full-color, coronal, 3D VR (volume rendering) thick slab cine (anterior to posterior), emphasizing cardiovascular structures. This type of reconstruction provides exquisite detail of vascular anatomy and extent of massive pulmonary embolism. *Access at www.fishmansonline.com*

Video 30-3 Full-color, coronal 3D VR (volume rendering) with 360 degrees of rotation about the long axis of the trachea, emphasizing central airways. **A.** Lower magnification with vertical and horizontal axis for spatial orientation. **B.** Higher magnification without axis. The images demonstrate an irregular, long region of segmental stenosis involving the upper trachea. The patient also presented with multiple pulmonary nodules, at least one of which was cavitary. A diagnosis of granulomatosis with polyangiitis or GPA (previously known as Wegener granulomatosis) was established on tracheal biopsy. *Access at www.fishmansonline.com*

For a standard contrast-enhanced CT, the injection rate and imaging acquisition relative to the contrast injection are tailored for maximum enhancement of parenchymal organs and soft tissues; consequently the images are acquired during the venous or equilibrium phase of contrast distribution. This is the standard approach for routine, contrast-enhanced chest CT.

CTA of the aorta and CTA of the coronary arteries are dedicated examinations that are tailored for maximum enhancement of these systemic vessels and are not covered further in this chapter. In particular, cardiac CTA is a thriving application that is usually performed in conjunction with ECG gating to compensate for cardiac motion. CTA of the pulmonary arteries is a well-established application and the current reference standard for the diagnosis of PE (Video 30-2A,B). With this CT technique, contrast injection and imaging acquisition are optimized for maximum enhancement of the pulmonary arteries. This requires a high rate of injection (4–6 mL/s, as opposed to 2 mL/s for regular contrast-enhanced CT) through a large-caliber peripheral IV access (ideally larger than 20G) and very fast volumetric imaging acquisition, usually using contrast bolus tracking to maximize the probability of scanning the patient at the peak of opacification of the pulmonary arteries. When optimally performed, this study allows confident diagnosis of PE in even small subsegmental vessels via direct visualization of vascular filling defects. It also allows accurate assessment of pulmonary vascular caliber and distribution to diagnose pulmonary hypertension, chronic thromboembolic disease, and vasculitides.

CTA of the pulmonary arteries has supplanted conventional pulmonary angiography (except for therapeutic applications) and largely supplanted ventilation–perfusion scanning, although the latter still has an important role in specific clinical settings, such as pregnancy, young patients with normal chest radiographs, or in patients with renal insufficiency. This advanced CTA technique not only allows the diagnosis of PE and possible complications, such as pulmonary infarcts, but also accurately reflects the overall clot burden and signs of right ventricular strain, both important prognostic indicators.[2]

An additional, specific advanced application of CT in the chest is the evaluation of the airways. The imaging protocol for CT of the airways utilizes thin-section (1 mm), volumetric, isotropic images, both in full inspiration and end expiration. The images are acquired from the base of the tongue to the basilar segmental bronchi to include the entire tracheobronchial tree and larynx. Postprocessing 3D techniques are routinely utilized—that is, volume rendering, minimal intensity projections, and virtual bronchoscopy (Video 30-3A,B). The result is accurate depiction of global, regional, and local large airway disorders, including tracheobronchomalacia, airway stenoses, infiltrative and obstructive neoplasms, and inflammatory conditions.

An important consideration recently receiving much attention is the issue of medical radiation exposure in CT. CT, as any imaging modality that utilizes x-rays, exposes the patient to ionizing radiation, which is a known carcinogen due to stochastic effects and which, at very high doses, can have deterministic detrimental effects. To understand the true magnitude of the risks associated with radiation exposure related to diagnostic chest CT, it is critical to have a basic understanding of the ways in which radiation dose is measured, as well as how to quantitatively estimate risk based on best available evidence.

Ionizing radiation dose equivalent (which takes into account energy absorbed (J/kg) and the biologic effects of the specific type of radiation) is measured in Sieverts (Sv). Every human is exposed to approximately 3 mSv/yr of background radiation from natural and man-made sources. In contrast, a chest radiograph delivers 0.1 to 0.2 mSv, whereas a chest CT performed using standard protocols delivers between 5 to 20 mSv. Deterministic effects are extremely rare below 2000 mSv of acute exposure. Although it is difficult to quantify the magnitude of stochastic effects, the International Commission of Radiological Protection (ICRP) estimates the risk coefficient (additional cancers due to radiation exposure) as 0.00005 per mSv of exposure (i.e., ~5% per 1000 mSv). In summary, CT delivers a low, but nonnegligible, radiation dose that is unlikely to cause detrimental biologic effects if used in a prudent and medically justifiable manner.

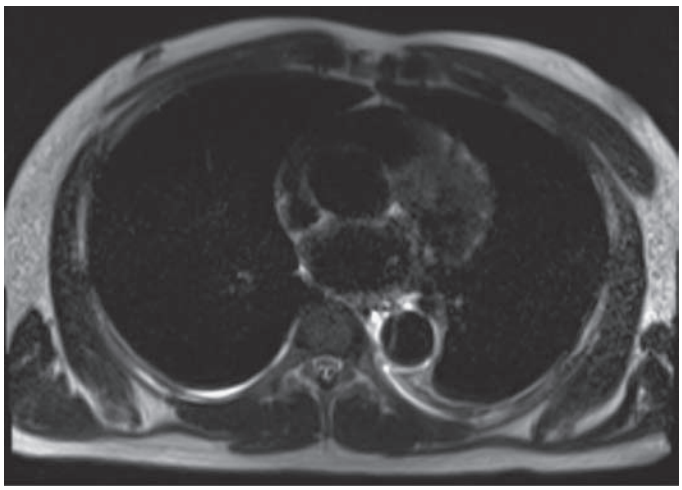
Notwithstanding the relative small risks, radiologists, engineers, and physicists have made substantial strides to develop reconstruction algorithms and protocol optimization techniques that decrease the radiation dose of thoracic CT to the lowest attainable level and that allows diagnostic-quality images. Among the recent dose-reduction methods that have become widely available are iterative reconstruction techniques, combined with tube current and voltage modulation. The combined effects can generate markedly reduced radiation dose, down to sub-mSv (<1 mSv) levels. This is particularly useful for low-dose screening CT, which is discussed in detail later (see Lung Cancer Evaluation).[3,4]

Finally, CT has a major role for guidance of thoracic interventional procedures, which is described in detail below.

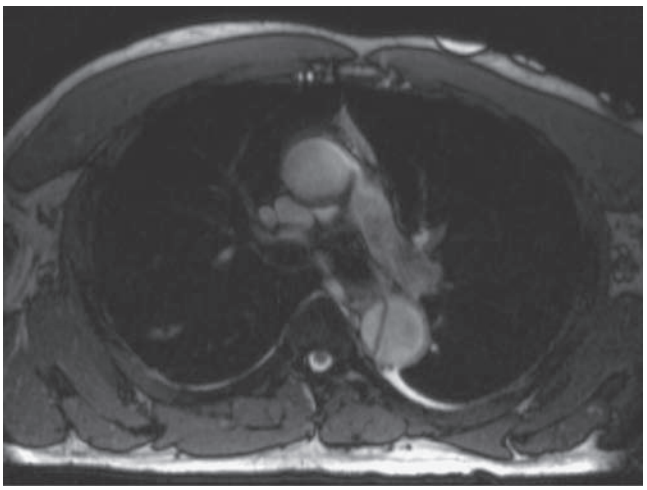
CHEST MR

MR is another advanced cross-sectional technique utilized in thoracic imaging. The physics behind MR is complex and beyond the scope of this chapter. Fundamentally, MR uses a very strong static magnetic field (main field) generated by superconducting coils in combination with a radiofrequency radiation pulse sequence and variable magnetic field (gradients) to cause oscillation of hydrogen proton nuclear spins. The result is generation of a radiofrequency signal, which is detected and measured. The signal can be also spatially localized to generate an image that can be obtained in any arbitrary plane. Image contrast with MR depends on the physical properties of the tissue being imaged, as well as on the specific pulse sequence utilized (Fig. 30-7).

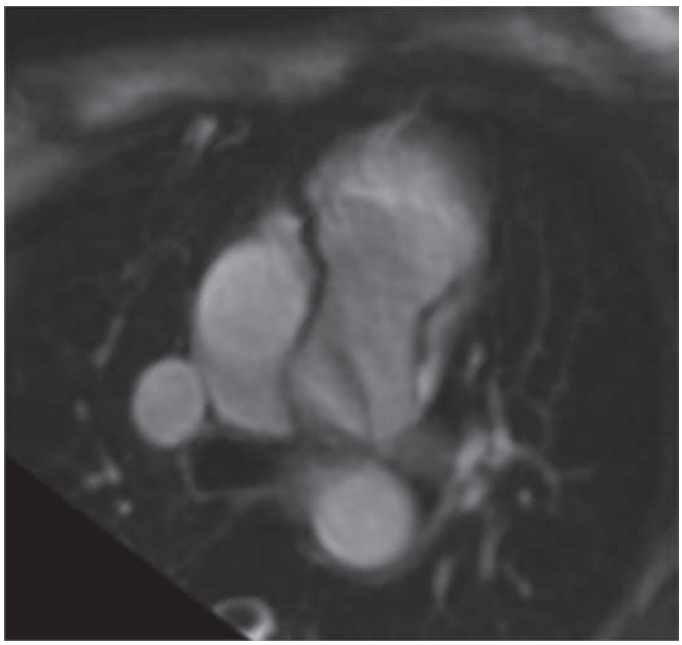
MR has advantages and disadvantages with respect to CT. The main advantage of MR is the lack of ionizing radiation. CT utilizes high-energy x-rays, whereas MR utilizes low-energy radiofrequency



A



B



C

Figure 30-7 MR offers lower spatial resolution than CT; however, it allows better contrast resolution and tissue characterization through utilization of varied pulse sequences that emphasize specific aspects of tissue composition. For example, (**A**) and (**B**) demonstrate a dissection of the descending thoracic aorta. **A.** The blood pool appears black and this is, therefore, termed a "black blood" sequence (typically, spin echo sequence). In contrast (**B**) demonstrates the blood pool to be bright and is, therefore, termed a "bright blood" sequence (typically, steady-state free precession gradient echo sequence). **C.** Different patient with a patent ductus arteriosus (PDA), which causes a linear flow artifact (dark band from the aorta to the left PA).

radiation which has minimal biologic effects and no ionization potential. MR also has better contrast resolution than CT and is exquisitely sensitive in the detection of water and fat. MR thus provides a greater degree of soft tissue characterization than is possible with CT. Examples of this greater resolution of soft tissue densities include identification of proteinaceous fluid in bronchogenic cysts, which can appear solid on CT, and the presence of fat in confirming thymic hyperplasia as a cause for an anterior mediastinal mass, thereby enabling differentiation from lymphoma. Another advantage of MR over CT is that iodinated contrast material is not used, obviating the potential problem of CT contrast allergy. In the past, MR also had the advantage of intrinsic multiplanar imaging, but modern multidetector-based CT now demonstrates similar capability.

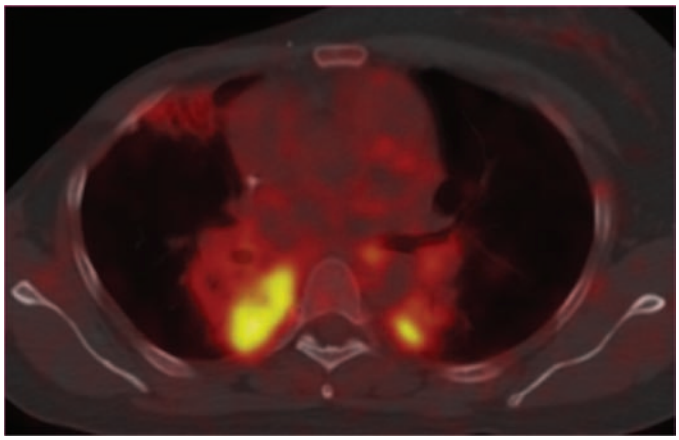
The disadvantages of MR include longer examination time, greater susceptibility to artifacts, lower spatial resolution, and generally very low signal-to-noise ratio in the lung parenchyma, making it unsuitable for optimal pulmonary parenchymal evaluation. However, it should be noted that recently developed fast-proton MR sequences appear promising for the evaluation of patients who need to undergo multiple serial imaging studies and in whom cumulative radiation exposure is of particular concern, such as in young patients with cystic fibrosis.

From a clinical perspective, MR is not the first-line advanced modality for assessment of pulmonary diseases, but it is a very valuable technique for evaluation of the heart and great vessels, for tissue characterization of mediastinal and chest wall masses, and for dynamic assessment of thoracic wall and diaphragmatic motion. Current applications of MR, in addition to those mentioned earlier, include evaluation of the brachial plexus, local staging of superior sulcus tumors, evaluation of neurogenic tumors and lesions involving the thoracic spine, and cardiac or paracardiac masses.[5,6]

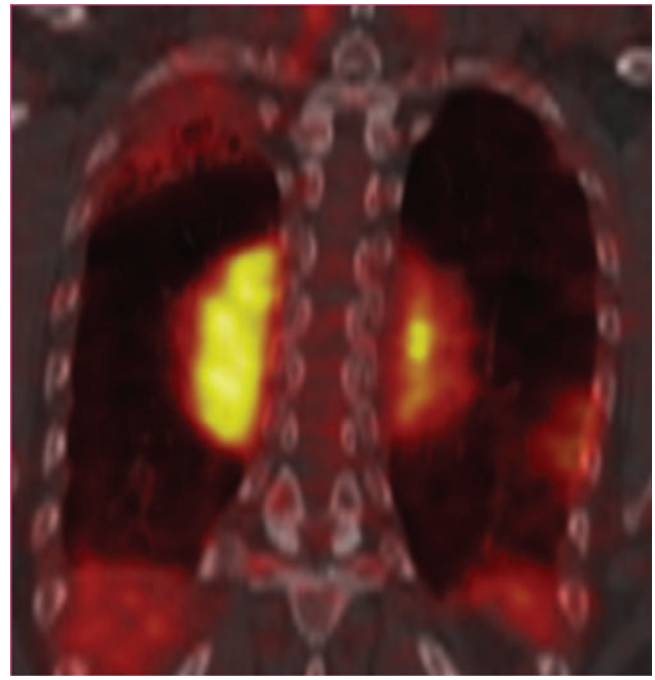
Recently considerable interest has arisen in the use of hyperpolarized gases, including helium-3 and xenon-129, for MR imaging of the lungs. Hyperpolarized gas MR can provide detailed images of pulmonary ventilation, as well as information on lung microstructure, beyond the resolution of CT. The latter includes measurements of alveolar size and alveolar–capillary membrane thickness. Nonetheless, to date, hyperpolarized gas MR remains investigational.

PET, PET/CT, AND PET/MR

PET is a nuclear medicine emission tomographic technique (see Chapter 32), in which an intravenously administered radionuclide that decays via positron emission (most often ^{18}F coupled



A



B

Figure 30-8 Fusion images combining CT and PET data in a patient with multifocal MALT pulmonary lymphoma. (**A**) Axial and (**B**) coronal images demonstrate that the areas of consolidation in the posterior medial lungs also demonstrate high FDG uptake, thus appearing bright yellow in this color scheme, a typical feature of metabolically active lymphomas.

to deoxyglucose [FDG]), generates an annihilation event (when a positron collides with an electron and two antiparallel 511-keV photons are simultaneously generated). The event is registered by coincidence detectors, allowing localization of the origin inside the body. Because FDG is very similar to glucose in biodistribution and pharmacokinetics, it effectively concentrates in tissues that have a high metabolic rate and therefore increased glucose uptake—namely, the brain, heart (in the nonfasting state), and many neoplasms; in addition, FDG is concentrated where it is metabolized and excreted: the liver, kidneys, and urinary collecting system. FDG-PET images essentially map the biodistribution of glucose in the body. CT and MR may be performed almost simultaneously with PET in dedicated hybrid scanners (PET/CT and, more recently, PET/MR). The higher spatial resolution of these modalities is helpful for localization of the abnormal PET signals in fused imaging analysis (Fig. 30-8).

It is a common misconception that PET/CT is specific for cancer diagnosis. In reality, it is not. Many normal tissues and inflammatory or infectious processes have a high metabolic rate and high glucose uptake and, therefore, are also bright on PET images. Moreover, many cancers are not highly metabolically active or are not FDG avid, and these may not be detectable by PET imaging. A typical example in the chest is an indolent adenocarcinoma in situ (AIS), formerly called bronchioloalveolar cell carcinoma (BAC).

The strength of PET/CT relies on its ability to accurately stage malignancy if the primary neoplasm is FDG avid. In this context, it is superior to CT or MR because it may demonstrate small metastases in normal-sized structures, particularly lymph nodes, which would not be detectable by CT or MR. PET/CT is, therefore, routinely employed for staging of malignancies such as lung cancer, lymphoma, head and neck carcinoma, and esophageal carcinoma.[7]

ULTRASOUND

US has a more limited application to thoracic imaging. The primary reason is that both the thoracic cage and the lungs act as reflecting interfaces that block penetration of the US mechanical wave. However, US has been shown to be useful for specific applications, such as detection of pneumothorax or pneumonia, as well as in evaluation of pleural effusions and chest wall pathology. In addition, it is useful in guiding imaging interventions. Thoracic US is discussed in detail in Chapter 31.

IMAGE-GUIDED INTERVENTIONS

Image-guided interventions have dramatically changed the diagnosis of thoracic diseases that require tissue sampling for pathologic confirmation. They have also impacted the treatment of many benign and malignant diseases. Increasingly, image-guided biopsy procedures are being performed for tumor genotyping to guide more targeted, personalized therapies. Half a century ago, surgical procedures were necessary to obtain tissue from the lungs, mediastinum, or chest wall. Surgical biopsies may require hospitalization, are costlier, and carry small, but measurable rates of morbidity and mortality. Currently, most diagnostic procedures can be performed percutaneously or via bronchoscopy in a minimally invasive fashion. Bronchoscopy and endobronchial interventions are described in Chapters 35 and 36 (Fig. 30-9).

Percutaneous transthoracic biopsies (PTBs) may be performed via a variety of imaging guidance systems, most commonly CT, but also fluoroscopy or US (Videos 30-4 and 30-5A,B). Different needle types, lengths, and calibers may be chosen according to the clinical question and lesion characteristics. As a general rule,

superficial chest wall lesions can be accessed via US or CT; pleural, pulmonary, and anterior mediastinal lesions are accessed via CT; central hilar lesions and deep mediastinal masses are not accessible via PTB.

There are two basic types of PTB: fine-needle aspiration (FNA) and automated core needle biopsies (CNBs). In FNA, a small-caliber needle (25–22G) is inserted through the chest wall into the lesion via CT guidance. The tip of the needle is positioned inside the lesion. Negative pressure (suction) is applied via a syringe, and fluid

or clusters of cells are aspirated. The material obtained via FNA is processed using cytopathology techniques, and specific stains and molecular tests can be performed.

In contradistinction, CNB uses a larger coaxial system in which a 19G introducer (outer core) hollow needle is advanced to the pleura or close to the edge of the lesion, followed by introduction of a 20G automated inner core biopsy needle, which is advanced to the lesion. An automated mechanism is then activated, rapidly moving the needle forward and filling the needle trough, or shallow receptacle, with cylindrical "cores" of tissue. The outer sheath instantly moves forward to cut the tissue and keep it in the trough. This process is repeated several times as multiple tissue cores are obtained. The material obtained via CNB is processed using surgical pathology techniques. Both FNA and CNB provide material for microbiology studies, including stains and cultures.

From a diagnostic perspective, FNA is almost equally accurate to CNB for diagnosis of malignant diseases, although CNB is superior for diagnosis of benign diseases. FNA sensitivity for diagnosis of lung cancer is 80% to 95%, and the rate is higher if onsite cytopathology is available and the procedure is approved and performed by experienced radiologists. Limitations of FNA include diagnosis of indolent or low-grade malignancies (for which more tissue or histoarchitecture is required for confident pathologic diagnosis) and inflammatory or infectious diseases—scenarios in which CNB is superior. The advantage of FNA over CNB is a lower complication rate and the capacity to engage and sample very small lesions that would otherwise be inaccessible.

Lesion location, lesion size, and patient body habitus are major determinants utilized by the radiologist in deciding the optimal biopsy technique. All other factors being equal, large pulmonary masses (>3 cm), pleural masses, chest wall masses, and large anterior mediastinal masses are best sampled via CNB. On the other hand, small pulmonary nodules (as small as 0.8 cm), pulmonary nodules in highly mobile regions (posterior or anterior lung bases), and small lymph nodes are best approached using FNA.

Complications related to PTB are relatively infrequent, but occasionally they can be life-threatening. For mediastinal, chest wall, and pleural biopsies, the major risk is hemorrhage, with infection and postprocedural pain following in incidence. Major vascular injury is rare, but it has been reported following biopsies of mediastinal masses. For lung biopsies, the major risk is pneumothorax, followed by hemorrhage, infection, and, rarely, air embolism. While air embolism is the rarest complication, with reported frequency of 0.05% to 0.10%, it is potentially the most life-threatening, due to its unpredictable nature and difficult treatment. Pneumothorax rate varies widely according to institution, and estimates from 5% to 50% have been reported. Most postprocedural pneumothoraces are small and not clinically significant; however, in up to 5% to 10% of patients, a large or symptomatic pneumothorax requires chest tube placement.

The following precautions are advised to minimize the risks associated with PTB: (1) critical appraisal of the clinical need for biopsy and whether PTB is the best approach; (2) thorough preprocedural laboratory assessment to ensure normal platelet count and function and normal coagulation profile. Anticoagulants and antiplatelet medications should be discontinued after conferring with the referring physician; (3) performance or supervision of the procedure by an experienced radiologist; (4) careful preprocedural planning, choosing a patient position and needle trajectory that minimizes the risk of vascular injury and decreases the distance to the lesion; (5) proper biopsy technique with purposeful, fast, accurate needle motion, confirming with imaging the needle location, depth, and relationship to the lesion prior to, and after, each needle movement; and (6) minimization of the effects of patient motion by tracking chest wall movement and advancing the needle in a consistent phase of the respiratory cycle.[8,9]

Therapeutic, percutaneous, image-guided techniques have also been increasingly accepted and utilized. These range from percutaneous chest tube or drain placement to ablation of neoplasms utilizing microwave or cryoablation techniques. The same principles of imaging guidance described for PTB apply for percutaneous therapeutic interventions. Given their complexity and the availability of alternative treatment options (such as surgery or radiation therapy), their use is best reserved for selected patients following discussion with multidisciplinary healthcare teams.

OBSTRUCTIVE LUNG DISEASES, WITH EMPHASIS ON COPD

Pulmonary ventilation, as is the case for pulmonary perfusion, is not homogeneous; it is affected by gravity, airway caliber, and chest wall mechanics. Ventilation is greater at the bases in the erect position due to greater regional changes in lung volume with inspiration, but the apical–basal ventilation gradient is smaller than the perfusion gradient (noting that perfusion is also greater at the bases). Therefore, the ventilation–perfusion ratio (V/Q) is greater at the apices in the erect patient. A similar pattern occurs in the supine patient between the dependent posterior and the nondependent anterior lungs, albeit to a lesser extent. Changes in relative ventilation affect the relative volume and average density of the lung parenchyma and, therefore, can be depicted by imaging.

Chronic obstructive pulmonary disease (COPD) is a complex group of disorders characterized by chronic, progressive airflow limitation that is not fully reversible and is associated with a range of pathologic changes in the lungs (Chapters 39 and 40). In addition, significant extrapulmonary effects caused by chronic inflammation and structural changes are observed. The chronic airflow limitation is caused by a mixture of small airway disease (obstructive bronchiolitis) and parenchymal destruction (emphysema). In addition, large airway inflammation, with increased sputum production and cough, is the hallmark of chronic bronchitis, part of the spectrum of COPD. The relative contributions of these components vary substantially from patient to patient. The presence and extent of each component has the potential to affect clinical presentation, disease severity, prognosis, and therapeutic response. COPD is strongly related to smoking. It has emerged as the third leading cause of death in the United States.

Another clinically prevalent obstructive lung disease is asthma, which is an inflammatory condition affecting mainly small airways, with increased mucus production, airway wall inflammation, and reduced luminal caliber (Chapters 44–46). Asthma differs from COPD from an imaging standpoint in that the clinical manifestations are usually intermittent and reversible, and the degree of hyperinflation tends to be mild, except in severe, longstanding disease.[10,11]

Chest radiographs are not particularly useful in diagnosing obstructive lung disease. In early disease, these are generally normal, as is the case with most asthmatic patients. In more severe or advanced disease, hyperinflation ensues and can be detected radiographically. The classic radiographic appearance of hyperinflation is manifested by increased radiolucency of the lungs; low, flat diaphragms; exaggerated verticality of the heart; increased AP diameter of the chest; and widening of the retrosternal lucent space. Of all these criteria, diaphragmatic flattening is probably the most reliable in supporting a diagnosis of COPD, as it is likely associated with severe emphysema. Care must be taken in making a diagnosis, however, as hyperinflation can be simulated radiographically when a healthy person exerts a maximal inspiratory effort. The lungs also appear hyperinflated in very slender persons. Therefore, it is unwise to make the diagnosis of emphysema solely on the basis of the radiographic finding of hyperinflation (Figs. 30-10 and 30-11).

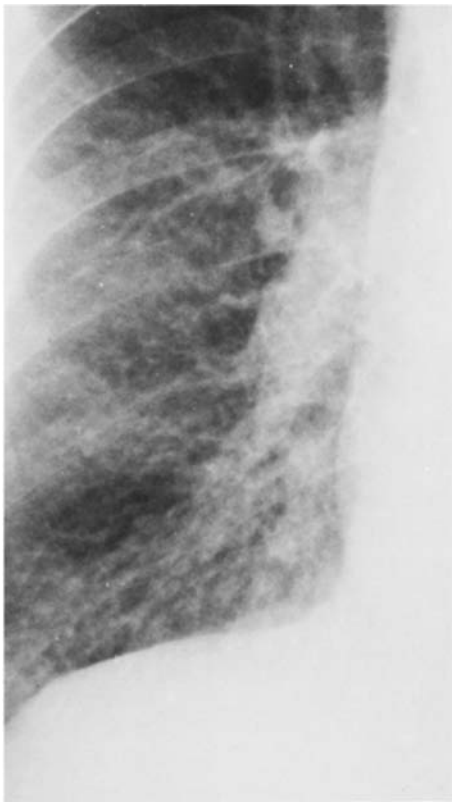

Figure 30-10 Detail view of the lung parenchyma in a PA radiograph, demonstrating increased bronchovascular markings, which are particularly prominent throughout the central lung fields. The patient has COPD with predominant chronic bronchitis. Hyperaeration is minimal.

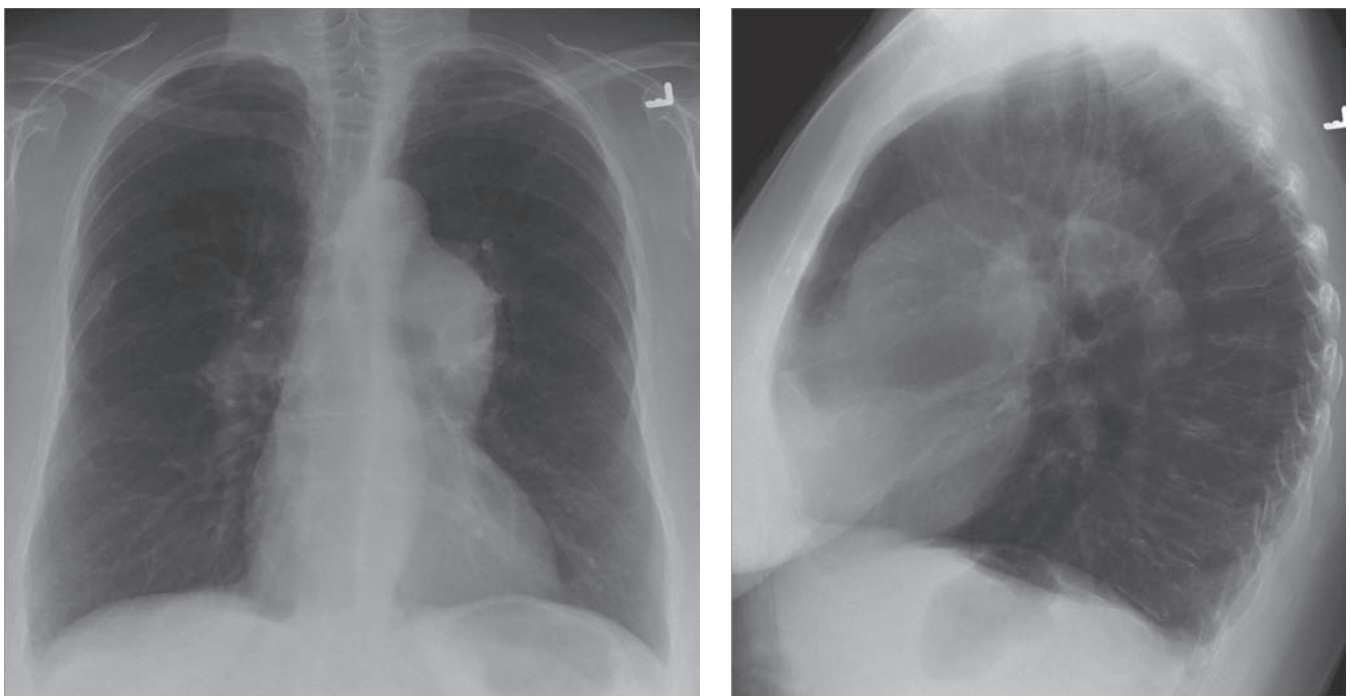
Radiographic evaluation of the pulmonary vessels may also support a diagnosis of emphysema. Two distinctly different vascular patterns have been identified in patients with chronic bronchitis and emphysema: arterial deficiency and increased lung markings. Patients who show the arterial deficiency pattern often have panlobular emphysema and manifest the clinical syndrome of the "pink puffer." Those who have the pattern of increased lung markings often have centrilobular emphysema and manifest the "blue bloater" syndrome. Notably, these radiographic findings occur relatively late in the clinical course of emphysema. Moreover, these findings are not specific and must be considered in the clinical context provided.

Similarly, the diagnosis of chronic bronchitis is a clinical one, based upon a history of chronic cough and sputum production and supplemented by characteristic abnormalities in pulmonary function tests. The radiograph rarely provides substantive help. Vascular markings throughout the lung fields are sometimes prominent, but this finding is nonspecific.

CT, on the other hand, is capable of demonstrating the pathologic changes associated with COPD, including large and small airway inflammation and parenchymal destruction (emphysema). Three basic types of emphysema can be detected by CT—centrilobular, paraseptal, and panlobular.

Centrilobular emphysema is characterized by focal areas of lucency within the centers of secondary pulmonary lobules and without perceptible walls. The lobular arteries and bronchi are maintained, appearing as small dots within the involved secondary lobules. These features help to differentiate the holes of centrilobular emphysema from the cysts of cystic lung disease, as the latter have thin walls and are devoid of internal structure.

Paraseptal emphysema occurs peripherally, adjacent to the visceral pleura, and adjacent to the bronchovascular interstitium. Centrilobular and paraseptal emphysema are both associated with



A **B**

Figure 30-11 (**A**) PA and (**B**) lateral of a patient with severe emphysema-predominant COPD. Salient features are hyperinflation (denoted by flattening of the diaphragms and increased craniocaudal and anteroposterior diameters of the chest) and hyperlucency of the parenchyma. Also note prominence of the central pulmonary arteries, compatible with pulmonary hypertension.

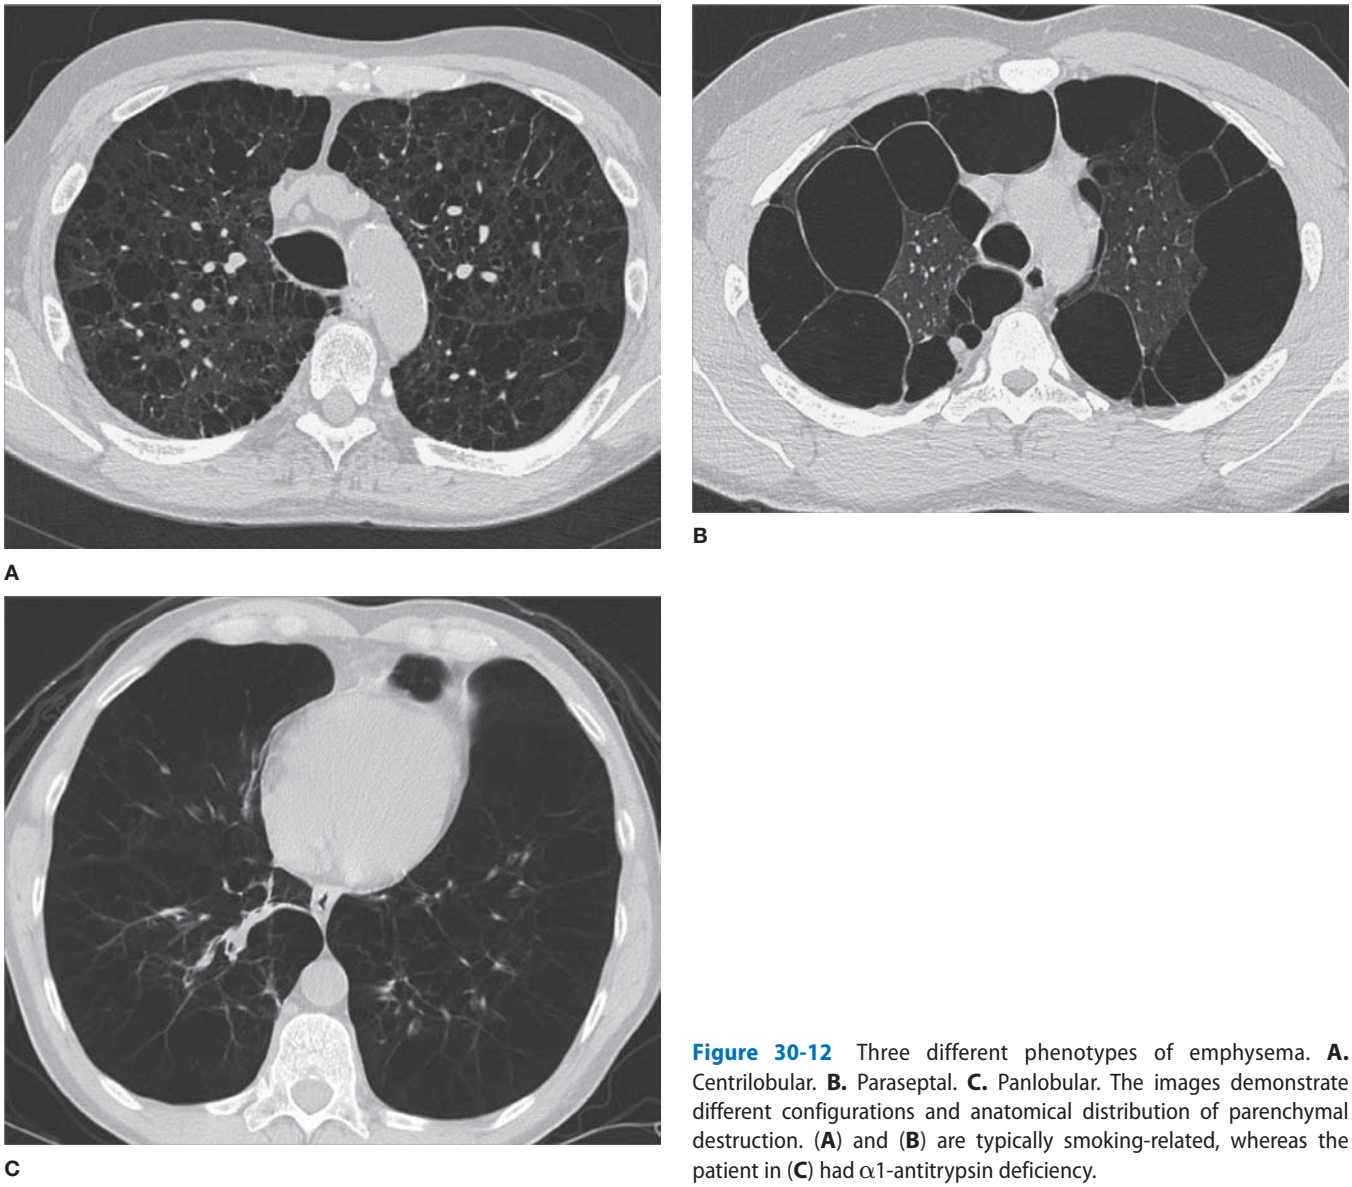


Figure 30-12 Three different phenotypes of emphysema. **A.** Centrilobular. **B.** Paraseptal. **C.** Panlobular. The images demonstrate different configurations and anatomical distribution of parenchymal destruction. (**A**) and (**B**) are typically smoking-related, whereas the patient in (**C**) had α1-antitrypsin deficiency.

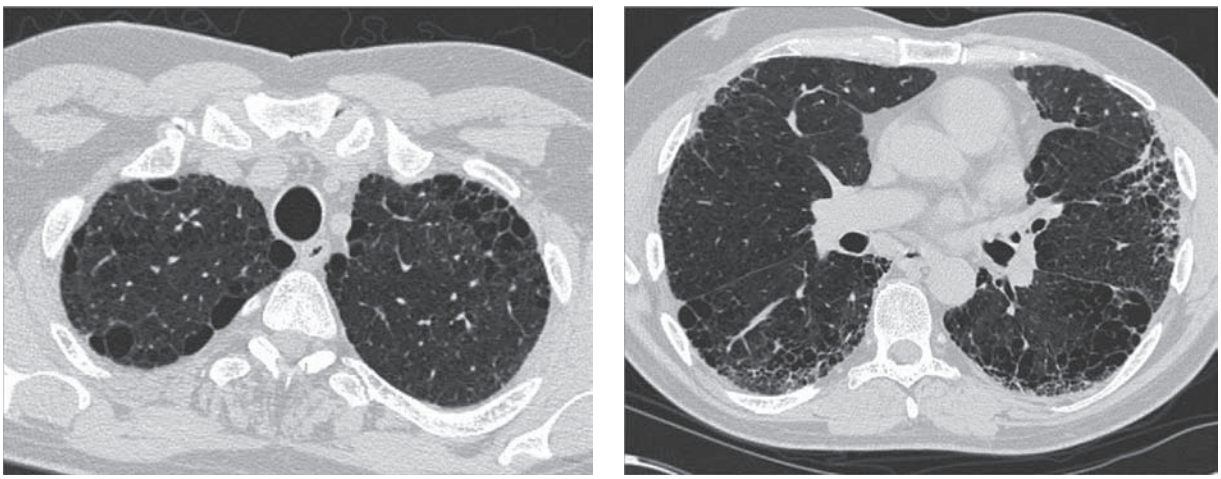
smoking and, therefore, tend to coexist, although the contribution of each form for the total amount of emphysema varies substantially. There is generally upper lung predominance, except in very severe disease. The extreme form of paraseptal emphysema is evident as bullous disease, in which the cystic spaces may become large enough to compromise lung mechanics due to their mass effect.

Finally, panlobular emphysema is a distinct entity in which there is diffuse hyperlucency, hypovascularity, and a paucity of interstitial markings, often with a basilar predominance. These important findings can be overlooked even in patients with marked panlobular emphysema, since there are no discrete holes, as is the case in centrilobular emphysema. This form of emphysema is less likely associated with smoking, and more likely associated with α1-antitrypsin deficiency, a genetic condition that can be exacerbated by smoking (Figs. 30-12 and 30-13).[12–14]

Large airway inflammation as a manifestation of chronic bronchitis may be suggested by the presence of airway wall thickening, the diagnosis of which is somewhat subjective, although several studies have described computer-assisted quantitative measurement methods. Mucoid impaction is a reliable indicator of airway inflammation, but it is not specific for COPD, as it can be seen in the setting of asthma, acute bronchitis, or bronchopneumonia.

Small airway inflammation was previously the most difficult component of COPD to diagnose by imaging. While it is still not possible to directly image inflammation of the very distal airways, expiratory CT now provides the best technique to indirectly diagnose small airway disease. The presence of small airway disease may be inferred by the presence of expiratory air trapping. Normally, the average CT attenuation of aerated lung parenchyma increases in expiration due to volume averaging of voxels that contain less air. In contrast, with air trapping, the increased lung attenuation with expiration is not observed. Thus, in the presence of small airway disease a "mosaic attenuation pattern" is demonstrated on CT images obtained in end expiration, with the darker (lower attenuation) areas corresponding to areas of regional air trapping. Up to 25% of the lung may show air trapping in healthy subjects (typically at the lung bases); higher degrees of air trapping correlate with decreases in functional parameters assessed with pulmonary function testing, such as residual volume (RV) or functional residual capacity (FRC) (Figs. 30-14 and 30-15).

The major future trend in the imaging of COPD is the development of computer-assisted quantification techniques for disease phenotyping, namely, detecting and measuring the severity and



A B

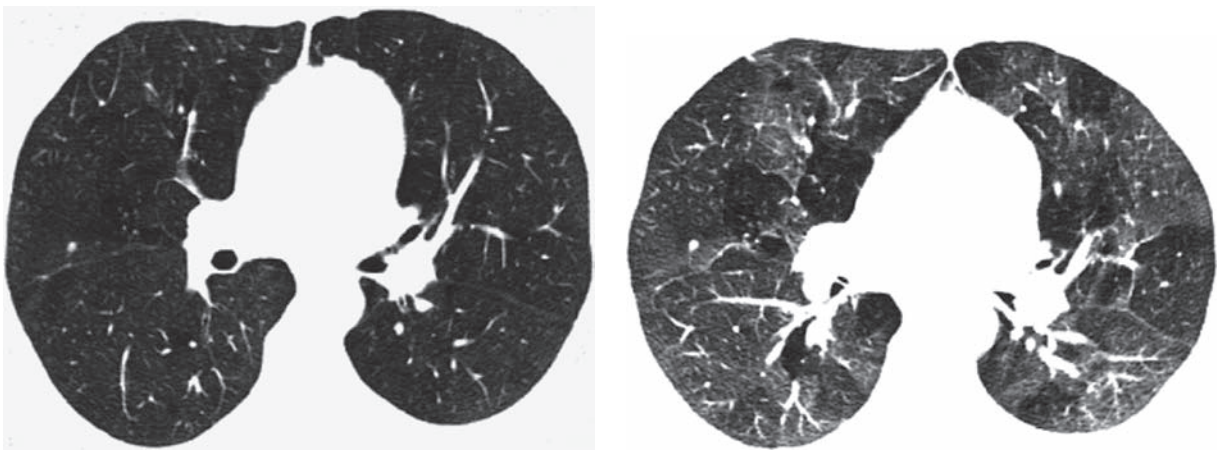
Figure 30-14 (**A**) Inspiratory and (**B**) expiratory CT images at the level of the mainstem bronchi, demonstrating dynamic expiratory collapse of the central airways, indicative of bronchomalacia, a common association with COPD.



A B

Figure 30-15 (**A**) Inspiratory and (**B**) expiratory CT images demonstrate the presence of mosaic attenuation (i.e., geographic areas of low parenchymal attenuation interspersed within normal, higher-attenuation areas in expiration), characteristic of air trapping. This patient had a diagnosis of bronchiolitis obliterans.

relative contributions of emphysema and large and small airway diseases to the overall clinical presentation and functional status. Many studies have been published on this subject in the last decade. For quantitative imaging, strict standardization of the scanning technique is required. Sophisticated computer algorithms are also required to accurately separate the lung parenchyma, central airways, central vasculature, mediastinum, and chest wall structures based upon attenuation characteristics and geometric constraints using thin-section, isotropic volumetric data sets primarily obtained using CT. A variety of computational methods can then be applied to detect several disease patterns and characterize their extent and distribution, for both diagnosis and disease quantification as a means of better assessing prognosis and response to therapies.[15,16]

It has been established that "attenuation masks" that separate all low attenuation voxels in the segmented lung parenchyma (e.g., areas of <–950 HU), not including central airways, can accurately quantify the volume of emphysema compared with the reference standard of pathologic assessment. Such CT measures of emphysema demonstrate strong correlation with functional metrics that denote obstruction (e.g., FEV1/FVC,%). Moreover, it is possible to measure the thickness of the central airways (to the fifth or sixth generation) as a quantitative metric in chronic bronchitis. In addition, small airway disease can be indirectly measured using quantification of expiratory air trapping, which can be accomplished via several different techniques. The simplest method uses attenuation masks in expiration. Voxels measuring less than –856 HU on expiratory CT are considered areas of air trapping. This attenuation threshold has been validated in multiple publications. More sophisticated techniques take into account how much each voxel varies in attenuation between full inspiration and end expiration (at FRC). The latter approach requires mathematical, nonrigid registration techniques that track individual voxel motion and regional volume changes between data acquired at two different time points, allowing for a one-on-one correspondence between lung voxels in inspiration and expiration.[17,18]

While these sophisticated quantitative applications are still largely investigational, they will likely reach the clinical realm within this decade. Studies continue to validate the superiority of quantitative imaging over standard qualitative assessment of thoracic imaging studies, demonstrating improved correlations with disease severity and functional impairment. Such quantitative imaging will ultimately provide better tools to estimate prognosis and monitor the efficacy of therapy.

INTERSTITIAL LUNG DISEASE

Interstitial lung disease (ILD) is a broad and complex topic, with many distinct and unrelated clinical entities potentially contributing to a single imaging pattern. Their detailed pathophysiology is described elsewhere. The focus of this discussion is the contribution of imaging to the differential diagnosis of ILD, emphasizing the most common and clinically relevant diseases.

The chest radiographic pattern of interstitial disease differs from the pattern of alveolar disease in that with interstitial disease the imaging pattern tends to be discrete and sharp, rather than fluffy and irregular; the lesions tend to be diffused, rather than localized. In addition, coalescence is not a typical feature in ILD, and the small opacities are characteristically nodular, reticular, or linear. Large masses or consolidations are not characteristic of the interstitial pattern (Fig. 30-16).

In and of itself, the recognition of an interstitial pattern on chest radiographs is not specific for a particular diagnosis. Most often a CT is necessary for further characterization. However, two observations that may provide useful insight into the likely diagnosis are the temporal course and distribution of disease.

Most interstitial diseases have a chronic, progressive course. Therefore, recognition of an acute interstitial pattern, that is, development and rapid evolution over hours or a few days, is strongly suggestive of interstitial pulmonary edema. This is even more likely if ancillary findings indicative of congestive heart failure or volume overload are present, such as cardiomegaly, pleural effusions, and widening of the vascular pedicle in the mediastinum. Occasionally, a rapidly changing interstitial pattern represents atypical pneumonia due to *Pneumocystis jiroveci*, cytomegalovirus, or mycoplasma. The acute interstitial disorders typically cause a radiographic linear or reticular pattern, which is characterized by prominent Kerley lines throughout the lungs.

In his original description in 1951, Kerley associated thin, radiographic parenchymal opacities with left ventricular failure. Initially, Kerley lines were thought to represent swollen pulmonary lymphatics. It is now recognized that Kerley lines usually represent edematous septae within the pulmonary interstitium. Three patterns exist. Kerley type B lines are the most familiar and are particularly prominent at the lung bases, where they appear as straight, thin, peripheral lines approximately 1 cm long and oriented parallel to the diaphragm. Kerley type A lines represent septae deep within the substance of the lungs; they radiate from the hili, but they are thinner than central vessels. Kerley type C lines probably represent coalescence of A and B lines and are difficult to recognize.

Chronic ILDs may be caused by a wide variety of diseases, including idiopathic interstitial pneumonias, connective tissue diseases, pneumoconiosis, sarcoidosis, lymphangitic spread of malignancy, infections, Langerhans cell histiocytosis (LCH), and lymphangioleiomyomatosis (LAM). Of note, LCH and LAM are not interstitial diseases per se, but rather cystic lung diseases that can present as an interstitial pattern on chest radiography; they are better characterized as cystic diseases on CT.

Characterization of the pattern of interstitial disease as nodular, reticular, or linear on chest radiograph may help in differential diagnosis, since many of the ILDs have a predilection for one of these three patterns. However, beyond that, the radiographic findings are not sufficient for a specific diagnosis. Nonetheless, separation of the distribution of disease into two broad categories can be helpful—upper lung predominant versus basilar predominant.

Upper lung–predominant distribution favors airway-related pathology, with inhalational diseases such as infections, LCH, and pneumoconiosis predominating in this group. Moreover, sarcoidosis is also typically upper lung predominant, a finding compatible with the hypothesis that the disease is triggered by an inhaled agent, although its exact cause remains elusive. On the other hand, basilar-predominant distribution favors idiopathic interstitial pneumonias and connective tissue diseases, in which increased blood flow and greater regional volume changes may play a role in explaining the lower lung predominance. Following such radiographic assessment, CT is generally the next diagnostic step.[19,20]

CT has been validated as the optimal imaging technique for evaluating chronic ILDs. CT can often identify interstitial disease that is not seen on chest radiography, and it provides better disease pattern characterization to enable identification of the underlying etiology, as well as better qualitative or quantitative assessment of severity. CT patterns of ILD follow, to some degree, the patterns seen on the chest radiograph; however, CT allows distinction of reticular, linear, and nodular patterns much more confidently. In addition, it permits evaluation of ancillary findings, such as honeycombing, traction bronchiectasis, ground-glass opacities, and cystic changes, all of which may be very challenging or impossible

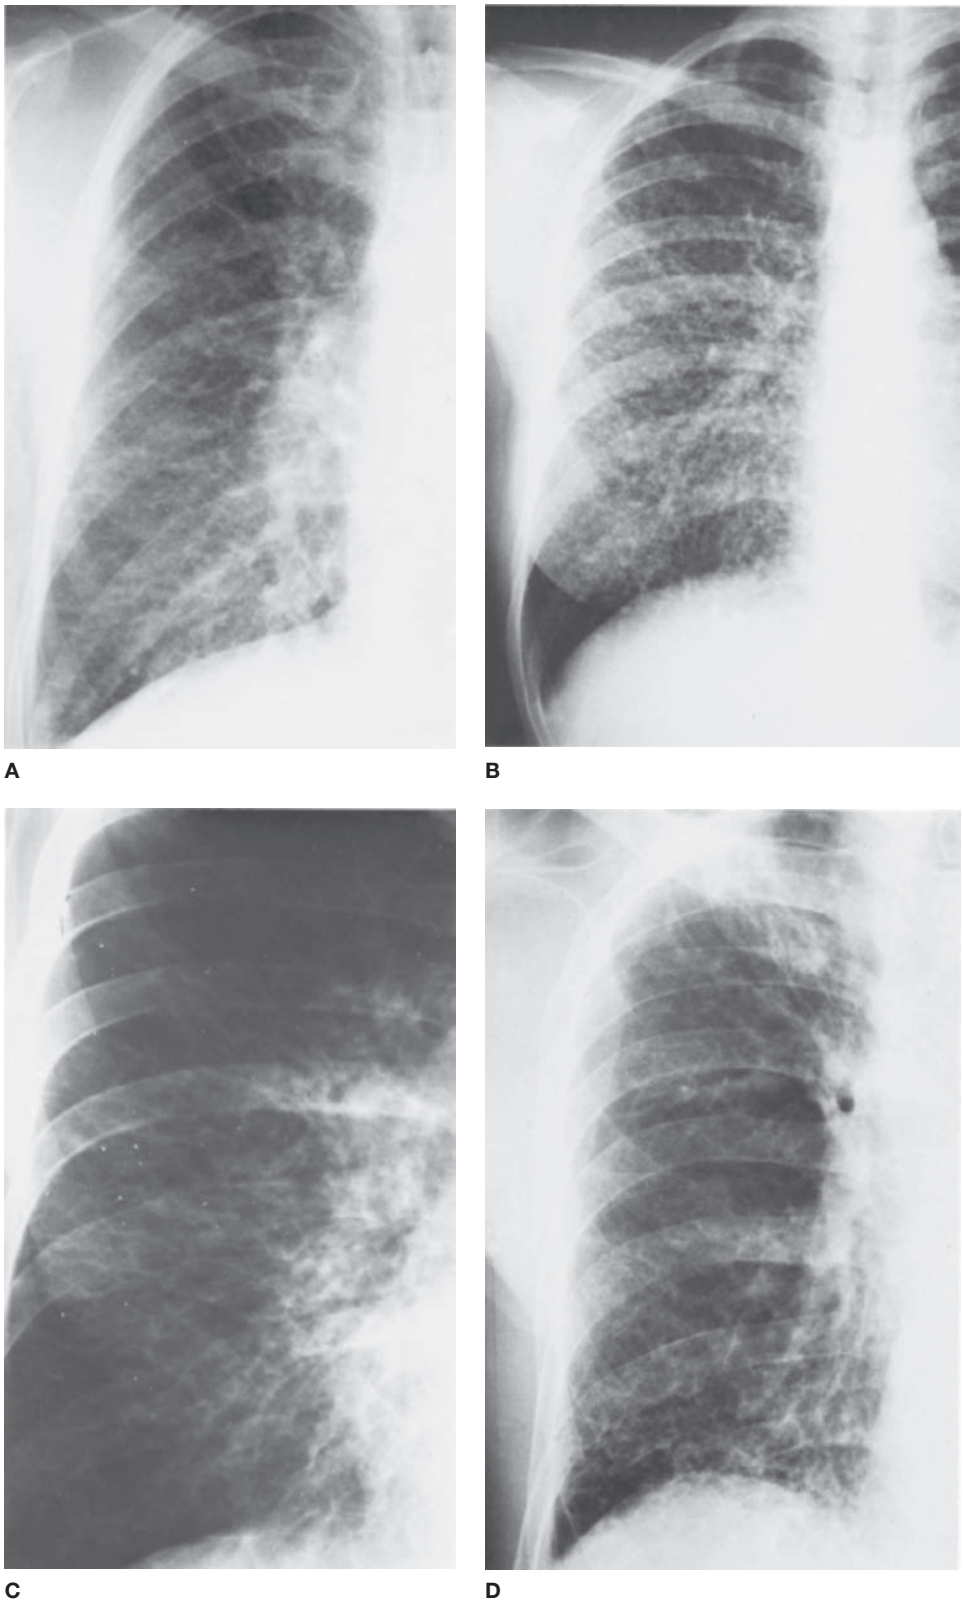


Figure 30-16 Radiographic patterns of interstitial disease. **A.** Linear interstitial pattern produced by interstitial pulmonary edema. The pattern is caused by fluid in the axial and septal interstitial spaces of the lungs, particularly in interlobar septae. **B.** Nodular interstitial pattern due to sarcoidosis. Multiple small, discrete nodules involve both lung fields diffusely. Adenopathy is absent. **C.** Lymphangitic spread of neoplasm. The linear interstitial pattern was caused by metastatic carcinoma of the pancreas. **D.** Reticular interstitial lung pattern. The pattern is most marked at the bases and is characteristic of idiopathic pulmonary fibrosis or collagen vascular disease, particularly scleroderma (as in this patient).

to recognize on chest radiographs. Important to emphasize is that, as previously discussed, every chest CT performed using current protocols on modern scanners may serve as a high-resolution examination. Therefore, the distinction between standard and high-resolution chest CT is obsolete, and detailed interstitial disease characterization can be performed on all current chest CT studies.[21]

Careful analysis of the CT in evaluating ILD can be described as comprising three steps.

The first step in the diagnostic approach of ILD on CT is to exclude interstitial pulmonary edema as the cause. An acute course and ancillary findings of cardiomegaly, bilateral pleural effusions, and central vascular engorgement strongly suggest interstitial pulmonary edema. CT findings include symmetric

Video 30-6 Axial cine images using lung window, demonstrating a typical usual interstitial pneumonia (UIP) pattern of fibrosing interstitial lung disease—in this case, idiopathic (and, therefore, classified as IPF, or idiopathic pulmonary fibrosis). *Access at www.fishmansonline.com*

Video 30-7 Axial cine images using lung window, demonstrating mild interstitial lung disease characterized by basilar-predominant ground-glass opacities without overt fibrotic features, likely reflecting cellular nonspecific interstitial pneumonia (NSIP). In this case, the findings were attributed to connective tissue disease (likely due to scleroderma). *Access at www.fishmansonline.com*

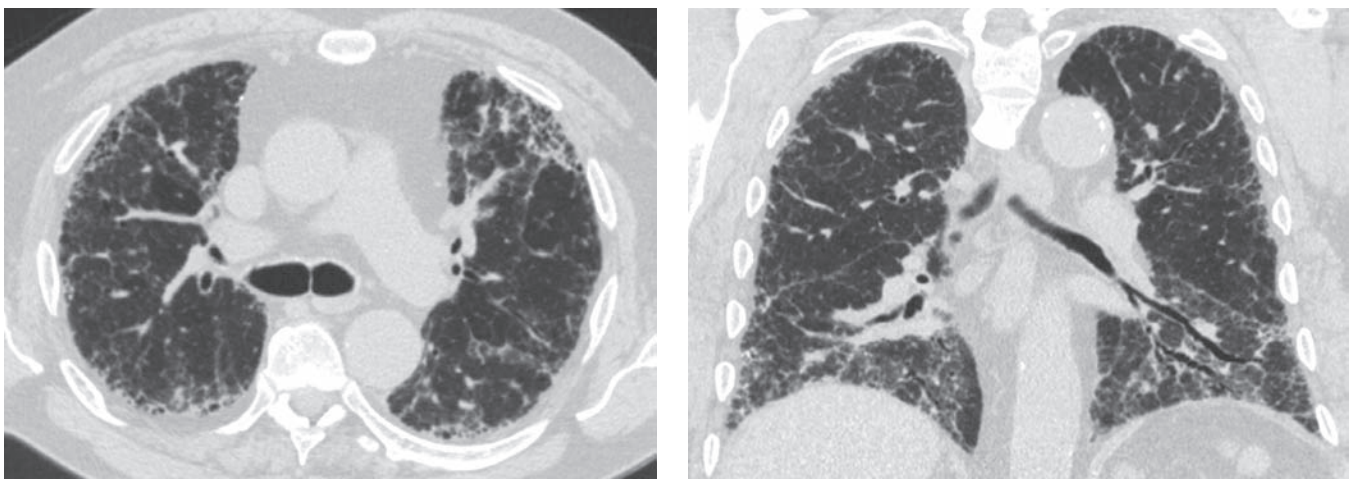
bilateral axial (peribronchovascular) and interlobular septal thickening, with central and basilar predominance. Ground-glass opacities may be present, denoting concomitant alveolar edema. It is important to remember that lymphangitic spread of neoplasm may present with a similar CT pattern; however, the temporal course is not acute and the findings are often asymmetric and more nodular, with additional features of malignancy present, such as pulmonary masses and hilar or mediastinal lymphadenopathy.[22,23]

The second step is to decide whether usual interstitial pneumonia (UIP) is the most likely cause of the pattern. UIP is the pathologic correlate of idiopathic pulmonary fibrosis, although it may also be associated with connective tissue disorders and asbestosis, as well. The latter should be considered if other findings that correlate with asbestos exposure, such as pleural plaques, are present. It is important to recognize UIP because it generally has a much worse prognosis than other causes of ILD and because typical CT features may be sufficient for diagnosis and obviate the need for surgical lung biopsy. CT imaging findings of UIP include symmetric, basilar-predominant reticular opacities, peripheral stacked layers of small cysts (honeycombing), and traction bronchiectasis (Video 30-6). Honeycombing, in particular, is the imaging finding most suggestive of, and specific for, UIP. If this constellation of findings is present, the pattern can be confidently diagnosed as typical UIP and a surgical biopsy avoided.[22]

The third step is to ascertain whether there are features that suggest fibrosis but which are not typical of UIP. In the absence of honeycombing, the combination of reticulation, architectural distortion, and traction bronchiectasis indicates the presence of fibrosis. If fibrosis is present, the differential diagnosis is relatively limited, including atypical UIP, fibrotic nonspecific interstitial pneumonia (NSIP), end-stage sarcoidosis, and chronic hypersensitivity pneumonitis (CHP). Fibrotic NSIP is favored over atypical UIP if there is central, rather than peripheral, predominance, and honeycombing and associated ground-glass opacities are absent. Moreover, the early phase of NSIP may manifest as multifocal bilaterally symmetric ground-glass opacities without fibrotic features or consolidation, denoting early inflammatory changes (cellular NSIP) (Video 30-7). Untreated cellular NSIP generally progresses to fibrotic NSIP, though cellular NSIP tends to respond to anti-inflammatory drugs such as steroids. Nonetheless, significant overlap occurs between fibrotic NSIP and atypical UIP. Both may be idiopathic or associated with connective tissue disorders. Clinical correlation and laboratory tests usually are required to exclude a connective tissue disorder. Of note, the presence of a patulous esophagus may be a clue to the diagnosis of CREST syndrome or systemic sclerosis (Figs. 30-17 and 30-18).[24]

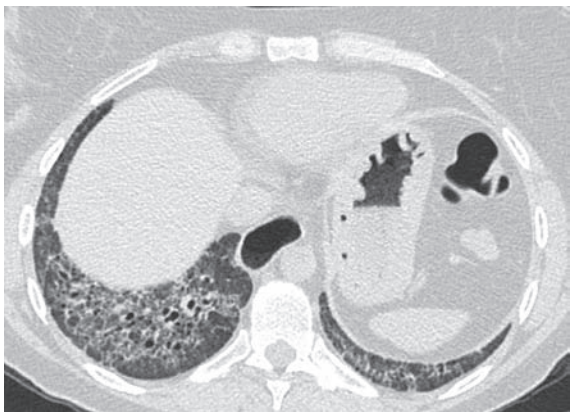
Sarcoidosis is suspected when there is a combination of upper lung–predominant disease that is bilaterally symmetric, axial and interlobular septal interstitial thickening, multiple diminutive nodules with perilymphatic distribution (see section on Pulmonary Nodules and Lung Cancer, below), and associated mediastinal and hilar lymphadenopathy. Mosaic air trapping may also be present. The presence of fibrotic features denotes end-stage disease (radiographic Stage IV). The differential diagnosis includes interstitial pulmonary edema and lymphangitic spread of neoplasm, with interlobular septal thickening as the unifying theme for these three entities.[25]

CHP frequently is associated with a mosaic attenuation pattern that is accentuated on expiratory imaging, denoting heterogeneous small airway air trapping. In addition, CHP tends to show upper zone predominance and may cause multiple tiny nodules. The presence of air trapping is somewhat specific for CHP in the setting of pulmonary fibrosis that does not conform to typical UIP or show features of sarcoidosis, unless the patient has superimposed asthma or COPD (Figs. 30-19–30-21).[26]

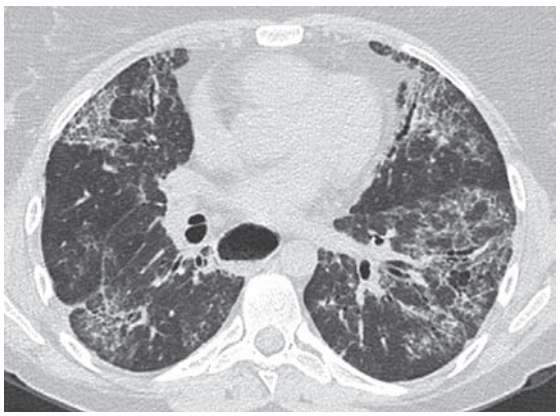


A B

Figure 30-17 (**A**) Axial and (**B**) coronal CT images demonstrate a classic usual interstitial pneumonia (UIP) pattern, depicting symmetric, basilar- and peripheral-predominant reticulation, traction bronchiectasis and honeycombing. A UIP pattern confers the worst prognosis among interstitial diseases and is associated with the clinical diagnosis of idiopathic pulmonary fibrosis (IPF).



A



B

Figure 30-18 (**A**) Axial basilar and (**B**) axial midlung CT images in a patient with nonspecific interstitial pneumonia (NSIP) pattern. This pattern is distinguished from UIP by the absence of honeycombing and the more central (or peribronchovascular) distribution of reticulation denoting fibrosis. Traction bronchiectasis is also noted. The patient had a clinical diagnosis of scleroderma.

E

Figure 30-19 (**A**) and (**B**) are axial apical and axial basilar CT images in a patient with biopsy-proved CHP (chronic hypersensitivity pneumonitis); (**C**), (**D**), and (**E**) are axial apical, axial basilar, and coronal CT images in another patient with the same diagnosis, but with a more severe presentation. CHP is a differential diagnosis of fibrosing interstitial disease. It differs from UIP and NSIP by the upper lung predominance, patchy (or nonhomogeneous) distribution, and presence of air trapping (noting mosaic attenuation).

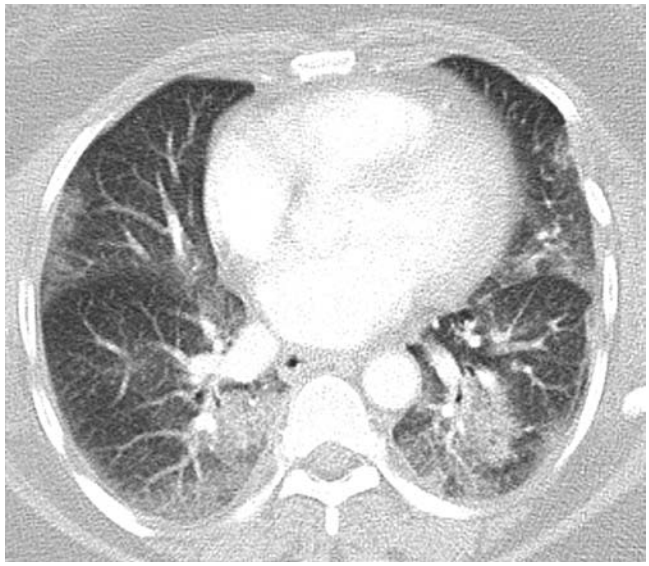

Figure 30-20 Multifocal airspace consolidation and ground-glass opacities in a patient with cryptogenic organizing pneumonia (COP). Infection is the most common differential diagnosis.

Pneumoconioses, particularly silicosis and berylliosis, may present with interstitial interlobular septal and axial thickening, as well as with perilymphatic nodules—a pattern that can be indistinguishable from sarcoidosis. The presence of calcified nodules and mediastinal or hilar lymph nodes support the diagnosis of pneumoconiosis, but these findings may also be seen with sarcoidosis. Specific environmental exposure history is, of course, central in suggesting the diagnosis of pneumoconioses.

Currently, severity of ILD is assessed routinely via subjective analysis of disease extent on CT, along with evaluation of the degree of restriction on pulmonary function testing. Ongoing research has shown the promise of computational quantitative imaging techniques, which allow not only accurate diagnosis based upon pattern, but also quantification of the individual contributions of each pattern feature (e.g., ground-glass opacities and septal thickening) to the overall disease extent. This approach offers the potential for better tools for monitoring disease progression, predicting prognosis, and development of quantitative, surrogate imaging biomarkers for future medication trials.[27]

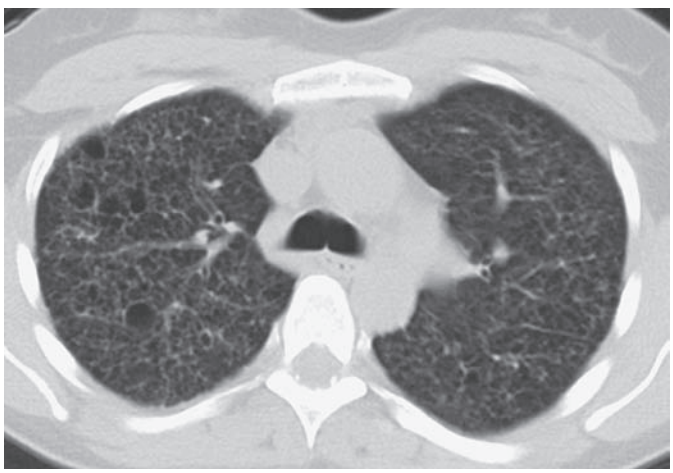
PULMONARY NODULES AND LUNG CANCER

Pulmonary nodules are exceedingly common and may be noted in up to 50% of CT examinations performed in hospital settings. Furthermore, the differential diagnosis is extremely broad and the imaging findings often nonspecific. Therefore, management of pulmonary nodules can be very challenging. We aim here to present a practical, evidence-based approach that is centered on answering four key questions: (1) Is the nodule likely malignant? If so, what is the best approach to tissue sampling? (2) If not, does the nodule need to be followed? If so, how often and for how long? (3) If it is not likely malignant, is the nodule likely to be manifestation of an infectious or inflammatory process that requires pathologic confirmation for proper management? (4) Does the nodule have any features that allow either a specific diagnosis or a confident diagnosis of benignity? The reader is also referred to Chapter 110 for further discussion.

The discussion of pulmonary nodules starts with their definition, which is not always straightforward. While there is no question that well-circumscribed round or ovoid opacities should be characterized as nodules, the distinction of nodules from focal consolidations and interstitial opacities can sometimes be cloudy, particularly when ill-defined or ground-glass nodules are taken into account. As a general rule, any opacity that has mostly convex borders and a shape that can be described as round or ovoid should be classified as a nodule. This has implications for differential diagnosis (Figs. 30-22 and 30-23).

From an imaging perspective, the following descriptors are important in assigning a nodule to a particular differential diagnostic category: number (solitary versus multiple), size, border, CT attenuation, and distribution (if multiple). Below each category is described and a strategic approach to diagnosis and management discussed, emphasizing a combination of clinical and CT findings.[28,29]

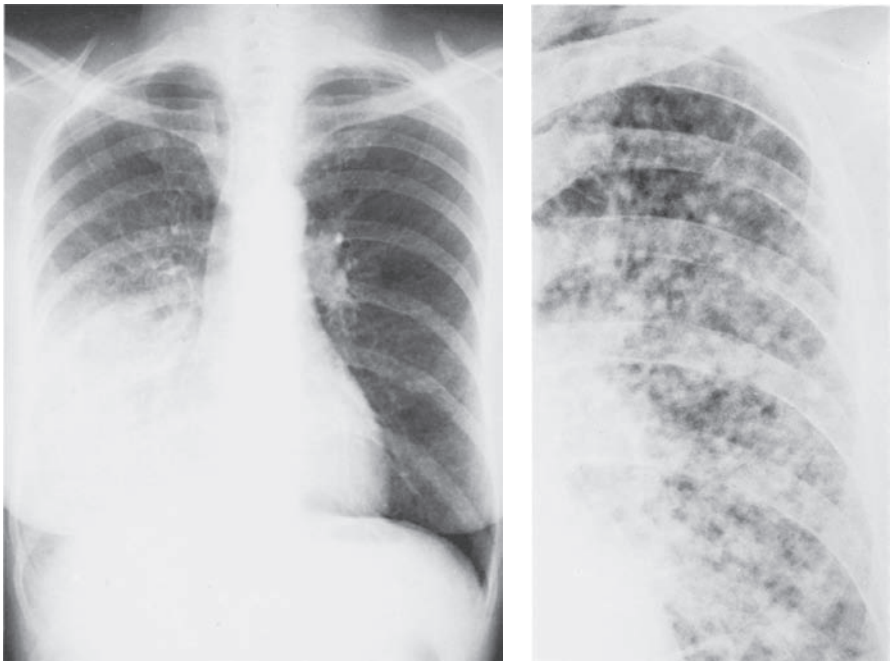
To answer the first question, that is, the nodule likely to be malignant, one must be cognizant of the pretest clinical probability. Age is important; the older the patient, the more likely that a lung nodule is malignant. Smoking history and COPD are major risk factors for lung cancer and should be taken into account. A known diagnosis



A

B

Figure 30-21 (**A**) and (**B**) are axial apical and axial basilar CT images in a patient with Langerhans cell histiocytosis (LCH). Although LCH is not considered an interstitial lung disease proper (instead, it is classified as a cystic lung disease), this disease does cause an interstitial pattern on chest radiographs. Key features are cysts with upper lung predominance, occasional nodules, and associated hyperinflation. A strong smoking history is often elicited.



A B

Figure 30-22 Radiographic patterns of adenocarcinoma. **A.** Large area of consolidation in the right lower lobe. The alveolar pattern suggests pneumonia, but it failed to improve with antibiotic treatment and was discovered to be an adenocarcinoma. **B.** Multiple ill-defined nodules. The nodules have irregular or fuzzy margins that are characteristic of alveolar, rather than interstitial, nodulation, in this patient with metastatic adenocarcinoma.

of malignancy also places the patient at a higher risk of pulmonary metastases.

Nodule features on CT are of considerable importance in suggesting malignancy. For a solitary nodule, the larger its size, the more likely it is malignant and represents a primary bronchogenic carcinoma. Ill-defined borders are also more highly associated with primary bronchogenic carcinoma than benign etiologies, although infectious processes, such as fungal pneumonia, also have to be considered in the proper clinical setting. Mixed attenuation nodules, that is, subsolid nodules with coexistence of solid and ground-glass components, are highly associated with a diagnosis of primary bronchogenic carcinoma. Multiple nodules that are well circumscribed, vary in size, and are basilar predominant are strongly suggestive of metastatic disease (Figs. 30-24–30-32).

The best evidence-based guidelines for management of solid pulmonary nodules are those published by the Fleischner Society.[30] Although originally described only for solitary nodules, the guidelines are oftentimes applied to multiple nodules.

The Fleischner Society guidelines stratify the risk of malignancy and recommend imaging follow-up intervals according to nodule size and clinical risk factors (Table 30-1). Nodules measuring <4 mm in a low-risk patient do not require follow-up, whereas larger nodules in higher-risk patients require follow-up at progressively shorter intervals (between a maximum of 12 months and a minimum of 3 months). Most nodules measuring more than 8 mm and lacking definitive benign imaging characteristics or confirmation of temporal stability are potentially malignant and, therefore, require more aggressive evaluation. Evaluation may include short-term interval CT follow-up, PET imaging, and often tissue sampling, which can be accomplished via minimally invasive transthoracic CT-guided or bronchoscopic techniques, or rarely, via surgical biopsy. As a general rule, peripheral and smaller nodules are more accurately sampled using transthoracic CT-guided techniques, whereas central or larger masses are more safely approached via bronchoscopic techniques.

It has been shown that only two CT features generally allow confident diagnosis of benignity for solid nodules: a benign pattern of calcification and absence of growth for at least 2 years.

A benign pattern of calcification includes any of the following: central, concentric, diffuse, or coarse ("popcorn" calcification). On the other hand, punctuate or eccentric calcifications are considered indeterminate, as both benign and malignant nodules may demonstrate these findings. Recognition of a benign pattern of calcification is, therefore, very important, as it may obviate the need for imaging follow-up or intervention, alleviating patient and clinician anxiety.

As noted, the second benign feature is interval stability for 2 years as measured by CT, following the Fleischner Society guidelines. The feature is based on the concept of doubling time, which is the time required for a nodule to double in volume. Very fast doubling time (<1 month) is most characteristic of inflammatory or infectious nodules. Extremely slow doubling time (>24 months) is more typical of benign processes, such as granulomas, hamartomas, intraparenchymal lymph nodes, or pulmonary arteriovenous malformations. Intermediate doubling times (>1 month but <24 months) are observed with most malignancies, as well as some indolent infections. In this indeterminate range of growth rate, tissue sampling should be strongly considered to exclude primary or metastatic malignancy.[31]

A CT finding of low-attenuation areas compatible with macroscopic fat in an otherwise well-circumscribed pulmonary nodule is strongly suggestive of a benign pulmonary hamartoma and can obviate the need for more aggressive workup. Care must be taken, however, in differentiating true fat from noise on thin-section CT performed with high-resolution ("HRCT") reconstruction kernels. The use of soft tissue kernels may help in making a more confident diagnosis of fat.

Cavitation is a useful finding in narrowing the differential diagnosis, although it is not specific for malignancy. A cavitary nodule suggests a necrotizing malignancy, particularly primary or metastatic squamous cell carcinoma. However, a number of benign entities may present with cavitary nodules, most typically septic emboli if multiple, granulomatous infections (including mycobacterial and fungal), bacterial abscesses, and granulomatosis with polyangiitis (GPA, formerly known as Wegener granulomatosis).

Ancillary findings on chest CT that support a diagnosis of malignancy include hilar and mediastinal lymphadenopathy, unilateral

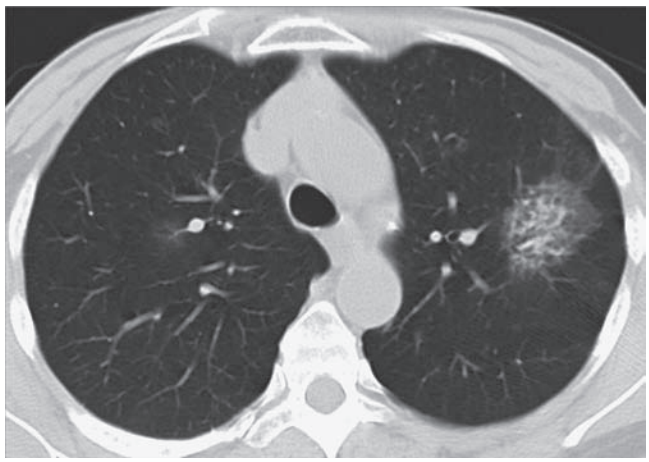
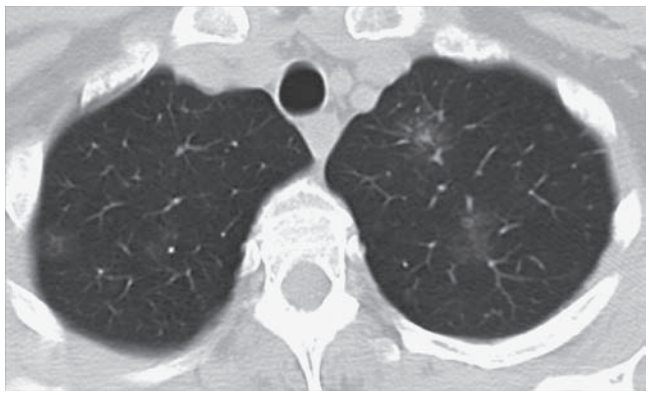
The right lower lobe mass was proved to represent a small cell carcinoma. **A.** Axial CT on soft tissue window demonstrates the primary RLL mass, a malignant right pleural effusion, and mediastinal lymphadenopathy. **B.** Axial CT on lung window demonstrates multiple metastatic nodules in the left lung. **C.** Axial CT on soft tissue window demonstrates bilateral adrenal metastasis. The constellation of findings indicates Stage IV disease.



A



B

Figure 30-26 Spectrum of pulmonary adenocarcinoma. **A.** Axial CT image demonstrates a dominant, mixed-attenuation left upper lobe nodule, with solid and ground-glass components, which was resected and characterized as an adenocarcinoma. **B.** Axial CT image at a higher level demonstrates multiple smaller nodules, some of them mixed, most of purely ground-glass attenuation, which are compatible with multiple lesions in the spectrum of atypical adenomatous hyperplasia (AAH), adenocarcinoma in situ (AIS), and minimally invasive adenocarcinoma (MIA). In the past, all of these lesions would have been classified as BACs (bronchoalveolar carcinomas), a terminology that should no longer be utilized, as discussed in the text.

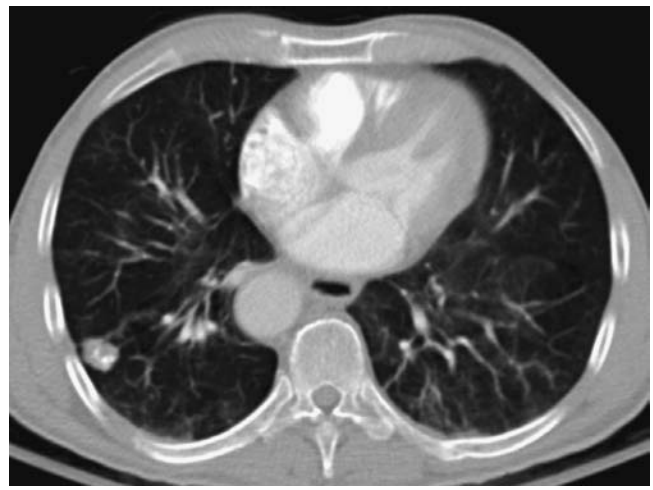


Figure 30-28 Right lower lobe nodule with coarse calcification, typical of a benign pulmonary hamartoma. Incidentally noted is a right-sided descending thoracic aorta.

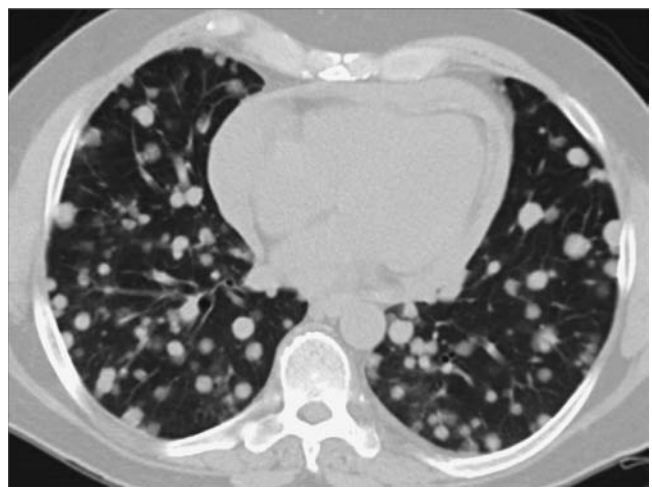

Figure 30-29 Differential diagnosis of multiple pulmonary nodules: axial CT image showing multiple well-circumscribed nodules, of varying size, characteristic of pulmonary metastases, in this case from renal cell carcinoma.

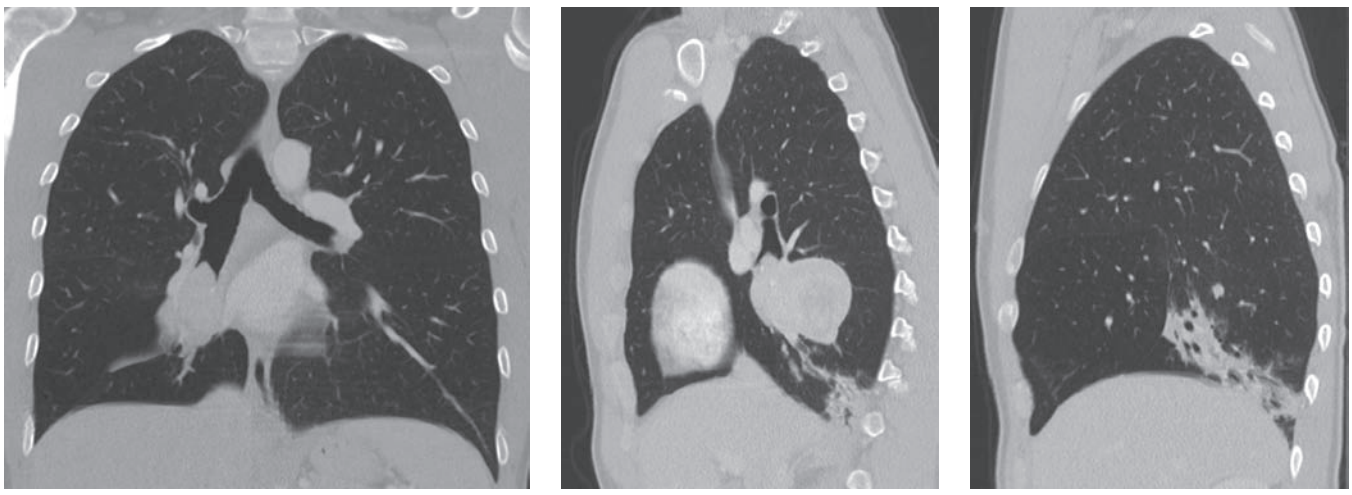

A B C

Figure 30-27 Coronal (**A**) and two sagittal CT images (**B**) and (**C**) showing a large endobronchial mass obstructing the RLL and growing concentrically into the lung parenchyma, with well-circumscribed borders. Note the associated atelectasis of the RLL basilar posterior segment. This mass was a carcinoid neoplasm.

Figure 30-30 Differential diagnosis of multiple pulmonary nodules: axial CT image demonstrating very numerous, very small (1–2 mm) pulmonary nodules with a perilymphatic distribution (along the septal and axial interstitial compartments), typical of sarcoidosis—the diagnosis in this patient. This pattern can also be seen in lymphangitic carcinomatosis.

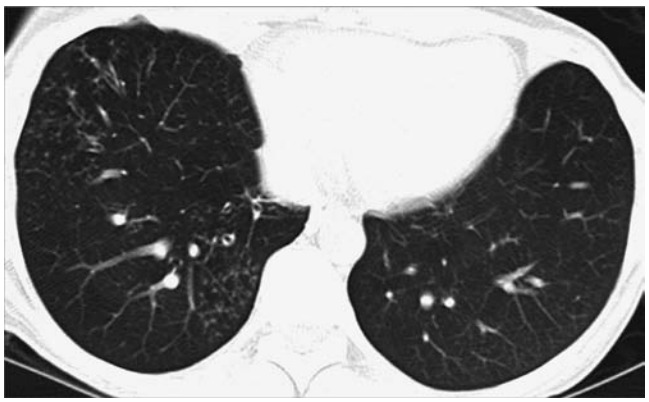

Figure 30-31 Differential diagnosis of multiple pulmonary nodules: axial CT images demonstrating multiple clusters of small nodules (measuring <2–3 mm each) in the RLL and RML, with centrilobular distribution and tree-in-bud configuration. This pattern is typical of infection and usually represents bronchiolitis. In this case, it was due to nontuberculous mycobacterial infection.

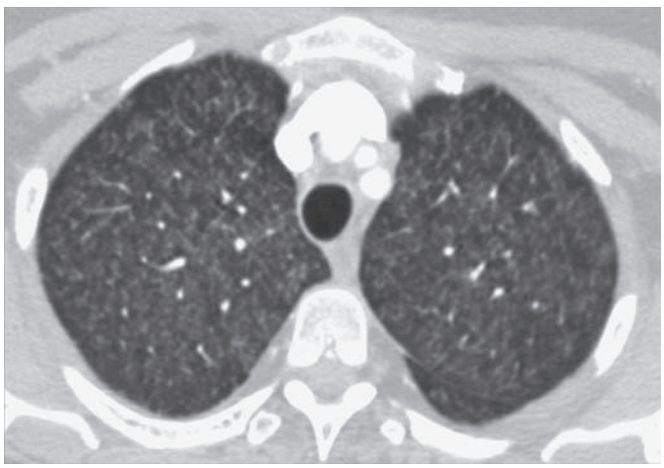
pleural effusion, pleural nodules, and hepatic, osseous, or adrenal metastases.

MULTIPLE PULMONARY NODULES

Most of the previously mentioned discussion applies to solitary or few pulmonary nodules, which should be approached similarly. In the setting of numerous, usually small (subcentimeter) pulmonary nodules, a different diagnostic approach must be utilized, emphasizing the distribution of the nodules. Two characteristics of the spatial distribution are relevant: (1) upper lung–predominant versus basilar predominant versus widespread; and (2) centrilobular versus perilymphatic versus random. The otherwise very long list of differential diagnoses can be substantially narrowed by correctly recognizing the distribution.

As discussed previously, an upper lung–predominant distribution suggests inflammatory or infectious etiologies, in which the inciting factor is inhaled; the exception is primary bronchogenic carcinomas that are more likely in the upper lungs, but uncommonly multiple. A lower lung–predominant distribution suggests hematogenously disseminated processes, such as hematogenous metastasis or hematogenous infectious processes. Diffuse distribution comprises a combination of both differential diagnoses and is the least specific.

The centrilobular distribution implies that the majority of nodules are in or near the center of the secondary pulmonary lobule. Such a distribution suggests small airway and acinar disease, indicative of endobronchial spread. This distribution can be further subclassified into two groups: (1) centrilobular nodules in which



A

B

Figure 30-32 Differential diagnosis of multiple pulmonary nodules: (**A**) axial and (**B**) coronal MIP (maximum intensity projection) images demonstrate very numerous, very small (1–2 mm) pulmonary nodules with centrilobular distribution, low attenuation, and indistinct contours. Also noted is symmetric upper lung field predominance. The diagnosis is acute hypersensitivity pneumonitis. In a smoker, the differential diagnosis includes respiratory bronchiolitis.

TABLE 30-1 Fleischner Society Recommendations for Follow-Up and Management of Nodules Smaller than 8 mm Detected Incidentally at Nonscreening CT

Nodule Size (mm)	Low-Risk Patient	High-Risk Patient
≤4	No follow-up needed	Follow up CT at 12 mo; if stable, stop
>4–6	Follow up CT at 12 mo; if stable, stop	Initial follow-up at 6–12 mo, then at 18–24 mo if stable
>6–8	Initial follow-up at 6–12 mo, then at 18–24 mo if stable	Initial follow-up at 3–6 mo, then at 9–12 mo and at 24 mo if stable
>8	Follow-up at around 3, 9, and 24 mo, CT, PET/CT, and/or biopsy[a]	Same as for low risk[a]

Notes:
These recommendations apply for solid, noncalcified nodules—see Table 30-2 for ground-glass nodules.
Size is measured as an average of length and width (axial), for nonspherical nodules.
High-risk patient has a more than minimal history of smoking, and/or other risk factors such as prior or known malignancy, and/or increased risk for metastatic disease. A low-risk patient does not have any known risk factors for primary or metastatic lung cancer.
The higher the risk and the bigger the nodule, the shorter the follow-up interval is and the longer the period of follow-up is, up to 24 months if there is continued stability.
[a]Nodules measuring >8 mm generally require tissue diagnosis via CT-guided percutaneous biopsy, bronchoscopy, or surgical resection, depending on clinical and technical considerations.
Source: Adapted with permission from MacMahon H, Austin JH, Gamsu G, et al. Guidelines for management of small pulmonary nodules detected on CT scans: a statement from the Fleischner Society, Radiology. 2005;237(2):395–400.

the nodules are fuzzy, ill-defined, and often of ground-glass attenuation—findings indicative of small airway inflammatory diseases, as can be seen with respiratory bronchiolitis–interstitial lung disease (RB-ILD) and subacute hypersensitivity pneumonitis; and (2) centrilobular nodules in which the nodules are sharp, well defined, and measure less than 2 mm—findings associated with distal bronchiolar filling, a pattern referred to as, "tree-in-bud." A tree-in-bud pattern strongly suggests infectious bronchiolitis of bacterial, viral, or mycobacterial etiology. Least commonly, the centrilobular distribution may indicate small vessel disease, such as pulmonary vasculitides or capillary hemangiomatosis. Among the vasculitides, Churg–Strauss syndrome and microscopic polyangiitis are primary considerations.

The perilymphatic distribution implies that the majority of nodules are within the septal and bronchovascular interstitial compartments. A perilymphatic distribution is associated with diseases with lymphatic system involvement. Such a distribution suggests a narrow differential diagnosis, including pulmonary interstitial edema, sarcoidosis, or lymphangitic spread of neoplasm ("lymphangitic carcinomatosis"). The latter two diagnoses are more likely if there is nodular interstitial thickening.

A random distribution usually implies hematogenous dissemination of metastases or infection. The archetypal infectious process with numerous random nodules is miliary tuberculosis, although miliary fungal infections can be indistinguishable. Patients with miliary infectious are often immunocompromised and may present with bacteremia or fungemia.

GROUND-GLASS PULMONARY NODULES

Ground-glass nodules deserve separate consideration, as their pathophysiology, differential diagnosis, biologic behavior, and management strategies differ considerably from solid pulmonary nodules.

Ground-glass attenuation is defined as increased attenuation of the lung parenchyma, although the attenuation is not as high as soft tissue attenuation and, therefore, is insufficient to obscure adjacent pulmonary vessels. From a pathology perspective, ground-glass attenuation implies partial filling of the distal airspaces (acini) at a scale below the spatial resolution of CT, causing volume averaging of gas, acinar structures, and material partially filling the alveoli. It is often associated with the lepidic growth pattern, that is, cellular proliferation along the walls of the alveoli, rather than the more common hilic (radial) growth pattern characteristic of most neoplasms.

Multiple ground-glass nodules were described previously, and the rationale for their imaging assessment is included in the description of multiple pulmonary nodules.

Solitary or few ground-glass attenuation nodules carry a different implication from solid nodules. The differential diagnosis is essentially limited to nonspecific infectious or inflammatory processes versus indolent primary bronchogenic adenocarcinoma or premalignant lesions. Therefore, these lesions must be followed to assess their persistence and chronicity. Most nonspecific infectious or inflammatory processes resolve spontaneously within 3 months. Therefore, lesions that persist on a 3-month follow-up chest CT are suspicious for malignancy.

Ground-glass nodules include a spectrum of premalignant to low-grade malignant diseases, which correlate pathologically with the diagnoses of atypical adenomatous hyperplasia (AAH) (a premalignant precursor to adenocarcinomas), AIS, and minimally invasive adenocarcinoma (MIA). These specific diagnoses cannot be differentiated accurately by CT imaging findings or by small biopsies; surgical biopsy is generally necessary. Nonetheless, CT features suggest a specific diagnosis. Namely, smaller lesions (particularly those ≤5 mm) with pure ground-glass attenuation are more likely AAH, whereas the larger the lesion and the more complex its structure (particularly if solid or cystic areas are noted), the more likely it represents AIS (formerly called bronchioloalveolar carcinoma, BAC) or MIA. Large (≥5 mm) or progressive solid components are strongly associated with invasive adenocarcinomas.

The Fleischner Society has published a statement with evidence-based recommendations for management of ground-glass (subsolid) nodules.[32] The statement is mostly based on the revised classification of pulmonary adenocarcinoma proposed in 2011 by the International Association for the Study of Lung Cancer (IASLC), the American Thoracic Society (ATS), and the European Respiratory Society (ERS).[33] In the same spirit as the original recommendations for solid nodules, subsolid nodules are stratified according to size, and different follow-up intervals are proposed. However, unlike the guidelines for solid nodules, those for ground-glass nodules do not differentiate between low- and high-risk

TABLE 30-2 Fleischner Society Recommendations for the Management of Subsolid Pulmonary Nodules Detected at CT

Nodule Size (mm)	Management Recommendations	Additional Remarks
Solitary pure GGNs		
≤5 mm	No CT follow-up required	Obtain contiguous 1-mm-thick sections to confirm that nodule is truly a pure GGN
>5 mm	Initial follow-up CT at 3 mo to confirm persistence, then annual surveillance CT for a minimum of 3 yr	FDG PET is of limited value, potentially misleading, and therefore not recommended
Solitary part-solid nodules	Initial follow-up CT at 3 mo to confirm persistence. If persistent and solid component <5 mm, then yearly surveillance CT for a minimum of 3 yr. If persistent and solid component ≥5 mm, then biopsy or surgical resection[a]	Consider PET/CT for part-solid nodules >10 mm
Multiple subsolid nodules		
Pure GGNs ≤5 mm	Obtain follow-up CT at 2 and 4 yr	Consider alternate causes for multiple GGNs ≤5 mm
Pure GGNs >5 mm without dominant lesions	Initial follow-up CT at 3 mo to confirm persistence and then annual surveillance CT for a minimum of 3 yr	FDG PET is of limited value, potentially misleading, and therefore not recommended
Dominant nodule(s) with part-solid or solid component	Initial follow-up CT at 3 mo to confirm persistence. If persistent, biopsy or surgical resection is recommended, especially for lesions with >5-mm solid component[a]	Consider lung-sparing surgery for patients with dominant lesion(s) suspicious for lung cancer

Notes:
These guidelines assume meticulous evaluation, optimally with contiguous thin sections (1 mm) reconstructed with narrow and/or mediastinal windows to evaluate the solid component and wide and/or lung windows to evaluate the nonsolid component of nodules, if indicated. When electronic calipers are used, bidimensional measurements of both the solid and ground-glass components of lesions should be obtained as necessary. The use of a consistent low-dose technique is recommended, especially in cases for which prolonged follow-up is recommended, particularly in younger patients. With serial scans, always compare with the original baseline study to detect subtle indolent growth.
[a]Small biopsies (CT-guided percutaneous biopsy vs. transbronchial biopsies) may be limited to establish a diagnosis of adenocarcinoma in situ or minimally invasive adenocarcinoma. Consider surgical resection for a complete pathologic analysis of the lesion.
Source: Reproduced with permission from Naidich DP, Bankier AA, MacMahon H, et al. Recommendations for the management of subsolid pulmonary nodules detected at CT: a statement from the Fleischner Society. Radiology. 2013;266(1):304–317.

groups because of the incidence of subsolid lesions in younger and nonsmoking patients.

The algorithm for subsolid lesions is more involved, also accounting for multiplicity of nodules and the fact that many subsolid nodules are inflammatory (Table 30-2). For example, a subsolid nodule measuring <5 mm does not need any follow-up. If it is >5 mm, then an initial follow-up chest CT should be obtained at 3 months to determine persistence. If persistent, then yearly surveillance is recommended for a minimum of 3 years (Many institutions, including our own, pursue longer surveillance.). If a subsolid nodule >5 mm demonstrates a solid component measuring more than 5 mm and is persistent after 3 months, then tissue sampling and/or resection is emphasized, as these nodules have a very high probability of representing AIS or MIA. The size of the solid component correlates with the likelihood of an invasive component being present.

For multiple ground-glass opacities, the algorithm is similar and the management dictated by the CT characteristics of the most suspicious nodule; the only difference is that if all nodules measure <5 mm, a longer initial follow-up interval (2–4 years) is suggested, as infectious or inflammatory etiologies become far more likely in that setting. Important caveats are the limited usefulness of PET/CT for evaluation of subsolid nodules, since most are not substantially metabolically active (therefore, a negative PET/CT can be misleading), the need to obtain clinical correlation, and the requirement for a meticulous evaluation protocol that includes thin-section (1 mm) volumetric images and consistent use of low radiation dose CT technique.[32]

A comprehensive management algorithm for both solid and subsolid pulmonary nodules was recently published by the American College of Chest Physicians.[34] The algorithm commences with identification of a new nodule on chest CT and proceeds with follow-up recommendations according to size, risk factors for malignancy, and surgical risk. The recommendations emphasize the need for tissue sampling for most nodules larger than 8 mm and compare the advantages and disadvantages of surgical biopsy, CT-guided percutaneous biopsy, and bronchoscopy with biopsy. The specific recommendations for nodules measuring <8 mm are in line with the Fleischner Society guidelines.

LUNG CANCER

The classification, pathophysiology, epidemiology, and management of lung cancer are described elsewhere (Chapters 112–118). This chapter focuses on the contributions of imaging to lung cancer screening, initial diagnosis, and staging.

Lung cancers are typically initially identified on chest radiography or are noted incidentally on chest CT performed for another clinical indication (except in the context of lung cancer screening). Most lung cancers present as pulmonary nodules or masses. Hilar or mediastinal lymphadenopathy and overt signs of metastatic disease are indicative of more advanced stages of disease. Central masses may cause obstructive atelectasis or consolidation.

At initial presentation, the clinical aim is to confirm the diagnosis pathologically, for which tissue sampling is required. In the past, surgical biopsies were the only available options, but in the last two decades, minimally invasive biopsies performed either percutaneously using CT guidance, or transbronchially with bronchoscopic techniques, have been strongly favored for their better risk/benefit ratio, lower complication rate, faster patient recovery, and good diagnostic accuracy. As a general rule, most peripheral lesions (i.e., within 3 cm of a costal pleural surface) are better accessed percutaneously using CT guidance, whereas central lesions, particularly if

an airway visible on CT leads to the lesion, are better accessed via bronchoscopy.[33,35]

Once the diagnosis of lung cancer is pathologically confirmed and fully characterized, staging is of paramount importance to determine the extent of disease and, therefore, the management approach. The most current staging system for lung cancer is the seventh edition of the TNM classification, which was published in 2010. Several references depict visual maps of the T, N, and M criteria and tables with the detailed revised classification.[36,37] In summary, the most important aspects of staging are the size and location of the primary tumor (T), the presence of abnormally enlarged lymph nodes and their location and distribution (N), and the presence of distant metastasis (M). By combining the T, N and M scores, a specific stage from I to IV is obtained, and management strategies are tailored for the type of cancer (histology and genotypic profile) and the staging classification. It cannot be overemphasized that imaging, particularly CT, plays an overarching role not only in tumor detection, but also in tumor staging. It is the primary method for obtaining TNM staging information. PET/CT is also valuable, particularly for nodal staging and identification of distant metastasis. Finally, nodal metastasis may be evaluated using endobronchial US combined with transbronchial biopsies of suspicious lymph nodes.

LUNG CANCER SCREENING

A discussion of the role of modern imaging in the diagnosis of lung cancer would not be complete without mention of the current status of lung cancer CT screening.

Several major prospective multicenter trials using low-dose CT to screen for lung cancer are currently underway. The two largest trials are the National Lung Screening Trial (NLST) in the United States and the Nederlands-Leuvens Longkanker Screenings Onderzoek (NELSON) in the Netherlands and Belgium. Many additional smaller prospective trials (including the DANTE trial in Italy and Danish Randomized Lung Cancer CT Screening Trial in Denmark) are also ongoing.

The NLST, launched in 2002, has published promising initial results. This trial compared the performance of low-dose chest CT versus single, frontal view chest radiographs. In the low-dose CT arm there was a statistically significant lung cancer–specific mortality reduction of 20.0% (95% CI: 3.8–26.7), far greater than that expected by chance. A lower, but still statistically significant decrease in all-cause mortality of 6.7% was also observed in the low-dose CT cohort.[38,39]

The NELSON trial, launched in 2003, compared low-dose CT against no screening. In addition, NELSON differed from the NLST in many important aspects, including serial imaging protocol and patient selection criteria. Final results are not available at the time of this writing, but partial results from the NELSON and other European trials did not demonstrate a significant difference in lung cancer mortality (RR 1.37, 95% CI: 0.63–2.97) or all-cause mortality (1.46, 95% CI: 0.99–2.15); these results are from the Danish trial, which is coordinated with the NELSON trial. The reasons for the discrepant results between the North American and European trials are being actively investigated and may be at least partially related to patient selection criteria and management protocols.[40,41]

In summary, while the NLST provides compelling evidence of the mortality benefit from low-dose CT screening in high-risk patients and demonstrates its superiority to radiographic screening, many important questions remain regarding cost-effectiveness of screening, as well as optimal management of false-positive results. Modeling studies are currently underway and recommendations based on cost-effective analysis are expected in the future.

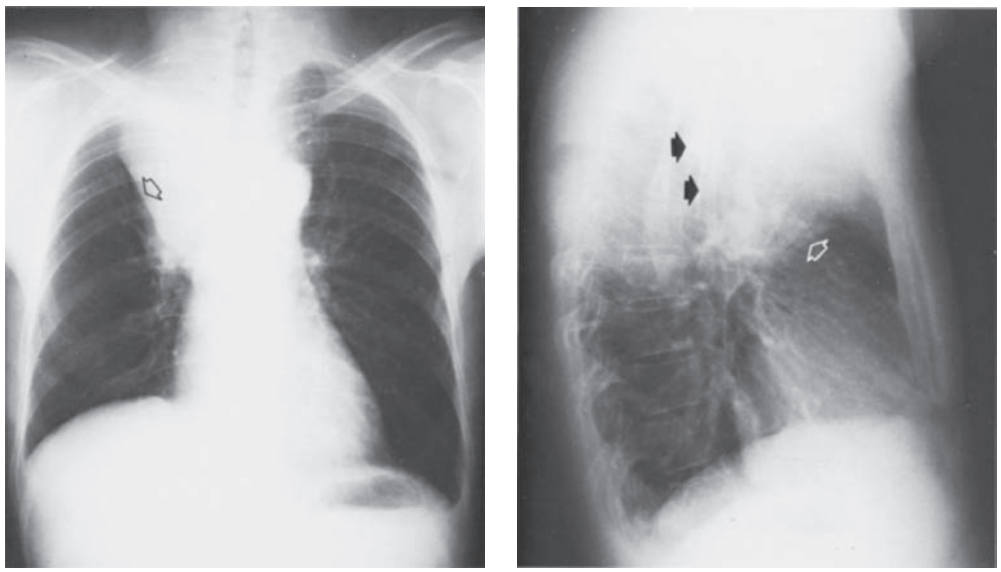
PULMONARY INFECTIONS

Pulmonary infections comprise a very broad group of diseases caused by a wide variety of viruses, bacteria, and fungi. The imaging findings are helpful to establish a diagnosis of pneumonia, but they are virtually never specific as to etiology. Therefore, most patients with suspected pulmonary infections are treated empirically, based upon epidemiologic considerations. Subgroups of vulnerable patients (particularly very ill or immunocompromised patients) may require etiologic confirmation, which can be obtained by sampling the abnormalities via percutaneous or bronchoscopic techniques and requesting microbiologic testing of the material.

The imaging approach to a suspected pulmonary infection involves identifying the imaging patterns that are more likely associated with an infectious etiology, as well as recognizing the more likely associations with a specific pattern. The most typical pattern of pneumonia is focal or multifocal consolidation, denoted by dense, conspicuous alveolar opacities that obscure vascular contours on CT and which may or may not be associated with air bronchograms. Other patterns include focal or multifocal ground-glass opacities (which can be difficult to recognize on chest radiographs and require CT for adequate evaluation); peribronchovascular patchy opacities (bronchopneumonia pattern); centrilobular nodules with tree-in-bud configuration (bronchiolitis pattern); multiple nodules or masses (cavitary or not); solitary cavitary nodule or mass; and nodules or masses associated with calcifications or ground-glass halo. None of these patterns is specific for infection; they are even less specific for a particular infectious etiology. Nonetheless, some imaging patterns allow a narrower differential diagnosis in the proper clinical setting and are worth recognizing.[42–49]

Notable radiographic patterns include: (1) focal or multifocal consolidation, which favors typical bacterial infection (e.g., *Streptococcus pneumoniae*). A bronchopneumonia pattern can be seen in a variety of bacterial and viral infections. (2) Focal or multifocal ground-glass opacities favor atypical infections, including *Pneumocystis jiroveci* and hematogenously disseminated bacterial and viral infections (e.g., CMV pneumonitis).[50,51] (3) A bronchiolitis pattern may be seen in community-acquired viral infections, including influenza, parainfluenza, and adenovirus. If associated with air trapping, respiratory syncytial virus (RSV) should be considered. (4) Multiple cavitary nodules or masses suggest septic emboli or virulent infections, such as those due to *Staphylococcus aureus*. (5) A solitary cavitary mass suggests a pulmonary abscess; anaerobic infections related to aspiration are primary considerations, although if in the upper lobes, reactivation tuberculosis must be excluded.[52] (6) Calcified nodules or masses suggest granulomatous infectious, typically chronic, and favor mycobacterial (tuberculous and nontuberculous) or fungal etiologies.[53,54] (7) Nodules or masses with ground-glass halo are suggestive of opportunistic fungal infection, particularly invasive aspergillosis, in the setting of immunocompromised hosts who are neutropenic.

With regard to localized alveolar disease, the very important distinction between atelectasis and consolidation needs to be clarified. Patchy opacification of airspaces without a decrease in the volume of the affected area suggests consolidation, while opacification of airspaces associated with a decrease in the volume of the affected area suggests atelectasis. The differential diagnosis depends largely on the extent to which lung volume is decreased. However, assessment of the magnitude of volume loss is not always useful. For example, while pneumonia usually is associated with minimal or no volume loss, occasionally, volume loss is considerable. On the other hand, atelectasis usually has moderate or severe loss of volume, but in some instances, there may be little volume loss (Figs. 30-33–30-37).



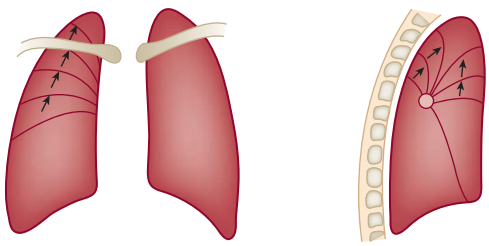


Figure 30-33 Right upper lobe atelectasis secondary to bronchogenic carcinoma. **A.** PA view. The minor fissure is elevated *(arrow)*. **B.** Lateral view. The minor fissure is displaced upward *(open arrow)*, and the major fissure is displaced anteriorly *(closed arrows)*. **C.** Schematic representation of atelectasis of the right upper lobe.

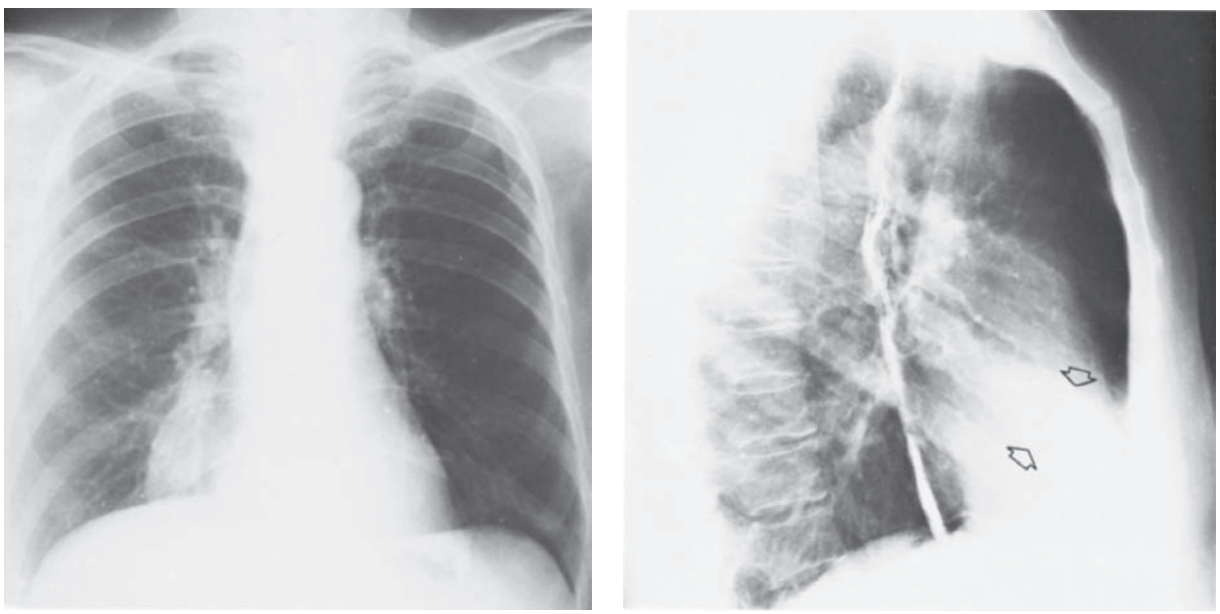

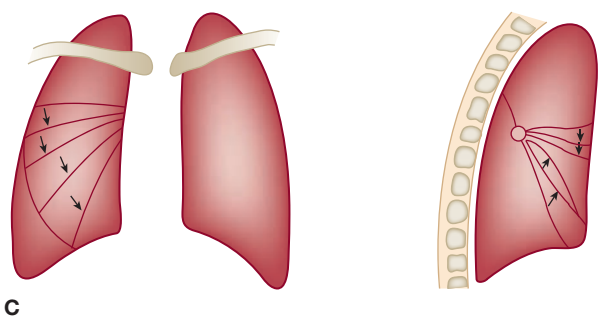

Figure 30-34 Right middle lobe atelectasis secondary to right middle lobe syndrome. **A.** PA view. The middle lobe is collapsed against the right side of the heart. **B.** Lateral view. The major and minor fissures are drawn together *(arrows)*, creating an opacity that overlies the cardiac shadow. **C.** Schematic representation of right middle lobe atelectasis.

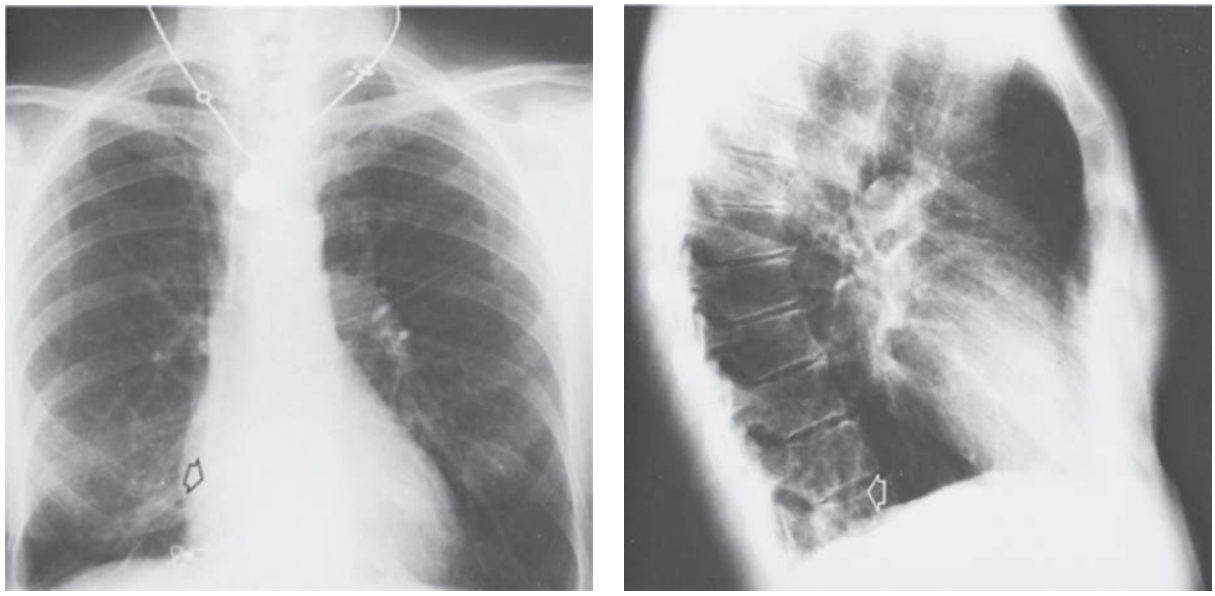
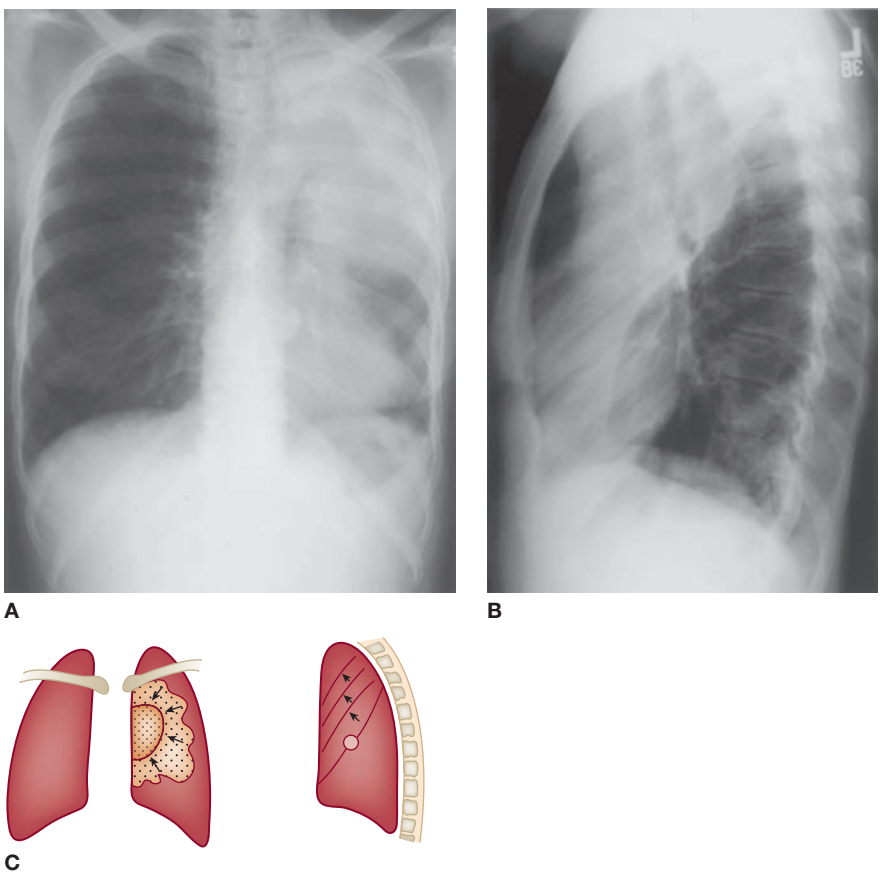


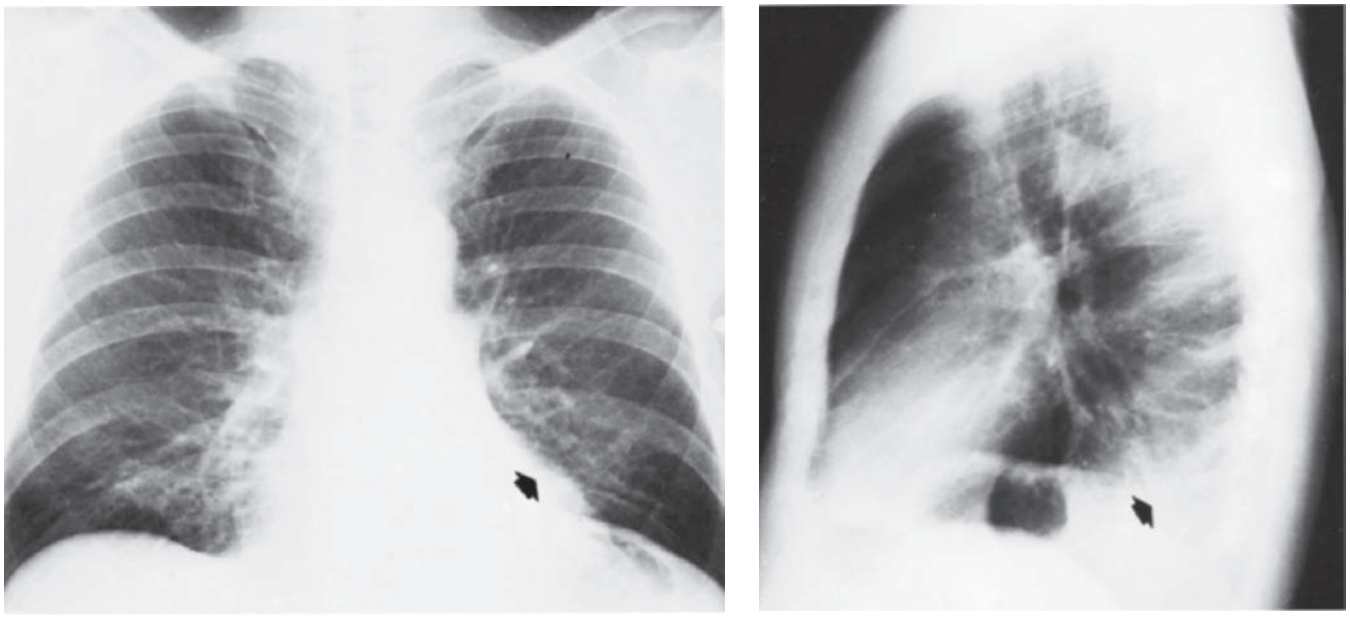
A B C

Figure 30-35 Atelectasis (severe) of the right lower lobe due to chronic inflammatory disease. **A.** PA view. Secondary signs of atelectasis are present in the right lung: small hemithorax, stretching of the pulmonary vessels, hyperlucent lung, and small hilus. In this instance, these secondary signs are important in suspecting atelectasis. In addition, there is downward displacement of the right hilus, and the collapsed lower lobe can be seen (poorly) through the right heart border *(arrow)*. **B.** Lateral view. The entire right lower lobe appears only as a diffuse opacity overlying the spine *(arrow)*. The posterior portion of the right hemidiaphragm cannot be identified (silhouette sign). **C.** Schematic representation of collapse of right lower lobe.



A B C

Figure 30-36 Left upper lobe atelectasis secondary to bronchogenic. **A.** PA view. The left superior mediastinum and left side of the heart are indistinct, due to collapse of the left upper lobe medially. **B.** Lateral view. The collapsed lung is seen as an opacity anterior to the major fissure, which is displaced anteriorly. **C.** Schematic representation of collapse of left upper lobe.



A B C

Figure 30-37 Left lower lobe atelectasis (postoperative). **A.** PA view. The collapsed left lower lobe is seen as a straight line *(arrow)* behind the left heart border. No vasculature can be seen through the heart shadow, and the medial border of the left hemidiaphragm is obscured by the collapsed left lower lobe *(arrow)*. **B.** Lateral view. Opacity over the spine and absence of left posterior diaphragm. This is difficult to differentiate from a pleural effusion. **C.** Schematic representation of collapsed left lower lobe.

Consolidations are statistically likely to represent pneumonias, especially in the acute setting, whereas atelectasis indicates airway obstruction (obstructive atelectasis), adjacent mass effect (compressive atelectasis), or, more rarely, surfactant deficiency or scarring (adhesive atelectasis). For practical purposes, focal airspace opacities, particularly if lobar, are considered consolidations if the degree of volume loss is negligible or mild, and atelectasis if the degree of volume loss is substantial. The various patterns of lobar atelectasis are important to recognize, since this radiographic finding is a very common manifestation of carcinoma of the lung or, occasionally, some other endobronchial neoplasm.

Atelectasis is also common in the postoperative patient (the so-called, "dependent atelectasis"), presumably because of hypoventilation of dependent parts of the lungs and inadequate clearing of respiratory secretions. In this instance, loss of volume may be mild or absent. Atelectasis may also occur as a consequence of inflammatory disease of the airways or aspiration of a foreign body. Atelectasis also invariably accompanies pleural effusions and pneumothorax. With pleural effusions, atelectasis is greatest in the vicinity of the pleural effusion. Rounded atelectasis is a subtype characterized by ovoid peripheral opacity, associated with underlying chronic pleural disease (manifested by loculated effusion or pleural thickening). There is architectural distortion and convergence of the bronchovascular structures supplying the area of rounded atelectasis ("comet tail sign"). It is important to recognize the typical features of rounded atelectasis, as it can be confused with pulmonary neoplasms.

In nonimmunocompromised hosts, most acute consolidations reflect bacterial pneumonias and should improve to complete resolution with treatment, generally within 4 to 6 weeks; radiographic clearance lags a few weeks behind clinical improvement. Therefore, in adult patients it is important to obtain chest radiographs at the end of this time frame to demonstrate complete resolution of the consolidation. Any consolidation that persists (>1 month) in spite of optimal empirical treatment should be considered potentially neoplastic; the differential diagnosis includes pulmonary mucinous adenocarcinoma (formerly classified as BAC), pulmonary lymphoma (of the MALT type, denoting low-grade extranodal lymphomas), or hemorrhagic metastasis (such as from breast, renal cell carcinoma, or melanoma primaries). In addition, atypical infectious processes (such as fungal or mycobacterial infection) may present as persistent consolidations, as well as several noninfectious or inflammatory processes, such as cryptogenic organizing pneumonia (COP), eosinophilic pneumonia, and granulomatous vasculitides (e.g., granulomatosis with polyangiitis). Most chronic consolidations ultimately require chest CT and tissue sampling (via transthoracic or bronchoscopic approaches) for final diagnosis (Figs. 30-38–30-43).

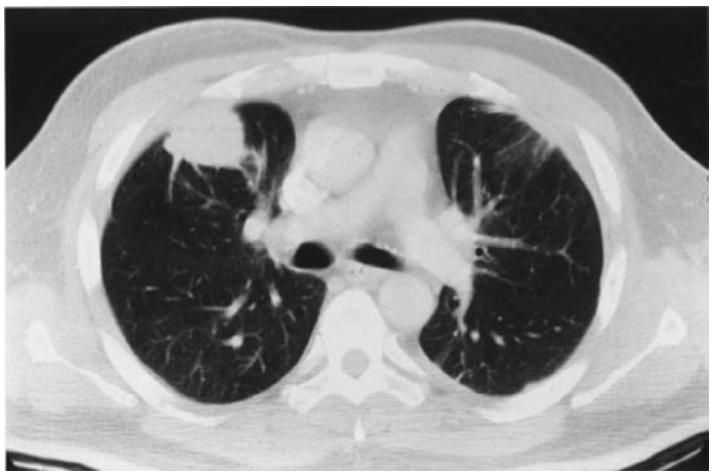


Figure 30-38 Axial CT image showing rounded atelectasis. A mass with a "tail" can be seen in the anterior segment of the right upper lobe. Pleural thickening is seen on the left side, with transpulmonary bands extending into the left upper lobe. The mass on the right represents rounded atelectasis, a finding usually associated with asbestos exposure or chronic pleural disease. The changes on the left probably represent an early stage in the development of rounded atelectasis.

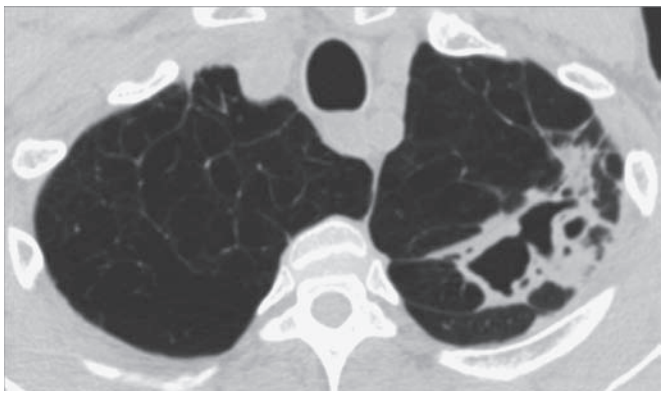
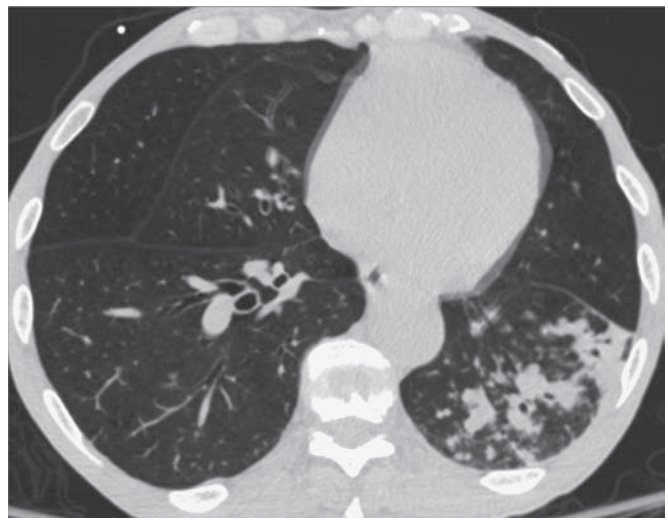
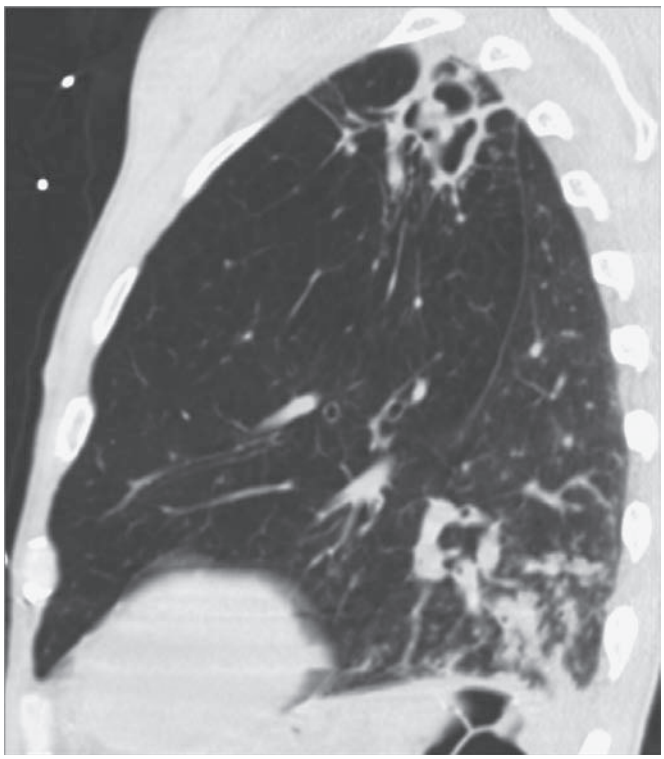


A



B



C

Figure 30-39 **A.** Axial CT image shows an irregular cavity in the left upper lobe, with architectural distortion of the surrounding parenchyma. **B.** Axial CT at a lower level demonstrates bronchiectasis, mucoid impaction and peribronchial consolidations in the left lower lobe, as well as a few centrilobular nodules. **C.** Sagittal CT at the median left lung demonstrates both disease processes. This constellation of findings is very characteristic of reactivation tuberculosis and is highly suggestive of the diagnosis, which was confirmed in this case. The left lower lobe opacities reflect endobronchial spread of the mycobacteria from the left upper lobe cavity.

Figure 30-43 **A.** Axial CT through the upper lung fields demonstrates a large right-side pneumothorax with a chest tube partially visualized. The lung parenchyma demonstrates diffuse, but nonhomogeneous, ground-glass opacities, as well as scattered cysts. **B.** Axial CT at a lower level demonstrates diffuse ground-glass opacities, small nodules, and patchy areas of consolidation. This patient had AIDS complicated by *Pneumocystis jiroveci* pneumonia. Spontaneous pneumothorax is a known complication of this disease.

PULMONARY EDEMA: CARDIOGENIC AND NONCARDIOGENIC

Imaging offers a comprehensive display of the anatomy of the cardiopulmonary system and its function. Chest radiographs can demonstrate the heart size and configuration, the width of the vascular pedicle, as well as the caliber and distribution of the pulmonary arteries and veins. Pulmonary arteries and veins can generally be distinguished on chest radiographs by their anatomical location, with the pulmonary veins more horizontal, more inferior, and more lateral to the pulmonary arteries in relationship to the hila. The distinction is, nonetheless, seldom useful radiographically and, therefore, the generic terms *pulmonary vessels* and *pulmonary vasculature* are used. CT and MRI more readily depict the pulmonary arteries and veins. The pulmonary arteries arise from the main pulmonary artery trunk, while the pulmonary veins enter the left atrium and are readily distinguished on cross-sectional imaging even without intravenous contrast. Moreover, CT and MRI can accurately evaluate cardiac structure and function, particularly cardiac MRI, providing quantitative metrics to assess ventricular and valvular function.

Congestive heart failure is a common clinical condition characterized by systolic and/or diastolic dysfunction of the left ventricle, leading to increasing diastolic filling pressure, increasing left atrial pressure, and fluid retention. Ultimately, left ventricular failure leads to right ventricular failure. The heart is almost invariably enlarged, and the central pulmonary vasculature appears prominent and indistinct. These changes are easier to recognize on PA and lateral views than on portable chest radiographs.

A rational progression of chest radiographic findings in congestive heart failure can be fully appreciated on PA, erect radiographs and is strongly correlated with increases in pulmonary capillary wedge pressure (PCWP, reflecting left atrial pressure), indicating progressive pulmonary venous congestion.

The first stage is correlated with a PCWP of 13 to 18 mm Hg and is characterized by increased width of the vascular pedicle and vascular redistribution in the erect patient; the caliber of the upper lung vessels is increased relative to the lower lung vessels (cephalization), and cardiomegaly is present.

The second stage is correlated with PCWP of 18 to 25 mm Hg and is characterized additionally by the presence of pulmonary interstitial edema—which is manifested on chest radiography as Kerley lines, thickened fissures, and peribronchial cuffing with indistinct contour of the central vessels. Kerley B lines, as previously described, represent small (1–2 cm), thin, linear opacities that are seen peripherally perpendicular to a pleural surface, reflecting edema involving interlobular septae.

Finally, the third stage is correlated with PCWP >25 mm Hg and is characterized by the additional presence of alveolar edema, manifested as fluffy (cotton-wool appearance), symmetric airspace consolidation with mid and lower lung field predominance. Pleural effusions are often present in stages II or III and may be present earlier if there is a substantial component of right ventricular dysfunction or central volume overload, such as in patients with pulmonary hypertension or superimposed chronic renal or liver disease.

Pleural effusions often accompany biventricular heart failure. However, while the pulmonary congestion usually clears rapidly in response to therapy, the pleural effusions often remain after the pulmonary vessels have returned to normal size and require a longer time to resolve. Pleural effusions in congestive heart failure may be unilateral or bilateral, although they are most often bilateral. The effusions are nearly always transudates. Therefore, the presence of a unilateral effusion, particularly an isolated left effusion, should prompt consideration of a diagnostic thoracentesis. If the effusion is an exudate, an alternate cause, such as malignancy or infection, should be considered (Figs. 30-44 and 30-45).

CT may demonstrate the same findings and the same pattern of progression according to the degree of left heart dysfunction and PCWP increase. Nonetheless, it allows better assessment of cardiac chamber size, vascular caliber, and presence of pulmonary interstitial or alveolar edema. Nonetheless, because the combination of clinical, laboratory, and radiographic findings generally suffices for the diagnosis of congestive heart failure, CT is not routinely obtained in patients in this setting, although it is not uncommon to establish the diagnosis on CT studies performed for other reasons.

As previously discussed, pulmonary interstitial edema presents on CT as axial (peribronchovascular) and septal interstitial thickening (interlobular and intralobular); the findings are usually symmetric, smooth, and lower lung field predominant. The differential diagnosis, especially if the pattern of interstitial thickening is nodular, upper lung predominant, or asymmetric, includes sarcoidosis and lymphangitic spread of neoplasm. Pulmonary

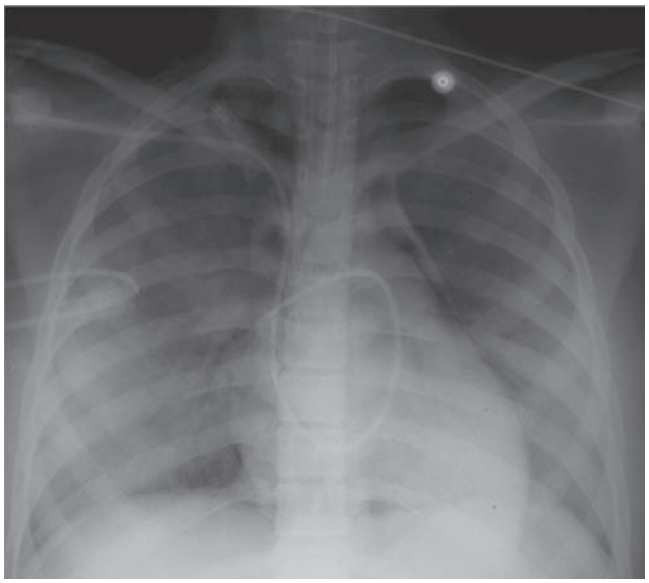
The vascular pattern is more prominent at the bases. **B.** Supine position. The vascular pattern is more uniform. **C.** Upside-down position. The vascular pattern is more marked at the apices.

A

B



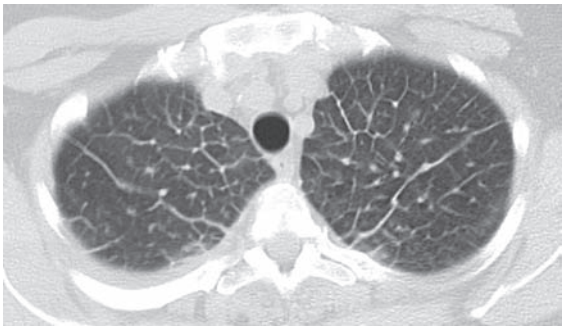
C

D

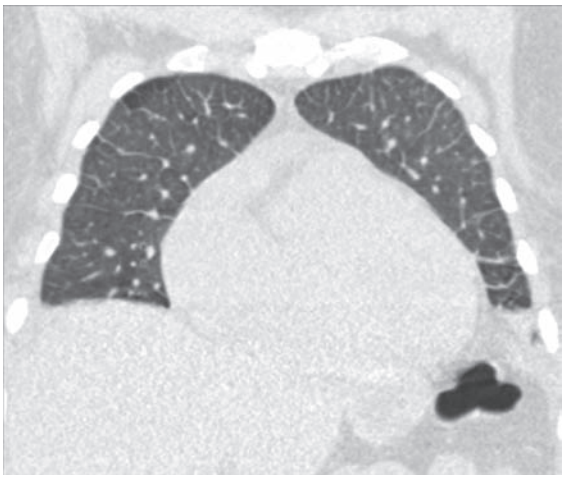
Figure 30-46 Patterns of diffuse alveolar disease. **A.** Normal PA chest radiograph, for comparison. **B.** Cardiogenic edema, with severe, symmetric, basilar-predominant airspace opacities, associated with cardiomegaly and likely small effusions. **C.** Noncardiogenic edema, with severe, symmetric, more diffuse airspace opacities; however, the cardiac size is normal and no pleural effusions are present. This patient has ARDS. **D.** Diffuse alveolar hemorrhage (DAH)—patchy, but fairly diffuse, airspace opacities are noted, with borderline heart size. This patient had systemic lupus erythematosus. Note that this pattern can be difficult to distinguish from diffuse pneumonia or pulmonary edema – clinical correlation is often needed.

alveolar edema is demonstrated as airspace opacities (ground-glass or consolidation), with fluid-filled acinar structures; the opacities are symmetric, ill-defined, confluent, and central and lower lung field predominant. Findings of pulmonary alveolar edema often coexist with pulmonary interstitial edema, but not vice versa. The exception is flash pulmonary edema, in which alveolar edema develops so rapidly that there is not enough time for interstitial edema to manifest. Flash pulmonary edema may occur with sudden changes in intravascular volume, such as following resuscitation in trauma patients or with sudden changes in cardiac function, as occurring with cardiac arrhythmias or myocardial infarction.

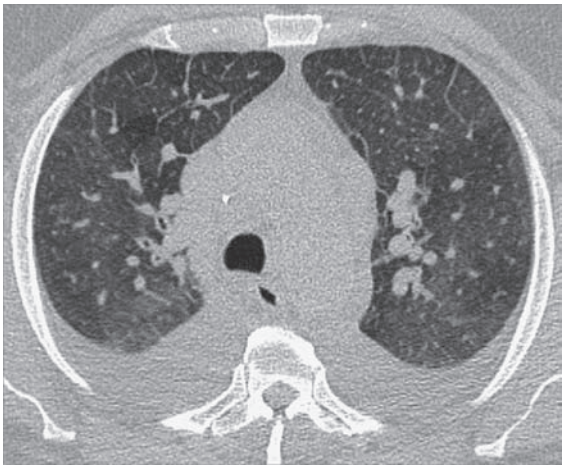
Pulmonary edema is the prototype of diffuse lung disease. Etiologically, it can be broadly separated into cardiogenic and noncardiogenic causes. Cardiogenic edema is caused by congestive heart failure.[55,56] Noncardiogenic edema is a manifestation of increased permeability of the pulmonary capillaries in which cardiac function is relatively preserved. Major differential diagnoses include acute hypersensitivity reactions, inhaled toxins, near-drowning, sepsis, and several processes that lead to the pathologic diagnosis of diffuse alveolar damage (DAD), most notably acute respiratory distress syndrome (ARDS).[57–61] From an imaging perspective, cardiogenic edema is more likely associated with cardiomegaly and functional impairment of the ventricles and tends to clear rapidly following administration of diuretics and drugs that optimize cardiovascular status. Noncardiogenic edema tends to resolve slowly and often requires clinical and laboratory correlation for etiologic characterization (Figs. 30-46–30-48).



A

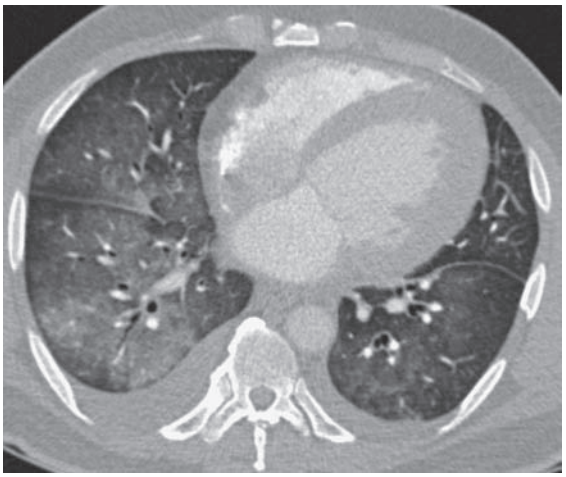


C

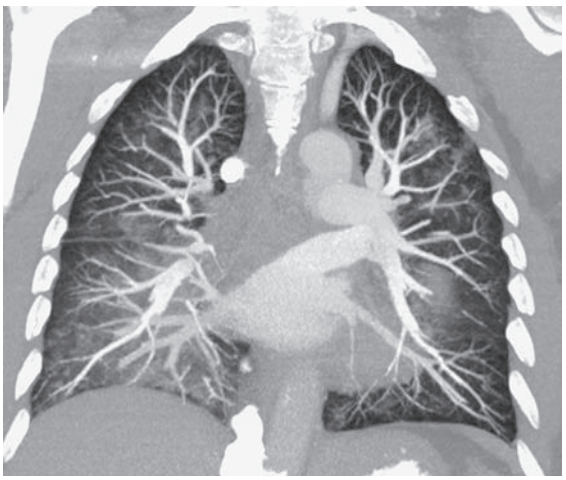


B

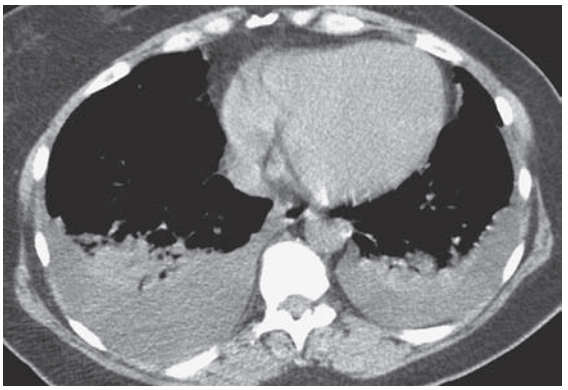
Figure 30-47 CT findings of pulmonary interstitial edema. **A.** Axial CT at the lung apices demonstrates classic smooth interlobular septal thickening, the hallmark of interstitial edema. **B.** Axial CT at the level of the carina demonstrates additional axial (peribronchial) interstitial thickening and vascular engorgement, indicating interstitial edema. Also note bilateral pleural effusions, in keeping with cardiogenic failure and volume overload. **C.** Coronal CT clearly demonstrates smooth interlobular septal thickening, which is diffuse, due to interstitial edema.



A

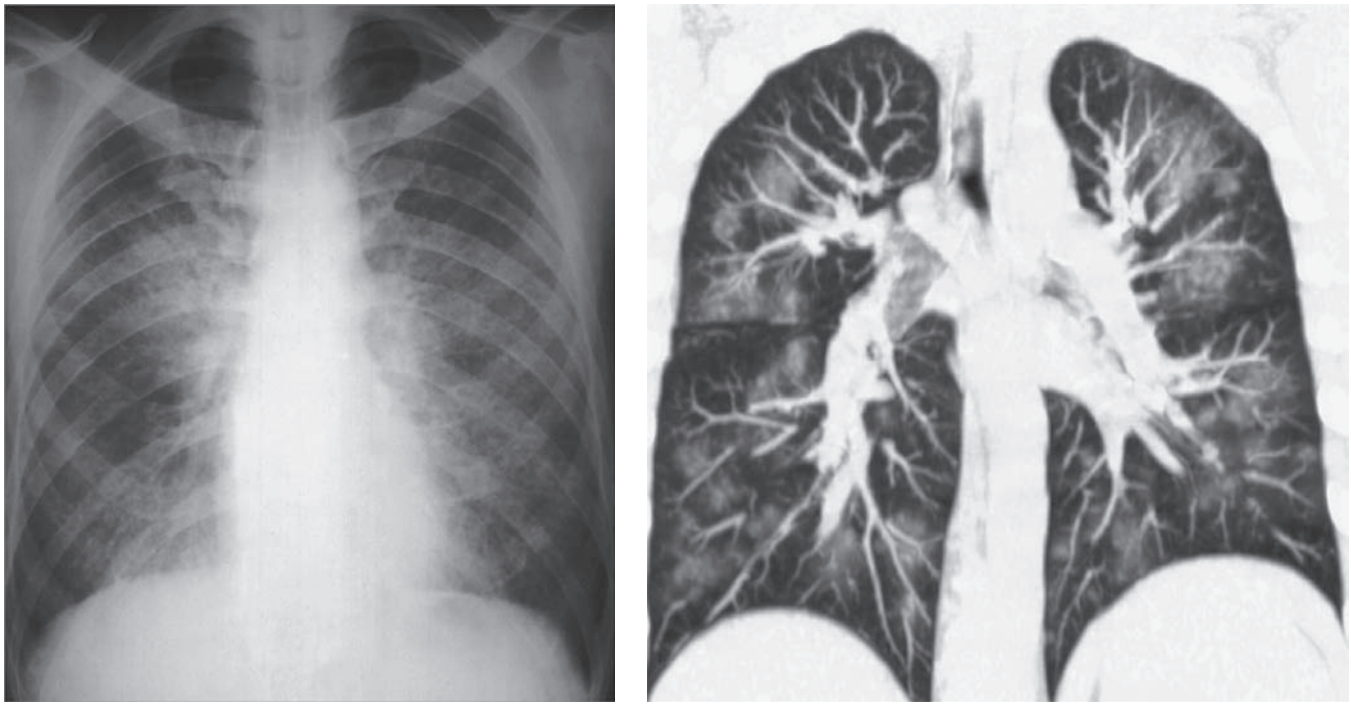


C



B

Figure 30-48 CT findings of pulmonary alveolar edema. **A.** Axial CT at the lung bases demonstrates diffuse ground-glass opacities, reflecting alveolar edema. Note left ventricular dilatation. **B.** Axial CT at the same level on mediastinal window demonstrates bilateral pleural effusions, in keeping with cardiogenic failure. **C.** Coronal MIP CT reconstruction clearly demonstrates diffuse ground-glass opacities more prominent along the bronchovascular bundles, characteristic of alveolar edema.



A B

Figure 30-49 CT findings of diffuse alveolar hemorrhage (DAH). **A.** PA chest radiograph demonstrates patchy, but predominantly perihilar, alveolar opacities. **B.** Coronal MIP CT reconstruction better demonstrates the patchy, but widespread, ground-glass opacities, more prominent along the bronchovascular bundles. This patient had a diagnosis of DAH due to Goodpasture syndrome. This pattern can be indistinguishable from pulmonary edema or diffuse infection. Clinical correlation is often needed to narrow the differential diagnosis.

In the proper clinical setting, diffuse alveolar opacities represent pulmonary edema until proved otherwise. If standard therapy for congestive heart failure fails to clear the opacities, and if clinical and laboratory findings exclude noncardiogenic pulmonary edema, other diagnostic entities must be considered. The most important is a diffuse pneumonia, which can be caused by several bacterial and viral agents, including, most notably, influenza. Other differential diagnostic considerations for diffuse lung disease include diffuse alveolar hemorrhage, pulmonary alveolar proteinosis, extensive multifocal mucinous adenocarcinoma, acute hypersensitivity pneumonitis, for example, that due to drug toxicity,[62] sarcoidosis, NSIP, and desquamative interstitial pneumonia (DIP). These entities are described elsewhere in Chapters 54–66 (Fig. 30-49).

PULMONARY EMBOLISM AND PULMONARY HYPERTENSION

Two critically important clinical entities involving the pulmonary vasculature can be assessed using CT: PE and pulmonary hypertension. Each is discussed subsequently.

■ PULMONARY EMBOLISM

Contrast-enhanced, multidetector chest CT provides a powerful and readily available technique for the evaluation of PE and has become the current reference standard for the diagnosis of acute and chronic pulmonary thromboembolic disease. Not only does CT enable direct visualization of clots, it also can provide alternative diagnoses to explain symptoms in the many patients who do not prove to have PE. Moreover, CT may facilitate diagnosis of associated right heart strain when present, a finding of prognostic importance. While CT may be limited in detecting small, peripheral, subsegmental clots, particularly if the study is not of optimal quality, it has a very high negative predictive value for PE. CT may also be combined with CT venography of the pelvis and lower extremities in selected cases, when clinically indicated.

The major disadvantage of CT relative to ventilation–perfusion scanning is the breast radiation dose, which is of concern in young women and pregnant patients. The problem is further heightened by the current overutilization of CT PE studies, manifested by a yield of positive cases that is generally under 10%. Technical methods to reduce the CT radiation dose continue to be introduced. However, the best approach to radiation dose reduction is to improve the appropriate utilization of CT. Better clinical pretest assessment of risk factors for PE is required. Such assessment using the Wells, Simplified Geneva, and PERC scores are frequently not used. Other more objective and easily implemented scoring systems have been advocated.

D-dimer measurement is a very useful screening test that carries a high negative predictive value for PE; measurement is particularly useful in the emergency room setting. A negative D-dimer in combination with a low or intermediate clinical suspicion for PE may obviate the need for CT in approximately 50% of outpatients and 20% of inpatients.

Young patients with normal chest radiographs (and without a history of asthma or COPD) can undergo radionuclide perfusion scans as an alternative to CT; the diagnostic yield of perfusion scans in this setting is high and the breast dose significantly lower than with CT. Patients with coexisting symptoms and/or signs of DVT should have Doppler US of their lower extremities as the initial test.[63–65]

The imaging workup of suspected PE in pregnancy presents several unique challenges, as both fetal and maternal breast radiation doses must be considered. Moreover, D-dimer is generally positive in pregnancy and, thus, not of value. In addition, there

Video 30-8 **A.** Full-color, coronal 3D VR (volume rendering) thick slab cine (anterior to posterior) emphasizing cardiovascular and pulmonary parenchymal structures and demonstrating marked ectasia of the central pulmonary arteries, compatible with pulmonary hypertension (in this patient, mean pulmonary artery pressure was 100 mm Hg). Also note asymmetry of arterial caliber, with relative oligemia of the left lower lobe and ectatic right upper lobe arteries, attributed to chronic thromboembolic pulmonary hypertension. **B.** Same patient as in Video 30.8A. Coronal, minimum intensity projection (minIP) thick slab cine (anterior to posterior). This type of reconstruction provides excellent assessment of mosaic attenuation, which, in this case is due to mosaic perfusion secondary to chronic thromboembolic pulmonary hypertension. The brighter areas of the lung parenchyma are relatively hyperperfused, whereas the darker areas are oligemic, and correlate with areas of diminished regional vascular caliber. *Access at www.fishmansonline.com*

are no useful pretest clinical risk assessment scoring systems for pregnancy. Recently published national guidelines recommend the use of ventilation–perfusion scans in pregnant women with normal chest radiographs (and without COPD or recently active asthma) and CT in the setting of chest radiographic abnormalities that do not provide an alternative diagnosis to PE.[66]

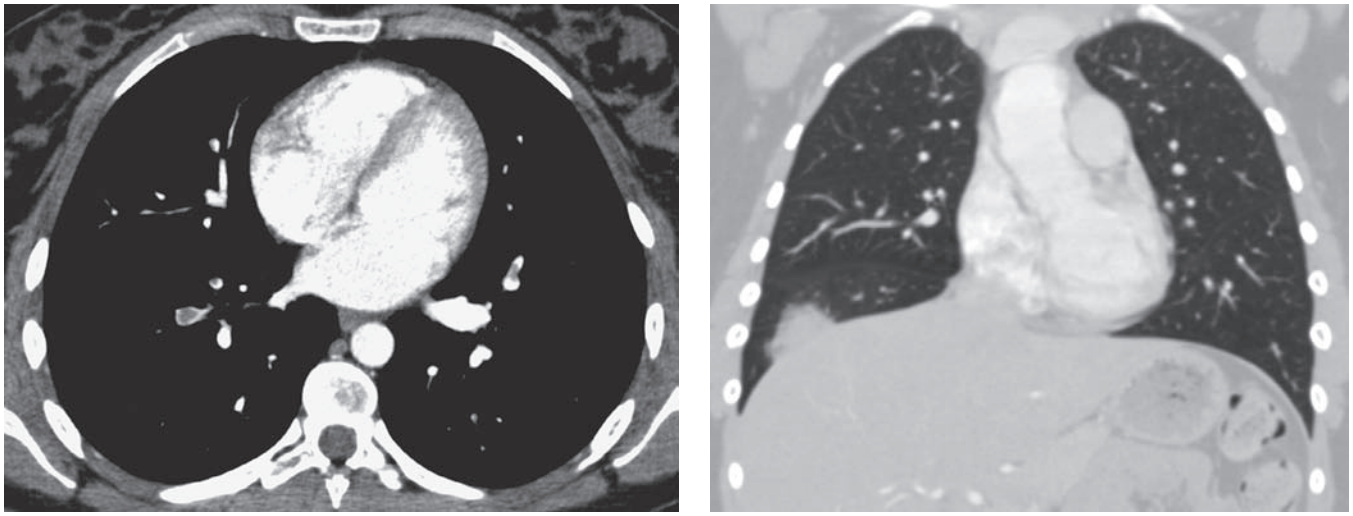
Acute and chronic pulmonary thromboembolic disease can be distinguished on CT imaging by the morphology of the pulmonary arterial filling defects. Acute emboli are usually more centrally located within the vessel lumen and may be occlusive. The nonopacified pulmonary arterial branches tend to be dilated in the setting of acute thromboembolic disease. In contrast, chronic clots are more likely eccentric along the vessel wall, nonocclusive, and sometimes calcified (if long-standing). The involved vessels tend to be smaller than normal. Moreover, chronic thromboembolic disease tends to present with associated dilated central pulmonary arteries, indicating pulmonary hypertension, whereas acute emboli generally present with normal caliber central pulmonary arteries, unless there is pre-existing pulmonary hypertension (Video 30-8A). Other findings suggesting chronic thromboembolic disease include a mosaic perfusion pattern and the presence of dilated bronchial or other systemic collateral vessels (Video 30-8B).

Given the immense functional reserve of the normal pulmonary vasculature, it is uncommon for acute PE to cause pulmonary hypertension and right ventricular dysfunction. Nonetheless, in the setting of large embolic burden, as measured by an obstruction index of the pulmonary arterial circulation of 40% or higher on helical chest CT, poor clinical outcomes are associated with right ventricular dysfunction. This situation generally only occurs with massive saddle emboli in the large proximal pulmonary arteries, or with a large number of relatively smaller emboli occluding the more distal segmental or subsegmental arteries. Chronic pulmonary thromboembolism, on the other hand, is far more prone to be associated with pulmonary hypertension, even in the absence of a substantial thromboembolic burden, due to molecular adaptation mechanisms that lead to remodeling of the pulmonary vasculature, including medial hypertrophy and in situ small vessel thrombosis.[67–69]

More recently, dual-energy CT has been proposed as a method for the combined assessment of acute and chronic emboli, pulmonary vascular anatomy, pulmonary parenchymal abnormalities, and pulmonary perfusion. Pulmonary perfusion, in particular, is obtained via dual-energy CT's ability to derive iodine maps. Identification of pulmonary perfusion defects can increase the sensitivity and specificity of CT for clot detection. Dual-energy CT has also been used for quantitative perfusion in chronic thromboembolic PE, given the strong correlation of dual-energy CT derived perfusion parameters with subjective assessment of a mosaic attenuation pattern. Consequently, contrast-enhanced chest CT is the most useful

Figure 30-50 Pulmonary angiogram, arterial phase. Note normal caliber of the pulmonary arteries, with multiple filling defects in the right main, right interlobar, and proximal right upper lobar arteries, diagnostic of acute pulmonary embolism.

Figure 30-51 Pulmonary angiogram, arterial phase. Note marked dilatation of the pulmonary arteries, without occlusive filling defects, but with overall poor delineation of the arteries, suggesting semiocclusive defects and increased contrast transit time. The constellation of findings indicates chronic thromboembolic pulmonary hypertension (CTEPH).



A B

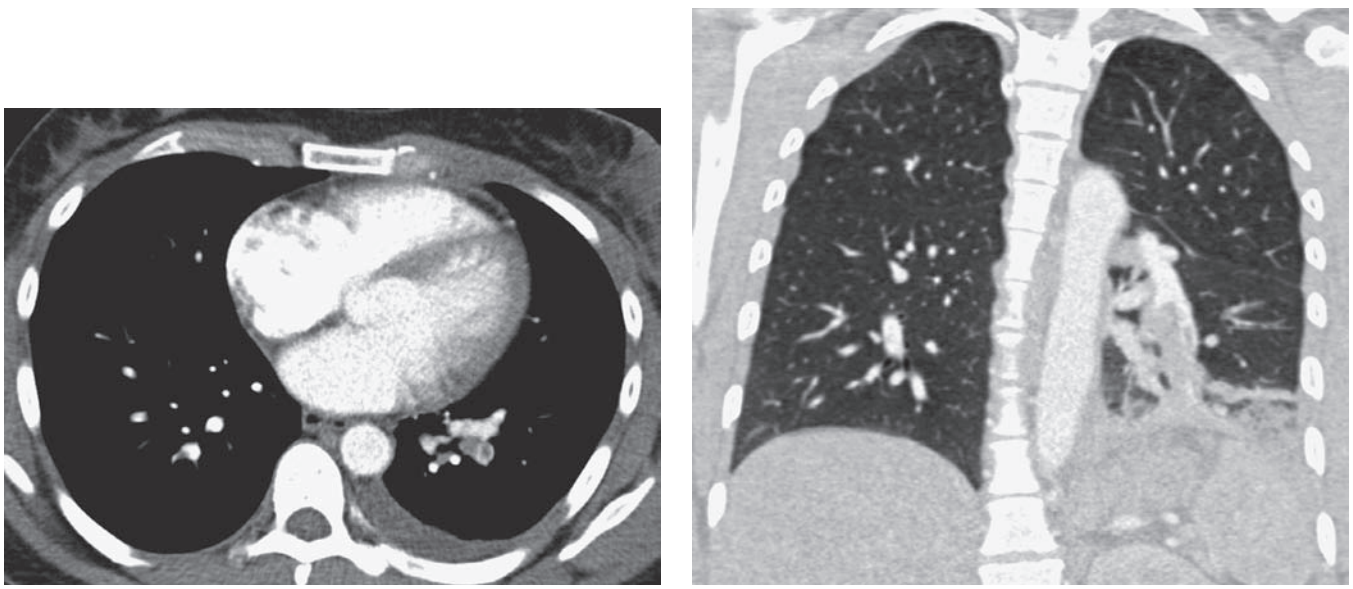
Figure 30-52 Acute pulmonary embolism. **A.** Axial CT at the lung bases demonstrates filling defects in the right lower lobe segmental arteries and left lower lobe anterior segmental artery, compatible with acute PE. **B.** Coronal CT image demonstrates a peripheral RLL consolidation, compatible with pulmonary infarct.

diagnostic modality for diagnosing chronic thromboembolic pulmonary hypertension (Figs. 30-50–30-53).[70–72]

■ PULMONARY HYPERTENSION

Because of its dual vascular supply (systemic and pulmonary, in series), the lungs effectively receive slightly greater than 100% of the cardiac output (100% via the pulmonary circulation and 1%–2% via the systemic bronchial circulation arising from the aorta), far more than the brain, heart, liver, or kidneys (which comprise the group of highly perfused organs). In addition, the pulmonary circulation is a low-pressure, low-impedance, high-flow system that demonstrates some remarkable physiologic adaptations, such as vasoconstriction whenever there is tissue hypoxia (the opposite response of arteries elsewhere in the body, which normally vasodilate in response to hypoxia), and the ability to adapt to major changes in flow with minimal changes in pressure. Inasmuch as the caliber and distribution of pulmonary vessels provide insight into the pathophysiology of the cardiopulmonary system, imaging methods can be used to study pulmonary vascular diseases.

Pulmonary blood flow is not uniform in the normal, upright human. Moreover, the blood flow pattern shifts with changes in posture, during exercise, and in a variety of heart and lung diseases. In the normal pulmonary circulation, gravity and distance from the heart are the predominant determinants of the pattern of



A B

Figure 30-53 Acute pulmonary embolism. **A.** Axial CT at the lung bases demonstrates filling defects in the left lower lobe segmental arteries, compatible with acute PE. Note small left pleural effusion. **B.** Coronal CT image demonstrates a peripheral LLL consolidation, compatible with pulmonary infarct.

blood flow, given that pulmonary vascular impedance is relatively uniform throughout the lungs (1/10 of average systemic vascular impedance). Assuming a normal average pulmonary arterial pressure of 15 mm Hg, in an adult patient in the erect position a gradient of 22 to 23 mm Hg exists between the apex (2–3 mm Hg) and the bases (25 mm Hg). Given that vascular impedance in the lungs is uniformly low, flow to the bases is approximately 10 times greater than flow to the apices. These differences are greatly reduced in supine position, in which there is a much smaller pressure gradient between the posterior and anterior lungs; consequently, flow is far more uniform in the supine position. In the healthy patient, exercise may increase cardiac output and pulmonary blood flow fivefold, with minimal changes in pressure due to decreased pulmonary vascular impedance. The decline in pulmonary vascular impedance is secondary to capillary recruitment and increased vascular distension.

In pathologic conditions in which pulmonary arterial or venous pressures are increased, or in which alveolar pressure is elevated, the importance of gravity as the major determinant of pulmonary flow is diminished. Furthermore, impaired gas exchange and ventilation may cause alveolar hypoxia that further interferes with pulmonary blood flow via hypoxic vasoconstriction of small arterioles.

The concept of lung "perfusion zones" is based on functional compartmentalization of the lung into three zones according to the relationships among pulmonary arterial, pulmonary venous, and alveolar pressures. In Zone 1, average alveolar pressure > arterial pressure > venous pressure, such that perfusion is minimal. In Zone 2, average arterial pressure > alveolar pressure > venous pressure, such that perfusion is pulsatile. In Zone 3, average arterial pressure > venous pressure > alveolar pressure, such that perfusion is continuous. Normal healthy subjects do not manifest Zone 1 physiology; however, patients on mechanical ventilation with high positive end-expiratory pressure (PEEP) or patients with COPD and air trapping may develop large areas of Zone 1 physiology. Moreover, heart diseases characterized by left ventricular dysfunction demonstrate increased left atrial and, consequently, increased pulmonary venous pressure. In the short term, this may cause vascular redistribution (with cephalization of the pulmonary vasculature) or pulmonary edema (if acute and more severe). In the long term, adaptation mechanisms of the pulmonary arterial circulation and right ventricle, including increased vascular impedance and right ventricular hypertrophy and dilatation, ultimately result in increased pulmonary arterial pressure; pulmonary hypertension ensues. Understanding the underlying pathophysiology is important for interpreting the imaging findings of pulmonary hypertension.

In its broadest sense, pulmonary hypertension is a pathophysiologic condition in which pulmonary hemodynamics are altered, including an increase in pulmonary vascular impedance and a consequent increase in mean pulmonary arterial pressure above 25 mm Hg (current diagnostic criteria). The pathophysiology, current WHO classification, and treatment of pulmonary hypertension are described in Chapter 72.

The reference standard for diagnosis of pulmonary hypertension is right heart catheterization, an invasive diagnostic modality which allows direct measurement of right ventricular pressure and pulmonary arterial pressure, as well as indirect measurement of pulmonary venous pressure throughout the cardiac cycle. Noninvasive imaging tests cannot measure pressure directly, although echocardiography can be used to estimate pulmonary arterial pressure via Doppler techniques that measure the velocity of the regurgitant jet through the tricuspid valve during systole. The right atrial pressure is usually assumed to be 7 to 8 mm Hg plus the central venous pressure, as estimated by physical evaluation of neck veins distention. These pressures cannot be directly measured by Doppler ultrasonography.

From a diagnostic standpoint, imaging tests may, nonetheless, provide important insight into the possible presence and potential etiology of pulmonary hypertension. The hemodynamic distinction between precapillary pulmonary hypertension (defined by mean pulmonary arterial pressure >25 mm Hg and PCWP <15 mm Hg) and postcapillary pulmonary hypertension (defined by mean pulmonary arterial pressure >25 mm Hg and PCWP >15 mm Hg) can generally be made by advanced imaging. Precapillary pulmonary hypertension includes pulmonary arterial hypertension, pulmonary hypertension due to lung parenchymal diseases, chronic thromboembolic pulmonary hypertension, and miscellaneous causes (WHO Classes I, III, IV, and V). Postcapillary pulmonary hypertension includes pulmonary venous hypertension associated with left heart disease (WHO Class II).

Imaging studies are important in separating pulmonary arterial hypertension from pulmonary hypertension related to pulmonary parenchymal diseases, left ventricular failure, and chronic thromboembolic pulmonary disease, since the management of these entities differs substantially.

Chest radiographs are helpful in the initial assessment of suspected pulmonary hypertension, although they are not sensitive for early diagnosis. Given their low cost and universal availability, chest radiographs can provide an assessment of cardiac size and pulmonary vasculature caliber and distribution, as well as suggest findings of congestive heart failure or diffuse lung parenchymal disease. Published studies suggest that on erect PA examinations, if PCWP is greater 13 but less than 18 mm Hg, there is usually vascular redistribution with relative hypervascularity of the upper lung fields; if between 18 and 25 mm Hg, there is also interstitial pulmonary edema; if greater than 25 mm Hg, there is usually alveolar edema and often pleural effusions. If pulmonary hypertension is present in these clinical settings, strong consideration should be given to left ventricular failure as a causal factor.

Chest CT and, increasingly, MRI have been proposed as diagnostic tests that can provide pertinent detailed information regarding the pulmonary parenchyma, cardiac anatomy and function, and the status of the pulmonary vasculature, with minimum patient risk.

Chest CT has a major role in evaluating patients with suspected pulmonary hypertension. It is the best imaging test to demonstrate lung parenchymal disease. A normal appearance of the lung parenchyma on chest CT in the setting of pulmonary hypertension effectively eliminates the possibility of COPD or ILD significantly contributing to the pulmonary hypertension and should prompt search for alternative etiologies.

Furthermore, chest CT is also useful for direct assessment of the pulmonary arteries in the setting of suspected pulmonary arterial hypertension. It has been reported that a main pulmonary artery caliber >29 mm, when measured 2 cm from the pulmonary valve, has a sensitivity of 84%, a specificity of 75%, and a positive predictive value of 97% for the presence of pulmonary arterial hypertension, as confirmed by invasive imaging. Moreover, if the main pulmonary artery has a maximum transverse diameter greater than that of the proximal ascending thoracic aorta, there is a sensitivity of 70%, specificity of 92%, and positive predictive value of 96% for the presence of pulmonary arterial hypertension. One should be mindful to first determine that the ascending aorta is not aneurysmal when performing these measurements.

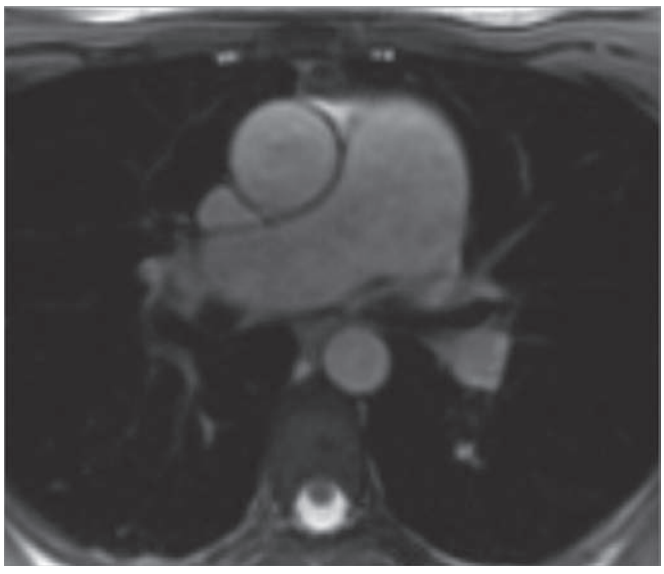
An additional chest CT finding suggesting pulmonary arterial hypertension is enlargement of the segmental arteries greater than 1.25 times the caliber of the adjacent bronchus. A combination of positive findings increases diagnostic confidence. For instance,

the presence of enlarged main pulmonary artery (>29 mm) and concomitant enlargement of three out of four segmental arteries (arterial/bronchial diameter > 1.25) provides a very high specificity (100%) for the diagnosis of pulmonary arterial hypertension. However, if pulmonary fibrosis or emphysema is present, the correlation between pulmonary artery dimension and severity of pulmonary hypertension is substantially weaker. In these clinical settings, a combination of findings is warranted to suggest the diagnosis.

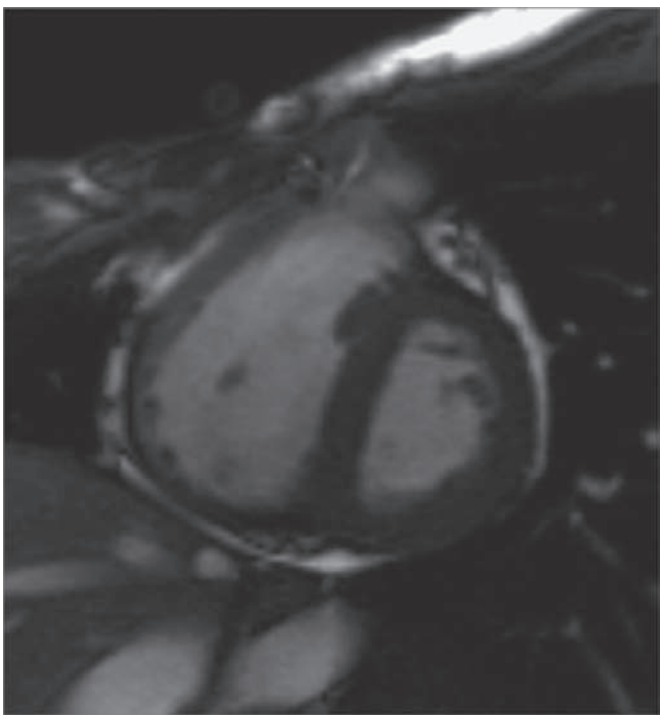
A prospective study comparing right heart catheterization and chest CT demonstrated that CT-derived measurement of the main pulmonary artery diameter (MPAD) correlates more strongly with the presence of pulmonary hypertension in patients without ILD (MPAD >31.6 mm associated with a PPV of 90.0% and a NPV of 58.3%) than in patients with ILD (MPAD >25 mm associated with a PPV of 46.3% and a NPV of 83.8%), although in both groups the MPAD was significantly greater in patients with pulmonary hypertension than in those without. One conclusion is that pulmonary hypertension is more likely to be present even with normal caliber pulmonary arteries if the underlying diagnosis is ILD. The presence of bronchial artery hypertrophy >1.5 mm has also been implicated in pulmonary arterial hypertension, although this sign is probably far more common in chronic pulmonary thromboembolic disease.

Several pulmonary parenchymal findings are associated with pulmonary arterial hypertension, although they are not individually sensitive or specific enough to warrant the diagnosis. The first is mosaic attenuation, which is more commonly seen in the setting of pulmonary hypertension due to chronic pulmonary thromboembolic disease, but which can also be seen in the presence of small airway disease without pulmonary hypertension, among other possibilities. Widespread tiny centrilobular ground-glass nodules may also be present, similar to those observed in hypersensitivity pneumonitis, but pathologically deemed to represent cholesterol granulomas or large plexogenic arterial lesions, which have been described in 7% to 47% of patients with pulmonary arterial hypertension.[73–75]

MRI is currently the reference standard for assessment of congenital heart diseases, as it accurately delineates structural changes, cardiac situs, intracardiac shunts, atrial–ventricular and ventriculoarterial relationships, and vascular dimensions, along with wall motion and valvular abnormalities. It is the most useful modality for assessing right ventricular anatomy and function, which is a critical prognostic determinant in pulmonary hypertension. Furthermore, contrast-enhanced MRI, through demonstration of delayed enhancement, uniquely enables detection of the presence and extent of myocardial scarring related to prior infarction, myocarditis, or infiltrative disease in the myocardium—findings that may be associated with left ventricular dysfunction and pulmonary venous hypertension. MRI, similar to Doppler echocardiography, can be used to quantitatively measure flow velocity using phase contrast imaging, allowing for estimation of arterial and intracardiac pressures. However, a major strength of MRI when compared with echocardiography is that arbitrary planes can be set without limitation by available acoustic windows, providing for greater accuracy and reproducibility. Further developments in MRI techniques will increase the clinical usefulness of this modality. In the future, it is conceivable that the combination of advanced CT and MRI techniques will be able to provide a thorough anatomical and functional assessment of the heart–lung unit in patients with suspected pulmonary hypertension, obviating the need for invasive right heart catheterization in selected patients (Figs. 30-54–30-56).[76–78]

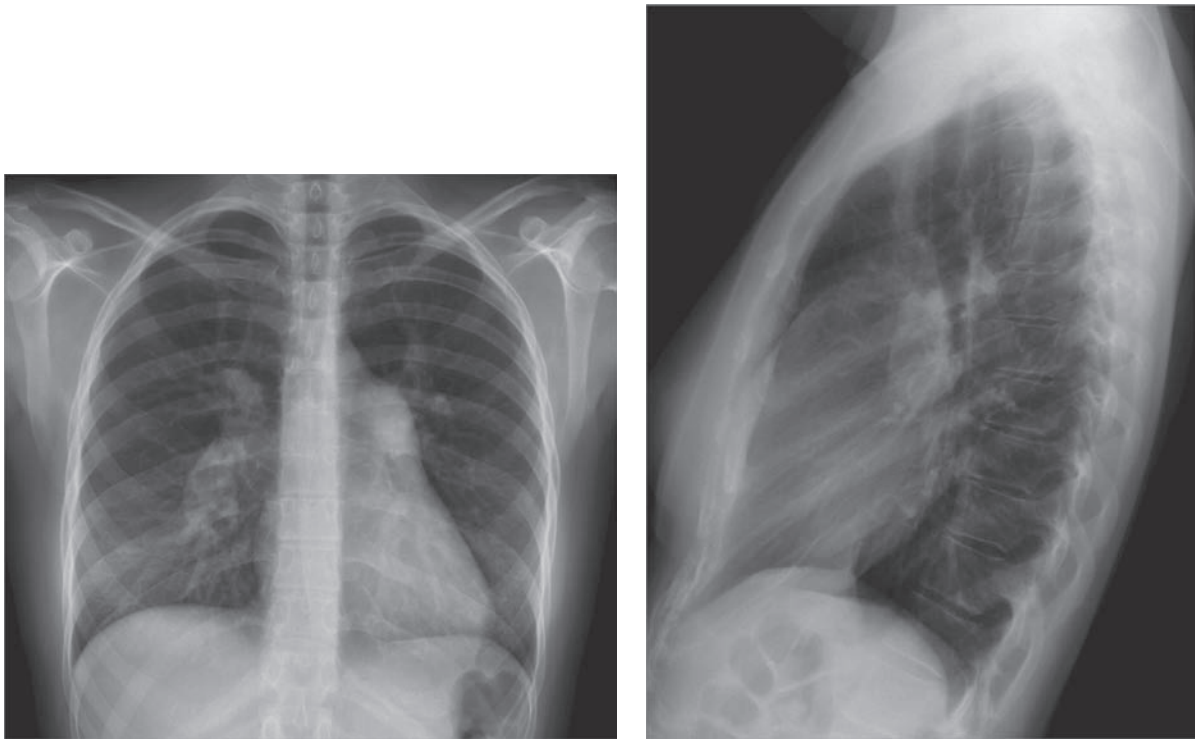


A



B

Figure 30-54 Pulmonary hypertension and right ventricular strain. **A.** Steady-state, free precession axial (SSFP) MR image ("bright blood") demonstrates dilatation of the central pulmonary arteries, with the main PA larger than the ascending aorta, compatible with pulmonary arterial hypertension. **B.** SSFP MR image, short axis of the heart, demonstrates right ventricular dilatation and straightening of the interventricular septum, indicative of right ventricular strain. The septum is normally convex toward the RV, due to normally higher LV pressure.



A B

Figure 30-55 Pulmonary hypertension due to cardiac shunt. (**A**) PA, (**B**) lateral chest radiographs demonstrate moderate dilatation of the central pulmonary arteries, secondary to a long-standing uncorrected atrial septal defect (ASD).

PLEURAL, DIAPHRAGMATIC, AND CHEST WALL DISEASES

Radiographic imaging of the pleural space, diaphragm, and chest wall plays an important role in the diagnosis and evaluation of common, clinically important disorders involving these structures.

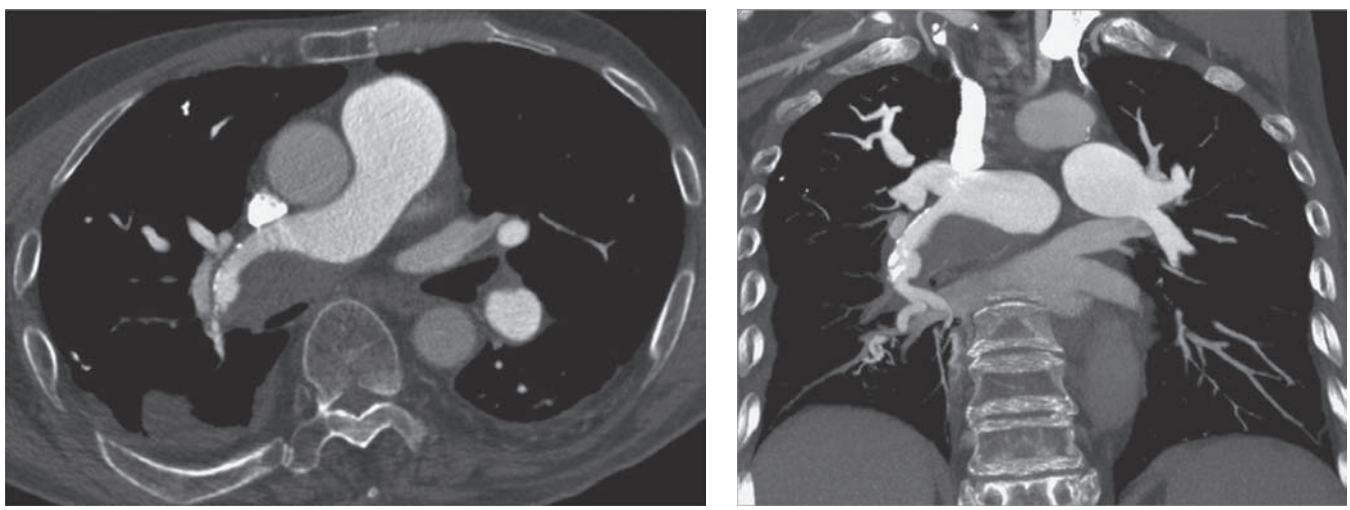
■ PLEURAL DISEASES

Pleural pathology can be broadly classified, for imaging purposes, into three major categories: pneumothoraces; pleural effusions; and pleural thickening, nodules, or masses. These are described in the subsections that follow.

Pneumothorax

Even though generally placed within the subgroup of pleural pathology, pneumothorax, characterized as the presence of gas within the pleural cavity separating the parietal from the visceral pleura, is rarely related to a disease process of the pleura itself (see also Chapter 31). Rather, it is associated with pulmonary or chest wall lesions. Nonetheless, pneumothorax is a very important clinical diagnosis, since it can lead to substantial morbidity or mortality if undetected or not properly treated.

Imaging is generally extremely accurate in the diagnosis of pneumothorax. The only exception is a portable chest radiograph obtained



A B

Figure 30-56 Chronic thromboembolic pulmonary hypertension (CTEPH): (**A**) axial CT image and (**B**) coronal MIP CT image demonstrating marked dilatation of the central pulmonary arteries, partially occlusive filling defect in the right main pulmonary artery, and tortuosity of the pulmonary arteries, with asymmetric vascular caliber. The constellation of findings reflects CTEPH.

in a supine position, which is relatively insensitive for detection of small pneumothoraces. In this scenario a pneumothorax should be suspected if there is increased lucency in the least dependent portion of the hemithorax (the anterolateral costophrenic angle in supine position), known as the "deep sulcus sign." This finding should prompt a lateral decubitus film, with the patient positioned with the suspected pneumothorax in the nondependent side; findings include a sharply marginated lucency along the lateral nondependent hemithorax.

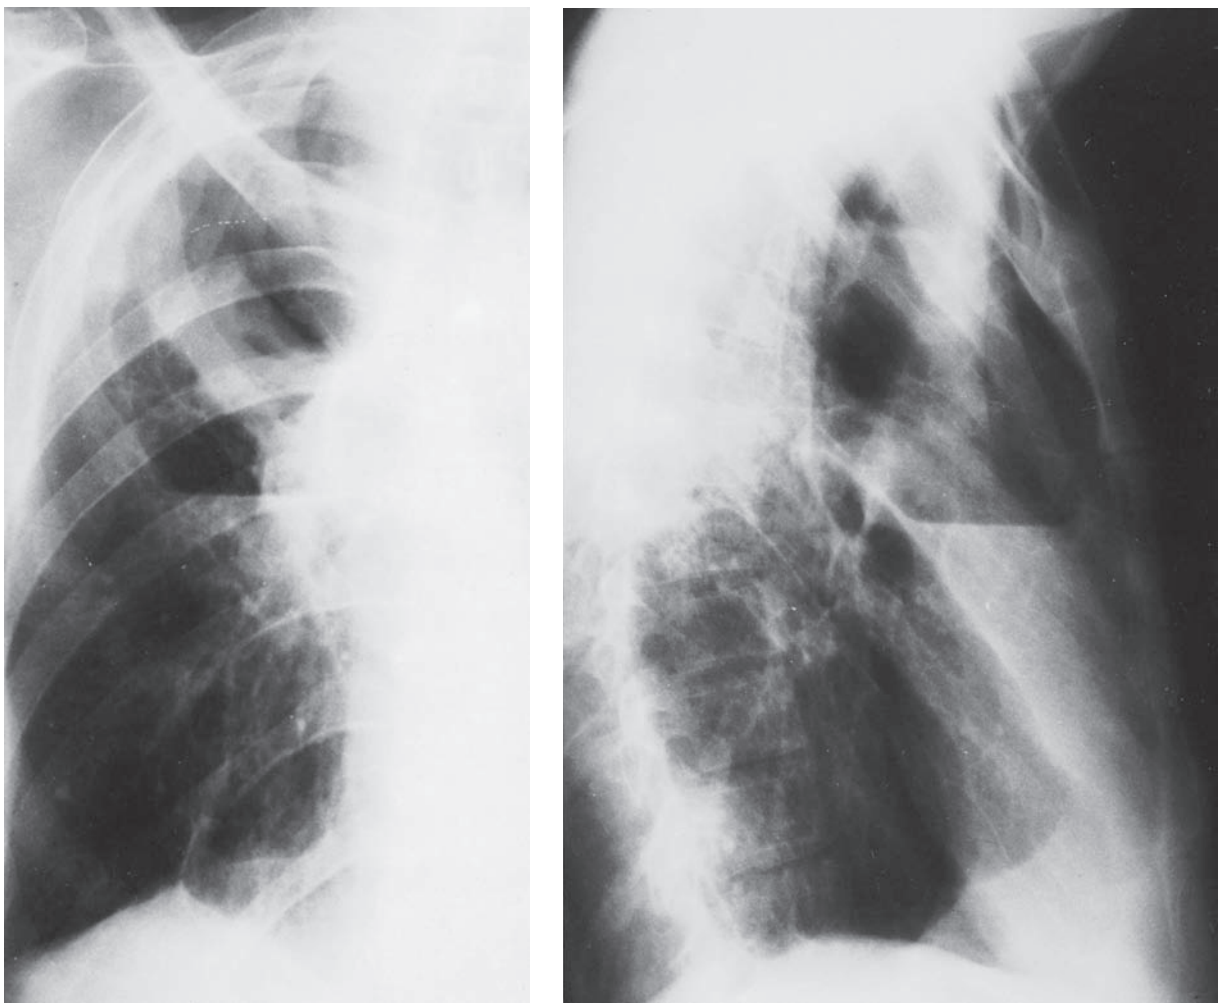
On the other hand, erect PA radiographs are very sensitive and can detect even very small pneumothoraces, which are identified as crescentic-shaped lucencies lateral and superior to the apex of the lung and delineated from the lung parenchyma by a thin visceral pleural line. If there is doubt regarding the presence of a very small pneumothorax, an expiratory view may help by increasing the conspicuity of the pneumothorax, as the lung volumes will be reduced while the pneumothorax volume remains constant, resulting in an increase in the percent volume of the hemithorax occupied by the pneumothorax. In addition, lung parenchymal attenuation will be slightly increased relative to the pneumothorax.

Finally, CT is the most accurate modality for detecting pneumothorax and can demonstrate even minuscule pneumothoraces (<1%) that cannot be detected by standard radiographic techniques.

Special cases include tension and loculated pneumothoraces. Tension pneumothorax is a critical diagnosis that requires emergent treatment. A tension pneumothorax manifests on imaging as substantial lung collapse, contralateral mediastinal shift, and downward ipsilateral diaphragmatic displacement. It is generally associated with respiratory and cardiovascular compromise and requires prompt decompression. Loculated pneumothorax occurs when there are inflammatory or neoplastic adhesions between the parietal and visceral pleura, causing gas to accumulate in the pleural space in unusual locations and geometric configurations that do not respect gravitational gradients.

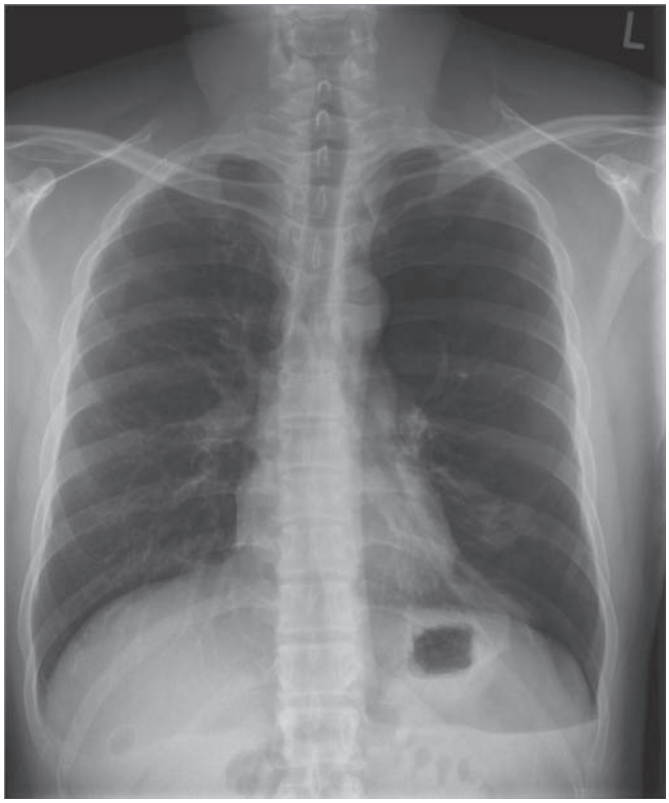
Imaging can also be performed to monitor a pneumothorax, for example, to decide if and when to place a chest tube, and also to investigate the etiology. Most pneumothoraces are either traumatic (in the setting of rib fractures or pulmonary lacerations) or iatrogenic (in the setting of pulmonary, mediastinal, or chest wall interventional procedures, which may be percutaneous, bronchoscopic, or surgical). CT is the best imaging modality to demonstrate rib fractures and pulmonary lacerations. Occasionally, a patient presents with a spontaneous pneumothorax. Most often these are related to rupture of pulmonary blebs or bullae, which may occur in patients with COPD or cystic lung diseases; in some cases, no specific cause can be demonstrated.[79]

A chronic pneumothorax usually occurs in association with pleural effusion, resulting in a hydropneumothorax. Hydropneumothoraces are generally associated with surgical procedures, malignancy, or severe infections, such as empyema. A chronic pneumothorax strongly suggests the presence of a bronchopleural fistula, as gas-forming infection in the pleural space is rare (Figs. 30-57 and 30-58).[80]



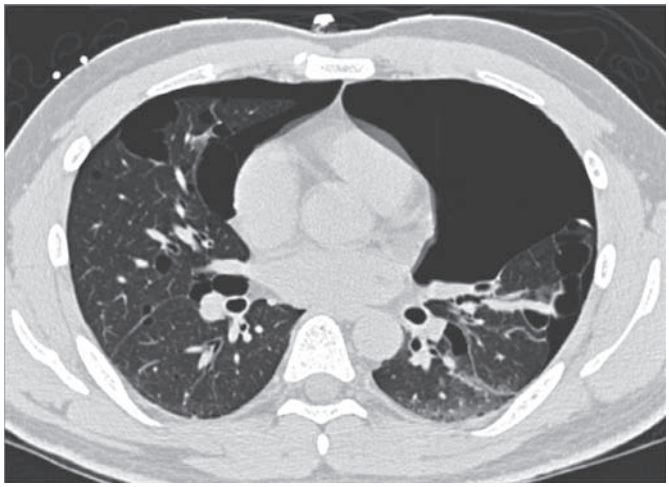
A B

Figure 30-57 Hydropneumothorax. **A.** PA view. A distinct air–fluid level is seen overlying the right hilus. **B.** Lateral view. The fluid and air are anterior to the hilus. The findings are difficult to differentiate from a lung cavity, but the very thin edge suggests localization in the pleural space. This was a hydropneumothorax and was secondary to a postoperative bronchopleural fistula.



A

B



C

Figure 30-58 Bilateral pneumothoraces. (**A**) PA and (**B**) lateral chest radiographs demonstrate bilateral pneumothoraces, approximately 20% on the right and 40% on the left. The patient presented with spontaneous pneumothoraces. **C.** Axial CT at the lung bases confirms bilateral pneumothoraces and also indicates the etiology, demonstrating multiple pulmonary cysts. The patient was found to have Birt–Hogg–Dubé syndrome, a genetic disease that causes pulmonary cysts and predisposes the patient to recurrent spontaneous pneumothorax.

Pleural Effusions

Fluid in the pleural cavity appears radiographically as a homogeneous opacity that generally occupies a dependent position. A small pleural effusion that is barely perceptible or is overlooked on the PA view is often readily apparent on the lateral radiograph as blunting of the posterior costophrenic sulcus. The best non-CT radiographic study for demonstrating small quantities of pleural fluid is the lateral decubitus view, with the suspected pleural effusion on the dependent side. Using this technique, as little as 25 mL of fluid can be detected. Larger pleural effusions usually blunt the lateral costophrenic sulcus on the PA radiograph as well.

Occasionally, pleural fluid remains between the diaphragm and the lung, that is, infrapulmonary or subpulmonic, displacing the lung upward so that the lateral costophrenic angle remains sharp. The presence of a subpulmonic accumulation of fluid should be suspected if the diaphragm appears elevated, particularly along its lateral aspect on the frontal radiograph; if the costophrenic sulcus is blunted posteriorly; or if the gastric gas bubble is separated from the dome of the apparent left hemidiaphragm by more than a few millimeters (The last finding is frequently normal, however). CT is especially sensitive in identifying even the smallest of pleural effusions, which may be undetectable on chest radiographs. In the intensive care unit, where many portable radiographs are obtained in supine patients, CT imaging is particularly helpful in the diagnosis of pleural effusions, often revealing sizable effusions that are unsuspected.

Pleural effusions can be classified into two major categories: transudates and exudates. Transudates are characterized by low protein concentration relative to the plasma, and very low cellularity; exudates are characterized by higher protein concentration and cellularity, as discussed in detail elsewhere (Chapters 76 and 77). Transudative pleural effusions are commonly caused by congestive

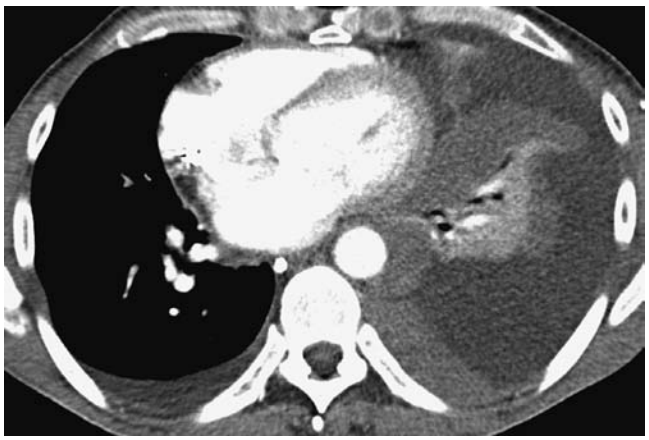


Figure 30-59 Malignant pleural effusion. Axial CT image demonstrates bilateral pleural effusions. The left effusion is associated with enhancing pleural masses, better visualized at the posterior medial costophrenic angle and adjacent to the descending thoracic aorta. This is characteristic of a malignant effusion. The patient was later diagnosed with mesothelioma.

heart failure, volume overload in the setting of renal dysfunction, or ascites in the setting of hepatic failure. Rarely, they are due to connective tissue disease or metastatic neoplasm. Broad causes of exudative effusions include parapneumonic collections, pulmonary infarction, malignancy (metastatic or due to primary pleural neoplasms), connective tissue disorders, subdiaphragmatic inflammatory processes, and infections (including empyema). Obtaining a specific diagnosis usually requires extensive evaluation that includes CT or MR, thoracentesis, and, possibly, pleural biopsy (Fig. 30-59).

Imaging modalities, particularly CT, may suggest, but not confirm, that an effusion is more likely a transudate or an exudate, thereby guiding patient management. Most transudates are bilateral, simple, nonloculated effusions occurring in dependent locations. Many exudates are unilateral, loculated effusions. A loculated effusion usually conforms to an unusual shape, commonly ovoid or with geometric edges, and sometimes along the fissures. Loculated effusions may resemble pulmonary masses on chest radiographs, although the pleural location can be readily ascertained on CT. The differential diagnosis of pleural effusions is one scenario in which US can be used to provide additional information beyond CT. For example, US may demonstrate internal septations within an effusion, a finding that can be difficult to demonstrate using CT and which is highly associated with exudative effusions. Furthermore, US can be used therapeutically to provide real-time guidance for thoracentesis and chest tube placement.[81–83] Conversely, US may occasionally fail to detect exudative pleural effusions, including empyemas, which are echogenic and which are readily detected by CT.

Pleural Thickening, Nodules, and Masses

Pleural diseases that cause diffuse thickening or localized nodularity may be separated into three broad etiologic categories: inflammatory, infectious, and neoplastic (both benign and malignant). Specific subgroups that are commonly encountered, but rarely clinically relevant, include apical pleural thickening (apical capping), which is usually bilateral and age-related and usually idiopathic (attributed to age-related ischemic changes); however, apical capping may potentially be associated with sequelae of granulomatous infections, particularly if accompanied by apical parenchymal scarring. Blunting of the lateral costophrenic angle on the PA view with sparing the posterior costophrenic angle on the lateral may be attributed to postinflammatory pleural thickening. Radiographic follow-up is helpful in excluding a focal mass. Multifocal pleural plaques, which are smoothly marginated, localized areas of pleural thickening, and which are often associated with calcifications, are common late manifestations of prior asbestos exposure. Frequently, they are the sole imaging manifestation of past asbestos exposure. CT is the optimal modality for their detection and characterization.

Diffuse pleural thickening involving both hemithoraces is more likely of inflammatory etiology, although bilateral pleural metastases can definitely occur and should be considered. Unilateral, extensive pleural thickening is more suspicious for a malignant etiology, either pleural metastases or primary malignancy, such as pleural mesothelioma. Nodular thickening of the mediastinal pleura and involvement of the interlobar fissures are particularly correlated with a malignant etiology; as a rule, the more nodular the pleural thickening appears, the more likely a malignant process is its cause. The differential diagnosis includes empyema, particularly tuberculous empyema, which may be indistinguishable from mesothelioma based on imaging appearance. Imaging cannot distinguish mesothelioma, pleural metastases, and tuberculous empyema; tissue sampling and correlation with other clinical and laboratory findings is required.[84–86]

A special case to consider is extensive pleural thickening associated with calcifications and diminished volume of the adjacent lung parenchyma—a fibrothorax. Most fibrothoraces reflect sequelae of prior substantial pleural inflammation caused by empyema or hemothorax, and their clinical significance is due to their potential to impair chest wall mechanics and restrict lung expansion.

A localized pleural nodule suggests a benign pleural neoplasm, such as a solitary fibrous tumor of the pleura or lipoma. The nodule may be difficult to distinguish from a localized area of pleural thickening, but generally it is larger and more symmetric in contour. On CT, these nodules usually have a characteristic appearance: Their shape is ovoid with their largest diameter parallel to the chest wall, and their edges are flat and tapering. The appearance is similar to the extrapleural sign on chest radiographs, which is defined as a shadow that has smooth margins, tapering edges with obtuse angles with the chest wall, and is generally seen well in only one of the two standard views of the chest. Occasionally, a peripheral nerve sheath tumor (e.g., schwannoma or neurofibroma) arising from an intercostal nerve may mimic a pleural nodule. These lesions, however, tend to cause indentation of adjacent ribs due to long standing mass effect, helping to suggest the diagnosis.

Rarely, solitary or multiple pleural nodules without associated effusion may represent a malignant process; the classic example is the so-called "drop" metastases from thymic neoplasms.

DIAPHRAGMATIC DISEASES

Diaphragmatic evaluation can be performed initially via chest radiographs, ideally PA and lateral views. The normal hemidiaphragm has smooth contours and gentle curvature, with its dome near its center and no focal protrusions, with the left hemidiaphragm slightly lower than the right. The most common diaphragmatic abnormality is an eventration, in which there is focal weakness of the muscle, correlated with focal protrusion or bulge. Diaphragmatic paralysis should be suspected when an entire hemidiaphragm is elevated, typically more than 2 cm in comparison to the normal side. To confirm diaphragmatic paralysis, the standard test is a fluoroscopic dynamic evaluation ("sniff test"), in which the patient is imaged during shallow breathing, deep breathing, and forceful inspiration ("sniff"). The normal hemidiaphragm moves downward with the sniff maneuver, while a paralyzed hemidiaphragm will demonstrate paradoxical upward motion.

Diaphragmatic hernias can be classified into three broad categories: hiatal, congenital, and traumatic. Hiatal hernias occurring

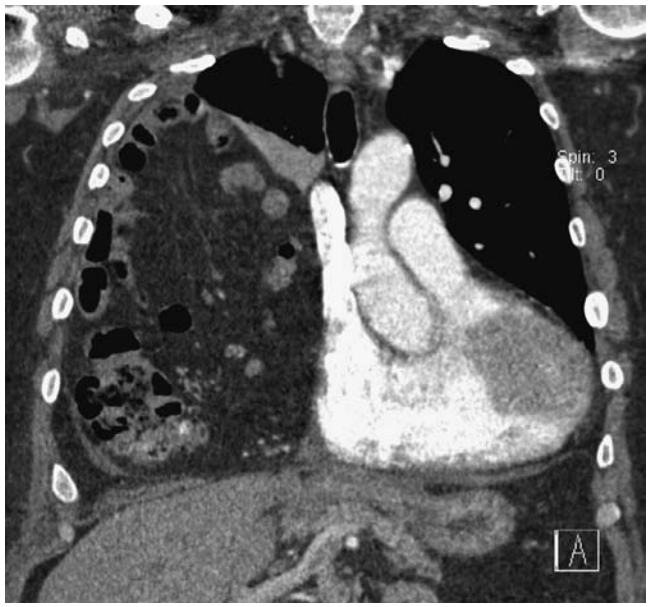

Figure 30-60 Diaphragmatic hernia. Coronal CT image demonstrates a wide defect in the right hemidiaphragm. The right lung is nearly completely collapsed, and the right hemithorax is nearly completely occupied by small and large bowel loops with associated mesenteric fat. This is diagnostic of diaphragmatic hernia, in this case due to blunt trauma to the abdomen.

through the centrally placed esophageal hiatus are the most common, and usually contain a portion of the stomach, although very large hernias can contain small or large bowel loops as well. Congenital hernias are usually through the paired foramina of Morgagni (anterior and medial) or the paired foramina of Bochdalek (posterior and central). The latter are more frequent and are usually small, incidental hernias containing fat. When large, these congenital hernias can contain viscera, either bowel loops (Morgagni) or retroperitoneal structures such as the kidney (Bochdalek), but these are virtually always diagnosed in infancy. Traumatic hernias should be suspected in patients who had blunt trauma and present with a newly elevated hemidiaphragm. These are more common on the left, as the liver usually prevents herniation on the right except in very large defects. Traumatic diaphragmatic ruptures may occur in the setting of trauma without detectable herniation, and the actual herniation of abdominal viscera into the thorax may occur days, months, or even years later. Inquiry regarding a history of remote trauma is thus important in the evaluation of diaphragmatic hernias. Multiplanar coronal and sagittal CT or MR images allow accurate assessment of diaphragmatic contour abnormalities, and are the reference standard for the diagnosis of diaphragmatic rupture. MR offers the additional advantage of functional assessment with fast gradient echo cine sequences (Figs. 30-60 and 30-61).[87–89]

CHEST WALL MASSES

Chest wall masses may extend into the pleura and cause pleural nodularity or masses. These are very difficult to detect radiographically unless causing bone destruction or substantial mass effect. CT or MR associated with tissue sampling is generally necessary for accurate diagnosis. The differential diagnosis of chest wall masses includes soft tissue infection (cellulitis, phlegmon, abscess), which is generally associated with trauma and surgical procedures; hematoma, also often associated with trauma or surgical procedures; extension of infection arising from the lung, with the prototype

Figure 30-61 Diaphragmatic paralysis. Coronal CT image shows marked elevation of the right hemidiaphragm. Fluoroscopic examination confirmed a paralyzed right hemidiaphragm.

disease being actinomycosis; and rarely neoplasms, such as soft tissue sarcomas, metastatic disease, and malignant nerve sheath tumors.

MEDIASTINAL DISEASES

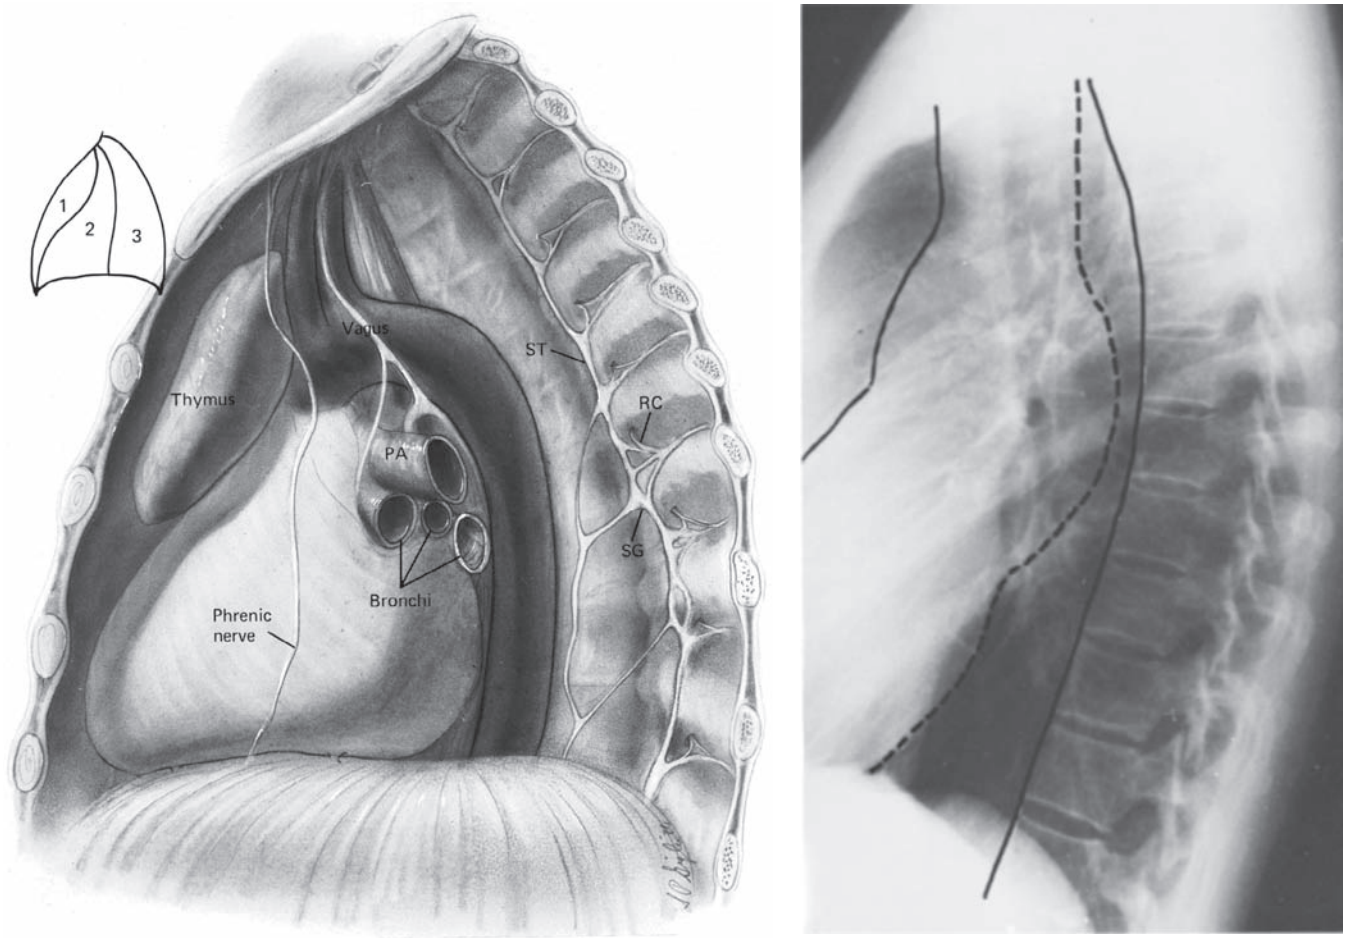
Mediastinal diseases encompass multiple systems, organs, and a vast array of differential diagnoses. Before discussing mediastinal diseases, it is necessary to define the contents of the mediastinum and its boundaries.

The anatomic delineations of "compartments" of the mediastinum are not defined consistently throughout the medical literature. For radiographic diagnosis, a simple classification has been employed: (1) The *anterior compartment*, which extends from the sternum anteriorly to the heart, aorta, and brachiocephalic vessels posteriorly, comprises only the thymus, fat tissue, and a few lymph nodes. (2) The *middle* or *visceral compartment* contains the heart, great vessels, trachea and its branches, esophagus, and descending aorta. It extends from the posterior border of the anterior compartment to the anterior border of the vertebral column. These boundaries differ from the anatomist's classification, which relegates portions of the esophagus and the descending aorta to the posterior mediastinum. (3) The *posterior compartment* contains the vertebrae and paravertebral sulci.

Application of this classification to the lateral chest radiograph facilitates generation of a relevant differential diagnosis. However, with modern modalities such as CT or MR, one is able to accurately categorize mediastinal masses according to their exact location within the mediastinum, obviating the need for compartmental localization. For example, instead of categorizing a mass as in the posterior mediastinum, CT or MR often allows accurate differentiation among different etiologies, such as paraspinal masses, neurogenic neoplasms, vascular lesions, and esophageal masses (Figs. 30-62 and 30-63).[90]

This section focuses on diseases of the lymph nodes and thymus. Cardiac and systemic vascular diseases are beyond the scope of this textbook and will be mentioned only briefly. Pulmonary vascular diseases have been described previously. Esophageal diseases and spinal or paraspinal diseases are discussed briefly (Fig. 30-64).

Before a discussion on mediastinal neoplasms, it is important to emphasize the role of CT for evaluation of suspected mediastinal infections in the postoperative patient.



A B

Figure 30-62 Compartments of the mediastinum: **A.** Anatomic view of the compartments of the mediastinum. The subdivisions (1, anterior; 2, middle; 3, posterior) in the small schematic *(top left)* correspond to those designated by the *solid black lines* in **B.** PA, pulmonary artery; ST; sympathetic trunk; SG, sympathetic ganglion; RC, ramus communicans. **B.** Radiographic division of the mediastinum. The *closed lines* delineate the anterior, middle, and posterior compartments. The *dashed line* represents the division of the middle and posterior mediastinum that is conventionally used by anatomists. *(**A:** Reproduced with permission from Jones KW, Pietra GG, Sabiston DC. Primary Neoplasms and Cysts of the Mediastinum, in Fishman AP (ed). Pulmonary Diseases and Disorders. New York: McGraw-Hill; 1980:1490–1521.)*

Mediastinitis is a catastrophic complication of multiple types of cardiothoracic surgeries and, if unrecognized and not treated aggressively, it often leads to a fatal outcome. In the immediate postoperative period in a patient status, post cardiac, central vascular, major pulmonary, or esophageal surgery, the presence of a small amount of gas and fluid in the mediastinum is an expected occurrence. The findings tend to subside within hours or a few days. While there is no absolute rule to apply to the time frame over which a pneumomediastinum or mediastinal fluid collection becomes clearly pathologic, some general guidelines are helpful in guiding management decisions: (1) It is expected that any postoperative fluid or gas collection will decrease in size over time, and any increase in size is suspicious for an evolving mediastinitis. (2) Large fluid and gas collections (those measuring >2 cm in the smallest diameter) are almost always pathologic. (3) Any persistent mediastinal fluid or gas collection more than 1 week following surgery is suspicious, and the index of suspicion rises if the patient is clinically worsening, if there are laboratory signs to support infection (e.g., leukocytosis with a left shift), and if there are CT features suggesting active inflammation, such as rim enhancement in the boundaries of the collection. Any of these findings should prompt aggressive management with percutaneous or surgical drainage of the collection and institution of broad-spectrum antibiotics.

A spontaneous pneumomediastinum has different clinical implications, as it may be a sign of an ominous condition, such as esophageal perforation (which warrants urgent surgical treatment), or a relatively benign condition when associated with barotrauma and tear of the distal airways or acini. Clinical correlation and careful clinical observation are very important to distinguish these etiologies (Fig. 30-65).[91,92]

The classical differential diagnosis of masses in the anterior compartment includes enlarged lymph nodes, substernal goiter or thyroid neoplasm, thymic hyperplasia and thymic neoplasms, and germ cell neoplasms. Distinction among these can be made on the basis of the patient's age and clinical presentation, their position within the anterior mediastinum, and the appearance on CT or MR.

Thyroid masses invariably lie high in the anterior mediastinum and often displace or compress the trachea and esophagus. On CT, the thyroid has characteristic high attenuation on unenhanced images due to its iodine content, and multinodular goiter often presents with a very heterogeneous texture containing cystic and calcified opacities within a background of dense thyroid parenchyma. Ultimately, any high anterior mediastinal mass with these imaging characteristics and unequivocal contiguity with the thyroid gland on CT or MR is deemed to represent a thyroid neoplasm or multinodular goiter, until proved otherwise.[93]

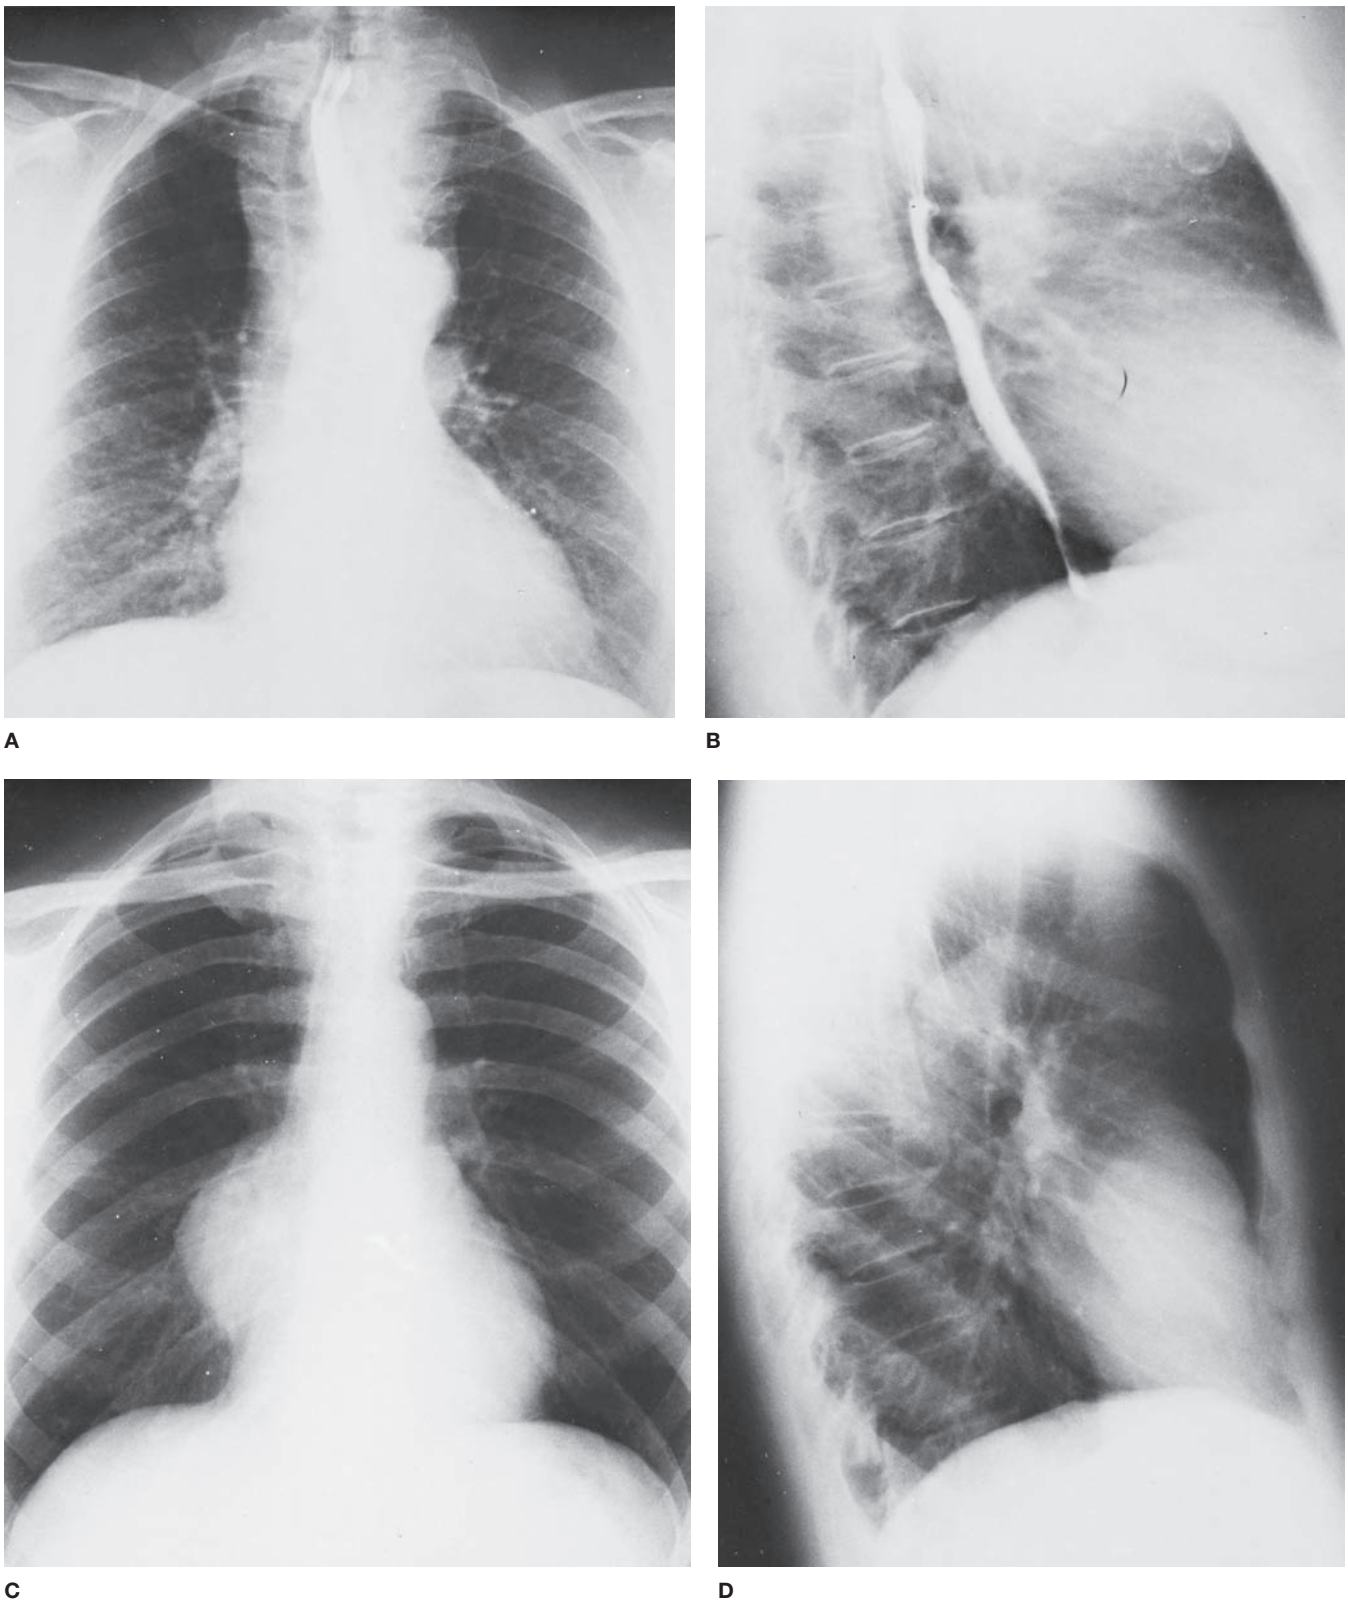


Figure 30-63 Radiographic spectrum of mediastinal masses: Substernal thyroid. **A.** PA view. A large mass in the neck extends below the clavicle. The trachea and esophagus are displaced to the right. **B.** Lateral view. The trachea and esophagus are also displaced posteriorly. Several calcifications are present within the mass. **C.** PA view. A discrete mass (thymoma) lies along the right heart border. **D.** Lateral view. The mass also overlies the anterior portion of the cardiac shadow. Despite being radiographically well circumscribed, the mass may be either invasive or noninvasive thymoma. CT is required for further characterization.

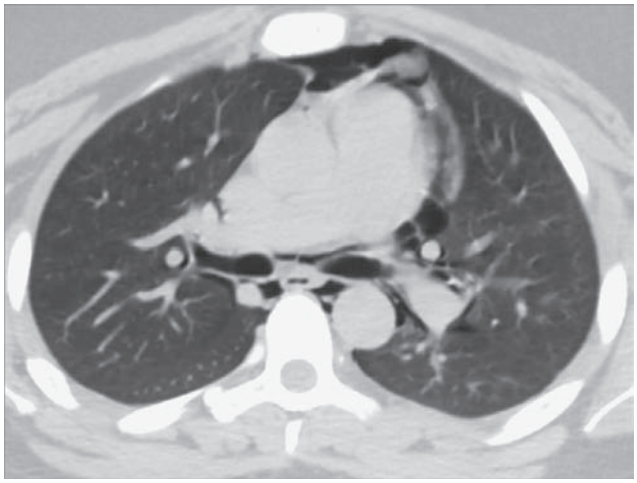
Figure 30-64 Lymphadenopathy: (**A**) PA and (**B**) lateral chest radiographs demonstrate marked widening of the bilateral paratracheal stripes and mild prominence of the bilateral pulmonary hila, compatible with mediastinal and hilar lymphadenopathy. (**C**) Axial noncontrast CT and (**D**) Coronal contrast-enhanced CT better demonstrate the extent of mediastinal and hilar lymphadenopathy. Pathology confirmed a large B-cell lymphoma. **E.** Axial FDG-PET at the level of the upper lung fields demonstrates increased glucose uptake within the enlarged mediastinal lymph nodes, indicative of increased metabolic activity. This study can be performed to monitor treatment response.

If an anterior mediastinal mass does not arise from the thyroid, the differential diagnosis of germ cell neoplasm, thymoma, and lymphoma can be challenging using imaging; tissue sampling is almost always necessary. Nonetheless, some clinical and imaging features may suggest a specific diagnosis. For example, germ cell neoplasms tend to occur in younger patients and are often heterogeneous—in particular, CT demonstration of fat and calcification within an anterior mediastinal mass is diagnostic of a teratoma.[94] Teratomas may also contain cystic components. Thymic hyperplasia or neoplasms tend to conform to the triangular shape of the thymus (particularly benign thymomas, although invasive thymomas and thymic carcinomas may have a more irregular configuration). Thymomas tend to occur in older patients and may be associated with the diagnosis of myasthenia gravis. Because of the presence of intracellular



A

Figure 30-65 Pneumomediastinum. **A.** Axial CT at the level of the mainstem bronchi demonstrates gas within the anterior, middle, and posterior mediastinal compartments, compatible with pneumomediastinum. **B.** Coronal CT demonstrates the full extent of the pneumomediastinum. Note absence of pneumothorax. There is also subtle pulmonary interstitial emphysema, denoted by linear lucencies parallel to the proximal airways. This patient had barotrauma related to a severe asthma exacerbation.

lipids in the normal thymus, thymic hyperplasia can be distinguished from thymomas and infiltration by lymphoma using proton chemical shift MR; signal loss is noted in out-of-phase sequences. Finally, lymphomas occur over a wide age range (with Hodgkin disease having a bimodal distribution) and are generally homogeneous on CT and MR, unless treated (Figs. 30-66 and 30-67).[95]

Lymphadenopathy in the thorax has an extremely broad differential diagnosis, and it is best assessed using CT or MR. Anatomically, the largest lymph nodal chains in the thorax can be divided in axillary, supraclavicular (which includes lower cervical chains), mediastinal, and bilateral hilar. Smaller chains include internal thoracic (mammary), anterior cardiophrenic (or paracardiac), and

Figure 30-66 Anterior mediastinal mass. (**A**) Axial contrast-enhanced CT and (**B**) Sagittal contrast-enhanced CT show a heterogeneous, well-circumscribed anterior mediastinal mass. The mass is mostly cystic, with a nodular component that measures fat attenuation. Enhancing components are also noted. **C.** Axial FDG-PET through the mass demonstrates lack of glucose uptake. The constellation of findings is diagnostic of a mature teratoma, a benign germ cell neoplasm.

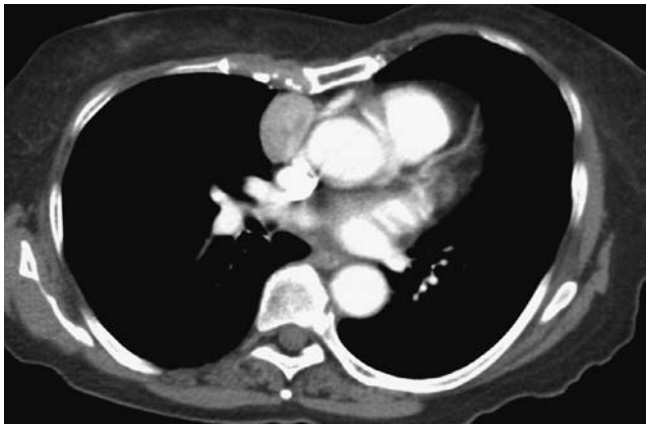

Figure 30-67 Anterior mediastinal mass. Axial contrast-enhanced CT demonstrates a homogeneous, enhancing, well-circumscribed anterior mediastinal mass along the anterior right heart border. Pathology confirmed a thymoma.

retrocrural. Mediastinal lymph node stations are further subdivided into prevascular, paratracheal (upper and lower, right and left), subaortic (or AP window), subcarinal, para-aortic, and paraesophageal.

A normal lymph node on CT or MR has an ovoid, reniform shape ("kidney shape") and a fatty hilum and measures less than 1 cm in its smallest diameter. An abnormal lymph node is frequently rounded, loses the delineation of the hilum, and measures more than 1 cm in its smallest diameter. It is important to emphasize that early neoplastic or infectious disease may be associated with "normal" lymph nodes on CT or MR, but "abnormal" lymph nodes on CT or MR are virtually never normal from a pathologic standpoint, even if the diagnosis is not clinically significant.

From an imaging perspective, establishing the etiology of mediastinal lymphadenopathy implies assessing the size, configuration, number, and location of the enlarged lymph nodes. Enhancement patterns on CT or MR have a limited role, although FDG uptake on PET/CT may be helpful. The presence of calcification is also an important sign in narrowing the differential diagnosis.

The following guidelines should be utilized in the general assessment of mediastinal and thoracic lymphadenopathy.[96–98]

Very large (measuring >2–3 cm), confluent, conglomerate lymphadenopathy is malignant until proven otherwise. Considerations include nodal metastasis and lymphoma, particularly high-grade, large B-cell lymphomas or Hodgkin disease. An anterior mediastinal, prevascular location favors lymphoma. Distribution of disease may help elucidate the origin of the primary neoplasm, in case the diagnosis is not obvious or previously established if one is cognizant of the typical lymphatic drainage pathways. For example, lung carcinomas present more frequently with ipsilateral hilar, subcarinal, and paratracheal lymphadenopathy; head and neck squamous cell carcinomas more often involve supraclavicular lymph nodes; breast carcinomas frequently involve ipsilateral axillary and internal thoracic lymph nodes; hepatocellular carcinomas usually involve anterior cardiophrenic lymph nodes (paracardiac nodes).

An increased number of nodes in disseminated lymphadenopathy, symmetric distribution involving multiple nodal stations, and moderately or substantially enlarged nodes suggest a low-grade lymphoproliferative disease, particularly chronic lymphocytic leukemia/small lymphocytic lymphomas (CLL/SLL). Note that early disease may present with only mildly enlarged lymph nodes.

Mild or moderately enlarged lymph nodes with a bilateral hilar and lower paratracheal distribution suggests the diagnosis of sarcoidosis.

Mild, bilateral, predominantly axillary lymphadenopathy can be seen in the setting of connective tissue diseases, such as systemic lupus erythematosus.

Mild disseminated lymphadenopathy can be seen in systemic infections, particularly "mono-like" syndromes caused by mononucleosis, CMV, and related infections.

Necrotizing lymphadenopathy may be seen in the setting of infectious lymphadenitis (particularly mycobacterial), but is also commonly seen in nodal metastasis.

Coarsely calcified lymph nodes, particularly mediastinal and hilar, suggest sequelae of granulomatous inflammation, including sarcoidosis and mycobacterial or fungal infection; however, treated malignancy and pneumoconiosis should also be considered in the differential diagnosis in the proper clinical setting.

Mild lymphadenopathy can be ascribed to a "reactive" etiology, including prior infections, congestive heart failure, or ILDs. Reactive lymphadenopathy is a diagnosis of exclusion.

Additional structures of the middle mediastinal compartment are the heart and central vessels. Aortic or aortic branch aneurysms can be suggested on chest radiographs by the presence of mediastinal widening and prominence of the aortic contours. Diagnostic confirmation and full characterization require CT or MR, typically with intravenous contrast. Duplication cysts of the foregut may arise from the esophagus or tracheobronchial tree and are also common in the middle compartment. These localized masses are smooth and well circumscribed; generally, they do not contain air, and their attenuation is low on CT (generally of simple fluid density) without contrast enhancement. However, duplication cysts containing highly proteinaceous fluid may have CT densities comparable to soft tissue, thus mimicking solid masses. As indicated earlier, MRI is useful in characterizing proteinaceous fluid and, thus, may be diagnostic in these cases. Bronchogenic cysts commonly occur at the tracheal carina or paratracheal region, whereas esophageal duplication cysts are characteristically located near the distal esophagus. However, esophageal and bronchogenic cysts may occur anywhere within the middle compartment.

A dilated (patulous) esophagus is sometimes seen on the chest radiograph as a long tubular mass in the middle compartment and is readily identified by CT. The significance of a patulous esophagus is its association with dysmotility disorders, such as achalasia, CREST syndrome, and presbyesophagus. Neoplasms of the esophagus or trachea may also present as more localized mediastinal masses by chest radiograph; usually, CT is required for recognition. Early esophageal neoplasms may involve primarily the mucosa and may not be well seen on the CT, even if clearly demonstrated on a barium swallow study or endoscopy. Hiatal hernias are readily diagnosed using CT. The presence of esophageal wall thickening is usually clinically relevant. Smooth and concentric wall thickening favors esophagitis, particularly reflux esophagitis; irregular and eccentric wall thickening is concerning for esophageal carcinoma.[99]

In the posterior (paraspinal) compartment, the most common radiographic abnormalities are neurogenic neoplasms. However, neoplasms or infections of the vertebral column may also present as masses in the posterior compartment. CT or MR usually distinguishes between a neurogenic neoplasm, which is unilateral and paraspinal in location, and lesions which erode or destroy the vertebrae and are generally present on both sides of the vertebral column. MR is the best modality to diagnose a neurogenic neoplasm (Figs. 30-68 and 30-69).[100,101] Other considerations in the posterior compartment include paraspinal hematoma in the setting of trauma, and rarely, extramedullary hematopoiesis in patients with hemoglobinopathies, myeloproliferative disorders, or bone marrow infiltration.

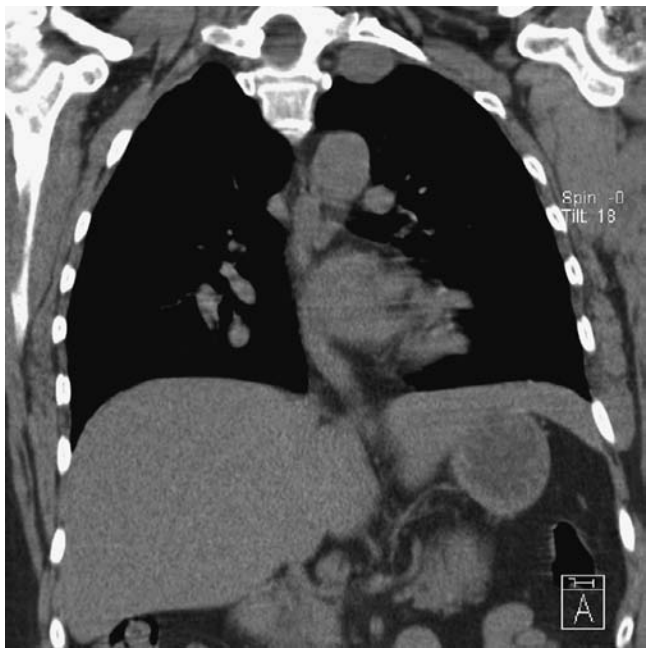

Figure 30-68 Posterior mediastinal mass. Coronal noncontrast CT shows a homogeneous, well-circumscribed posterior mediastinal mass in the left superior sulcus medially. Note absence of aggressive features by CT. Pathology confirmed a neurogenic neoplasm (schwannoma).

OUTLOOK FOR THE FUTURE

This chapter provides a modern, evidence-based overview of the wide scope and central role imaging plays in the diagnosis and management of thoracic diseases. Currently, it is inconceivable to imagine practicing thoracic medicine and surgery without the constant support of radiologist consultants and their armamentarium of basic and advanced imaging modalities.

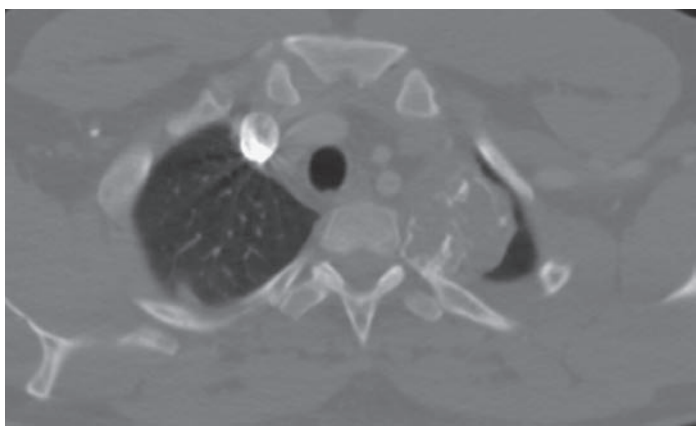
Predicting the long-term future is most often a futile endeavor. However, there are clear trends that allow us to attempt to forecast likely innovations and changes in the field of thoracic imaging over the next decade.

The most important trend is demonstrating that imaging-based diagnostic and therapeutic approaches are beneficial to patient care, improving morbidity and mortality, and decreasing the overall cost of care. This trend is imposed by the current global economic environment and the mandate to increase the efficiency of healthcare systems by diminishing waste and redundancy and eliminating procedures that do not positively impact patient outcomes. Future clinical trials will emphasize what imaging can offer to empower practitioners to diagnose thoracic diseases earlier, faster, and in a less invasive manner. In addition, studies will address delivery of therapeutic approaches that will be more effective and less costly and contribute to better patient outcomes and quality of life.

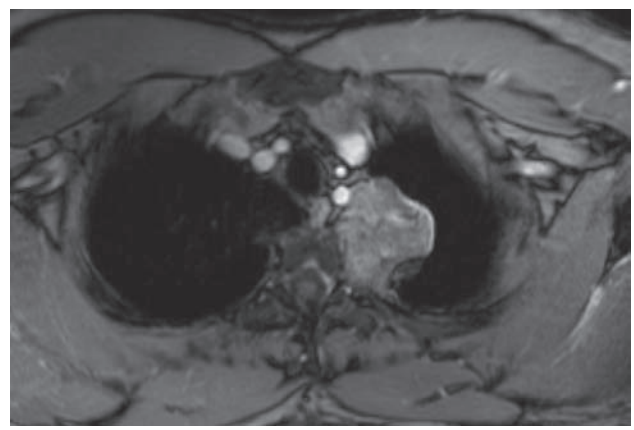
Another important trend is combining functional and anatomical information within a single imaging modality. PET/CT already offers this capability by coupling anatomic and metabolic imaging. MR and CT, when performed with 4D cine sequences, may provide insight into chest wall, central airway, and lung mechanics, as well as detect air trapping related to small airway disease. MR performed with specific pulse sequences may provide surrogates of tissue characterization. Thoracic oncology will greatly benefit from new molecular imaging agents that target important cellular and subcellular biochemical pathways associated with carcinogenesis. Furthermore, molecular imaging will allow in vivo real-time assessment of the genetic and epigenetic processes underlying a number of pathologic conditions in the heart, lungs, and mediastinum, leading to more targeted, individualized, and, ultimately, more effective therapeutics.

Quantitative imaging will be another trend, which will aim to provide a much better assessment of disease severity, particularly for diffuse lung diseases, such as COPD and ILD. Instead of simply reporting the presence of a specific disease and, at most, subjectively classifying the severity of the disease, radiologists will utilize computational image analysis tools to provide accurate disease quantification that reflects, and highly correlates with, physiologic metrics. Quantitative imaging utilizing computer-assisted detection and quantification of disease-specific imaging patterns on CT, MR, and PET/CT will, therefore, allow development of biomarkers that will reflect disease prognosis and response to therapies far more accurately and earlier then currently possible. Future drug trials will particularly benefit from this approach.

More distant on the horizon is computer-assisted diagnosis utilizing pattern recognition and classification. Its development will allow radiologists and clinicians to improve diagnostic accuracy, particularly in complex diffuse diseases or in the setting of coexisting diseases.



A



B

Figure 30-69 Posterior mediastinal mass. **A.** Axial noncontrast CT demonstrates a large left posterior mediastinal mass that appears to arise from the left posterior second rib, which demonstrates expansion and cortical destruction. Note irregular calcifications within the mass. **B.** Axial T1-weighted postcontrast MR shows moderate enhancement throughout the lesion. The constellation of findings suggests a primary bone neoplasm with chondroid differentiation. Pathology confirmed a chondrosarcoma.

Finally, it is of interest to consider what role plain chest radiography will play in the future, if any. Practical and economic considerations imply that chest radiographs will not disappear soon, given their low cost, very low radiation dose, universal availability, portability, and capacity to address basic clinical questions. Nevertheless, we hypothesize that this century-old technique will not last another century; rather, it will be replaced in the next decades by newer generations of CT scanners that will offer similar qualities of portability and ultralow radiation dose, along with vastly improved diagnostic accuracy and 4D capabilities.

Irrespective of the many uncertainties, challenges, and exciting prospects for the future, it is undeniable that thoracic imaging will continue to be an indispensable companion to the practicing physician caring for patients with thoracic disorders and a central component of modern pulmonary medicine.

ACKNOWLEDGMENT

The authors dedicate this chapter to the memory of the late Wallace Miller, Sr., MD, who authored the previous version. Dr. Miller was an enlightening presence and a major source of inspiration to generations of thoracic radiologists and pulmonologists.

CHAPTER 31

Thoracic Ultrasonography

Lisa Chen
Paul H. Mayo

INTRODUCTION

Thoracic ultrasonography is a readily available, noninvasive imaging method that has proved particularly useful for pulmonary and critical care specialists. The technique is easy to learn and engenders multiple applications related to lung and pleural disease. The ease of use and portability of ultrasonography allows physicians to perform point-of-care imaging and reduce dependence on traditional thoracic imaging techniques, such as chest computerized tomography (CT) and standard radiography (CXR).

This chapter focuses on use of ultrasonography for diagnosis and management of pleural and lung diseases and emphasizes those areas that are of particular interest to the pulmonary specialist. Many elements of thoracic ultrasonography that have utility for the pulmonary consultant are also germane to critical care medicine. However, this chapter focuses on the broad context of pulmonary medicine, rather than the elements of thoracic ultrasonography that are specific to critical care. Furthermore, the chapter is written with the assumption that the pulmonary consultant will personally perform image acquisition, interpret the image, and apply results at the bedside—a paradigm that is different from the standard one of thoracic imaging requiring reliance on a radiologist's acquisition and interpretation of the image. While this approach is advantageous with regard to cost and clinical efficiency, it requires technical and cognitive skills. An additional advantage of clinician-performed, point-of-care thoracic ultrasonography is that it couples imaging results with the clinician's overall knowledge of the case. Indeed, thoracic ultrasonography is not performed in vacuo, rather, it is always combined with other key elements of clinical evaluation, such as the history, physical examination, and laboratory analysis. Ultrasonography is an *additional* tool in the diagnosis and management of pleuropulmonary disease.

TRAINING IN THORACIC ULTRASONOGRAPHY

The goal of training in thoracic ultrasonography is, of course, to enable clinical competence in performing the procedure. "Competence" must be defined to facilitate development of specific learning objectives as the goals of training. One pragmatic approach is to establish a reasonable minimum standard for competence. The Statement of Critical Care Ultrasonography provides a well-defined description of training goals in pleural and lung ultrasonography.[1] The statement is a good starting point for pulmonary specialists who seek training in the field, and the competencies outlined should constitute the initial learning objectives.

No definitive literature is available to guide the optimal duration of training or the minimal number of studies to be performed and interpreted. No widely accepted course of study for the cognitive elements of the field exists, and, at present there is no formal certification process.

Despite these limitations, many clinicians are competent in thoracic ultrasonography. Compared with the training required in the complex fields of cardiac and abdominal ultrasonography, training in thoracic ultrasonography is straightforward. The authors have considerable experience in training many fellows and attending physicians in thoracic ultrasonography and have found that a motivated learner will achieve skill in the basic elements of pleural and lung ultrasonography within several hours of formal teaching. Training should include practicing image acquisition, initially on normal human models and then on patients at the bedside. In addition, training should include a review of a comprehensive image set of normal and abnormal findings, enabling the learner to recognize a wide range of findings during their initial encounter at the bedside. The cognitive elements of the field may be learned through reading chapters or review articles.[2–4] For more advanced training, comprehensive textbooks are available.[5,6] Formal courses on thoracic ultrasonography are offered. In addition, the learner may choose to develop a local training resource, which requires identification of a local expert who is able to help with bedside training.

EQUIPMENT NEEDS

Thoracic ultrasonography may be performed using a wide variety of ultrasound machines. Virtually any machine that is used for or cardiac or abdominal ultrasonography will generally yield adequate image quality. A probe designed for cardiac ultrasonography, employing a frequency range of 3.5 to 5.0 MHz works well, as the small footprint of the probe allows for easy placement between rib interspaces; frequency selection allows for adequate penetration to enable imaging the deeper structures of the thorax. A larger, curvilinear abdominal probe gives serviceable images as well. A linear vascular probe using a frequency range of 7.5 to 10.0 MHz is required for detailed imaging of the pleural surface; the higher frequency improves the resolution, but at the sacrifice of signal penetration.

Every machine has its own design characteristics, so that the operator must adapt machine setup to optimize image quality. What works well using one machine may not translate into the same effectiveness when using another. Some machines have presets for thoracic ultrasonography, but they may not necessarily be the optimal setup for thoracic imaging. Consequently, the operator must be prepared to alter machine settings from standard cardiac, abdominal, or thoracic presets. Machines from the 1990s that lack extensive postimage processing often give excellent results. Modern, high-end cardiac echocardiography machines give excellent cardiac image quality, but they often yield poor near-field images. Many modern portable machines have acceptable thoracic imaging capability and provide the additional advantage that they are designed specifically for point-of-care scanning.

SCANNING TECHNIQUE

For the pulmonary specialist, thoracic ultrasonography may be performed with the patient in a seated position. The supine scanning position is more typical for the critically ill patient, but it has the disadvantage that it is difficult to scan the posterior chest. The standard transducer orientation is the transducer indicator oriented in a cephalad position, defining the primary scanning plane in a longitudinal axis. With the screen indicator placed to the left of the screen, images on the left side of the screen represent cephalad structures.

Machine control is integral to good quality image acquisition; hence, total, near, and far field gains must be adjusted for optimization. Depth should be set to place the target structure in the middle of the screen, and the focal point should be adjusted for optimal image quality of the target structure. Using adequate ultrasound coupling gel and application of firm pressure, the transducer is applied perpendicular to the chest wall and adjusted

to examine the rib interspace. Adjacent interspaces are examined by sliding the transducer to the next interspace. In this way, the examiner performs a scan line while the transducer is moved over the chest wall. In an orderly fashion, multiple adjacent scan lines are performed so that the entire chest wall can be imaged. Using this approach, the examiner obtains multiple, two-dimensional, tomographic ultrasound planes of the thorax, in effect, developing a three-dimensional model. If a focal abnormality is identified, the examiner may then perform a more detailed ultrasonographic examination of the area.

Aerated lung blocks ultrasound, whereas the liver and spleen do not. Consequently, to visualize the peridiaphragmatic area, the transducer may be angled such that the scanning plane passes through the liver or spleen to obtain an adequate image window. In addition, bone also blocks ultrasound. So, when an abnormality lies deep to a rib, the transducer may need to be angled to look over or under the rib. Conversely, pleural effusion and consolidated lung each transmit ultrasound. Their presence may yield a window for examination of the heart, mediastinum, or, in the case of pleural effusion, the lung. While the standard scanning plane is longitudinal, a transverse plane may be utilized on occasion. This may be required when examining for a "lung point" or to establish an optimal angle for needle insertion for access to a lung mass. Most thoracic ultrasonography is performed using a cardiac or abdominal transducer. A vascular transducer is preferred if detailed examination of pleural anatomy is required.

PLEURAL ULTRASONOGRAPHY

Ultrasonography is particularly effective for identifying pleural fluid, since fluid is either anechoic or hypoechoic relative to adjacent soft tissue. While physical examination is neither specific nor sensitive for detection of pleural effusion,[7] a pleural effusion as small as 5 cc may be identified with ultrasonography.[8] Pleural ultrasonography is superior to standard chest radiography in identifying pleural effusions and in differentiating a pleural effusion from pleural thickening or atelectasis.[7,9] Compared with chest CT, pleural ultrasound demonstrates 93% sensitivity and specificity for identification of pleural effusion.[10] When a patient has complete hemithoracic opacification on CXR, ultrasound has 95% sensitivity for identification of pleural effusion.[9]

IDENTIFICATION OF PLEURAL FLUID

The pulmonary specialist will generally examine the patient in the seated position. Pleural fluid, unless loculated, distributes by gravitational effect to the most dependent part of the thorax. Therefore, the ultrasonography examination focuses on the lower, dependent area of the posterior thorax.

The examiner seeks to identify three characteristic findings indicating the presence of a pleural effusion: (1) An anechoic or hypoechoic space that is surrounded by typical anatomic boundaries. This space represents the pleural effusion. Diagnosis requires definitive identification of a relatively echo-free space surrounded by the typical anatomic boundaries (Fig. 31-1; Video 31-1). (2) Typical anatomic boundaries. This element requires definitive identification of the chest wall, lung surface, and diaphragm. The heart may form an anatomic boundary on the left side. Recognition of the diaphragm requires definitive identification of the subdiaphragmatic organs (including liver, spleen, and kidneys) (Fig. 31-2; Video 31-2). (3) Dynamic changes typical of a pleural effusion, as described later) (Video 31-3).

Usually, pleural fluid is hypoechoic relative to the liver or spleen. However, complex pleural effusions may demonstrate echogenicity similar to these organs. The chest wall, as a "stationary" structure, does not show dynamic changes with respiration. Lung that is adjacent to, or surrounded by, pleural fluid is compressed by the pleural effusion and, consequently, is airless. The atelectatic lung, which is of tissue density and presents a pattern of alveolar consolidation on ultrasonography examination, is visualized as "floating" in the pleural fluid. It moves in both cardiac- and respiratory-phasic fashion—one of the typical dynamic changes required for identification of pleural effusion. Other typical dynamic changes include those of swirling debris or fibrin strands agitated by respiratory

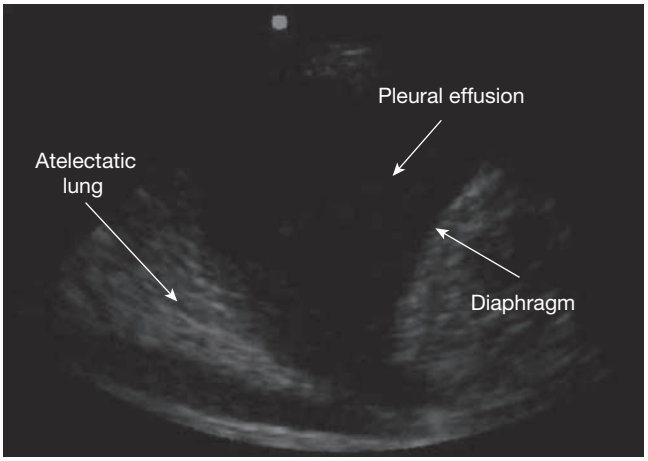

Figure 31-1 Typical anatomic boundaries that surround a hypoechoic pleural effusion. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the seventh intercostal space in the right midaxillary line.

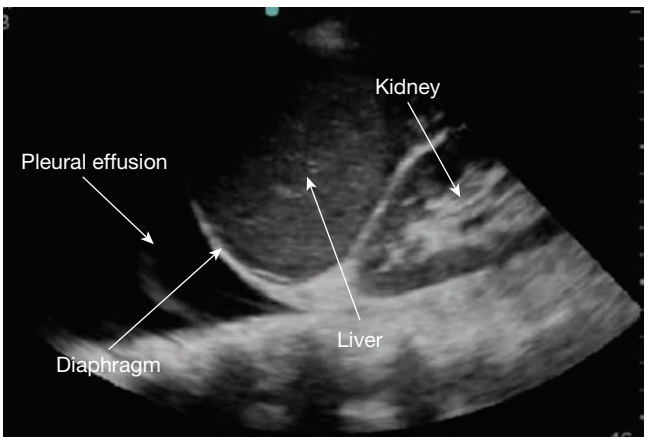

Figure 31-2 Pleural effusion above the diaphragm, liver, hepatorenal space, and kidney. These structures must be positively identified before thoracentesis to avoid inadvertent subdiaphragmatic device insertion. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the eighth intercostal space in the right midaxillary line.

or cardiac motion. On occasion, a highly cellular pleural effusion forms a layer because of gravitational effects if the patient is immobile for a period of time; patient movement disrupts the fluid-to-cell interface.

Identification of the diaphragm is imperative for localizing a pleural effusion and enabling safe performance of thoracentesis. Subdiaphragmatic device insertion is a serious complication of thoracentesis.

The diaphragm is a curvilinear structure lying above the spleen and liver, which demonstrates respirophasic movement. The inexperienced operator may mistake the hepatorenal or splenorenal space for the diaphragm, as they appear as curvilinear structures that resemble the diaphragm. The overlying spleen or liver may then be mistaken for an echo-dense pleural effusion. This may result in inadvertent subdiaphragmatic device insertion while attempting a thoracentesis with potentially catastrophic consequence to the patient (Fig. 31-2; Video 31-2). It is helpful to identify the kidney when scanning below the diaphragm to avoid this dangerous pitfall. Identification of the chest wall allows measurement of the depth required for needle penetration when planning thoracentesis. Identification of the underlying lung allows the operator to limit the depth of needle insertion to avoid visceral pleural laceration.

■ CHARACTERIZATION OF THE PLEURAL EFFUSION

Ultrasound examination can be helpful in distinguishing transudative from exudative effusions. Transudates lack constituents that are ultrasound reflectors and are, therefore, echo-free (anechoic) (Fig. 31-3; Video 31-4). An anechoic pleural effusion is very likely to be transudative, although some may have a complex, nonseptated pattern.[11] Slow flowing movement of ill-defined heterogeneous elements within a hypoechoic effusion, referred to as swirling, may be observed with a transudate, but its presence suggests an exudative cellular effusion, such as that associated with malignancy.[12]

A heterogeneously echogenic pattern, with swirling echoes, septations, fronds, or strands is typically observed with exudates. However, very cellular exudates, such as empyema or hemothorax, may demonstrate homogeneous echogenicity (Fig. 31-4; Video 31-5).[13] Exudates are usually echogenic, but are occasionally anechoic. The presence of strands, debris, or septations is characteristic of a parapneumonic effusion or empyema.[14]

The presence of a septated effusion on ultrasonography suggests the need for fibrinolytic therapy or surgical intervention, prolonged chest tube drainage, and longer hospital stay when compared with

Video 31-3 Dynamic findings typical of a pleural effusion, including movement of atelectatic lung, movement of the diaphragm, and movement of echogenic elements within the effusion (plankton sign). The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the right midaxillary line. *Access at www.fishmansonline.com*

effusions lacking ultrasound complexity (Fig. 31-5; Video 31-6).[15] Pleural ultrasound is superior to CT scanning in detecting pleural fluid complexity.[16]

By making a number of defined measurements, the volume of a pleural effusion may be reasonably estimated using ultrasonography.[17] For clinical purposes, it generally suffices to characterize the effusion as small, moderate, or large. Finally, pleural effusions may become loculated collections, which characteristically develop in nondependent positions and fail to move with changes in body position. The loculum may be thick-walled and often has internal hyperechoic complexity.

■ PERFORMANCE OF THORACENTESIS

Pleural ultrasonography facilitates performance of thoracentesis. When compared with physical examination combined with standard chest radiography, ultrasonography is superior in identifying a safe site for needle insertion.[7] A meta-analysis supports the use of ultrasonography to guide thoracentesis to reduce the risk of pneumothorax.[18] As needle insertion is required not only for simple thoracentesis, but also for a wide variety of pleural procedures requiring use of guidewires and device placement, pleural ultrasonography is an essential component of interventional practice.

Thoracic ultrasonography allows for identification of a safe site, depth, and angle for needle insertion. Using the technique of scan lines described previously, the operator identifies the pleural effusion and establishes the best site and trajectory for needle insertion and, hopefully, avoiding any injury to structures that surround the fluid collection. The site is marked by indenting the skin with a needle cap. Just prior to sterile skin preparation, the operator rescans to confirm site selection, depth of needle penetration required,

Video 31-4 Anechoic pleural effusion, likely a transudate. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the right midaxillary line. *Access at www.fishmansonline.com*

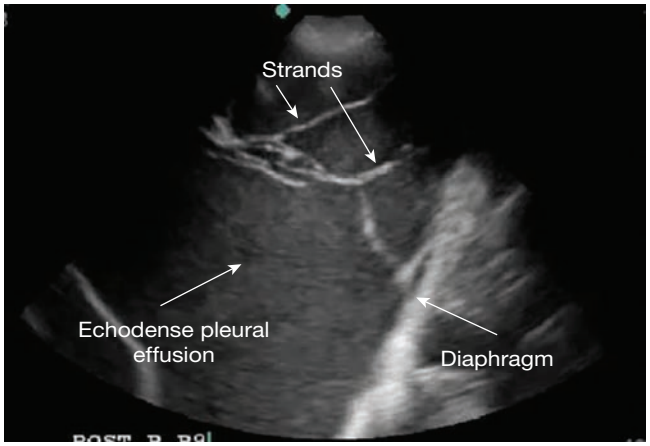

Figure 31-4 Pleural effusion with a homogeneously echogenic pattern and mobile strands suggestive of an exudate. Thoracentesis showed a hemothorax. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the right midaxillary line.

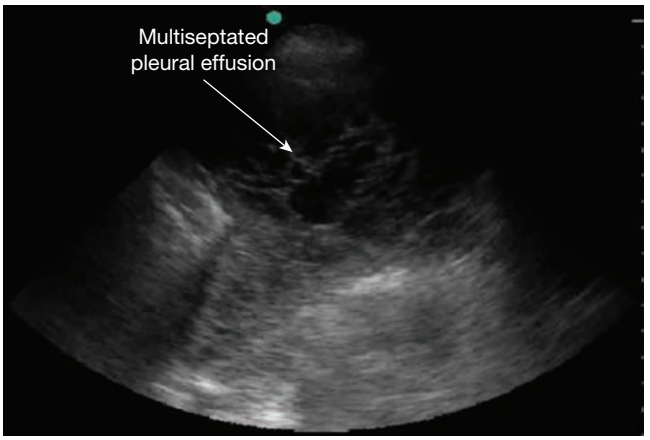

Figure 31-5 Multiseptated pleural effusion. The pattern is consistent with a complex parapneumonic effusion or empyema that will likely require fibrinolytic treatment or surgical drainage. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the fourth intercostal space in the left midaxillary line.

and the angle of insertion. The procedure is then performed using an angle of insertion of the needle and syringe assembly that duplicates the angle of the transducer employed at the time of the final scan. No patient movement is permitted between the final scan and needle insertion, as this may cause movement of the fluid within the thorax.

For the pulmonary specialist, thoracentesis is usually performed with the patient in the seated position. For more complex procedures requiring tunneling of a catheter or chest tube insertion, the patient may be supine or in lateral decubitus position. Using the same scan line technique as utilized for the upright patient, the operator identifies the pleural effusion based on the previously described ultrasound criteria; once again, the site, angle, and depth for safe needle insertion are determined. Immediately before final skin preparation, the operator rescans to confirm that it is a safe site for device insertion and, without patient movement, proceeds with device insertion.

While ultrasonography facilitates pleural access, pitfalls exist. Although pneumothorax is a rare occurrence with ultrasound-assisted thoracentesis, the operator should always check for pneumothorax before and after the procedure by examining the anterior chest for lung sliding (see Lung Ultrasonography). The presence of sliding lung rules out pneumothorax. The most common cause of pneumothorax following ultrasound-assisted thoracentesis is the presence of nonexpandable lung, rather than visceral pleural laceration.[19]

In selecting a site, the operator needs to be aware that the lung may move in a respirophasic fashion. Safe site selection is predicated on the absence of intermittent respirophasic movement of lung into the needle path. When such movement is observed, constituting the so-called "curtain sign," needle insertion is contraindicated at that point.

In performing ultrasound-assisted thoracentesis, several causes may account for failure of fluid return, despite good site selection.

In edematous or obese patients, the operator may press the probe into the skin surface with some force, causing a compression artifact. As the measurement for depth of needle penetration is made when the skin is indented by the probe, if the skin has rebounded, the distance of needle penetration required may be greater than that predicted during initial measurement.

In performing the procedure in patients who lack subcutaneous tissue, the operator may place tension on the skin at the time of mark placement, displacing the skin from the underlying soft tissue. When the tension is released, the mark may rebound to a new position on the chest wall that is not optimal for needle insertion.

While it is not necessary to use real-time needle guidance in performing ultrasound-assisted thoracentesis, failure of needle insertion to yield fluid may warrant rescanning to confirm appropriate site selection. Occasionally, a "dry" tap results from tissue impaction in the needle during insertion or as a result of septations occluding the needle.

PLEURAL PATHOLOGY

In addition to identification of pleural fluid, ultrasonography allows visualization of a variety of pleural pathologies.

A number of pleural diseases cause echogenic abnormalities within the pleural space. Some of these solid pleural abnormalities may coexist with pleural effusions. For example, metastatic pleural disease often occurs with a coexisting pleural effusion, such that the pleural effusion acts as an acoustic window that allows ready observation of the metastatic disease. Metastatic tumors are usually hyperechoic and are often multiple (Fig. 31-6; Video 31-7). They may demonstrate a variety of different sizes and shapes, such as nodular, hemispheric, or circular. The tumors may be broad-based

Video 31-5 Pleural effusion with homogeneous echogenic pattern and mobile strands, suggestive of an exudate. Thoracentesis showed a hemothorax. The image was obtained using a 3.5-MHz transducer. Figure 31-7 Complex, multiloculated pleural effusion with thick septations caused by an empyema. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the right midaxillary line.

or have frond-like protrusions. Chest wall or diaphragmatic invasion may cause disruption of normal tissue interfaces and direct extension of tumor into adjacent structures, each of which is visible with ultrasonography. Ultrasonography is superior to chest CT for the diagnosis of transpleural chest wall invasion.[20]

Benign pleural tumors, such as benign mesothelioma, chondroma, lipoma, or thoracic sclerosis are very uncommonly found during pleural ultrasonography. They are usually hyperechoic, have a distinct capsule, and do not demonstrate invasion through adjacent tissue planes. Ultrasonographic morphology is not sufficiently diagnostic, but the technique may be used to guide biopsy.

Primary pleural malignancy, such as malignant mesothelioma, has ultrasonographic features that include pleural thickening with unclear and irregular borders, nodularity, and evidence of chest wall or diaphragmatic invasion.

Inflammatory diseases that involve the pleural space are characteristically caused by infection. Both parietal and visceral pleurae are thickened and hyperechoic, while the underlying lung may demonstrate an alveolar consolidation pattern. Within the pleural fluid collection, linear mobile echogenic elements float freely. Over time, the elements may thicken and divide the effusion into multiple fluid-filled cavities that have variable echogenicity. Eventually, the infected space becomes a multiseptated conglomerate of thick-walled cavities (Fig. 31-7; Video 31-8). A homogeneously echogenic empyema may be so dense that no dynamic findings are discernible within the pleural collection. This makes differentiation from the underlying liver or spleen difficult and may even complicate delineation of the diaphragm, which is a key element in identifying a safe site for device insertion.

Pleural fibrosis shows variable echogenicity, so it may be difficult to differentiate fibrosis from an adjacent pleural effusion. Color-flow Doppler is helpful in distinguishing between the two.[21] Color-flow Doppler signals are generally absent from areas of fibrosis but are present in pleural effusions due to small ultrasound reflectors moving within the fluid.

LUNG ULTRASONOGRAPHY

Lung ultrasonography is performed using the same equipment and scanning techniques as used for pleural ultrasonography. As with pleural ultrasonography, the results are immediately available for integration into the standard tools of patient evaluation, including the history, physical examination, and laboratory analysis. Lung ultrasonography is designed to be used in a goal-directed fashion at the point of care.

In a series of landmark articles, Daniel Lichtenstein described and validated the important elements of the field of lung ultrasonography, the clinical utility of which is now supported by a growing literature. The following discussion is based on Lichtenstein's terminology.[5]

■ BASIC FINDINGS OF LUNG ULTRASONOGRAPHY

Several basic findings are central to the diagnostic application of ultrasonography to lung diseases. These include lung sliding, lung pulse, A lines, B lines, and consolidation. Each is discussed in subsequent sections.

Lung Sliding

When the transducer is placed perpendicular to the chest wall and orientated to enable imaging through rib interspaces, the pleural line is visualized approximately 5 mm deep to the rib periosteum. Normally, examination of the pleural line demonstrates a shimmering to-and-fro movement that is respirophasic—the so called "lung sliding," which is caused by movement of the visceral pleura against the parietal pleura during breathing (Fig. 31-8; Video 31-9).

The presence of lung sliding indicates that, at that point of examination, no pneumothorax is present; that is, the lung is fully

Video 31-7 Pleural effusion with pleural masses on the diaphragm. The patient had metastatic breast cancer in the pleural space. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the left midaxillary line. *Access at www.fishmansonline.com*

Video 31-8 Complex multiloculated pleural effusion with thick septations caused by an empyema. The transducer was in longitudinal orientation and placed perpendicular to the chest wall. The examiner moved the transducer over several intercostal spaces to show the extent of the fluid collection. The scan line is in right midaxillary line. *Access at www.fishmansonline.com*

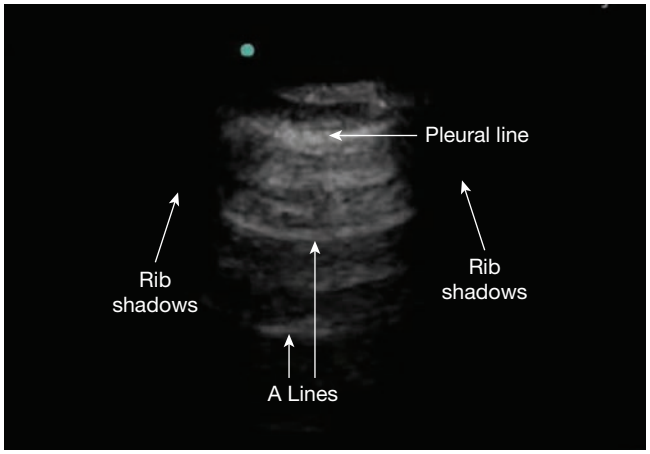

Figure 31-8 Pleural line, A lines, and adjacent rib shadows. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line.

inflated against the inside of the chest wall.[22] Lung sliding can be detected rapidly over the anterior upper chest by moving the probe over multiple interspaces. Since a loculated pneumothorax is very uncommon, in the supine or upright patient, examination of several anterior interspaces suffices to rule out pneumothorax. Free air in the pleural space rises to the nondependent part of the thorax, unlike fluid, which gravitates to the dependent position. Lung sliding is generally more prominent at the base of the lung as a result of the effect of diaphragmatic movement on lung inflation; lung sliding may be more difficult to detect at the lung apex. To optimize visualization of lung sliding, the ultrasound machine gain should be decreased and depth adjusted to place the pleural line in center of the screen.

A finding related to lung sliding is lung pulse. If a normal subject suspends respiration, lung sliding is temporarily absent; however, cardiophasic movement of the pleural line continues due to the lung movement that derives from transmission of cardiac contraction. The finding of lung pulse has the same implication as lung sliding; when noted, there is no pneumothorax at the site of the examination.

While lung sliding and lung pulse, when present, rule out pneumothorax, their absence is less helpful (Video 31-10). The absence of lung sliding indicates the *possibility* of pneumothorax. Other causes for absence of lung sliding include pleurodesis, apnea, mainstem bronchial obstruction, giant lung bullae, and severe parenchymal lung disease. The absence of lung sliding should be correlated with the clinical context. For example, if a patient demonstrates lung sliding before an ipsilateral thoracentesis or central-line insertion, the absence of lung sliding following the procedure suggests a very high probability of a procedure-related pneumothorax. On the other hand, the patient who has had prior chemical pleurodesis will lack lung sliding upon initial ultrasonographic evaluation.

While the absence of lung sliding is only indicative of the possibility of pneumothorax, it is still feasible to diagnose the disorder using lung ultrasonography, based on identification of a so-called "lung point."[23]

Most pneumothoraces result in only partial collapse of the affected lung; hence, the partially deflated lung is, at some point, still apposed to the chest wall. Under these circumstances, when the transducer is placed into an anterior interspace, no lung sliding will be noted, as the lung is not inflated against the inside of the chest wall. More laterally, lung sliding may become apparent if there is partial collapse of the lung. At the interface between the aerated lung and the pneumothorax space, the lung will be seen to enter the scanning plane in respirophasic manner (Video 31-11). This interface is called the *lung point*. Identification of a lung point is diagnostic of pneumothorax and allows for an estimate of pneumothorax size. While a lung point is 100% specific for pneumothorax, its sensitivity depends on the skill of the examiner; furthermore, a very large pneumothorax will not have a lung point. High-frequency vascular probes are useful in examining for lung point.

A Lines

Once the pleural line has been examined, the depth setting on the machine is increased to examine deeper structures within the thorax. The normal lung reveals *A lines,* which are one or more horizontally orientated lines visible deep to the pleural line (Fig. 31-8; Video 31-9). When multiple, they are equidistant; their separation distance corresponds to the distance between the chest wall and pleural line. A lines are reverberations of the pleural line caused by echoes reflecting off the air just deep to the pleural line, which then reflect off of the probe face. When this reflection returns to the probe, it appears on the screen as an ultrasound interface similar to the pleural line, but twice as far away. A lines may be single or multiple, but they are always separated by the same distance. In the presence of sliding lung, A lines indicate normally aerated lung. When present without lung sliding, they suggest the possibility of a pneumothorax. A lines correlate with a normal aeration pattern seen on a CT scan.[24]

B Lines

Using standard scanning technique and a depth set to visualize deeper structures, B lines may be observed instead of A lines. B lines have several distinct characteristics: (1) They are vertical in orientation; (2) one or more per field may be seen; (3) they extend to bottom of the device screen; (4) they originate at the pleural interface; (5) they move with the pleural interface (if it is mobile); and (6) they efface A lines where A lines and B lines intersect (Fig. 31-9; Video 31-12). The presence of B lines correlates with an interstitial

Video 31-9 This video demonstrates the presence of lung sliding. The image is obtained using a 7.5-MHz vascular transducer. The transducer is in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line. The resolution of the 7.5-MHz transducer is superior to that of the 3.5-MHz transducer at the expense of reduced penetration (See also Video 78-1). *Access at www.fishmansonline.com*

Video 31-10 Absence of lung sliding. The image was obtained using a 7.5-MHz vascular transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line. The resolution of the 7.5-MHz transducer is superior to that of the 3.5-MHz transducer, although depth of penetration is reduced (See also Video 78-2). *Access at www.fishmansonline.com*

Video 31-11 Lung point. A pneumothorax has caused partial deflation of the lung. Respirophasic movement of the partially deflated lung into the pneumothorax space is seen. The image was obtained using a 7.5-MHz vascular transducer. The transducer was in transverse orientation and placed perpendicular to the chest wall to scan through the fifth intercostal space in the right anterior axillary line (See also Video 78-4). *Access at www.fishmansonline.com*

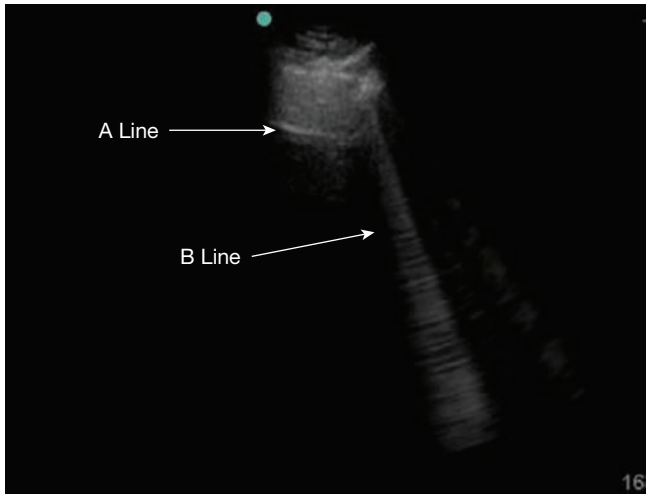

Figure 31-9 B lines. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line.

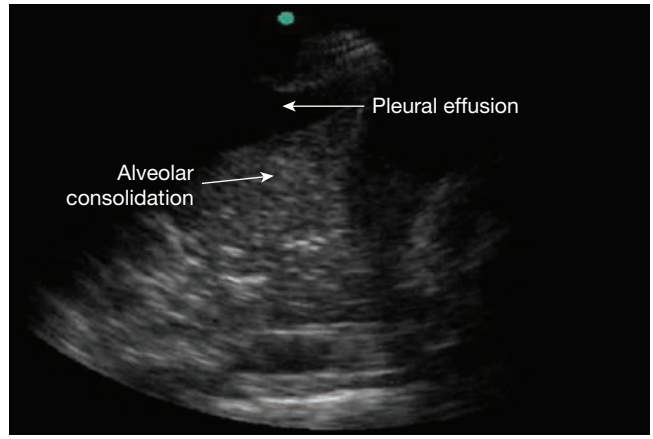

Figure 31-10 Alveolar consolidation of the left lower lobe and pleural effusion. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the left posterior axillary line.

pattern or alveolar abnormalities noted on CT scanning (reticular pattern or ground glass abnormality).[25]

B lines result from of any interstitial infiltrative process, such as inflammation, neoplasm, fibrosis, or edema.[26–30] B lines may be focal, scattered, or profuse in distribution, based on the underlying disease process. Disorders associated with a granular pattern on standard chest radiography or with ground glass opacification on chest CT are associated with B lines.

As with any radiographic abnormality, clinical correlation is required to determine the cause of B lines. For example, normal individuals often have one or two inconsequential B lines on examination of the lateral lower rib interspaces. More than two B lines in a single field is considered significant. Pneumonia may be manifest with focal B lines detected over the involved lobe or segment. Pulmonary fibrosis results in scattered B lines, whereas cardiogenic pulmonary edema yields profuse bilateral B lines. Pleural morphology may be useful in distinguishing B lines related to elevation of left atrial pressure from those caused by a primary lung process. Typically, the B lines noted in cardiogenic pulmonary edema are associated with a smooth pleural surface, while those seen in primary lung injury manifest an irregular pleural surface.[30] As B lines originate from the area of the visceral pleura, their presence rules out pneumothorax.

Consolidation

Consolidated lung is manifest as tissue density on ultrasound.[31] Its echogenicity is similar to that of the liver (sonographic hepatization of lung) (Fig. 31-10; Video 31-13). Consolidation may be localized to a specific lobe or segment of the lung and may also be observed in the lung periphery as a subpleural consolidation pattern. Within the consolidated lung, punctate, hyperechoic foci are often visible. These foci represent air retained within the bronchi. If they move in respirophasic manner, the finding indicates patency of the bronchus supplying that portion of the lung (Video 31-14).[32] Demonstration of consolidation on lung ultrasonography correlates strongly with results of chest CT scanning.[25]

As with chest radiography and CT scanning, the finding of alveolar consolidation on lung ultrasonography is not diagnostic. While pneumonia may result in alveolar consolidation, so will atelectasis (compressive, resorptive, or cicatricial). Severe pulmonary edema, with complete filling of the alveolar compartment, and infiltrative processes, such as tumor, may result in the ultrasonographic finding of lung consolidation. While lung ultrasonography identifies consolidation, the pulmonary specialist determines its cause.

■ ADVANCED LUNG ULTRASONOGRAPHY

A wide variety of additional lung ultrasound findings have been described. Mastery of the basic findings is the first step of training for the pulmonary specialist. The reader is referred to standard texts for a complete review of the subject.[5]

■ LIMITATIONS OF LUNG ULTRASONOGRAPHY

Any disease process resulting in focal abnormality surrounded by aerated lung, for example, a solitary pulmonary nodule with normal surrounding lung, will not be visible with ultrasonography. Similarly, mediastinal structures are not visible using surface ultrasonography unless there is a convenient acoustic window related to lung consolidation or pleural effusion.

Documentation of the results of lung ultrasonography is challenging compared with CXR and chest CT scanning, in which results can be stored indefinitely in a durable format and serial studies compared. While a written report of lung ultrasonography is important and can be generated in a durable format, comparison of serial studies is difficult.

Video 31-12 B lines. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the second intercostal space in the midclavicular line (See also Video 78-5). *Access at www.fishmansonline.com*

Video 31-13 Alveolar consolidation of the left lower lobe and pleural effusion. The image was obtained using a 3.5-MHz transducer. Video 31-14 Mobile air bronchograms in an area of alveolar consolidation. The gain was turned down to bring out the punctate hyperechoic mobile foci that have respirophasic movement. The foci represent air within the bronchi surrounded by alveolar consolidation. The image was obtained using a 3.5-MHz transducer. The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the sixth intercostal space in the right midaxillary line. *Access at www.fishmansonline.com*

CLINICAL APPLICATIONS

With development of high-quality, portable ultrasound machines, it is now feasible to integrate lung ultrasonography into both hospital- and office-based pulmonary practice. Ultrasonography will never completely replace CXR or chest CT, and it should be viewed as a complementary imaging modality. Its utility has been well characterized for critical care applications, and it is being increasingly utilized in pulmonary medicine.

PROCEDURES

In addition to its utility in performing pleural procedures, ultrasonography may be used to guide other transthoracic interventions. For example, thoracic ultrasonography is useful in localizing masses abutting the pleural surface. As noted previously, although a lung mass that is entirely surrounded by aerated lung is not visible with ultrasonography, if part of the mass abuts the pleural surface, it may be visualized, and its size and pattern of echogenicity characterized (Fig. 31-11; Video 31-15). While lung ultrasonography has limited utility in establishing etiology of masses, localization of the abnormality and delineation of a safe path for needle insertion may be helpful. Furthermore, ultrasonography may be used as an alternative to CT to guide transthoracic needle insertion.[33]

Pneumothorax is a complication of a variety of pulmonary procedures, including bronchoscopy, thoracentesis, and transthoracic needle insertion. Ultrasonography is superior to CXR in the detection of pneumothorax and can be used in place of radiography for postprocedure evaluation.[34,35]

Following pleural drain insertion, ultrasound may be useful in determining whether the lung is expanded. In addition, ultrasound may assist in determination of when to remove the chest drain following tube clamping and may be used to rapidly ascertain whether there is continued leakage of air into the pleural space.[36]

The transducer was in longitudinal orientation and placed perpendicular to the chest wall to scan through the fifth intercostal space in the left anterior axillary line. *Access at www.fishmansonline.com*

ASSESSMENT OF DIAPHRAGMATIC FUNCTION

Thoracic ultrasonography is useful in assessing diaphragmatic function.[37] The diaphragm is easy to identify with ultrasonography, and characteristics of diaphragmatic function, such as velocity, force, and amplitude of contraction can be readily assessed.

DIAGNOSIS OF SPECIFIC DISEASES

Lung ultrasonography is useful for the diagnosis and follow-up of community-acquired pneumonia.[38] It also has utility in the diagnosis of pulmonary embolism.[39,40] Thoracic ultrasonography may be useful in the evaluation of dyspnea in the critical care setting and may be helpful in assessing dyspnea in less acute settings.[30,41]

REDUCTION IN USE OF CHEST RADIOGRAPHY AND CHEST CT SCANNING

Thoracic ultrasonography has been compared with both CXR and chest CT scanning. For many indications, it is superior to CXR and similar to chest CT.[24,42,43]

CONCLUSION

Thoracic ultrasonography is a useful imaging modality for the pulmonary consultant. Thoracic ultrasonography is easy to learn and has multiple applications as a point-of-care tool. The technique may allow the pulmonary consultant to reduce the use of CXR and chest CT while providing information of immediate clinical relevance.

CHAPTER 32

Physiologic and Metabolic Study of Pulmonary Disorders Using Conventional Imaging Techniques and Positron Emission Tomography

Ghassan El-Haddad

Daniel Worsley
Abass Alavi

INTRODUCTION

Since the mid-1950s, the use of radiopharmaceuticals has made it possible to assess a variety of pulmonary disorders. In 1955, ^{133}Xe was introduced for the study of regional pulmonary ventilation.[1] Shortly thereafter, it became possible to evaluate regional pulmonary blood flow using inhaled carbon dioxide containing radioactive $^{15}O_2$ or intravenous injection of ^{133}Xe dissolved in saline solution.[3] In 1964, intravenous injection of ^{131}I-macroaggregated albumin made it feasible to obtain perfusion scans of the lungs.[4] Although these techniques rapidly gained wide acceptance as tests of regional abnormalities in ventilation and pulmonary blood flow, the main practical application has been in the diagnostic evaluation of patients with suspected pulmonary embolism (PE). Increasingly, the role of nuclear medicine in respiratory medicine has been expanded to include disorders such as preoperative assessment of lung function, inflammatory lung disease, and lung cancer. The more widespread availability of positron emission tomography (PET) and integrated PET/CT (computed tomography) has provided powerful tools to aid in the diagnosis, staging, and management of patients with lung cancer.

RADIOPHARMACEUTICALS AND TECHNIQUES IN VENTILATION–PERFUSION LUNG SCANNING

Radiopharmaceuticals commonly utilized in both perfusion and ventilation studies, as well as the techniques employed are discussed in subsequent sections.

PERFUSION AGENTS AND TECHNIQUES

Clinical application of perfusion lung scanning was first described in 1964, when iodine 131–labeled macroaggregates of albumin was utilized in the evaluation of pulmonary perfusion.[4] Currently, the two agents used for pulmonary perfusion imaging are technetium 99m–labeled human albumin microspheres (^{99m}Tc HAM) and macroaggregated albumin (^{99m}Tc MAA). ^{99m}Tc MAA particles range in size from 10 to 150 μm; more than 90% of injected particles measure between 10 and 90 μm. ^{99m}Tc HAM particles are relatively uniform in size and range between 35 and 60 μm. However, ^{99m}Tc MAA is considered the agent of choice for routine perfusion lung scanning because of its availability, short residence time in the lungs, and relatively low cost.

Radiolabeled particles are injected intravenously while the patient is in the supine position, thereby limiting the effect of gravity on regional pulmonary arterial blood flow. Following the administration of ^{99m}Tc MAA, particles mix uniformly with venous blood flowing to the heart; the particles lodge in precapillary arterioles of the lungs, obstructing approximately 0.1% of their total number. The usual administered dose of radioactivity is between 74 and 185 MBq (2–5 mCi) (typically, 200,000 to 500,000 particles are injected during clinical perfusion scan). The usual pediatric-administered activity is 0.5 to 2.0 MBq/kg (20–80 mCi/kg), with a minimum of 7 to 8 MBq (approximately 200 mCi).

The blockage of pulmonary precapillary arterioles by ^{99m}Tc MAA is transient; the biologic half-life in the lung ranges between 2 and 8 hours. The physical half-life of ^{99m}Tc is 6 hours. The MAA particles are cleared by enzymatic hydrolysis, forming smaller particles that are phagocytized by reticuloendothelial cells. In pediatric patients and patients with suspected or known right-to-left shunts, severe pulmonary hypertension, poor respiratory function, pregnancy, prior pneumonectomy, or a single lung transplant, the number of particles injected should be reduced. In infants and children, the use of low number of particles can be calculated based on weight.[5] The distribution of particles in the lungs is proportional to regional pulmonary blood flow at the time of injection.[6] A routine perfusion scan should include at least six views of the lungs: Anterior, posterior, right and left lateral, and right and left posterior oblique views, using large field of view high-resolution gamma camera. Right and left anterior oblique views may be helpful in selected cases. In spite of imaging in multiple projections, the perfusion scan may underestimate perfusion abnormalities. A solitary segmental perfusion defect within the medial basal segment of the right lower lobe is completely surrounded by normal lung. Consequently, a perfusion defect in this segment will not be detected on planar perfusion imaging.

Perfusion lung scans are routinely utilized to examine patients with suspected PE. Unfortunately, perfusion imaging is sensitive, but not specific, for diagnosing PE. Virtually all lung diseases (including tumors, infections, asthma, and chronic obstructive pulmonary disease [COPD]) may cause decreased pulmonary arterial blood flow in the affected lung zones. Therefore, combined use of perfusion and ventilation studies improves the diagnostic specificity of lung scanning for PE (Fig. 32-1). PE almost always causes abnormal perfusion, while ventilation is preserved (mismatched defects) (Fig. 32-2). In contrast, in parenchymal pulmonary disorders, decreased ventilation and perfusion are noted in the same lung region (matched defects). Conditions in which the ventilation abnormality may appear larger than the perfusion abnormality (reverse mismatch), indicating a functional right-to-left shunt, include airway obstruction, mucus plug, atelectasis, and pneumonia.[7] Reverse mismatch may be exacerbated in patients on positive end-expiratory pressure (PEEP)[8] as PEEP is less efficiently transmitted to obstructed, well-perfused areas, in patients with metabolic alkalosis,[9] or in patients treated with inhaled albuterol.

VENTILATION AGENTS AND TECHNIQUES

Historically, ^{133}Xe has been the agent used to determine regional ventilation.[1,10] ^{133}Xe has a physical half-life of 5.24 days and a low gamma energy emission of 81 keV compared to 140 keV for ^{99m}Tc. The examination is somewhat laborious and encompasses three phases. Thus, other tracers, such as ^{81m}Kr, and, the ^{99m}Tc-labeled aerosols – Technegas and Pertechnegas – are now replacing it.

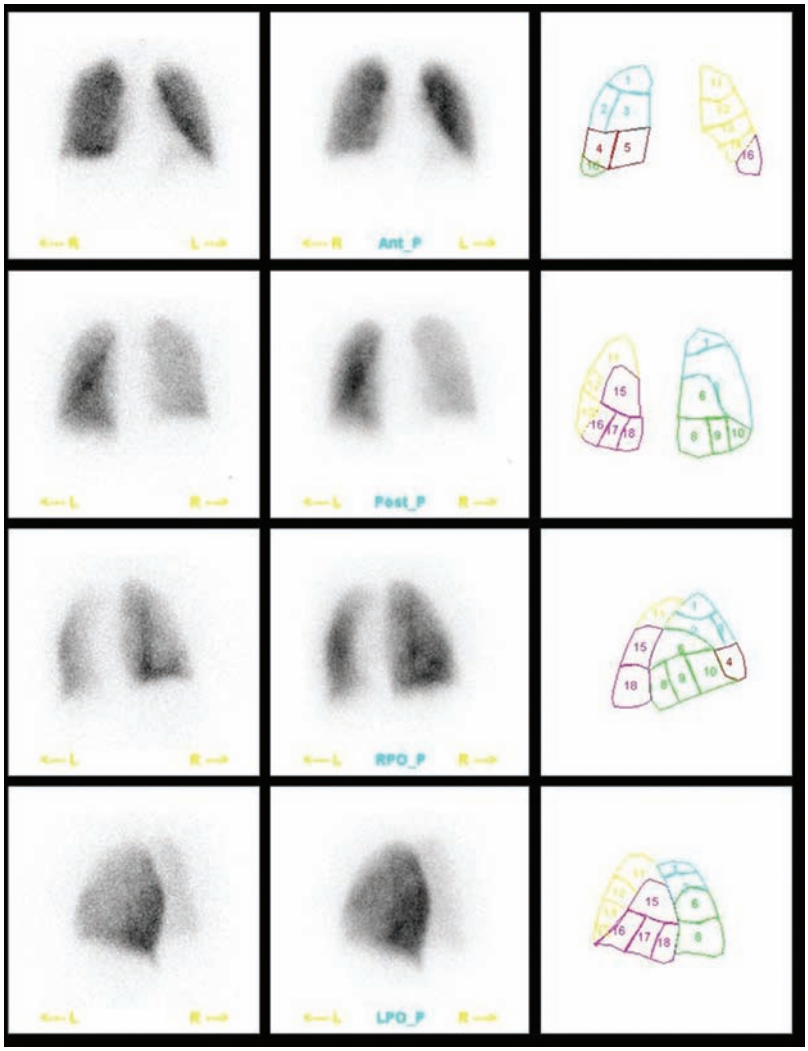

Figure 32-1 Normal ventilation–perfusion lung scanning. Ventilation scan using ^{99m}Tc Technegas® aerosol *(left column)*: Uniform distribution of the aerosol throughout both lungs. Perfusion scan using ^{99m}Tc MAA *(middle column)*: Uniform distribution of particles throughout both lungs.

^{81m}Kr is a noble gas that has a very short physical half-life (13 seconds). Therefore, images acquired using this agent reveal ventilation to major airway systems only. However, the short physical half-life of ^{81m}Kr allows generation of lung images in multiple projections that can be matched with perfusion images. ^{81m}Kr is produced from a rubidium-81 generator. The parent radionuclide has a physical half-life of 4.7 hours, which limits the useful lifetime of the generator to only 1 day. Imaging with ^{81m}Kr is generally performed following the perfusion scan due to its higher energy than ^{99m}Tc.

A radioaerosol is produced by nebulizing the radiopharmaceutical into a fine mist, which is subsequently inhaled. ^{99m}Tc-labeled aerosol studies can be performed following the inhalation of several preparations; ^{99m}Tc DTPA (diethylene triamine penta-acetic acid) is the most popular and commonly used worldwide. The advantages of ^{99m}Tc aerosols are that they are widely available, inexpensive, and have a 140-keV energy photopeak, which is ideal for gamma camera imaging. One limitation of this agent is its relatively rapid absorption across the pulmonary capillaries into the blood in the presence of inflammation, including that caused by smoking (typical ^{99m}Tc DTPA aerosol biologic half-life is about 80 minutes compared to ~20 to 30 minutes in smokers).[11,12] Since ^{99m}Tc DTPA aerosol is cleared from the alveoli by transepithelial diffusion, the clearance rate may be used as an index of alveolar–epithelial membrane integrity.[11]

^{99m}Tc-labeled radioaerosols have particles between 0.5 and 2 μm in size and are produced by utilizing commercially available nebulizers.[13] The patient generally breathes from the nebulizer (with oxygen at 8 to 10 L/min) for 3 to 5 minutes or until 37 MBq (1 mCi) of radioactivity is deposited in the lungs. Only 2% to 10% of administered radioactivity goes to the lungs. The regional distribution of radioactivity in the lungs is proportional to local ventilation. ^{99m}Tc-labeled radioaerosol studies are generally performed before perfusion imaging. Although less preferred, the ventilation study can be performed following the perfusion scan, but the dose placed in the nebulizer should be increased to at least 1665 MBq (45 mCi), instead of the usually used 1110 MBq (30 mCi) to overwhelm the activity present in the lungs from ^{99m}Tc MAA.

The lungs are imaged in multiple projections, which correspond to those obtained during the subsequent perfusion study. Ventilation studies using ^{99m}Tc-labeled radioaerosols require minimal patient cooperation and can be performed at the bedside and on patients who are on ventilators. Disadvantages of ^{99m}Tc-labeled radioaerosols include the central deposition of radioactivity in patients on PEEP, patients with COPD or airway obstruction, and the need to dispose of the substantial unused amount of radioactivity that is deposited in the nebulizer. Indeed, the central deposition of ^{99m}Tc-labeled radioaerosol in patients with COPD is a major drawback to the use of aerosol agents, and newer agents have been developed to overcome this deficiency, including ^{99m}Tc Technegas and ^{99m}Tc Pertechnegas.[14]

LUNG SCANNING IN THE DIAGNOSIS OF ACUTE PULMONARY EMBOLISM

PE is a common and potentially fatal disorder for which treatment is highly effective in decreasing mortality and morbidity if initiated soon after the event.[15] The accurate and expeditious diagnosis of acute PE can be difficult because of the nonspecificity of clinical, laboratory, and radiographic findings. Despite diagnostic advances, delays in diagnosis of PE are still common and represent an important clinical issue.[16]

Venous thromboembolism (VTE) and PE are no longer considered a one-time only event, as they have a high recurrence and mortality rate.[17] Although the incidence of PE has not significantly changed over the past three decades,[18] the overall mortality rate from PE has decreased substantially (by roughly 30% from 1998 to 2009),[19] which has been attributed to better detection and treatment of deep venous thrombosis (DVT), risk factor modification, and improvement in PE diagnostic tests.[19–21] Although prompt anticoagulation therapy remains the cornerstone of PE treatment, as it is effective and reduces mortality, it is not without risks, including hemorrhagic complications.[22] Therefore, accurate diagnosis of PE is essential, not only to prevent death from recurrent embolism but also to avoid complications related to unnecessary anticoagulant therapy.

Ventilation–perfusion (V/Q) lung imaging has been shown to be a safe, noninvasive technique in evaluating regional pulmonary function undertaken for a variety of purposes. The technique has been widely used in the assessment of patients with suspected PE.

The first major study that utilized perfusion lung scanning as a screening test for the diagnosis of PE was the Urokinase Pulmonary Embolism Trial (UPET).[23] In more than 90% of patients enrolled in the trial, perfusion lung scanning was performed following intravenous administration of ^{131}I-labeled MAA. Lung imaging was

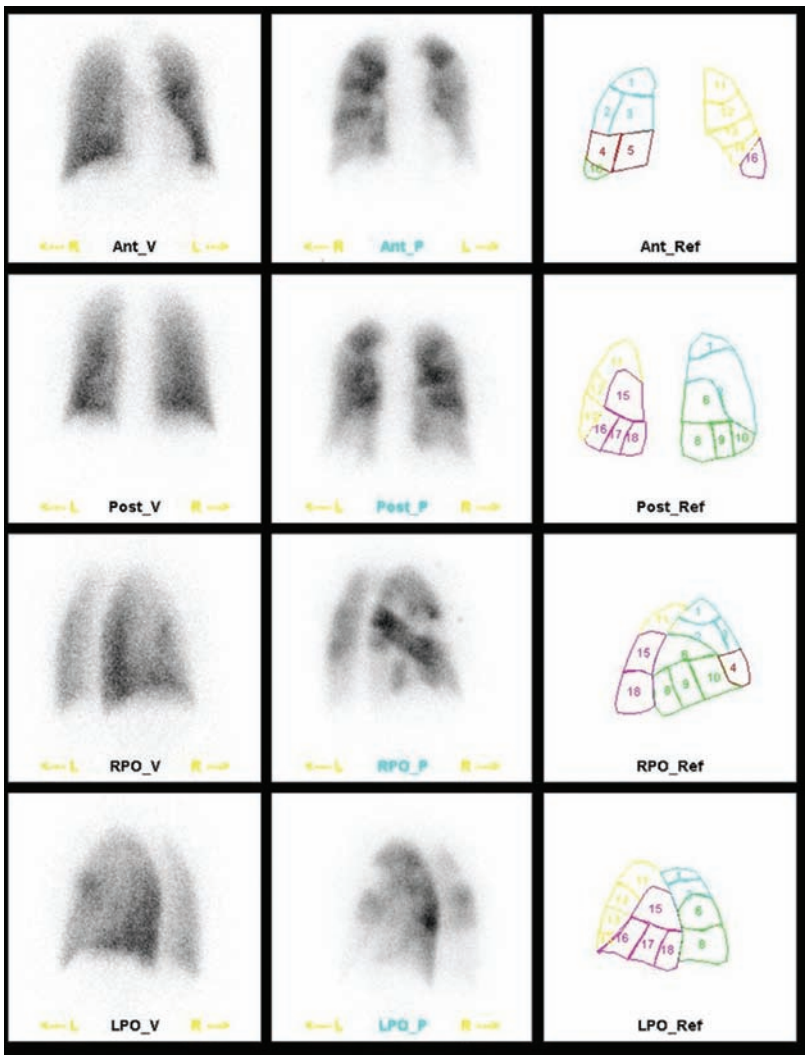

Figure 32-2 High probability scan for pulmonary embolism. Ventilation scan using ^{99m}Tc Technegas® aerosol *(left column)* is within normal limits. Perfusion scan using ^{99m}Tc MAA *(middle column)* shows large segmental defects in both lungs. This combination of findings (mismatch) is consistent with pulmonary embolism.

carried out using rectilinear scanners; ventilation studies were not performed. Despite utilizing a suboptimal radiopharmaceutical and imaging equipment, the UPET study established perfusion lung scanning as an effective technique in both screening for PE and assessing restoration of pulmonary blood flow following an embolic event. Approximately 75% to 80% of perfusion defects resolved by 3 months; those that did not, persisted after 1 year, indicating that most patients with acute PE either completely lyse the thrombi or partially recanalize the pulmonary artery.

Data from prospective, large, outcome-based studies have reported on the important diagnostic information provided by V/Q scanning in patients suspected of having acute PE when coupled with clinical assessment and noninvasive leg testing.[24,25] In patients with suspected PE who had a non–high probability or nondiagnostic V/Q scan, normal cardiorespiratory reserve, and negative serial noninvasive leg tests for proximal venous thrombosis (as determined by serial impedance plethysmography [IPG]), PE at 3 months of follow-up occurred in only 0.6% of cases while the patients were not on anticoagulation.[24] Among patients with suspected PE, but who had a low probability clinical assessment and negative serial noninvasive leg tests, as well as a nondiagnostic V/Q scan, PE at 3 months follow-up occurred in 0.5% of patients.[25] When the probability for clinical assessment was intermediate, PE occurred in only 0.4% of patients.[25]

These studies demonstrated that anticoagulation could be safely withheld in patients with adequate cardiorespiratory reserve who did not have high probability V/Q scans or proximal venous thrombosis, since the incidence of recurrent PE is very low. Unfortunately, the criteria used in the studies to categorize the probability of PE ("normal," "nondiagnostic," or "high") were different than those used in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED), and direct comparison is not possible. In the Prospective Investigative Study of Acute Pulmonary Embolism Diagnosis (PISA-PED),[26] which utilized perfusion scanning alone in conjunction with the chest radiograph, the sensitivity and specificity of scintigraphy were 92% and 87%, respectively. The prevalence of PE was high (39%). When considered in conjunction with clinical assessment of the likelihood of PE ("very likely," "possible," or "unlikely"), the positive predictive value (PPV) of a perfusion scan was 99%; the combination of a near-normal or abnormal perfusion scan without segmental defects and low clinical likelihood of PE had a negative predictive value (NPV) of 97%. Using standardized clinical assessment and perfusion lung scanning, the authors were able to accurately diagnose or exclude PE (PPV, 96%; NPV, 98%). CT angiography (CTA) was required in only a minority of cases having discordant clinical and scintigraphic findings.

PROSPECTIVE INVESTIGATION OF PULMONARY EMBOLISM DIAGNOSIS STUDY

To date, the most comprehensive prospective investigation addressing the role of V/Q scanning in the diagnosis of PE has been the PIOPED study. This multi-institutional study was designed to evaluate the efficacy of various conventional methods for diagnosing acute PE. In particular, PIOPED focused on the sensitivity and specificity of lung scans in the diagnosis of acute PE. Although the clinical diagnosis of PE is not definitive, results from PIOPED emphasize the importance of incorporating clinical assessment in evaluating patients suspected of having acute PE. As expected, combining clinical assessment with lung scan interpretation improves diagnostic accuracy of the imaging technique.

Ninety-two percent of patients with PE in PIOPED had at least one of the following risk factors: Immobilization and recent surgery (two most common risks), underlying malignancy, history of DVT or PE, estrogen use, or pre-existing cardiac disease. Of patients diagnosed with PE in PIOPED, >90% had dyspnea, tachycardia, or pleuritic chest pain. Similarly, although chest radiographic findings alone are not sensitive or specific for PE, they are essential for diagnosing conditions that can mimic PE clinically. The most common radiographic findings in patients with PE were atelectasis or parenchymal opacity. Furthermore, chest radiographic findings heavily influence the criteria utilized for estimating the probability of PE based on lung scan patterns. For example, in patients with COPD, the sensitivity of a high probability V/Q scan is significantly lower than in patients with no cardiopulmonary disease. The more severe the underlying cardiopulmonary disease, the higher the likelihood of the scan will be of intermediate probability. Intermediate probability occurred in 60% of patients with COPD in PIOPED, compared with only 13% of patients with a normal chest x-ray.[27]

The sensitivity, specificity, and PPV from PIOPED of V/Q lung scans in detecting acute PE are presented in Table 32-1.

TABLE 32-1 Sensitivity, Specificity, and Positive Predictive Value of Lung Scans in Detecting Pulmonary Embolism in Patients Enrolled in PIOPED

Lung Scan Interpretation (Probability)	Sensitivity (%)	Specificity (%)	Positive Predictive Value (%)
High[a]	40	98	87
High, intermediate[b]	82	64	49
High, intermediate, low[c]	98	12	32

[a]*Only high-probability scans considered indicative of PE; all other classifications considered negative for PE.*
[b]*High- and intermediate- probability scans considered indicative of PE; all other classifications considered negative for PE.*
[c]*High-, intermediate-, and low- probability scans considered indicative of PE; normal or near-normal scans considered negative for PE.*

All patients enrolled in PIOPED were to undergo a V/Q scan and pulmonary arteriogram. However, a large number of patients with low probability or normal V/Q scans did not undergo pulmonary arteriography to avoid additional risks. Therefore, there was a selection bias toward patients with intermediate or high probability scans, leading to an overestimation of the sensitivity, but underestimation of the specificity of V/Q scanning. In an analysis of the angiography results in PIOPED, PE occurred more frequently on the right than on the left, and more commonly in the lower lung zones. One of the limitations of V/Q scanning in PIOPED was the interobserver variability in scan interpretation. As expected, agreement among readers was excellent for normal, high, and very low probability V/Q scans (92%–95%). However, it was not as good for intermediate and low probability studies.[27]

Use of anatomic lung segment reference charts has been shown to reduce interobserver disagreement when interpreting scans. Other interpretative pitfalls include false-negative and -positive readings. False-negative interpretations (i.e., low probability read with PE present) do occur, and patients who have a recent history of immobilization (bed rest for 3 days), recent surgery, trauma to the lower extremities, or central venous instrumentation are particularly at risk. In patients with low or very low probability scans who have none of the aforementioned risk factors, the prevalence of PE is only 4.5%. Conversely, in patients with low or very low probability scans and one or more of the risk factors, the prevalence of PE is 12% and 21%, respectively (Table 32-2).

TABLE 32-2 Risk Factors and Prevalence of Pulmonary Embolism in Patients with Low Probability and Very Low Probability Lung Scans Enrolled in PIOPED

	Patients with 0 Risk Factor[a]	Patients with 1 Risk Factor[a]	Patients with ≥2 Risk Factors[a]	Total
PE positive	14 (2.2%)	19 (2.9%)	37 (5.7%)	70
PE negative	301 (46.4%)	136 (21.0%)	142 (21.9%)	579
Prevalence of PE	4.5%	12.2%	20.7%	10.8%

[a]*Risk factors include immobilization, trauma to lower extremities, surgery, and central venous instrumentation within 3 months of enrollment.*

Patients with false-negative lung scans tend to have nonocclusive subsegmental thrombi and a low pulmonary clot burden. The prognostic value of a low probability scan is excellent, particularly in patients with a low clinical pretest likelihood of disease or negative lower leg ultrasound.[28] The most common cause of V/Q mismatch in patients who do not have acute PE is chronic or unresolved PE. Other causes include compression of the pulmonary vasculature (e.g., from mass lesions, lymphadenopathy, or mediastinal fibrosis), vessel wall abnormalities (e.g., pulmonary artery tumors or vasculitis), nonthromboembolic intraluminal obstruction (e.g., tumor emboli or foreign body emboli), and congenital vascular abnormalities (e.g., pulmonary artery agenesis or hypoplasia).

In patients who have unilateral V/Q mismatch (hypoperfusion or absent perfusion) within an entire lung or in multiple contiguous segments and normal perfusion in the contralateral lung, extrinsic compression of the pulmonary vasculature, congenital abnormalities, or proximal PE should be considered. Patients with a suspected false-positive scan or unilateral V/Q mismatch often require further imaging using CTA, even though emboli are frequently multiple (in 90%) and bilateral (in 85% of cases), and unilateral decreased or absent perfusion to one lung is uncommonly the result of PE.

Shortly after the PIOPED study, helical CTA was introduced.[29] This led to PIOPED II, which is the largest multicentered, prospective, outcome-based study to date designed to assess the accuracy of CTAin evaluation of acute PE in comparison to the composite reference standard.[30]

In PIOPED II, CTA had a sensitivity, specificity, PPV, and NPV of 83%, 96%, 86%, and 95%, respectively, in detecting acute PE.[30] Study results suggested that the predictive value of CTA is highly concordant with the pretest clinical probability of PE using Wells' criteria.[25] The PPV of PE with a positive CTA was 97% for a main or lobar artery, 68% for a segmental vessel, and 25% for a subsegmental branch. The probability of a false-negative chest CTA is minimal in large PE, but false-negative findings may occur in the small group of patients with clot limited to subsegmental arteries. The PPV of PE in patients with positive CTA and high, intermediate, or low clinical probability was 96%, 92%, 58%, respectively. NPV of PE in patients with negative CTA and low, intermediate, or high clinical probability was 96%, 89%, and 60%, respectively.

The limitations of the study included use of 4- to 16-slice multidetector CT (mostly 4-detector) and use of noninvasive diagnostic test in the reference standard. In contrast to original PIOPED population, of whom 68% were inpatients, PIOPED II included only 11% inpatients. Inpatients are more likely to have abnormalities on chest radiographs, which would potentially interfere with optimal V/Q scan reading.[31] Also, the accuracy of CTA would be lower if patients with inconclusive interpretations of CT (51 patients or 6%) were included, giving an overall sensitivity and specificity of 78% and 90%, respectively. The overall PPV of 86% and NPV of 95% are comparable to V/Q performance parameters. The combination of CT venography and CTA increased the sensitivity from 83% to 90% when using CTA alone. CT venography, however, showed similar results in diagnosing or excluding DVT as compression ultrasound.[32]

Finally, PIOPED III, a multicenter collaborative investigative trial was designed to determine the diagnostic accuracy of gadolinium-enhanced magnetic resonance angiography (Gd-MRA) of the pulmonary arteries in combination with magnetic resonance venography (MRV) of the veins of the thighs in patients with clinically suspected acute PE. In PIOPED III, most centers had difficulty in obtaining MR pulmonary angiograms of adequate quality; indeed, studies were deemed inadequate in 25% of patients.[33] Adequacy of the studies varied between 11% and 52% among centers. Adequate quality images were obtained in assessing the main or lobar pulmonary arteries in 91% of patients, segmental pulmonary arteries in 87%, and subsegmental branches in 73%. A technically adequate

MRA had a sensitivity of 78% and specificity of 99%. These findings led the PIOPED III investigators to conclude that MRA should only be considered at centers that routinely perform it well, and for patients who have contraindications to other standard tests.

V/Q SCAN INTERPRETATION AND MODIFICATIONS TO ORIGINAL PIOPED CRITERIA

Several diagnostic schemes have been suggested for interpretation of V/Q scans. The original PIOPED criteria were developed to interpret scans generated from the study based upon experience gathered over the preceding decade. A PE is characterized by V/Q mismatch, which is an area of normal ventilation corresponding to a segmental, wedge-shaped area of decreased or absent perfusion extending to the pleural surface. The segmental defect should correspond to vascular anatomy. Due to the high proportion (44%) of intermediate probability V/Q scans in PIOPED[34] and interobserver disagreements, several revisions and modifications have been made to the original criteria.

One nuance in V/Q scan interpretation is the so-called "gestalt interpretation," which is based on an experienced nuclear medicine physician's subjective estimate of the likelihood of PE (without using specific interpretation criteria). This interpretation takes into account various published lung image interpretation algorithms, clinical data, ancillary findings, and pathophysiologic features of PE, which are integrated with the individual case presentation. The gestalt interpretation has been shown to correlate well with the fraction of patients with angiographic evidence of PE in the PIOPED study, with good-to-excellent intra- and interobserver variability.[35,36] Thus, experienced readers (such as the PIOPED investigators) can provide an accurate estimate of the probability of PE based on clinical, radiographic, and scintigraphic findings.

Another nuance is the "triple match," which is a reference to matching perfusion, ventilation, and chest radiographic abnormality. Based on the PIOPED data, in the presence of a triple match, the prevalence of PE varies depending on the location of the abnormality. A triple match in the upper (prevalence of PE, 11%) or middle lung (prevalence of PE, 12%) zones is considered low probability for PE, but a triple match in the lower lung zones should be interpreted as intermediate probability (prevalence of PE, 33%).[37]

Yet another nuance is the "stripe sign," which describes a rim of perfused lung tissue between the perfusion defect and adjacent pleural surface.[38] In PIOPED, this sign excluded the diagnosis of PE within the affected zone in 93% of cases. Hence, in the absence of other perfusion abnormalities, a V/Q scan with a stripe sign should be considered very low probability for PE. A single, moderate-sized V/Q mismatch was found to harbor PE in 36% of cases in PIOPED[39]; if present, the V/Q scan should be described as intermediate probability for PE. A single matched V/Q defect (of any size) was found to correspond to PE in 26% of cases in PIOPED; such a finding should be classified as intermediate probability.[39]

The limitations in original PIOPED led the investigators to revise the original interpretation criteria for easier application and better integration of clinical pretest probability of PE. Modifications to the original PIOPED interpretation criteria were used in the PIOPED II trial (Table 32-3),[40] which decreased the number of intermediate scan readings (73.5% of patients had V/Q scans with definitive interpretation) and provided a more accurate assessment of angiographically proven PE than the original criteria (sensitivity increased to 83%; specificity essentially unchanged at 96%).

On the other hand, the PISA-PED[26] criteria (Table 32-4) for interpretation of perfusion lung scans were based on diagnosing PE when there was one or more wedge-shaped perfusion defects. PE was considered absent when there was normal or near-normal perfusion or a nonsegmental, non–wedge-shaped perfusion defect.[41] All other scans were called nondiagnostic.

TABLE 32-3 Revised PIOPED Criteria for Interpretation of Lung Scans[a]

High probability (≥80%)
≥2 Large segmental perfusion defects (>75% of a segment) without corresponding ventilation or radiographic abnormalities
One large segmental perfusion defect and ≥2 moderate segmental perfusion defects (25–75% of a segment) without corresponding ventilation or radiographic abnormalities
≥4 Moderate segmental perfusion defects without corresponding ventilation or radiographic abnormalities
Intermediate probability (20–79%)
One moderate to <2 large segmental perfusion defects without corresponding ventilation or radiographic abnormalities
Corresponding ventilation–perfusion defects and radiographic parenchymal opacity in lower lung zone
Single, moderate, matched ventilation–perfusion defects with normal radiographic findings
Corresponding ventilation–perfusion defects and small pleural effusion
Difficult to categorize as normal, low, or high probability
Low probability (<19%)
Multiple matched ventilation–perfusion defects, regardless of size, with normal radiographic findings
Corresponding ventilation–perfusion defects and radiographic parenchymal opacity in upper or middle lung zone
Corresponding ventilation–perfusion defects and large pleural effusion
Any perfusion defects with substantially larger radiographic abnormality
Defects surrounded by normally perfused lung (stripe sign)
>3 Small segmental perfusion defects (<25% of a segment) with a normal radiograph
Nonsegmental perfusion defects (cardiomegaly, aortic impression, enlarged hilum)
Very low probability
≥3 Small segmental perfusion defects (<25% of a segment) with a normal radiograph
Normal scan
No perfusion defects; perfusion outlines the shape of the lung seen on the radiograph

[a]*Criteria generated after completion of prospective study.*

According to modified PIOPED II criteria (Table 32-4) established in 2008, PE was diagnosed when there were equivalent of two large, segmental perfusion scan–chest radiograph mismatches (which may include one large and two moderate segmental mismatches, or four moderate segmental mismatches).[41] PE was considered absent when there was normal perfusion. PE was deemed very low probability when there was a nonsegmental perfusion defect smaller than the corresponding radiographic lesion, one to three small segmental defects, a solitary matched chest x-ray abnormality and perfusion defect in the mid or upper lung zones, a stripe sign, or a pleural effusion ≥1/3 of the pleural cavity with no other perfusion defect in either lung. The scan was considered nondiagnostic with all other findings.

When perfusion scans obtained in PIOPED II were reinterpreted using a composite reference standard (all PIOPED II patients were eligible for this study if they had a diagnosis based on CTA or digital subtraction angiography [DSA], an interpretable perfusion scan and chest radiograph, and a positive Wells' score), investigators

TABLE 32-4 Modified PIOPED II and PISA-PED Criteria for Interpretation of Perfusion Scans

	Modified PIOPED II	PISA-PED
PE present	• High probability (≥2 segments of perfusion scan—chest radiograph mismatch. May be ≥2 large segmental mismatches, or 1 large and 2 moderate mismatches, or 4 moderate segmental mismatches)	• ≥1wedge-shaped perfusion defects

PE absent	• Normal perfusion
	• Very low probability
	  • Nonsegmental lesion (eg, prominent hilum, cardiomegaly, elevated diaphragm, linear atelectasis, costophrenic angle effusion with no other perfusion defect in either lung)
	  • Perfusion defect smaller than radiographic lesion
	  • 1–3 small segmental defects
	  • Solitary CXR-Q matched defect in the mid or upper lung zone confined to a single segment
	  • Stripe sign present around the perfusion defect (best tangential view)
	  • Pleural effusion ≥1/3rd the pleural cavity with no other perfusion defect in either lung
		• Normal perfusion
		• Near normal
		  • Contour defect (caused by enlarged heart, mediastinum, or diaphragm)
		• Perfusion defect, not wedge-shaped

Not diagnostic	• All other findings	• Cannot classify as PE-positive or PE-negative

Source: Data from Miniati, M, Pistolesi, M, Marini, C, et al. Value of perfusion lung scan in the diagnosis of pulmonary embolism: results of the Prospective Investigative Study of Acute Pulmonary Embolism Diagnosis (PISA-PED). Am J Respir Crit Care Med. 1996;154(5):1387–1393; and Sostman, HD, Miniati, M, Gottschalk, A, et al. Sensitivity and specificity of perfusion scintigraphy combined with chest radiography for acute pulmonary embolism in PIOPED II. J Nucl Med. 2008;49(11):741–748.

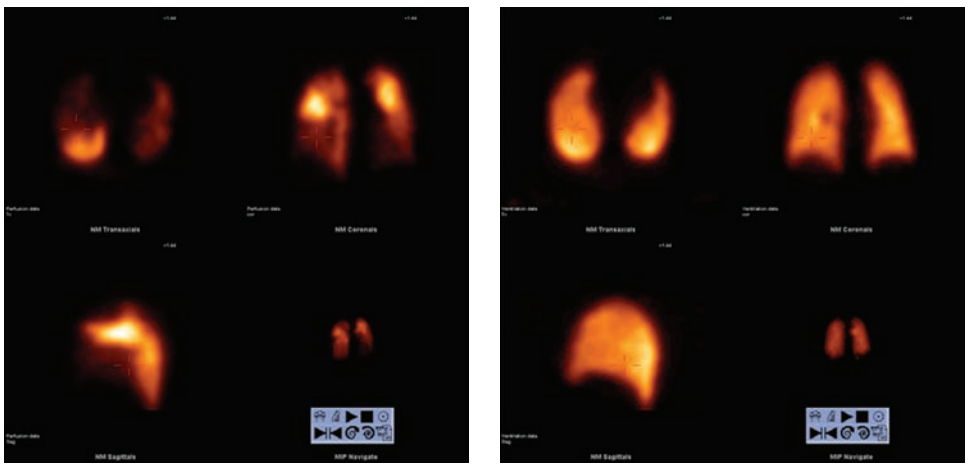
found only 21% of patients with nondiagnostic results using revised PIOPED II criteria.[41] Only 11% patients had nondiagnostic perfusion scans among the 72% of patients with normal or near-normal chest radiographs. The prevalence of PE in the sample was 19%. Using the modified PIOPED II criteria, and after excluding nondiagnostic perfusion scans, the sensitivity of "PE present" reached 85%, and the specificity of "PE absent" reached 93%. When using PISA-PED criteria, none had nondiagnostic perfusion scans; the sensitivity of a "PE present" scan was 80% and the specificity of "PE absent" scan was 97%. Based on these findings, it was postulated that perfusion scintigraphy combined with chest radiography can provide diagnostic accuracy similar to CTA at a lower cost and, most importantly, with a lower radiation dose.[41]

SPECT V/Q IMAGING FOR THE EVALUATION OF PULMONARY EMBOLISM

Single-photon emission tomography (SPECT) V/Q imaging has several advantages over planar imaging, including higher contrast resolution and avoidance of overlapping small perfusion defects by normal tissue, particularly at the lung bases.[42] In the last two decades, technologic advances have been made with SPECT and new radiopharmaceuticals developed for SPECT ventilation studies, such as ^{99m}Tc Technegas.[43] Due to the availability of Technegas outside the United States, most SPECT V/Q scanning is performed in Australia and Europe (Figs. 32-3 and 32-4).

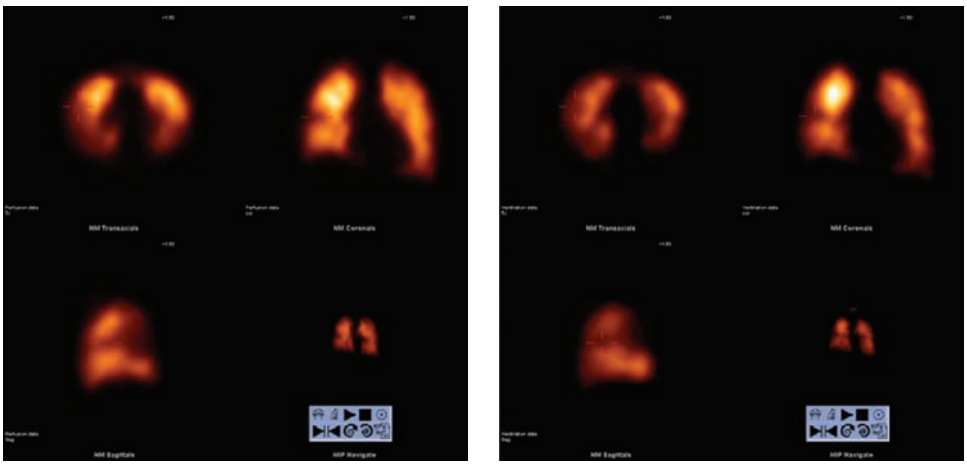
Total acquisition time for the SPECT V/Q examination is between 20 and 30 minutes for a dual-headed camera.[44] The advantages of SPECT over planar imaging in the evaluation for PE have been reported in several studies.[45–48] Importantly, SPECT V/Q scans have been reported by most investigators to be ≤3% nondiagnostic.[44] When compared to planar V/Q scans, SPECT V/Q scans show more and better delineated mismatched defects, better quantification, and less interobserver variation.[46]

In most studies, sensitivity (80%–100%) of SPECT V/Q scanning is higher than planar V/Q scan, but the specificity (93%–100%) is not always higher.[44] Some investigators have also suggested the



A B

Figure 32-3 High probability V/Q SPECT scan for pulmonary embolism. Perfusion scan using ^{99m}Tc MAA in transaxial, coronal, and sagittal views (**A**) shows large segmental defects in both lungs. Ventilation scan using ^{99m}Tc Technegas® aerosol in transaxial, coronal, and sagittal views (**B**) is within normal limits. This combination of findings (mismatch) is consistent with pulmonary embolism.



A B

Figure 32-4 V/Q SPECT scan for pulmonary embolism. Perfusion scan using ^{99m}Tc MAA in transaxial, coronal, and sagittal views (**A**) and ventilation scan using ^{99m}Tc Technegas® aerosol in transaxial, coronal, and sagittal views (**B**) show matched defects.

use of combined SPECT V/Q scan and low-dose CT scanning to improve accuracy in diagnosing PE.[49] The interpretation criteria, however, for SPECT V/Q scanning are not yet clearly defined or universal (i.e., it remains unclear whether modified PIOPED or PISA-PED criteria can be simply transposed from planar to SPECT V/Q scanning). Despite the many advantages of SPECT, substitution of planar V/Q by SPECT V/Q scan in patients with suspected PE remains controversial.[31,50,51]

There is a growing interest in "positive" imaging based on the use of antibody fragments and radiolabeled peptides directed against components of thromboemboli and glycoprotein IIb/IIIa receptors on the surface of activated platelets. ^{99m}Tc-labeled apcitide is a synthetic peptide that binds with high affinity and specificity to the glycoprotein IIb/IIIa receptor on the membrane of activated platelets.[52] The main advantage of the agent is its ability to distinguish between acute and chronic DVT.

Several ^{99m}Tc-labeled peptides directed against activated platelets are currently under investigation in the evaluation of patients with suspected PE. Radiolabeled peptide imaging has the potential to serve as a single, comprehensive modality in the evaluation of patients with VTE.

Finally, another agent under investigation is ^{99m}Tc-labeled anti–D-dimer (DI-80 B3) monoclonal antibody Fab′ fragment that binds specifically to thromboemboli. In a recent prospective, multicenter study to investigate the sensitivity and specificity of ^{99m}Tc DI-80 B3/SPECT in patients with suspected acute PE, ^{99m}Tc-DI-80 B3/SPECT had a sensitivity of 76.2% and a specificity of 90.5%.[53] At the current time, further studies and development of newer radiopharmaceuticals are required to fully realize this potential.

RECOMMENDATIONS FOR THE USE OF V/Q SCANNING AND CT ANGIOGRAPHY IN SUSPECTED PULMONARY EMBOLISM

Over the past decade, significant technical improvements have occurred in both CTA and V/Q scanning. However, use of CTA of the chest in patients with suspected PE has increased significantly and has markedly surpassed use of V/Q scanning.[54] Although studies show equivalent outcome-based results, the ready availability of CTA, particularly after hours, and the bias toward anatomic, rather than functional imaging, has made CTA the favored diagnostic test for PE.[55]

In a recent large prospective randomized study with high pretest probability and/or positive D-dimer levels, the false-negative rates for V/Q scan and CTA were very close at 1% and 0.4%, respectively.[56] Despite the fact that CTA can detect more small emboli than V/Q scan,[56] the risk of recurrent PE and death have not decreased during the CTA era.[57] In fact the ability of sophisticated new multidetector CT scans to detect emboli in subsegmental branches of the pulmonary arteries has created a healthcare challenge, pushing clinicians to now treat patients who have incidental, asymptomatic pulmonary emboli, whose natural history and optimal management are currently unknown (except in cancer patients in whom these emboli carry a poor prognosis).[58,59] These scans are usually ordered in the emergency department with no particular pretest diagnosis. The same logic will probably be true with SPECT V/Q scan, as it is not yet clear whether treating small, peripheral PE will confer a benefit unless the patients have significant clot burden and limited cardiovascular reserve.[34]

In patients with a normal chest radiograph, the V/Q lung scan is an effective, noninvasive initial study. However, in patients with significant chest radiographic abnormalities, CTA is more likely to provide a definitive diagnosis of PE or an alternative diagnosis, as well as a risk assessment of PE based on the evaluation of right ventricular size and function.[60,61] Furthermore, the combination of CTA and CT venography has the potential to provide a single, comprehensive evaluation of patients with suspected VTE, albeit with increased radiation exposure. V/Q scan remains an important alternative to CT in patients with contrast allergy or renal failure.

V/Q scan may be the modality of choice to evaluate patients with chronic thromboembolic disease and in providing follow-up of PE after therapy.[31] There is concern regarding the high radiation exposure, particularly to the female breast, associated with chest CTA.[62,63] CTA delivers a minimum radiation dose of 20 mGy (2.0 rad) to the breasts of an average-sized woman,[64] whereas breast irradiation with V/Q scan is approximately 0.28 to 0.9 mGy.[65] Furthermore, concern exists that increasing use of CTA may result in an increased incidence of radiation-related cancer in the future.[62] The potential latent carcinogenic effects of such radiation exposure at this time remain unknown.

As part of the American Board of Internal Medicine's *Choosing Wisely* campaign, which focused on potentially unnecessary or harmful medical tests and procedures, the Society of Nuclear Medicine recommended avoiding CTA to diagnose PE in young women with a normal chest radiograph, and consideration of a V/Q study instead.[66] Considerable debate exists regarding fetal radiation doses from pulmonary CTA versus V/Q scanning.[67] During pregnancy, when only a perfusion scan with 50 MBq of ^{99m}Tc MAA is used, the fetal absorbed dose is 0.1 to 0.2 mGy. It is estimated that a 16-slice MDCT scan gives an absorbed fetal dose of 0.24 to 0.66 mGy during the first trimester.[68] A comparison between CTA and V/Q scan for the evaluation of PE is summarized in Table 32-5.

In summary, based upon results from prospective and outcome-based studies, the following conclusions can be drawn regarding the use of V/Q scan and CTA in evaluating patients with suspected PE:

TABLE 32-5 Comparison of CTA and V/Q Scan in the Evaluation of PE

	Advantages	Disadvantages
CTA	– Accuracy – Interobserver agreement – Provides alternative diagnosis, and risk assessment based on the evaluation of right ventricular size and function – After hours availability – High speed in image acquisition – Suitable for unstable patients – Binary reports ("PE" or "no PE")	– Radiation exposure – Contrast allergy – Nephrotoxicity – Relative cost – Potential overdiagnosis of nonclinically relevant peripheral PE
V/Q scan	– High NPV in low pretest probability – High PPV in high pretest probability – Low radiation – Relative cost – Serial follow-up	– Low overall specificity – Low interobserver agreement – After hours availability – Slower speed in image acquisition – Unsuitable for unstable patients – Limited in providing alternative diagnosis – Unpopular probabilistic reports

Source: Data from Reid, JH, Coche, EE, Inoue, T, et al. Is the lung scan alive and well? Facts and controversies in defining the role of lung scintigraphy for the diagnosis of pulmonary embolism in the era of MDCT. Eur J Nucl Med Mol Imaging. 2009;36(3):505–521.

1. Proper pretest clinical probability scoring is important irrespective of the modality used. When imaging results for either V/Q scan or CTA are discordant with the pretest probability, the alternative test should be recommended.
2. A normal V/Q scan excludes the diagnosis of clinically significant PE.
3. Patients with very low or low probability scans and a low clinical likelihood of PE have a low (<5%) prevalence of PE and generally do not require pulmonary angiography or anticoagulation.
4. Patients with very low or low probability scans, intermediate or high clinical likelihood of PE, and negative serial noninvasive venous studies of the lower extremities generally do not require anticoagulation. In selected cases, CTA is helpful in excluding PE and providing an alternative diagnosis.
5. Clinically stable patients with intermediate probability scans require noninvasive venous studies of the legs; if negative, CTA is required for definite diagnosis of PE.
6. A clinically stable patient with a high probability scan and high clinical likelihood of PE, or a patient suspected of having a false-positive scan, requires treatment; no further diagnostic tests are required to confirm the diagnosis.
7. Clinically stable patients with high probability scans and a low clinical likelihood of PE require noninvasive venous studies of the legs; if negative, CTA may be required for definitive diagnosis.
8. V/Q scintigraphy has a high NPV and should be used particularly where low radiation dose is desirable, such as in young female with normal chest radiograph, in an outpatient with low clinical probability plus normal chest radiograph, a patient with high clinical probability plus normal chest radiograph, a patient with prior contrast anaphylaxis and strong allergic history, and a patient with renal failure or multiple myeloma. Since, in most patients, PE can be excluded on the basis of a normal perfusion pattern, to minimize radiation to the fetus in a pregnant patient, a 1- to 2-day protocol is suggested. Perfusion-only scans should be performed on day 1, using a reduced dose of ^{99m}Tc MAA.
9. V/Q scan is preferred over pulmonary CTA for follow-up of PE and investigation of the etiology of pulmonary hypertension.
10. If after-hours imaging is not available and a patient has a high clinical suspicion of PE, a reasonable approach includes administering a single dose of low–molecular-weight heparin and imaging the patient the next morning. This strategy may be particularly advisable for performing V/Q scintigraphy in young women to avoid the excessive breast radiation exposure associated with CTA.
11. If there is a contraindication to V/Q scan or CTA, MRA of the pulmonary artery may be performed in centers that perform it well. There is always concern about nephrogenic systemic fibrosis/nephrogenic fibrosing dermopathy, which occurs rarely in patients with poor renal function who receive gadolinium-containing contrast material.[69,70]
12. Whenever possible V/Q scintigraphy should be interpreted as either "positive for PE," "nondiagnostic," or "no evidence of PE."

EVALUATION OF CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

Chronic thromboembolic pulmonary hypertension (CTEPH) is defined as the persistence of pulmonary hypertension (defined as a mean pulmonary artery pressure >25 mm Hg) after a single or recurrent PE (see Chapter 73). CTEPH is a serious, underdiagnosed disease and the only cause of pulmonary hypertension that can be potentially cured by pulmonary endarterectomy (PEA). Estimates are that between 0.5% and 3.8% of patients eventually develop CTEPH after an acute PE; CTEPH may develop in up to 10% of those with a history of recurrent PE.[71,72]

It is not entirely clear why some patients with a history of acute PE go on to develop CTEPH. The risk of developing CTEPH increases in patients with a history of prior PE, presentation at a younger age, larger perfusion defects, and idiopathic PE at presentation.[71] Diagnosis is the key to survival in CTEPH, as without appropriate treatment long-term prognosis is poor. There is positive correlation between increased mean pulmonary artery pressure and mortality.[73] Unfortunately, the clinical features, laboratory studies, chest radiograph, electrocardiogram, and echocardiogram are often unreliable in distinguishing CTEPH from primary and nonthromboembolic secondary pulmonary hypertension.

In most centers, conventional pulmonary angiography remains the gold standard imaging study to confirm the diagnosis of CTEPH and determine whether surgical intervention is indicated; chest CTA and MRA provide complementary information, if needed.

V/Q lung scanning is a safe, noninvasive technique that facilitates selection of patients with pulmonary hypertension for pulmonary angiography to confirm the diagnosis of chronic PE. V/Q scanning remains one of the most important diagnostic tests to help distinguish CTEPH from other forms of pulmonary hypertension. In a retrospective analysis, V/Q scanning had a sensitivity of 97.4% for detection of chronic thromboembolic disease, while that for CTA was only 51%.[74]

Patients with CTEPH usually have at least one, and often several, segmental or larger, mismatched perfusion defects.[75] To prevent potential adverse hemodynamic effects when performing V/Q scans in patients with pulmonary hypertension, the number of ^{99m}Tc MAA particles administered should be reduced. V/Q scanning may underestimate the magnitude of central vascular occlusion by

chronic emboli, as determined at conventional pulmonary angiography or thromboendarterectomy.[76]

Most patients with primary or secondary nonthromboembolic pulmonary hypertension have low probability scans. The distribution of ^{99m}Tc MAA particles within the lungs is diffuse and nonhomogenous. Patients with CTEPH rarely, if ever, have normal or very low probability scans. Thus, a low probability V/Q scan effectively excludes chronic thromboembolism as the cause of pulmonary hypertension. In patients with primary pulmonary hypertension, areas of reverse mismatch on the V/Q scan have been shown to correlate with areas of mosaic-increased attenuation on high-resolution CT scans.[77] In a small study of 55 patients suspected of having CTEPH, the detection rates for central emboli with CTA were similar to conventional pulmonary angiography, although detection of segmental disease was superior with conventional pulmonary angiography.[78]

Even though SPECT is more sensitive than planar perfusion lung scanning for identifying obstructed segments in CTEPH, the technique still underrepresents the true extent of the vascular occlusions in CTEPH.[79] Although CTA and MRA may provide complementary information, they often miss the eccentric lesions of CTEPH. Accordingly, the V/Q scan remains the screening study of choice for CTEPH. Any patient with unexplained pulmonary hypertension should be evaluated for the presence of CTEPH; a V/Q scan is recommended as screening method of choice.[80]

QUANTITATIVE VENTILATION–PERFUSION LUNG SCANNING

In patients undergoing pulmonary resection, bronchoscopic lung volume reduction, or lung transplantation, quantitative V/Q lung scanning is a useful method for determining regional lung function and, thus, predicting postoperative pulmonary function (see Chapter 103).[81–83]

Currently, the presurgical assessment to predict response to lung volume reduction surgery (LVRS) in patients with emphysema is mainly performed using chest CT scanning,[84] which provides an anatomic diagnosis of emphysema, delineates its extent and distribution, and detects any other incidental findings that may represent a contraindication to the procedure. A V/Q scan can provide additional information concerning the heterogeneity and distribution of the functional disruption caused by emphysema.[84] Patients with advanced, upper lobe–predominant emphysema derive the most benefit from LVRS,[85] and perfusion scintigraphy is a commonly available test for assessing the distribution of emphysema by reflecting regional lung function.[86] Rectangular regions of interest over the anterior and posterior scintigraphic images of each lung are divided into upper, middle, and lower zones of equal craniocaudal height, and the geometric mean for a given zone is obtained and presented as the percent perfusion to that zone.[87]

In patients being considered for lung cancer surgical resection, a V/Q scan can predict postoperative pulmonary function and enable assessment of the risk of surgery for patients with borderline pulmonary function.[88] The predicted postoperative forced expiratory volume in 1 second (ppo FEV_1) is calculated by multiplying the preoperative value by the ratio of the counts in the remaining lung to total lung activity (Fig. 32-5).[89,90]

Lung perfusion scintigraphy can be used to quantify the degree of right-to-left shunting due to patent foramen ovale, atrial septal defect, elevated right heart pressures, or hepatopulmonary syndrome (HPS).[91,92] The number of injected ^{99m}Tc MAA particles should be reduced in patients with suspected right-to-left shunt. Normally, <5% of ^{99m}Tc MAA is taken up in the brain, but in HPS, fewer MAA particles are entrapped in pulmonary vasculature and are able to enter the systemic circulation and lodge in different organs (thyroid, spleen, liver, kidneys, and brain), leading to >6% uptake in the brain (Fig. 32-6). The major disadvantage of perfusion scintigraphy is that it cannot distinguish intracardiac from intrapulmonary right-to-left shunt. Estimation of the right-to-left shunt fraction is calculated using the following equation: 100 × (TBC − TLC)/(TBC), where TBC is total body count and TLC is total lung count. A less precise alternative method of right-to-left shunt quantification derives an estimate of total body counts from the measurement of renal and/or cerebral activity.

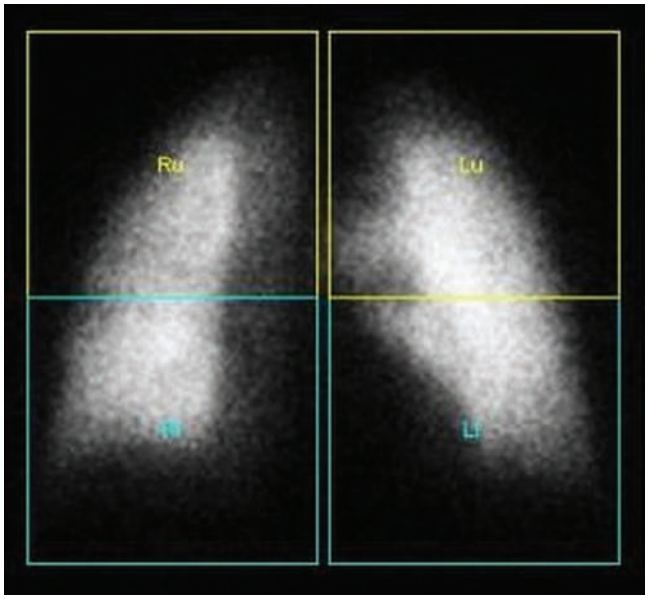


Figure 32-5 Quantitative perfusion lung scan. Regional perfusion can be quantified by outlining regular or irregular regions of interest and generating ratios that correspond to percent of total pulmonary function. Images shown were analyzed by dividing each lung into two equal rectangles.

ASSESSMENT OF ALVEOLAR–CAPILLARY MEMBRANE PERMEABILITY AND MUCOCILIARY CLEARANCE

The clearance rate of inhaled ^{99m}Tc DTPA aerosol from the lungs can be measured using a gamma camera and provides an index of lung epithelial permeability.[11] Aerosols of relatively small aerodynamic diameter (e.g., ^{99m}Tc DTPA) are deposited largely within the small airways and alveoli; the normal half time of ^{99m}Tc DTPA wash out from the lungs is about 80 minutes.[12] In the presence of epithelial

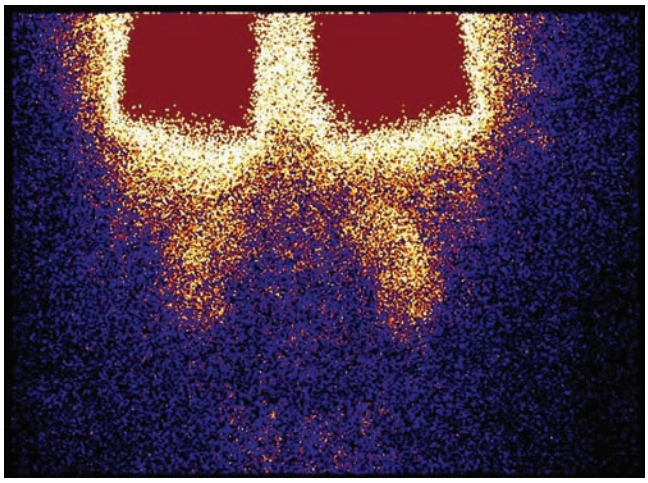

Figure 32-6 Right-to-left shunt in a patient with hepatopulmonary syndrome. Perfusion scan using ^{99m}Tc MAA is showing particles in the systemic circulation lodged in the kidneys.

alveolar damage, the clearance of ^{99m}Tc DTPA is accelerated.[11] Examples of such injuries include amiodarone toxicity, inhalation damage in fire victims, pneumoconiosis, idiopathic pulmonary fibrosis, collagen vascular diseases, sarcoidosis, acute respiratory distress syndrome, and pneumocystis pneumonia.[11,93] Cigarette smoking or physiologic factors, such as posture and exercise, also influence epithelial lung clearance.[11,94] Since increased alveolar–capillary membrane permeability is relatively nonspecific, ^{99m}Tc DTPA aerosol clearance studies have been utilized only to assess the effects of therapy in patients with known pulmonary diseases.

Mucociliary clearance is a primary physiologic defense mechanism, protecting the lungs from damage caused by inhaled particles and microorganisms. Determination of mucociliary clearance may be obtained after the inhalation of relatively large aerosolized particles, followed by measurement of the rate of clearance using a gamma camera. The rate of mucociliary clearance depends on several factors, including ciliary activity and mucus production. Inhaled particles, such as ^{99m}Tc MAA or ^{99m}Tc sulfur colloid, tend to be deposited within the proximal airways.[95] The normal mucociliary clearance half time is approximately 24 hours. Delayed mucociliary clearance is seen in patients with airway inflammation (e.g., cystic fibrosis, COPD, asthma, or viral respiratory tract infections), following bronchial surgery, or after irradiation.

Scintigraphic assessment of alveolar–capillary membrane integrity and mucociliary clearance has not gained wide clinical use,[93] but it is employed in the development of orally inhaled drugs that are administered by inhalation by assessing their deposition patterns, extent of delivery, and depth of penetration into the lungs.[96] In addition, the technique is applicable in quantification of the impact of new drugs on the rate of mucociliary clearance—a key biomarker for products in development for the treatment of respiratory diseases.[97]

POSITRON EMISSION TOMOGRAPHY

PET is used in assessing nonmalignant thoracic disease, as well as pulmonary nodules and known or suspected malignancy. Following are considered basic principles and the role of PET in evaluating inflammatory lung diseases in the overall population, and infections in immunocompromised hosts. Comparison is made with other diagnostic tests, including ^{67}Ga-citrate scanning. The role of PET in assessment of lung nodules and cancer is discussed in a separate section (see Role of Positron Emission Tomography in the Assessment of the Solitary Pulmonary Nodule and Lung Cancer).

BASIC PRINCIPLES

PET is a nuclear medicine imaging modality that provides a 3D image of molecular processes in the body. A PET scan detects gamma rays emitted by positron-emitting tracers. The most commonly used radiopharmaceutical in clinical PET is 2-[^{18}F] fluorodeoxy-D-glucose (FDG), a fluorine-labeled glucose analog with a favorable, 110-minute half-life. FDG competes with glucose for transport into cells and for enzymatic phosphorylation by hexokinase. Unlike glucose, once phosphorylated to FDG-6-phosphate, FDG does not undergo further metabolism; rather, it is trapped inside the cell, and its net accumulation allows for detection by PET.[98]

FDG uptake is proportional to the metabolic activity of the cells that have undergone malignant transformation and, as such, have increased glucose transport and metabolism and increased hexokinase activity. FDG accumulation also depends on various factors, including cellular mitotic rates, level of hypoxia (hypoxia-inducible factor-1-alpha upregulates glucose transport receptors), and degree of cell differentiation (well-differentiated tumors have low FDG uptake).[99] In addition, inflammatory cells share many of the same features as malignant cells; therefore, FDG-PET imaging can be employed to assess infectious and inflammatory processes and diseases. FDG-PET imaging is performed in the fasting state to minimize competitive inhibition of FDG uptake by circulating glucose in the plasma (hyperglycemia may result in decreased FDG accumulation in either malignant or inflammatory cells).

A key advantage of PET over conventional imaging techniques is the possibility of accurate quantification of the ongoing metabolic activities in normal or diseased states. The most common means used for this purpose is measurement of the standardized uptake value (SUV), a semiquantitative expression of the intensity of FDG accumulation in a region of interest (ROI) assigned on the PET scan. SUV normalizes the amount of FDG accumulation in an ROI to the total injected dose and the patient's body weight. It is calculated by dividing the mean activity within a selected region (or volume) of interest (in mCi/mL) by the injected dose (in mCi/kg). SUVmax is derived from the single voxel showing the highest uptake within a defined ROI, which typically represents the most metabolically active part of a tumor or inflammatory process.[100,101] However, it is important to note that several factors can impact SUV, including extravasation of the compound administered, hyperglycemia, respiratory motion, time from injection, and size of ROI.

Today, the mainstay for PET imaging is integrated PET/CT scanners, which allow combining metabolic and structural imaging modalities into a single device. Based on existing data from the past decade, PET/CT scans have been shown to be superior to images generated from separate PET and CT studies for assessing a multitude of disorders.[102] The newest generation of PET/CT scanners contain a state-of-the-art multidetector CT machine that provides up to 128 slices, and time-of-flight PET technologies that reconstruct high-quality images using low FDG doses and short scan times, especially in large patients.[103] PET/CT has some limitations related to attenuation artifacts, leading to false-positive results on corrected images. In addition, motion and misregistration between PET and CT images can also result in major artifacts in regions adjacent to the heart and diaphragm.[104] Combined PET/MRI systems are now commercially available, but their added potential clinical benefit has not yet been validated.[105] This is particularly true in thoracic disorders.

ROLE OF POSITRON EMISSION TOMOGRAPHY IN PULMONARY INFLAMMATION AND INFECTION

FDG-PET has been used in the evaluation of patients with a variety of inflammatory disorders, including venous thromboembolic disease, infections in immunocompromised hosts, and other noninfectious inflammatory conditions. Each of these entities is discussed in subsequent sections.

Potential Role for FDG-PET in Evaluating Suspected Venous Thromboembolism

In recent years, FDG-PET/CT has been explored in many inflammatory conditions. Activated inflammatory cells demonstrate increased FDG uptake due to increased numbers of cell surface glucose transporters following cellular stimulation by various cytokines.[106] Similar biochemical changes are also seen with VTE.

Based on our own experience and that reported in the literature,[107] the potential value of PET in assessing VTE is clear for several reasons. Current imaging techniques, which are based on structural detection of thrombi, are limited; DVT and PE are only two manifestations of VTE, which may occur in parts of the venous system (e.g., within the pelvis) that are not easily accessible by conventional methods. This limitation also applies to the detection of occult disease (e.g., cancer), which is often a key factor in developing VTE (Fig. 32-7). Furthermore, structural imaging techniques cannot differentiate among different phases of thrombus formation, which may hold therapeutic implications.

We believe that many of these shortcomings will be overcome by using FDG-PET/CT. Several case reports have addressed the incidental detection of VTE with FDG-PET/CT in patients with

Figure 32-7 Left femoral thrombosis on FDG-PET/CT scan. Maximum intensity projection PET scan (**top left**), transaxial PET scan (**bottom left**), fused coronal PET/CT scan (**top right**), and fused transaxial PET/CT scan (**bottom right**) in a patient with venous thromboembolism having a FDG-PET/CT in search of underlying malignancy. Increased FDG uptake is seen along the acutely thrombosed vein *(interrupted arrows)*, and focally increased FDG uptake is seen in the cecum *(solid arrows)* corresponding to a biopsy-proven colon cancer.

cancer or bacteremia.[108,109] Inflammatory processes also play a key role in nonmalignant, noninfectious VTE, that is, local vessel wall inflammation and inflammatory components, including activated leukocytes in the thrombus itself.

In a small, prospective, proof-of-concept series,[110] both DVT and PE were shown to be visible on FDG-PET/CT. All patients with proved acute lower extremity DVT had marked FDG uptake along the venous wall at the site of thrombus. Diagnosis was established by positive compression ultrasound in patients with symptoms less than a week; no history of cancer, infection, or prior DVT; and a high clinical probability by Wells' DVT score. Conversely, none of the control patients with suspected, but disproved, DVT had FDG uptake in any part of the venous vasculature. The diagnosis was disproved by negative compression ultrasound in patients with symptoms less than a week; no history of cancer, infection, or prior DVT; and a low clinical probability by Wells' DVT score. Results were more equivocal in PE with some patients with high probability V/Q scans showing no FDG uptake in the pulmonary arteries. However, this may be attributed to significantly longer symptom duration (i.e., months) in some patients. It may, in fact, be that FDG-PET/CT was truly negative for active thrombi, since recent data suggest a significant decrease in FDG avidity over time.

In a pivotal study of 12 patients with confirmed proximal thrombosis in the lower extremity, the authors not only found a specificity of 87.5% to 100% and sensitivity of 87.5% to 100% (depending on SUVmax threshold used), but also a steady decrease in SUVmax and possible complete normalization within 3 months.[111] These findings are in accordance with VTE pathophysiology: The thrombus may be classified as acute when inflammatory cells and mediators are abundant, subacute with subsiding inflammation and increasing fibrosis, and finally, chronic with recanalization and loss of inflammation. This pathophysiology will have significant clinical implications, since active thrombi need therapy, while unresolved old clots require no treatment. However, a substantial fraction of patients with VTE experience symptoms of recurrence, and in as many as half the morphologic features suggestive of the diagnosis remain for years after the first event.[107] FDG-PET/CT likely will differentiate new, active clots from old, inactive ones and facilitate an individualized therapeutic approach.

Although the literature is still sparse, the role of FDG-PET/CT imaging appears to be very promising in VTE and may contribute significantly by detecting clots at any location throughout the body, by early diagnosis of underlying malignancy, and by differentiating acute from chronic thrombi.

Imaging of the Thorax in the Immunocompromised Host

In the last three decades, ^{67}Ga-citrate and white blood cells labeled with ^{111}In or ^{99m}Tc were considered as appropriate agents for imaging pulmonary infection and inflammation. However, due to poor image quality, laborious labeling techniques, and the requirement for imaging several days after injection, imaging with either ^{67}Ga-citrate or radiolabeled white blood cells is now considered obsolete. In recent years these methods have been largely replaced by FDG-PET/CT in the evaluation of suspected infection or inflammation in many anatomic locations. This is also the case in the lungs, where FDG-PET/CT is employed for evaluating suspected pulmonary infections, fever of unknown origin in the immunocompromised host (Fig. 32-8), opportunistic infections in patients infected with

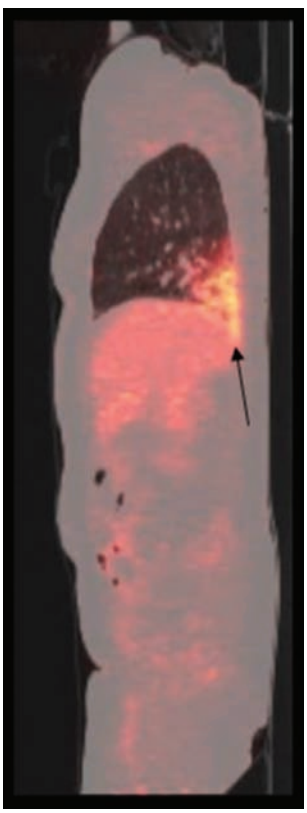

Figure 32-8 Fever of unknown origin in an immunocompromised patient with a kidney transplant. Conventional chest x-ray was normal. Fused sagittal FDG-PET/CT image shows characteristically increased FDG uptake in the right lower lung *(arrow)* consistent with lobar pneumonia.

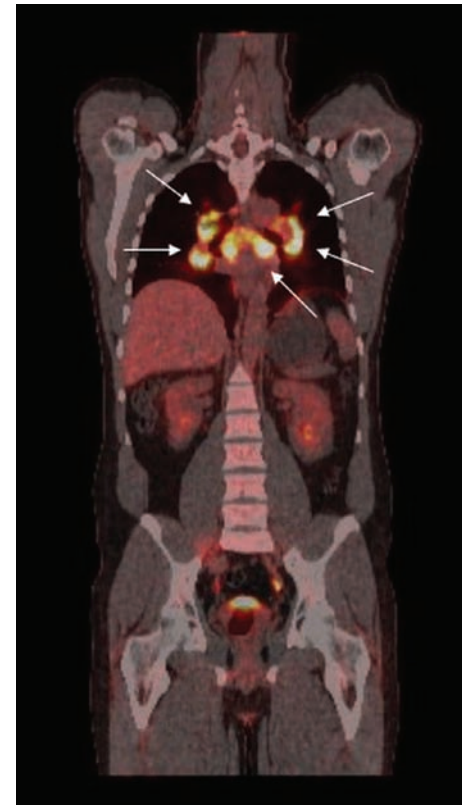

Figure 32-10 Sarcoidosis. Typical presentation of sarcoidosis on FDG-PET/CT with markedly increased FDG uptake in mediastinal and hilar lymph nodes *(arrows)*. Similar patterns are seen in patients with lymphoma.

HIV (Fig. 32-9), and a multitude of inflammatory disorders.[112] In spite of limited data, an early pilot study also suggested that FDG-PET might be helpful in determining treatment response in patients with tuberculosis.[113]

Noninfectious Inflammatory Lung Disease

^{67}Ga-citrate lung imaging has been used to quantify the degree of alveolitis in various interstitial lung diseases, particularly sarcoidosis and idiopathic pulmonary fibrosis. Unfortunately, pulmonary accumulation of ^{67}Ga in idiopathic pulmonary fibrosis was found not to be reliable in predicting the response to treatment or prognosis.[114] Also, in these settings, FDG-PET/CT appears to be substantially superior to ^{67}Ga. A novel potential indication is the assessment of inflammatory disease activity in COPD using FDG-PET/CT. Even with sparse reports in the literature, the evidence points toward a correlation between the distribution and severity of emphysema and the degree of FDG uptake, which may have significant implications for managing patients with this serious disorder.

Sarcoidosis is a multisystem inflammatory granulomatous disease, which involves the lungs in 90% of patients; it may affect any organ in the body. Scintigraphy with ^{67}Ga-citrate has been advocated for assessment of disease activity, but in recent years, this technique has been overshadowed by FDG-PET, which has several technical advantages, including lower radiation exposure, shorter time interval between injection and imaging, and higher quality images. Hilar and mediastinal lymph nodes (as well as any other soft tissues) harboring active granulomas due to sarcoidosis accumulate FDG (Fig. 32-10). Although FDG-PET cannot distinguish sarcoidosis from other diseases, such as Hodgkin or non-Hodgkin lymphomas, the technique is quite effective in assessing the extent of disease after an initial diagnosis, thereby selecting the appropriate site for a successful biopsy. FDG-PET can also provide a means for assessing response to treatment (Fig. 32-11).

FDG-PET has been found to be more sensitive (97%) than ^{67}Ga-citrate scintigraphy (88%) in detecting active sarcoidosis.[115] Comparative studies have shown that FDG-PET can detect more intra- and extrathoracic lesions than ^{67}Ga scintigraphy, with better interobserver agreement.[115–118] High FDG uptake in the involved lung parenchyma correlates with disease severity as revealed by bronchoalveolar lavage.[119] FDG-PET will likely have an increasing role in evaluating the efficacy of therapeutic interventions in this serious disease.[118] In a recent study of 90 patients with chronic sarcoidosis and persistent symptoms, FDG-PET/CT proved helpful in detecting active inflammatory sites, especially in patients with normal ACE levels, thereby influencing adjustment of therapy.[120]

Pneumoconioses may be progressive, even after dust exposure has ceased. The inhaled particles activate pulmonary macrophages that secrete cytokines that mediate an inflammatory reaction, inducing fibroblast proliferation and collagen deposition. FDG is taken up by both fibroblasts and alveolar inflammatory cells. The intensity of pulmonary FDG uptake in pneumoconioses depends on whether active inflammation (increased uptake) or end-stage fibrosis (reduced uptake) predominates at the time of the scan.[121] In addition, progressive massive fibrosis has been shown to be associated with increased FDG accumulation.[122] The findings from FDG-PET have direct clinical implications, as therapeutic interventions are ineffective in end-stage fibrosis.

Interstitial lung disease may also be FDG-avid, but there is limited data on the use of FDG-PET in this setting (Fig. 32-12). In a small prospective study of 21 patients, FDG-PET did not allow differentiation of idiopathic from nonidiopathic pulmonary fibrosis.[123] However, dual–time point FDG-PET imaging holds promise in differential diagnosis and prediction of disease progression in patients with idiopathic interstitial pneumonia.[124]

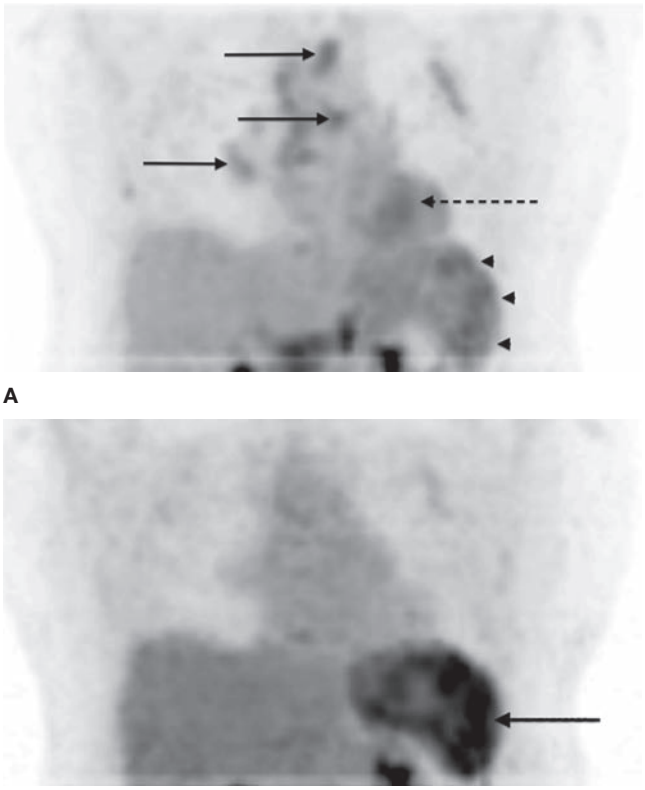

Figure 32-11 **A.** FDG-PET/CT images of the thorax and upper abdomen reveal significant disease activity in mediastinal and hilar lymph nodes *(solid arrows)*, the myocardium *(interrupted arrow)*, and the spleen *(arrow heads)*. **B.** Following successful treatment, there is substantial response in the affected site in the heart and the lymph nodes. However, there is significantly increased uptake of FDG in the splenic lesions *(solid arrow)*, which demonstrates the complexity of the biologic behavior of sarcoidosis in various organs during the course of the disease.

Figure 32-12 Interstitial lung disease. The patient presented with dyspnea and intermittent fever and the PET/CT showed diffusely increased FDG uptake in both lungs *(arrows)*.

ROLE OF POSITRON EMISSION TOMOGRAPHY IN ASSESSMENT OF THE SOLITARY PULMONARY NODULE AND LUNG CANCER

Current clinical indications for FDG-PET imaging in malignant lung disease include evaluation of the solitary pulmonary nodule (SPN), staging of lung cancer (nonsmall cell, small cell, mesothelioma), and planning and monitoring the response to therapy.

EVALUATION OF THE SOLITARY PULMONARY NODULE

An SPN is defined as a round or oval radiographic opacity in the lung parenchyma that measures up to 3 cm in size and is not associated with mediastinal adenopathy or atelectasis (see Chapter 110).[125] An SPN is commonly identified on chest radiographs or CT scans. In the United States, approximately 150,000 new SPNs are diagnosed per year; 30% to 50% of such lesions are malignant and may represent a potentially curable stage of bronchogenic carcinoma.[126] Therefore, early and accurate diagnosis is essential for timely intervention, as lung cancer remains, by far, the leading cause of cancer death among both men and women in the world. Importantly, survival depends on the stage of the cancer when diagnosed.[127]

The most common type of lung cancer is nonsmall cell lung cancer (NSCLC) (adenocarcinoma, squamous cell carcinoma, and large cell carcinoma), which accounts for about 85% of lung cancers.[127] About 10% to 15% of lung cancers are small cell carcinoma, which tend to spread quickly; fewer than 5% of lung cancers are neuroendocrine (carcinoid) tumors, which tend to grow slowly and rarely spread.[127] Most malignant SPNs are adenocarcinoma (47%), followed by squamous cell carcinoma (22%), and small cell lung cancer.[126] Of benign SPNs, about 80% are caused by infectious granulomas.[125]

While a number of benign etiologies for SPNs may have a characteristic appearance on CT, many cannot be characterized accurately using CT and often require further invasive assessment for accurate diagnosis. Certain factors, including smoking history, characteristics of the nodule (size, edge irregularity, and spiculation, pure ground-glass opacity, and absence of calcification), and the age when such lesions are detected are features that determine the probability of malignancy. Despite application of radiographic and other clinical criteria employed for distinguishing benign from malignant lesions, considerable overlap exists.[128] CXRs and CT scans are not accurate in differentiating benign from malignant noncalcified pulmonary nodules that range from 1 to 3 cm in diameter. However, benign patterns of calcification and morphologic stability over 2 years are the most reliable signs of benignity.[128] Bayesian analysis can be used to stratify risk (based on clinical information and imaging characteristics) and guide management of SPN.[129]

FDG-PET provides an accurate, noninvasive diagnostic assessment of SPNs, without the morbidity and costs associated with invasive tissue sampling.[130] In a prospective multicenter trial designed to determine the utility of FDG-PET in discriminating between benign and malignant pulmonary nodules, the sensitivity and specificity of FDG-PET ranged from 92% to 98% and 69% to 100%, respectively (Table 32-6).[130] False-positive studies are seen with active granulomas due to aspergillosis, tuberculosis, or sarcoidosis.[106] False-positive findings may also be related to injection technique (Fig. 32-13). False-negative results are noted with hyperglycemia, malignancies that have a low metabolic activity (e.g., adenocarcinoma *in situ*, previously known as bronchoalveolar cell carncinoma, or carcinoid tumors),[131] and nodules that are <8 mm in diameter.

TABLE 32-6 FDG-PET in Evaluation of Solitary Pulmonary Nodules

Nodule Size (cm)	Type of Analysis	Sensitivity %	Sensitivity 95% Confidence Interval	Specificity %	Specificity 95% Confidence Interval	Accuracy (%)

In one meta-analysis of 40 studies that included 1474 pulmonary lesions evaluated using FDG-PET (including dedicated and gamma camera-based PET), the technique had an average sensitivity of 97% and specificity of 78%.[132]

In general, SUVmax >2.5 has been shown to be very sensitive and specific for differentiating malignant lesions from benign ones.[133] Several studies have shown that no significant differences are noted between results using a semiquantitative analysis of FDG uptake with SUV and those based on qualitative visual assessment.[132,134,135] FDG uptake greater than that in the liver or mediastinum (which typically have an SUV of about 2.0) is considered indicative of malignancy.[130] Visual analysis may be more sensitive for nodules that are smaller than 1.5 cm in diameter, but it carries a lower specificity.[130] Lesions that have no visually detectable FDG uptake have a very low probability for malignancy.[136]

The low accuracy of FDG-PET in assessing nodules having a "ground-glass" or "mixed" appearance on CT scanning is likely related to the cell types that predominate in these lesions, including pure adenocarcinoma *in situ* (bronchioloalveolar cell cancer) or adenocarcinomas with bronchioloalveolar features.[137] In a study of 344 patients in whom a definitive diagnosis was known (prevalence of malignancy: 53%, average size of nodule: 16 mm), FDG-PET had a sensitivity of 92% compared with 96% for CT, but the specificity of PET was markedly better than that of CT, at 82% versus 41%.[138]

As noted previously, the sensitivity of FDG-PET is a function of lesion size and the degree of respiratory motion. In one study addressing the issue of size, the technique's sensitivity in detecting malignancy was 69% for nodules ranging from 5 to 10 mm in diameter and 95% for nodules >10 mm in diameter.[139] The lower limit of spatial resolution of PET, which is about 5 to 6 mm, is lower than

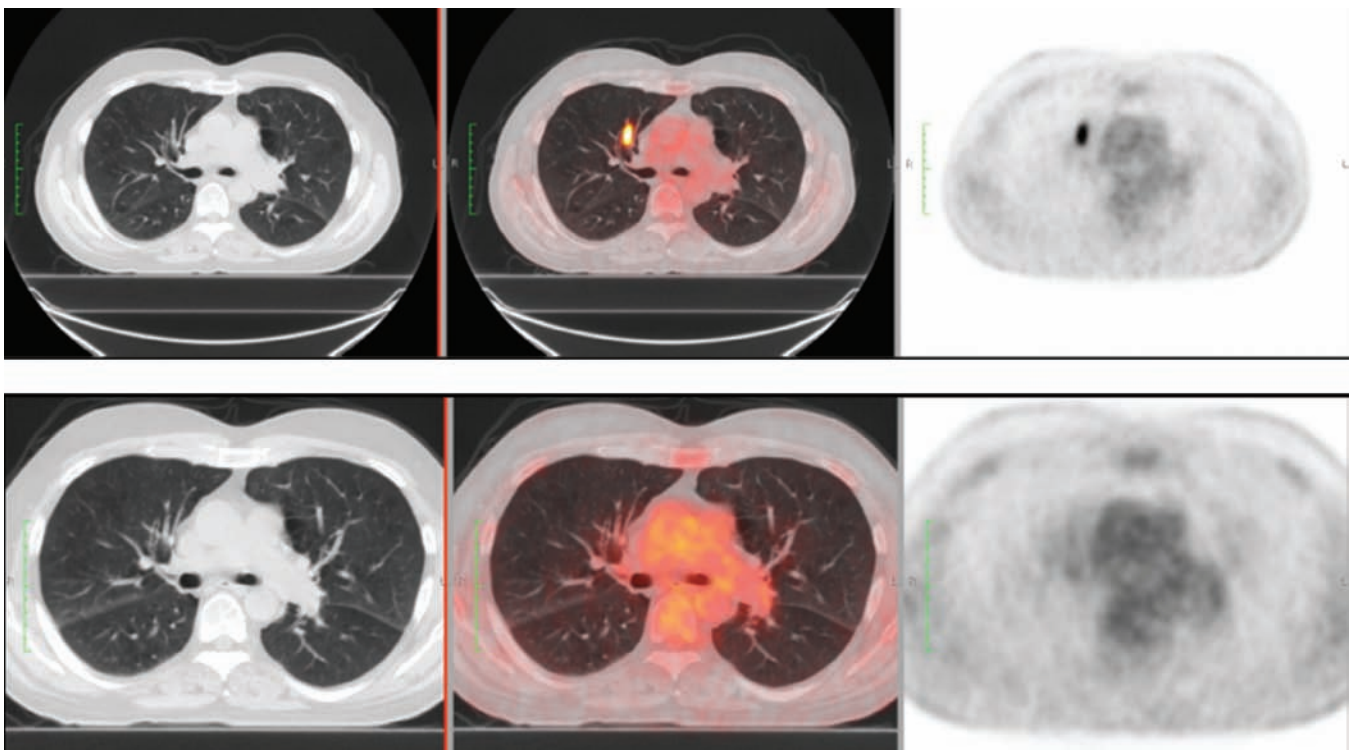

Figure 32-13 A patient referred for characterization of the right upper lobe pulmonary nodule. Transaxial CT, fused PET/CT, and PET images at baseline (**top row**) show solitary, intense focal uptake in the right upper lope. The intense focal uptake was not present in a repeat scan one week later (**bottom row**). This is an example of a false positive finding related to injection technique.

that of CT or MRI. Therefore, PET is not recommended for SPN <8 mm.[140] One method aimed at compensating for this limitation is based on using lesion size measured on CT imaging to correct the underestimated SUV with conventional measurements.

Lung cancers have a wide range of FDG uptake. Furthermore, while most infectious or inflammatory pulmonary disorders generally have a lower FDG uptake than malignancies, overlap exists. An SUV threshold of 2.5, measured at a single point in time, has been proposed to separate malignant (higher SUV) from benign (lower SUV) disorders. Based on the observation in animal and human studies that FDG uptake by malignant tumors increases over time, while that of inflammatory tissue decreases, dual–time point FDG-PET scanning has been proposed as a potentially useful means of improving discrimination between benign and malignant diseases.

Using dual–time point FDG-PET scanning, images are obtained 1 hour and a later time point after administration of FDG. In one study in which an SUV cutoff value of 2.5 and a 10% increase in SUV were used to indicate malignancy, the sensitivity and specificity of FDG-PET were 80% and 94%, respectively, for the single–time point method, and 100% and 89%, respectively, for the dual–time point technique.[141] Recent meta-analysis comparing diagnostic performance of integrated PET/CT scanners showed that dual–time point FDG-PET/CT is more specific than single–time point FDG-PET/CT.[142] Dual time imaging is not required in lesions with a baseline SUV of <1.0, since these lesions have a very high likelihood of being benign, and dual time imaging may result in false-positive examinations.[141] Even for nodules with SUVmax of <2.5, dual time imaging technique may not discriminate accurately between benign and malignant lesions, particularly in areas with a high incidence of granulomatous disease, since false-positive examinations have been reported in association with granulomatous inflammation.[143]

In a study comparing the accuracy of integrated FDG-PET/CT scanning with dynamic CT scanning for pulmonary nodule characterization, FDG-PET/CT scanning was found to be more sensitive and accurate than dynamic CT scanning. The sensitivity, specificity, and accuracy for malignancy with dynamic CT scanning were 81%, 93%, and 85%, respectively, whereas the values for PET/CT scanning were 96%, 88%, and 93%, respectively.[144] Assessment of multiple pulmonary nodules using FDG-PET is limited because of false-positive findings in instances of active granulomatous disease, such as tuberculosis, fungal disease, sarcoidosis, or rheumatoid lesions. In this setting, pattern recognition on CT, in combination with FDG-PET, may improve characterization of the lesions.

Guidelines from the American College of Chest Physicians (ACCP) recommend use of FDG-PET in patients where the probability of cancer is low or moderate (5%–60%) and an indeterminate nodule measures at least 8 to 10 mm.[140] Current National Comprehensive Cancer Network (NCCN) guidelines version 4.2014 recommend FDG-PET for the diagnosis of suspected NSCLC in solid, noncalcified pulmonary nodules >8 mm in diameter.[145] PET/CT scan is not recommended as a screening tool for healthy individuals, since the likelihood of finding cancer is extremely low and the risk increased with detecting harmless findings that may lead to more tests or invasive procedures.[66]

We wish to point out that the data in the literature are based on assigning standard ROIs to the lesions visualized by FDG-PET. Unfortunately, because of the limited spatial resolution of PET imaging, along with respiratory motion of pulmonary lesions, the SUVs generated by this approach result in substantial underestimation of values; the degree of underestimation is proportional to the size of the lesion and the degree of respiratory motion. The physical factors described are known as the "partial volume effect" and, as such, introduce substantial errors to the quantitative data from PET studies, particularly those performed in the evaluation of pulmonary nodules.[146] Therefore, methodologies that can correct for partial volume effects should be employed for accurate measurement of metabolic activity of the lesions assessed. By adopting this approach, significant changes will be noted in the SUVs in most clinical settings. Therefore, total reliance on what has been described in the literature will result in significant mismanagement of patients with SPNs.[147] In particular, adopting an SUV of 2.5 as a threshold for separating malignant and benign lesions is fraught with error and should be abandoned. Many lesions that are smaller than 3 or 4 cm will be prone to such errors.

USE OF POSITRON EMISSION TOMOGRAPHY IN LUNG CANCER

The application of FDG-PET in assessing NSCLC is considered later, followed by a discussion of FDG-PET in small cell lung cancer.

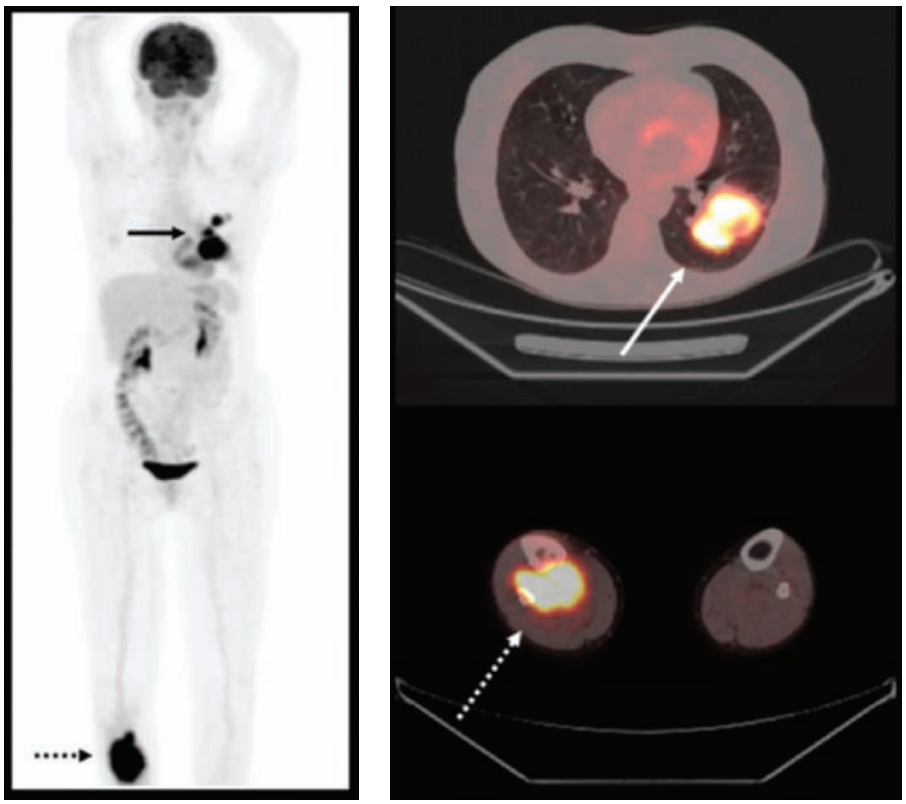
Nonsmall Cell Lung Carcinoma

A major role of FDG-PET is in the staging of NSCLC. Correct lung cancer staging is important because treatment options and prognosis vary significantly by stage. FDG-PET imaging may have a significant impact on patient management by identifying unsuspected sites of disease and by guiding selection of a biopsy site (Fig. 32-14). Similarly, a negative PET scan indicates a low likelihood for malignancy and supports use of conservative management and follow-up (Fig. 32-15). Patients with stage I or II NSCLC are typically referred for surgical resection, while those with stage III or stage IV disease are almost never surgical candidates; in these advanced stages, chemotherapy, radiation therapy, or both may be offered.

The basis for staging NSCLC is the TNM system. For T (tumor) staging, CT and MRI remain the best imaging modalities to demonstrate the local extent of the tumor and its relationship to adjacent organs and vessels. FDG-PET is limited for T staging due to its inability to accurately define the tumor limits. However, FDG-PET/CT has demonstrated a clear advantage in T staging of certain cases, especially in areas of postobstructive atelectasis[148] or low CT density variation and may in the future replace CT and MRI alone for this purpose.[149,150]

In a prospective study of 50 patients with NSCLC, integrated FDG-PET/CT provided additional diagnostic information in 41% of patients and was significantly more accurate in TNM disease staging than either PET or CT alone.[151] Integrated PET/CT provides important clinical information by virtue of accurate localization of known disease and identification of lesions that do not consistently accumulate FDG, such as carcinoid tumors and adenocarcinoma *in situ* (bronchioloalveolar cell carcinoma).[151] PET/CT without contrast-enhanced CT is unable to distinguish confined, centrally located tumors from those producing direct invasion of mediastinal structures. Therefore, clinicians may still rely on contrast-enhanced CT scans to help define mediastinal vascular invasion. From a prognostic point of view, FDG uptake in NSCLC has been correlated with tumor growth rate, aggressiveness, and proliferation capacity, and it has been found to be an independent prognostic factor correlated with survival in patients with NSCLC, especially early-stage disease.[152]

Mediastinal nodal staging most often determines appropriateness for surgical resection. Mediastinal staging using CT scanning is based primarily on assessment of lymph node size; nodes <1 cm in their short axis are considered benign, while those >1 cm are considered potentially malignant. Unfortunately, up to 21% of nodes <1 cm are malignant, and up to 40% of nodes >1 cm are benign.[153,154] A systematic review of the medical literature relating to the accuracy of CT scanning for noninvasive staging of the mediastinum in patients with lung cancer showed a sensitivity and specificity of 51% and 86%, respectively.[155] A large meta-analysis reported the median sensitivity and specificity of CT scanning for identifying malignant mediastinal nodes as 61% and 79%, respectively.[156] These results were similar to an earlier meta-analysis that reported an average sensitivity and specificity of 60% and 77% for CT scanning, respectively (using a transaxial short axis >1.0 cm).[157] In that same meta-analysis of 14 studies (514 patients) for FDG-PET and 29 studies (2,226 patients) for FDG-PET/CT, sensitivity and

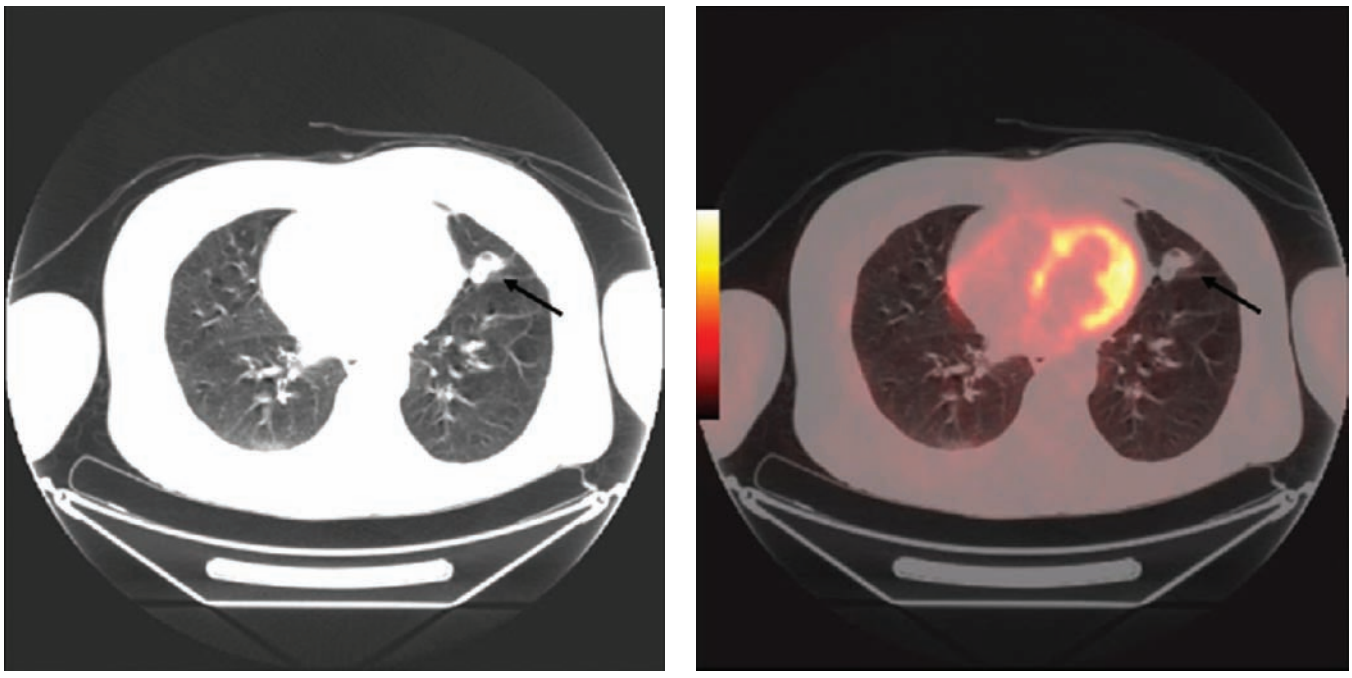


A B

Figure 32-14 Lung cancer. Preoperative evaluation of a patient with a lung cancer in the left lower lobe intended for curative surgery. Whole-body maximum intensity projection PET (**A**) and fused transaxial PET/CT (**B**) show increased FDG uptake in the lung tumor *(solid arrows)*, and unexpected focal FDG uptake in a soft tissue mass in the left proximal tibia *(interrupted arrows)*. Biopsy showed metastasis from the lung cancer obviating surgery.

specificity were higher for determining nodal status in patients with NSCLC (sensitivity and specificity of 79% and 91%, respectively).[157]

The accuracy of FDG-PET in the evaluation of mediastinal lymph nodes depends on the size of the nodes. As reported in a large meta-analysis of 39 studies, the sensitivity and specificity of FDG-PET was 100% and 78%, respectively, in patients with enlarged mediastinal lymph nodes.[156] Sensitivity and specificity were 82% and 93%, respectively, for normal-sized nodes.[156] Positive PET findings in this situation should be confirmed by directed biopsy, as inflammatory or infectious processes can lead to false-positive results. Absence of tissue diagnosis could result in patients with surgically resectable disease being denied curative surgery.



A B

Figure 32-15 Suspected lung cancer. CT scan (**A**) shows a mass suspected of malignancy *(arrow)*. Transaxial fused PET/CT (**B**) shows no abnormal FDG uptake in the mass *(arrow)* consistent with benign process. There is slight misalignment between CT and PET images, but this had no bearing on the interpretation.

Exact classification as N1 or N2 disease is somewhat difficult using FDG-PET alone; anatomic information provided by a CT scan as part of combined FDG-PET/CT imaging is important for this purpose. Integrated PET/CT scanners combine the advantages of both studies, but there are as yet few studies addressing the accuracy of this modality. In one study, the accuracy of mediastinal lymph node staging increased from 89% with FDG-PET alone to 93% with FDG-PET/CT, compared to 63% with CT; a change in the planned treatment was noted in up to 15% of patients.[154] In another study, FDG-PET/CT was significantly better than CT alone for nodal staging: Sensitivity rose from 70% for CT to 85% for FDG-PET/CT; specificity rose from 69% to 84%; and accuracy rose from 69% to 84%.[158] FDG-PET is the best modality to detect tumor in normal-size lymph nodes.

Using an SUVmax of 2.5 is a reasonable threshold for distinguishing between benignity and malignancy, but SUV may be falsely low in lymph node <1 cm due to partial volume effect, and visual assessment is generally accurate.[159] Lymph nodes containing calcification are more likely to be benign, even if they accumulate FDG.[160] Interestingly, studies have shown that FDG-PET/CT has a lower specificity and accuracy for nodes >1 cm compared with those <1 cm, but it still performs better for large lymph nodes than does CT alone.[161,162] The incidence of false-positive nodes is generally larger than that of true-negative nodes as staged by FDG-PET.[162] For patients with stage II or III disease, the incidence of false-negative results is higher with PET than with mediastinoscopy (11.7% and 3%, respectively).[163] These studies illustrate an important limitation of FDG-PET. Therefore, this modality is not currently considered the "gold standard" for confirmation or exclusion of N2/N3 disease in patients with NSCLC.

The variability in false-positive examinations suggests that FDG-PET results should not replace histologic confirmation for suspected mediastinal nodal metastases.[164] FDG-PET–positive lymph nodes still require pathologic confirmation, usually by mediastinoscopy. Other choices of nodal sampling include transbronchial, transthoracic, or transesophageal needle aspiration, or more extensive surgery. These invasive procedures may be guided by the PET findings, as mediastinoscopy is limited to the anterior mediastinum; in addition, approximately 15% of patients may still be found to have N2 disease at thoracotomy.[165] The use of intraoperative FDG-sensitive gamma probes to guide lymph node sampling following the injection of FDG may be helpful.[166]

While studies have demonstrated that patients with metastases detected at mediastinoscopy have a worse prognosis than patients in whom N2 disease is found only at surgery,[167,168] no prospective studies have yet been conducted to determine whether patients with negative mediastinal nodes on preoperative FDG-PET have a similar prognosis to those in whom N2 disease is found at thoracotomy following a negative mediastinoscopy. Therefore, mediastinoscopy still remains part of the standard protocol for mediastinal staging.[163] Guidelines from the ACCP recommend the use of FDG-PET to evaluate for mediastinal and extrathoracic disease in the staging of patients with clinical IA, IB to IIIB lung cancer being treated with curative intent.[140] Patients with abnormal FDG-PET scan need sampling of abnormal lymph nodes prior to surgical resection of the primary tumor.[140]

In addition to being the most accurate noninvasive imaging modality available to evaluate the mediastinum in patients with lung cancer, whole-body FDG-PET imaging is useful in evaluating extrathoracic sites for possible metastatic disease. FDG-PET is superior to conventional imaging in detecting distant metastases. In one prospective study, FDG-PET showed a high sensitivity and specificity in the detection of distant metastases alone (92% and 83%, respectively); 11% of patients had distant metastases detected by FDG-PET that other modalities had failed to detect.[164] Detection of unsuspected extrathoracic metastases may be identified in 6% to 24% of patients (mean frequency of about 13%), and the likelihood for detecting unsuspected metastases increases with the patient's stage.[163] This is particularly important in patients with locally advanced stage III lung cancer.[169] In one multicenter trial, addition of FDG-PET to the conventional workup prevented unnecessary surgery in one out of five patients with suspected NSCLC, with a 50% decrease in futile thoracotomy in comparison to a conventional workup.[170] The likelihood for occult metastatic disease at presentation can be found in up to 30% of patients with adenocarcinoma or large cell carcinoma, but is less common with squamous cell carcinoma (under 15% of patients).[163]

The two most common sites for NSCLC metastases are the adrenal glands and bone marrow. Studies have shown that FDG-PET has a sensitivity of 93% to 100% for the characterization of metastatic adrenal lesions in patients with bronchogenic carcinoma (specificity, 80%–100% and accuracy, 92%–100%).[171–173] Necrotic or hemorrhagic adrenal metastases and small lesions can lead to false-negative FDG-PET.[173] Despite the fact that benign adrenal adenomas generally demonstrate mild FDG uptake that is less than the liver, false-positive studies may still occur.[172] FDG-PET/CT can improve characterization of adrenal masses by improving the specificity based on the combination of SUV and CT attenuation.[174] A Hounsfield Unit (HU) measurement of <10 is indicative of a benign adrenal lesion, even if the SUV measurement is >3.1.[174]

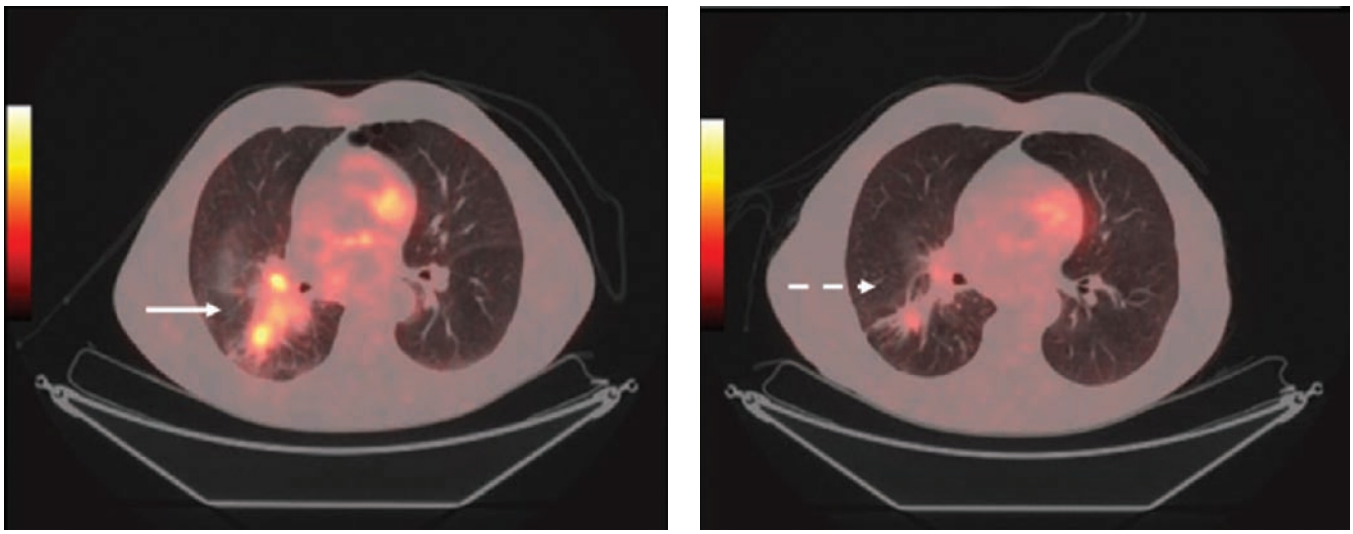
In detecting bone marrow metastases, a comparison of ^{99m}Tc methylene diphosphonate (^{99m}Tc MDP) standard bone scintigraphy to FDG-PET showed a higher accuracy with FDG-PET, (96% vs. 66%).[175] FDG-PET may detect bone marrow metastases before reactive bone formation takes place or prior to development of gross anatomic abnormalities. In a comparison of FDG-PET/CT to ^{99m}Tc MDP and ^{18}F-fluorine PET (F-PET), FDG-PET/CT had a lower sensitivity than F-PET, but was superior to ^{99m}Tc MDP. However, FDG-PET/CT had a higher specificity.[176]

Numerous benign skeletal conditions (including trauma, infection, and physiologic variants) may cause a false-positive FDG-PET. A recent meta-analysis of 17 studies addressed this issue comparing FDG-PET/CT, FDG-PET, MRI, and ^{99m}Tc MDP. The pooled sensitivity of each modality in the detection of bone marrow metastases was 92%, 87%, 77%, and 86%; the specificity was 98%, 94%, 92%, and 88%, respectively.[177]

In the initial evaluation for brain metastases in patients with NSCLC, FDG-PET brain imaging does not provide additional clinical information.[178] Current ACCP recommendations for patients with clinical stage IIIA and IIIB NSCLC are to obtain routine imaging for extrathoracic metastases, including a head CT scan or MRI, plus either whole-body FDG-PET or bone scan plus abdominal imaging.[140]

Until recently, radiation therapy planning has been based on CT imaging because of its excellent delineation of structures in attaining precise assignments of the radiation portals. However, a number of studies have demonstrated the added benefit of PET in defining and refining radiation treatment volumes, thereby reducing (or increasing) the radiation portal and allowing an increase in dose delivery to target tissues, as well as eliminating exposure to normal tissues to avoid toxicity from this therapy.[179] PET/CT is particularly helpful in planning radiation therapy for patients with lung cancer associated with atelectasis. In a prospective study of 76 patients, 34% of patients eligible for radical radiation therapy after conventional staging received palliative therapies instead because of FDG-PET/CT-based detection of advanced disease.[180] FDG-PET/CT frequently changed the planning target volume, which was associated with excellent survival.[180]

FDG-PET imaging may allow for better evaluation of the response to treatment than anatomic imaging, and it may also provide prognostic information that correlates strongly with survival rate following initiation of therapy (Fig. 32-16).[181] Assessment of prognosis can be improved with early FDG-PET imaging, as a 50% decrease in SUV between scans performed at 1 and 3 weeks following initiation of chemotherapy was shown to predict a favorable response.[182]



A B

Figure 32-16 Treatment response in lung cancer. Fused transaxial PET/CT scan at baseline (**A**) showed marked FDG uptake in a tumor in the right lung hilum and mediastinal lymph nodes *(solid arrow)*. Repeat scan (**B**) after three cycles of chemotherapy reveals marked response to treatment *(interrupted arrow)*.

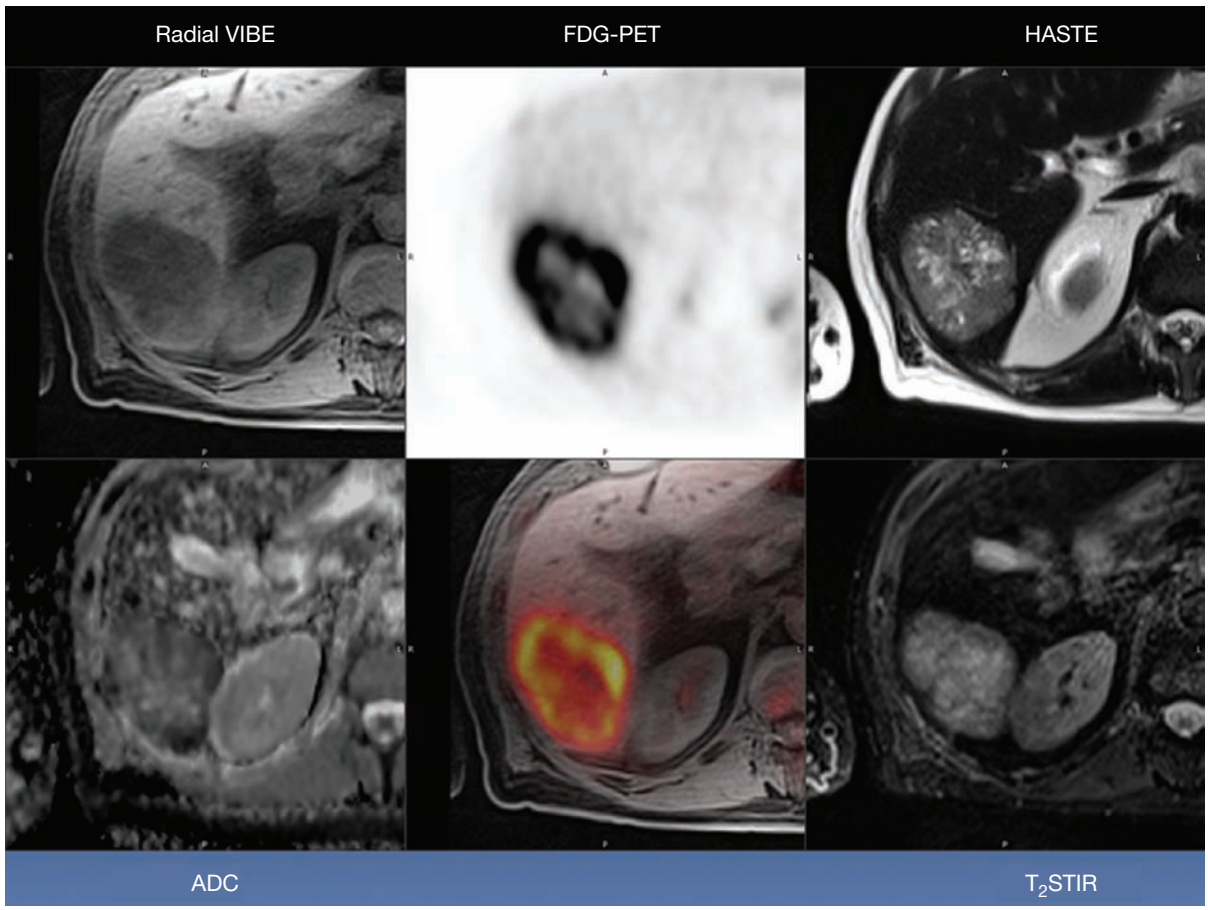


Figure 32-17 A 72-year-old male with lung cancer and liver metastases. Multisequence PET/MR of the liver demonstrates excellent co-registration of PET and multiple MRI sequences. Simultaneous acquisition maximizes accuracy of image registration and facilitates voxel-to-voxel correlations to support quantitative imaging. *(Used with permission of Dr. Kent Friedman. Department of Radiology. Nuclear Medicine Section. New York University School of Medicine, New York, USA.)*

In patients with residual parenchymal abnormalities following radiotherapy for lung cancer, FDG-PET scanning can be used to distinguish between persistent or recurrent cancer and radiation fibrosis.[183] In a study evaluating changes in FDG uptake following definitive radiation therapy, the higher the residual SUVmax in the primary tumor (cutoff, 3.7) or lymph nodes (cutoff, 3.1), the worse was the prognosis.[183] FDG-PET is also useful in assessing response to percutaneous radiofrequency ablation of NSCLC.[184] The novel hybrid method PET/MRI is emerging and shows great potential in lung cancer management (Fig. 32-17).

Small Cell Lung Carcinoma

Small cell lung carcinoma (SCLC) accounts for 18% to 25% of cases of lung cancer. SCLC has a high proliferation rate that results in avid FDG uptake.[185] At presentation, patients are either considered to have limited disease (LD), in which tumor is confined to unilateral chest, or extensive disease (ED), in which tumor has spread to contralateral chest or distant sites. Approximately 60% to 70% of patients present with ED, while 30% to 40% of patients have LD. Except in rare cases of surgically operable, limited-stage SCLC, patients with LD receive chemotherapy and radiation; those with ED are treated with chemotherapy alone. The role of FDG-PET in the staging of SCLC remains controversial, but it may change management in up to 37% of patients for initial staging, and in up to 15% of patients for restaging.[185] Complete metabolic response on posttherapeutic FDG-PET/CT in patients with SCLC is an important prognostic factor, as overall survival is significantly longer compared with that for patients who do not have a complete response.[186]

Mesothelioma

Benign fibrous mesothelioma is a rare, nonmalignant, localized tumor of the pleura that is unrelated to asbestos exposure. The tumor can be cured by excisional surgery. In contrast, malignant pleural mesothelioma (MPM), which is a rare cancer, is the most common primary pleural neoplasm. Affected patients have a median survival of 12 to 18 months. Thus, it is important to differentiate between benign pleural lesions and MPM. The radiologic appearances of benign and malignant pleural diseases are very similar. More than 50% of patients have a pleural effusion at the time of diagnosis; however, pleural fluid cytology is positive in only approximately 25%.[187] Reverse bevel needle biopsy and CT-guided percutaneous needle biopsy of the pleura have low sensitivities of about 21% to 43% and 25% to 60%, respectively.[187] Distinction based on histopathologic criteria is also difficult.

Currently, definitive diagnosis is based on video-assisted thoracoscopic surgery (VATS) (sensitivity, 90%), which, for MPM, carries the risk of tumor seeding along the operative tract. Therefore, radiation therapy is performed to all entry ports following the procedure. CT scan and MRI cannot always differentiate between benign and malignant pleural processes and are of limited value in staging of MPM.[188] Findings from CT and MRI studies can be used in tandem with those from FDG-PET in managing these difficult patients (Fig. 32-18).

Use of FDG-PET in mesothelioma in the mid-90s provided a paradigm shift in the management of patients with this serious cancer.[189] Because of the rarity of this disease, only limited studies have been performed, but FDG-PET has shown promising results in differentiating MPM from benign pleural disease. FDG uptake in MPM is significantly greater in benign pleural disease.[190] For the first time, this approach allowed separating malignant transformations from those that were purely related to inflammatory reactions. This significantly improved the clinician's ability to determine the sites of biopsy in this population. The degree of metabolic activity

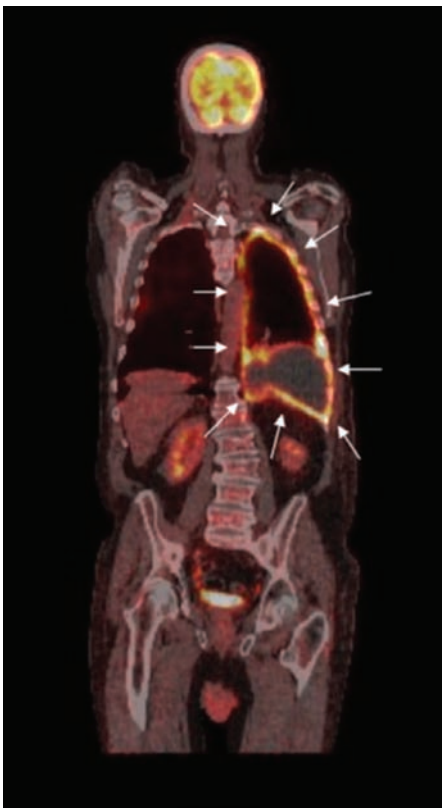

Figure 32-18 Transaxial coronal view of FDG-PET/CT scan demonstrating diffusely increased FDG activity throughout the diaphragmatic, mediastinal, and lateral left pleura, consistent with malignant mesothelioma.

of the lesion has been shown to correlate with survival[191]; higher FDG uptake in MPM is associated with significantly shorter survival.[188] Using the single SUV cutoff technique, however, may not be the optimal approach. Dual–time point imaging and SUVmax on FDG-PET/CT in the delayed phase (120 minutes) have been found to be more reliable, diagnostic, and prognostic factors than that in the early phase (60 minutes)[192]; dual–time point imaging enhances the role of FDG-PET in this population.[193] This approach allows separation of malignant from inflammatory lesions. While malignant lesions show increasing activity over time, inflammatory lesions show a decline. In recent years, global disease assessment has become feasible using modern quantitative techniques. In general, it provides a single number expressing the disease activity in the entire body as one summed score, "the global disease burden," instead of assessing the parameters independently on a per-lesion basis.[194] The so-called "image segmentation methodologies" permit better definition of the boundaries of malignant lesions based on PET images and determination of lesional and whole-body metabolic burden.[194]

In addition to differentiating benign from malignant pleural disease and facilitating assessment of prognosis in MPM, FDG-PET has shown good results in staging, planning of radiotherapy, evaluation of therapy response, and posttreatment surveillance.[194] In a study of 15 patients, FDG-PET upstaged 13% of patients, downstaged 27% of patients, and changed management in 20% of cases.[195] In another study of 29 patients, FDG-PET/CT had a major impact on increasing the accuracy of MPM-TNM staging and determining appropriate therapy.[196]

Finally, FDG-PET is useful in identifying the extent of disease locally and in the mediastinum. In addition, it is helpful in

evaluating abnormal findings in the contralateral lung, and in detecting occult extrathoracic metastases. The metabolic response after neoadjuvant chemotherapy, as determined by FDG-PET, was found to be an independent prognostic factor for patients with resectable MPM, thereby helping to determine which patients are good candidates for extrapleural pneumonectomy.[197]

CHAPTER 33

Pulmonary Function Testing

Michael A. Grippi
Gregory Tino

INTRODUCTION

The assessment of human pulmonary function dates back to the seventeenth century, when the earliest measurements of tidal volume were noted. In 1800, Humphry Davy employed a hydrogen dilution technique to measure his own residual volume (RV).[1] Subsequently, John Hutchinson, in his treatise, *On the Capacity of the Lungs and on Respiratory Functions,* defined the functional subdivisions of lung volume and reported the results of vital capacity measurements performed in more than 1800 subjects. He related these measurements to the subjects' height, age, and weight, thereby establishing a basis for determining normal values.[2,3]

Progress in development of techniques for pulmonary function testing progressed slowly over the next century. However, in the 1950s, pulmonary physiologists made use of the tools provided by the evolving fields of electronics and computer science. Currently, many techniques exist for assessing both the integrated performance of the cardiovascular and respiratory systems and their individual components. This chapter focuses on commonly used tests of pulmonary function.[4] Detailed assessment of integrated pulmonary and cardiovascular function is described in Chapter 34. Additional tests that have not yet been validated or are not routinely available for clinical purposes[5] are not included in the discussion.

LUNG VOLUMES AND SUBDIVISIONS

Important quantitative aspects of respiratory function are the changes in lung volume with inspiration and expiration and the absolute volume of air that the lungs hold at various times during the respiratory cycle. These volumes and changes in volume are described in subsequent sections.

DEFINITIONS AND ASSESSMENT

For purposes of quantification and comparison, the total volume of gas in the lungs is conventionally subdivided into compartments (volumes) and combinations of two or more volumes (capacities). For many of these subdivisions, the end-expiratory volume – the volume of gas remaining in the lungs at the end of normal expiration – is the point of reference. Lung volumes and capacities are defined in Table 33-1 and are depicted schematically in the tracing shown in Figure 33-1, which was obtained using a device called a spirometer. The relationships between the volumes recorded directly by the spirometer and the other lung volumes and capacities – including total lung capacity (TLC), functional residual capacity (FRC), RV, and inspiratory capacity (IC) – are highlighted in the figure.

Spirometers that measure volume or change in volume versus time have been used extensively in pulmonary function laboratories. Previously, through manual calculations, or, in modern times, through application of microprocessors, the relationships among volume, flow, and time are generated to provide a measure of the respiratory system's ability to move air. Two examples of volume-type spirometers of historical note are shown in Figure 33-2. They are discussed briefly to highlight the ingenuity behind their use in determining clinically important physiologic measurements.

In the water-sealed spirometer (Fig. 33-2A), a mouthpiece is attached to a tube through which air passes into a lightweight bell that is inverted over a water bath. Air movement through the mouthpiece into the bell during expiration causes the bell to rise; conversely, as air is withdrawn from the system during inspiration, the bell falls. The change in volume with time can be recorded on a calibrated rotating drum or digitally noted by a computer and displayed on a screen in both graphic and numeric formats.

In the dry, rolling-seal spirometer (Fig. 33-2B), a cylinder with a rolling plastic seal is substituted for the spirometer bell and its water seal. Movement of air through the mouthpiece effects a change in the position of the piston, which is attached to a variable resistor. The resistor, in turn, generates voltage signals proportional to volume changes reflected in displacement of the piston. These signals are processed by a computer to generate graphic and numeric outputs similar to those of the water-sealed spirometer.

Currently, most pulmonary function laboratories utilize flow-type spirometers using pneumotachographs or rotating turbines to determine airflow. Two types of pneumotachographs are in general use: hot wire and flow resistive. In the hot-wire type, air flowing past

TABLE 33-1 Glossary for Static Lung Volumes and Capacities

Term	Symbol	Definition
Volumes		
Residual volume	RV	Volume of air remaining in the lungs after maximal expiration
Expiratory reserve volume	ERV	Maximal volume of air expired from the resting end-expiratory level
Tidal volume	TV[a]	Volume of air inspired or expired with each breath during quiet breathing
Inspiratory reserve volume	IRV	Maximal volume of air inspired from the resting end-inspiratory level
Capacities		
Inspiratory capacity	IC	Maximal volume of air inspired from the end-expiratory level (the sum of IRV and TV)
Vital capacity	VC	Maximal volume of air expired form the maximal inspiratory level
Inspiratory vital capacity	IVC	Maximal volume of air inspired form the maximal expiratory level
Functional residual capacity	FRC	Volume of air remaining in the lungs at the end-expiratory level (the sum of RV and ERV)
Total lung capacity	TLC	Volume of air in the lungs after maximal inspiration (the sum of all volume compartments)

[a]*The symbol TV is traditionally used for tidal volume to indicate a subdivision of static lung volumes. However, the symbol V_T is used for tidal volume in formulas for gas exchange.*

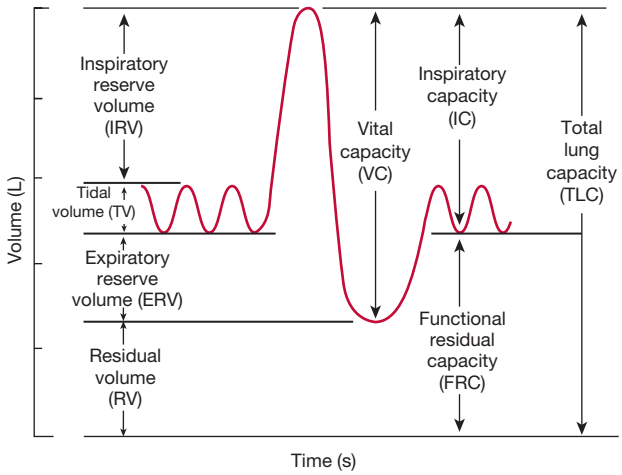

Figure 33-1 The subdivisions of lung volume as recorded by a spirometer. The record is generated on paper calibrated for volume in the vertical direction and time in the horizontal. The term *capacity* is applied to a subdivision composed of two or more *volumes*. The definitions of these subdivisions are found in Table 33-1.

a heated wire cools the wire, thereby altering its resistance in proportion to changes in airflow. Flow-resistive pneumotachographs contain a resistive element composed of parallel tubes (Fig. 33-3), a wire mesh, or a fibrous, paperlike element. Airflow through the resistive element results in a pressure gradient across the device, which can be measured by a very sensitive differential pressure gauge. In the model depicted in Figure 33-3, the array of parallel,

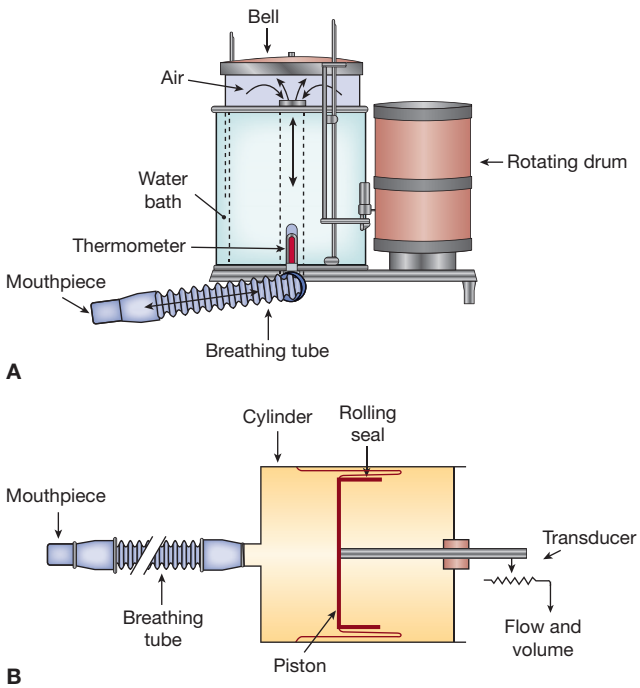

Figure 33-2 Two types of spirometers: water sealed (**A**) and dry rolling seal (**B**). Movement of air through the breathing tube results in movement of the bell (**A**) or piston (**B**). The output signal is either mechanical (pen on rotating drum) or electrical (flow and volume as voltage changes). The primary design criteria for these instruments are that inertia and resistance to airflow must be held to negligible levels, and the calibration must be accurate and stable.

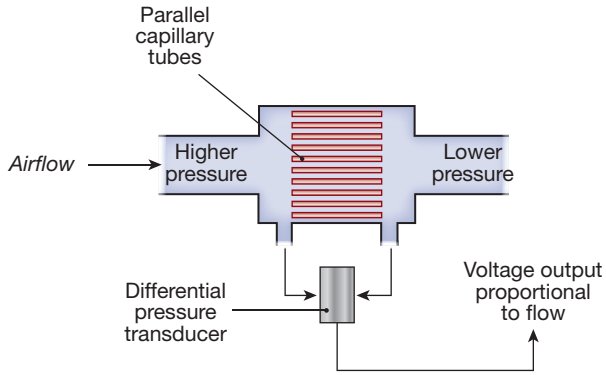

Figure 33-3 Principle of pneumotachography. During unidirectional airflow, a pressure drop is created across a resistive element made up of an array of parallel capillary tubes. The magnitude of the pressure drop is related to airflow, as described by Poiseuille's law for a laminar flow system. The pressure drop is transduced to a proportional voltage output, which can be recorded. A heating element (not shown) maintains the temperature of the expired gas near body temperature.

small-bore tubes maintains a laminar gas flow pattern through the pneumotachograph. As a result, the pressure–flow characteristics of the system can be described by Poiseuille's law:

$$\Delta P = \dot{V}\frac{8\eta l}{\pi r^4}$$

where

ΔP = pressure drop across the resistive element, dyn/cm^2
$\dot{V}$ = gas flow, cm^3/s
η = viscosity of gas, dyn s/cm^2
l = length of resistive element, cm
r = radius of resistive element, cm

Hence, under laminar flow conditions, the flow of gas in each tube is proportional to the pressure drop across the tube. The calculation for the overall pressure drop across the entire resistive element is based on the parallel arrangement of the array of tubes. The pressure drop across the resistive element is sensed by a pressure transducer and converted to a voltage output that is proportional to flow. The flow signal can be integrated electronically to yield volume. The output signals for flow and volume are displayed on a monitor and recorded. Minimal standards have been established by the American Thoracic Society (ATS) and the European Respiratory Society (ERS) (Table 33-2) for spirometers used either for diagnostic purposes or patient monitoring.[6–8]

In a diagnostic setting, spirometers are used to (1) evaluate symptoms, signs, or abnormal laboratory tests; (2) measure the effect of disease on pulmonary function; (3) screen persons at risk of having pulmonary disease; (4) assess preoperative risk; (5) assess prognosis; and (6) assess health status before enrollment in strenuous physical activity programs.

On the other hand, spirometers used for patient monitoring are used to (1) assess therapeutic interventions, including bronchodilator therapy, management of congestive heart failure, etc.; (2) characterize the course of diseases affecting lung function (e.g., obstructive or interstitial lung diseases, congestive heart failure, or neuromuscular diseases); (3) track pulmonary function in persons working in occupations or receiving medications known to affect the lung; (4) evaluate large numbers of people in disability assessments; and (5) provide data as part of epidemiologic surveys.[8]

In general, the diagnostic spirometer is used to assess a patient's lung function for purposes of comparison with values expected in a

TABLE 33-2 Minimal Recommendations for Diagnostic Spirometry

Test	Range/Accuracy (BTPS)	Flow Range (L/s)	Time(s)	Resistance and Back Pressure	Test Signal
VC	0.5–8 L ± 3% of reading or ± 0.050 L, whichever is greater	0–14	30		3-L cal syringe
FVC	0.5–8 L ± 3% of reading or ± 0.050 L, whichever is greater	0–14	15	<1.5 $cmH_2O/L/s$	24 standard waveforms 3-L cal syringe
FEV_1	0.5–8 L ± 3% of reading or ± 0.050 L, whichever is greater	0–14	1	<1.5 $cmH_2O/L/s$	24 standard waveforms
Time zero	The time point from which all FEV_t measurements are taken			Back extrapolation	
PEF	Accuracy: ± 10% of reading or ± 0.30 L/s, whichever is greater Precision: ± 5% of reading or ± 0.15 L/s, whichever is greater	0–14		Mean resistance at 200, 400, 600 L/s must be <2.5 $cmH_2O/L/s$	26 flow standard waveforms
$FEF_{25–75\%}$	7.0 L/s ± 5% of reading or ± 0.200 L/s, whichever is even greater	±14	15	Same as FEV_1	24 standard waveforms
Instantaneous flows	±5% of reading or 0.200 L/s, whichever is greater	0–14		<1.5 $cmH_2O/L/s$	Proof from manufacturer
MVV	250 L/min at TV of 2 L within ± 10% of reading or ± 15 L/min, whichever is greater	±14 ± 3%	12–15	<1.5 $cmH_2O/L/s$	Sine wave pump

Note: BTPS, body temperature and pressure, saturated with water vapor; VC, vital capacity; FVC, forced expiratory vital capacity; FEV_1, forced expiratory volume in 1 s; PEF, peak expiratory flow; $FEF_{25–75\%}$, forced expiratory flow, 25–75%; MVV, maximal voluntary ventilation; TV, tidal volume.

normal population. The monitoring spirometer, which is less expensive and more portable, is used to evaluate a patient's performance over time and to study large numbers of people for epidemiologic or other purposes.

THE VITAL CAPACITY AND ITS SUBDIVISIONS

Two methods of performing a vital capacity maneuver can be used: closed-circuit and open-circuit methods. In the closed-circuit method, the seated patient, with nose clip in place, breathes quietly into the apparatus. After several breaths to establish the resting end-expiratory level, which serves as a point of reference for all subsequent measurements, the patient is urged to inspire fully and then, after reaching a plateau at maximal inspiration, to expire maximally. This expiration must be performed slowly and evenly; attempts by the patient with obstructive pulmonary disease to maximize flow often reduce expiratory volumes because of dynamic compression of the airways caused by high positive pleural pressures (see Chapter 10). Figure 33-1 illustrates schematically this relaxed or "slow" vital capacity maneuver. From the record, tidal volume, inspiratory reserve volume, expiratory reserve volume (ERV), vital capacity, and IC are calculated. A similar maneuver in which the subject breathes out as rapidly and forcefully as possible after a maximal inspiration provides a measure of the forced vital capacity (FVC). Other timed measurements of expiratory airflow (e.g., the forced expiratory volume in 1 second, or FEV_1) are also determined from this type of record (see Dynamic Mechanical Properties of the Respiratory System).

In the open-circuit method of determining vital capacity, the patient inspires maximally, inserts the mouthpiece, and then exhales with a slow, constant effort to the point of maximal expiration. With this technique, the resting end-expiratory position is not recorded. Thus, only the vital capacity, not its component volumes, can be measured. The open-circuit technique offers some advantages. Since the patient inspires from room air before expiring into the apparatus, concern over acquisition of infection from contaminated inspired air is minimized. In addition, the open-circuit method is generally completed in a shorter time, providing a major advantage when epidemiologic studies are being performed on large numbers of subjects.

FUNCTIONAL RESIDUAL CAPACITY AND RESIDUAL VOLUME

One compartment of the TLC that cannot be measured by spirometry is RV, the volume of air remaining in the lungs at the end of a maximal expiration. RV is determined indirectly in three steps: (1) FRC is typically measured using one of the three techniques: closed-circuit helium, open-circuit nitrogen, or total-body plethysmograph. (2) ERV is determined spirometrically. (3) RV is calculated as the difference between FRC and ERV. In principle, it is possible to determine the RV using a dilution technique or body plethysmography after maximal expiration. In practice, however, the resting end-expiratory level is a more reproducible starting point for determining FRC than is the maximal end-expiratory level for determining RV.

Closed-Circuit Helium Method

The closed-circuit helium dilution method for determining FRC is a variation of the hydrogen dilution method first used in the early 19th century. Both methods take advantage of the virtual insolubility of the test gas in body tissues and the law of conservation of mass. The development and simplification of this test were accomplished over a 20-year span in the mid-20th century. Schematic depictions of the principle upon which the technique is based and the apparatus used are shown in Figure 33-4.

When a fully manual device is used for measuring FRC, the system is prepared by the addition of about 2 L of air and sufficient helium to achieve an initial helium concentration of approximately 10% in the apparatus. The patient, with nose clip in place, then breathes room air through the mouthpiece (Fig. 33-4A). After a preliminary period of quiet breathing to familiarize the patient with the mouthpiece, apparatus, and environment, and after the baseline resting end-expiratory level is established, the test begins.

At the end of a normal expiration, the valve at the mouthpiece is turned to connect the patient to the spirometer system

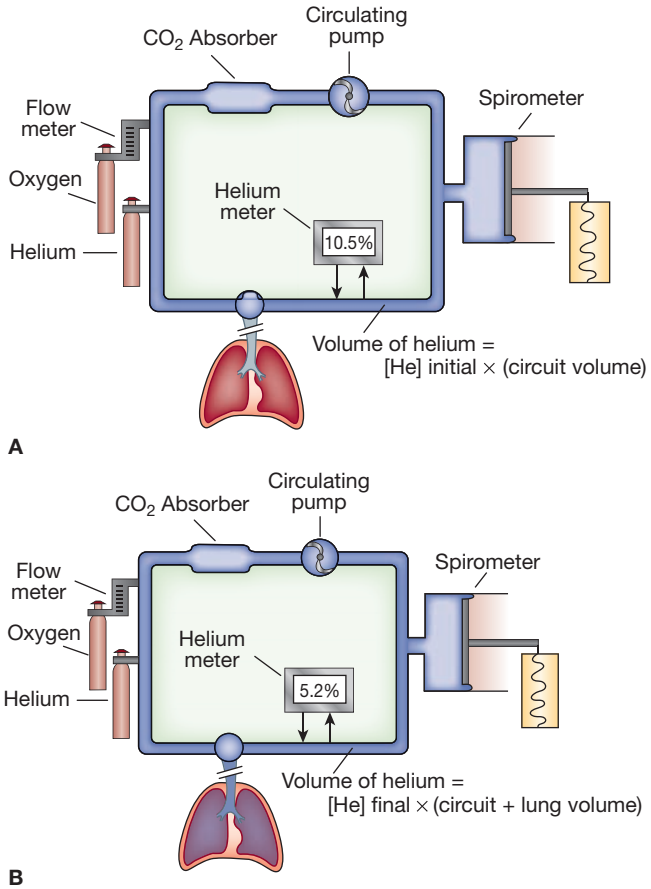

Figure 33-4 Closed-circuit helium dilution method for measurement of FRC. **A.** Spirometer and tubing system with helium before subject begins breathing through the circuit. At the end of an expiration, the mouthpiece valve is turned and the patient rebreathes through the circuit. Expired CO_2 is "scrubbed" out of the system, and O_2 is added to compensate for continued O_2 uptake in the lungs. **B.** During equilibration, the measured helium concentration falls, reflecting a dilutional effect of the additional volume (FRC) on the spirometer circuit.

(Fig. 33-4B). As the patient rebreathes from the closed circuit, the blower circulates the gas mixture. The CO_2 is absorbed by soda lime (CO_2 absorber), while O_2 is added through a valve and flowmeter at a rate corresponding to the subject's O_2 consumption. As the helium, which was at first contained entirely within the apparatus, mixes with air contained in the lungs, its concentration, as monitored by the helium analyzer, falls. Stabilization of the helium concentration, indicated by a rate of change in concentration of less than 0.02% over a 30-second interval, signals the point at which the helium concentration has equilibrated throughout the lung-breathing circuit system; equilibration, the end-point of the test, occurs within 7 minutes in normal persons. However, in patients in whom the distribution of ventilation is abnormal – for example, those with chronic obstructive pulmonary disease (COPD)– equilibration may take much longer. Upon equilibration, the following equation, based on the law of conservation of mass, is applied:

$$F_{0He} \times V_0 = F_{F_{He}} \times V_F$$

where

F_{0He} = initial concentration of helium
V_0 = initial volume of system, L
$F_{F_{He}}$ = final concentration of helium
V_F = final volume of system, L

The initial volume of the system is the volume of the spirometer and circuit tubing, whereas the final volume consists of the initial volume plus FRC. The latter value is the only unknown in the preceding equation. Corrections are usually made for the small amount of helium dissolved in body tissues during the test and for slight volume changes caused by a respiratory exchange ratio that is not equal to 1.0.[9] Although the method described here is based on a manually operated device, the same principles hold when all the mechanical and computational steps are accomplished with a computer-controlled system.

Nitrogen Washout Method

Conceptually, the nitrogen washout method is similar to the helium dilution method described previously; however, it relies on an open circuit rather than the closed circuit used in the helium dilution method. The open-circuit nitrogen washout method for determining FRC.[10] requires that the subject breathe 100% O_2 for 7 minutes; during this period, the concentration of N_2 in expired gas is monitored. When the expired N_2 concentration falls to zero, all the N_2 present in the lungs at the start of O_2 breathing has been "washed out." The total volume of gas expired and the concentration of N_2 in the expired gas are measured.

The calculation of FRC is based on the reasonable assumption that the volume of N_2 in the lungs at the start of the test (i.e., the product of lung volume and the concentration of N_2 in the lungs) is the same as the total volume of N_2 expired and collected during the period of the test – that is, the product of the total volume of gas expired and the concentration of N_2 in the expired gas:

$$F_{0_{N_2}} \times V_0 = F_{E_{N_2}} \times V_E$$

where

$F_{0_{N_2}}$ = concentration of N_2 in the lungs
V_0 = volume of gas in the lungs, L
$F_{E_{N_2}}$ = concentration of N_2 in the expired gas
V_E = volume of expired gas, L

Since the test is started at the end of a quiet expiration, the volume of gas in the lungs is FRC. This volume is calculated by substituting into the above equation the initial concentration of N_2 in the lungs, estimated at 0.81 in fasting and 0.79 to 0.80 in nonfasting subjects, and the measured values for volume and N_2 concentration of expired gas.

Body Plethysmography

The word plethysmography is derived from the Greek plethysmos, meaning "enlargement." Although the concept of measuring FRC by recording changes in the volume of the body during "enlargement" of the chest was described in 1882, not until 1956 did DuBois and coworkers introduce a practical plethysmographic technique, based on Boyle's law, for determining thoracic gas volume (TGV).[11]

Any of three types of body plethysmographs can be used: (1) the *pressure plethysmograph,* in which pressure during breathing varies while volume remains constant; (2) the *volume plethysmograph,* in which volume varies during breathing while pressure remains constant; and (3) the *pressure-corrected flow plethysmograph,* which couples the pressure plethysmograph's fidelity of response to high-speed events with the volume plethysmograph's ability to follow large changes in volume. Since the conceptual basis for all three devices is similar, only the most popular one – the pressure plethysmograph – will be described.

The pressure plethysmograph (Fig. 33-5) contains a pneumotachograph and transducer for measuring flow and volume, and two strain-gauge transducers, one for sensing pressure at the mouth (Pm) and the other for sensing pressure in the box (Pbx). A solenoid-operated shutter mechanism is situated between the mouthpiece and the pneumotachograph. The three transducers are connected to

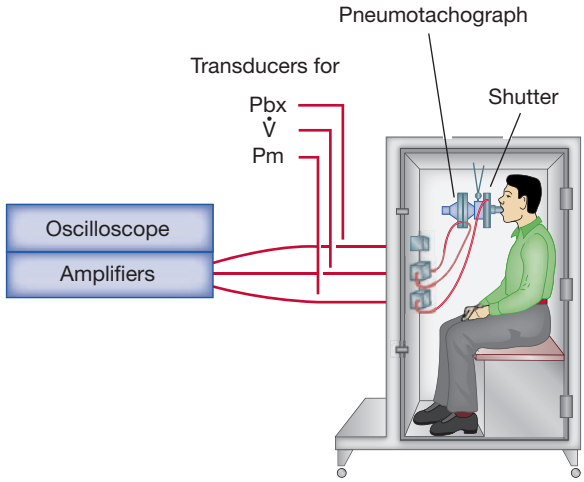

Figure 33-5 Constant-volume, variable-pressure plethysmograph used for measuring functional residual capacity and airway resistance. The device has a fixed volume. Thoracic gas volume changes associated with changes in alveolar pressure are reflected as changes in pressure within the plethysmograph.

an amplifying and monitoring system so that box pressure (or lung volume) and mouth pressure are displayed simultaneously on the X and Y axes, respectively, of an oscilloscope (Fig. 33-6).

In order to determine FRC, the patient, seated comfortably within the box with nose clip in place, is asked to breathe quietly through the mouthpiece. At the end of a quiet expiration, the shutter is closed and the patient is instructed to pant gently against it. The panting movements cause both mouth pressure and box pressure to change. With each inspiratory effort, as mouth pressure falls and gas in the lungs is rarefied, lung volume increases. Because the plethysmograph is a closed box, the increase in lung volume produces a corresponding increase in box pressure. With each expiratory effort, as lung volume decreases, box pressure falls. Because the shutter is closed while the measurements are made, mouth pressure equals alveolar pressure (P_A). These oscillations in mouth pressure and box pressure or lung volume appear on the oscilloscope as a closed loop (Fig. 33-6). Measurement of the slope of this loop is used to determine the volume of gas in the lungs at the time of shutter closure – that is, TGV or V_{TG}. When the occlusion occurs at resting, end-expiratory lung volume, the measurement yields FRC (see below).

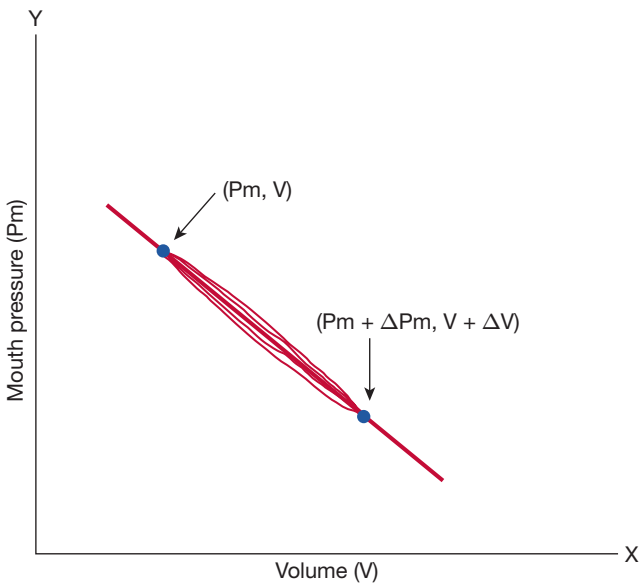

Figure 33-6 Pressure–volume loop obtained from a person seated in a body plethysmograph. Pressure at the mouth represents alveolar pressure; pressure in the box represents thoracic gas volume. After the shutter has closed at end-expiration (Pm, V), the subject attempts to inspire. Pm falls, and the pressure in the box increases. This increase in box pressure is calibrated in terms of an equivalent volume change. The new position of the trace at the end of the inspiratory effort is (Pm + ΔPm, V + ΔV). The slope of the loop depends on the volume of gas in the lungs when the shutter is closed (FRC).

Applying Boyle's law to the plethysmographic determination of lung volume,

$$PV = (P + \Delta P)(V + \Delta V)$$

where

P = pressure in the lungs at end-expiration (atmospheric pressure), cmH_2O
ΔP = change in pulmonary pressure produced by respiratory efforts, cmH_2O
V = volume of gas in the lungs at end expiration (FRC), L
ΔV = change in gas volume in the lungs produced by compression (during expiration) and rarefaction (during inspiration) secondary to respiratory efforts, L

In the pressure plethysmograph, ΔV is sensed as a change in pressure within the box, and ΔP is determined from the change in mouth pressure during breathing efforts against the closed shutter.

Rearranging the above equation and solving for V yield

$$V = \frac{\Delta V}{\Delta P}(P + \Delta P)$$

However, since ΔP is small compared to P (atmospheric pressure), it may be disregarded. The equation then becomes

$$V = P \times \frac{\Delta V}{\Delta P}$$

where

V = functional residual capacity, L
P = atmospheric pressure, cmH_2O
$\Delta V/\Delta P$ = inverse of slope of the loop on the oscilloscope

Therefore, the only unknown in this equation is V, which can be calculated by incorporating values for barometric pressure and the inverse of the slope of the plot of mouth pressure versus box pressure ($\Delta P/\Delta V$).

Two methods for measuring static lung volumes using plethysmography have been standardized by the ATS and ERS. One entails shutter closure at FRC, followed by expiration to RV, and then an IC maneuver to TLC; the other method is shutter closure at FRC, followed by an IC maneuver to TLC, and then an expiratory vital capacity maneuver to RV.[12] Application of each method may yield different calculations of lung volumes.[13]

Comparison of Methods

Compared to the dilution and washout techniques, body plethysmography is, by far, the fastest method available for determining FRC. Indeed, it enables several determinations to be made per minute. Although the equipment required for body plethysmography is more expensive than that required for the other methods, in a busy laboratory this technique generally proves to be more economical because of the time saved and the additional uses to which the equipment can be put (e.g., measurement of airway resistance; see Airway Resistance). Technically, the test is only slightly more difficult than the inert gas dilution method.

Sources of error inherent in the use of body plethysmography and discrepancies between results obtained by body plethysmography and the inert gas techniques should be noted. In patients with COPD[14] or asthma,[15] values for FRC obtained by body plethysmography may be artifactually high because of pressure differences between the mouth and alveoli generated during panting across narrowed airways. Consequently, pressures recorded at the mouth during shutter occlusion of the airway underestimate changes in alveolar pressure. Overestimation of TLC using body plethysmography appears to be greatest in patients whose FEV_1 (see below) is less than 30% predicted.[16]

The inert gas dilution and washout methods are similar both in principle and in results. The values for FRC with these techniques match those from the body plethysmograph except in persons in whom considerable areas of the lungs are poorly ventilated, usually due to obstructive airway disease. In these individuals, complete mixing or washout of the indicator gas is very slow, at times requiring 45 minutes or longer. Because of the slow equilibration of gas concentrations in the poorly ventilated areas, the usual time allotted for the test is inadequate, resulting in a lower value for FRC by the washout methods than by body plethysmography. One strategy commonly used to deal with this problem is to prolong the washout time. The primary advantage of these techniques over body plethysmography is that they can be used in persons for whom the plethysmograph is impractical – for example, those with marked obesity, skeletal abnormalities, or claustrophobia.

TEMPERATURE CORRECTION FACTORS

By convention, all lung volumes described above and airflows (see below) are expressed in terms of body temperature and pressure, saturated with water vapor (BTPS). This practice enables direct comparison of pulmonary function data from laboratories operating at different ambient temperatures and altitudes. To convert the volume of gas collected in a volume-type spirometer under ambient conditions (i.e., ambient temperature and pressure, saturated with water vapor, or ATPS) to BTPS, a conversion factor is applied (Table 33-3). Previously, it was presupposed that air entering a spirometer was cooled *immediately* to ambient temperature and remained saturated with water vapor (ATPS). Under this assumption, only ambient temperature was considered in determining the appropriate correction factor. However, studies have addressed the assumption that expired gas is immediately cooled,[17,18] as well as the practical consequences of temperature correction errors. The ATS recommends temperature correction of results from volume-type spirometers based on *measured* gas temperature at the time of testing.

TABLE 33-3 Factors for Converting Volumes from ATPS to BTPS at Barometric Pressure of 760 mm Hg[a]

Ambient Temperature (°C)	Multiplier to Convert Volumes to BTPS[b]
20	1.101
21	1.096
22	1.091
23	1.085
24	1.080
25	1.074
26	1.069
27	1.062

[a] *Based on Boyle's, Charles's, and Dalton's laws.*
[b] *Volume at ATPS × multiplier = volume at BTPS.*
Note: ATPS, ambient temperature and pressure, saturated with water vapor; BTPS, body temperature and pressure, saturated with water vapor.

RADIOGRAPHIC ASSESSMENT OF LUNG VOLUME

Although initial reports describing use of radiographic techniques to measure lung volumes date back over 40 years, these methods have not found widespread use in adult populations. More sophisticated computerized tomographic (CT) applications have demonstrated good correlation with plethysmographic and gas dilution techniques in normals. However, significant differences may be observed in patients with COPD,[19] in whom TLC determinations using plethysmography may be up to 2 L greater than TLC assessed with CT scanning.[20]

STATIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

Exploration of the elastic properties of the respiratory system and their effect on lung volumes and work of breathing began in earnest during the earlier part of the 20th century. Although the groundwork had been laid centuries before (by Robert Hooke's *The Theory of Springs* in 1678), between 1923 and 1956 investigators provided a wealth of information about the elastic properties of the respiratory system and its components and the work done in overcoming these elastic forces during breathing.

STATIC COMPLIANCE OF THE LUNGS

The elastic properties of the lungs are determined by relating the change in the volume of air contained in the lungs to the corresponding change in the recoil force of the lungs. Change in lung volume is most easily measured by determining the volume of gas inspired or expired at the mouth. Although expedient, this approach to determining the elastic properties of the lungs can underestimate the change in lung volume when incorporated into techniques (see below) that require the subject to expire gently against a closed shutter, a maneuver that compresses thoracic gas. However, the problem can be circumvented by placing the subject in a volume plethysmograph that uses a spirometer attached to the plethysmograph to record changes in TGV due to gas compression.

The recoil force of the lungs, measured as the transpulmonary pressure (Fig. 33-7), is the difference between the alveolar and pleural pressures (P_A and Ppl, respectively). Alveolar pressure is determined as the pressure at the airway opening (Pao) – that is, the mouth – when airflow is arrested and the glottis is open. The pleural pressure is determined indirectly by measuring the pressure in the esophagus using an esophageal balloon catheter. This technique, first introduced in 1949, has been improved over the years and provides accurate reflections of changes in pleural pressure at all lung volumes except those below FRC.[21]

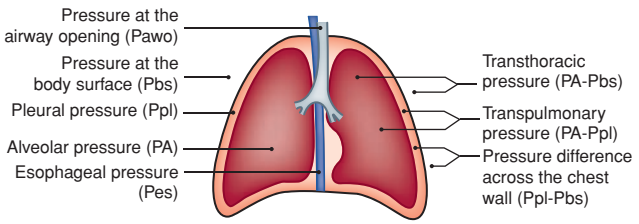

Figure 33-7 Schematic representation of the chest depicting pressure terms and gradients used in analysis of the mechanics of breathing. The expressions for individual pressure measurements on the left are relative to atmospheric pressure. Pleural pressure (Ppl) is not routinely measured directly but is approximated by esophageal pressure (Pes) measured with a balloon catheter.

A thin rubber balloon, about 10 cm long, is placed over a small-diameter polyethylene catheter. Several holes in the terminal portion of the catheter allow pressure to be transmitted from the balloon, through the catheter, to a transducer. The balloon is positioned in the lower third of the esophagus, where esophageal pressure and, therefore, balloon pressure accurately reflect the pressure acting on the lung surface (pleural pressure). Use of an elongated balloon of low volume helps to minimize changes in pressure due to esophageal contractions. By conveying mouth pressure and esophageal pressure to opposite sides of a differential pressure transducer, an output signal is generated that is proportional to the difference between these two pressures – that is, the transpulmonary pressure ($P_A - P_{pl}$).

To determine the elastic properties of the lungs, the patient, with esophageal balloon in place, is seated in a closed body plethysmograph. The patient then breathes ambient air through a tube to the outside until the volume trace, inscribed by the plethysmograph spirometer, indicates that the end-expiratory level is stable. At this juncture, the patient is instructed to first inspire slowly to TLC and then to expire slowly to the resting end-expiratory level (FRC). This maneuver is then repeated; during the second expiration, the shutter is activated to occlude the airway intermittently. Since each closure of the shutter interrupts the expiration briefly, the recorded trace of expiratory volume versus time displays a staircase pattern (Fig. 33-8A). The plateau resulting from each closure of the shutter marks a finite period of zero change in lung volume as the lungs empty during expiration. Associated with each plateau is a corresponding plateau in transpulmonary pressure.

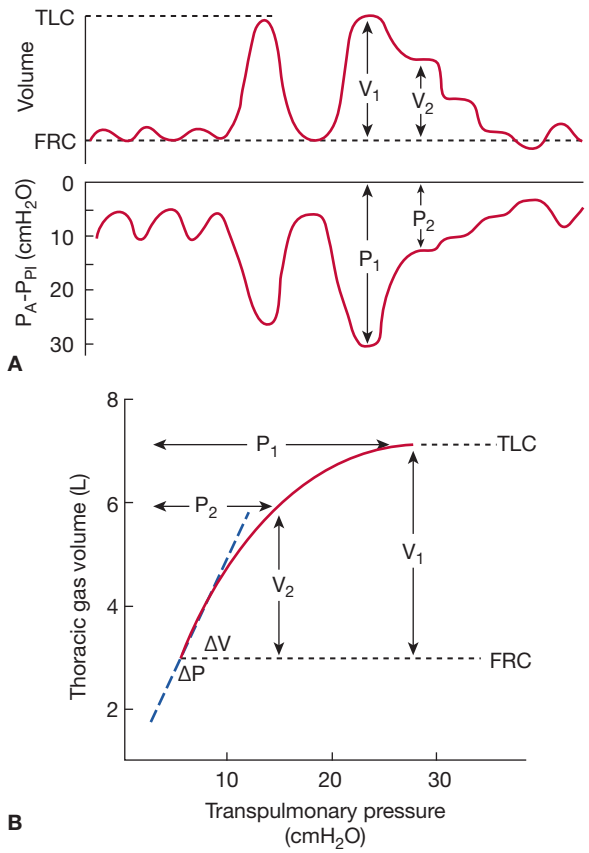

Figure 33-8 Measurement of the elastic properties of the lungs. **A.** Recordings of changes in lung volume and transpulmonary pressure ($P_A - P_{pl}$) using the esophageal balloon technique described in the text. Simultaneous measurements of volume and pressure are obtained during periods of arrested airflow at lung volumes ranging from TLC to just below FRC. **B.** Thoracic gas volume is plotted on the ordinate and transpulmonary pressure on the abscissa. The curve formed by the plot using values from **A** describes the elastic properties of the lungs. The slope of the line, $\Delta V/\Delta P$, over the range of the tidal volume is the static compliance of the lungs.

The relationship between the change in volume and the change in pressure is a measure of the *recoil force* of the lungs at each of the lung volumes that are registered (Fig. 33-8B). The resulting curve provides several useful indices of the elastic behavior of the lungs. The slope of the curve over the range corresponding to the tidal volume is the *static lung compliance.* The transpulmonary pressure attained at TLC is the *maximal static recoil pressure.* The ratio of the maximal static recoil pressure to the corresponding maximal lung volume is the *coefficient of retraction.* However, since these values are derived from only small segments of the curve, inspection of the total static pressure–volume curve remains the most comprehensive means of assessing the elastic properties of the lungs.

STATIC COMPLIANCE OF THE CHEST WALL

Functionally, the chest wall includes the bony thorax, intercostal muscles, overlying soft tissue, pleura, and diaphragm. The chest wall is distensible and has its own distinctive elastic properties. In the normal, end-expiratory, resting position of the respiratory system (FRC), the inward recoil of the lung is balanced by the outward recoil of the chest wall (Fig. 33-9B). As the volume of the thoracic cavity enlarges progressively during inspiration from FRC to TLC, the outward recoil pressure of the chest wall lessens, becoming zero at approximately 70% of TLC; beyond this point, the chest wall begins to recoil inwardly (Fig. 33-9C). Conversely, as the chest wall is compressed below FRC by the action of the expiratory muscles, the natural outward recoil tendency is increased (Fig. 33-9A).

In practice, assessment of the elastic properties of the chest wall is accomplished by first determining the compliance curve of the respiratory system as a whole and then subtracting the contribution of the lungs. For a given lung volume, the pressure across the chest wall, Ppl – Pbs (Fig. 33-7), is simply the difference between the transthoracic ($P_A - P_{bs}$) and transpulmonary ($P_A - P_{pl}$) pressures. As indicated above, Ppl is determined using an esophageal balloon catheter.

ELASTIC PROPERTIES OF THE RESPIRATORY SYSTEM AS A WHOLE

The elasticity of the respiratory system as a whole is determined by measuring the change in volume resulting from a change in pressure applied to the system – that is, the transthoracic pressure ($P_A - P_{bs}$) – *while the respiratory muscles are completely relaxed.*

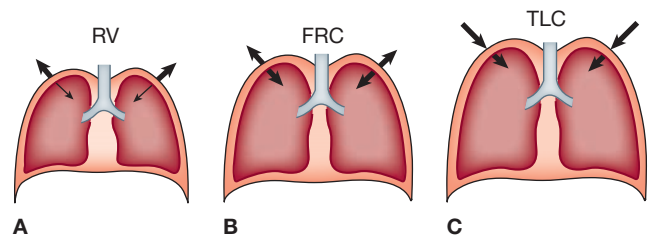

Figure 33-9 Schematic depiction of elastic recoil vectors across the lung and chest wall as determined by the level of inflation. **A.** At RV, the outwardly directed recoil pressure of the chest wall is large and the inwardly directed recoil pressure of the lung is small. **B.** At FRC, the recoil pressures of the lung and chest wall are equal and in opposite directions. **C.** At TLC, both recoil pressures are directed inward, and each contributes substantially to the overall recoil pressure of the respiratory system.

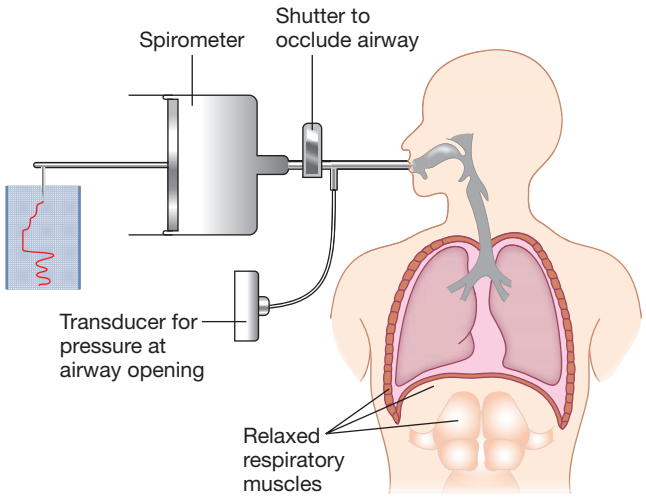

Figure 33-10 Relaxation technique for measurement of elastic recoil pressure of the respiratory system. After a period of normal tidal volume breathing, the subject inspires to TLC. A shutter in the airway is closed, and the subject relaxes his or her respiratory muscles. The shutter is periodically opened, permitting exhalation of a small volume of air measured by the spirometer. Airway pressures are recorded at times of shutter closure (i.e., during no airflow, when mouth pressure equals alveolar pressure). A pressure–volume curve is then constructed from the simultaneously recorded values for pressure and volume.

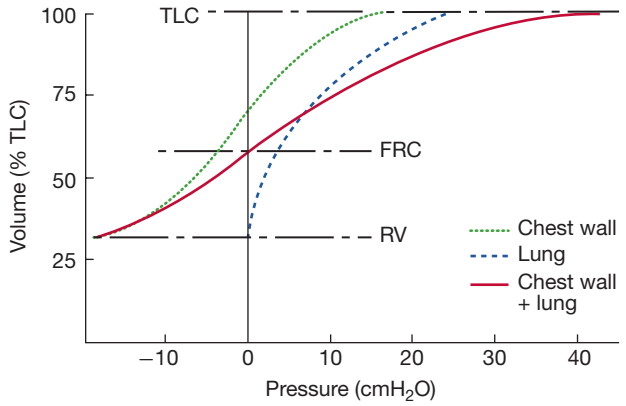

Figure 33-11 The pressure–volume curves of the respiratory system and its components. The elastic recoil pressures of the total respiratory system *(solid line)* over the vital capacity range are the sum of the recoil pressures of the lung *(dashed line)* and chest wall *(dotted line)*. At FRC, the chest wall recoil pressure is counterbalanced by the lung recoil pressure. The net result is a total system recoil pressure of 0. The total system recoil pressure is obtained by relaxation pressure or continuous positive-pressure breathing techniques. The chest wall recoil pressure is calculated as the difference between the recoil pressure of the entire respiratory system and the recoil pressure of the lungs.

The first method used for this evaluation employed the relaxation technique described by Rahn and associates.[22] The subject breathes quietly into an apparatus consisting of a spirometer, a shutter, and a pressure transducer connected to the subject's side of the shutter (Fig. 33-10). After a period of quiet breathing, the subject is instructed to inspire maximally; the shutter is closed at peak inspiration, and the subject is then asked to relax the respiratory muscles completely while keeping the glottis open. Periodically, the shutter is opened, allowing a small volume of air to move from the subject into the spirometer; the shutter is then closed again. This maneuver is repeated until FRC is reached. During the periods of arrested airflow, pressure at the mouth (Pao) is equal to the pressure in the alveoli (P_A). Provided the pressure at the body surface is atmospheric and the respiratory muscles are completely at rest, this value represents transthoracic pressure. In practice, however, full relaxation of the respiratory muscles is difficult, and a contribution by them to the pressure at the airway opening is frequently unavoidable.

A more practical technique entails the application of continuous positive pressure to the airways during spontaneous breathing. The subject breathes quietly into a water-sealed spirometer until a constant end-tidal level is achieved. A weight is then placed on the spirometer bell to increase the pressure in the respiratory system and, thereby, to raise the resting end-expiratory lung volume. This procedure is repeated using several different weights so that a pressure–volume curve of the total respiratory system can be constructed.

The individual pressure–volume curves for the lungs and chest wall and the composite curve for the intact respiratory system are shown in Figure 33-11. As illustrated, the elastic recoil of the chest wall alone is determined by subtracting the recoil pressure of the lung from that of the total respiratory system. Chest wall elasticity is an important determinant of the subdivisions of lung volume and the overall compliance of the respiratory system; the latter is, in turn, an important determinant of the work of breathing.

Several features of the pressure–volume relationships shown in Figure 33-11 are worth emphasizing. As lung volume approaches RV, the elastic recoil pressure of the respiratory system is largely due to the outwardly directed recoil pressure of the chest wall. At RV, the contribution of the lung to the recoil pressure of the respiratory system is minimal. At the other extreme of lung volume, TLC, elastic recoil pressure is high and directed inwardly, due to the combined elastic recoils of the lung and chest wall. At FRC, the outwardly directed recoil of the chest wall balances the inwardly directed recoil of the lung, and the transthoracic pressure is zero (i.e., $P_A - P_{bs} = 0$). Indeed, the system "comes to rest" at FRC because of the counterbalancing of these forces at that volume. Since alveolar pressure at FRC is zero, no pressure gradient exists for airflow. Therefore, the system remains stationary until acted upon by the muscles of inspiration or expiration.

ELASTIC PROPERTIES OF THE RESPIRATORY SYSTEM IN HEALTH AND DISEASE

The elastic properties of the respiratory system are altered by a wide variety of diseases that can affect the lung parenchyma or chest wall, either selectively or in concert. Most instances of clinically significant reductions in static compliance are due to abnormalities in the lung. The two standard clinical measures of the elastic properties of the lung are static lung compliance and maximal static recoil pressure.

Static lung compliance, Cst,L, is determined over the linear portion of the pressure–volume curve, between FRC and a lung volume corresponding to FRC plus 0.5 L. Normal values vary among laboratories, ranging from 0.147 to 0.375 L/cmH_2 O, with a mean of 0.262 L/cmH_2O. Some variability is related to age and sex; Cst,L decreases with age and is higher in males than in females.

Maximal static recoil pressure is the recoil pressure at TLC. Once again, normal values vary. Data from one series of 51 normal subjects.[23] are shown in Table 33-4.

In disease states characterized by an increased elastic recoil pressure, such as diffuse interstitial fibrosis, the pressure–volume curve is shifted to the right and the static lung compliance decreases (Fig. 33-12A and B). The increased elastic recoil pressure contributes to a

TABLE 33-4 Normal Maximal Static Recoil Pressures for Adults (cmH_2O)

	Male Age (Yr)			Female Age (Yr)		
	25–35	36–64	65–75	25–35	36–64	65–75
Mean ± SD	35.9 ± 8.5	33.0 ± 8.7	33.0 ± 2.9	36.4 ± 5.8	25.7 ± 4.0	23.7 ± 3.9

decrease in FRC and TLC. By expressing the volume axis of the pressure–volume curve in terms of *percent predicted TLC* (Fig. 33-12B), instead of *absolute TLC* (Fig. 33-12A), the reduction in maximal lung volume is clearly evident; that is, maximal recoil pressure is increased, despite the reduced TLC.

In contrast to the effects of fibrosis, emphysema, which destroys alveolar walls and enlarges alveolar spaces, reduces lung elastic recoil pressure (Pel). This change increases both TLC and FRC. The shift of the pressure–volume curve upward and to the left (Fig. 33-12A and B) indicates that lung compliance increases and that the maximal recoil pressure decreases. If the volume axis is expressed as percent predicted TLC (Fig. 33-12B), the increase in lung volume is more clearly demonstrated.

As noted previously, disorders affecting primarily the chest wall can also significantly alter the elastic properties of the respiratory system. Among these are obesity, kyphoscoliosis, and fibrothorax. These disorders limit chest wall excursion and lung expansion and reduce FRC. In addition, they produce decreases in static compliance of the lung and chest wall and maximal recoil pressure.

RESPIRATORY MUSCLE STRENGTH

Ventilatory performance depends not only on the mechanical properties of the lungs and chest wall, but also on the strength of the respiratory muscles. Evaluation of respiratory muscle strength was undertaken as early as the mid-19th century. Subsequently, using simplified methods of measurement, Black and Hyatt established normal values (Table 33-5).[24]

The maximal pressure generated by an isometric contraction varies directly with the resting length of the muscle. Consequently, values for maximal inspiratory and expiratory pressures depend on the lung volume at which the tests are performed (Fig. 33-13).[25] When TLC is less than 70% of the predicted value, the maximal expiratory pressure will be low. Similarly, when RV exceeds 40% of the predicted TLC, the maximal inspiratory pressure will be low.

The only equipment required for measurement of maximal inspiratory or expiratory pressure is an aneroid vacuum and pressure gauge. To determine maximal expiratory pressure, the patient is urged to inspire fully to TLC and then to expire as forcefully as possible into the gauge. The highest pressure attained and held for at least 1 second is the *maximal expiratory pressure* ($P_{E_{max}}$). The *maximal inspiratory pressure* ($P_{I_{max}}$) is determined by having the patient inspire maximally from the gauge after having expired completely to RV. The value recorded is the lowest pressure attained and held for at least 1 second.

Measurement of maximal static respiratory pressures is particularly important in evaluating respiratory muscle weakness in patients with neuromuscular disease, as described in Chapters 84 and 85 . In such patients, spirometric tests are often normal, despite respiratory muscle weakness, because maximal pressures are not required to achieve maximal expiratory flow rates (see Flow–Volume Curves).

Another useful function of these measurements is in examining patients whose coordination in performing spirometry or whose degree of motivation is suspicious In such patients, determination of maximal pressures is often helpful in determining whether optimal efforts are being expended during pulmonary function testing (see Approach to Interpreting Commonly Performed Pulmonary Function Tests).

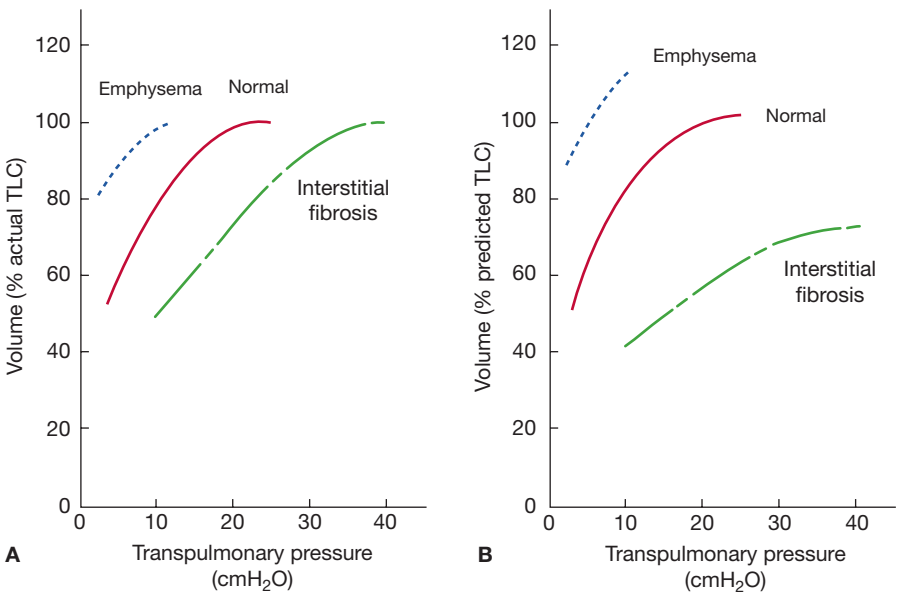

Figure 33-12 Pressure–volume curves of the lungs in health and disease. **A.** Volume expressed as percent of actual TLC. Differences in transpulmonary pressures in normal and diseases states are evident. Changes in lung volume that occur with disease are demonstrated on the plots. **B.** Volume expressed as percent of predicted TLC. In addition to the differences in transpulmonary pressures, alterations in lung volumes in the disease states are evident.

DYNAMIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

The static tests of pulmonary function described in the previous section are based on measurements of volume and pressure made while airflow is arrested. These static tests are particularly useful in defining the elastic properties of the respiratory system. Considerable additional information can be gained from tests done during airflow – that is, under "dynamic" conditions.

Although measurements of static lung volumes began about 300 years ago, the assessment of pulmonary function during airflow began in 1933, when the test now known as the *maximal voluntary ventilation* (MVV) was first proposed. This test did not become popular until a few years later, when Cournand and Richards developed regression equations to determine normal values. Subsequently, investigators proposed that the volume of air expired during specific time intervals be determined. In 1955, determination of the average airflow during the middle half of a forced expiratory vital capacity was described. Determination of these indices of dynamic lung function is now generally part of the battery of tests, both static and dynamic, included under the designation *spirometry.*

The more practical tests of dynamic function can, for convenience, be divided into four categories: FVC, flow–volume curves, MVV, and airway resistance. Other dynamic tests, including assessment of airway reactivity and the function of small airways, will be considered separately.

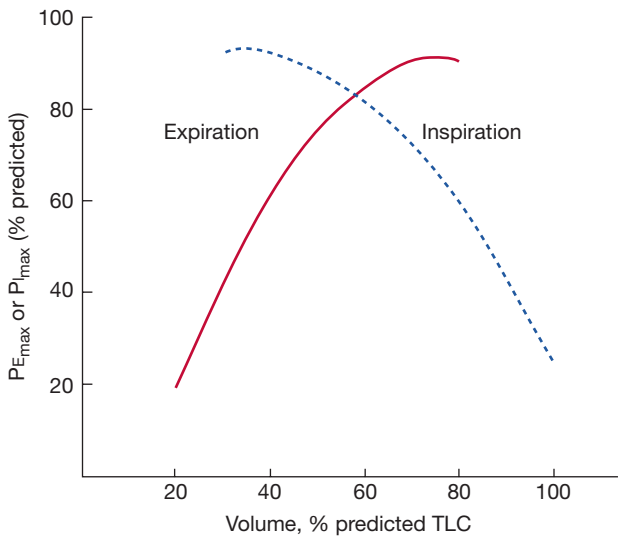

Figure 33-13 Effect of lung volume on maximal inspiratory *(dashed line)* and maximal expiratory *(solid line)* pressures. See text for discussion.

■ FORCED VITAL CAPACITY

Both expiratory and inspiratory measurements of the FVC are routinely made in pulmonary function laboratories. Unless otherwise specified, FVC refers to the forced *expiratory* maneuver.

Forced Expiratory Vital Capacity

The forced expiratory vital capacity is measured during expiration. The maneuver entails two steps: a full inspiration to TLC, followed by a rapid, forceful, maximal expiration (to RV) into a spirometer. The forced expiratory vital capacity (FVC) is normally equal to the relaxed or slow vital capacity (VC). However, a discrepancy between FVC and VC appears in obstructive disease of the airways: the FVC is less than the VC.

The relationship between expired volume and time during an FVC maneuver is used to determine airflow during expiration and the volume of air expired within designated intervals; these values provide an indirect measure of the flow-resistive properties of the lung. The FVC is displayed in one of the two ways: expired volume plotted against time (Fig. 33-14) or airflow plotted against lung volume – that is, an expiratory "flow–volume curve" (see below). The normal volume–time display of the FVC consists of a smooth curve with a gradually and progressively decreasing slope. Irregularities in the curve suggest either a failure of coordination or a suboptimal

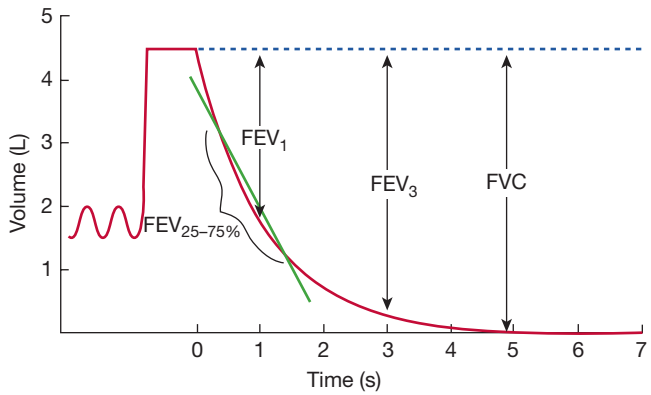

Figure 33-14 Forced expiratory vital capacity maneuver. After an initial period of tidal volume breathing, the patient inspires maximally to TLC and then exhales as rapidly and as forcefully as possible into a spirometer. Shown on the left of the tracing are a series of tidal volume breaths and the maximal inspiration to TLC. The forced expiration begins at time 0. Nearly all the volume is exhaled in the first 3 seconds of the maneuver. The values for FVC, FEV_1, and FEV_3 are measured from the maximal inspiratory level. The $FEF_{25–75\%}$ is the slope of the line connecting the points on the volume–time trace that correspond to 25% and 75% of the FVC.

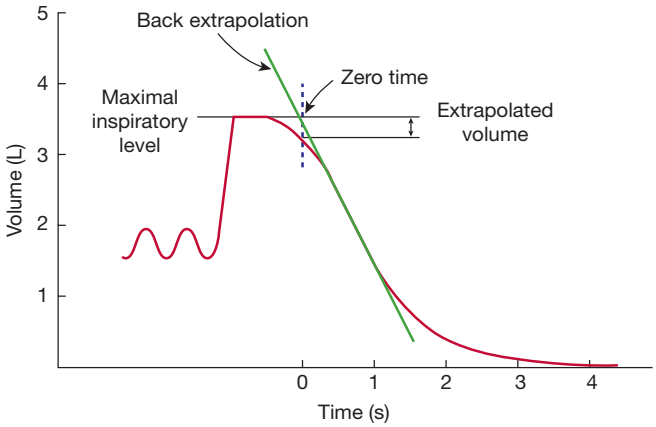

Figure 33-15 Technique of back extrapolation for determining the zero time in calculation of FEV_1. Zero time is determined as the point of intersection of a tangent drawn through the steepest portion of the spirogram and a line drawn horizontally through the maximal inspiratory level.

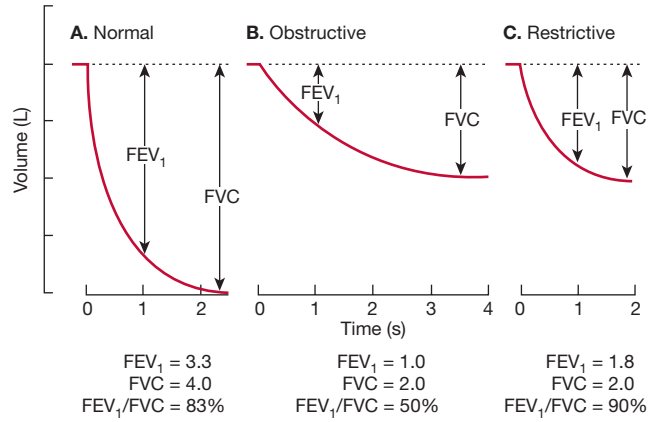

Figure 33-16 Representative spirograms from a normal subject (**A**), a patient with obstructive lung disease (**B**), and a patient with restrictive lung disease (**C**), obtained during a forced expiratory vital capacity maneuver. In the normal subject, expiration is completed within 3 seconds, and 83% of the volume is expired in the first second ($FEV_1/FVC\% = 83$). In the patient with obstructive disease, expiration is prolonged, and only half the volume is expired in the first second ($FEV_1/FVC\% = 50$). In the patient with restrictive disease, although the magnitude of the reduction in exhaled volume is the same as in the obstructed patient, most of the volume is exhaled within the first second ($FEV_1/FVC\% = 90$).

effort. At times, the onset of the forced expiration is unclear (Fig. 33-15) because of hesitation on the part of the patient. When this occurs, the start of expiration ("zero time") is determined with the "back extrapolation" method (Fig. 33-15).[8] A tangent taken through the part of the curve with the steepest slope is extrapolated back to the maximal inspiratory volume; the point of intersection is considered to be the time of onset of expiration.

Several values are commonly determined from the volume–time plot of the FVC (Table 33-6, Fig. 33-14): (1) the *volume expired in the first second*, expressed either as an absolute volume (FEV_1) or as a percentage of the FVC ($FEV_1/FVC\%$); (2) *the volume expired in the first 3 seconds*, expressed either as an absolute volume (FEV_3) or as a percentage of the FVC ($FEV_3/FVC\%$); and (3) *the forced midexpiratory flow rate* ($FEF_{25–75\%}$). The $FEF_{25–75\%}$ is determined by locating the points on the volume–time curve corresponding to 25% and 75% of the FVC and then calculating the slope of a straight line passing through those two points. The slope of this line represents the average airflow over the midportion of the FVC.

Although the *relaxed* or *slow vital capacity* (VC) may be normal or only modestly reduced in patients with obstructive disease of the airways, the volume–time relationship of the FVC maneuver is usually distinctly abnormal in such patients (Fig. 33-16A and B). Most obvious is a flattening of the slope of the curve at any given lung volume, reflecting the reduced airflow. In addition, the duration of the forced expiratory maneuver is prolonged. Normally, expiration is complete within 6 seconds; in obstructive airway disease, expiratory airflow may continue for 10 to 12 seconds. These changes in the expiratory airflow reduce the FEV_1 and FEV_3, the $FEV_1/FVC\%$, the $FEV_3/FVC\%$, and the $FEF_{25–75\%}$.

Restrictive lung disorders reduce the slow vital capacity. However, the *configuration* of the volume–time relationship may not be abnormal (Fig. 33-16C). Although the FEV_1 and FEV_3 are reduced because of the reduced vital capacity, the $FEV_1/FVC\%$ and $FEV_3/FVC\%$ remain normal or even exceed normal values. Often, because of the reduced vital capacity, the $FEF_{25–75\%}$ is also less than predicted.

Forced Inspiratory Vital Capacity

Measurement of the forced inspiratory vital capacity (FIVC) consists of two steps: (1) full expiration to RV, followed by (2) a rapid maximal inspiratory effort (Fig. 33-17). The rate of airflow over the middle half of the forced inspiratory vital capacity ($FIF_{25–75\%}$) is determined using a procedure similar to that described previously for the $FEF_{25–75\%}$.

In normal subjects, the $FIF_{25–75\%}$ is greater than the $FEF_{25–75\%}$. Since inspiratory flow is more dependent on effort than is expiratory

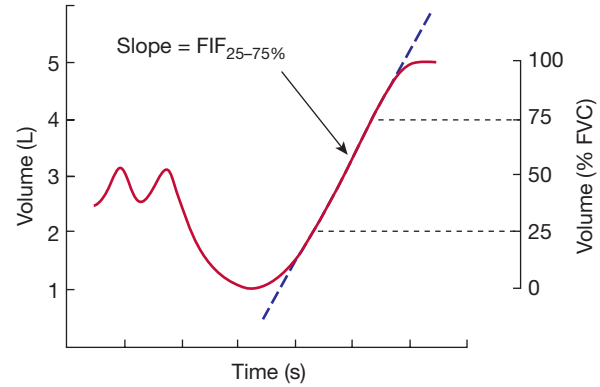

Figure 33-17 Forced inspiratory volume–time curve. The $FIF_{25–75\%}$ is the slope of a line between the points on the trace corresponding to 25% and 75% of the inspired volume.

TABLE 33-6 Values Obtained from Forced Expiratory Volume–Time Curves

FVC (BTPS) (L)	Forced vital capacity; the total volume expired
FEV_1 (BTPS) (L)	Volume of air expired in the first second
$FEV_1/FVC\%$	Volume of air expired in the first second, expressed as percent of the FVC
$FEV_3/FVC\%$	Volume of air expired in the first 3 s, expressed as percent of the FVC
$FEF_{25–75\%}$ (BTPS) (L/s)	Forced midexpiratory airflow

Note: BTPS, body temperature and pressure, saturated with water vapor.

flow, a fall in the $FIF_{25–75\%}$ is usually a more sensitive indicator of respiratory muscle dysfunction or a suboptimal effort than is the $FEF_{25–75\%}$. When airway resistance is high, a disproportionate fall in $FIF_{25–75\%}$ relative to $FEF_{25–75\%}$ suggests an extrathoracic site of airway obstruction (see Approach to Interpreting Commonly Performed Pulmonary Function Tests).

■ FLOW–VOLUME RELATIONSHIPS

In addition to analysis of the relationship between volume and time depicted on a spirogram, examination of the relationship between flow and volume provides useful information about lung function. A flow–volume curve, which shows the relationship between lung volume and maximal airflow as lung volume changes during a forced expiration, is shown in Figure 33-18. The test comprises four phases of breathing into a spirometer: (1) tidal breathing for several breaths, (2) a maximal inspiratory effort to TLC, followed by (3) a maximal expiration to RV done as forcefully and quickly as possible, and (4) another maximal inspiratory effort to TLC. Volume is displayed on the horizontal axis and airflow on the vertical axis. Airflow is measured at the mouth using a pneumotachograph; volume is measured either by integrating the pneumotachographic record during expiration or as a change in TGV, determined by a pressure-corrected flow plethysmograph. The records obtained by the two techniques for determining volume differ because the body plethysmograph senses compression of intrathoracic gas during a forced expiration, whereas measurements of volume made at the mouth do not (Fig. 33-19). Differences between curves obtained with the two techniques for measuring volume are most marked in patients with airway obstruction in whom considerable gas compression occurs during a forced expiration.

For the sake of comparison, tracings of flow versus volume and volume versus time, recorded during the same FVC maneuver and aligned by using a common volume axis as the abscissa, are shown in Figure 33-20. Selected measurements are more evident in one tracing or the other – for example, maximal expiratory flow in the flow–volume curve and volume expired in 1 second (FEV_1) in the volume–time curve.

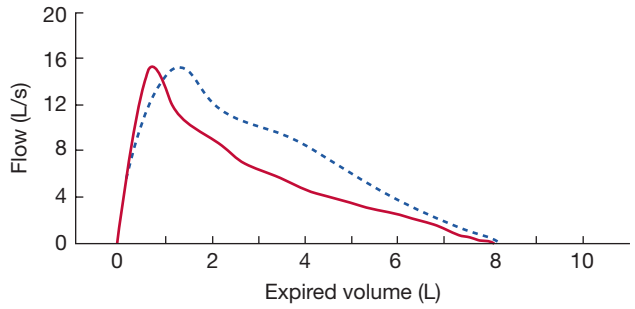

Figure 33-19 Comparison of the flow–expired-volume curve *(solid line)* with a simultaneously recorded flow–thoracic-gas-volume curve *(dashed line)*. The difference between the two curves results from the compression of gas in the lungs during a forced expiration.

Comparison of serial curves from a single person or curves from different subjects requires that the curves be aligned on the volume (horizontal) axis so that points of maximal inspiration or maximal expiration coincide. As may be seen in Figure 33-21A, which illustrates typical curves from a normal subject and two patients, one with pulmonary fibrosis and the other with obstructive airway disease, the information provided by this form of representation is limited; that is, the vital capacities and airflows from the patients are abnormally low. The limitation stems from the fact that the change in volume during expiration is shown relative to the *maximal inspiratory level* rather than to an *absolute volume* of gas in the lungs – that is, RV or TLC. When RV or TLC is known so that absolute volumes can be plotted on the horizontal axis (Fig. 33-21B), additional insight is gained into the flow–volume relationship depicted in Figure 33-21A. The patient with obstructive disease of the airways manifests a reduction in expiratory airflow at elevated lung volumes,

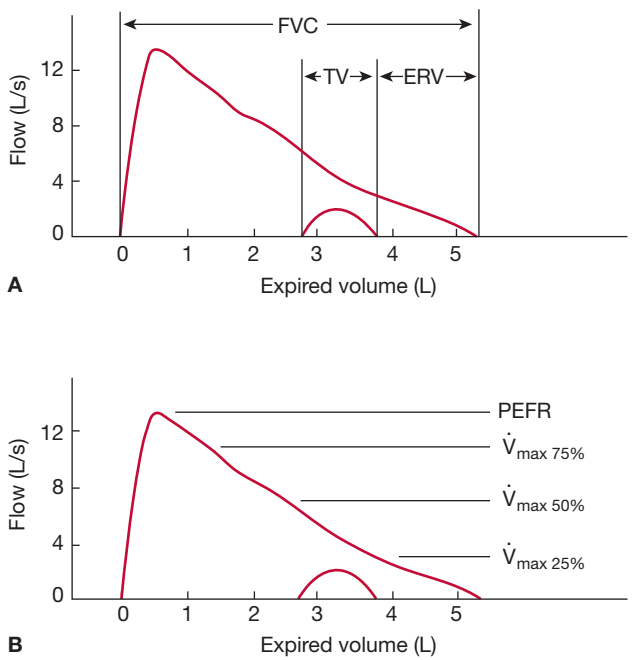

Figure 33-18 Flow–volume plots during forced expiration *(outer trace)* and quiet expiration *(inner trace)*. **A.** The subdivisions of lung volume. **B.** The common flow measurements. PEFR = peak expiratory flow rate; $\dot{V}_{max,75\%}$, $\dot{V}_{max,50\%}$, and $\dot{V}_{max,25\%}$ = flows at 75%, 50%, and 25% of the vital capacity, respectively.

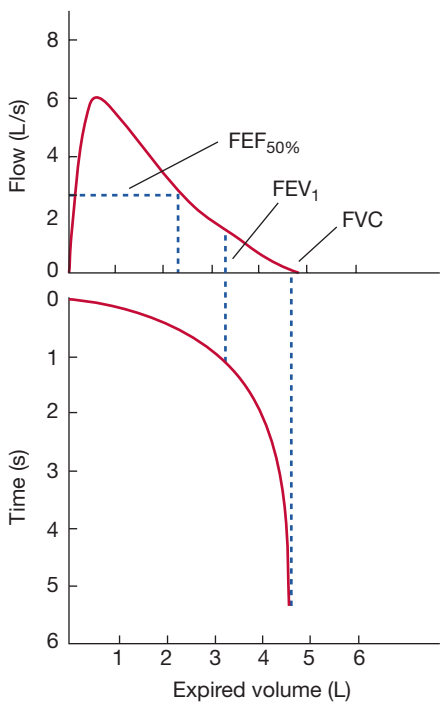

Figure 33-20 Flow–volume and volume–time curves depicting the same forced expiration aligned along a common volume axis (abscissa). Points corresponding to the FEV_1, FVC, and $FEF_{50\%}$ obtained from the volume–time plot are shown on the flow–volume curve.

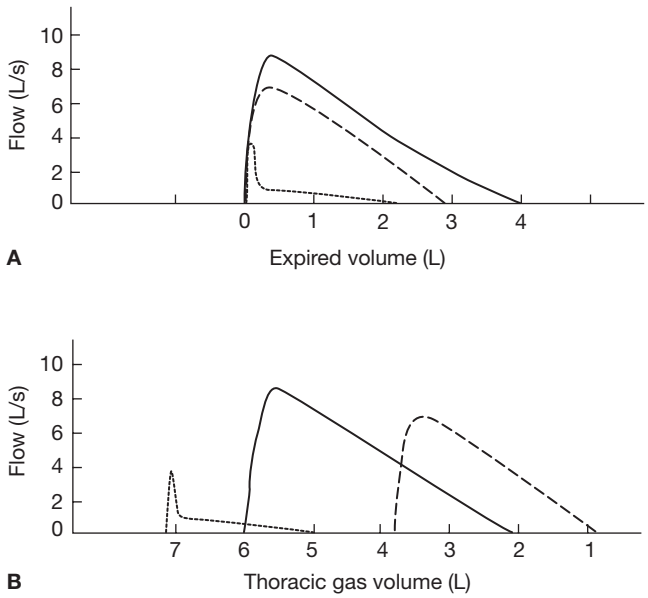

Figure 33-21 Airflow at different lung volumes. **A.** Flow–volume curves aligned at TLC. **B.** Flow–volume curves displayed relative to thoracic gas volume. Although the curves aligned at TLC (**A**) show striking differences in the pattern of airflow, they provide no insight into the relationship between lung volumes and airflow. See text for discussion.

which should enhance airflow. In contrast, the reduced rate of airflow in the patient with pulmonary fibrosis is normal, or even supranormal, when the lung volume at which the airflow occurs is taken into account; that is, the reduced airflow is primarily a function of the reduced lung volume, rather than of airway obstruction.

MAXIMAL VOLUNTARY VENTILATION

The previous considerations of dynamic lung function focus on a single timed maximal expiratory or inspiratory maneuver. In contrast, the MVV depends on the movement of air into and out of the lungs during continued maximal effort throughout a preset interval (Fig. 33-22). The MVV is a simple, informative test that provides an overall assessment of effort, coordination, and the elastic and flow-resistive properties of the respiratory system.[26,27]

In performing the test, the patient is urged to breathe as hard and as fast as possible. As a rule, the patient automatically adjusts

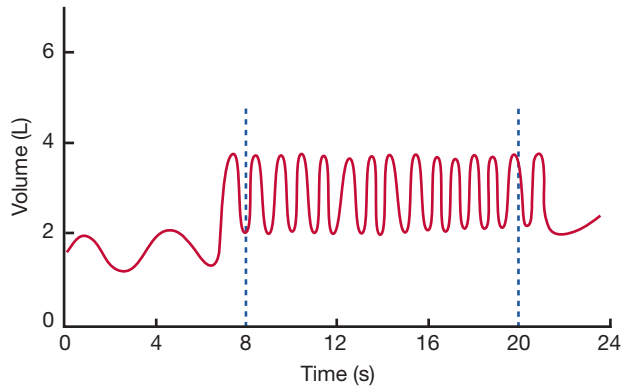

Figure 33-22 Maximal voluntary ventilation (MVV). After a period of relaxed breathing, the subject breathes rapidly and as forcefully as possible. The total volume of air inspired over 12 seconds and expressed in L/min is the MVV.

frequency and tidal volume for optimal performance. However, extremes of frequency or tidal volume are to be avoided, since neither panting nor slow deep breathing leads to the highest possible values. The total volume that is expired during a 12-second interval, expressed in liters per minute (BTPS), is the MVV. In some patients the test cannot be done because of an inability to continue the necessary effort for 12 seconds.

A normal value for MVV indicates that the overall integrated performance of the respiratory system is intact, thereby excluding moderate to severe restrictive or obstructive disease. In addition, a normal value suggests that the elastic and flow-resistive properties of the respiratory system, respiratory muscle strength, coordination of respiratory performance, and motivation of the patient are all normal. Although this test is very useful in detecting overall disturbances in integrated performance and diffuse tracheobronchial and pulmonary parenchymal diseases, other tests are required to pinpoint specific disorders.

The difference between the MVV and the resting minute ventilation is the *breathing reserve.* At one time, a low breathing reserve was correlated with the breathlessness in lung diseases. However, this determination is now primarily of historical interest.

RESPIRATORY RESISTANCE

Total respiratory resistance (Rrs) is the resistance to airflow and chest expansion offered by the airways (Raw), chest wall (Rw), and lung tissue (Rti):

$$Rrs = Raw + Rw + Rti$$

The overall resistance of the respiratory system can be determined with a technique employing forced oscillation (see Small-Airway Function). However, further methodologic refinements permitting determination of *pulmonary resistance* – the sum of airway and tissue resistances (Raw + Rti) – have not proved to be worthwhile clinically, particularly since measurement of transpulmonary pressure with an esophageal balloon is necessary. Other variations of the determination of resistance measurements have also been explored. However, the only clinically useful measurement of resistance is airway resistance, which is now routinely determined in pulmonary function laboratories.

AIRWAY RESISTANCE

Airway resistance (Raw) is defined as the ratio of the driving pressure (P) for flow to the actual rate of airflow ($\dot{V}$) along the airways – that is, the mouth, nasopharynx, larynx, and central and peripheral airways:

$$Raw = \frac{\Delta P}{\dot{V}}$$

where ΔP, the drop in pressure over the entire length of the airways, is determined as the difference between alveolar pressure (P_A) and pressure at the mouth (Pm) or airway opening (Pao).

Although airflow and pressure at the airway opening are easily measured, the difficulty in measuring alveolar pressure prevented the routine determination of airway resistance until DuBois and colleagues introduced the plethysmographic technique in 1956.[28]

With this technique, the patient, seated in the body plethysmograph, pants at a rate of about two breaths per second while airflow is measured using a pneumotachograph. During inspiration and expiration, gas in the alveoli is alternately rarefied and compressed, causing changes in pressure within the sealed plethysmograph. The relationship between plethysmograph pressure and airflow during the panting maneuver is displayed on the X and Y axes of an oscilloscope (Fig. 33-23).

While the panting continues, a shutter at the airway opening is closed so that airflow is transiently interrupted. Using the

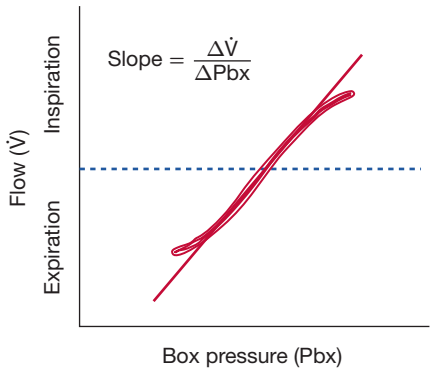

Figure 33-23 Plot of airflow (V̇) versus body plethysmograph pressure (Pbx). The slope of this curve, in the range of 0 to 0.5 L/s of inspiratory flow, divided into the slope of the loop obtained when the shutter is closed (see Fig. 33-7) provides a measure of airway resistance (Raw).

technique employed in the determination of FRC, changes in pressure in the plethysmograph (equivalent to changes in lung volume) and at the mouth are displayed on the X and Y axes, respectively, of the oscilloscope (Fig. 33-6). However, since airflow is zero while the shutter is closed, the pressure at the mouth equals alveolar pressure (Pao = P_A).

Panting while the shutter is open allows the determination of the relationship between airflow (V̇) and plethysmograph pressure (Pbx) – that is, V̇/Pbx. Similarly, panting against a closed shutter enables the determination of the relationship between alveolar pressure (P_A) and plethysmograph pressure – that is, P_A/Pbx. Airway resistance is calculated by dividing the slope of the loop obtained by plotting P_A versus Pbx while the shutter is closed by the slope obtained by plotting V̇ versus Pbx while the shutter is open:

$$\text{Raw} = \frac{P_A / Pbx}{\dot{V} / Pbx} = \frac{P_A}{\dot{V}}$$

where

Raw = airway resistance, $cmH_2O/L/s$
P_A = alveolar pressure, cmH_2O
V̇ = airflow, L/s

Raw is measured during a panting maneuver for several reasons:[29] (1) The rapid respiratory frequency in panting circumvents the poor low-frequency response characteristics of many plethysmographs. (2) The small inspired and expired volumes minimize temperature fluctuations in the plethysmograph that would otherwise occur as tidal breaths of air at body temperature are exchanged with breaths of air at room temperature. (3) During panting, the glottis remains open, thereby minimizing its contribution to overall airway resistance. Use of plethysmographs linked to microprocessors that automatically correct for temperature-related volume differences has made possible the determination of airway resistance during quiet breathing instead of during panting.

Airway resistance varies inversely with lung volume; it is low at large lung volumes and increases curvilinearly as lung volume and, consequently, airway diameters are reduced (Fig. 33-24A).[30] In contrast, the inverse of airway resistance, airway *conductance*, is linearly related to lung volume (Fig. 33-24B). Interpretation of a given value for airway resistance or airway conductance requires that the lung volume at which the measurement is made be taken into account. *Specific conductance* (SGaw) is calculated by dividing airway conductance by the lung volume.

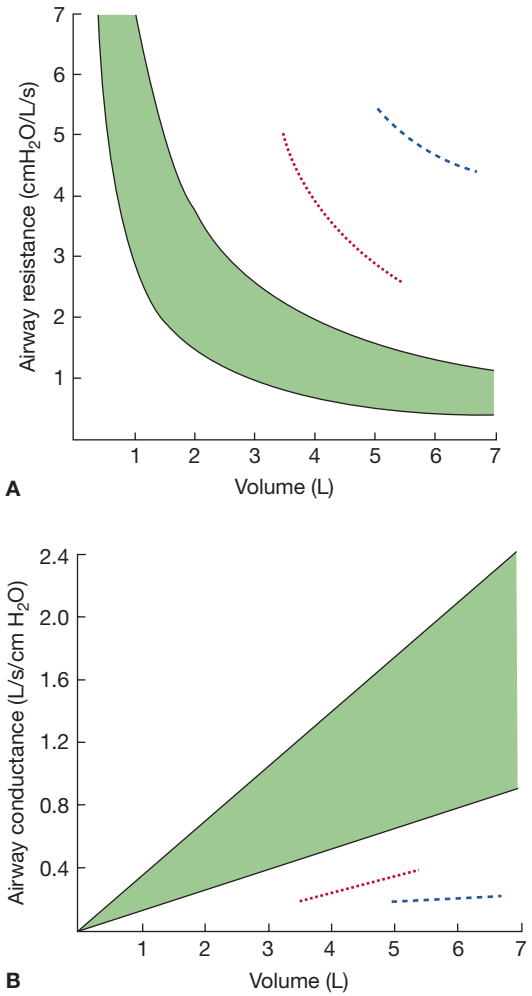

Figure 33-24 The relationship between airway resistance (**A**) and airway conductance (**B**). The shaded area represents the predicted normal range. Values are shown for an asthmatic patient before *(dashed line)* and after *(dotted line)* bronchodilator therapy. Airway resistance increases as lung volume decreases. Conversely, airway conductance, the inverse of resistance, decreases as lung volume decreases.

Defining the range of normal for Raw is difficult because of the lack of data obtained from populations sorted into smoking and nonsmoking groups and because of the inter- and intraindividual variations of Raw with lung volume. One classification scheme proposed for defining normal and abnormal Raw in adults in whom FRC exceeds 2 L is given in Table 33-7.

At times, an apparent discrepancy occurs between forced expiratory flow rates and values for airway resistance. For example,

TABLE 33-7 Categorization of Increased Airway Resistance (Raw)

Category	Raw ($cmH_2O/L/s$)
Mild	2.8–4.5
Moderate	4.54–8.0
Severe	>8.0

although the FEV_1 and $FEF_{25-75\%}$ may be abnormally low (suggesting some degree of airway obstruction), Raw may be within normal limits (arguing against appreciable airway obstruction). This apparent contradiction arises because Raw is determined during *inspiration,* when airways are enlarged because of surrounding negative pleural pressure, whereas FEV_1 and $FEF_{25-75\%}$ are determined during a forceful *expiration,* when airways are compressed by high positive pleural pressures. Therefore, the discrepancy is simply a manifestation of dynamic airway obstruction in which the narrowing is confined to expiration.

■ MEASUREMENT OF EXHALED NITRIC OXIDE

Over the last two decades, the important role of nitric oxide (NO) in a variety of biologic processes has been described.[31] The concept that NO is a marker of airway inflammation, and, hence, has a potential role as a measure of airway function in the setting of inflammatory airway diseases, has been investigated.[32,33] Studies have demonstrated that, at least in asthma, levels of exhaled NO are elevated during exacerbations (when other measures of airway inflammation show activity), even in the absence of symptoms or changes in spirometry.[34,35] Exhaled levels of NO may also be helpful in classifying the severity of asthma.[36] Levels of NO decrease with inhaled corticosteroid use and rise with corticosteroid tapering. Some advocate measurement of exhaled NO as part of routine chronic asthma management.[31]

Standards have been developed for measuring exhaled NO levels.[31] While exhaled NO measurement has not yet assumed the status of a "standard" pulmonary function test, pulmonary function laboratories will likely soon add the test to their repertoires.

AIRWAY REACTIVITY

The dynamic tests of airway function described previously are designed to determine intrinsic properties of the airways in a subject breathing room air at rest. In many clinical situations, such as evaluation of chronic cough, assessment of airway hyperresponsiveness is desirable. This section reviews *bronchoprovocation testing* (BPT),[37,38] which assesses reactivity of the airways to selected pharmacologic or environmental agents.

■ BACKGROUND

One test of bronchial reactivity that has been incorporated into routine pulmonary function testing is determination of the effect on airflow of administration of a nebulized bronchodilator agent. However, bronchoprovocation tests are designed to quantify the degree of bronchoconstriction following the application of a particular stimulus. A number of tests of bronchial reactivity are currently in clinical use (Table 33-8). Among the agents used for inhalation challenges are methacholine, histamine, carbacholine, and specific antigens chosen in accord with the patient's history. In addition to the inhalation challenge tests in which pharmacologic agents are used, tests of bronchial reactivity may be based on inhalation of cold or dry air, isocapnic hyperventilation, or exercise.

■ INDICATIONS FOR BRONCHOPROVOCATION TESTING

The principal indication for BPT is a history suggestive of bronchospasm induced by an environmental or occupational agent, generally in the setting of normal pulmonary function tests (including determination of airflow before and after administration of an inhaled bronchodilator). For example, comparison of FEV_1 before and after administration of a pharmacologic agent such as methacholine or histamine can be useful in establishing the diagnosis of asthma. Also, inhalation of a suspected specific antigen may be useful in uncovering asthma when skin tests are equivocal, or in proving that asthma is occupation related. In some instances, exercise testing may disclose airway hyperreactivity in persons who are free of bronchoconstriction while at rest. Airway hyperresponsiveness to methacholine may presage an accelerated decline in pulmonary function.[39] However, the impact of therapy with agents like inhaled bronchodilators or corticosteroids in preventing progression is unclear.

■ METHODS OF BRONCHOPROVOCATION TESTING

Several methods of BPT are in general clinical use. These include methacholine challenge, exercise challenge, and antigen challenge, each of which is described briefly in subsequent sections.

Inhalation Challenge: Methacholine

Inhalation challenge using methacholine has become popular because of standardization of the technique, ease and safety of performing the test, and high sensitivity of the test in detecting asthma.[40,41] Methacholine is a synthetic cholinergic agent that evokes airway smooth muscle constriction. Because baseline pulmonary function and breathing pattern influence the site of deposition of the inhaled methacholine particles and, thereby, the response, a standard method for aerosolizing the agent is used to ensure reproducible results.[42]

One method in common use is that of intermittent aerosol generation. Standardization entails the delivery of a 0.6-second pulse of airflow at 20 $lb/in.^2$ to a nebulizer, which, in turn, discharges particles that range from 0.3 to 4 μm in diameter into the airways. Methacholine for delivery by aerosol is prepared in concentrations ranging from 0.1 to 25 mg/mL using bicarbonate-buffered isotonic saline (containing 0.4% phenol) as the diluent. The cumulative dose delivered is expressed in inhalation units. One inhalation unit is equivalent to the single inhalation of a solution containing 1 mg of methacholine per milliliter (Table 33-9).

TABLE 33-9 Concentrations and Cumulative Doses of Methacholine Employed in the Methacholine Challenge Test

Methacholine Concentration (mg/mL)	Cumulative Dose (Inhalation Units)[a]
0.1	0.5
0.5	3
1.0	8
2.0	18
5.0	43
10.0	93
25.0	218

[a]*After five inhalations of a nebulized solution containing methacholine in a concentration of 1 mg/mL.*

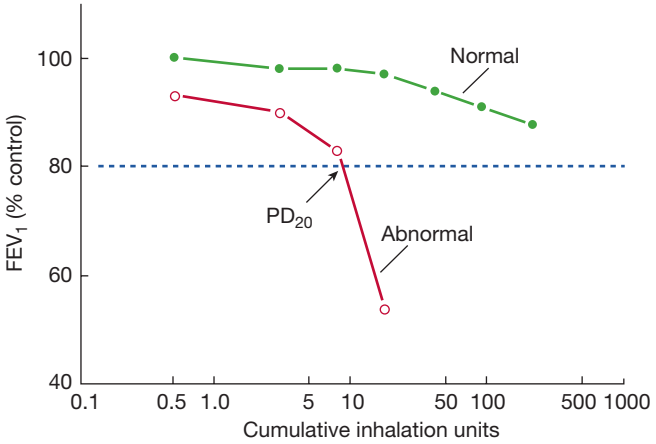

Figure 33-25 Plot of FEV_1,% control versus cumulative dose of methacholine administered by inhalation (logarithmic scale), to a normal subject and a subject with hyperreactive airways. The PD_{20} is the cumulative dose, which results in a 20% drop in the FEV_1 from the baseline measurement (after inhalation of diluent alone). In the subject with normal airway reactivity, the maximal cumulative dose of methacholine administered fails to elicit a 20% drop in FEV_1.

At the outset, the patient is challenged with five inhalations containing only aerosolized diluent. The necessity of the diluent step has been recently questioned. In addition to adding time and expense, it may force a greater absolute drop in FEV_1 needed to prove bronchial hyperreactivity. A fall in FEV_1 below 90% of the baseline value (i.e., the prechallenge control FEV_1) establishes that the airways are hyperreactive, and therefore, the test is terminated. However, if the FEV_1 does not fall below 90% of the control value, increasing concentrations of methacholine are given in stepwise increments of five-breath inhalations. The breaths are taken slowly from FRC to TLC. Then, 1 to 1.5 minutes after each dose, an FVC maneuver is performed. The interval between each increase in concentration is kept to a minimum because the response is judged in terms of the *cumulative* dose. However, the deep inspiration that immediately precedes the expiratory portion of the FVC maneuver may decrease bronchomotor tone in airways narrowed by methacholine. This effect lasts up to 6 minutes, thus limiting the shortest acceptable interval between dosage steps.[43] If the postchallenge FEV_1 falls below 80% of the control FEV_1, or if the patient experiences cough or chest tightness at any step, the test is stopped. The magnitude of the bronchoconstrictor response to inhalational challenge is related to the control FEV_1. A lower baseline FEV_1 (even in the normal range) correlates with increased bronchial reactivity.[44–47] Additional measurements of dynamic airway function (e.g., specific conductance) may provide supplemental data but also prolong the study. Another dosing option in use is the 2-minute tidal breathing protocol. This protocol typically yields results similar to the one described previously.

The results are plotted on four-cycle semilog graph paper: the number of cumulative inhalation units, expressed logarithmically, against the FEV_1, as percent of control (Fig. 33-25). A curve is constructed through the points; the dose corresponding to the point at which the FEV_1 is 80% of the control FEV_1 is designated as the *provocation dose,* or PD_{20} FEV_1.

Exercise Challenge

Persons without a history of asthma who develop cough, wheezing, or dyspnea after exercise may have exercise-induced bronchospasm (EIB). In these individuals, an exercise test may prove useful in establishing the diagnosis. Such exercise testing in asthmatics can be useful to assess the degree of impairment during exercise, or the impact of therapies.

Several factors that may influence the outcome of the test should be kept in mind. The temperature and humidity of the laboratory should be tightly controlled. Some centers use dry air inhalation during exercise. In addition, the duration of the test needs to be monitored. The goal of testing for EIB is to produce at least 4 minutes of exercise at the target heart rate and ventilation. Exercise should not continue for more than 6 to 8 minutes, in order to avoid "run-through" of the bronchospasm – that is, reversal at the end of the test.

The type of exercise also influences the outcome. As a rule, the more intense the exercise, the more likely is bronchoconstriction to occur. Free-range running provides the most potent stimulus for bronchoconstriction, followed by treadmill running, bicycle ergometry, swimming, and walking. An asthmatic may swim comfortably at a level of exercise that is incapacitating on the treadmill. The motor-driven treadmill or electromagnetically braked cycle ergometer are the preferred modes of exercise for formal testing.

The FEV_1 is the most useful measurement made during testing for EIB. Measurements are made just before and immediately after the exercise and at 5-minute intervals for the following 30 minutes. A decrease in FEV_1 of 10% or more below the pre-exercise value constitutes a positive test. Some have suggested that a decrement of 15% is of greater diagnostic value. False-positive responses can occur in patients with vocal cord dysfunction or abnormal posterior arytenoid motion.

Inhalation Challenge: Antigen

Compared with the relatively safe methacholine challenge test, BPT using a specific antigen is unpredictable and potentially hazardous. Since establishing the minimum dose required to induce bronchoconstriction is difficult, too much of the antigen may be given. A late response, far more severe than the initial one, often develops about 6 hours after the challenge. Despite these reservations about antigen challenge, testing is warranted under certain circumstances: to uncover a particular agent in the environment that causes bronchoconstriction, to establish the diagnosis of occupational asthma, to prove that bronchoconstriction is caused by a particular antigen after routine skin tests have failed to support the clinical suspicion, and to convince a skeptical patient about the cause of his or her asthma. Recommendations for preparing concentrations of antigens and the technique of antigen challenge testing are specific to the antigen in question and may be found in the literature. These tests should only be performed in laboratories which have considerable experience in BPT.

TABLE 33-10 Bronchoprovocation Testing: Precautions and Contraindications

- Baseline FEV_1/FVC% <60 (relative) or <50 (absolute)
- Recent upper respiratory tract infection
- Recent influenza vaccination
- Recent administration of bronchodilator
- Ingestion of caffeine within 6 h before testing
- Cold-air breathing, hyperventilation, exercise within 6 h before testing
- Recent acute myocardial infarction or cerebrovascular accident, uncontrolled hypertension, or known aortic aneurysm

PRECAUTIONS AND CONTRAINDICATIONS

Although the overall risk of serious complications is low, bronchoprovocation tests may be unnecessary, invalid, or even dangerous in some circumstances (Table 33-10). For example, the patient who manifests appreciable airway obstruction by conventional testing may develop life-threatening airway narrowing during a bronchoprovocation test. In such a patient, a simple bronchodilator study would be more appropriate and informative. If bronchodilators fail to reverse the increase in airway resistance, and if it is important to prove that bronchial hyperreactivity does exist, BPT is sometimes done, with extreme caution, on another day, as antigen dosages are titrated carefully and details of the procedure monitored closely.

Absolute contraindications include severe airways obstruction (FEV_1 <50% predicted), myocardial infarction or stroke in the preceding 3 months, uncontrolled hypertension, or known aortic aneurysm. Moderate airflow limitation, pregnancy, lactation, and concurrent use of cholinesterase inhibitor medication represent relative contraindications.

A recent viral upper respiratory tract infection can cause airway hyperreactivity for up to 6 weeks in normal subjects. Similarly, influenza vaccination increases responsiveness to inhalation challenges in asthmatics for a few days to a week. In these conditions, BPT should not be undertaken until the sensitization effects of the infection or vaccination have worn off. Also, bronchodilators, including caffeine, should be withheld for at least 6 hours before a bronchoprovocation test, if possible, in order to prevent blunting of the bronchoconstrictor response. Finally, cold air, hyperventilation, and exercise should be avoided for at least 6 hours before testing in order to prevent the induction of a refractory period or late response that would overlap the test results.

SMALL-AIRWAY FUNCTION

Up to this point, discussion of tests of dynamic lung function has addressed the tracheobronchial tree as a unit. However, in a variety of common clinical settings, including asthma, COPD, cigarette smoking, lung transplantation complicated by bronchiolitis obliterans syndrome, ARDS, and cystic fibrosis,[48–52] structural (and functional) abnormalities of the airways may be centered primarily in the small, peripheral airways – that is, those 2 mm or smaller in diameter. Because of their small contribution to airway resistance, estimated to be about 10% to 38% (at a lung volume equivalent to 50% of VC), the small airways can undergo considerable damage before the usual tests of either static or dynamic lung function become abnormal.[53,54] Consequently, efforts have been made to utilize tests aimed at early detection of small-airway disease in the hope of early intervention to limit progression of the disease.

Once obstructive disease of the peripheral airways arises, the small airways' contribution to overall resistance increases, and abnormalities in their function may be detected using specialized tests (see below), or, in some cases, analysis of selected aspects of the expiratory VC maneuver. In particular, abnormal values for $FEF_{25–75\%}$, in conjunction with normal values for FVC and FEV_1, are often useful in identifying small-airway disease. The basis for this approach is that $FEF_{25–75\%}$ measures airflow during the effort independent part of the FVC, when the small airways contribute substantially to the limitation of airflow.

A number of specialized tests of small airways' function have been developed over the last several decades, and some have found resurgent use in evaluating selected patient populations.[48] Several, along with their underlying physiologic basis, are described in subsequent sections.

FORCED OSCILLATION TECHNIQUE AND IMPULSE OSCILLOMETRY

The forced oscillation technique (FOT) and a variation of FOT, impulse oscillometry, are based on assessment of airway impedance and a component of airway impedance, airway resistance. Using a loudspeaker applied to the airway opening and measuring pressure and flow over a range of oscillation frequencies, airway resistance can be measured and compartmentalized into segments reflecting resistance in medium-to-large and small airways. In normals, over an oscillatory range of 5 to 25 Hz, respiratory resistance and its major component, airways resistance, are frequency independent. With development of airways obstruction, respiratory resistance becomes frequency-dependent. Furthermore, as small airways narrow or close, a component of impedance distinct from resistance – reactance (a concept which refers to the "out-of-phase" relationship between pressure and flow during oscillation and which is ascribed to energy storage, as determined by the elastic properties of the respiratory system) – is significantly affected, particularly when measured during the expiratory phase of respiration.[48,51,52,55]

DYNAMIC COMPLIANCE

Dynamic compliance, defined as the change in lung volume during airflow produced by a given change in transpulmonary pressure, is normally independent of breathing frequency. However, under conditions of nonuniformity of ventilation throughout the lung, increases in breathing frequency are associated with a fall in dynamic compliance. This frequency dependence of compliance was first noted in a patient with emphysema.[56,57]

During the test, the patient, with an esophageal balloon in place, first inspires maximally to TLC and then expires to the resting end-expiratory position (FRC); the patient then breathes at a normal tidal volume and respiratory rate (15 breaths per minute). In order to enable the patient to monitor these parameters, tidal volume and the resting end-expiratory level are displayed on an oscilloscope within sight of the patient. At the same time, changes in tidal volume and transpulmonary pressure are displayed on another oscilloscope (Fig. 33-26). The slope of the line connecting the end-inspiratory and end-expiratory points on the pressure–volume loop – that is, the points of zero airflow – is the dynamic compliance. This procedure is repeated with breathing frequencies of 30 and 60 breaths per minute. Values for dynamic compliance (Cdyn,L) at the various frequencies are expressed as a ratio of the dynamic compliance to the static inspiratory compliance (Cst,L) or as a percentage of Cst,L (Fig. 33-27) for the same range of tidal volumes.

In normal subjects, Cdyn,L/Cst,L remains above 0.8, even at frequencies greater than 60 breaths per minute. However, in the presence of obstructive disease of the small airways, Cdyn,L/Cst,L falls progressively to values below 0.8 as breathing frequency increases. It is worth emphasizing that interpretation of frequency dependence of compliance with regard to small-airway disease is valid only if the static compliance and overall airway resistance are normal. Abnormalities in these other measurements indicate

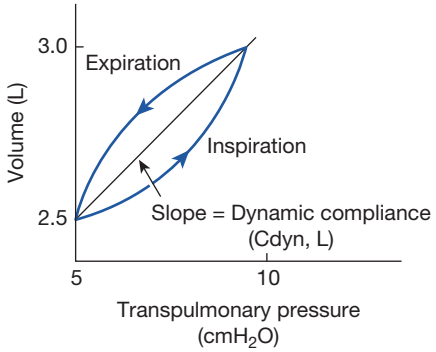

Figure 33-26 Measurement of dynamic lung compliance (Cdyn,L). During the inspiratory and expiratory phases of the respiratory cycle, a loop relating volume to transpulmonary pressure is generated. The slope of a line drawn through the points of zero airflow (at end inspiration and end expiration) is the dynamic compliance. Determination of Cdyn,L can be done at a variety of respiratory frequencies to assess the frequency dependence of compliance (Fig. 36-27).

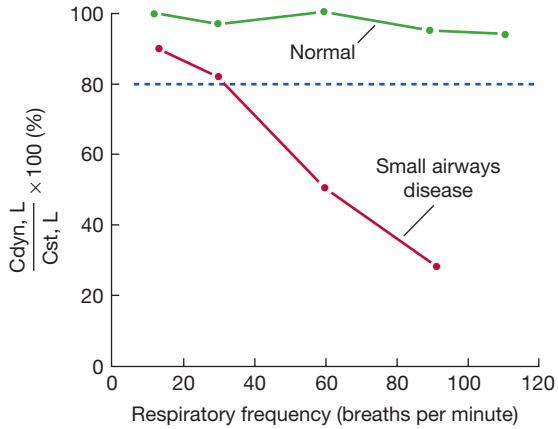

Figure 33-27 Determination of frequency dependence of dynamic compliance. Dynamic compliance is determined as shown in Figure 36-26 and is expressed as a percentage of static lung compliance (Cdyn, L/Cst, L × 100,%) at a variety of respiratory frequencies. Normally, Cdyn,L is ≥80% of Cst,L and is independent of respiratory frequency. In patients with obstructive airway disease, including those with disease limited to the small airways, Cdyn,L falls relative to Cst,L as respiratory frequency increases.

disease that is not likely to be confined to the small airways and for which frequency dependence of dynamic compliance is another manifestation. The physiologic basis for the fall in Cdyn,L/Cst,L as respiratory frequency increases is the presence of unequal time constants throughout the lung (see above).

■ SINGLE-BREATH NITROGEN WASHOUT, MULTIPLE BREATH NITROGEN WASHOUT, AND CLOSING VOLUME

In 1949, Fowler described the single-breath nitrogen washout test for assessing the uniformity of ventilation throughout the lungs. In performing this test, the patient first expires maximally to RV before filling his or her lungs by taking a maximal breath of 100% O_2. During the subsequent expiration, the concentration of nitrogen at the mouth is continuously recorded and plotted against the volume of expired gas. Originally, interest focused on the initial part of the tracing that depicts the changing concentration in expired nitrogen as the first 750 to 1200 mL of gas is exhaled. Over this range, the change in nitrogen concentration in persons with normal lungs is less than 2.5%. In contrast, when disease of the lungs or tracheobronchial tree results in abnormal intrapulmonary distribution of inspired gas, the change in nitrogen concentration exceeds 2.5%.

Almost 20 years later, Fowler's test was modified to include a bolus of xenon at the beginning of inspiration and to record the concentration of xenon during the following expiration.[58] Abrupt changes in the concentration of expired xenon as RV was approached suggested that important information about the small airways could be obtained from the terminal portion of the curve.

These observations with xenon rekindled interest in Fowler's original technique and also directed attention to the terminal portion of expiration. The procedure is depicted in Figure 33-28. To perform the maneuver for this measurement, the seated patient

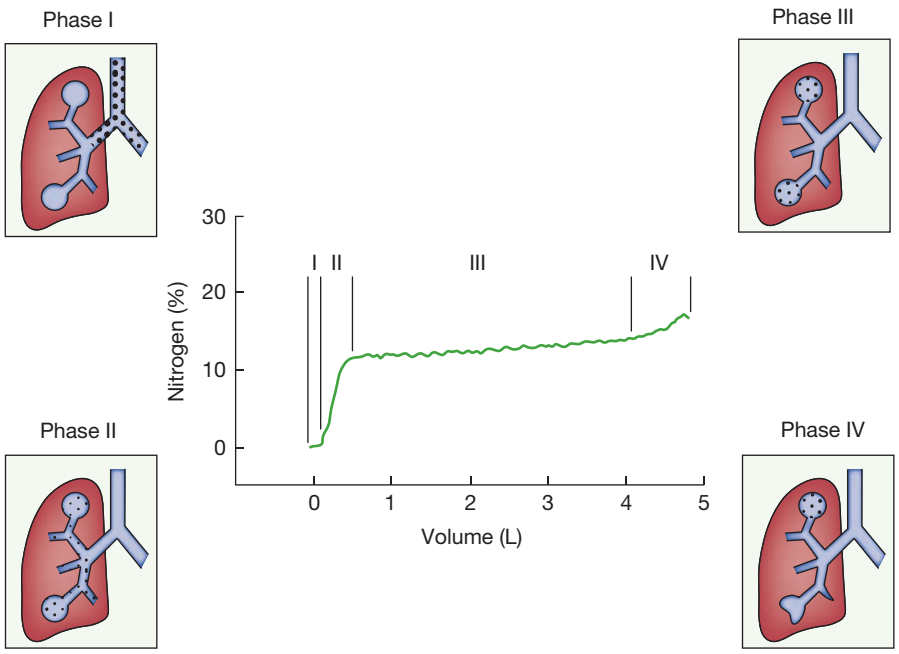

Figure 33-28 Contributions of different lung regions to the nitrogen concentration–volume curve obtained during the single-breath nitrogen washout test. See text for discussion.

takes two deep breaths of air and then expires to RV. At the end of this maximal expiration, a valve is opened so that the patient can take a full breath of 100% O_2 to TLC. The patient then expires slowly to RV while N_2 concentration and expired volume are recorded continuously.

Four distinct phases can be identified in the continuous record relating N_2 concentration to expired volume. Phase I, the initial expirate, contains virtually no N_2, since it derives from the O_2-containing dead space. Phase II represents a mixture of gases from the dead space and the alveoli. Phase III is due to a mixture of gases from alveoli located at the apices, midlung fields, and bases. Phase IV, characterized by an upward shift in N_2 concentration, is caused by closure of alveoli in the dependent parts of the lungs at low lung volumes. This final expirate derives from alveoli in the middle and upper regions of the lungs, where N_2 concentrations are higher than at the bases.

The explanation for these phases resides in the intrapulmonary distribution of gases during the respiratory maneuvers used in performing the test. In the normal upright person, a gradient of pleural pressures exists from apex to base, so that pleural pressure is more negative at the apices than at the bases. Because the alveoli at the bases operate on a lower portion of their pressure–volume curve (Fig. 33-11), they expand more than do apical alveoli per unit change in pleural pressure. However, the less negative pleural pressures and decrease in elastic recoil pressure at the bases also cause small airways to close during expiration as lung volume approaches RV. Thus, the pleural pressure gradient from top to bottom of the chest causes nonuniform distribution of gas within the normal upright lungs.

In the single-breath nitrogen washout test, a breath of 100% O_2 is taken, starting from RV. At RV, small basal airways are closed. Therefore, at the start of the O_2 breath, the N_2-containing air remaining in the dead space is preferentially drawn into the middle and apical lung zones as 100% O_2 gradually replaces air in the dead space. As the inspiration continues, the small airways at the bases open. Since their compliances are greater than those in the middle or at the top of the upright lungs, the inspired O_2 is then preferentially distributed to the bases.

During the expiration from TLC, the four phases then represent, as indicated above, the sequential emptying of dead-space gas and a mixture of dead-space and alveolar gas, followed by mixtures of alveolar gases from different parts of the lungs, as determined by the preceding intrapulmonary distribution of inspired O_2.[59]

The volume from the onset of phase IV to the completion of the full expiratory maneuver is termed the *closing volume* (CV). In healthy young adults, the normal closing volume averages about 10% of the VC. Narrowing or obstruction of small peripheral airways causes closing volume to enlarge. The closing volume also increases progressively as people grow older, so that by the age of 50, the closing volume sometimes reaches 25% of the VC. Cigarette smokers consistently experience an increase in closing volume. In both aging normal persons and cigarette smokers at any age, a decrease in pulmonary elasticity seems to be responsible for the increase in closing volume.

HELIUM–OXYGEN FLOW–VOLUME CURVES

In 1963, the effects of changes in gas density and viscosity on maximal expiratory flow throughout the vital capacity range were described.[60] Almost 10 years later, gas-density-related and viscosity-related concepts were applied to determine the site of airway obstruction in asthma. These principles were then applied for the specific purpose of detecting obstruction of small airways when other tests of pulmonary function were within normal limits.[61] While application of helium–oxygen flow–volume curves in the assessment of small airways function is physiologically elegant, the test is rarely performed in clinical practice.

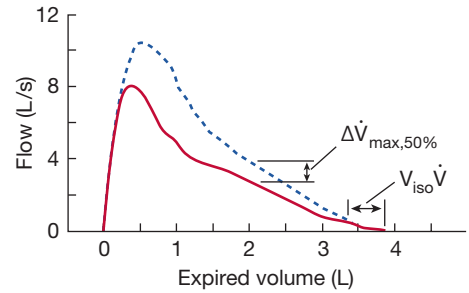

Figure 33-29 Maximal expiratory flow–volume curves generated in breathing room air *(solid line)* and breathing a helium–oxygen mixture *(dashed line)*. The airflows achieved with the less dense helium mixture are higher than those with air at all but the lowest lung volumes. The point of first intersection of these two curves demarcates the volume of isoflow ($V_{ISO}\dot{V}$). The difference between the flows achieved when 50% of the vital capacity has been expired is the $\Delta\dot{V}_{max,50\%}$. The use of these measurements as indicators of small-airway disease is described in the text.

The use of a helium–oxygen mixture to detect small-airway disease requires comparison of two maximal expiratory flow–volume curves, one that is generated while the patient breathes air and the other while the patient breathes helium and oxygen (Fig. 33-29). At least three maximal expiratory flow curves are obtained with room air and three with helium–oxygen.[29]

In normal subjects, at lung volumes greater than 10% of the VC, the primary site of resistance to airflow is in the larger airways, where flow is turbulent and, therefore, density dependent. At these lung volumes, the flow attained with the helium–oxygen mixture will be higher than that attained with air. At lung volumes less than 10% of the VC, the primary site of resistance is in the smaller airways, where flow is laminar and, therefore, not density dependent. In this circumstance, the less dense helium mixture has no effect on flow (Fig. 33-29). In disease of the small airways, the primary site of resistance shifts at large volumes from the larger to the smaller airways. As a result, the flow-enhancing effect of the less dense gas disappears at volumes well above 10% of the VC.

In practice, two sets of maximal expiratory flow–volume curves are obtained, one while the subject is breathing air and the other after three VC breaths of the helium–oxygen mixture to replace at least 95% of the alveolar N_2. Comparisons are then made of the superimposed curves (Fig. 33-29). One comparison is made at 50% of the VC in order to compare maximal expiratory flows (i.e., the $\Delta\dot{V}_{max,50\%}$); the other is at the volume at which the flows become identical – that is, the *volume of isoflow* ($V_{iso}\dot{V}$).[62] The curves are superimposed at RV or TLC, as long as the vital capacities of each curve are within 2.5% to 5.0% of the largest VC recorded.[29]

The percentage change in expiratory flow while breathing helium–oxygen compared to air at 50% of the VC, $\Delta\dot{V}E_{max,50\%}$, is calculated as

$$\Delta\dot{V}E_{max,50\%} = \frac{\dot{V}E_{max,50\%}(\text{helium–oxygen}) - \dot{V}E_{max,50\%}(\text{air})}{\dot{V}E_{max,50\%}(\text{air})} \times 100$$

where $\dot{V}E_{max,50\%}$ (helium–oxygen) and $\dot{V}E_{max,50\%}$ (air) are the expiratory flows at 50% of the VC during helium–oxygen and air breathing, respectively. As noted previously, the volume of isoflow is normally less than 10% of the VC; when it is increased, it indicates small-airway obstruction. The $\Delta\dot{V}E_{max,50\%}$ is also specific for small-airway disease, and unlike the closing volume, it is considered to be unaffected by changes in the elastic properties of the lung. Questions remain, however, about the validity and sensitivity of tests of density dependence of flow in assessing small-airway disease. Although they

are conceptually attractive, the practical value of helium–oxygen flow–volume curves in detecting small-airway disease is debatable.

GAS EXCHANGE FUNCTIONS

Traditional measurements of the gas exchange functions of the lung include oxygen uptake ($\dot{V}_{O_2}$), carbon dioxide elimination ($\dot{V}_{CO_2}$), respiratory dead space (V_D), alveolar gas composition ($P_{A_{O_2}}$ and $P_{A_{CO_2}}$), diffusing capacity for carbon monoxide ($D_{L_{CO}}$), and arterial blood gas tensions (Pa_{O_2} and Pa_{CO_2}). These determinations require a steady state of the ventilation and circulation and constant body stores of O_2 and CO_2. A steady state with respect to O_2 implies that O_2 uptake measured at the mouth equals the rate of O_2 transport across the alveolar membrane, and that, in turn, both rates are equal to O_2 consumption by the tissues. The same type of definition applies to CO_2 exchange in the tissues, in the alveolar capillaries, and at the mouth.

VENTILATION, OXYGEN UPTAKE, AND CARBON DIOXIDE ELIMINATION

The total volume of air breathed per minute ($\dot{V}_E$) is the *minute ventilation.* It is equal to the product of the tidal volume (V_T) and the breathing frequency (f). As a rule, minute ventilation is determined by measuring the volume of expired gas relative to time. When the measurement is performed manually, the necessary equipment includes gas-collecting bags, low-resistance directional valves, a stopwatch, and a device for measuring gas volume. In practice, the patient, with nose clip in place, breathes through a mouthpiece for at least 3 to 5 minutes while expired gas is vented to the atmosphere. This preliminary period is intended to put the patient at ease and to achieve a steady state of respiration and circulation. When a steady heart rate and breathing pattern are achieved, a valve is turned without the patient's knowledge, and expired gas is collected for 3 minutes.

The minute ventilation is determined by dividing the total volume of expired gas collected in the spirometer by the time of collection (3 minutes). The average tidal volume is obtained by dividing $\dot{V}_E$ by the number of breaths per minute. Values for minute ventilation and tidal volume are expressed in terms of body conditions (BTPS). In the resting adult, the minute ventilation is typically 6 to 8 L/min; the corresponding tidal volume is 0.4 to 0.6 L.

The quantity of CO_2 in inspired air is negligible. Consequently, the amount of CO_2 produced per minute ($\dot{V}_{CO_2}$) can be calculated as the product of the expired volume of ventilation ($\dot{V}_E$) and the concentration of CO_2 in the expired air ($F_{E_{CO_2}}$):

$$\dot{V}_{CO_2} = \dot{V}_E \times F_{E_{CO_2}}$$

Oxygen uptake ($\dot{V}_{O_2}$) is calculated as the difference between the amounts of O_2 in inspired and expired air:

$$\dot{V}_{O_2} = (\dot{V}_I \times F_{I_{O_2}}) - (\dot{V}_E \times F_{E_{O_2}})$$

where

$\dot{V}_I$ = inspired volume of ventilation, L/min
$F_{I_{O_2}}$ = concentration of O_2 in the inspired air
$F_{E_{O_2}}$ = concentration of O_2 in the expired air

In the steady state, O_2 uptake by alveolar capillary blood exceeds CO_2 output from alveolar capillary blood. As a result, the expired volume of gas is less than the corresponding inspired volume. Since N_2 does not undergo exchange in the lungs, the difference between CO_2 output and O_2 uptake results in a higher concentration of N_2 in expired air than in inspired air. Based on the change in nitrogen concentration, the inspired volume of ventilation can be calculated from the expired volume of ventilation:

$$\dot{V}_I = \dot{V}_E \frac{F_{E_{N_2}}}{F_{I_{N_2}}}$$

where

$F_{E_{N_2}}$ = concentration of N_2 in expired air
$F_{I_{N_2}}$ = concentration of N_2 in inspired air

In the normal, resting subject who is tested after several hours of fasting, the ratio of CO_2 output to O_2 uptake, the *respiratory exchange ratio* (R), is about 0.8. The respiratory exchange ratio at any instant is calculated by simultaneously determining the P_{O_2} and P_{CO_2} in an alveolar gas sample. As indicated above, in the steady state, the R determined by sampling alveolar gas equals the R of alveolar capillary blood, which, in turn, equals the R of the tissues. The steady-state R, when alveolar gas, blood, and tissue are all in dynamic equilibrium, is the *respiratory quotient* (RQ). Hence, in the steady state, when the O_2 and CO_2 stores of the body are not changing, the RQ, reflecting cellular metabolism, can be determined by analyzing alveolar gas for O_2 and CO_2.

Unlike tidal volume and ventilation, which are expressed in terms of BTPS, $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ are given in terms of standard temperature and pressure, dry (STPD).

DEAD SPACE

Not all of the air breathed participates in gas exchange. Part of each breath remains in the mouth, nose, pharynx, larynx, trachea, bronchi, and bronchioles. This volume, the *anatomic dead space,* is about equal, in milliliters, to the subject's ideal body weight, in pounds (e.g., about 150 mL in a typical adult male). Inspired air reaching alveoli that are not exposed to pulmonary capillary blood also does not participate in gas exchange. This volume plus the anatomic dead space equals the *physiologic dead space.* In a normal person, the anatomic and physiologic dead spaces are virtually identical and constitute about one-third of the tidal volume.

Determination of the physiologic dead space has proved to be of practical importance in a variety of clinical conditions. It is calculated by considering each breath (V_T) to consist of dead space (V_D) and an alveolar volume that participates in gas exchange (V_A):

$$V_T = V_D + V_A$$

Physiologic dead space can be calculated using a modification of the *Bohr equation,* which recognizes that all of the test gas expired derives from two sources: the physiologic dead space and the alveolar gas-exchanging volume. If we use CO_2 as the marker gas, the total amount of CO_2 eliminated per minute equals the sum of the CO_2 coming from the dead space per minute and from the alveolar compartment per minute:

$$\dot{V}_E \times F_{E_{CO_2}} = (\dot{V}_D \times F_{I_{CO_2}}) + (\dot{V}_A \times F_{A_{CO_2}})$$

where

$\dot{V}_E$ = minute ventilation, L/min
$F_{E_{CO_2}}$ = fractional concentration of CO_2 in expired gas
$\dot{V}_D$ = minute dead space ventilation, L/min
$F_{I_{CO_2}}$ = fractional concentration of CO_2 in inspired gas
$\dot{V}_A$ = minute alveolar ventilation, L/min
$F_{A_{CO_2}}$ = fractional concentration of CO_2 in alveolar gas.

Since, in a subject breathing room air, $F_{I_{CO_2}}$ is practically zero, the last equation is generally simplified as follows.

$$V_E \times F_{E_{CO_2}} = V_A \times F_{A_{CO_2}}$$

where V_E and V_A represent volumes of ventilation, rather than rates.

Recalling that $V_A = V_T - V_D$ and substituting partial pressures for the fractional concentration terms, the relationship becomes

$$V_E \times P_{E_{CO_2}} = (V_T - V_D)\, P_{A_{CO_2}}$$

where $P_{E_{CO_2}}$ and $P_{A_{CO_2}}$ are the partial pressures of CO_2 in mixed expired gas and alveolar gas, respectively.

Assuming that arterial blood and alveolar gas are in equilibrium with respect to CO_2, when Pa_{CO_2} is substituted for $P_{A_{CO_2}}$ and the equation rearranged, it becomes

$$V_D = V_T \frac{Pa_{CO_2} - P_{E_{CO_2}}}{Pa_{CO_2}}$$

Thus, if arterial blood is sampled during collection of expired gas, and if the partial pressures of CO_2 in expired gas and arterial blood are determined, the physiologic dead space can be calculated. In order for the physiologic dead space to be separated from the total dead space determined by the above equation, the dead space of the apparatus is subtracted from the value for total dead space.

■ ALVEOLAR GAS COMPOSITION

In normal subjects, values for P_{O_2} and P_{CO_2} in an end-tidal sample approximate mean alveolar values. However, when imbalances exist in alveolar ventilation and blood flow because of lung disease, inhomogeneity in alveolar gas composition often invalidates the use of end-tidal gas tensions as a measure of mean alveolar gas composition.

In practice, mean alveolar P_{O_2} ($\bar{P}A_{O_2}$) and mean alveolar P_{CO_2} ($\bar{P}A_{CO_2}$) are often determined indirectly. Arterial P_{CO_2} is assumed to equal mean alveolar P_{CO_2} on the grounds of the narrow arteriovenous difference for P_{CO_2} across the lungs, the high solubility of CO_2, and the presumed role of pulmonary capillary blood as a tonometer. Mean alveolar P_{O_2} is calculated using the alveolar gas equation:

$$\bar{P}A_{CO_2} = \bar{P}I_{O_2} - \bar{P}A_{CO_2}\left[FI_{O_2} + \frac{1 + FI_{O_2}}{R}\right]$$

The alveolar gas equation takes advantage of the fact that the total pressure of gases in the alveoli is equal to the sum of the partial pressures of the individual gases. This equation simply states that the mean alveolar P_{O_2} is the difference between inspired P_{O_2} and mean alveolar P_{CO_2}, allowing for a correction factor when the respiratory exchange ratio differs from 1.0.

■ DIFFUSING CAPACITY

The diffusing capacity of the lung for carbon monoxide ($D_{L_{CO}}$) can be determined by steady-state, rebreathing, and single-breath methods. The most frequently used method is a modification of the single-breath method first described in 1915 and subsequently modified in 1957.[63] Although the single-breath test has been shown to exhibit a large interlaboratory variation, it has proved to be a valuable measure of lung function in a wide variety of disease states. In fact, with continuing refinement of the standards,[6,64,65] the variability, which may be as much as 12% or greater, is likely to decrease; however, the variability will probably not be reduced to the range for vital capacity measurements (about 4%).

The diffusing capacity is intended to provide an estimate of the rate at which test molecules – usually CO – move by diffusion from alveolar gas to pulmonary capillary blood. Factors that influence the measurement are the physicochemical properties of the test gas, the extent and thickness of the alveolar capillary barrier, the resistance to diffusion offered by the red blood cell membrane, and the reaction rates of the test gas and hemoglobin, and pulmonary capillary blood volume. As a rule, the diffusing capacity is interpreted as an index of the surface area engaged in alveolar capillary diffusion. Clinical entities that can reduce the diffusing capacity include parenchymal lung diseases, particularly interstitial lung disease, emphysema, pulmonary hypertension, and anemia. Polycythemia and alveolar hemorrhage syndromes, on the other hand, may increase the diffusing capacity.

Carbon monoxide has emerged as the most practical test gas because of its affinity for hemoglobin. The diffusing capacity for CO is defined as the amount of CO transferred per minute per mm Hg of driving pressure:

$$D_{L_{CO}} = \frac{\dot{V}_{CO}}{\bar{P}A_{CO} - \bar{P}C_{CO}}$$

where

$D_{L_{CO}}$ = the diffusing capacity of the lung for CO, mL/min/mm Hg (STPD)
$\dot{V}_{CO}$ = the amount of CO transferred, mL/min
$\bar{P}A_{CO}$ = the mean alveolar PCO, mm Hg
$\bar{P}C_{CO}$ = the mean capillary PCO, mm Hg.

Since the blood P_{CO} in nonsmokers is essentially zero, the term $\bar{P}C_{CO}$ is customarily neglected. In practice, $D_{L_{CO}}$ is determined by calculating $\dot{V}_{CO}$ as the difference between inspired and expired samples and estimating the mean alveolar P_{CO}. Generally, one of the two techniques is used to determine $D_{L_{CO}}$: the single-breath or the steady-state technique.

The Single-Breath Method

The breathing maneuvers required for the single-breath method consist of tidal breathing for a few breaths, unforced expiration to RV, and then a single full, rapid inspiration of a gas mixture containing approximately 0.3% CO and an inert gas – traditionally, 10% helium (some newer systems use methane). The breath is held for 10 ± 2 seconds and then rapidly expired. An inspiratory time of less than 4 seconds, and a sample collection of no more than 3 seconds are required. Longer expiratory times and sample collection time greater than 3 seconds should be noted in the test report. The initial portion of the expirate containing dead-space gas is discarded; the remainder is collected, and the concentrations of CO and helium are measured.[63] A variety of automated systems are commercially available for performing the single-breath diffusing capacity. However, the essential components in all systems are a source of the special inspired gas mixture, a device for measuring the volume of gas inspired and expired, rapid response analyzers to measure the concentration of gases (see below), a timer, and appropriate valving and collection devices to trap the desired portion of the expirate.

The diffusing capacity of the lung for CO is calculated according to the following equation.

$$D_{L_{CO}} = \frac{V_A \times 60}{(\text{barometric perssure} - 47)} \times \text{time} \times \text{In}\frac{F_{A_{CO}}, \text{initial}}{F_{A_{CO}}, \text{final}}$$

where

V_A = alveolar volume
$F_{A_{CO}}$, initial = alveolar concentration of CO at the start of breath hold
$F_{A_{CO}}$, final = alveolar concentration of CO at the end of breath hold.

The concentration of CO in the alveoli at the start of the period of breath holding ($F_{A_{CO}}$, initial) is calculated from the inspired concentration of CO and, for helium-based systems, the inspired concentration of helium and the expired concentration of helium, according to the equation

$$F_{A_{CO}}, \text{ initial} = \frac{F_{E_{He}}}{F_{I_{He}}} \times F_{I_{CO}}$$

where

$F_{E_{He}}$ = expired concentration of helium
$F_{I_{He}}$ = inspired concentration of helium
$F_{I_{CO}}$ = inspired concentration of CO

The concentration of CO in the alveoli at the end of the breath-holding period ($F_{A_{CO}}$, final) is equal to the concentration of CO in the expired gas. The alveolar volume (V_A) is determined in one of two ways. Originally, V_A was calculated as the sum of the RV, determined by the closed-circuit helium or body plethysmograph techniques described previously, and the volume of inspired gas, as recorded on the spirometer. Later, V_A came to be calculated from the single-breath dilution of helium that occurs during the determination of $D_{L_{CO}}$. Finally, the time of breath holding is measured (in seconds) from the spirometer recording of the maneuver.

Although the single-breath method is relatively simple and has the advantage of requiring no blood samples, breath holding is clearly artificial, and the maneuver is difficult for dyspneic patients. Therefore, a steady-state method is sometimes used.

The Steady-State Method

In the steady-state method, a gas mixture containing 0.1% carbon monoxide is breathed until the rate of CO uptake from the lung is constant.[66] CO uptake ($\dot{V}_{CO}$) is determined from the difference between the amount of CO in the inspired and expired gas using an equation similar to that presented previously for calculation of O_2 consumption.

Comparison of Single-Breath and Steady-State Methods

Certain differences between the single-breath and steady-state techniques merit special mention.[29] The single-breath method is more popular because it is relatively easy to perform; it is well standardized, and it is less effected by nonuniformity of ventilation in comparison to the steady-state method. However, one drawback is that the patient is required to perform an inspiratory vital capacity maneuver of at least 88% of the VC and to hold his or her breath for 10 seconds. Another is that the test is extremely difficult to perform during exercise. The steady-state method is more attractive intrinsically than the single-breath method, since it requires no respiratory maneuvers and can be done during exercise. However, it does require an arterial blood sample (for determination of P_{CO_2}), and it is technically more difficult to perform.

The steady-state method for determining diffusing capacity tends to give lower values for the resting subject than does the single-breath method. The discrepancy is generally attributed to the fact that the surface area for diffusion is smaller during the quiet tidal breathing employed in the steady-state method than during the full inspiration to TLC, as required in the single-breath method. Also, during quiet breathing, some areas of the lung receive considerably less ventilation than during a breath hold at TLC.

Factors Other than Diffusion that Influence Test Results

A low $D_{L_{CO}}$ need not indicate a diffusion defect. A number of additional respiratory and nonrespiratory factors may reduce or increase the $D_{L_{CO}}$. A reduction in the lung volume alone can reduce the $D_{L_{CO}}$. Therefore, some laboratories "normalize" the diffusing capacity for lung volume by dividing $D_{L_{CO}}$ by alveolar volume – a manipulation that assumes a linear relationship between $D_{L_{CO}}$ and V_A, which is not the case.

Anemia artificially decreases the $D_{L_{CO}}$ as determined by either method, but the effect of low hemoglobin concentration can be adjusted by application of a correction factor.[67] Conversely, polycythemia and intrapulmonary hemorrhage tend to increase the value for $D_{L_{CO}}$. In fact, an unexpectedly high value for $D_{L_{CO}}$ may be a helpful clinical clue in detecting radiographically occult pulmonary hemorrhage.

Although the equation for $D_{L_{CO}}$ assumes that the CO back pressure in blood is negligible, the blood of a heavy smoker sometimes contains as much as 10% carboxyhemoglobin. Such levels of carboxyhemoglobin will be accompanied by appreciable concentrations of dissolved CO in the plasma. The resulting back pressure of CO will reduce the $D_{L_{CO}}$. A correction equation may be applied to adjust the $D_{L_{CO}}$ for this effect.

Altitude also affects the $D_{L_{CO}}$.[6] Pa_{O_2} falls with increasing altitude above sea level. The reduction in Pa_{O_2} allows CO to diffuse more rapidly into the blood. A specific adjustment should be made for inspired oxygen partial pressure.

Measurement of diffusing capacity is quite useful in the evaluation of patients with a number of pulmonary conditions. Decrement in $D_{L_{CO}}$ has been shown to predict exertional hypoxemia. In addition, $D_{L_{CO}}$ levels have been correlated with disease severity and prognosis in primary pulmonary hypertension, idiopathic pulmonary fibrosis, and alveolitis associated with systemic sclerosis.

■ ARTERIAL BLOOD GAS COMPOSITION

The determination of arterial P_{O_2} and P_{CO_2} provides useful information about the overall efficiency of external gas exchange. Heavy reliance is placed upon them for this purpose in managing acute respiratory failure, particularly in intensive care units. Less dramatic, but important, is their use in a variety of other settings (e.g., exercise testing) and for assorted calculations (e.g., the alveolar–arterial O_2 gradient and respiratory dead space).

Technique for Sampling Arterial Blood

Arterial blood is sampled either through an indwelling arterial catheter or by percutaneous arterial puncture. Sampling through an indwelling catheter avoids the acute changes in ventilation that sometimes result from apprehension and pain associated with percutaneous puncture.

Three anatomic sites are generally used for obtaining arterial blood samples: the radial, brachial, and femoral arteries. For several reasons, the radial artery is the preferred sampling site. Because of its superficial location at the wrist, the radial artery is easy to palpate and easy to compress by direct pressure, facilitating hemostasis when sampling is complete. In addition, no large veins lie in its immediate vicinity. Furthermore, the ulnar artery usually provides an adequate collateral circulation to the hand in the rare instance of postsampling thrombosis of the radial artery.

Arterial blood samples are drawn anaerobically into plastic or glass syringes coated with heparin. Because room air at sea level has a P_{O_2} of approximately 150 mm Hg and a P_{CO_2} of approximately zero mm Hg, air bubbles in the syringe will artificially increase the arterial P_{O_2} and reduce the arterial P_{CO_2}. The sample either is immediately analyzed or is placed on ice in order to minimize the metabolism of blood cells, particularly the white cells. If the icing precaution is neglected and the analysis is delayed, the Pa_{CO_2} of the sample will increase and the Pa_{O_2} and pH will decrease; the rate of change depends on the temperature of the sample and the elapsed time before analysis (Table 33-11).[68]

TABLE 33-13 Classification of Primary Respiratory Disorders of Acid–Base Balance

Disorder	Definition
Acute respiratory alkalosis (acute alveolar hyperventilation)	Pa_{CO_2} below lower limit of normal (<36 mm Hg), with accompanying alkalemia (pH >7.44)
Chronic respiratory alkalosis (chronic alveolar hyperventilation)	Pa_{CO_2} below lower limit of normal, with pH normal (or near normal) due to renal compensation and lowered serum bicarbonate concentration (<19 mEq/L)
Acute respiratory acidosis (acute alveolar hypoventilation	Pa_{CO_2} above upper limit of normal (>44 mm Hg), with accompanying acidemia (pH <7.36)
Chronic respiratory acidosis (chronic alveolar hypoventilation)	Pa_{CO_2} above upper limit of normal, with pH normal (or near normal) due to renal compensation and elevated serum bicarbonate concentration (>30 mEq/L)

Interpretations

Analysis of arterial blood gases as part of pulmonary function testing is based primarily on determination of Pa_{O_2}, Pa_{CO_2}, and pH. As a rule, these parameters are measured directly. Other values, including O_2 saturation, bicarbonate concentration, and base excess (or deficit), are usually calculated. This section deals with the interpretation of Pa_{O_2}, Pa_{CO_2}, and pH. Additional consideration of arterial blood gases, with particular reference to acid–base balance, is found in Chapter 17.

Arterial P_{O_2} (Pa_{O_2}) The physiologic determinants of normal Pa_{O_2} have been described elsewhere. For example, normal values for arterial P_{O_2} depend on altitude (Table 33-12). Therefore, normal values for arterial P_{O_2} in Denver (altitude of approximately 1500 m) are less than those at sea level by about 20 mm Hg.

Arterial P_{O_2} also decreases with age. A regression equation can be used to predict the decrease:[69]

$$Pa_{O_2} = 109 - 0.43 \text{ (age in years)}$$

The standard deviation of this relationship is ±4.10 mm Hg.

A third physiologic influence is body position. Assumption of the supine position causes abdominal contents to displace the diaphragm cephalad, thereby closing small airways at the lung bases and creating ventilation-perfusion inhomogeneities that decrease Pa_{O_2}.

Many more pathologic conditions than physiologic states can lower Pa_{O_2}. In each instance, however, arterial hypoxemia may be attributed to one or more of the following generic mechanisms: alveolar hypoventilation, ventilation-perfusion mismatch, diffusion impairment, and venous admixture ("shunt"). Considerations of the individual disorders within these categories and the mechanisms leading to hypoxemia are found throughout this book.

Arterial P_{CO_2} (Pa_{CO_2}) and pH In a steady state, the level of Pa_{CO_2} reflects the level of alveolar ventilation. In the absence of a disorder in metabolic acid–base balance, an increase or decrease in Pa_{CO_2} beyond normal limits indicates a primary disorder in alveolar ventilation. A summary of these disorders and useful criteria for distinguishing among them, based on arterial blood gas composition, are given in Table 33-13.

Acute *respiratory alkalosis,* produced by alveolar hyperventilation, is characterized by hypocapnia (Pa_{CO_2} < 36 mm Hg) and an appropriately elevated pH (>7.44). In time (e.g., 24 hours or more), renal compensation occurs, and the concentration of bicarbonate in serum decreases. If alveolar hyperventilation continues, a chronic respiratory alkalosis, partly or completely "compensated," ensues.

A low Pa_{CO_2} is not necessarily indicative of a primary disturbance in alveolar ventilation. Instead, it may be a consequence of respiratory compensation (partial or complete) for metabolic acidosis; this possibility is signaled by the coexistence of hypocapnia and a low pH (<7.36). Since the kidney and respiratory system do not overcompensate for acid–base derangements, the coexistence of hypocapnia and acidemia suggest the presence of two primary disturbances.

Acute respiratory acidosis, caused by alveolar hypoventilation, is characterized by an abnormally high Pa_{CO_2} (>44 mm Hg) and a subnormal pH (<7.36). Again, in time (24 hours or more), renal compensation for the primary respiratory disorder restores the serum bicarbonate concentration and blood pH toward normal. A high value for Pa_{CO_2} may also reflect respiratory compensation for a primary metabolic alkalosis ($[HCO_3^-] > 30$ mEq/L). In this circumstance, however, blood pH will be abnormally high (pH > 7.44), rather than low. In general, the elevation in Pa_{CO_2} in compensation for metabolic alkalosis does not exceed about 55 mm Hg. A Pa_{CO_2} exceeding this value in the setting of a metabolic alkalosis suggests the likely coexistence of a primary respiratory acidosis.

This discussion has been limited primarily to alterations in arterial blood gas values in primary respiratory acidosis or alkalosis. Metabolic derangements often complicate the picture. These disorders are considered elsewhere (Chapter 17).

■ TESTING FOR AIR-TRAVEL-RELATED HYPOXEMIA

Travel in commercial jet airliners typically results in exposure of passengers and crew to conditions equivalent to about 6000 to 8000 ft above sea level. For individuals with normal pulmonary gas exchange, the resulting Pa_{O_2} falls within a clinically acceptable range. However, for many patients with lung disease, the resulting Pa_{O_2} may well be problematic, even in those patients who do not require supplemental oxygen at sea level. Consequently, assessment of patients with chronic lung diseases, particularly COPD and interstitial lung diseases, has become part of the repertoire of tests offered by many pulmonary function laboratories.[70–74] One approach to estimating the resultant Pa_{O_2} during air travel is based upon use of regression equations (Fig. 33-30). Using the patient's resting Pa_{O_2} at

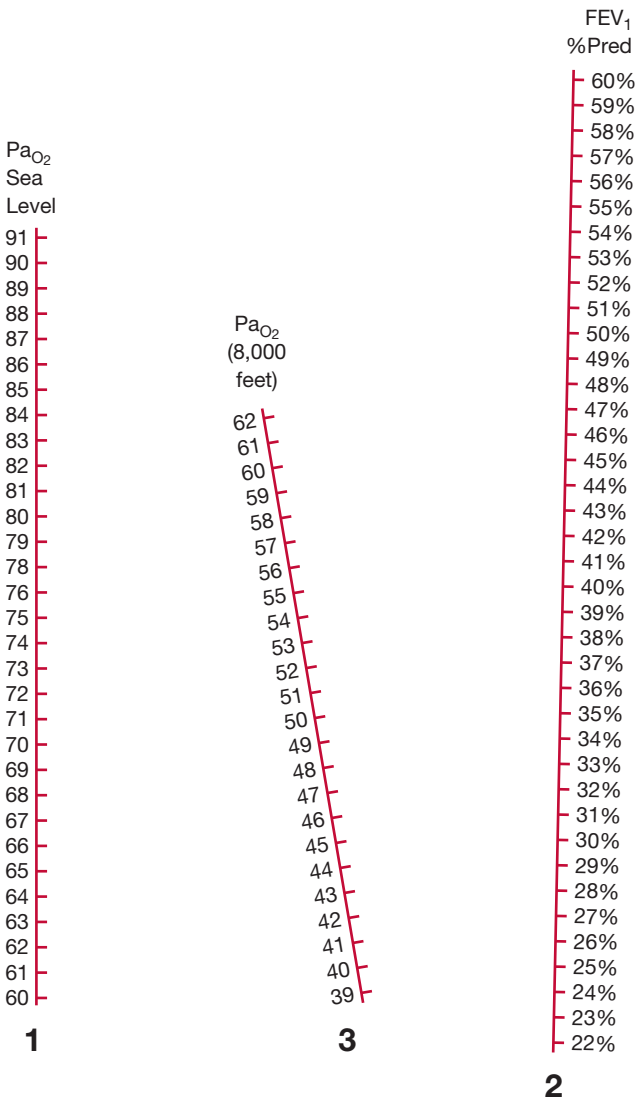

Figure 33-30 Nomogram for predicting in-flight oxygen tension. Using a straight edge, the patient's resting Pa_{O_2} at sea level (*Column 1*) is aligned with his or her FEV_1 percent of predicted (*Column 2*). The expected in-flight Pa_{O_2} (*Column 3*) is estimated as the value where the line crosses the center scale. *(Data from Dillard TA, Berg BW, Rajagopal KR, et al. Hypoxemia during air travel in patients with chronic obstructive pulmonary disease. Ann Intern Med. 1989;111:362–367; and Knudson RJ, Slatin RC, Lebowitz MD, et al. The maximum expiratory flow-volume curve: Normal standards, variability, and effects of age. Am Rev Respir Dis. 1976;113:587–600.)*

sea level and his or her FEV_1 percent of predicted, the expected in-flight Pa_{O_2} can be estimated. Some experts advocate use of the nomogram for determining which patients ought to undergo hypoxia inhalation testing (HIT), while others advocate performance of HIT for all traveling patients at risk for in-flight hypoxemia.

HIT is based on the observation that exposure to hypoxic gas mixtures can reproducibly mimic the Pa_{O_2} arising under true hypobaric conditions. Exposure to 15.1% oxygen for 20 minutes reliably duplicates the resultant Pa_{O_2} at 8000 ft. During performance of the test, the patient, with nose clips in place, breathes from a reservoir though a mouthpiece. The electrocardiogram is monitored, and arterial blood gases are obtained at the conclusion of the test. Supplemental oxygen can then be titrated and prescribed according to the findings.

The British Thoracic Society (BTS) has published recommendations for use of supplemental oxygen during air travel, based on the patient's oxygen saturation at sea level and the presence or absence of risk factors.[71]

The BTS recommends no in-flight supplemental oxygen if the oxygen saturation at sea level is >95%; if the oxygen saturation is 92% to95%, supplemental oxygen is recommended if additional risk factors are present, including: hypercapnia, FEV_1 <50% predicted, lung cancer, interstitial lung disease with fibrosis, chest wall or respiratory muscle disorders, need for mechanical ventilation, cardiac or cerebrovascular disease, or travel within 6 weeks of hospital discharge following an acute exacerbation of chronic lung or heart disease. Supplemental oxygen is also recommended if oxygen saturation is <92% or if the patient uses supplemental oxygen at sea level, for whom an increase in oxygen flow during flight is advised.

The BTS also recommends supplemental oxygen for patients whose Pa_{O_2} on challenge testing (using an FI_{O_2} of 15% for 20 minutes) is <50 mm Hg and, possibly, for those whose Pa_{O_2} is between 50 and 55 mm Hg; in the latter group, a walk test may be helpful.[71]

CONTROL OF BREATHING

The rate, depth, and pattern of breathing reflect a complex interplay of neurohumoral and chemical regulatory mechanisms that drive the respiratory apparatus. Tests used to evaluate the control of breathing, based on assessment of the ventilatory response to controlled hypercapnia or hypoxia, are uncommonly performed in the clinical setting. However, since these tests highlight important physiologic mechanisms that affect the level and pattern of ventilation, they are summarized in subsequent sections.

VENTILATORY RESPONSE TO CO_2

The ventilatory response to changes in Pa_{CO_2} is linear over a broad range (Fig. 33-31). Determination of the ventilatory response to controlled hypercapnia generally is based on one of the two methods: the steady-state method[75] or the rebreathing method.[76]

Steady-State Method

After a control period in which CO_2-free air is breathed to establish a baseline, the patient is subjected to two or more periods of breathing CO_2-enriched air. Care is taken to achieve a steady state of ventilation and circulation during each exposure. Especially at the higher concentrations of inspired CO_2, at least 10 to 20 minutes is required for a steady state to be reached in alveoli, arterial blood, cerebrospinal fluid, and the chemosensitive areas of the brain. The ventilatory response to CO_2 is then determined from a plot of $\dot{V}_E$ versus Pa_{CO_2}. In patients without underlying lung disease, end-tidal CO_2 concentration is often substituted for Pa_{CO_2}. In addition, in order to eliminate the influence of variations in arterial PO_2 on the

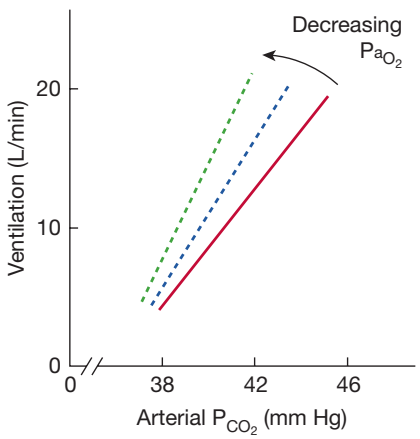

Figure 33-31 Linear relationship between minute ventilation ($\dot{V}_E$) and arterial P_{CO_2}. The dashed lines show the increased slope of the relationship of $\dot{V}_E$ versus P_{CO_2} as Pa_{O_2} decreases.

ventilatory response to CO_2, the inspired gas is enriched with O_2 during the control and test periods.

Rebreathing Method

This method entails rebreathing a CO_2-enriched gas mixture from a bag for approximately 4 minutes. The validity of the approach requires rapid equilibration of CO_2 among alveolar gas, arterial and mixed venous blood, and the chemosensitive areas of the brain. The bag is filled at the outset with a mixture of 7% CO_2 in O_2; O_2 is substituted for air in this mixture to avoid the ambiguity of a hypoxic stimulus to ventilatory drive.

The result of the CO_2 rebreathing test is described by the use of two terms: (1) the *slope* of the line relating change in ventilation response to change in end-tidal P_{CO_2} ($\Delta\dot{V}E/P_{CO_2}$), determined by using the method of least squares linear regression analysis, and (2) the *x-intercept* of the relationship between $\dot{V}E$ and end-tidal P_{CO_2}.

Normal Response to CO_2 and Modifying Influences

As indicated above, the normal increase in ventilatory response to increasing concentrations of inspired CO_2 is linear. Normal responses are categorized as low (<1.5 L/min/mm Hg), intermediate (1.5–5.0 L/min/mm Hg), or high (>5.0 L/min/mm Hg). Most normal persons (about 80%) have an intermediate ventilatory response. A variety of factors, both genetic and environmental, seem to influence the ventilatory response to CO_2 (Table 33-14).

■ VENTILATORY RESPONSE TO HYPOXIA

The response to acute hypoxia in normal persons is largely determined by the peripheral arterial chemoreceptors, as long as the level of hypoxia is mild to moderate. Even at sea level, the level of arterial P_{O_2} in normal persons provides an appreciable chemoreceptor drive, accounting for about 10% of the minute ventilation. Unlike the linear response of $\dot{V}E$ to progressive hypercapnia, the response to hypoxemia is curvilinear (Fig. 33-32). The magnitude of the ventilatory response to a decrease in arterial P_{O_2} depends on the Pa_{CO_2}, increasing as the concentration of CO_2 in arterial blood is increased.

As may be seen from the hyperbolic curves in Figure 33-32, the rate of change in ventilation is greater over the lower range of oxygenation (when Pa_{O_2} falls below 60 mm Hg). Not shown in Figure 33-32 is the depression of ventilation brought about by severe hypoxemia, presumably because of the central depressing effect of severe hypoxia on respiratory neurons.

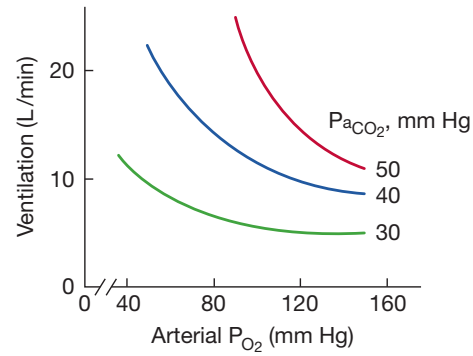

Figure 33-32 The curvilinear relationship between ventilation and arterial P_{O_2} at various levels of arterial P_{CO_2}. The rate of change of ventilation as P_{O_2} falls (slope) increases precipitously at a P_{O_2} of approximately 60 mm Hg when P_{CO_2} is 40 mm Hg. The abrupt increase in ventilation occurs at a higher P_{O_2} when the level of P_{CO_2} is elevated, and at a lower P_{O_2} when the prevailing P_{CO_2} is lower.

Although tests for assessing the ventilatory response to hypoxia are less well standardized than those for measuring the hypercapnic response, they, too, may be conveniently categorized into steady-state and nonsteady-state methods. In one steady-state method,[75] successive ventilatory responses are determined to a series of increasingly severe hypoxic gas mixtures, each administered for at least 10 minutes; Pa_{CO_2} is kept constant by the addition of CO_2 to the inspired gas mixture as hypoxia-induced hyperventilation develops. In another, the effect of hypoxia on the slope of the plot of $\dot{V}E$ versus P_{CO_2} as P_{O_2} is lowered from hyperoxic (at least 200 mm Hg) to hypoxic (40 mm Hg) levels is determined. The normal response to diminished inspired oxygen concentrations is characterized by an increase in sensitivity (slope) without a change in the CO_2 threshold.

Three nonsteady-state techniques are currently in use. In the hypoxic rebreathing test,[77] the subject rebreathes a hypoxic gas mixture containing 7% CO_2. As arterial hypoxemia intensifies, causing an increase in ventilation and in CO_2 elimination into the closed circuit, the P_{CO_2} in the system is held constant at a predetermined level by the diversion of a fraction of the expired gas through a CO_2 absorber. The ventilatory response is determined at two or more levels of P_{CO_2}, since the hypoxic response is influenced by P_{CO_2}. An alternative rebreathing test[78] induces progressive hypoxemia by adding N_2 to the inspired gas mixture over a 20-minute period. Finally, in a relatively simple test, the patient induces a transient drop in arterial P_{O_2} by inhaling pure N_2 for a few breaths. The relationship between $\dot{V}E$ and Pa_{O_2} is plotted; the slope of the relationship is the sensitivity to hypoxia. Because the duration of the hypoxia is brief, presumably only the peripheral chemoreceptors are stimulated. No adjustment is made for the drop in P_{CO_2} that occurs during the hypoxia-stimulated increase in ventilation.

Finally, in a relatively simple test,[79] a transient drop in arterial P_{O_2} is induced by having the patient inhale pure N_2 for a few breaths. The relationship between $\dot{V}E$ and Pa_{O_2} is plotted; the slope of the relationship is the sensitivity to hypoxia. Because the duration of the hypoxia is brief, presumably only the peripheral chemoreceptors are stimulated.

Normal Responses to Hypoxia and Modifying Influences

The normal ventilatory response to acute hypoxia varies among individuals. Several factors may influence the relationship (Table 33-15). A high ventilatory response to CO_2 may be associated with a high sensitivity to hypoxia; in addition, higher levels of arterial P_{CO_2} are associated with a higher ventilatory response to hypoxia. Interestingly, a long duration of hypoxia before the test period, as is the case for example, in native residents at high altitude and persons with cyanotic congenital heart disease, a blunted response to acute hypoxia is observed. Finally, a variety of other clinical disorders, including myxedema and hypothyroidism, autonomic nervous system dysfunction, chronic narcotic addiction, and the chronic use of methadone, are characterized by a reduced hypoxic response.

■ NONVENTILATORY MEASURES OF VENTILATORY DRIVE

Measurement of ventilation in response to acute hypoxia or hypercapnia provides a useful index of respiratory output when the ventilatory apparatus (thorax, diaphragm, abdominal muscles, lung, and airways) is normal. This situation obviously does not apply in certain neuromuscular disorders in which the thorax and diaphragm behave abnormally. In addition, it does not apply in some instances of pulmonary disease, notably obstructive airway disease, in which the respiratory apparatus may not be capable of responding normally, even though it is intact and chemosensitivity is normal. In this instance, a decrease in ventilatory response may be attributable to the excessive mechanical load placed on the muscles of respiration.

When ventilation fails to provide a reliable measure of the ventilatory drive (efferent discharge from the respiratory neurons), the diaphragmatic electromyograph (EMG) or the pressure generated by the inspiratory muscles during the first 0.1 second of an occluded inspiration (the $P_{0.1}$)[80] has been used for the clinical assessment of the control of breathing.

The electrical activity of the diaphragm is directly related to neural activity of the phrenic nerve. Therefore, it provides a measure of efferent neural traffic to the diaphragm. The diaphragmatic EMG may be recorded in patients by placing the tip of an esophageal catheter, containing bipolar electrodes, at the level of the diaphragm.

The second approach to obtaining a nonventilatory measure of ventilatory drive is the determination of $P_{0.1}$, which is the negative pressure generated by the inspiratory muscles during the first 100 milliseconds of an inspiratory effort made against an occluded airway. During this brief period, contraction of the respiratory muscles is virtually isometric, and the force generated correlates with activity recorded by the diaphragmatic EMG.

In performing the test, airflow in the inspiratory line of the breathing circuit is randomly interrupted during the preceding expiration. The 100-millisecond period has proved to be so brief as to be imperceptible, thereby obviating any corrective action by the subject during the breath against the occlusion. However, the $P_{0.1}$ is far from foolproof. A major concern is that $P_{0.1}$ is affected by resting lung volume: $P_{0.1}$ is reduced when FRC is abnormally high, a common occurrence in obstructive disease of the airways.

ASSESSMENT OF INTEGRATED FUNCTIONS: 6-MINUTE WALK TEST

A complete evaluation of a patient with respiratory symptoms often requires assessment of exercise capacity, in addition to traditional pulmonary function tests and radiographic studies. A number of exercise studies can be employed, including cardiopulmonary exercise tests (Chapter 34), cardiac stress tests, and exercise-induced bronchospasm protocols. One of the most widely used, practical modalities is the 6-minute walk test (6MWT). Despite its simplicity, the 6MWT has become a powerful tool in the evaluation of functional status and prognosis of patients with a variety of functional impairments.

■ TECHNICAL ASPECTS

The 6MWT is performed indoors. There is an initial period of rest in a chair for at least 10 minutes, during which baseline vital signs are taken. The patient then stands and is asked to rate baseline dyspnea and overall fatigue using the Borg scale (from 1 to 10). The patient, walking at a comfortable pace, completes 60-m laps on a walking course which is 30 m in length. Cones are used to mark

the turnaround points. For patients using supplemental oxygen, the oxygen is delivered at standard rate, or as prescribed by a physician, or as determined by protocol. The patient should not carry or push the oxygen source during testing. The number of laps and a postwalk Borg scale assessment are recorded, as is the total distance walked over 6 minutes (6MWD).

Although pulse oximetry during the 6MWT is considered optional, it has become standard at many institutions. In some cases, pulse oximetry can be used to titrate levels of oxygen supplementation. Obtaining a high-quality oximeter signal is imperative.

A number of sources of variability are inherent in 6MWT. A modest training effect has been reported when two studies are performed within 1 week. Concomitant medication use can also impact the 6MWT. Improved test performance, for example, occurs after bronchodilator use in patients with COPD. Shorter height, female sex, and higher body weight are associated with reduced performance.[81] Despite these factors, the 6MWT has been found to have excellent reproducibility, especially when performed in evaluation of specific clinical entities, such as idiopathic pulmonary fibrosis.[82]

Several modifications of the 6MWT are in clinical use. During a *shuttle-walking test*, the patient walks on a 10 m course while the walking speed is increased every minute until the patient cannot reach the turnaround point within the set time. The *timed walk test (TWT),* which has been designed for patients with idiopathic pulmonary fibrosis, has three stopping criteria based on changes in oxyhemoglobin saturation.

Absolute contraindications to performing the 6MWT include unstable angina or myocardial infarction within 1 month of the study. Resting tachycardia of greater than 120 beats per minute, systolic blood pressure greater than 180 mm Hg, or diastolic blood pressure greater than 100 mm Hg are relative contraindications. The study should be terminated if the patient develops chest pain, severe dyspnea, leg cramps, diaphoresis, or profound oxyhemoglobin saturation.

INTERPRETATION

Although the 6MWT is limited in its inability to provide objective measures of functional capacity, such as oxygen uptake, the test provides very useful clinical information. In addition, it realistically represents the patient's functional capacity during physical effort that more closely reflects his or her daily activity. Reliable reference equations establishing standard performance during a 6MWT in healthy patients are not currently available.

The 6MWT has several indications, including, most notably, measurement of the response to a number of medical and surgical interventions. Pulmonary rehabilitation clearly improves 6MWT performance in patients with COPD, while pharmacologic interventions for pulmonary arterial hypertension and heart failure, among other disorders, have also been shown to favorably affect test results. Lung transplantation (unilateral and bilateral) and lung volume reduction surgery for emphysema have been shown to significantly improve results of the 6MWT.

6MWT also has been used to assess functional status in patients with COPD, cystic fibrosis,[83] heart failure, and peripheral vascular disease, and in determining eligibility for, and timing of, lung transplantation. In the absence of well-established reference standards, the clinical value of performing a single test in these patient groups is limited. Serial studies are likely to be more useful than a single 6MWT.

Recently, a number of publications have established the value of the 6MWT in predicting morbidity and mortality from heart and lung disease. Results from the test have been shown to have an inverse relationship with mortality in severe COPD. Walk distance and velocity, as well as magnitude of oxyhemoglobin desaturation, are correlated with survival in idiopathic pulmonary fibrosis. Similar correlations have been made in heart failure and primary pulmonary hypertension.

Finally, at some institutions, results of the 6MWT are utilized to not only establish the presence of exertional hypoxemia, but also to titrate supplemental oxygen with activity.

QUALITY CONTROL IN THE PULMONARY FUNCTION LABORATORY

Meaningful interpretation of pulmonary function tests requires confidence in the accuracy and reproducibility of results provided by the pulmonary function laboratory. Previously, it was tacitly assumed that all data from all laboratories, especially when reported as "percent predicted," were equally reliable. In recent years, the fallacy of this assumption has been explicitly recognized, and steps have been taken to standardize equipment and procedures and to ensure accuracy, reproducibility, and uniformity in testing and reporting.[6,8] To accomplish this goal, both analytical and nonanalytical factors must be taken into account.

NONANALYTICAL FACTORS IN QUALITY CONTROL

A familiar example of a confounding influence that may distort test results is the anxious patient who pauses outside the laboratory door to "calm the nerves" by smoking one or more cigarettes before undergoing pulmonary function testing. Cigarette smoking before the diffusing capacity of the lungs is determined can generate enough carboxyhemoglobin to reduce a normal value to subnormal levels.

Another example of a nonanalytical factor is the failure to achieve patient understanding and comfort for tests that usually require patient cooperation. Unfortunately, a preliminary explanation before the patient arrives at the laboratory or prior exposure of the patient to the laboratory and its personnel is usually impractical. Use of explanatory sheets or descriptive brochures may prove helpful. If such materials are not available, laboratory personnel are obligated to make the patient comfortable and even perform "practice runs" before undertaking final testing.

When the patient arrives at the pulmonary function laboratory, an assessment should be made of his or her prior experiences. Did the patient undergo other tests or procedures that could alter the outcome of the pulmonary function tests in question? Is the patient fatigued or in pain? Should a period of rest precede the tests in order to ensure optimal performance? If delay is impractical, the test report should include the fact that the patient was fatigued or in pain.

Medication use before pulmonary function testing can seriously affect the results. For example, self-administration of bronchodilators before testing can artificially enhance tests of airflow. If medications have been taken before the patient arrives at the laboratory, the time of administration should be part of the record. Also, a request for pulmonary function test results for patients who regularly take bronchodilators should indicate whether the tests are to be done without interruption of the regular schedule of medications, whether bronchodilators are to be discontinued before the test is done, or whether regular bronchodilators are to be discontinued so that the effects of bronchodilation can be tested. Appropriate comments about bronchodilators are part of the report.

A major nonanalytical cause of misinterpreting results is the inappropriate application of predicted normal values to the patient population by the laboratory (see Approach to Interpreting Commonly Performed Pulmonary Function Tests). For example, normal values based on data obtained using physically fit hospital personnel do not necessarily apply to those who have a sedentary existence. Noncomparable race, as well as lifestyle, may complicate comparisons. Anthropologic differences among control and test populations are not easily reconciled. Extraordinary height, weight, or age cannot be easily extrapolated if corresponding subjects are not represented in the control group. Using patient-reported height, rather

than making measurement of patient height, may introduce an error in the selection of appropriate normal values.[84] Comparison of control and test results at different altitudes can be invalid if due regard is not paid to the influence of hypoxia on certain measurements (e.g., diffusing capacity).

ANALYTICAL FACTORS IN QUALITY CONTROL

Performance of pulmonary function tests is replete with opportunities for error. The equipment, techniques, use of control values, and calculations are potential sources of error. In an attempt to minimize errors, standardization of techniques has been advocated. For example, with respect to performing the FVC maneuver, guidelines have been established for the number of attempts required, acceptable variability between efforts, and methods for selecting test data in order to arrive at acceptable results. To avoid misuse of spirometers, criteria have been set for minimal performance with respect to capacity, accuracy, and frequency response of various spirometers; in addition, standards have been developed for determining the single-breath diffusing capacity. Potential sources of discrepancies – such as breath-holding time, concentration of hemoglobin, dead space of the equipment and the patient, F_{IO_2}, volume of the alveolar sample, number of tests, and acceptable variability in results – are taken into account.

QUALITY CONTROL OF TEST RESULTS

Guidelines for standardization play a major role in reducing discrepancies between laboratories. However, measures are also required to ensure accuracy and reproducibility within any given laboratory. Among the elements of control that merit consideration are calibration, validation of calibration, and performance of a control measurement. *Calibration* is the adjustment of an instrument's output so that it validly reflects a known input. *Verification of calibration* entails introduction of the same known input and demonstration that the correct output is reproduced. *Performance of a control measurement* refers to the testing of a substrate that has known properties, similar to those usually tested, to prove the accuracy of the instrumentation.

One example of the application of these principles is blood gas analysis. Use of control measurements derived from tonometered blood or commercially prepared buffer solutions is now widespread. Another example is assessment of diffusing capacity[85] and routine incorporation of simulator testing in its measurement.[86]

Unfortunately, similar controls do not exist for pulmonary function tests. Therefore, laboratory technologists have the responsibility for continuing to be alert, not only with respect to faithful observance of guidelines for standardization, but also to detect in-house sources of error – for example, a leak in the system, malfunction of gas analyzers, faulty analog-to-digital converters, and faulty electronics that reduce frequency response.

RESPONSIBILITY AND COST IN QUALITY CONTROL

All who work in the laboratory must be concerned with quality control[87] and resist the frequent temptation to cut corners. Time has to be set aside for the technologist to care for and calibrate equipment, to establish proper control values for the laboratory, to search for inconsistencies in the data and interpretation, and to keep up with changing standards. Also, equipment and supplies, including calibrating syringes and calibrating gases, are expensive. However, when put into the balance, the cost and waste of producing erroneous results exceed, by far, the expense of practicing quality control.

INFECTION CONTROL

Given the relatively close contact between patients and technical staff during performance of pulmonary function tests, the issue of infection control is one that must be carefully considered. To date, the role of pulmonary function equipment in transmission of disease appears to be minimal. Although the presence of potential pathogens on laboratory mouthpieces, valves, and tubing has been well documented, implication of these organisms in the transmission of disease has not been established. Nevertheless, the potential hazards should be recognized and appropriate care exercised.

Infection control begins with practice of the basic principles of hygiene. Hand washing between patients and use of protective gloves by staff when they are handling potentially contaminated equipment are important considerations. Care must be taken in working with mouthpieces, nose clips, and any other implements that come in contact with mucosal surfaces. These devices, if reused, should be disinfected or sterilized after each use. Other equipment – manifolds, tubing, etc. – should be sterilized on a regular basis. In fact, guidelines from the ATS call for the disinfection or sterilization before reuse of any equipment surface with visible condensation from expired air.[6,88]

Because of recent growing concern over cross-contamination among patients and laboratory personnel, manufacturers now produce a variety of in-line filters and disposable pneumotachographs. Care should be taken, however, to assure that response characteristics of the test equipment are not driven to unacceptable levels by use of these devices. Current literature on this topic should be consulted regularly.

APPROACH TO INTERPRETING COMMONLY PERFORMED PULMONARY FUNCTION TESTS

A standard battery of pulmonary function tests is commonly used to identify and quantify abnormalities in the performance of the respiratory system. An organized approach to interpreting these studies is critical. Once a patient's baseline values are established, the tests are valuable in tracking the course of the disorder and its response to treatment.

Results of pulmonary function tests are interpreted by comparing individual patient data with reference or predicted values for normal subjects.[89,90] Ideally, predicted values should be generated from large groups of well-defined, normal or healthy subjects with proper distribution of anthropometric characteristics such as sex, age and height, and ethnic background. Despite dedicated attempts to improve prediction formulas, however, many still fail to take into account important sources of discrepancy, such as the racial and ethnic backgrounds of the patients and the control population, the effects of altitude and exposure to air pollution, and effects of inordinate body size or old age. As a result, not all sets of predicted normals are applicable in pulmonary function laboratories outside the immediate vicinity of the patient populations from whom the data were collected.[91] Extrapolation beyond the characteristics of the reference population should be avoided.

Published guidelines from a joint Task Force of the ATS and ERS recommended that in the United States, ethnically appropriate reference equations from the National Health and Nutrition Examination Survey (NHANES) III be used for individuals aged 8 to 80 years. The Task Force did not recommend any specific set of reference equations for laboratories in Europe, but it suggested the need for an investigation conducted throughout Europe to derive contemporary equations for prediction of normal lung function.

The same ATS/ERS Task Force recommended that each pulmonary function test result falling below the fifth percentile of the frequency distribution of values measured in the reference population be considered abnormal. If normal test results fall in a normal distribution, values below the fifth percentile can be estimated using Gaussian statistics. If the distribution of normal values is non-Gaussian, the lower limit of normal is estimated using a nonparametric technique, for example, the 95th percentile method. Traditionally, but without a sound statistical basis, most laboratories have used an arbitrary cut-off of 80% predicted to define normal. While this method may be reasonable in children, errors may arise if it is applied to adult test results.

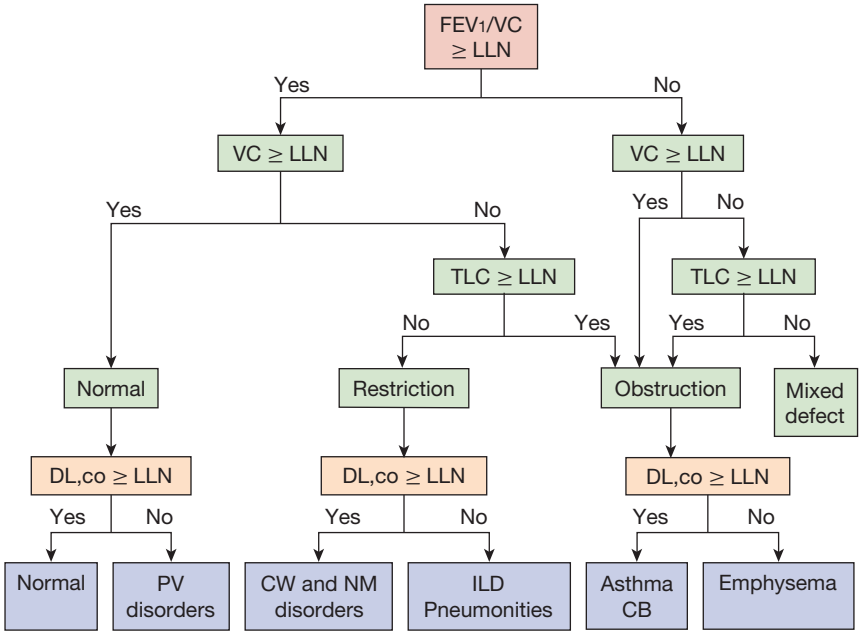

Figure 33-33 Proposed sequence of test review in the interpretation of pulmonary function tests. See text for discussion. Interpretive strategies for lung function tests. Eur Respir J. 2005;26(5):948–968.)*

INTERPRETATION SCHEME AND CLASSIFICATION OF ABNORMAL PATTERNS

A variety of schemes have been proposed for sorting out abnormalities in pulmonary function test results. Many are based on initial categorization of findings reflective of one of the four basic patterns described in the following paragraphs.

An *obstructive* pattern stems from narrowing of any portion of the airways – from upper airway to bronchioles less than 2 mm in diameter – that results in a reduction of maximal airflow in relation to maximal volume.

A *restrictive* pattern is elicited by diseases of the lung, chest wall, pleural space, or neuromuscular respiratory apparatus that reduce lung volumes, particularly TLC, and vital capacity.

A *combined obstructive–restrictive* pattern results from pathologic processes that reduce lung volumes, vital capacity, and airflow, and that also include an element of airway narrowing.

Finally, *abnormal gas transfer* may be noted as part of one of the aforementioned patterns or in isolation and reflects an abnormality in the alveolar capillary membrane, impairing oxygen uptake from alveolar gas to pulmonary capillary blood.

Overlap among categories is not uncommon. For example, widespread interstitial disease, as in idiopathic pulmonary fibrosis, often shows a pattern that indicates important components of both restrictive disease and abnormal gas transfer.

One useful sequence recommended by the ATS/ERS Task Force for analyzing a conventional battery of pulmonary function test results is illustrated in Figure 33-33.

Analysis begins with evaluation of the ratio of FEV_1 to VC. While, historically, the ratio of FEV_1 to FVC (FEV_1/FVC%) served as the basis for distinguishing obstructive disorders from normality or restrictive disease, the ATS/ERS Task Force currently recommends using as the denominator the FVC, *or* the VC ("slow" VC or SVC), *or* the FIVC, whichever is greatest. If the ratio is less than the lower limit of normal (i.e., below the fifth percentile) and the VC (defining VC as any of the three previously noted vital capacity measurements) is at or above the lower limit of normal, the pattern is obstructive. If TLC is not at or above the lower limit of normal, a mixed obstructive–restrictive pattern is suggested. Distinction between asthma and chronic bronchitis on the one hand, and emphysema on the other, is based upon whether the D_{LCO} is normal (asthma or chronic bronchitis) or reduced (emphysema). The previous practice of using a value for FEV_1/FVC% of less than 70% to define obstruction results in misdiagnosis of airway obstruction in men over 40 years and women over 50 years of age, as well as overdiagnosis of COPD in elderly, asymptomatic nonsmokers.

If FEV_1/VC and VC are each equal to or greater than the respective lower limits of normal, spirometry is considered normal; measurement of the D_{LCO} can then help distinguish between normal pulmonary function and pulmonary vascular disorders. If VC is below the lower limit of normal, a reduced TLC supports a diagnosis of restriction, while a normal TLC indicates an obstructive pattern. Once again, in the setting of a restrictive pattern, measurement of D_{LCO} can be used to distinguish between pulmonary parenchymal disorders and disorders of the chest wall or respiratory muscles. Note that according to these guidelines, an obstructive pattern may be diagnosed in the setting of a *normal* FEV_1/VC, if VC is reduced and TLC is normal or elevated.

Once the predominant abnormality is defined with initial pulmonary function testing, the whole battery may not be necessary in following the course of the disease or in assessing its response to treatment. For example, particular determinations, such as spirometry, may suffice in patients with airway diseases. Notably, according to the ATS/ERS guidelines, the severity of the abnormality in each of the obstructive, restrictive, or mixed patterns is expressed on the basis of the FEV_1 (Table 33-16). Standards have been established for

TABLE 33-16 Grading of Severity of Abnormal Spirometry Based on FEV_1

Severity	FEV_1 Percent Predicted
Mild	>70
Moderate	60–69
Moderately severe	50–59
Severe	35–49
Very severe	<35

TABLE 33-17 Conditions Associated with Reduced Peak Inspiratory ($P_{I_{max}}$) and Expiratory ($P_{E_{max}}$) Pressures

Condition	$P_{I_{max}}$	$P_{E_{max}}$
Poor effort	↓	↓
Fatigue	↓	↓
Neuromuscular disease	↓	↓
Increased lung volume	↓	N
Decreased lung volume	N	↓

Note: ↓, decreased; N, normal.

defining significant changes in results over time: A 15% or greater change in FVC or in FEV_1, or a greater than 10% change in $D_{L_{CO}}$ is considered significant.

ASSESSING RESPIRATORY MUSCLE STRENGTH AND EFFORT

One additional measurement that is frequently useful in assessing results of routine spirometry is assessment of respiratory muscle strength. Respiratory muscle strength is expressed in terms of peak inspiratory ($P_{I_{max}}$) and peak expiratory ($P_{E_{max}}$) pressures, determined under static conditions.[24] The technique was outlined in a previous section. Any of a number of factors may be responsible for low peak inspiratory or expiratory pressures (Table 33-17): suboptimal effort, fatigue, weakness of the respiratory muscles, deformity of the chest wall, or intrinsic diseases of the lungs or chest wall. Although the first three factors characteristically reduce both peak inspiratory and expiratory pressures, disease of the lungs or chest wall often reduces, selectively, one or the other peak pressure. Thus, diseases that reduce lung volumes (e.g., widespread interstitial fibrosis) and shorten the length of the expiratory muscles at the end-inspiratory position generally reduce maximal expiratory pressure. Conversely, diseases that increase lung volume, such as obstructive airway disease, by decreasing the inspiratory muscle length at end-expiration generally reduce maximal inspiratory pressure.

If airflow during spirometry is reduced, determination of the peak inspiratory and expiratory pressures may be helpful in suggesting the mechanism. Many pulmonary function tests depend on the cooperation of the patient. Poorly reproducible peak flows that are consistently subnormal raise the question of poor effort. Conversely, consistently low values that occur despite maximal effort may signal neuromuscular disease.

ADDITIONAL DETAILS OF PULMONARY FUNCTION TEST RESULTS IN AN OBSTRUCTIVE PATTERN

Included in the obstructive pulmonary disorders (Table 33-18) are chronic obstructive diseases of the airways (chronic bronchitis and emphysema), bronchiectasis, asthma, small-airway disease, and upper-airway obstruction.

Except for diseases confined to the small airways, as noted previously, the hallmark of the obstructive pattern is a reduction in the FEV_1/VC%. Notably, some healthy subjects have a reduced FEV_1/FVC% and an FEV_1 in the normal range. The clinical significance of these findings is unclear. Results of additional tests (e.g., lung volumes, $D_{L_{CO}}$, assessment of bronchodilator responsiveness) may help distinguish those with airway obstruction from true normals.[92] Measurement of airway resistance (Raw) or specific airway conductance (SGaw) may be useful in assessing airway obstruction in subjects unable to perform a maximal forced expiratory maneuver.

Changes in lung volume commonly accompany the abnormal findings on spirometry, but, as indicated in Figure 33-33, lung volume measurement is not mandatory in establishing the presence of obstruction. Frequently, but not invariably, lung volumes are abnormally high. Typically, all three lung volumes – RV, FRC, and TLC – are increased.

In addition to uncovering the pattern of chronic obstructive airway disease described above, certain additional tests provide insight into the sites and mechanisms of obstructive airway disease.

Reversible Versus Irreversible Obstructive Airway Disease

The response to inhaled bronchodilators traditionally has been used to help distinguish between chronic obstructive airway disease (chronic bronchitis and emphysema), in which airway resistance is virtually fixed, and asthma, in which bronchoconstriction is a prominent feature. This is an oversimplification, since a sizable minority of patients with COPD manifest a bronchodilator response. Furthermore, the absence of a bronchodilator response in a laboratory setting does not necessarily predict lack of a clinical response.

A universally agreed upon definition of reversibility is lacking. Expressing change in FEV_1 or FVC as percent of predicted values may be more advantageous than expression of changes in the values relative to baseline. In general, an increase in FEV_1 or FVC of at least 12% above baseline *and* an absolute increment of at least 200 mL is considered evidence of significant bronchodilation. If the increase in spirometric values is not significant, a decrease in lung volumes toward normal may be an indication of bronchodilator responsiveness.

TABLE 33-18 Causes of an Obstructive Pattern

Disease Process	Anatomic Location of Lesion	Cause of Reduced Airflow
Chronic obstructive pulmonary disease (COPD)		
Chronic bronchitis	Large and small (<2-mm diameter) airways	Narrowing of airways by fibrosis, secretions, edema
Emphysema	Lung parenchyma	Loss of lung elastic recoil
Cystic fibrosis	Large and small airways	Narrowing of airway by fibrosis, retained secretions, edema Loss of elastic recoil
Asthma	Large and small airways	Narrowing of airways by smooth muscle contraction, edema, retained secretions
Small-airway disease	Small airways	Narrowing, stenosis of small airways
Upper-airway obstruction	Major, central airways (trachea, main bronchi)	Anatomic or functional narrowing of upper airway

Chronic Bronchitis Versus Emphysema

Although chronic bronchitis and emphysema usually coexist, occasionally one or the other exists in virtually pure form. Two pulmonary function tests have proved valuable in distinguishing between the two – diffusing capacity (D_{LCO}), which is routinely measured, and static lung compliance (Cst,L), which is uncommonly measured clinically. Emphysema, characterized by a loss of alveolar units and a decrease in alveolar surface area, is associated with a low D_{LCO}, whereas the D_{LCO} in chronic bronchitis is usually normal or near normal.

The loss of alveolar units in emphysema also causes a decrease in the elastic recoil pressure of the lungs. As a result, Cst,L is increased in emphysema, whereas it is usually not appreciably altered in chronic bronchitis.

Small-Airway Disease

In obstructive disease of the small airways (i.e., those less than 2 mm in diameter), expiratory flow is usually normal, except at low lung volumes; that is, the FEV_3 and $FEF_{25–75\%}$ are abnormally low. Other, uncommonly performed tests for isolated, small-airway disease, including the helium–oxygen flow–volume loop, nitrogen washout test, and frequency dependence of dynamic compliance, would also be anticipated to be abnormal. Lung volumes and D_{LCO} are normal. Bronchodilators are virtually without effect.

The practical value of tests of small-airway function is problematic. At one time, high hopes were held that early detection of small-airway disease might reinforce measures, such as cessation of smoking, that would prevent or arrest progression to irreversible obstructive disease of the airways. However, enthusiasm for testing for small-airway disease has waned, since it is still unclear if small-airway disease is a reversible phase in the evolution of clinically significant obstructive airway disease that affects larger bronchi.

Upper-Airway Obstruction

The designation *upper-airway obstruction* is an umbrella for anatomic or functional narrowing of the large upper airways – the larynx, extra- and intrathoracic trachea, and lobar bronchi. Although upper-airway obstruction of any cause may reduce expiratory or inspiratory airflow, an alteration in the contour of the flow–volume loop has proved to be the most reliable abnormality in conventional pulmonary function testing. The observation from routine spirometry that the ratio of FEV_1 to peak expiratory flow rate (PEFR) exceeds 8 mL/L/min should prompt careful performance and review of the flow–volume loop, as described later.

Upper-airway obstruction can be divided into three major types: (1) fixed obstruction, (2) variable extrathoracic obstruction, and (3) variable intrathoracic obstruction.[93]

A *fixed obstruction,* such as tracheal narrowing by scar tissue at the site of a previous tracheotomy, is one in which the geometry and cross-sectional area of the lesion do not change during the respiratory cycle. Characteristically, both inspiratory and expiratory flows are affected about equally (Fig. 33-34A).

A *variable obstruction* is one in which the configuration of the obstructive lesion changes with the phases of respiration. Depending on its location in the tracheobronchial tree (extra- or intrathoracic), this type of lesion usually affects predominantly either inspiration or expiration.

The inspiratory arm of the flow–volume loop is primarily affected by a *variable extrathoracic* obstruction, leaving the expiratory limb relatively unaffected (Fig. 33-34B). The abnormal configuration of the flow–volume loop is attributable to the following sequence: during forced expiration, tracheal pressure exceeds atmospheric, so that the degree of obstruction decreases; conversely, during forced inspiration, intratracheal pressure becomes less than atmospheric and the trachea tends to collapse.

The expiratory arm of the flow–volume loop is primarily affected by a *variable intrathoracic* obstruction (Fig. 33-34C). The following sequence is responsible for producing this abnormality in the flow–volume loop: during forced expiration, as pleural pressure reaches and then exceeds intratracheal pressure downstream from the lesion (i.e., toward the mouth), the obstruction tends to increase; conversely, during a forced inspiration, as intratracheal pressure exceeds pleural pressure, the intrathoracic obstruction decreases.

Variable intrathoracic lesions often coexist with obstructive airway disease. In considering a variable intrathoracic lesion, the respective roles played by obstructive disease of the airways (i.e., chronic bronchitis, emphysema, and asthma) and an obstructive upper-airway lesion (anatomic or functional) in deforming the flow–volume loop must be determined. Fortunately, this distinction is often possible. Although both upper-airway obstruction and obstructive airway disease (reversible and irreversible) do decrease maximal expiratory flow, the shapes of the flow–volume cures are frequently quite distinctive (Fig. 33-34C and D). Thus, in obstructive airway disease, despite a decrease in airflow, the

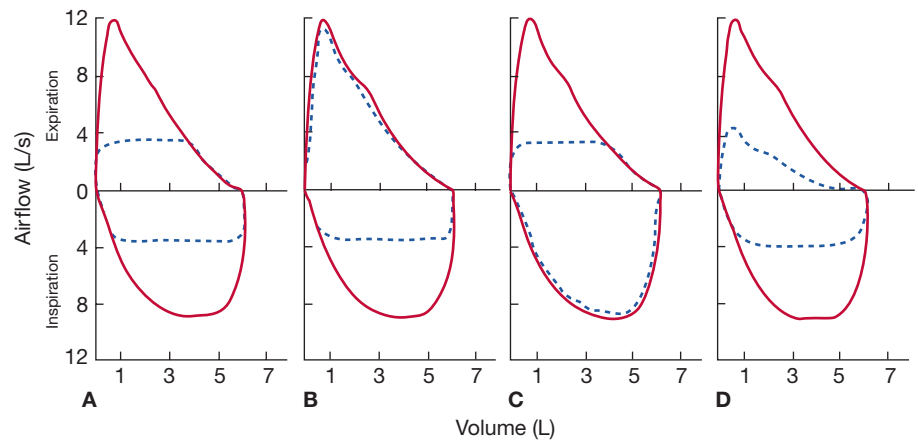

Figure 33-34 Schematic flow–volume loops in four pathologic conditions. **A.** In a fixed upper-airway obstruction, both inspiratory and expiratory limbs are truncated. **B.** In a variable extrathoracic obstruction, the inspiratory limb is flattened while the expiratory limb is not altered. **C.** In a variable intrathoracic obstruction, the expiratory limb is flattened while the inspiratory portion is unchanged. **D.** In chronic obstructive airway disease, although expiratory airflow is reduced, the tapering in airflow during expiration is generally maintained so that the configuration of the loop is different from that in variable intrathoracic obstruction.

TABLE 33-19 Distinguishing Features of Disorders Producing an Obstructive Pattern

Disorder	FEV_1	FVC	FEV_1/VC%	Response of FEV_1 to Administration of Bronchodilator	Tests of Small-Airway Function	Lung Volumes	D_{LCO}	Flow–Volume Loop
COPD								
Chronic bronchitis	↓	↓	↓	NC	ABN	↑	NL	ABN
Emphysema	↓	↓	↓	NC	ABN	↑	↓	ABN
Asthma	↓	↓	↓	↑	ABN	↑	NL	ABN
Small-airway disease	NL	NL	NL	NC	ABN	NL	NL	NL
Upper-airway obstruction	↓	↓	↓	NC	NL or ABN	NL or ↑	NL	ABN[a]

[a]*Configuration frequently characteristic for upper-airway obstruction.*
Note: ↓, decrease; ↑, increase, NC, no significant change; NL, normal; ABN, abnormal.

expiratory limb of the loop generally retains its normal configuration (Fig. 33-34D) – that is, an early peak in flow, followed by gradual tapering. In contrast, in upper-airway obstruction (fixed and variable intrathoracic), the expiratory limb is flat and flow is decreased throughout most of expiration (Fig. 33-34C).

In addition to changes in the shape of the flow–volume loop, clues from routine pulmonary function tests often alert the clinician to the possibility of upper-airway obstruction. As noted previously, when FEV_1/PEFR >8, the possibility of upper-airway obstruction should be considered. Finally, the presence of any of the following may also provide clues: $FEF_{50\%}/FIF_{50\%}$ of at least 1, where $FEF_{50\%}$ and $FIF_{50\%}$ are the forced expiratory flow at 50% of FVC and the forced inspiratory flow at 50% of FIVC, respectively; $FIF_{50\%}$ less than 100 L/min; and $FEV_1/FEV_{0.5}$ at least 1.5.

Distinguishing test features of disorders producing an obstructive pattern are summarized in Table 33-19.

■ ADDITIONAL DETAILS OF PULMONARY FUNCTION TEST RESULTS IN A RESTRICTIVE PATTERN

The restrictive pattern (Table 33-20) characteristically occurs in several groups of disorders including: (1) a primary disorder of the lung parenchyma in which functional tissue is lost through disease (e.g., an alveolar filling process, such as pneumonia, tumor, atelectasis, or fibrosis); (2) surgical removal of lung tissue (e.g., lobectomy); (3) constrictive disease of the pleura and chest wall (e.g., extensive pleural fibrosis, large pleural effusion or pleural mass, kyphoscoliosis, obesity); and (4) neuromuscular diseases, notably those in which the generation of respiratory force is reduced (e.g., disorders of the spinal cord, peripheral nerves, neuromuscular junction, and muscle).

The diagnosis of restriction is based upon the finding of a normal FEV_1/VC and reduced VC in the setting of a decreased TLC. While TLC generally is reduced in most disorders producing a restrictive pattern, FRC is usually preserved in disorders characterized by decreased respiratory force (e.g., the neuromuscular disorders) and is reduced in the others. In neuromuscular disorders, ERV is decreased because of loss of expiratory force, so that RV is often increased. In the other types of restrictive disorders, RV is usually reduced.

Whether or not the D_{LCO} is reduced in the restrictive disorders depends on the underlying disease process. Primary parenchymal disorders and removal of lung tissue decrease the diffusing surface area and reduce D_{LCO}. Diseases of the pleura and chest wall that limit thoracic excursion during the inspiratory vital capacity maneuver, which is part of the technique for determining D_{LCO}, also reduce this measurement.

■ ADDITIONAL DETAILS OF PULMONARY FUNCTION TEST RESULTS IN A MIXED OBSTRUCTIVE–RESTRICTIVE PATTERN

Occasionally, a battery of pulmonary function tests demonstrates features of both obstructive and restrictive patterns. Most often, the mixed pattern is characterized by a low FEV_1/VC% (indicating obstructive airway disease) and VC and reduced TLC (indicating coexisting restrictive disease).

A number of disorders can produce the mixed obstructive/restrictive pattern. Sarcoidosis and interstitial fibrosis, when severe, generally result in this pattern because the parenchymal disease causes restriction and narrowing of the airways by adjacent fibrosis, evoking signs of airway obstruction. The mixed pattern also occurs in complicated situations when there is more than one cause – for example, a lobar pneumonia or large pleural effusion occurring in a patient with underlying chronic bronchitis or emphysema.

■ ISOLATED DECREASE IN THE EFFICIENCY OF GAS TRANSFER

An isolated reduction in the D_{LCO} suggests one of the two possible abnormalities: (1) interstitial lung disease that is so mild as not to affect measurements of airflow or lung volume, or (2) widespread occlusive disease of the pulmonary microcirculation (e.g., due to an inflammatory process or multiple small emboli). In occlusive vascular disorders, tests of airflow and lung volume are usually normal.

TABLE 33-20 Causes of a Restrictive Pattern

Disease Process	Anatomic Location of Lesion	Cause of Pulmonary Function Test Abnormality
Primary parenchymal disease	Lung parenchyma	Loss of lung tissue ⟶ reduced volumes and flows
Surgical removal of lung tissue	Lung parenchyma	Loss of lung tissue ⟶ reduced volumes and flows
Diseases of pleura and chest wall	Pleura, chest wall	Limited expansion of thoracic cavity ⟶ reduced volumes and flows
Reduced generation of expiratory force	Central nervous system, peripheral nerves, neuromuscular junction, muscles of respiration	Reduced muscle tension ⟶ reduced expiratory flow, atelectasis

TABLE 33-21 Categorization of Reduction in Efficiency of Gas Transfer: Measurement of $D_{L_{CO}}$

Severity	$D_{L_{CO}}$, Percent Predicted
Mild	>60, but less than lower limit of normal
Moderate	40–60
Severe	<40

Source: Modified with permission from Pellegrino R, Viegi G, Brusasco V, et al. Interpretive strategies for lung function tests. Eur Respir J. 2005;26(5):948–968.

Although other disorders can also decrease $D_{L_{CO}}$, almost invariably they also reduce airflow, lung volumes, or both. Quantification of the degree to which the $D_{L_{CO}}$ is reduced by any of these processes is indicated in Table 33-21. Notably, interlaboratory differences are substantial for measurements of $D_{L_{CO}}$.

SUMMARY OF APPROACH TO INTERPRETATION

Pulmonary function tests are designed to detect common disorders. Test interpretation relies heavily on recognition of major patterns of abnormality (Table 33-22). These patterns often suggest pathogenetic mechanisms and are helpful to the clinician in arriving at a diagnosis. The degree of abnormality provides a quantitative measure of the extent of involvement at a particular time. Moreover, repeated testing makes it possible to pace and quantify the course of the illness and to assess the effects of therapeutic interventions.

TABLE 33-22 Characteristic Alterations in Pulmonary Function Tests According to the Major Patterns of Abnormality

Pattern	Airflow (FEV_1/VC%)	Airflow Response to Bronchodilators	Volumes	Lung $D_{L_{CO}}$
Obstructive				
Irreversible	↓	↔	↑	↔ or ↓
Reversible	↓	↑	↑	↔
Small-airway disease	↓	↔	↔	↔
Upper-airway obstruction	↓	↔	↔ or ↑	↔
Restrictive				
Parenchymal disease	↔ or ↑	↔	↓	↓
Surgical resection	↔	↔	↓	↓
Pleural, chest wall disease	↔	↔	↓	↔
Reduced expiratory force generation	↔	↔	↓	↔
Mixed obstructive–restrictive	↓	↔ or ↑	↓	↓
Isolated reduction in efficiency of gas transfer	↔	↔	↔	↓

Note: ↓, decreased; ↑, increased; ↔, no change or normal.

CHAPTER 34

Principles and Applications of Cardiopulmonary Exercise Testing

Karl T. Weber
Kevin P. Newman

INTRODUCTION

Cardiopulmonary exercise (CPX) testing draws on the recognition that the thorax represents a metabolic gas transport unit, the function of whose requisite components – diaphragm, heart, lungs, rib cage, and corresponding skeletal muscles – is to transport O_2 to and CO_2 from metabolizing tissues. Unit O_2 and CO_2 transport must adjust to physiological and pathophysiological stresses that augment the body's consumption of oxygen ($\dot{V}_{O_2}$) and carbon dioxide production ($\dot{V}_{CO_2}$). During strenuous levels of muscular work, for example, $\dot{V}_{O_2}$ may rise eightfold, accompanied by increased $\dot{V}_{CO_2}$. Cardiovascular or ventilatory disease can disrupt the unit's functional integrity. With severe disease, an abnormality in respiratory gas transport may be apparent at rest, when the body's O_2 requirements are modest. Resting function is preserved with less severe expressions of disease, but abnormal respiratory gas transport becomes apparent when the unit is stressed by an elevation in $\dot{V}_{O_2}$.

CPX testing includes the monitoring of respiratory gas exchange ($\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$), minute ventilation ($\dot{V}_E$), and its components, tidal volume and respiratory rate, together with blood pressure, heart rate, and the electrocardiogram. CPX testing represents a useful approach in the clinical evaluation of a whole host of disorders and circumstances. This chapter addresses physiological principles and the clinical application of CPX testing in the evaluation of major disorders that impair heart or lung function. The chapter is by no means an exhaustive review. For a more detailed discussion of specific entities, the interested reader is referred to several other textbooks.[1,2]

PRINCIPLES, DEFINITIONS, AND CLINICAL APPLICATION OF CARDIOPULMONARY EXERCISE TESTING

The metabolic gas transport unit, also referred to as the "cardiopulmonary unit," links metabolizing tissues to the atmosphere and its supply of O_2. O_2 transport to tissues must be precise and based upon prevailing need. CO_2 produced by tissues must be eliminated into the atmosphere in an equally efficient manner.

RESTING OXYGEN UPTAKE AND TRANSPORT

Concepts and calculations pertaining to $\dot{V}_{O_2}$ and O_2 content, transport, and extraction are reviewed in Table 34-1. The heart and lungs accommodate to the metabolic requirements of tissues; they must do so on a moment-to-moment basis, according to physiological priorities. Tissue requirements for O_2 dictate a certain $\dot{V}_E$ and cardiac output. In an average-sized person, resting $\dot{V}_{O_2}$ averages 250 mL/min or 3.5 mL/min/kg body weight (one metabolic equivalent) and is associated with a $\dot{V}_E$ of 8 to 10 L/min and cardiac output of 4 to 6 L/min. O_2 transport, also termed O_2 delivery, ranges between 730 and 1040 mL/min and is more than adequate to satisfy resting $\dot{V}_{O_2}$. On average, 25% of arterial O_2 content is extracted by tissues. O_2 delivery and extraction each increase during physiological stress in proportion to the elevation in O_2 demand. Factors that normally determine O_2 availability at rest and during exercise include cardiac output, hemoglobin concentration and its percent saturation, and O_2 extraction.

EXERCISE OXYGEN UPTAKE AND TRANSPORT

$\dot{V}_E$ and O_2 delivery must each rise during exercise. Strenuous work can raise $\dot{V}_E$ 8 to 10 times its resting level. Ventilation normally poses no limitation on the ability of tissues to carry out aerobic work. By contrast, the extent to which cardiac output rises during progressive work is less dramatic. In untrained subjects, cardiac output increases four to five times its resting value. Cardiac output rises 600 mL/min for every 100 mL/min increment in $\dot{V}_{O_2}$. This is considered the normal "gain" setting between the heart and its cardiac output and $\dot{V}_{O_2}$. O_2 availability during physical activity is further ensured by enhanced O_2 extraction and circulatory autoregulation. Reflexive and humoral influences produce vasoconstriction in less

TABLE 34-1 Oxygen Utilization, Content, Transport, and Extraction

$\frac{O_2 \text{ utilization}}{250 \text{ mL/min}}$	$\begin{cases} = \text{Cardiac output} \cdot (\text{arterial } O_2 \text{ content} - \text{venous } O_2 \text{ content}) \\ = 5000 \text{ mL/min} \cdot (19 \text{ mL/dL} - 14 \text{ mL/dL}) \end{cases}$
$\frac{\text{Arterial } O_2 \text{ content}}{19 \text{ mL/dL}}$	$\begin{cases} = \text{Hemoglobin} \cdot \%\text{ saturation} \cdot O_2 \text{ combining capacity} \\ = 14 \text{ g/dL} \cdot 0.96 \cdot 1.34 \text{ mL/g} \end{cases}$
$\frac{\text{Venous } O_2 \text{ content}}{14 \text{ mL/dL}}$	$= 14 \text{ g/dL} \cdot 0.96 \cdot 1.34 \text{ mL/g}$
$\frac{\text{Arteriovenous } O_2 \text{ difference}}{5 \text{ mL/dL}}$	$\begin{cases} = \text{Arterial } O_2 \text{ content} - \text{venous } O_2 \text{ content} \\ = 19 \text{ mL/dL} - 14 \text{ mL/dL} \end{cases}$
$\frac{O_2 \text{ transport}}{950 \text{ mL/min}}$	$\begin{cases} = \text{Cardiac output} \cdot \text{arterial } O_2 \text{ content} \\ = 5000 \text{ mL/min} \cdot 19 \text{ mL/dL} \end{cases}$
$\frac{O_2 \text{ extraction}}{25\%}$	$\begin{cases} = \frac{\text{Arteriovenous } O_2 \text{ difference}}{\text{Arterial } O_2 \text{ content}} \cdot 100\% \\ = \frac{19 - 14}{19} \cdot 100\% \end{cases}$

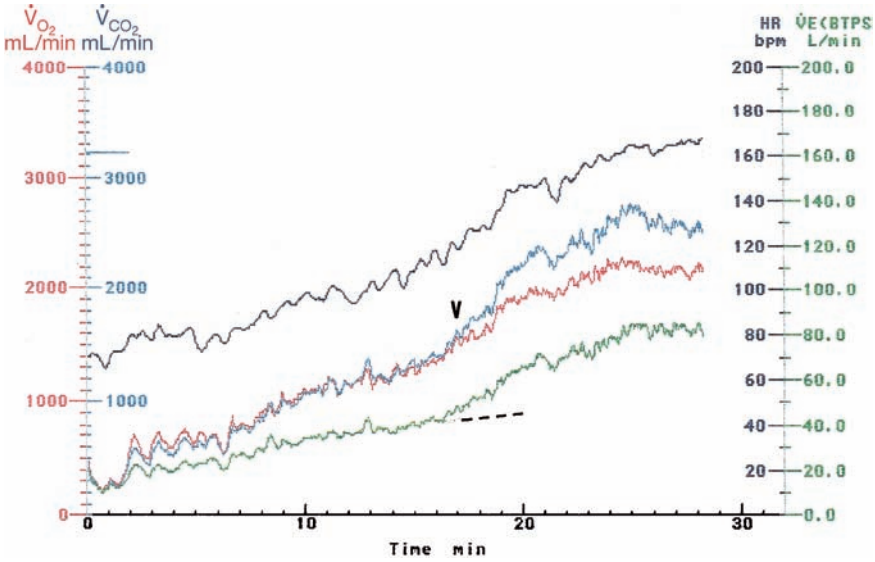

Figure 34-1 Cardiopulmonary exercise response in a 40-year-old man without heart or lung disease. Shown are 2 minutes of standing rest, followed by incremental treadmill exercise. Individual responses *(color coded)* include oxygen uptake ($\dot{V}_{O_2}$), carbon dioxide production ($\dot{V}_{CO_2}$), minute ventilation ($\dot{V}_E$), and heart rate (HR). Maximal O_2 uptake, a plateau in $\dot{V}_{O_2}$ was attained after the crossover of $\dot{V}_{CO_2}$ and $\dot{V}_{O_2}$ *(arrowhead)*, representing the AT and accompanied by a disproportionate (broken line) rise in $\dot{V}_E$.

metabolically active tissues, permitting a greater apportionment of blood flow to exercising muscle.

Physiological limits to the elevation in cardiac output (i.e., cardiac reserve) and O_2 extraction (approximately 75%–80% of arterial O_2 content) determine aerobic capacity of untrained subjects to incremental exercise. Beyond these physiological limits, any additional increment in work is not accompanied by an elevation in O_2; a plateau in $\dot{V}_{O_2}$ is attained and is termed the *maximal oxygen uptake* ($\dot{V}_{O_{2max}}$). CPX test results, including $\dot{V}_{O_{2max}}$, are shown in Figure 34-1 for a 40-year-old man without clinically apparent heart or lung disease. Shown are individual responses in $\dot{V}_{O_2}$, $\dot{V}_{CO_2}$, $\dot{V}_E$, and heart rate during progressive increments in treadmill work. A $\dot{V}_{O_{2max}}$ of 2198 mL/min (27.2 mL/min/kg) was attained. This is a true plateau in $\dot{V}_{O_2}$, with $\dot{V}_{O_2}$ remaining invariant for 2.5 stages (5 minutes) of exercise.

$\dot{V}_{O_{2max}}$ should not be equated or used synonymously with peak $\dot{V}_{O_2}$ achieved during symptom-limited exercise. $\dot{V}_{O_{2max}}$ reflects a person's aerobic capacity—a physiological capacity of the cardiovascular system. In an average-sized, untrained person whose maximum cardiac output and arteriovenous oxygen difference are 20 L/min and 12 mL/dL, respectively, a $\dot{V}_{O_{2max}}$ of 2400 mL/min is expected. In athletes, a greater cardiac reserve and enhanced capacity for oxidative metabolism by trained skeletal muscle are available, providing for greater aerobic capacity. In patients with heart disease, whose ability to raise cardiac output during exercise is impaired, $\dot{V}_{O_{2max}}$ is proportionally reduced (see above).

CARBON DIOXIDE PRODUCTION

The right heart "accepts" metabolically produced CO_2, and the alveolar exchange surface expels CO_2 into the atmosphere. CO_2 is a major respiratory stimulant that maintains eucapnia. Seventy-five to 80% of O_2 is converted to CO_2. Accordingly, resting $\dot{V}_{CO_2}$ averages 190 mL/min and represents a *metabolic source* of CO_2. The resting $\dot{V}_{CO_2}/\dot{V}_{O_2}$ ratio, or respiratory gas exchange ratio (R), typically ranges between 0.75 and 0.85. The absolute value of R depends on the proportion of carbohydrates and fats available from the diet. $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ rise in proportion to one another during physical activity as long as an adequate amount of O_2 is available to sustain oxidative metabolism.

With strenuous levels of muscular work, $\dot{V}_{O_2}$ rises to a level where the heart is unable to provide O_2 at a commensurate rate. Consequently, tissue O_2 availability becomes inadequate. Working skeletal muscle enhances its use of less efficient anaerobic metabolism to derive energy. This leads to lactate production from working muscle beyond that normally produced. This *nonmetabolic source* of CO_2 is derived from rapid buffering of the lactate by bicarbonate; the CO_2 generated serves as a respiratory stimulant. The accompanying increase in $\dot{V}_E$ maintains eucapnia and raises the respiratory gas exchange ratio above that associated with aerobic metabolism. Anaerobic metabolism during a progressive exercise test is heralded by this disproportionate rise in $\dot{V}_E$ and $\dot{V}_{CO_2}$ relative to $\dot{V}_{O_2}$. The corresponding level of $\dot{V}_{O_2}$ at which anaerobic metabolism occurs is termed the *anaerobic threshold* (AT).[1] The point during exercise at which $\dot{V}_{CO_2}$ exceeds $\dot{V}_{O_2}$ and $\dot{V}_E$ rises disproportionately is shown in Figure 34-1. Anaerobiosis normally occurs when 60% or more of a person's aerobic capacity has been attained. For the 40-year-old man whose exercise response is shown in Figure 34-1, the AT occurred at a $\dot{V}_{O_2}$ of 18.8 mL/min/kg, or 69% of his $\dot{V}_{O_{2max}}$.

CLINICAL APPLICATION OF CARDIOPULMONARY EXERCISE TESTING

Patients with cardiovascular or respiratory disease of mild-to-moderate severity frequently note limiting symptoms of fatigue or breathlessness during physical activity. Because their quality of life is compromised, they seek or are referred for medical evaluation. Re-creating muscular work in a monitored setting permits an evaluation of the nature and severity of such symptoms and the relative importance of abnormal heart or lung function. This strategy provides information surpassing that available from static measures of heart and lung function, such as ejection fraction, lung volumes, or airflows, determined at rest. The continuous monitoring of $\dot{V}_{O_2}$, $\dot{V}_{CO_2}$, $\dot{V}_E$, respiratory rate, and tidal volume during incremental exercise can be performed simply and on a breath-by-breath basis. Data shown in Figure 34-1 are displayed throughout the test. The choice of a particular CPX test (see above) depends on the nature and expression of the clinical disorder and the particular problem to be addressed. For most clinical evaluations, isotonic forms of exercise are used. Isotonic work is an acceptable, negotiable, and reproducible form of exercise for patients with heart or lung disease.

It should be noted, however, that while noninvasive CPX testing may help determine the impairment in aerobic capacity, abnormalities in ventilation with exercise, and their severity in patients with lung disease, these parameters are not necessarily diagnostic. For example, $\dot{V}_{O_{2max}}$, AT, or exercise $\dot{V}_E$ do not identify the underlying structural defect responsible for a patient's abnormal response. This may require invasive monitoring during CPX testing to identify specific hemodynamic abnormalities. Echocardiography and specialized pulmonary function studies may be required. The physician must draw upon sound clinical judgment and complementary laboratory tests to derive an understanding of the nature and severity of the heart or lung disease.

NONINVASIVE TREADMILL EXERCISE

Walking represents a common daily exercise rather than a specialized skill. A patient who walks into the physician's office or down a hospital corridor can walk on a treadmill at 1.0 or 1.5 mph, zero grade. Treadmills are programmable. The Bruce protocol, which employs marked increments in treadmill speed and slope over short periods in the evaluation of myocardial ischemia, may not be useful for patients with limited exercise tolerance. A modified Naughton protocol of gradually progressive exercise (Table 34-2) serves to stress the cardiopulmonary unit for patients with heart or lung disease who have a wide range of exercise tolerance. In this protocol, the first two stages of exercise represent very low workloads and are a warmup for patients with heart or lung disease of minor severity; the stages represent near-maximal exercise for patients with more advanced disease.

$\dot{V}_{O_2max}$ is defined as $\dot{V}_{O_2}$ that remains invariant (<1 mL/min/kg for 30 seconds or more) despite an increment in workload. An invariant $\dot{V}_{O_2}$ for at least two stages of exercise is preferred (Fig. 34-1). $\dot{V}_{O_2max}$ follows the AT, and this definition of $\dot{V}_{O_2max}$ presumes that the AT has already been achieved. The AT generally occurs at 60% of a patient's aerobic capacity. $\dot{V}_{O_2max}$ associated with incremental treadmill exercise provides a greater aerobic capacity than does cycle ergometry because it works a larger group of muscles.[3] A patient's aerobic capacity to incremental treadmill exercise is used to grade the functional impairment (Table 34-3). $\dot{V}_{O_2max}$ is an objective measure of functional status—in contradistinction to the New York Heart Association classification, which is based on perceptions and biases of the patient and physician. Treadmill O_2max determination is reproducible in patients with a wide variety of cardiovascular disorders.[2] A $\dot{V}_{O_2max}$ of under 20 mL/min/kg has been selected as the cutoff for grading impaired aerobic capacity; adult men and women, including the elderly (over 65 years of age), have an expected $\dot{V}_{O_2max}$ of more than 20 mL/min/kg.[4]

The duration of symptom-free treadmill exercise should not be equated with $\dot{V}_{O_2max}$. Treadmill time suffers from not having an objective, quantitative end-point. Differences in gait and body weight create different levels of work for equivalent stages of treadmill exercise. Symptom-limited exercise time is subject to patient motivation and physician bias.[5] Peak heart rate attained with exercise is also a less precise measure of $\dot{V}_{O_2max}$. This is particularly true in patients with atrial fibrillation.

Determination of the AT can be defined according to one or more criteria.[1] These include (1) a disproportionate rise in $\dot{V}_{CO_2}$, $\dot{V}_E$, or R relative to $\dot{V}_{O_2}$ and (2) a disproportionate rise in end-tidal CO_2 relative to end-tidal O_2. These criteria can best be applied to breath-by-breath respiratory gas exchange data. In our laboratory, a simpler strategy is used. The AT is identified as the level of $\dot{V}_{O_2}$ attained during treadmill work after the plots of $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ cross, when R exceeds 1.0. Figure 34-1 depicts the crossover in $\dot{V}_{CO_2}$ and $\dot{V}_{O_2}$ from breath-by-breath gas exchange data monitored throughout incremental treadmill exercise. It also demonstrates the point at which $\dot{V}_E$ rises disproportionately. Measured days or weeks apart, this noninvasive determination of the AT is reproducible in a wide range of patients with cardiac or circulatory failure and correlates with lactate threshold (see above).[2,6,7]

The normal ventilatory response to incremental treadmill exercise consists of an increase in $\dot{V}_E$ created by an increase in respiratory rate and tidal volume. Ventilatory reserves, represented by maximal voluntary ventilation (MVV) and vital capacity determined during routine pulmonary function testing, are only partly utilized during light, moderate, and maximal exercise by normal persons. The ratio of maximal exercise $\dot{V}_E$ to MVV reflects use of this ventilatory reserve. Exercise $\dot{V}_E$ in normal subjects and patients with predominant cardiovascular disease rarely exceeds 50% of MVV.[8] The same is true of the ratio between maximal exercise tidal volume and vital capacity. These limitations in ventilatory responses are consistent with a ventilatory effort that can be voluntarily sustained at rest without the appearance of fatigue or breathlessness.

TABLE 34-2 Modified Naughton Treadmill Exercise Protocol

Stage	Speed	Grade	Physical Activities
1	1.0	0	Driving a car
			Sitting and writing or eating
2	1.5	0	Dressing; knitting
			Walking to bathroom
			Light auto repair
3	2.0	3.5	Shave self in bathroom

TABLE 34-3 Classification of Cardiac and Circulatory Failure

Class	Severity	V_{O_2max} (mL/kg/min)	Anerobic Threshold (mL/kg/min)	Predicted Cardiac Index (L/m²/min)
A	Mild to none	>20	>14	>8
B	Mild to moderate	16–20	11–14	6–8
C	Moderate to severe	10–16	8–11	4–6
D	Severe	6–10	5–8	<4

Source: Adapted with permission from Weber KT, Janicki JS, McElroy PA. Pulmonary hypertension. In: Weber KT, Janicki JS, eds. Cardiopulmonary Exercise Testing: Physiologic Principles and Clinical Applications. Philadelphia, PA: Saunders; 1986.

An oximeter, worn on either an earlobe or a finger, provides noninvasive monitoring of arterial O_2 saturation during exercise. This is a useful screening procedure in patients in whom O_2 desaturation might be anticipated (e.g., those with congenital heart disease with right-to-left shunt, restrictive or obstructive lung disease, or pulmonary vascular disease). Normal subjects and patients with chronic cardiac or circulatory failure do not develop arterial hypoxemia (arterial O_2 saturation under 90%) during exercise. In patients in whom O_2 desaturation is evident from oximetry, confirmatory evidence from direct measurement of arterial blood gases during repeat exercise may be advisable.

Thus, incremental treadmill exercise can be used to determine the following: the AT with a submaximal test, the AT and $\dot{V}_{O_2max}$ with a maximal test, the ventilatory response to submaximal or maximal exercise, and arterial O_2 desaturation during submaximal or maximal exercise.

INVASIVE TREADMILL EXERCISE

Invasive hemodynamic monitoring may be necessary to better define the nature and severity of an underlying cardiopulmonary disorder.[2] A triple-lumen flotation catheter can be safely used for hemodynamic monitoring during upright exercise. The hemodynamic response to incremental treadmill exercise in normal subjects is characterized by a progressive rise in cardiac output, accomplished with minimal elevations in left and right ventricular filling pressures. The rise in cardiac output occurs because of an increment in stroke volume, which is most apparent at low and moderate workloads, and because of an elevation in heart rate, which accompanies the entire exercise response. Systemic O_2 extraction rises progressively with incremental exercise to exceed 70% at maximal workloads. A rise in mixed venous lactate concentration, as observed with pulmonary arterial blood sampling, occurs when O_2 extraction exceeds 60% and when the subject is working at greater than 60% of $\dot{V}_{O_2max}$.

Systolic and mean arterial pressures rise during upright exercise. Because of skeletal muscle vasodilatation, arterial diastolic pressure remains essentially invariant during exercise. Systemic vascular resistance falls by 50% to approximately 600 dynes·s·cm^{-5} during incremental, isotonic treadmill exercise. In normal persons, pulmonary artery systolic, mean, and diastolic pressures rise only minimally with exercise and only with higher workloads. Pulmonary vascular resistance, like systemic vascular resistance, falls 50% to about 60 dynes·s·cm^{-5} during incremental isotonic exercise.

CHRONIC CARDIAC FAILURE

In physiological terms, *cardiac failure* is defined as an impairment in cardiac output secondary to a disease process affecting the myocardium. Ischemic heart disease and dilated cardiomyopathies are examples of disease entities that can result in chronic cardiac failure. $\dot{V}_{O_2max}$ and the AT each predict cardiac reserve and, thereby, the severity of cardiac failure. These parameters further serve to objectively demonstrate a patient's functional capacity, which is not predicted from the cardiac ejection fraction. Patients with an ejection fraction under 20% may still be able to swim.

SYSTOLIC DYSFUNCTION

In patients with chronic cardiac failure, $\dot{V}_{O_2max}$ attained during incremental treadmill exercise is primarily a function of maximal cardiac output.[8,9] This conclusion has been confirmed by numerous studies.[10–14] An impairment in aerobic capacity is gauged according to the exercise AT and $\dot{V}_{O_2max}$ and assigned a functional class as reviewed in Table 34-3. These parameters are, in turn, used to predict maximal exercise cardiac index (or cardiac reserve). Examples of $\dot{V}_{O_2max}$ and the AT attained by two patients with chronic cardiac

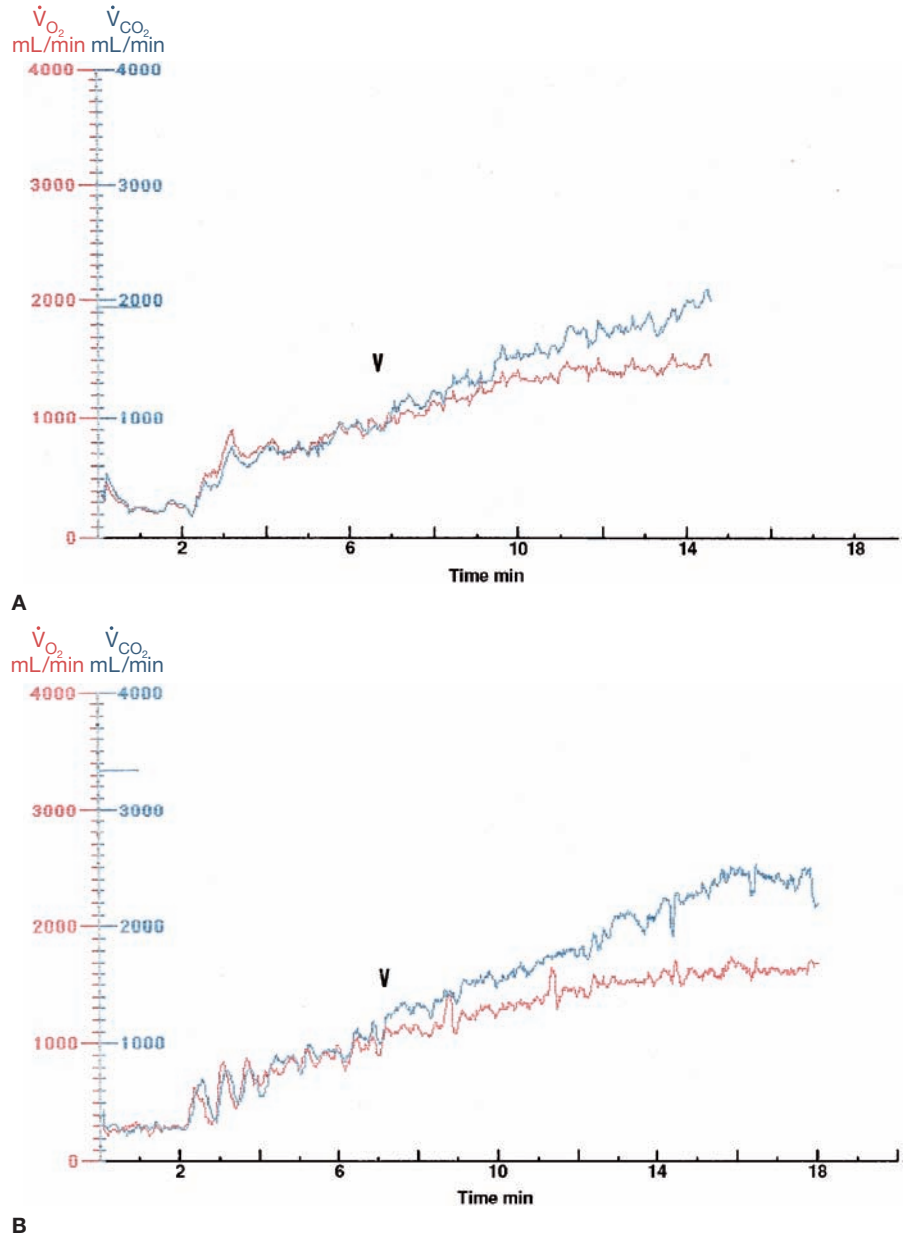

Figure 34-2 Cardiopulmonary exercise test results for a 45-year-old woman (**A**) and a 40-year-old man *(right panel)*, each with ischemic heart disease and chronic cardiac failure. Only $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ are shown, to better demonstrate the anaerobic threshold (AT) and $\dot{V}_{O_2max}$ attained by each patient. On the left, the AT was seen with a $\dot{V}_{O_2}$ of 11.6 mL/min/kg and a $\dot{V}_{O_2max}$ of 16.5 mL/min/kg. This represents a functional class B response. The AT and $\dot{V}_{O_2max}$ are 8.5 and 13.7 mL/min/kg, respectively (**B**). This corresponds to functional class C.

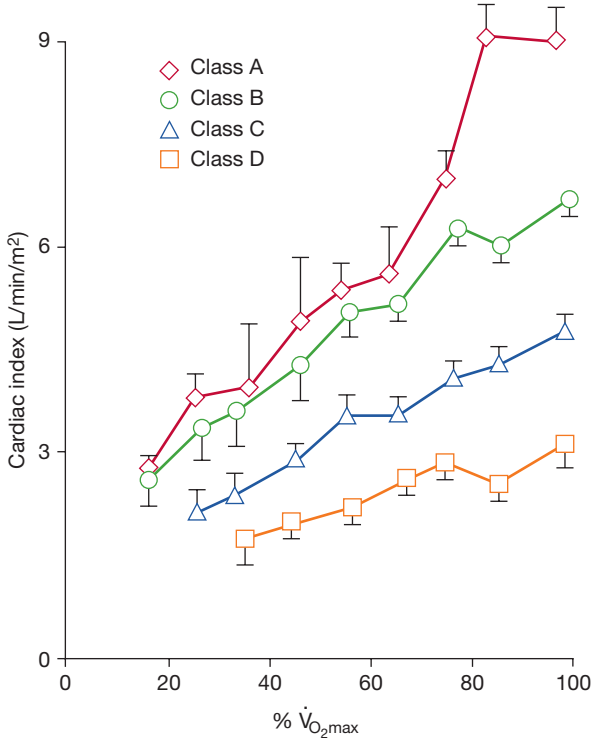

Figure 34-3 Relationship between treadmill exercise cardiac index and normalized aerobic capacity for patients with chronic cardiac failure of diverse origin and severity, subdivided according to each functional class. *(Reproduced with permission from Weber KT, Janicki JS. Cardiopulmonary exercise testing for evaluation of chronic cardiac failure. Am J Cardiol. 1985;55(2):22A–31A.)*

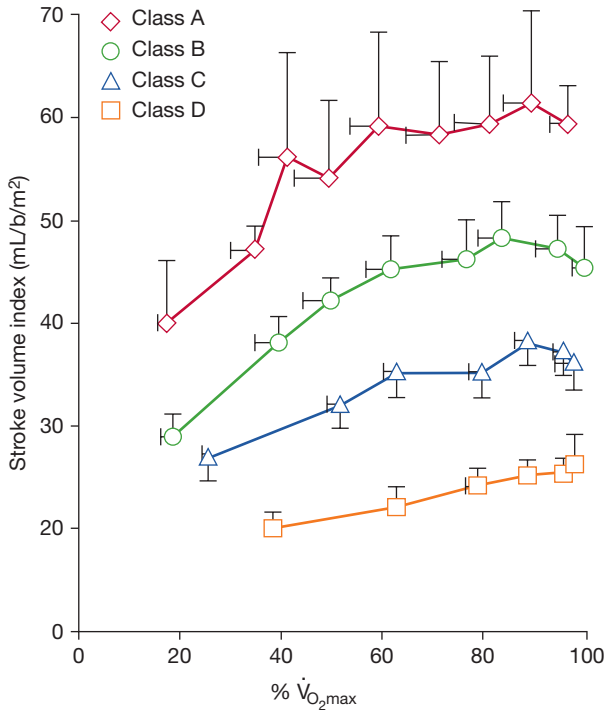

Figure 34-4 Relationship between treadmill exercise stroke volume index and normalized aerobic capacity for patients with chronic cardiac failure of varying severity, as expressed by each functional class. *(Reproduced with permission from Weber KT, Janicki JS. Cardiopulmonary exercise testing for evaluation of chronic cardiac failure. Am J Cardiol. 1986;55(2):22A–31A.)*

failure (one class B, the other class C) are given in Figure 34-2. To measure $\dot{V}_{O_2max}$ in such patients, they must be exercised to exhaustion. The AT is achieved at submaximal workloads short of exhaustion; it, too, stratifies the degree of cardiac dysfunction.

Validation of these concepts was obtained during treadmill exercise using invasive measures of cardiac output and mixed venous lactate concentration.[15,16] Patients had chronic cardiac failure of varying severity (classes A to D), due to either ischemic or myopathic heart disease. In each exercise class, the arteriovenous O_2 difference rose to 12 mL/dL or more at maximum exercise, corresponding to a systemic O_2 extraction in excess of 70%, suggesting that O_2 extraction reached maximal physiological levels. The reduction in aerobic capacity of a patient with chronic cardiac failure is, therefore, due primarily to impaired cardiac reserve. The cardiac output–O_2 relation to progressive treadmill exercise for these patients is given in Figure 34-3. For each exercise class, cardiac output is presented as a percentage of $\dot{V}_{O_2max}$ (set equal to 100%) that existed at rest and throughout each stage of exercise. Cardiac output rose by 600 mL/min/m^2 for each dL/min/m^2 increase in $\dot{V}_{O_2}$ in each class. This indicates that the heart responds to tissue O_2 requirements irrespective of the severity of heart failure, but it is limited by the maximal cardiac output it can attain. Differences in cardiac output achieved at peak exercise are seen between classes. Progressive reductions in cardiac reserve are responsible for different aerobic capacities observed in these patients. $\dot{V}_{O_2max}$, therefore, serves as a noninvasive measure of peak exercise cardiac output and is given for each functional class in Table 34-3.

The cardiac output response to exercise is a function of the rises in stroke volume and heart rate. Responses in stroke volume for patients with chronic cardiac failure are shown in Figure 34-4 for each exercise class. In class A and B patients, stroke volume rises 50% during lighter workloads that represent less than 60% of $\dot{V}_{O_2max}$; at larger workloads, further increments in stroke volume are less apparent. A 25% rise in stroke volume occurs at submaximal exercise in class C patients, whereas in class D patients, exercise stroke volume is no different from its resting value. Exercise stroke volume is a result of several factors, including systolic wall stress, mitral or tricuspid regurgitation that may appear during exercise, and depressed myocardial contractility.

For each functional class of chronic cardiac failure, the heart rate–$\dot{V}_{O_2}$ response to upright incremental exercise is represented by a common slope.[17] The average slope is 3.6 beats/min for every 1-mL/min/kg increment in $\dot{V}_{O_2}$. Peak heart rate achieved is a function of maximal workload performed. Maximal exercise heart rate is, therefore, different for each class. In class D patients, the elevation in heart rate is the sole mechanism by which cardiac output rises during exercise.

Some patients with chronic cardiac failure deviate from this heart rate– $\dot{V}_{O_2}$ relation by having an inappropriate sinus tachycardia, either at rest and throughout exercise or simply during exercise. In the presence of a reduced ejection fraction and ventricular dilation, this inappropriately rapid heart rate further compromises exercise cardiac output and reduces aerobic capacity. β-Adrenergic receptor blockade is useful in attenuating resting or exercise heart rate under these circumstances.[18] Such chronotropic dysfunction (see below) to exercise may also apply to patients with chronic atrial fibrillation. An example of an inappropriate rapid heart rate relative to incremental treadmill exercise (Naughton protocol) is given in Figure 34-5 for a patient with atrial fibrillation and dilated cardiomyopathy of uncertain origin.

As in normal persons, lactate production appears in patients with chronic cardiac failure when systemic O_2 extraction exceeds 60%. Mixed venous lactate concentration during exercise rises above resting values when 60% or more of $\dot{V}_{O_2max}$ is attained.[7,16] Given

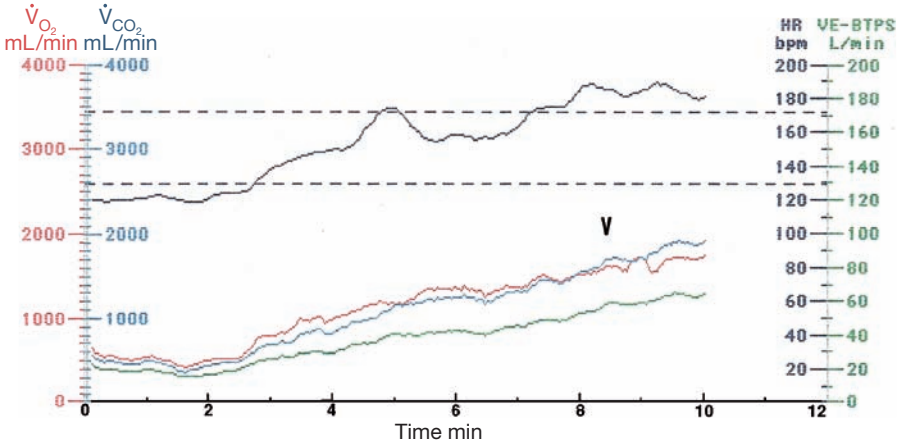

Figure 34-5 Cardiopulmonary exercise test results in a 48-year-old man with atrial fibrillation and dilated (idiopathic) cardiomyopathy. Note the rapid heart rate at rest and throughout incremental treadmill exercise. Predicted maximum heart rate range in this patient is shown by the broken lines. He achieved this rate during the first stage of exercise and exceeded it during the last stage of exercise. This is an inappropriate heart rate response. The AT is 13 mL/min/kg *(arrow)*, in keeping with functional class B. He did not achieve $\dot{V}_{O_2max}$ and, therefore, had a peak $\dot{V}_{O_2}$ of 15 mL/min/kg.

differences in aerobic capacity between exercise classes, different workloads are associated with this lactate threshold (Fig. 34-6). In class D patients whose cardiac output response is limited, the lactate threshold occurs at very light workloads ($\dot{V}_{O_2}$ of 5–8 mL/min/kg). Corresponding values for class C, B, and A patients are 8 to 11 mL/min/kg, 11 to 14 mL/min/kg, and more than 14 mL/min/kg, respectively. Thus, lactate threshold and $\dot{V}_{O_2max}$ reflect the severity of chronic cardiac failure as given in Table 34-3. A noninvasively determined AT based on measurements of respiratory gas exchange, as discussed previously, corresponds to the invasively measured lactate threshold.[7,12,16,19]

Exercise left ventricular filling pressure, as gauged from an occlusive wedge pressure recording, rises to a different degree in each exercise class with chronic cardiac failure (Fig. 34-7). In class A patients, the rise in wedge pressure during isotonic exercise rarely exceeds 18 mm Hg. This resembles a normal response. In class B patients, more dramatic elevations in exercise wedge pressure – to 25 mm Hg or higher – are frequently noted. Resting filling pressure is increased in class C and D patients; a further rise may be seen during upright exercise, often to levels in excess of 30 mm Hg. Despite these marked levels of pulmonary venous pressure, patients do not develop evidence of pulmonary congestion after exercise. Moreover, elevations in wedge pressure neither would predict exercise cardiac reserve and aerobic capacity nor are responsible for exertional dyspnea in these patients. Dyspnea corresponds with the lactate threshold and a disproportionate rise in $\dot{V}_E$ relative to $\dot{V}_{O_2}$.[8,16,20,21] Patients can be encouraged to exercise to exhaustion, attaining $\dot{V}_{O_2max}$ in the presence of dyspnea. In patients with acute cardiac failure, pulmonary congestion and dyspnea correlate with the elevation in wedge pressure; pulmonary edema occurs when hydrostatic pressure exceeds the colloidal osmotic pressure of 25 mm Hg and these patients should not be exercised.

$\dot{V}_E$ rises appropriately during incremental exercise in patients with chronic cardiac failure. The response in $\dot{V}_E$ most closely corresponds to $\dot{V}_{CO_2}$ throughout exercise (aerobic and anaerobic work) and is sufficient to sustain alveolar ventilation, thereby preventing hypoxemia and hypercapnia. Maximum $\dot{V}_E$ attained with exercise is less than 50% of MVV. Thus, these patients do not exhaust their ventilatory reserve in responding to exercise, even when their pulmonary compliance may be adversely elevated as a result of chronic pulmonary congestion and elevations in pulmonary venous pressure that appear with exercise. To minimize the work of breathing during exercise, class C and D patients use a pattern of rapid, shallow breathing to increase $\dot{V}_E$. Thus, the rise in tidal volume during exercise above its resting value is modest and compatible with a substantial portion of each breath being wasted in ventilation of anatomic dead space.[8] The response of class A and B patients more closely approximates that of healthy persons, in whom respiratory rate rises progressively during incremental exercise and the rise in tidal volume occurs early during the transition from rest to low-level exercise.

■ DIASTOLIC DYSFUNCTION

In 30% or more of patients with symptomatic heart failure, primary diastolic dysfunction is held responsible. The ejection fraction is normal or only minimally impaired in these patients. Diastolic dysfunction relates to an inability of the left ventricle to accommodate left atrial and pulmonary venous blood flow during diastole without a marked increase in filling pressure. Abnormal diastolic relaxation and filling typically appear in patients with chronic ischemic heart disease (with previous myocardial infarction), in those with hypertensive heart disease, and especially in elderly women. Responsible mechanisms are thought to include abnormal tissue structure, as occurs with

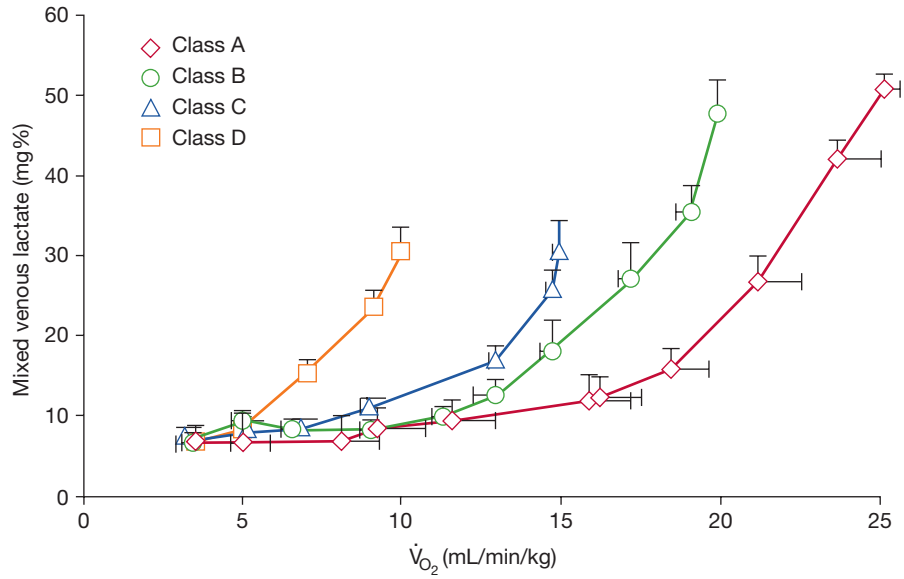

Figure 34-6 Relationship between mixed venous lactate concentration and $\dot{V}_{O_2}$ to incremental treadmill exercise for patients with chronic cardiac failure of varying severity, as expressed by each functional class. *(Reproduced with permission from Weber KT, Janicki JS. Cardiopulmonary exercise testing for evaluation of chronic cardiac failure. Am J Cardiol. 1987;55(2):22A–31A.)*

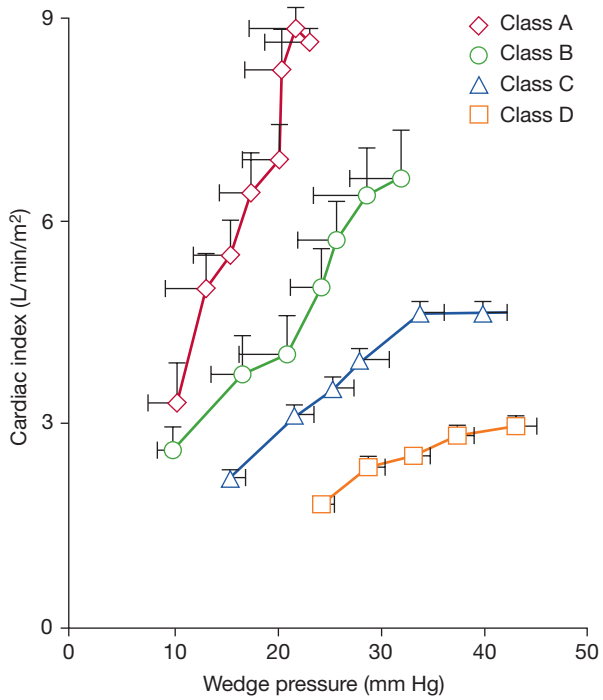

Figure 34-7 Relationship between treadmill exercise cardiac index and occlusion wedge pressure in patients with chronic cardiac failure, subdivided according to functional class. *(Reproduced with permission from Weber KT, Janicki JS. Cardiopulmonary exercise testing for evaluation of chronic cardiac failure. Am J Cardiol. 1988;55(2):22A–31A.)*

fibrous tissue accumulation or amyloid infiltration and abnormal calcium handling by sarcoplasmic reticulum. Factors extrinsic to the myocardium may also be contributory. Examples include the interaction between the pressure- or volume-overloaded right ventricle with the left ventricle and leftward shift of the interventricular septum and the interplay between the heart and pericardium.

Invasive CPX testing, together with incremental bicycle exercise, has been used to address the hemodynamic response of patients with primary diastolic dysfunction.[22] Most patients studied had systemic hypertension, and many were elderly; all had a clinical history of pulmonary congestion. Peak exercise $\dot{V}_{O_2}$ was reduced, owing to a reduction in exercise cardiac output and stroke volume responses; arteriovenous O_2 difference rose above 10 mL/dL. The level of $\dot{V}_{O_2}$ achieved with exercise correlated with peak cardiac output response. In comparison to age-matched controls, expected exercise-associated increments in left ventricular end-diastolic volume were not seen and were accompanied by increased left ventricular filling pressure. Thus, abnormalities in diastolic filling abrogated the Frank–Starling mechanism, thereby restricting the rise in exercise cardiac output; this finding may serve to explain symptoms of fatigue and breathlessness that these patients experience on exertion.

Primary diastolic dysfunction has been observed in patients following cardiac transplantation[23] in whom there is an abnormal blunting of stroke volume and heart rate responses to exercise. Despite the slower exercise heart rate in the transplanted, denervated heart, in which diastolic filling periods would accordingly be longer, diastolic dysfunction is present, limiting the exercise cardiac output response. Abnormal diastolic function has also been observed in the elderly and contributes to impaired exercise cardiac output response.[24]

■ CHRONOTROPIC DYSFUNCTION

Cardiac reserve in exercise depends not only on systolic and diastolic functions but also on heart rate and rhythm, including a coordinated contraction of the atria and ventricles. CPX testing has been used to address the contribution of abnormal heart rate and rhythm on the AT and $\dot{V}_{O_{2max}}$, broadly categorized here as chronotropic dysfunction. This includes abnormal sinus tachycardia, bradyarrhythmias, atrioventricular dissociation, and atrial fibrillation. CPX testing has proved useful in the evaluation of pacemaker function and technique.[25] Improvements in the AT at submaximal levels of work have been demonstrated for single-chamber, activity-triggered pacing compared with fixed-rate atrial or ventricular pacing. It too can help determine the optimum upper rate limit in heart failure patients with pacemakers. This can be determined by the highest pacing rate which still produces an increase in oxygen consumption.[26] With recent advancements in pacemaker technology, cardiac resynchronization therapy (CRT) is being increasingly offered to patients with heart failure. In a study involving CRT patients undergoing CPX testing, significant increments in peak $\dot{V}_{O_2}$, $\dot{V}_{O_2}$ at AT and all ventilation and metabolic parameters were noted. Patients with baseline $\dot{V}_{O_2}$ of less than 14 mL/min/kg had the most benefit.[27] Similarly, patients with severe heart failure and atrial fibrillation had better hemodynamic performance with chronic biventricular pacing than left ventricular pacing alone.[28]

Some patients with chronic cardiac failure deviate from this heart rate– $\dot{V}_{O_2}$ relation by having inappropriate sinus tachycardia, either at rest and throughout exercise, or simply during exercise. In the presence of reduced ejection fraction and ventricular dilation, this inappropriately rapid heart rate further compromises exercise cardiac output and reduces aerobic capacity. Under these circumstances, β-adrenergic receptor blockade is useful in attenuating the resting or exercise heart rate. Such chronotropic dysfunction (see below) to exercise may also apply to patients with chronic atrial fibrillation. An example of an inappropriate rapid heart rate during incremental treadmill exercise (Naughton protocol) is given in Figure 34-5 for a patient with atrial fibrillation and dilated cardiomyopathy of uncertain origin.[29]

■ SURVIVAL AND PROGNOSIS

Various gas exchange parameters have been used to assess prognosis in patients with heart failure, including AT, peak $\dot{V}_{O_2}$, and $\dot{V}_E/\dot{V}_{CO_2}$ slope (a marker of ventilatory efficiency).[13,30–33] $\dot{V}_{O_2}$ at AT and $\dot{V}_{CO_2}$ slope are less subject to patient motivation or premature cessation of exercise and hence are more useful parameters. Class D patients with little or no exercise cardiac reserve (see Table 34-3) with AT <8 mL/min/kg have a marked reduction in 1- and 2-year survival as contrasted to Class A and B patients with respective exercise cardiac index responses of >8 and 6 to 8 L/min/m^2.[13,30,31] $\dot{V}_{O_2}$ at AT combined with $\dot{V}_E/\dot{V}_{CO_2}$ is a better prognostic indicator than peak $\dot{V}_{O_2}$ alone.[34] A low peak Pa_{CO_2} with exercise is responsible for the prognostic power of $\dot{V}_E/\dot{V}_{CO_2}$ slope and by itself is also an independent predictor of prognosis.[35] Resting end-tidal CO_2 has been shown to be a predictor of cardiac-related events.[36] Another $\dot{V}_{O_2}$ kinetics parameter that is a strong predictor of survival and less dependent on motivation is the mean response time ($\dot{V}_{O_2}$ deficit/Δ $\dot{V}_{O_2}$).[37] In the recovery period, slow normalization of $\dot{V}_{O_2}$ is associated with poor prognosis.[38]

The fluctuations in breathing patterns and its association with prognosis have also been studied in heart failure. Cyclic fluctuations in $\dot{V}_E$ at rest that persist during effort (external oscillatory ventilation) are associated with poor prognosis, whereas oscillations at rest alone are not.[39–41]

■ EFFICACY OF MEDICATIONS

The response to various heart failure medications on gas exchange and hemodynamics has been studied. Patients with heart failure taking spironolactone had a significant increase in peak oxygen consumption, D_{LCO}, and membrane diffusing capacity.[42,43] In a study in which losartan was added to an ACE inhibitor, there was

a significant increase in peak $\dot{V}_{O_2}$ and exercise capacity;[44] however, in another study in which candesartan was added, there was no increase in the peak $\dot{V}_{O_2}$ or exercise capacity.[45] Peak $\dot{V}_{O_2}$ has been used as a prognostic marker in heart failure, but in a study involving patients with chronic heart failure taking carvedilol, peak $\dot{V}_{O_2}$ was not found to be a useful prognostic marker.[46]

EXERCISE TRAINING

Exercise training leads to an improvement in exercise tolerance and peak $\dot{V}_{O_2}$ in patients with heart failure who have left ventricular dysfunction.[47] Exercise training in moderate stable heart failure results in favorable qualitative, rather than quantitative, changes in skeletal muscle.[48] Correction of maximum oxygen uptake for skeletal muscle mass, rather than total body mass, is a more sensitive measure of changes associated with exercise training.[48] Only progressive/increasing workload seems to markedly improve oxygen uptake.[49]

ISCHEMIC HEART DISEASE

Ischemia can be diagnosed with the help of ST segment changes during incremental exercise on treadmill or an ergometer during CPX testing. The sensitivity and specificity of ST changes for ischemia is not high. Parameters of gas exchange on CPX testing can be used to improve the diagnostic ability of the exercise-induced ST changes. Using O_2 pulse flattening duration and $\Delta \dot{V}_{O_2}/\Delta$ work rate slope with ST changes, the sensitivity and specificity for diagnosing ischemia improved from 46% to 66%, respectively, to 87% and 74%, respectively.[50] Myocardial stress/rest scintigraphy was used as the standard for detecting ischemia in this study. In another study, exercise cardiac output estimated from $\dot{V}_{O_2}$ at AT correlated with multivessel coronary artery disease, adverse cardiac events and clinically driven revascularization.[51] In postmyocardial infarction patients undergoing 3 weeks of exercise training, a significant improvement in $\dot{V}_{O_2}$ was found.[52]

Parameters of gas exchange measured during CPX testing have proven useful in the diagnosis of ischemia. Myocardial ischemia produces transient depression of left ventricular systolic function and, consequently, a reduction in stroke volume and cardiac output. Graphically, this decline in cardiac output should be reflected in a decline in the rate of increase in oxygen consumption per workload ($\Delta \dot{V}_{O_2}/\Delta$ Work Rate [WR] in watts). Thus, a blunted slope of $\Delta \dot{V}_{O_2}/\Delta$ WR should reflect myocardial ischemia. This analysis of gas exchange has been compared to SPECT myocardial scintigraphy. CPX testing demonstrates improved sensitivity and specificity in the detection of myocardial ischemia. Another valid parameter for the detection of myocardial ischemia is a flattening of the graph of O_2 pulse (mL/beat).[50] As is the case with heart failure, peak $\dot{V}_{O_2}$ and AT are prognosticators of adverse prognosis in patients with ischemic heart disease.

CPX testing has been utilized to assess the presence of right ventricular dysfunction in patients following an inferior myocardial infarction. Right ventricular dysfunction was analyzed utilizing echocardiographic parameters. Patients with right ventricular infarction had significantly lower oxygen consumption than those who had suffered an inferior infarction without right ventricular involvement.[53]

CHRONIC CIRCULATORY FAILURE

Circulatory failure, in physiological terms, refers to an inability of the heart to raise its cardiac output in a manner commensurate with prevailing $\dot{V}_{O_2}$. Responsible factors are extrinsic to the myocardium and include such entities as valvular heart disease, intrinsic pulmonary vascular disease, pericardial disease, and anemia.

VALVULAR HEART DISEASE

Mitral or aortic valve disease may alter the functional integrity of the cardiopulmonary unit by impairing the heart's ability to increase cardiac output in accordance with $\dot{V}_{O_2}$. Pathophysiological alterations within the unit that result from chronic valvular disease and that determine the clinical course and outcome following valve replacement include right heart overload and structural remodeling of the pulmonary vasculature and lung interstitium. The more marked the preoperative impairment in cardiac reserve, the poorer the long-term prognosis. Similarly, the greater the elevation in pulmonary vascular resistance, the more delayed is its return to normal levels and the slower the postoperative abatement of symptoms. The decision for surgical intervention requires an assessment of cardiopulmonary status—one that can be assessed noninvasively and monitored over time to detect a decline in cardiac reserve. Noninvasive CPX testing serves this purpose. Because of the heightened risk of syncope and the myocardial ischemia and arrhythmias that can occur during exercise in patients with aortic valvular stenosis, these patients should exercise with extreme caution, if at all.

Incompetence of the mitral and aortic valves is an example of a disorder that can result in chronic circulatory failure. Each creates a volume overload on the left ventricle. The onset of ventricular dysfunction is generally unpredictable and may initially appear only during vigorous levels of physical activity. As dysfunction progresses, symptoms appear at lower levels of activity and, finally, at rest.

Resting cardiac output is often not distinguishable among class A, B, C, or D patients with mitral or aortic regurgitation. Cardiac reserve is reduced, however, and, accordingly, so is aerobic capacity.[2] No impairment in systemic O_2 extraction has been reported. Thus, as in chronic cardiac failure, any observed decrease in aerobic capacity must be due to a decline in maximal forward cardiac output. To the extent that cardiac output can rise, the exercise cardiac output– $\dot{V}_{O_2}$ relation is preserved among these classes, averaging 600 mL/min/m^2 for every dL/min/m^2 rise in $\dot{V}_{O_2}$. Responses in cardiac output and wedge pressure for each exercise class are given in Figure 34-8. As in chronic cardiac failure, marked elevations in wedge pressure are seen in class C and D patients; this is also true for class B patients with mitral or aortic regurgitation. However, these

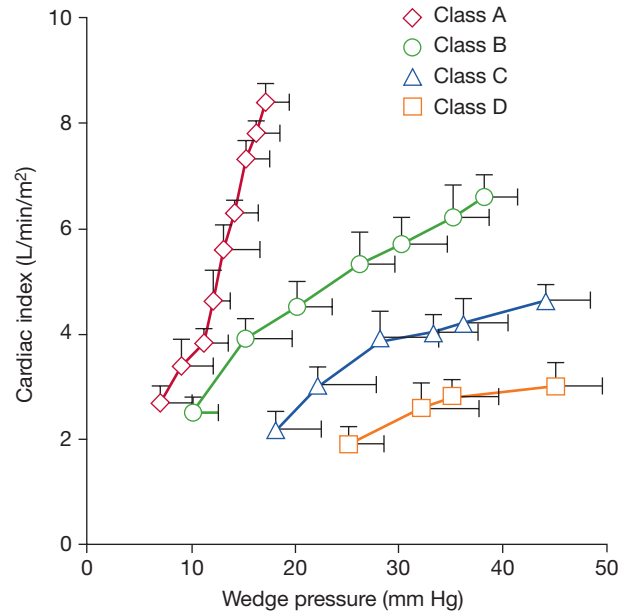

Figure 34-8 Relationship between treadmill exercise cardiac index and wedge pressure in patients with chronic mitral or aortic regurgitation, divided according to functional class. *(Reproduced with permission from Weber KT, Janicki JS (eds). Cardiopulmonary Exercise Testing: Physiologic Principles and Clinical Applications. Philadelphia: WB Saunders; 1986.)*

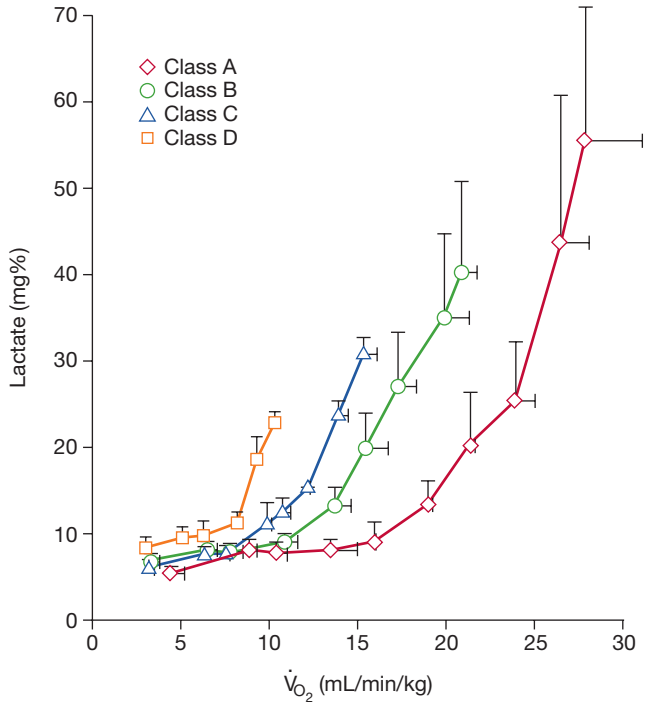

Figure 34-9 Relationship between mixed venous lactate concentration and $\dot{V}_{O_2}$ observed during incremental treadmill exercise in patients with chronic mitral or aortic regurgitation. As in chronic cardiac failure, the lactate threshold (lactate >12 mg/dL) occurs at different levels of $\dot{V}_{O_2}$, depending on functional class. *(Reproduced with permission from Weber KT, Janicki JS (eds). Cardiopulmonary Exercise Testing: Physiologic Principles and Clinical Applications. Philadelphia: WB Saunders; 1986.)*

patients do not develop clinical evidence of pulmonary congestion following exercise, and dyspnea correlates with the lactate threshold. Exercise wedge pressure does not presage aerobic capacity or functional class in these patients.

AT can be used as an alternative measure in patients with valvular incompetence who are unable to attain $\dot{V}_{O_{2max}}$. The lactate threshold occurs at 60% to 70% of the patient's aerobic capacity and corresponds to a level of systemic O_2 extraction of 60% or more. Figure 34-9 depicts the response in mixed venous lactate concentration as a function of O_2 for each exercise class with mitral or aortic regurgitation. As in patients with chronic cardiac failure, the lactate threshold occurs at progressively lower levels of work as the severity of valvular disease increases.[2] The invasively measured lactate threshold correlates well with the valve obtained using noninvasive respiratory gas exchange measurements (see above).

The reduced mitral valve orifice that accompanies rheumatic mitral valvular stenosis leads to left atrial chamber enlargement, pulmonary venous hypertension, and right heart pressure overload. Pulmonary vascular resistance in most patients ranges between 200 and 600 dynes·s·cm^{-5}. Mitral stenosis is responsible for reduced left ventricular filling at rest and during exercise. An exercise-associated rise in heart rate reduces the diastolic filling period to further curtail left ventricular filling.

Cardiac output fails to rise appropriately with exercise in patients with chronic circulatory failure due to mitral stenosis.[2] For most symptomatic patients, cardiac output fails to rise appropriately during symptom-limited exercise because of a limited stroke volume response. Systemic O_2 extraction increases markedly with exercise, as do pulmonary capillary wedge and mean pulmonary artery pressures. Preoperative assessment of mitral stenosis should include not only calculation of mitral valve area but also exercise test-determined cardiac reserve and functional status. A decision regarding surgery should be based on these objective measures and clinical judgment, not simply on a laboratory-based calculation of reduced valve area.

A preoperative assessment of valvular surgery patients by CPX testing can help predict the degree of postoperative recovery. Preoperative peak $\dot{V}_{O_2}$ of 19 mL/min/kg and greater in patients undergoing surgery for mitral and aortic regurgitation correlates with higher percentage of patients attaining NYHA Functional Class I at 1 year after surgery.[54,55] $\dot{V}_{O_{2max}}$ along with AT has been used to follow progress of postoperative rehabilitation and training in valve surgery patients.[56,57] Exercise parameters can be helpful in assessing patients with valvular disease patients in whom there is a discrepancy between symptoms and echocardiographic data. A $\dot{V}_{O_{2max}}$ less than 75% predicted in moderate-to-severe mitral stenosis correlates with higher transvalvular gradients and higher pulmonary artery pressures at the end of exercise than does a $\dot{V}_{O_{2max}}$ greater than 75% of max predicted.[58]

In the absence of pulmonary arterial hypertension in patients undergoing mitral valve replacement, the presence of significant tricuspid regurgitation is associated with lower $\dot{V}_{O_{2max}}$ and AT and steeper $\dot{V}_E/\dot{V}_{CO_2}$ than when significant tricuspid regurgitation is absent.[59]

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy, the best known genetically determined cardiovascular condition, is marked by significant left ventricular hypertrophy, which may be asymmetric, concentric, or localized (apical). Two major clinical concerns in the disorder are the risk of sudden death and the difficulty in making the diagnosis when the classic asymmetric septal hypertrophy and the classic hemodynamic findings are absent. Exercise testing, in general, is a simple, but imprecise, method to screen for malignant dysrhythmias. CPX testing has been useful in distinguishing the physiologic left ventricular hypertrophy of athletes from hypertrophic cardiomyopathy.[60] Peak $\dot{V}_{O_2}$ is significantly higher in the athletes. A peak $\dot{V}_{O_2}$ 20% above predicted $\dot{V}_{O_{2max}}$ separates this group from those with genetically proven hypertrophic cardiomyopathy. A number of patients with hypertrophic cardiomyopathy experience symptoms of fatigue and dyspnea which do not correlate with hemodynamic findings. CPX testing can separate real from perceived symptoms. The percent predicted peak $\dot{V}_{O_2}$, combined with a quality of life questionnaire, appears to be helpful in making this distinction.[61]

OBSTRUCTIVE SLEEP APNEA

CPX testing can safely be performed in patients with sleep apnea to evaluate abnormalities in gas exchange and the response to continuous positive airway pressure therapy. Patients with moderate or severe obstructive sleep apnea have impaired exercise capacity, low peak $\dot{V}_{O_2}$, and low AT.[62] The abnormal parameters on CPX testing can be improved with continuous positive airway pressure therapy. In one study involving severe sleep apnea, 2 months of nasal continuous positive airway pressure treatment resulted in higher right ventricular ejection fraction, peak $\dot{V}_{O_2}$, peak $\dot{V}_{O_2}$, AT, and oxygen pulse.[63]

Patients with heart failure who have central sleep apnea have an increased mortality rate compared to those without it. Patients with heart failure often lack the classical symptoms of central sleep apnea and, hence, its presence may be underestimated. Treating central sleep apnea in heart failure has beneficial effects on cardiac function. Patients with heart failure with central sleep apnea have a highly augmented ventilatory response to exercise. This is manifested by a significantly increased slope of $\dot{V}_E/\dot{V}_{CO_2}$, which correlates with the severity of sleep apnea. Thus, patients with heart failure who have an increased $\dot{V}_E/\dot{V}_{CO_2}$ slope should be considered for a full sleep study to confirm the presence of sleep apnea.[64]

CONGENITAL HEART DISEASE

Patients with cyanotic congenital heart disease have limitations in exercise tolerance. CPX testing can be used to objectively assess their exercise limitation and ventilatory efficiency.

In a study of 25 adults with uncorrected cyanotic congenital heart disease, peak oxygen uptake and Pa_{O_2} were significantly reduced compared with normal subjects, while Pa_{CO_2} was only slightly reduced. Ventilatory efficiency, expressed as $\dot{V}_E/\dot{V}_{CO_2}$, was found to be markedly impaired at rest and during exercise. $\dot{V}_E/\dot{V}_{CO_2}$ correlated more strongly with patients' symptoms than hypoxemia and peak oxygen uptake.[65] For the corresponding NYHA class, patients with adult congenital heart disease and patients with heart failure had no significant differences in peak $\dot{V}_{O_2}$.[66]

CPX testing has also been used for assessing the response to transcatheter closure of atrial septal defect in adult patients. Improved peak oxygen uptake, peak oxygen pulse, and vital capacity have been reported following closure.[67] In one study, improvements in the prolonged $\dot{V}_{O_2}$ slope and $\dot{V}_{CO_2}$ slope were noted, reflecting improvement in recovery from maximal exercise.[68]

Tricuspid valve surgery in patients with Ebstein's anomaly produces reduced right ventricular volumes, increased pulmonary blood flow, and increased left ventricular filling and cardiac output. This is reflected by an increased $\dot{V}_{O_{2max}}$.[69]

PULMONARY HYPERTENSION

Pulmonary hypertension is expressed as an abnormal elevation in resting or exercise pulmonary artery pressure (see Chapter 72). Chronic left heart failure with attendant elevated left atrial pressure remains the most common cause of pulmonary *venous* hypertension. Pulmonary *arterial* hypertension (PAH) accompanies intrinsic pulmonary vascular disease or arteriolar vasoconstriction associated with hypoxemia due to intrinsic lung disease. PAH creates right ventricular pressure overload and an impediment to left ventricular filling. Accordingly, exercise cardiac output is compromised and aerobic capacity declines. PAH represents an example of chronic circulatory failure.

Patients with PAH have been studied with elective right heart catheterization using a triple-lumen flotation catheter and subsequent exercise testing.[2] Resting and peak treadmill exercise hemodynamic responses are given in Table 34-4. At rest, right heart and pulmonary arterial pressures exceeded the normal range. Right ventricular systolic pressure at rest was in excess of 50 mm Hg, and in one-quarter of patients it approximated or exceeded left ventricular (and systemic arterial) systolic pressure. Resting wedge pressure was normal in these patients. Calculated pulmonary vascular resistance exceeded the upper range of normal (170 dynes·s·cm^{-5}) in all patients; in more than one-third, it was above 1000 dynes·s·cm^{-5}, approximating systemic vascular resistance.

Peak cardiac output attained with maximal exercise for each functional class (Table 34-3) is similar to that observed for chronic cardiac failure and valvular heart disease. The impairment in exercise cardiac output is related to the extent to which pulmonary vascular resistance is elevated. Patients with a markedly elevated resting pulmonary vascular resistance (above 1000 dynes·s·cm^{-5}) proved to be functional class D. In this group of patients with intrinsic pulmonary vascular disease, arterial O_2 desaturation during exercise was not observed, emphasizing the importance of compromised cardiac reserve—a function of the inability of the right ventricle to generate sufficient pulmonary blood flow to sustain left ventricular filling and, thereby, systemic blood flow. Patients with PAH stopped exercising because of breathlessness or fatigue or both; none experienced retrosternal chest pain, light-headedness, or syncope; none developed arrhythmias. In most, it was possible to determine the $\dot{V}_{O_{2max}}$; in all, the AT could be attained (see above). CPX test results for a 42-year-old woman with PAH are shown in Figure 34-10.

Patients with PAH have significant ventilation–perfusion mismatch; during exercise ventilation is increased. This abnormality in ventilatory inefficiency is reflected by the reduction in end-tidal CO_2 (pET_{CO_2}). The reduction in end-tidal CO_2 is proportional to the decrease in percent predicted $\dot{V}_{O_2}$ and increase in the mean pulmonary artery pressure. In normal subjects, the pET_{CO_2} increases from rest to AT, whereas in patients with PAH, the pET_{CO_2} decreases from rest to AT.[70] On CPX testing the slope of regression between CO_2 production and minute ventilation can also be used to assess the ventilation–perfusion mismatch. The $\dot{V}_E/\dot{V}_{CO_2}$ slope is greater in patients with PAH compared with cardiac dysfunction and the same peak $\dot{V}_{O_2}$. Conversely, for the same $\dot{V}_E/\dot{V}_{CO_2}$ slope, patients with LV dysfunction have a lower peak $\dot{V}_{O_2}$.[71]

Measurement of CPX testing-based parameters in PAH is reliable and reproducible, even in patients with limited exercise tolerance. The parameters correlate well with the decrease in D_{LCO} and NYHA class.[72,73] Even in children with pulmonary hypertension, peak $\dot{V}_{O_2}$ strongly correlates with pulmonary vascular index.[74] CPX testing can be used for the objective assessment of safety and efficacy of treatment strategies in patients with PAH.[75–77] Peak $\dot{V}_{O_2}$ is an independent, strong predictor of survival in these patients.[78]

TABLE 34-4 Resting and Peak Exercise Hemodynamics for Patients with Nonhypoxic Pulmonary Vascular Disease and Pulmonary Hypertension

		Resting	Exercise
PA	(mm Hg)	29 ± 9	47 ± 20
RVSP	(mm Hg)	52 ± 30	86 ± 37
RVDP	(mm Hg)	7 ± 4	16 ± 10
PCW	(mm Hg)	10 ± 3	22 ± 14
PVR	(dynes · s · cm^{-5})	412 ± 319	302 ± 331
CO	(L/m^2/min)	2.8 ± 1.6	5.3 ± 2.2
AP	(mm Hg)	106 ± 6	130 ± 8
Art O_2 sat	(%)	97 ± 2	96 ± 2

PA, mean pulmonary artery pressure; RVSP and RVDP, right ventricular systolic and diastolic pressures, respectively; PCW, wedge pressure; PVR, pulmonary vascular resistance; CO, cardiac output; AP, mean arterial pressure.

CHRONIC LUNG DISEASES

In a normal subject performing maximal exercise, minute ventilation rarely exceeds 50% of MVV; in addition, tidal volume uncommonly exceeds 50% of vital capacity. Given this large ventilatory reserve, exercise is normally not limited by ventilation. This is not the case in patients with lung disease, in whom ventilatory reserve is reduced. A number of factors may limit exercise in patients with lung disease, including altered lung mechanics, impaired gas exchange and resultant hypoxemia, pulmonary hypertension, or respiratory muscle fatigue.

OBSTRUCTIVE LUNG DISEASE

Exercise intolerance commonly accompanies chronic obstructive pulmonary disease (COPD), with dyspnea limiting physical activity to modest levels of work. Patients with COPD have a higher $\dot{V}_E$ for any given workload; this is largely due to increased dead space ventilation. Given their reduction in MVV and greater exercise $\dot{V}_E$, these patients often exercise with a $\dot{V}_E$/MVV ratio that exceeds 75%.

Use of such a large portion of the ventilatory reserve cannot be sustained, accounting for breathlessness and termination of exercise. In patients with moderate or severe COPD, this generally occurs before they reach their AT, implying a ventilatory, rather than cardiac, limitation to exercise. The workload at which patients terminate exercise represents a peak $\dot{V}_{O_2}$; it is not their $\dot{V}_{O_2max}$, as can be attained in patients with chronic cardiac or circulatory failure in whom ventilatory responses pose no limitation to exercise.

In severe emphysema, D_{LCO} is reduced, in keeping with alveolar capillary destruction. In such patients, a significant fall in arterial O_2 saturation often appears during exercise. This is in contrast to patients with chronic bronchitis, in whom O_2 saturation may actually increase. The improvement in oxygenation in these patients is a result of improved ventilation in areas with low ventilation–perfusion ratios. D_{LCO} portends exercise-induced arterial O_2 desaturation. Patients with a D_{LCO} less than 55% of predicted are most likely to experience hypoxemia with exercise. Arterial hypoxemia limits effort tolerance, for several reasons: (1) reduced O_2 delivery to exercising muscle, including those associated with respiration; (2) increased chemical drive to respiration, with a corresponding inappropriate $\dot{V}_E$ for a given level of work; and (3) secondary pulmonary vasoconstriction.

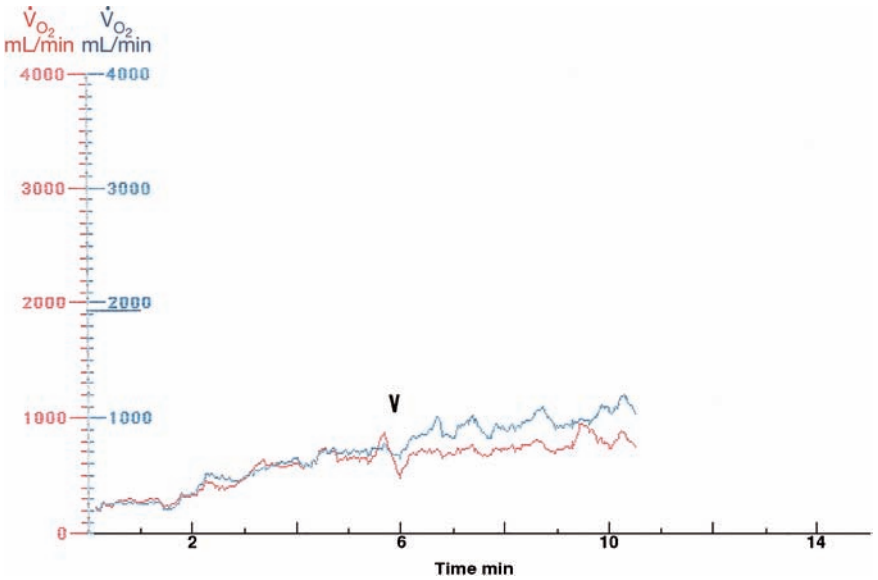

Figure 34-10 Cardiopulmonary exercise test results for a 42-year-old woman with pulmonary arterial hypertension of uncertain origin. The first 2 minutes represent standing rest. The patient attained the AT (7 mL/min/kg) during stage 2 of exercise (1.5 mph, 0 grade) and a $\dot{V}_{O_2max}$ of 10 mL/min/kg, corresponding to functional class D.

By measuring $\dot{V}_{O_2}$ peak in patients with COPD undergoing CPX testing, an objective assessment of exercise capacity can be made. Peak $\dot{V}_{O_2}$ in severe COPD correlates with resting FEV_1% predicted, total treadmill time, and total metabolic equivalent values.[79] CPX testing can better define respiratory limitations than pulmonary function testing alone in patients with COPD filing for disability due to shortness of breath.[80]

The increase in breathing capacity with exercise in COPD, measured by the ratio of $\dot{V}_E$/MVV, correlates with peak $\dot{V}_{O_2}$ and can be predicted by FEV_1/FVC measured during resting pulmonary function testing.[81] In chronic COPD, peak $\dot{V}_{O_2}$ can be estimated by equations that take into account the distance walked by the patient and the lung function tests. However, the correlation between measured and estimated peak $\dot{V}_{O_2}$ is not strong enough to predict exercise capacity. If peak $\dot{V}_{O_2}$ has to be used for clinical decision making, it should be measured, rather than estimated.[82] In COPD, skeletal muscle abnormalities have been described and contribute to reduced exercise capacity. Peak $\dot{V}_{O_2}$ in COPD correlates well with fat-free mass, a bioimpedance index of muscle mass.[83] In patients with COPD, physiologic parameters measured by CPX testing have prognostic implications as well. Based on multivariate analysis the Pa_{O_2} slope ($\Delta Pa_{O_2}/\Delta \dot{V}_{O_2}$) is most closely associated with survival.[84] Similarly, Pa_{O_2max}, along with FEV_1, has been found to independently predict mortality.[85] Overall, a linear relationship exists between peak $\dot{V}_{O_2}$ and pulmonary function testing parameters in COPD.[86]

■ RESTRICTIVE LUNG DISEASE

Patients with known interstitial lung disease, a diverse group of disease entities, experience limiting dyspnea on exertion. This may be secondary to reduced ventilatory reserve or development of arterial O_2 desaturation. The evaluation of exercise performance may also be useful in patients who complain of dyspnea out of proportion to their pulmonary function studies. Dyspnea on exertion may appear in a patient with an abnormal chest radiograph before pulmonary function studies are abnormal. Exercise testing may be indicated in these patients to detect abnormal ventilatory reserve and its response over time. Patients with interstitial lung disease tend to breathe at a higher respiratory rate and lower tidal volume than do normal subjects for any given $\dot{V}_{O_2}$. Because they have a reduced MVV, their ability to exercise is limited by nearly full utilization of their reduced ventilatory reserve.

As in patients with airway disease, the D_{LCO} is a good predictor of arterial O_2 desaturation during exercise in patients with interstitial lung disease. Most patients with a D_{LCO} below 60% develop desaturation. If a patient has a normal D_{LCO}, he or she is unlikely to develop exercise-induced arterial O_2 desaturation. Measurement of D_{LCO} can be used to screen patients for exercise studies. Finally, the degree of arterial O_2 desaturation during exercise correlates with the reduction in D_{LCO}.

CPX testing is a sensitive test for gas exchange abnormalities. In one study involving biopsy-proven sarcoidosis, CPX testing predicted pulmonary dysfunction earlier than did physical examination, chest radiography, and spirometry.[87,88] In another study involving survivors of severe acute respiratory distress syndrome, aerobic capacity using CPX testing was found to be below normal in 41% of patients in whom mild pulmonary function abnormalities were not enough to explain low exercise tolerance.[89] CPX testing has been used for procuring prognostic information in patients with interstitial lung disease. Peak $\dot{V}_{O_2}$ in patients with parenchymal lung disease awaiting transplant, along with Pa_{O_2} slope, has been used to predict survival.[90,91] In other parenchymal lung diseases, such as cystic fibrosis, breathing reserve index at AT has been used to distinguish ventilatory-limited patients from those without ventilatory limitations.[92]

EVALUATION OF EXERTIONAL DYSPNEA

Normally, a person is unaware of the act of breathing and the fact that 500 to 750 mL of air enters and leaves the lungs 10 to 15 times each minute. $\dot{V}_{O_2}$ increases secondary to normal or abnormal chemical stimuli (e.g., hypercapnia, hypoxemia, acidemia) or anxiety. When breathing is perceived to be inappropriate relative to the level of physical activity, it is considered an abnormal awareness of breathing that is termed breathlessness, shortness of breath, or dyspnea.[2] Dyspnea on exertion is common in patients

with heart disease, pulmonary parenchymal or airway disease, and pulmonary vascular disease. Deformities of the chest wall and diseases associated with weakness of the respiratory muscles are also accompanied by exertional breathlessness. Dyspnea may seriously hinder a patient's ability to carry out muscular work, thereby compromising quality of life. The evaluation of dyspnea includes requisite historical information that characterizes its nature, onset, severity, relationship to exercise, and the patient's underlying physical condition and customary daily activity. Other associated symptoms – such as palpitations, anginal chest pain, and lightheadedness – must be taken into consideration.

An objective and reliable estimate of dyspnea on exertion and its severity can be gauged from exercise testing. Dyspnea occurs when $\dot{V}_E$ is excessive relative to $\dot{V}_{O_2}$ and when $\dot{V}_E$ is driven by chemical stimuli or altered lung mechanics. Dyspnea with exercise can appear when $\dot{V}_E$ occupies an excessive proportion of MVV. An estimation of MVV can be derived by multiplying the patient's FEV_1 by 35. As a corollary, maximal encroachment on the vital capacity by exercise tidal volume cannot be sustained for long. Such ventilatory effort poses a substantial workload on respiratory muscles. An MVV maneuver during pulmonary function testing cannot be sustained for more than a few seconds, while more than 70% of the MVV cannot be sustained by normal subjects for more than several minutes. Hence, the ventilatory response to exercise that is associated with dyspnea in patients with heart or lung disease follows a similar pattern of short-lived, near-maximal ventilation.

The patient with pulmonary vascular disease or advanced interstitial lung disease may be unable to sustain alveolar ventilation during exercise at a level commensurate with that required for adequate arterial O_2 saturation. Consequently, hypoxemia may compound the patient's exercise response and be responsible for a heightened chemical drive to respiration. In the case of COPD, the need to move air through a partly obstructed tracheobronchial tree creates an added workload on respiratory muscles. Air flows in these patients are already compromised at rest and must increase with exercise; they may approach peak expiratory flows observed with maximal effort during pulmonary function testing.

Patients with mild, moderate, or severe cardiac or circulatory failure rarely use more than 50% of their ventilatory reserve at maximal exercise, and they do not experience arterial O_2 desaturation during exercise. If one estimates MVV from the FEV_1 (as noted earlier), for an FEV_1 of 1, 2, or 3 L, MVV is expected to equal 35, 70, or 105 L, respectively. In patients with chronic cardiac or circulatory failure, exercise maximum $\dot{V}_E$ has been found to range between 62 and 29 L/min for class A through D patients, respectively. Hence, unless there is a major reduction in MVV (or in FEV_1 to <3 L), these patients will not have a ventilatory limitation to exercise. Finally, patients are able to cross their AT and, if encouraged, may reach their point of exhaustion attaining $\dot{V}_{O_2max}$. By monitoring the breath-by-breath response in $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ during exercise, the physician can immediately determine when the patient has achieved the AT and $\dot{V}_{O_2max}$. These end-points are not attained in the patients with lung disease or those with coexistent heart and lung disease in whom the respiratory system is the primary limitation to exercise. Table 34-5 summarizes the salient features used to differentiate primary ventilatory from cardiac or circulatory failure as the cause of exertional dyspnea, as detected by exercise testing.

OTHER APPLICATIONS OF CARDIOPULMONARY EXERCISE TESTING

CPX testing, with its ability to foretell cardiac and ventilatory reserves, has proved useful in clinical decision making in a variety of circumstances, including assessment of a patient's candidacy for cardiac transplantation and preoperative assessment of risk.

TABLE 34-5 Ventilatory versus Cardiac/Circulatory Failure as the Predominant Cause of Exertional Dyspnea

Ventilatory Failure
1. Exercise maximum $\dot{V}_E$ utilizes >70% of MVV
2. Exercise-associated arterial hypoxemia
3. Failure to cross AT and to achieve $\dot{V}_{O_2max}$
Cardiac/Circulatory Failure
1. Cross AT and can achieve $\dot{V}_{O_2max}$
2. Maximum exercise $\dot{V}_E$ does not exceed 50% of MVV
3. Does not develop arterial hypoxemia with exercise

MVV, maximal voluntary ventilation; AT, anaerobic threshold.

CARDIAC TRANSPLANTATION

The severity of chronic cardiac and circulatory failure is gauged according to $\dot{V}_{O_2max}$ and the AT (Table 34-3) and is used to predict exercise cardiac reserve. This approach has been applied to patients with systolic dysfunction secondary to chronic ischemic heart disease or dilated (idiopathic) cardiomyopathy, who are considered potential candidates for cardiac transplantation. The ejection fraction or resting hemodynamic parameters (e.g., resting cardiac index or wedge pressure) do not help predict the severity of cardiac failure or functional capacity and are no longer a mainstay in decision making. The same is true for subjective evaluation of functional status using the New York Heart Association criteria. Incremental exercise testing, with identification of AT and peak $\dot{V}_{O_2}$ achieved thereafter, has emerged as a valuable tool to objectively address cardiac reserve and functional capacity and which predicts survival.[30,31,93–95] In fact, consensus has been reached on recommending transplantation based on clinical criteria, in combination with functional stratification based on exercise test results.[96] Class D patients, having little or no cardiac reserve, have a marked reduction in 1- and 2-year survival and, therefore, are candidates for urgent transplantation. Class C patients with a modest increment in exercise cardiac output are probable candidates. On the other hand, class A patients in whom cardiac reserve remains intact, or class B patients in whom cardiac reserve is only minimally impaired, do not have an adequate indication for transplantation. Decision is deferred, and serial exercise studies are used to assess recovery or deterioration in the setting of optimal medical therapy.

Incremental exercise testing may also provide useful information after cardiac transplantation, including recovery of cardiac and ventilatory reserves. The importance of diastolic dysfunction in limiting exercise tolerance following cardiac transplantation was reviewed earlier. A blunted heart rate response to exercise is expected in these patients owing to cardiac denervation. Such chronotropic incompetence is demonstrated in Figure 34-11, along with exercise test results.

Recipients of lung or heart/lung transplant do not experience the degree of return in cardiac reserve and gas exchange as do patients with heart transplant alone. These patients experience considerable exercise limitation and reduced maximum oxygen uptake despite normalization of resting cardiopulmonary function. Such limitation may be a function of peripheral factors, such as abnormalities in the peripheral circulation and peripheral neuromuscular function.[97] CPX testing may be utilized to predict survival in lung transplant recipients. Lower exercise capacity as defined by lower percent predicted peak $\dot{V}_{O_2}$ appears to have prognostic value.[98]

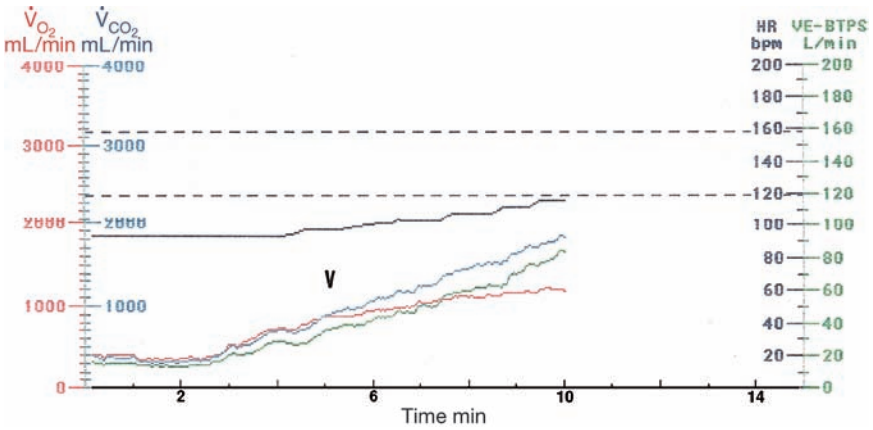

Figure 34-11 Cardiopulmonary exercise test results for a 62-year-old male cardiac transplant recipient. During this incremental treadmill test he attained an AT and $\dot{V}_{O_{2max}}$ of 8 and 11 mL/min/kg, respectively. Note the blunted heart rate response (predicted peak heart rate range shown as *broken lines*).

SURGICAL RISK ASSESSMENT

Preoperative incremental exercise testing has proved useful in assessing postoperative morbidity and mortality in the elderly and patients with underlying heart or lung disease who are scheduled for major intrathoracic or intra-abdominal surgery. The premise underlying this approach is based on recognition that during and after surgery, there may be a need to call on cardiac and ventilatory reserves—namely, the ability to increase cardiac output and maintain O_2 delivery, and to increase $\dot{V}_E$ and prevent hypoxemia. Several studies have demonstrated the utility of measuring the AT and peak $\dot{V}_{O_2}$, using exercise testing, in addressing these reserves and in identifying patients prone to postoperative complications.[99–101] Pulmonary function testing proved insensitive in forecasting postoperative course. Class C and D patients, with little or no cardiac reserve, had a greater number of morbid and mortal events following surgical interventions than did class A or B patients. Class A patients had few, if any, postoperative complications and no mortality. The risk of complications could, therefore, be gauged best by a patient's preoperative aerobic capacity.[99–102] The direct assessment of the AT or $\dot{V}_{O_{2max}}$ and prediction of cardiac reserve, and, by inference, ventilatory reserve supersede the value of an age-determined impairment in aerobic capacity.

AT is a particularly important parameter in assessing preoperative risk. It gives an objective assessment independent of patient motivation and does not require excessive amounts of exercise. In a large study of elderly patients undergoing major intro-abdominal surgery, an AT of less than 11 mL/min/kg along with preoperative ischemia was associated with high mortality.[100] Patients evaluated by CPX testing with unfavorable AT can be electively admitted to intensive care units and their hemodynamics optimized before major surgery.[100,103] Risk stratifying based on AT is even better at predicting patients who are not at risk for adverse events.[100,103]

Patients undergoing other major surgeries, such as radical esophagectomy with three-field lymphadenectomy, have also been risk stratified by CPX testing. Extensive fluid shifts are expected in the postoperative period with surgical interventions on the lymphatic system. CPX testing can provide a thorough assessment of the cardiopulmonary reserve in such patients. In a study involving such patients, a peak $\dot{V}_{O_2}$ of 800 mL/min/m^2 was associated with low risk of complications.[104] In another study involving patients with abdominal aortic aneurysm repair. a higher percentage of patients with adverse complications had a peak $\dot{V}_{O_2}$ less than 20 mL/min/kg.[105] Peak $\dot{V}_{O_2}$ has also been used to risk stratify liver transplant patients. Patients dying within 100 days of transplantation are more likely to have peak $\dot{V}_{O_2}$ <60% of predicted and AT <50% of predicted peak $\dot{V}_{O_2}$ compared with survivors.[106]

Patients with lung cancer have a high likelihood of concomitant COPD and coronary artery disease due to the common risk factor of smoking. Surgery might offer the only chance of cure in these patients and often implies resection of a variable portion of the lung tissue surrounding the cancer to ensure eradication. Removal of functional lung tissue in an already compromised cardiopulmonary system resection can be risky. It is imperative that a preoperative assessment of cardiopulmonary reserve be made before such a surgery (see Chapter 103). By performing preoperative CPX testing in patients being considered for lung cancer resection surgery, an objective assessment of the cardiopulmonary reserve can be made. Peak $\dot{V}_{O_2}$ has been used to risk stratify these patients, along with FEV_1 and D_{LCO}.[107] Correcting peak $\dot{V}_{O_2}$ for weight and expressing it as a percentage of predicted improves the predictive power of peak $\dot{V}_{O_2}$. Elderly patients, female patients, and patients with short stature may have a peak $\dot{V}_{O_2}$ below the absolute cutoff value, but they may still be eligible for surgery when peak $\dot{V}_{O_2}$ is expressed as percentage predicted.[108]

The predictive value of peak $\dot{V}_{O_2}$ is greater in patients with a FEV_1 <70%.[109] Peak $\dot{V}_{O_2}$ <50% of predicted is associated with a high complication rate. Patients with peak $\dot{V}_{O_2}$ >50% predicted can undergo surgery without excess mortality.[108] A peak $\dot{V}_{O_2}$ <10 mL/min/kg is generally considered prohibitive for surgery.[110] Risk stratification based upon peak $\dot{V}_{O_2}$ is particularly useful in assessing patients for lung resection who have borderline pulmonary function (predicted postoperative FEV_1 or D_{LCO} <40%). In these patients, a peak $\dot{V}_{O_2}$ <15 mL/min/kg is associated with an increased risk, and peak $\dot{V}_{O_2}$ <10 mL/min/kg carries a very high risk of postoperative complications.[111]

SUMMARY

CPX testing provides for an extensive evaluation of patients having diseases and disorders of the cardiorespiratory unit. The diagnostic information provided extends far beyond that obtained by testing of heart and lung function measured at rest, or by standard exercise testing with electrocardiographic monitoring. Position papers on CPX testing should be consulted for further diagnostic and prognostic stratification.[112,113]

CHAPTER 35

Diagnostic Bronchoscopy, Transthoracic Needle Biopsy, and Related Procedures

Anil Vachani
Daniel H. Sterman

INTRODUCTION

Gustav Killian reported his experience with the first bronchoscopy in 1898. Technological advances during the next century facilitated development of bronchoscopy as a pivotal diagnostic and therapeutic tool in pulmonary medicine. Although a number of bronchoesophagologists contributed to refinement of the technique based upon use of a rigid instrument, the advent of flexible fiberoptic bronchoscopy, pioneered by Ikeda in 1967, opened new horizons to clinicians. More recently, transthoracic needle biopsy (TTNB) has been added to the pulmonologist's diagnostic armamentarium, although it is now most frequently performed by radiologists under CT guidance.

This chapter comprises an overview of bronchoscopy, TTNB, and related techniques. Following a general discussion of bronchoscopy and associated general instrumentation, indications for the technique and patient preparation are considered. Specific applications of diagnostic bronchoscopy are discussed. Subsequently, safety factors related to bronchoscopy and complications of the technique are reviewed. Finally, TTNB is described.

GENERAL INSTRUMENTATION

The initial bronchoscope, developed by Killian in Europe and further perfected by Chevalier Jackson in the United States, was a rigid metal tube that permitted either spontaneous or mechanical ventilation. With development of fiberoptic and advanced electronic technology, the flexible bronchoscope has, to a large extent, replaced the rigid bronchoscope for most diagnostic and some therapeutic indications. Therapeutic interventional bronchoscopy, including the use of rigid bronchoscopes, is discussed in Chapter 36.

FLEXIBLE FIBEROPTIC AND VIDEOBRONCHOSCOPY

Although the optical resolution of early fiberoptic bronchoscopes was inferior to that of rigid devices, their flexibility, ease of manipulation, and simplicity of use, which permit rapid examination under topical anesthesia, have made flexible bronchoscopy the primary endoscopic procedure in pulmonary diseases.

Unlike the larger-bore rigid bronchoscope, the flexible bronchoscope varies from ultrathin – allowing for neonatal endoscopy – to larger, adult size therapeutic devices. The diameter of the working channel permits aspiration of secretions or introduction of accessories required for diagnostic purposes (see Bronchoscopy Technique). With flexible bronchoscopy, the patient's ventilation is assured by airflow around the bronchoscope, between the external wall of the device and the tracheobronchial tree. Thus, the appropriate selection of bronchoscope size is crucial.

Fiberoptic systems have largely been replaced by videobronchoscopes, which utilize a miniaturized CCD camera at the tip of the scope that provides electronic transmission of images to a television monitor. Flexible bronchoscopes are more fragile and more prone to damage than are rigid metal instruments. Appropriate care and adherence to safety techniques during procedures, as well as during routine cleaning and maintenance of the instruments, help assure extended instrument life and reduce repair costs.

ULTRATHIN BRONCHOSCOPES

Ultrathin bronchoscopes, flexible scopes with external diameters ≤3 mm, were initially developed for pediatric applications; however, these have now incorporated larger working channels, allowing for their use in the diagnosis of peripheral pulmonary lesions in adults.[1,2] Ultrathin bronchoscopes can be advanced to more peripheral bronchi than conventional bronchoscopes under direct observation, allowing for examination of sixth- to eighth-generation bronchi. Ultrathin scopes may be particularly useful when combined with additional diagnostic tools, such as navigational bronchoscopy and radial ultrasound probes (see Ultraminiature Radial Probes and Navigational Bronchoscopy).

DIAGNOSTIC BRONCHOSCOPY ACCESSORIES

The working channel of the fiberoptic or videobronchoscope, although of relatively small diameter, allows the insertion of various diagnostic and therapeutic accessories.

■ BIOPSY FORCEPS

Simple visualization of lesions is usually not sufficient to determine a precise diagnosis and to guide management. Pathological confirmation through biopsy is frequently required. A variety of instruments with improved distal control (i.e., control beyond the tip of the bronchoscope) have been developed that permit tissue cutting and retrieval of biopsy specimens.

The cutting cups of biopsy forceps may be round or elliptic and may have smooth or jagged edges. The use of nonserrated edges, however, seems to reduce tissue trauma and the concomitant risk of bleeding. The biopsy procedure is simple and generally associated with only minimal complications in the case of a visible lesion. Even peripheral lesions, which are not visible through the bronchoscope, may be biopsied. With diffuse parenchymal or interstitial lung disease, specimens may be obtained without fluoroscopic guidance. With smaller or focal lesions, however, the diagnostic yield of biopsies increases when fluoroscopy is used. The development of new electromagnetic and remote guidance systems suggests that further improvement in the diagnostic yield of bronchoscopic biopsies can be expected.

■ BRONCHIAL BRUSHES

Lesions not accessible to direct biopsy with a forceps can at times be approached with a bronchial brush. This device consists of a rigid central wire surrounded by brushes of various sizes and shapes. To-and-fro movement of the brush against the adjacent tissue produces minor trauma but enables collection of ample specimens for cytological or microbiological analysis.

In some clinical circumstances, there is a need to obtain an uncontaminated specimen from the lower respiratory tract for microbiological studies. A brush protected by an additional sheath and tip may be passed through the working channel of the bronchoscope (protected brush specimen, as discussed later). In these cases, special attention is needed not to use an excessive amount of local anesthetic or saline lavage, since these solutions contain bacteriostatic material that may inhibit microbial growth. The diagnostic yield depends on use of proper technique, appropriate choice of brush, and careful collection and preservation of the specimen.

■ NEEDLES FOR ASPIRATION AND BIOPSY

The first performance of a transbronchoscopic needle aspiration (TBNA) through a rigid bronchoscope was reported by Schieppati in 1958. Wang et al.[3] then developed a flexible needle technique using a fiberoptic bronchoscope in 1978. Initially, several models of needles were designed to obtain cytological material; subsequently, histological specimens from peribronchial mediastinal and hilar lymph nodes were obtained with larger-bore needles. These biopsy needles are also useful in the diagnosis of endobronchial and submucosal lesions and can serve as a complementary technique to percutaneous needle aspiration of peripheral pulmonary nodules or masses.

The tip of the needle is protected by a metal hub during the insertion and withdrawal to avoid damage to the flexible scope. Perforation of the working channel of the scope may occur if the needle is advanced in an exposed position. The diagnostic yield depends on two factors: Optimization of the bend of the tip of the bronchoscope and proper performance of bronchial wall puncture by the needle through the intercartilaginous space. Familiarity with the type of needle used increases the success rate.

TBNA is generally safe, although pneumothorax and hemomediastinum can occur. Clinically significant bleeding is extremely rare, particularly when a 22-gauge needle is used, even if a major vessel is inadvertently punctured or if the patient suffers from superior vena cava syndrome.

ENDOBRONCHIAL ULTRASOUND

Among the new diagnostic modalities available to chest physicians, endobronchial ultrasound (EBUS) has unquestionably had the most profound impact.[4] Two major barriers to EBUS development existed: Ultrasound probe size and sound wave transmission in air-filled structures. Ultrasound engineering advances allowed the former barrier to be overcome. The latter was surmounted by developing an integrated, fluid-filled balloon surrounding the EBUS probe, thereby allowing for a sound wave–transducing medium interface to exist between the ultrasound probe and airway wall (i.e., ultrasonographic coupling).

Ultrasound frequency is an important consideration for EBUS application. Lower frequencies give better penetration depth with less resolution; higher frequencies provide better spatial resolution, but less penetration depth. For EBUS applications, the frequencies range from 7.5 to 30 MHz. Currently, there are three EBUS probes available for different applications: (1) Ultraminiature radial probes (20 and 30 MHz), (2) radial balloon probes (20 MHz), and (3) convex probe or curvilinear EBUS (CP-EBUS). Each of these is discussed in greater detail later.

■ ULTRAMINIATURE RADIAL PROBES

Ultraminiature EBUS (UM-EBUS) was developed to allow for improved assessment and sampling of peripheral pulmonary lesions (Fig. 35-1A). There are two ultraminiature radial probes currently available, with diameters of 1.4 and 2.0 mm, allowing insertion into bronchoscopes with working channels of 2.0 and 2.6 mm, respectively. When a lesion is reached with the probe, the usual normal lung "snowstorm" appearance is replaced by a focal ultrasound alteration that can be marked by fluoroscopy, a guide sheath (GS), or both fluoroscopy and GS (Fig. 35-1B and Video 35-1). After the lesion is localized, the GS can be left in place, allowing for guided biopsies of the lung using forceps, brush, or needle biopsy.

■ RADIAL BALLOON PROBE

To overcome the ultrasonographic coupling problem with UM-EBUS probes in the central airways, a radial EBUS probe was developed; the probe is inserted into an outer sheath with a distal tip balloon. The balloon is filled with saline to provide a fluid medium to allow for sound wave transmission from the probe to the airway wall. The radial balloon EBUS (RB-EBUS; Olympus Corporation, Tokyo, Japan) probe provides <1-mm resolution with a 360-degree visualization of paratracheal and peribronchial structures (Fig. 35-1). Five to seven layers of the tracheal and proximal bronchial wall have been described using RB-EBUS.[5]

■ CONVEX PROBE EBUS

The convex probe EBUS (CP-EBUS) bronchoscope, introduced in 2005, has a built-in curvilinear ultrasound transducer with a

Video 35-1 The ultraminiature (UM)-EBUS probe is used via the working channel of a fiberoptic bronchoscope to identify a focal lung lesion. When the lesion is reached with the probe, there is an alteration in the ultrasound image, with replacement of the usual normal lung "snowstorm" appearance by the presence of a denser focal lesion that surrounds the centrally located probe. *Access at www.fishmansonline.com*

B

Figure 35-1 **A.** The ultraminiature (UM)-EBUS probe contains a circulating ultrasound crystal that provides a 360-degree view of the surrounding structures when full airway ultrasonographic coupling occurs. The probe is inserted through a guide sheath (*arrow*; Olympus Corporation, Tokyo, Japan), which can remain in the airway on UM-EBUS probe removal to allow for instrument guidance for biopsy. **B.** This UM-EBUS image demonstrates a focal lung lesion *(asterisk)* surrounding the probe.

larger distal diameter (6.9 mm) compared with a standard bronchoscope. White light videobronchoscopy occurs at a 35-degree oblique angle with EBUS at 90 degrees from the longitudinal axis. Dedicated biopsy needles (21 or 22 gauge) are inserted through the 2-mm working channel to perform aspirations of the target lesion (Fig. 35-2A). Real-time EBUS imaging displays needle penetration through the tracheobronchial wall into the target during the biopsy maneuver (Fig. 35-2B). If there is difficulty in achieving adequate EBUS images because of poor ultrasonographic coupling, a saline-filled balloon surrounding the transducer can be used to improve image quality. In addition, Doppler capabilities allow vascular structure differentiation, which minimizes the risk of unintended vascular puncture.

NAVIGATIONAL BRONCHOSCOPY

A recent advance in the evaluation of peripheral pulmonary lesions and mediastinal and hilar adenopathy has been the development of navigational approaches, such as electromagnetic navigational bronchoscopy (EMB) and virtual bronchoscopy (VB) (Fig. 35-3).[6–9]

EMB utilizes an electromagnetic board to generate a magnetic field around the patient, a magnetic sensor probe, an extended working channel, and three-dimensional integration of CT scan reconstruction and bronchoscopy position. In essence, this system works on the same triangulation principle as a global positioning system and allows the bronchoscopist to direct the FB through the airways to the target.

VB-based approaches utilize virtual navigation by creating a CT scan–based "road map" that can be overlaid onto real-time endoscopic images. Navigational systems can be used in conjunction with ultrathin bronchoscopies combined with radial EBUS probes and GSs to confirm that a lesion has been reached and to maintain the position for acquisition of diagnostic material. The role of navigational bronchoscopy in the evaluation of peripheral pulmonary nodules is discussed later.

In addition to diagnostic indications, navigational bronchoscopy is increasingly used for targeted cancer therapeutic delivery, including guided stereotactic radiosurgery, fiducial placement, or implantation of radiotherapy monitoring devices.[10,11]

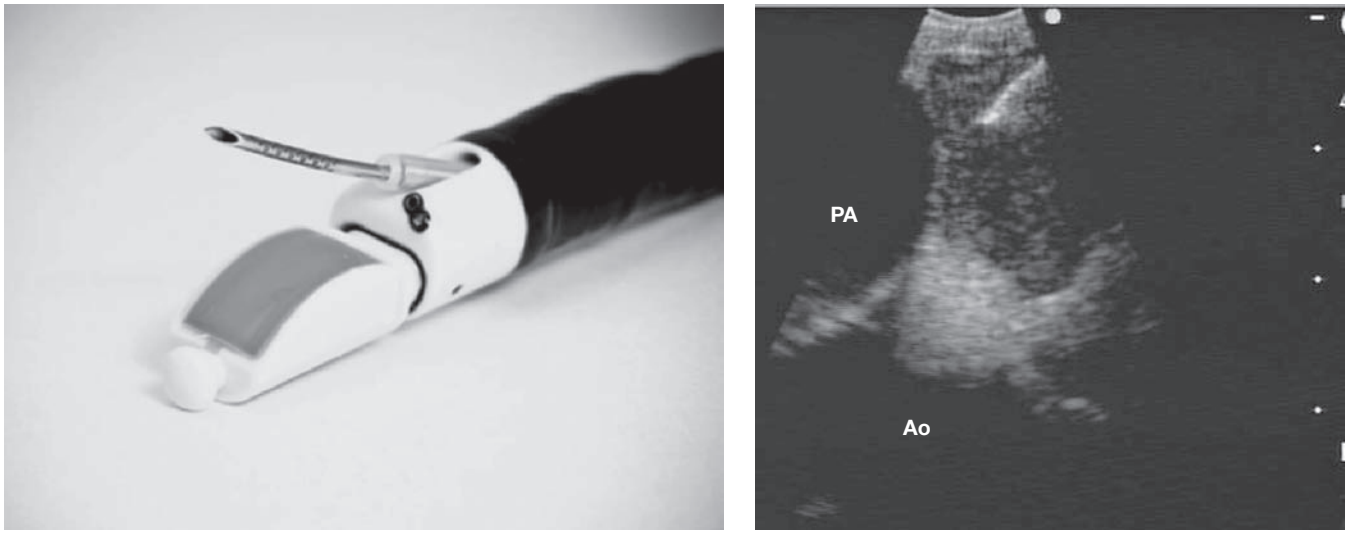
Navigational bronchoscopy systems may be limited in general application by their high capital cost and training necessary for optimal system utilization. At the current time, the greatest experience and yield with these technologies has occurred in centers of excellence, with results unlikely to be reproducible in less experienced centers.

PATIENT PREPARATION AND MONITORING DURING BRONCHOSCOPY

Success of bronchoscopy, whether diagnostic or therapeutic, depends, in large part, on proper preparation of the patient, including relief of anxiety, muscle relaxation, cough suppression, and adequate anesthesia. Time spent in achieving these goals will be well worth it in reducing the risks of complications and in increasing the ease of performance of the procedure. As with any other procedure, analysis of the risk–benefit ratio helps reduce the complication rate. During and shortly after the procedure, appropriate monitoring of hemodynamic parameters (heart rate, rhythm, and blood pressure), oxygenation, and ventilation contributes to the safety of bronchoscopy.

Most flexible bronchoscopies are performed after patient premedication with sedative agents and the use of bronchoscopically instilled lidocaine for local anesthesia of the upper airway, larynx, and tracheobronchial tree. Most frequently, moderate sedation is achieved using a combination of a short-acting benzodiazepine (e.g., midazolam) and a narcotic agent (e.g., fentanyl). Intravenous propofol may also be used to provide moderate sedation and appears to provide similar results in terms of patient satisfaction and degree of hypoxia, with the advantage of a faster recovery time.[12] Because the use of propofol can lead to deep sedation, it is important that these patients receive careful monitoring. Deep sedation (i.e., a deeper state of depressed consciousness with potential for compromised airway function and spontaneous respiration) and general anesthesia are increasingly being employed given the shift of diagnostic and therapeutic bronchoscopy toward more complex and lengthier diagnostic procedures.

Anticholinergic medication (e.g., atropine or glycopyrrolate) has been advocated by some to reduce the risk of vasovagal reactions and to minimize airway secretions, thereby allowing for better examinations of the tracheobronchial tree. However, in a large randomized trial comparing these two drugs with placebo, glycopyrrolate, but not atropine, led to a reduction in airway secretions.[13] There was no significant reduction in cough, patient discomfort, oxygen desaturation, or procedure time with either drug. Current recommendations discourage the use of these agents during bronchoscopy.[12]



A B

Figure 35-2 **A.** The convex probe (CP)-EBUS TBNA (BF-UC160 F-OL8; Olympus Corporation, Tokyo, Japan) videobronchoscope has an integrated ultrasound probe that scans 90 degrees perpendicular from the longitudinal axis, a 35-degree forward oblique video view, and a 2.0-mm working channel through which a dedicated biopsy needle can be passed. Distal tip dimples on the needle provide an echogenic surface to reflect ultrasound waves to allow needle visualization. **B.** This CP-EBUS image demonstrates a left paratracheal lymph node with the ascending aorta (Ao), the pulmonary artery (PA), and the needle present in the lymph node.

BRONCHOSCOPY TECHNIQUE

Central components of the routine bronchoscopic technique are discussed later.

■ ASSESSMENT OF AIRWAY ANATOMY AND FUNCTION

Thorough bronchoscopic evaluation begins with examination of the upper airways. Special attention should be paid to the integrity of air passages and the function of the nasopharynx and larynx. The vocal cords should be examined for the presence of polyps and tumors and for evidence of cord paralysis.

Once upper airway inspection is completed, a systematic evaluation of the lower respiratory tract should be performed. Critically important is the distinction among normal anatomy, anatomic variations without clinical significance, and frankly pathological conditions. These considerations have important implications regarding potential diagnostic and therapeutic approaches. For example, finding an abnormal branching of a bronchus may be of no clinical significance. On the other hand, such an abnormality could explain symptoms of frequent infections due to impaired ventilation and drainage of the affected area. Special skills and observational experience are required for bronchoscopic examination after surgery, especially following creative bronchoplastic procedures or lung transplantation.

Assessment of airway integrity, with special attention to dynamic changes in airway caliber during either relaxed breathing or forced expiration and coughing, may be crucial in determining appropriate therapeutic maneuvers. Flexible bronchoscopy is superior to rigid bronchoscopy for this assessment. Relaxation and prolapse of the membranous portion of the trachea and main bronchi secondary to destruction of elastic connective tissue may account for exacerbations of expiratory airflow obstruction. On the other hand, finding localized, posttraumatic chondromalacia has very different therapeutic implications. On the basis of these bronchoscopic determinations, the choice of performing an open surgical approach or bronchoscopic therapeutic correction may be made.

Bronchoscopic examination generally permits evaluation and localization of congenital or postsurgical pathological changes in bronchial integrity, such as tracheoesophageal or bronchopleural fistulas. Bronchoscopic observation and early diagnosis of bronchial rupture after chest trauma also greatly influence further therapy and prognosis. The same is true for evaluation of postsurgical anastomoses following reconstructive surgery or lung transplantation.

Advances in airway management of critically ill patients who require prolonged intubation or tracheotomy have resulted in a lower incidence of tracheal injuries. Tracheal injuries documented by bronchoscopy are not rare, however. Important complications of tracheotomy include tracheal stenosis, tracheomalacia, and tracheoinnominate artery fistula. Complications specific to the use of percutaneous tracheotomy, which is increasingly used in the intensive care unit, include flaps of cartilage protruding into the tracheal lumen and extraluminal placement of the tracheostomy tube. Such complications can have significant bearing on clinical outcome.

■ EVALUATION OF TRACHEOBRONCHIAL MUCOSA

Careful examination of the mucosal surface is crucial in the formulation of differential diagnosis. Rapid development of granulation tissue is frequently associated with reaction to a foreign body. Inflammatory mucosal reactions, although not very characteristic, should raise the possibility of mycobacterial infection, nonspecific viral and nonviral infections, and other granulomatous diseases, such as sarcoidosis.

The distinction between normal, pale-pink mucosa and hypervascular areas in the tracheobronchial tree may provide important diagnostic clues. Most frequently, changes in mucosal coloration are associated with an inflammatory reaction due to bronchitis. These findings are, however, very distinctive from small hemangiomas or vascular distentions due to compression by enlarged, neoplastic lymph nodes. Similarly, a network of small mucosal lymphatics may be visible, with lymphatic interruption due to surgery, radiation therapy, fibrosis, or malignancy. This is most frequently associated with local edema, which contributes to airflow obstruction. In addition, distinct and characteristic mucosal discoloration can be observed in Kaposi sarcoma.[14–16]

Video 35-2 White light and autofluorescence bronchoscopy (AFB) demonstrating a focal airway lesion at the carina between the lingua and superior division of the left upper lobe. The lesion demonstrates abnormal autofluorescence, manifested by a brownish color on AFB. The remainder of the airway examination demonstrates normal green fluorescence. *Access at www.fishmansonline.com*

Ulcerations of the mucosa are more characteristic of Wegener granulomatosis or malignancy. Loss of the usual mucosal luster and presence of a roughened surface may alert the expert bronchoscopist to an early infiltrative or neoplastic process. Previously sustained injuries are characterized by the formation of mucosal and submucosal fibrosis, resulting in airway retraction or distortion.

Autofluorescence bronchoscopy (AFB) permits observation and analysis of tracheobronchial mucosal surfaces using the discriminant characteristic of tissue autofluorescence (Video 35-2). It is well known that when stimulated with light of a specific wavelength, normal tissues emit specific fluorescence. Changes in the structural integrity of the same tissues due to pathological processes modify or suppress the autofluorescence. The fluorescent emissions are too low in intensity to be seen by the human eye. With the use of a monochromatic light source, computer-controlled image analysis, and a sophisticated camera attached to a fiberoptic bronchoscope, the airways can be examined for varying degrees of autofluorescence as an indicator of early-stage malignant changes. The acquisition of images is obtained in real time and helps in the detection of minute areas of change in normal tracheobronchial mucosal fluorescence. Biopsies from areas of abnormal fluorescence increase the rate of detection of small, premalignant (dysplasia) or early malignant (carcinoma in situ) lesions in the tracheobronchial tree. Confirmation is provided by biopsy of the suspect or abnormal areas under direct bronchoscopic control, followed by pathological review.

Although AFB may provide the ability to localize these early lesions with greater sensitivity than white light bronchoscopy (WLB),[17–20] longitudinal studies demonstrate that only 0% to 9% of moderate dysplastic foci and 0% to 32% of severe dysplastic foci progress to CIS or invasive cancer,[21–23] and 60% to 65% of moderate/severe dysplastic lesions regress or resolve spontaneously.[21] The uncertainty of the natural history of central airway dysplastic lesions, combined with the increasing incidence of peripheral adenocarcinomas not accessible to bronchoscopic visualization, makes it unlikely that AFB will find a role as a routine screening tool for lung cancer in large populations.

Narrow band imaging (NBI) uses a unique filter to select light wavelengths that preferentially are absorbed by hemoglobin, thereby permitting superior microvasculature detection. Because angiogenesis occurs preferentially in dysplastic and neoplastic lesions, NBI may identify early dysplastic lesions better than WLB or AFB. Early studies with NBI in high-risk patients demonstrated its ability to detect lesions that could not be visualized by WLB, with a similar sensitivity to AFB.[24,25] A recent study compared WLB, AFB, and NBI in the same patients who presented for airway surveillance and revealed similar sensitivity for AFB and NBI, but improved specificity with NBI for detecting abnormal lesions.[24] Although current clinical applications for AFB and NBI are limited, they may play a role in future risk stratification, prognostication, or chemoprevention trials in high-risk patients.

Video 35-3 This video demonstrates the findings on "alveoloscopy" using a confocal microscopy probe (Cellvizio™, Mauna Kea Technologies, Paris, France). A thin probe is advanced into the distal lung parenchyma through the working channel of a flexible bronchoscope and is able to image autofluorescence of structures of the lung. In particularly, elastin in the alveolar wall is readily detected, and therefore allows for visualization of the architecture of the alveolus, including areas of breakdown in the alveolar wall as may be seen in emphysema. In addition, intra-alveolar macrophages emit significant autofluorescence and are therefore readily visualized with the Cellvizio™ probe. These are the cells seen to be mobile within the elastin-containing alveolar walls on the video. Type I and type II pneumocytes are not readily visualized with this technology. *Access at www.fishmansonline.com*

Another promising technique, optical coherence tomography (OCT), is analogous to ultrasound imaging except that infrared light waves, rather than acoustic waves, are used.[26–31] By using light instead of sound waves, OCT overcomes the major limitations of ultrasound in the lung: The inability to image through air and its poor spatial resolution. At present, OCT can resolve structures as small as 3 μm, rendering this imaging technique superior to conventional CT or magnetic resonance imaging for detecting microscopic airway abnormalities. The ability to acquire such precise views in real time may have important clinical implications in the near future.[32,33] A similar modality, fibered confocal fluorescence microscopy (FCFM) is based on confocal microscopy that allows thin section imaging via use of a flexible fiberoptic miniprobe that can be introduced through a fiberoptic bronchoscope. This technology does not rely on light reflectance as in OCT, but rather cellular and tissue autofluorescence upon laser excitation. This technique may offer the possibility of an "optical biopsy" of peripheral lung lesions in the future (Video 35-3).

EVALUATION OF PERIBRONCHIAL STRUCTURES

The trachea and bronchi are surrounded by mediastinal and parenchymal structures. Developmental or pathological changes in these organs may be noted during bronchoscopic evaluation. An enlarged goiter or thymus can compress upper airways, resulting in airflow obstruction. Lymphadenopathy may produce structural changes, including widening of the carina due to subcarinal involvement and compression of other bronchi—as, for example, in the right middle lobe syndrome. Calcification of peribronchial lymph nodes may result in erosion of the bronchial wall and formation of a broncholith. These lesions are potential sources of obstruction, infection, or dangerous hemoptysis.

Development of the techniques of standard TBNA and EBUS-TBNA provide diagnostic options for the evaluation of peribronchial structures that pose much less risk and a lower complication rate than mediastinoscopy; in addition, they are less costly.

PERFORMANCE OF BRONCHIAL AND PARENCHYMAL BIOPSIES

Improvements in bronchoscopic instrumentation since the days of Chevalier Jackson have permitted performance of endobronchial biopsies, as well as biopsy of peripheral lung lesions. Knowledge of the underlying disease process has a significant influence on the choice of specific diagnostic procedures and risk of complications. In the case of diffuse lung diseases, such as sarcoidosis, use of fluoroscopy has not been demonstrated to improve the diagnostic yield of transbronchial biopsies (TBBs). Fluoroscopy is useful, however, in providing information regarding the proximity of the forceps to the pleura and in more rapidly establishing the diagnosis of complications (e.g., pneumothorax).

Bronchoscopically visible lesions are generally biopsied with minimal risk; if bleeding occurs, it can usually be controlled easily

Figure 35-4 "Hot" forceps biopsy of a vascular endobronchial lesion. Use of the electrocautery forceps allows for safe, hemostatic biopsy of friable or vascularized endobronchial lesions (such as bronchial carcinoids), while obtaining pathologically interpretable tissue biopsy specimens.

(Fig. 35-4). The diagnostic yield of bronchoscopy for peripheral lesions depends on a number of factors, including lesion size, its location in the lung, and on the relationship between the lesion and bronchus. The presence of a bronchus sign on chest CT predicts a much higher yield of bronchoscopy for peripheral lung lesions. In these cases, fluoroscopy is mandatory to assure proper positioning of the cytology brush, biopsy forceps, or needle. An exciting new area is the potential application of radial EBUS in evaluation of peripheral pulmonary nodules. Radial probe EBUS allows for acquisition of diagnostic tissue via TBB performed with fewer passes; it may permit differentiation between benign and malignant nodules based entirely on nodule architecture. In the future, peripheral EBUS nodule characterization may even obviate the need for pathological diagnosis in certain patients with suspicious nodules.

The diagnosis of various infectious diseases can be established using a variety of transbronchoscopic sampling techniques. The role of bronchoscopic biopsy has been reaffirmed in immunocompromised hosts, in whom documentation of the precise pathogen is crucial for appropriate therapy. For example, while the presence of cytomegalovirus (CMV) in bronchoalveolar lavage (BAL) fluid may not be diagnostic, documentation of intracellular inclusion bodies on a biopsy specimen is practically pathognomonic. Simple, cost-effective transbronchoscopic tissue sampling can obviate much more complicated, expensive, and higher-risk thoracic surgical procedures.

SAMPLING OF AIRWAY AND ALVEOLAR CONSTITUENTS

Bronchoscopy provides easy and relatively safe access to material in the tracheobronchial tree and distal alveolar spaces. A variety of studies are routinely performed on specimens obtained from the airways and alveolar spaces using several techniques. For example, aspirated secretions can be sent for microscopy and culture to determine the offending organism in cases of infection or suspected infection. Cytological analysis of bronchoscopically obtained materials can provide proof of malignancy. With the advent of lung transplantation, the success of the procedure depends, in large measure, on the early diagnosis of rejection or infection in these immunocompromised

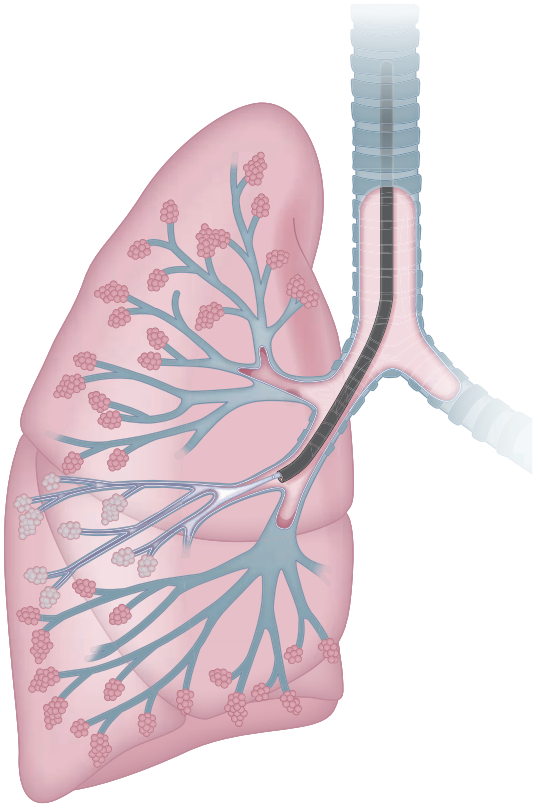

Figure 35-5 Bronchoalveolar lavage is performed by wedging the tip of bronchoscope in the segmental bronchus of interest. Normal saline is instilled into the distal air spaces, and then collected by suctioning back into a sterile container.

subjects. The most commonly employed bronchoscopic techniques for sampling the airways and alveolar spaces include "bronchial washing," bronchial brushing, and BAL.

■ BRONCHOALVEOLAR LAVAGE

A very useful bronchoscopic technique is BAL.[34,35] BAL is safe, even in critically ill patients, when biopsy or brushings may be contraindicated because of the risk of bleeding. Normal saline solution, devoid of any bacteriostatic material, is instilled into distal air spaces through the "wedged" bronchoscope and then aspirated through the instrument's suction channel (Fig. 35-5). The fluid collected in this manner is analyzed for gross appearance to detect possible alveolar hemorrhage. The fluid may also be subjected to a variety of tests, depending on the clinical circumstances: Microbiological testing, specific cytological analysis and cell count, immunological parameters, presence of various biochemical mediators related to pathological processes, tissue markers, polymerase chain reaction, electron microscopy, flow cytometry, and DNA probes.

Overall, the diagnostic yield of BAL is very much dependent on specific patient characteristics, underlying pathological process, and many technical factors.

INDICATIONS FOR DIAGNOSTIC BRONCHOSCOPY

Although there are several indications for diagnostic bronchoscopy (Table 35-1), evaluation of a lung nodule or mass and mediastinal staging of a lung cancer are the most common. There are many other potential indications, some of which are discussed subsequently.[36]

■ BRONCHOGENIC CARCINOMA

Bronchoscopy plays a central role in the evaluation of lung masses and nodules, including those suspicious for bronchogenic carcinoma.

TABLE 35-1 Indications for Diagnostic Flexible Bronchoscopy

Signs and symptoms
Hemoptysis
Stridor
Unilateral wheezing
Hoarseness
Unexplained chronic cough
Infections
Pneumonia in immunocompromised host
Nonresolving pneumonia
Cavitary lesion
Diffuse lung disease
Interstitial lung disease
Diffuse alveolar damage and hemorrhage
Drug-induced lung disease
Malignancy
Lung nodule or mass
Endobronchial tumor
Suspected airway invasion by adjacent malignancies (e.g., esophagus or thyroid)
Early detection (positive sputum cytology/negative CT scan)
Mediastinal or hilar lymphadenopathy or mass
Mediastinal staging or restaging
Other airway disorders
Mucus plugging
Foreign body aspiration
Benign airway stricture (e.g., idiopathic, granulomatosis with polyangiitis [formerly known as Wegener granulomatosis], sarcoidosis, or tuberculosis)
Intensive care
Bronchoscopy-guided intubation (difficult airway)
Endotracheal tube position
Miscellaneous
Lung transplant
Bronchopleural fistula
Aerodigestive fistula
Chest trauma
Chemical/thermal injury of airways
Preoperative and postoperative for lung resection surgery

Diagnosis

Bronchoscopy most commonly is performed in the evaluation of patients with suspected lung cancer. It remains the most commonly used modality for the diagnosis of bronchogenic carcinoma and plays an important role in staging of the disease, as well. Centrally located lesions generally may be approached using flexible bronchoscopy with minimal risk. Bronchogenic carcinoma of the central airways may manifest as exophytic mass lesions with partial or total bronchial lumen occlusion, as peribronchial tumors with extrinsic compression of the airway, with submucosal tumor infiltration, or with some combination of these entities. The mucosal abnormalities seen with peribronchial tumors or with submucosal infiltration often are subtle—the airways should be examined closely for

Video 35-4 Demonstrated in this video is the utilization of a standard 22-gauge Wang™ transbronchial aspiration needle (MW-122, ConMed, Utica, NY) for sampling of a partially necrotic endobronchial lesion in the right main stem bronchus. The advantages of bronchoscopic needle aspiration of endobronchial lesions include decreased bleeding risk compared to endobronchial biopsy or brushing; facilitation of sampling of material from the center of the lesion avoiding necrotic surface; and the ability to obtain real-time feedback through rapid on-site evaluation (ROSE) of aspirates by cytopathology. *Access at www.fishmansonline.com*

characteristic changes such as erythema, loss of bronchial markings, and nodularity of the mucosal surface.

Central lesions usually are sampled using a combination of bronchial washes, bronchial brushings, and endobronchial biopsies. The yield of bronchoscopy is highest for endoscopically visible lesions, with a diagnostic yield of approximately 90%.[37] Attempts should be made to obtain biopsy specimens from areas of the lesion that seem viable. Endobronchial needle aspiration (EBNA) to obtain a "core" biopsy from centrally located tumors should be considered, particularly if the lesion appears necrotic (Video 35-4). For submucosal lesions, EBNA can be performed by inserting the needle into the submucosal plane at an oblique angle; in patients with peribronchial disease causing extrinsic compression, the needle should be passed through the bronchial wall into the lesion. For all of these indications, EBNA has been shown to increase the diagnostic yield over conventional sampling methods.

Evaluation of Peripheral Lesions and Lung Nodules

The evaluation of peripheral lesions or lung nodules remains a common dilemma for chest physicians. A balance between pretest probability of a specific diagnosis and the complication risk associated with a biopsy method must be assessed.[38] Surgical biopsy offers a superior yield at the cost of increased cost and morbidity. TTNB has a high yield, but it carries a 15% to 25% risk of pneumothorax.[39–41] Although bronchoscopy has the advantage of a low complication risk, it has been hampered by a significantly lower diagnostic yield than these other modalities.

The yield of flexible bronchoscopy for peripheral pulmonary lesions, defined as lesions that are not visible beyond the segmental bronchi, is significantly lower than for central lesions. The overall sensitivity of standard bronchoscopy, based on studies that used a combination of TBB, cytology brush, BAL, and TBNA is 78% for peripheral disease.[42–58] Success depends on several factors, including lesion size, distance from the proximal airways, and the presence of a bronchus sign. The bronchus sign on CT may reflect the relationship of a tumor with the airway, and it has been categorized into four patterns by Tsuboi[59]: type I, in which the bronchial lumen is patent up to the tumor; type II, in which the bronchus is contained in the tumor mass; type III, in which the bronchus is compressed, narrowed, and displaced by the tumor, but the bronchial mucosa is intact; and type IV, in which the proximal bronchus is narrowed by the submucosal and peribronchial spread or tumor or by the enlarged lymph nodes (Fig. 35-6). TBB has the lowest diagnostic yield for lesions with a type III or IV tumor–bronchus pattern. In these cases, the use of peripheral TBNA may improve the overall diagnostic yield of bronchoscopy.

A recent study evaluating the use of conventional diagnostic bronchoscopy for screen-detected nodules demonstrated a diagnostic yield of only 13.5%, with a negative predictive value of 47.6%.[60] Given this poor performance, conventional bronchoscopy should not be performed in the evaluation of small, peripheral pulmonary nodules.[39,54] The use of guided bronchoscopic approaches (e.g., navigational bronchoscopy, UM-EBUS, or ultrathin bronchoscopy) has significantly improved the diagnostic yield of small, peripheral pulmonary

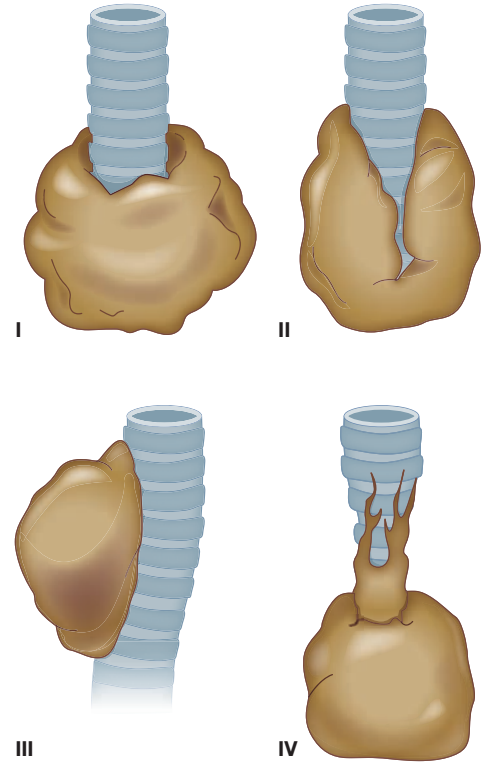

Figure 35-6 Tsuboi classification of tumor–bronchus relationship. (see text for details)

lesions. In a randomized comparison of traditional, fluoroscopically guided TBBs versus UM-EBUS–guided TBB, no statistical difference was found in establishing a diagnosis for lesions greater than 3 cm; however, for lesions smaller than 3 cm and for lesions smaller than 2 cm, the sensitivity of EBUS-guided TBB remained at 75% and 71%, whereas that of standard TBB fell dramatically to 31% and 23%, respectively.[61] Similar improvements have also been reported with the use of EMB- or VB-based systems for peripheral pulmonary lesions.

A recent meta-analysis of 30 studies with >3000 nodules reported a combined diagnostic yield of 70% for all available guided bronchoscopic techniques.[62] The diagnostic yield was influenced by the size of the primary lesion, with a yield of 61% for lesions <2 cm and 82% for lesions >2 cm.[62] Several other factors have also been described that impact the likelihood of obtaining diagnostic tissue using guided bronchoscopy: Ability to place UM-EBUS probe completely within a lesion (as opposed to adjacent to it), presence of a bronchus sign on CT scan, location in the middle lobe or lingula, and distance from the visceral pleura.[63–66] The use of TBNA in addition to conventional diagnostic procedures (TBB and BAL) in UM-EBUS–localized lesions also significantly improves diagnostic yield.[67]

Although it is increasingly clear that guided approaches are better than conventional bronchoscopy for smaller lesions, there are few comparative studies guiding the selection of a particular modality. In one randomized study of EMB alone, UM-EBUS alone, or EMB followed by confirmatory UM-EBUS, there was a significantly higher yield with the combined approach (combination, 88%; UM-EBUS, 69%; EMN, 59%),[68] suggesting that the highest yield may come from combined diagnostic modalities. However, a recent randomized study comparing ultrathin bronchoscopy with and without VB did not demonstrate any significant difference in the overall diagnostic yield (67% vs. 60%), although VB-assisted bronchoscopy was better for lesions in the RUL, lesions invisible on plain films, and lesions in the peripheral third of the lung.[69] Further studies are needed to help define the utility and specific indications for combination approaches for the diagnosis of peripheral lung lesions.

Video 35-5 This video demonstrates use of a 22-gauge EBUS-TBNA aspiration needle (Olympus, Center Valley, PA) to sample a left hilar node. The convex probe-EBUS scope is used to identify the left hilar node, allowing visualization of the TBNA needle entering the node in real time. The TBNA needle can be seen entering the left hilar node from the upper left portion of the video. The to-and-fro needle movement allows for collection of lymph node aspirate material. *Access at www.fishmansonline.com*

Staging

Bronchoscopy is an important modality for establishing lung cancer stage. In patients with potentially resectable tumors, a thorough airway examination helps confirm the absence of a concomitant, radiographically occult lesion. For lesions that involve the central airways, it is important to document the extent of disease and the degree of involvement of the main stem bronchi and main carina.

The use of CP-EBUS allows for real-time visualization and TBNA of hilar and mediastinal lymph nodes (Video 35-5). Sampling of lymph nodes using EBUS-TBNA is now commonly performed for nodal staging in patients with lung cancer. This technique frequently allows the establishment of both diagnosis and nodal stage, obviating the need for, and avoiding the risks associated with, sampling of the primary parenchymal lesion. TBNA has proved particularly useful with the employment of rapid on-site evaluation (ROSE), in which a cytopathologist present in or near the bronchoscopy suite can evaluate specimens in real time.

In general, patients with lung cancer may be separated into four categories with respect to intrathoracic radiographic characteristics, as suggested by the American College of Chest Physicians (ACCP) guidelines on lung cancer staging (Fig. 35-7).[70] In radiographic pattern A, mediastinal infiltration is extensive, with encircling of vessels and airways. In this case, the risk of malignant involvement can be assumed, and biopsy to establish diagnosis should be performed by the safest method available for that particular case. In pattern B, there is discrete lymph node enlargement that can be measured by CT, which may also be FDG-avid. In this case, sampling is recommended as the likelihood of mediastinal involvement is high and requires confirmation. In radiographic pattern C, the presence of a central tumor or suspected N1 disease makes the likelihood of mediastinal node involvement relatively high (20%–25%), necessitating invasive sampling. In the final group (i.e., those with a

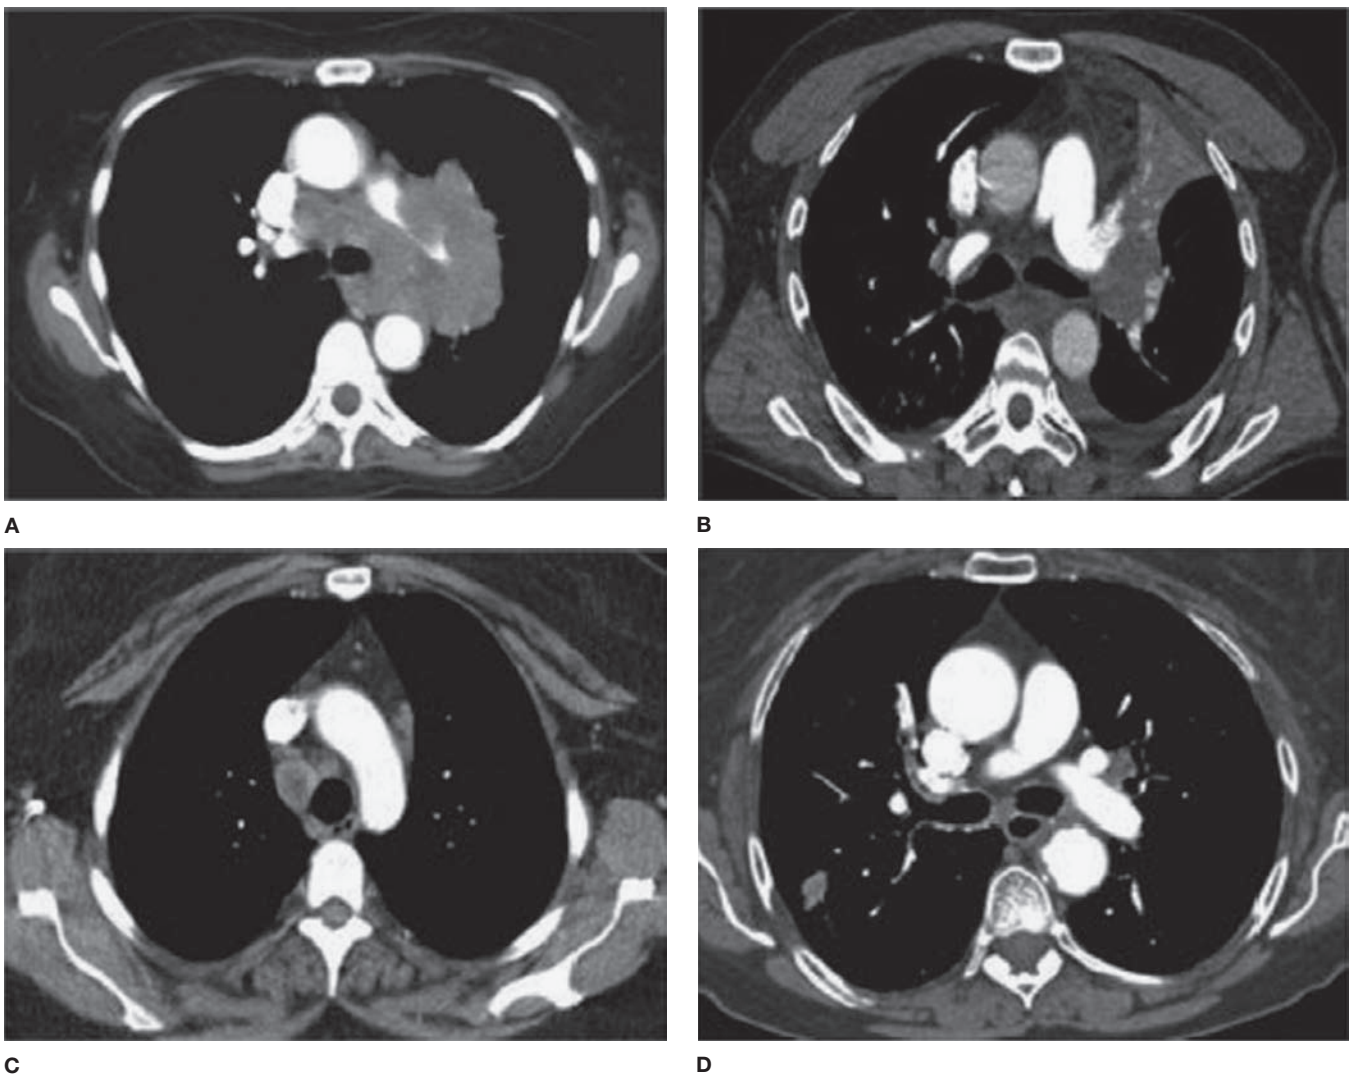

Figure 35-7 American College of Chest Physicians intrathoracic radiographic (CT scan) categories of lung cancer. **A.** Mediastinal infiltration by tumor. **B.** A central tumor or a tumor with enlarged N1 nodes, but a normal mediastinum. **C.** Enlarged discrete N2,3 nodes. **D.** A peripheral small tumor (seen in lower left corner of image) with normal-sized lymph nodes. *(Reproduced with permission from Silvestri GA, Gonzalez AV, Jantz MA, et al. Methods for staging non-small cell lung cancer: Diagnosis and management of lung cancer, 3rd ed. American College of Chest Physicians evidence-based clinical practice guidelines. Chest. 2013;143(5 Suppl):e211S–250S.)*

peripheral clinical stage I tumor), the chance of either distant metastases or mediastinal involvement is quite low (radiographic group D), especially if the mediastinum is also normal by positron emission tomography (PET) scan. The decision to pursue invasive staging should be considered on an individual case basis.

Several systematic reviews have confirmed that the sensitivity of EBUS-TBNA is equivalent to that of mediastinoscopy.[70–73] A recent randomized study of 241 patients with potentially resectable NSCLC compared mediastinoscopy alone to a combined approach of EBUS-TBNA and EUS-FNA, followed by surgical staging if the needle technique did not identify nodal metastases.[74] The needle approach followed by mediastinoscopy resulted in a significantly greater sensitivity (94%) compared to the other approaches and resulted in fewer unnecessary thoracotomies. One limitation to this approach has been the difficulty in many centers to operationalize a combined EBUS-TBNA and endoscopic ultrasound (EUS)-FNA procedure. Interestingly, recent studies have shown that the EBUS-TBNA scope can be used through both the airway and the esophagus, resulting in similar results.[75,76] The ACCP guidelines now recommend that a needle approach should be used first when performing mediastinal staging. However, because of a relatively high false-negative rate, a negative result with a needle technique should prompt consideration of surgical staging methods.

EVALUATION OF HEMOPTYSIS

One of the most frequent indications for bronchoscopy is hemoptysis. Bronchoscopic evaluation can be of help in determining the precise location and source of bleeding. The choice of instrument (rigid vs. flexible scope) and timing of the procedure are dictated by clinical circumstances.[77] Studies have shown that active bleeding and its site are visualized more commonly with early bronchoscopy (within 48 hours) than with more delayed examination.[77–79] In the case of a normal chest radiograph and hemoptysis, trace signs of bleeding are commonly seen, but not the site of origin.[80] In these circumstances, examination using an ultrathin flexible instrument may be beneficial in identifying the source of bleeding in a peripheral airway once the more proximal airways have been cleared of blood by a therapeutic scope. In some instances, bronchoscopy is useful not only as a diagnostic method, but also to perform therapeutic maneuvers (see Chapter 36, Interventional Bronchoscopy).

PULMONARY INFECTIONS

Bronchoscopy is a useful technique in the diagnosis of pulmonary infections, allowing for the collection of respiratory samples for evaluation with special stains and culture. Several common clinical areas in which bronchoscopy may play an important diagnostic role are described subsequently.

Pneumonia

In general, bronchoscopy is not indicated for the diagnosis of community-acquired pneumonia, which is currently treated empirically with appropriate antibiotic therapy; however, bronchoscopy is likely to be useful in cases of nonresolving pneumonia,[81,82] defined as a lack of improvement or worsening of symptoms despite a minimum of 10 days of antibiotic therapy or failure of radiographic abnormalities to resolve after 2 to 3 months. The causes of nonresolving pneumonia are myriad and include inadequate antibiotic therapy, resistant or highly virulent organisms, impaired host defenses, obstructing endobronchial lesions, or a noninfectious cause. Although controversial, bronchoscopy should be considered in these patients.

Ventilator-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is defined as a pneumonia occurring more than 48 hours after intubation and initiation of mechanical ventilation.[83,84] VAP is usually suspected when an intubated, mechanically ventilated patient has signs of infection and an abnormal chest radiograph. Intubated patients experience colonization of their upper and lower airways with nosocomial organisms; because of an abnormal mucociliary clearance mechanism, these patients are at greater risk for developing pulmonary infections. In addition, mechanically ventilated patients are often treated empirically with broad-spectrum antibiotics and, therefore, are at greater risk for infection with resistant organisms and unusual lower respiratory tract pathogens. Guidelines support the use of either a quantitative or semiquantitative strategy in the diagnosis of VAP.[83] Quantitative sampling can be performed using endotracheal aspirates, or BAL or protected specimen brush (PSB) collected with or without a bronchoscope.[83,85]

Quantitative BAL entails the performance of a standardized BAL, with infusion of at least 120 mL of saline for adequate sampling of a pulmonary subsegment. Quantitative culture of the aspirated material is performed to determine the number of colony-forming units (CFUs) recovered.

PSB uses a double catheter system in which an outer cannula and distal, biodegradable plug protect the bronchoscopic brush within the inner cannula from contamination with secretions in the upper airway and suction channel of the bronchoscope. When the bronchoscope is positioned proximal to the segmental orifice of interest, the PSB inner cannula is advanced into a subsegment and the protective distal plug ejected. The brush is then advanced peripherally, rotated gently, and retracted into the inner cannula. The inner cannula is subsequently retracted into the outer cannula and the bronchoscope removed from the airway. The distal portion of the catheter is cleaned with 70% alcohol and the brush clipped into saline solution under sterile conditions. The PSB is then submitted for quantitative bacterial culture within 15 minutes of performance of the procedure.

The threshold for diagnosis of VAP using PSB is 10^3 CFU/mL. PSB has higher specificity than sensitivity for the presence of VAP—a positive result greatly increases the likelihood that pneumonia is present. For quantitative BAL, a threshold of 10^4 or 10^3 CFU/mL is used for diagnosis of VAP.[86] The detection of VAP by quantitative BAL culture has a sensitivity of 40% to 90% and a specificity of 45% to 100%.[86] Because a larger proportion of lung parenchyma is sampled with BAL, this may be a better method than PSB for VAP diagnosis. However, samples contaminated by upper airway secretions (based on a high percentage of squamous epithelial cells) should be interpreted with caution. There are likely a number of factors that affect the diagnostic yield of the bronchoscopic methods, such as a change in antibiotics before sampling, inadequate technique in sampling, and lack of a gold standard for comparison.

Infections in Immunocompromised Patients

Pulmonary infections in immunocompromised patients constitute the most common complication in this population and represent an important contributor to mortality. Such infections are increasingly common, reflecting the expanding use of aggressive chemotherapeutic regimens and the ever increasing number of solid organ and hematopoietic stem cell transplantations. The differential diagnosis of pulmonary infiltrates is broad in scope; however, most cases are caused by infectious agents, including bacterial, fungal, viral, and mycobacterial pathogens.[87] Bronchoscopy is the most commonly used diagnostic procedure in these patients and should be performed as early as possible, because a delay in diagnosis of longer than 5 days has been shown to significantly increase mortality.

The sensitivity of bronchoscopy varies, depending on the immunocompromised population studied and the specific etiological disorder. In non–human immunodeficiency virus (HIV)-infected patients, the yield of BAL for *Pneumocystis jirovecii* pneumonia (known previously as *Pneumocystis carinii* pneumonia [PCP])

is approximately 80%, compared with a greater than 90% yield observed in HIV-seropositive patients.[88,89] This difference is due to the much lower organism load present in non–HIV-seropositive subjects. Although empirical therapy often is initiated in patients suspected of having PCP infection, bronchoscopy should be performed in most cases to confirm the diagnosis. Bronchoscopic lung biopsy may increase the diagnostic yield of BAL for diagnosis of PCP infection, particularly in the non–HIV-infected population.[88] Bronchoscopy also has a high diagnostic yield for CMV; however, because CMV cultures from BAL are not specific, the diagnosis of CMV pneumonia should be limited to patients with pathological evidence of CMV infection demonstrated by the presence of CMV inclusion bodies on BAL or biopsy. Although bronchoscopy also is useful for the diagnosis of aspergillosis – the sensitivity is approximately 50% – the disease often is peripheral and patchy and, thus, is not easily diagnosed by BAL or bronchoscopic biopsy. Overall, in immunocompromised patients with infiltrates, the diagnostic yield of bronchoscopy varies from 30% to 80% and is impacted by factors such as the prevalence of an infectious etiology, timing of bronchoscopy, and use of prophylactic antibiotics.[90–97]

Mycobacterial Infections

In cases in which pulmonary tuberculosis is suspected, the initial diagnostic evaluation should consist of serial examination of sputum for the presence of acid-fast bacilli in stained smears. Ideally, induced sputum samples should be obtained. If sputum study results are negative, or if a patient is unable to produce sputum and tuberculosis is still suspected, bronchoscopy with BAL and biopsy should be performed. The use of bronchoscopy allows for the opportunity to establish a rapid diagnosis (by positive smear or histopathology), providing the potential for earlier intervention and treatment while awaiting culture results. Bronchoscopy should be performed with appropriate infection control precautions to minimize the risk of nosocomial transmission. A bronchoscopy may cause the patient to produce sputum for several days afterward; these specimens also should be collected and analyzed, if possible.

The utility of bronchoscopy in establishing a rapid diagnosis varies widely in the literature, with reported diagnostic yields of 30% to 70%, although the overall yield of culture is considerably higher.[98] One study has shown an improvement in diagnostic yield from 58% to 81% with use of UM-EBUS–guided biopsy and washings.[99] The yield in patients with miliary tuberculosis, in whom sputum smears frequently are negative, is approximately 70%. Bronchoscopy also is useful in tuberculosis manifesting as an endobronchial lesion or with mediastinal and hilar adenopathy, in which case, diagnostic tissue may be obtained with TBNA.

Human Immunodeficiency Virus Syndrome

The introduction of highly active antiretroviral therapy (HAART) has resulted in a sharp decline in the incidence of opportunistic infections in HIV-infected patients. Nevertheless, infectious complications remain one of the most common indications for bronchoscopy in this population. PCP remains the most frequent serious opportunistic infection in HIV-seropositive patients. Bronchoscopy with BAL remains the preferred diagnostic procedure for this disease, although in select centers, use of sputum induction has had a relatively high diagnostic yield and may mitigate the need for bronchoscopy. As previously mentioned, bronchoscopic lung biopsy may increase the diagnostic yield of BAL.[88] Empirical therapy often is initiated in patients with suspected Pneumocystis infection; such therapy can impair the diagnostic yield of BAL if the procedure is not performed within 24 hours. In patients receiving pentamidine prophylaxis, the diagnostic yield is decreased unless the upper lobes are sampled.[100–102] Several PCR assays have been tested on BAL fluid, induced sputum, and oral wash specimens; these generally have been more sensitive, but less specific, than traditional microbiological methods.

Bronchoscopy also plays an important diagnostic role in HIV-positive patients with infections caused by mycobacteria, including tuberculosis, atypical bacterial pneumonias, and various fungal infections. Kaposi sarcoma, caused by human herpesvirus type 8 (HHV8), can manifest with violaceous endobronchial plaques that typically occur at airway bifurcations; pulmonary parenchymal involvement is characterized by lymphangitic infiltration of tumor, leading to the development of nodules and masses.

DIFFUSE LUNG DISEASES

A wide range of acute and chronic pulmonary disorders are capable of causing a diffuse interstitial lung disease pattern of injury. These processes include infection, neoplasm, pulmonary edema, alveolar hemorrhage, alveolar proteinosis, occupational lung diseases, drug-induced disease, and various types of idiopathic or collagen vascular disease–associated interstitial lung disease. The pattern of lung injury should first be evaluated using high-resolution chest CT imaging, which helps to narrow the differential diagnosis and, in some cases, is virtually diagnostic of certain disorders. In many cases, it is still necessary to obtain samples for cytological and histological evaluation to confirm a specific diagnosis and to help exclude other possible disorders.

The most common bronchoscopic procedures used to help establish the diagnosis in diffuse lung disease are BAL and TBB. The findings on high-resolution CT (HRCT) can be used to determine the best location for BAL or TBB. In truly diffuse disease, the right middle lobe and the lingula are the best locations for BAL; with these sites, ease of access and good fluid retrieval are typical. BAL should be performed using a total of 100 to 200 mL of saline instilled in multiple aliquots. It is important to obtain a reasonable sampling of the alveolar spaces for the necessary cellular analysis.

The value of BAL is well documented in the diagnosis of diffuse parenchymal diseases, and findings may be diagnostic in eosinophilic pneumonia, eosinophilic granuloma, and pulmonary alveolar proteinosis.[36] In most other diffuse disorders, BAL findings are mostly supportive of a suspected diagnosis (Table 35-2) and helps to rule out potential infectious etiologies. In disorders such as sarcoidosis, hypersensitivity pneumonitis, and organizing pneumonia, the use of BAL in combination with bronchoscopic lung biopsy can often establish the diagnosis and avoid the need for surgical lung biopsy. For example, with pulmonary sarcoidosis, the diagnosis usually is established by a combination of BAL and biopsy findings. The BAL can be used to exclude the presence of tuberculosis and fungal infections and may demonstrate the characteristic high CD4+/CD8+ ratio seen in sarcoidosis, whereas bronchoscopic biopsy specimens may demonstrate the classic finding of noncaseating granulomas. In general, TBB should be performed in several affected areas, and at least five or six specimens should be taken. The sensitivity of TBB for diagnosis of sarcoidosis is only approximately 60% to 70%, and many patients require further invasive testing, such as surgical lung biopsy.[103,104]

In patients with mediastinal and hilar adenopathy, needle techniques for lymph node sampling should also be considered, as this can provide diagnostic evidence of noncaseating granulomas in 80% to 90% of cases.[105–110] A recent randomized study showed endosonographic needle approaches to have a greater diagnostic yield when compared with bronchoscopic lung biopsy.[111] The addition of TBNA to TBB results in an improved overall diagnostic yield in suspected cases of sarcoidosis.[105] At present, the data suggest that all patients with suspected sarcoidosis should undergo a needle technique for lymph node sampling, but it is unclear if bronchoscopic biopsy should be performed in all cases, given the added risk of pneumothorax and hemorrhage. The presence of mediastinal and hilar adenopathy, with or without parenchymal lung changes, also

TABLE 35-2 BAL Findings in Diffuse Lung Disease

Diffuse Lung Disease	Typical BAL Cellular Pattern	T lymphocyte CD4/CD8 Ratio	Other Relevant BAL Findings
Sarcoidosis	↑ Total cell count ↑ Lymphocytes	↑	-
Hypersensitivity pneumonitis	↑ Total cell count ↑ Lymphocytes	↓	Neutrophils can be increased with recent exposure to antigen
Chronic beryllium disease	↑ Total cell count ↑ Lymphocytes	↑	BAL lymphocyte proliferation with beryllium salts
Asbestosis	↑ Neutrophils	↑	Ferruginous bodies
Idiopathic pulmonary fibrosis	↑ Neutrophils ↓ Lymphocytes	-	-
Cryptogenic organizing pneumonia	↑ Neutrophils ↑ Lymphocytes	↓	Foamy macrophages
Pulmonary alveolar proteinosis	Variable	-	Milky fluid and foamy macrophages with PAS-positive material
Drug-induced lung disease	Variable	↓	Foamy macrophages with amiodarone exposure
Pulmonary Langerhans cell histiocytosis	↑ Total cell count Variable differential	-	CD1+ Langerhans cells
Eosinophilic pneumonia	↑↑ Eosinophils	-	Eosinophil counts greater in acute than in chronic pneumonia

raises the possibility of lymphoma. In these cases, TBNA samples should also be evaluated with flow cytometry for evidence of clonal proliferation to exclude the possibility of lymphoma.

Bronchoscopy has a limited role in the diagnosis of idiopathic pulmonary fibrosis (IPF).[112] A nonspecific increase in levels of neutrophils, eosinophils, and, less commonly, lymphocytes has been documented in BAL fluid. Histological evidence of IPF generally requires documentation of a number of pathological changes consistent with usual interstitial pneumonia. This is often difficult with bronchoscopic biopsies, which are frequently limited by the small size of the specimen obtained and lack of histological preservation because of mechanical crushing of the tissue. Cryobiopsy may improve the yield of bronchoscopy in IPF, as it allows for increased size of the obtained specimens with increased amounts of alveolated lung parenchyma. In cases in which the diagnosis of IPF is probable or definite on the basis of clinical and HRCT criteria, bronchoscopy (and surgical lung biopsy) is not required. In situations in which the HRCT findings are not atypical for IPF, bronchoscopy can be performed to evaluate for the presence of other potential etiological disorders. If the specific diagnosis cannot be established on the basis of BAL and TBB findings, surgical lung biopsy should be considered.

COMPLICATIONS OF BRONCHOSCOPY

Bronchoscopy is a potentially hazardous procedure. Complications are generally due to inappropriate preparation of patients before bronchoscopy, effects of local or general anesthesia, and manipulation of various instruments. Appropriate training and experience of the bronchoscopist and supporting team are crucial in reducing the rate of complications.

Any diagnostic or therapeutic manipulation should be considered in relation to the underlying condition of the patient, localization of the area of investigation, and other surrounding structures in the thorax. It is essential to develop good communication between the bronchoscopist and other members of the team. While the bronchoscopist concentrates on the field of work – which, as seen through the bronchoscope, is two-dimensional – other team members are responsible for monitoring the patient (oxygen saturation, blood pressure, heart rhythm, etc.) and checking and maintaining the adequacy of ancillary equipment (suction, oxygenation, and accessories such as forceps, balloons, catheters, and laser light guides). Risks are decreased if, for example, special attention is paid to the control of accessories during their manipulation beyond the tip of the bronchoscope. Premature deployment of the needle biopsy device or inappropriate bending of the bronchoscope while an instrument is inside the flexible portion can result in perforation of the bronchoscope. Activation of the laser with a broken light guide inside the bronchoscope or inadequate protrusion of the tip of the fiber beyond the bronchoscope may result in airway fires or severe burns to the patient. Attention to details and proper maintenance of the equipment, including accessories, enhance safety for the patient and staff. Diagnostic yield and therapeutic results are also improved. Overall, when bronchoscopy is performed by an experienced endoscopist, backed up by a well-trained team and appropriate facilities, mortality and morbidity are very low.

■ ANESTHESIA AND RELATED BLOOD GAS ABNORMALITIES

Approximately half of the life-threatening complications of diagnostic bronchoscopy are associated with the risk of topical anesthesia and sedation. Risk is significantly increased in the elderly, and in those with serious concomitant illnesses. Predisposing factors include cardiovascular disease, chronic pulmonary disease, renal and hepatic dysfunction, seizures, and altered mental status. Mild sedation, anxiolysis, muscular relaxation, and anterograde amnesia increase patient cooperation and permit quicker and less traumatic procedures. Doses of benzodiazepines, opiates, propofol, and topical anesthetics must be adjusted if there is underlying organ dysfunction. In the event of severe respiratory depression from excess sedation, flumazenil and naloxone can be administered to reverse the effects of benzodiazepines and narcotics.

Inadequate topical anesthesia potentiates coughing, gagging, and patient discomfort and increases the risk of injury during bronchoscopy. However, topical anesthetics such as lidocaine, the

most frequently used agent, are absorbed systemically through the respiratory mucosa, increasing the risk of cardiac or central nervous system toxicity. Although rare, these complications are more likely to occur in patients with underlying low cardiac output, hepatic dysfunction, and oropharyngeal candidiasis.

Another, less frequent complication of excessive lidocaine use is methemoglobinemia and resultant tissue hypoxia. This condition should be suspected when cyanosis occurs following the procedure in combination with low oxygen saturation, but a higher than expected Pa_{O_2} for the degree of cyanosis, and low oxygen saturation. Sampling of arterial blood reveals chocolate-brown blood. Methemoglobinemia occurs because lidocaine causes the rate of hemoglobin oxidation to exceed the reductive capacity of erythrocytes, leading to accumulation of methemoglobin. The diagnosis of this disorder can be made using co-oximetry. Treatment with methylene blue (1–2 mg/kg body weight) should be administered to symptomatic patients or when methemoglobin levels exceed 30%.

Introduction of the bronchoscope under general anesthesia or under conscious sedation with topical anesthesia frequently results in a decrease in oxygenation and in hypoventilation, with demonstrable increases in Pa_{CO_2}. The mechanism responsible for hypoxemia include acute upper airway obstruction, hypoventilation, and ventilation–perfusion mismatching. In patients with underlying chronic lung disease, severe hypoxemia may occur, triggering life-threatening cardiac arrhythmias. Skillful manipulation of rigid and flexible bronchoscopes reduces the risk of injury to the upper airways, which can result in life-threatening laryngospasm during or after completion of the procedure. Particular caution must be exercised in patients with underlying bronchospastic disorders, superior vena cava syndrome, or history of angioedema.

All patients undergoing bronchoscopic procedures should be monitored continuously (electrocardiogram, blood pressure, O_2 saturation, and, if indicated, expiratory CO_2 concentration). Use of supplemental oxygen during the procedure should be routine. Bronchoscopy probably should not be performed in patients who are unable to maintain adequate oxygenation on full ventilator support with high levels of supplemental oxygen.

Significant oxygen desaturation may occur during BAL. The degree of desaturation is directly related to the duration of the procedure and the volume of lavage fluid used. Return to the prebronchoscopy level of O_2 saturation may be prolonged after removal of the bronchoscope, and supplemental O_2 should be continued throughout the procedure and during the postbronchoscopy observation period.

FEVER AND INFECTION

Appearance of transient fever after bronchoscopy, reported in 5% to 30% of procedures, generally does not require any therapy. The incidence of fever is increased in the elderly, in those with underlying chronic pulmonary disease or documented endobronchial obstruction, and in those with bronchoscopic interventions for malignancy. The incidence of fever and extension of pulmonary infiltrates increase with the volume of BAL fluid and the total number of pulmonary segments lavaged. In most cases, these complications resolve spontaneously within 24 hours. However, persistent fever in the setting of progressive radiographic infiltrates suggests postprocedure pneumonia and necessitates antibiotic therapy. The incidence of postbronchoscopic infections is higher in immunocompromised hosts and those with chronic suppurative lung disease (e.g., cystic fibrosis). There have also been reports of purulent pericarditis and mediastinitis following TBNA of mediastinal nodes or masses.[113,114]

In high-risk cardiac patients, including those with prosthetic valves, prior endocarditis, complicated cyanotic heart disease, or surgically constructed systemic-pulmonary shunts, American Heart Association guidelines indicate that prophylactic antibiotics are optional prior to flexible bronchoscopy.

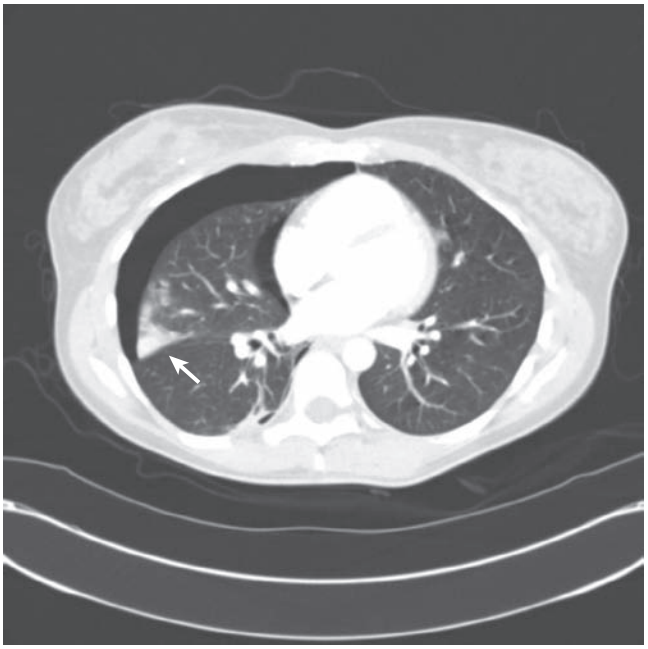

Figure 35-8 CT image demonstrating a pneumothorax of the right lung following transbronchial lung biopsy. An area of focal hemorrhage in the lateral right upper lobe *(white arrow)* as a result of biopsy can also be seen.

PNEUMOTHORAX

Most of the serious complications related to diagnostic bronchoscopy have been reported in association with performance of TBBs. Pneumothorax following TBB occurs in 4% to 5% of cases, (Fig. 35-8) although a recent population-based study suggested pneumothorax rates of approximately 1%.[115–124] The impact of fluoroscopy on the incidence of pneumothorax remains controversial. Uncontrolled studies have not found a difference in the incidence of pneumothorax following TBB when performed with and without fluoroscopy.[125]

The risk of pneumothorax is not related to the size of the bronchoscopic biopsy forceps. The incidence of pneumothorax is increased, however, in immunocompromised hosts. This is likely due to the increased risk of pneumothorax associated with PCP. The risk is also elevated in mechanically ventilated patients, with peripheral lung biopsies, and in the presence of bullous lung disease. For these reasons, a postbronchoscopic expiratory chest radiograph is routinely performed. In rare cases, the development of pneumothorax can be delayed, with patients developing the complication after discharge. In case of a significant pneumothorax, a chest tube should be inserted immediately to avoid oxygen desaturation or tension physiology.

HEMORRHAGE

One of the most frequently reported complications related to bronchoscopy is hemorrhage. Clinically significant bleeding as a consequence of diagnostic bronchoscopy is reported to occur in 1% to 4% of cases, but it is more likely to occur after TBB and brushings.[123,124,126,127] Although hemorrhage may also occur from inadvertent perforation of pulmonary vessels during TBNA, this is a very rare complication. Bleeding is more common in patients with immunosuppressed state, thrombocytopenia, uremia, liver disease, pulmonary hypertension, concurrent anticoagulation, and those on positive pressure ventilation.

The incidence of postbronchoscopy hemorrhage in uremic patients is reported as high as 45%. Consequently, a blood urea nitrogen (BUN) level above 30 mg/dL or a creatinine level above

3 mg/dL should be considered relative contraindications to bronchoscopy. TBB or brushing should not be performed if the platelet count is below 50,000/mm^3. Thrombocytopenic patients may receive platelet transfusions if biopsy is necessary. Similarly, coagulopathic patients should receive vitamin K, fresh frozen plasma, or cryoprecipitate prior to the procedure and biopsy.

Increasingly, patients referred for bronchoscopy are receiving antiplatelet therapy. Importantly, aspirin use has not been shown to increase hemorrhage risk, and it generally does not require discontinuation prior to diagnostic bronchoscopy.[128] In contrast, the risk of bleeding from clopidogrel therapy is very high following TBB.[129] If TBBs are necessary, clopidogrel should be discontinued 5 to 7 days prior to the procedure. We also recommend discontinuation prior to TBNA, although the risk of major bleeding is lower, and successful TBNA can be performed without discontinuation. In cases where clopidogrel therapy cannot be discontinued (e.g., recent coronary artery stenting), careful assessment of the goals of bronchoscopy should be considered and the need for TBB should be clearly defined.

TRANSTHORACIC NEEDLE BIOPSY

TTNB has proved a valuable diagnostic procedure in patients with a variety of thoracic radiographic abnormalities.

■ INDICATIONS AND CONTRAINDICATIONS

TTNB was first used for the diagnosis of pulmonary disease in 1883, when Leyden performed the procedure on three patients with pneumonia. Since that time, many published series have described the use of TTNB for the diagnosis of a variety of benign and malignant thoracic lesions.[130–139] The approach to biopsy may employ either an aspiration approach or an approach based on procuring histological samples with use of cutting needles. The use of histological samples provides improved diagnostic accuracy in lymphoma, both Hodgkin and non-Hodgkin varieties, in which anatomic structure is important in delineating the type of lymphoma, and in distinguishing between clonal, neoplastic processes, and inflammatory conglomerations of lymphocytes. Histological specimens may also improve the yield in the diagnosis of pulmonary hamartomas, characterized by the presence of cartilage or adipose tissue.

The major indications for TTNB include evaluation of solitary lung nodules and masses, (Fig. 35-9) mediastinal and hilar lesions, metastatic disease to the lung from a known extrathoracic malignancy, chest wall invasion by lung carcinoma, and pulmonary consolidation or infiltrates that are likely to be of infectious origin.

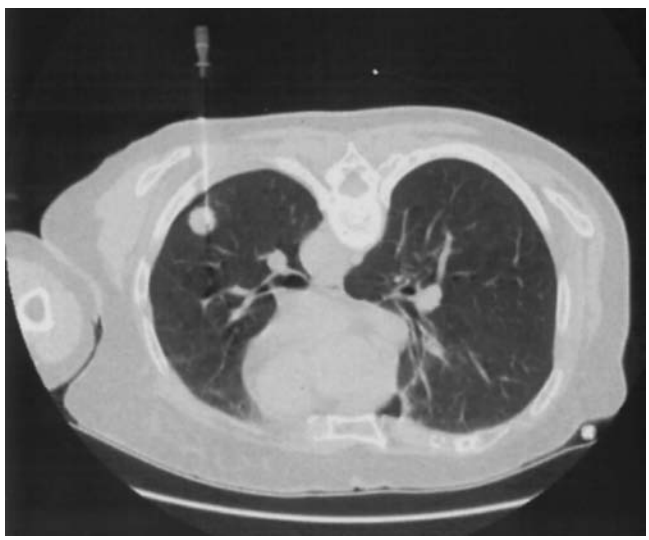

Figure 35-9 Transthoracic needle aspiration of pulmonary nodule. CT scan image of TTNA performed for a 2-cm right lower lobe nodule using a 22-gauge Westcott needle (Becton Dickinson & Co, Franklin Lakes, NJ). The needle can be seen entering the nodule. *(Used with permission of Ana Kolansky, MD.)*

With the "reemergence" of thoracoscopy and development of video-assisted and robotic-assisted thoracic surgical techniques, patients can more easily undergo complete excision of pulmonary nodules. In the past, many pulmonologists performed TTNB as the initial diagnostic procedure for intrapulmonary lesions, especially those in the lung periphery. Physicians are now faced with the dilemma of whether to send patients directly to thoracoscopic biopsy for a definitive answer. Two commonly used strategies – the use of PET or serial CT scanning – can be used to obtain additional evidence regarding the likelihood of malignancy. In appropriately selected patients, the presence of a PET-positive lesion or a lesion increasing in size on serial CT scans may obviate the need for TTNB.

Few absolute contraindications to TTNB exist. These include an uncooperative patient or one with an intractable cough, as patients must be able to suspend respirations for 5 to 10 seconds while the needle crosses the pleura. In addition, TTNB is absolutely contraindicated in patients with a suspected pulmonary hydatid cyst because of the risk of capsule rupture and systemic dissemination. Relative contraindications include bullous emphysema, pulmonary arterial hypertension, and coagulation or platelet disorders. Patients with bullous emphysema are at increased risk of developing symptomatic or tension pneumothoraces after biopsy, although most induced pneumothoraces are small and can be treated conservatively. Those with pulmonary hypertension who undergo TTNB have a higher chance of developing pulmonary hemorrhage and significant hemoptysis.

■ TECHNIQUE

Proper technique in performing TTNB is critical in obtaining adequate material for reliable interpretation. In addition to the mechanics of needle insertion and aspiration, the choice of needle type and careful specimen processing are important aspects of the procedure.

Choice of Needle

Many needle types are available for TTNB.[140,141] They vary in both length and width. In the early 1960s, TTNA was performed using large-bore cutting needles; significant hemorrhagic complications were reported. More recently, thin-needle aspiration has become standard, with devices ranging in size from 18 to 22 gauge. Coaxial needle systems have been introduced for the purpose of obtaining multiple samples from a single pleural penetration. These systems are also useful for procuring specimens for histological evaluation.

Radiographic Guidance and Biopsy Planning

Although TTNB can be performed under fluoroscopic or ultrasound guidance, CT is now the most commonly used image guidance approach for this procedure. CT can be used either intermittently during the procedure to guide needle placement, or with CT fluoroscopy (CTF), which allows for near real-time acquisition of images to guide needle adjustments. The diagnostic yield from either of these CT-based approaches appears to be similar.

Ultrasound-guided biopsies should be considered for peripheral lung lesions that extend to the pleural edge, or for the diagnosis of mediastinal masses. Ultrasound guidance also offers the advantage of real-time lesion imaging, easy portability, and absence of exposure to ionizing radiation for both the clinician and the patient.

Biopsy planning is an important step and should be performed prior to the procedure. Considerations include choosing a needle path that avoids traversal of bullae, vessels, and bronchi. Crossing of interlobular fissures should also be avoided, as this increases the risk of pneumothorax.[142] In cases with more than one lesion, a more peripheral lesion is preferred to decrease the amount of lung

traversed during needle insertion. In addition, upper lobe lesions are preferred over the lower lobe because of less respiratory motion in the upper lobes.

There are a number of different biopsy needles available for use, varying in length, gauge, and sampling mechanism. In general, needles can be divided into those used for aspiration, cutting needles for histological evaluation, and automatic core biopsy needles. The choice of biopsy needle depends on various factors, including characteristics of the lesion, amount of tissue desired, and operator preference.

Needle Insertion

The lesion is localized using CT guidance, and the overlying skin is marked and anesthetized with 1% or 2% lidocaine. The needle is first inserted through the skin into the subcutaneous tissues. The needle is then advanced to the level of the pleura, followed by verification of the needle position and angle by CT. The needle is then advanced in one motion through the pleura to the prescribed length. The needle position can be confirmed prior to biopsy.

Ideal aspiration technique necessitates having the tip of the needle as close to the center of the lesion as possible. If an aspiration or cutting needle is used, the inner stylet should be removed. A syringe is attached to the needle hub. While suction is applied, the needle tip is advanced and withdrawn about 0.5 to 1 cm within the lesion. The needle is then removed from the chest, suction is released, and the aspirated material is flushed into a specimen container. Several samples should be obtained to increase the diagnostic yield. With a necrotic mass, aspiration should also be performed in peripheral locations of the lesion to obtain viable cells and to decrease the risk of false-negative results.

A coaxial technique can also be employed using a larger entry needle, which is advanced into the lesion, followed by a smaller biopsy needle that can be passed through the lumen of the larger needle into the lesion. This approach allows multiple passes into the lesion without repositioning of the needle with each pass.

■ RESULTS

TTNB has an excellent success rate in the diagnosis of primary or metastatic pulmonary malignancies, with meta-analyses demonstrating pooled sensitivity of 90% (95% CI, 88%–91%);[54] lower yields are seen for lesions smaller than 1.5 cm.[135,139,143] CT guidance yields better performance when compared with fluoroscopy.[144] Aspiration biopsies have similar sensitivity to biopsies performed with cutting needles, but a poorer ability to determine a specific diagnosis from benign lesions. There is also concern that aspiration samples provide a lower likelihood of yielding sufficient tissue for molecular analysis, which is increasingly required in patients diagnosed with lung cancer.

Major causes of false-negative results in malignant disease are inadequate sampling of the lesion and aspiration in an area of necrosis or postobstructive pneumonia. In addition, small, central malignant lesions may be difficult to diagnose accurately. Aspiration of vascular tumors, such as angiosarcoma, carcinoid, or metastatic renal cell carcinoma, may yield a bloody aspirate with few, if any, malignant cells. False-positive results are extremely rare (1%–2%) and are typically reported in the setting of inflammatory processes, such as tuberculosis, radiation fibrosis, organizing pneumonia, and pulmonary infarction.

In the absence of a specific benign diagnosis, a lung biopsy that is negative for malignancy does not rule out the presence of neoplastic disease, especially if the biopsy was unsatisfactory. The degree of suspicion of malignancy in a particular clinical situation becomes extremely important in dictating the next step following a negative TTNB. For a smoker with a high risk of bronchogenic carcinoma, the proper course may lead to videothoracoscopic biopsy of the lesion, whereas in a young, otherwise healthy nonsmoker, close observation with serial CT scans may be the preferred option.

■ COMPLICATIONS

As mentioned previously, the most common complication of TTNB is pneumothorax; incidence rates reported in the literature vary from 8% to 61%. A recent population-based analysis reported a rate of pneumothorax of 15%, with 7% of all biopsies resulting in a pneumothorax requiring management with a chest tube.[40] Preexisting lung disease – in particular, bullous emphysema – is the most significant predisposing factor to development of pneumothorax after TTNB.[142,145–148] The vast majority of patients who develop clinically significant pneumothoraces after the procedure have an underlying diagnosis of chronic obstructive pulmonary disease. Other risk factors are smaller nodule size, crossing more than one pleural surface with the needle, needle size, and increased patient age.[142,145–148] Factors such as depth of lesion and increased number of transthoracic passes are controversial.[145,149]

Uncommon complications of TTNB include hemorrhage and hemoptysis, reported in approximately 1% of all biopsies. Although these are typically minor, one large study reported a transfusion requirement in 18% of cases with hemorrhage.[40] Cases of fatal hemorrhage from tracheobronchial obstruction from clot and subsequent asphyxia after use of large-bore (18-gauge) cutting needles have been reported.

Air embolism is a rare complication caused by creation of a communication between atmospheric air and a pulmonary vein. To minimize this risk, the needle should never be left open to air while in the chest, and the patient should be discouraged from deep breathing, straining, or coughing during the procedure. The procedure should be halted and the needle withdrawn if the patient is actively coughing. If an air embolism is suspected, 100% oxygen should be administered through a nonrebreather face mask and the patient placed in the left lateral decubitus position, with the head down: This position optimizes capture of air in the right heart. The patient should be transferred immediately to a hyperbaric chamber.

SUMMARY

Technological advances in diagnostic bronchoscopy continue to improve our ability to perform minimally invasive, accurate evaluations of the tracheobronchial tree and to perform an ever increasing array of diagnostic procedures. The continued development of imaging technologies and ancillary tools will certainly provide improvements in many of the modalities described earlier. Future improvements will include refinements in video and ultrasound imaging technology and the development of newer modalities, such as molecular imaging. This will be accompanied by further improvements in the ancillary tools, such as miniaturization of diagnostic accessories and further refinements in steerable probes that will allow improved access to peripheral regions of the lung. These opportunities will need to be accompanied by well-designed studies to delineate the appropriate use of these techniques in clinical practice.

CHAPTER 36
Interventional Bronchoscopy

Andrew R. Haas
Daniel H. Sterman

INTRODUCTION

The first interventional bronchoscopy (also referred to as therapeutic bronchoscopy throughout this chapter) was performed by Gustav Killian in 1897 when he removed a pork bone from the right mainstem bronchus of a patient. For nearly 70 years bronchoscopy was predominantly a therapeutic procedure performed for foreign body extraction. Two events shifted the landscape of bronchoscopy—the lung cancer epidemic and the development of flexible bronchoscopy by Shigeto Ikeda in 1967. Following an escalation in lung cancer incidence, malignant airway obstruction requiring therapeutic intervention became much more common than foreign body extraction. As a result, new tools were developed to address malignant airway obstruction based upon a minimally invasive bronchoscopic approach. In addition, bronchoscopy-based technology has been developed to address chronic obstructive pulmonary disease (COPD) and asthma. Application of the technology has entered clinical trials and may alter the therapeutic options for these diseases processes. This chapter presents an overview of interventional bronchoscopy modalities that can be utilized for benign and malignant airway obstruction, COPD, and asthma.

INDICATIONS FOR INTERVENTIONAL BRONCHOSCOPY

Many potential indications for interventional bronchoscopy have been recognized, including malignant airway obstruction, benign airway obstruction, and foreign body extraction, among others. (Table 36-1). The majority of therapeutic bronchoscopies performed today are undertaken for management of malignant airway obstruction, most commonly from lung cancer. It is estimated that up to 40% of patients with lung cancer develop symptomatic airway obstruction at some point during their disease process. Although lung cancer is the most common source of malignant airway obstruction, any primary thoracic malignancy, or any malignancy with pulmonary metastases, may result in symptomatic airway obstruction. Regaining airway patency to palliate symptomatic dyspnea and other respiratory symptoms may have significant impact on the quality of life of patients with advanced malignancy.

Benign airway obstruction etiologies are listed in Table 36-2 and consist of a variety of localized inflammatory and systemic conditions. Although the etiologic airway process is benign and not malignant, the interventions and management of these complex processes is far from benign to the patient. Interventional bronchoscopy techniques can often correct the presenting symptoms; however, the stenosis and symptoms often recur and patients may require repeat procedures to maintain airway patency. Selected patients may need to proceed with airway resection of the benign stenotic airway segment.[1]

Most patients with airway obstruction have clinical symptoms; dyspnea as the most common patient complaint. Depending on the rapidity of airway obstruction, dyspnea may have a rapid onset, or more commonly, an insidious evolution that gradually limits the patient activities. It is not uncommon for a family member to recognize this limitation more readily than the patient. As the airway obstruction worsens, the patient may begin to have orthopnea, which is a harbinger of an evolving critical airway obstruction. Other symptoms, such as cough, inability to clear secretions, chest discomfort, or fever from post obstructive pneumonia may develop. Early intervention is important to prevent worsening respiratory compromise or death.

SPECIAL CONSIDERATIONS FOR PATIENT PREPARATION, SEDATION, AND MONITORING

All patients undergoing bronchoscopy should undergo a complete pre-bronchoscopy evaluation, including a medical history, physical examination, and chest imaging. Although routine laboratory tests are not required, each evaluation should be individualized on the basis of patients' underlying conditions and therapeutic procedures planned. CT scan is important to assess the degree of airway involvement and to plan interventions to be undertaken.

Sedation and analgesia for patients undergoing interventional bronchoscopy must be considered carefully. Stable patients who can lay flat without distress can undergo bronchoscopy with moderate sedation. Should the patient have moderate or severe respiratory distress or be unable to lay flat, strong consideration should be given to additional monitoring or anesthesiology procedural assistance. Patients with high oxygen requirements may require endotracheal intubation to reduce the risk of developing hypoxemic respiratory failure during moderate sedation. Moreover, if patients are unable to lie flat, they may require an initial upright bronchoscopy under minimal sedation to temporize luminal diameter before undergoing general anesthesia and more definitive interventional bronchoscopy.

Similar to diagnostic bronchoscopy, if a patient is stable for moderate sedation, topical analgesia of the oropharynx and airways should be achieved with lidocaine, followed by administration of a combination of a short-acting benzodiazepine (e.g., midazolam) and a narcotic (e.g., fentanyl).[2] Rigid bronchoscopy is most safely

TABLE 36-1 Indications for Interventional Bronchoscopy

Hemoptysis
Atelectasis from inspissated secretions
Foreign body removal
Tracheobronchial tree neoplasms (primary or metastatic)
Direct bronchoscopic debulking
Laser therapy
Electrocautery/Argon plasma coagulation
Cryotherapy
Brachytherapy
Photodynamic therapy
Stent placement
Airway strictures and stenoses
Rigid bronchoscopic dilation
Stricture/stenosis incision
Balloon tracheobronchoplasty dilation
Stent replacement
Lung lavage (pulmonary alveolar proteinosis)
Bronchoscopic drainage—lung abscess
Endotracheal tube and percutaneous tracheostomy placement
Treatment of persistent air leak
Evolving therapies for emphysema
Bronchial thermoplasty in severe asthma

TABLE 36-2 Etiologies of Benign Tracheobronchial Stenosis

Endotracheal intubation
Tracheostomy tube
Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis)
Amyloidosis
Sarcoidosis
Tuberculosis
Inflammatory bowel disease
Idiopathic
Trauma
Lung transplantation
Post resection or airway repair
Trauma
Recurrent stenosis after prior stenosis resection
Sleeve resection
External beam radiotherapy or high dose-rate brachytherapy (HDRB)
Photodynamic therapy
Thermal injury from fire exposure
Tracheobronchopathia osteochondroplastica
Postpneumonectomy syndrome
Fibrosing mediastinitis
Large vascular aneurysms

performed with a patient receiving general anesthesia and breathing spontaneously or being ventilated with a jet ventilator.[3] General anesthesia with inhaled anesthetics (e.g., sevoflurane) should be avoided in favor of total intravenous anesthesia in order to avoid exposure of the bronchoscopist to inhaled anesthetics when the ventilator circuit is open. With appropriate planning and monitoring, the vast majority of patients can undergo interventional bronchoscopy with low complication rates.

TYPES OF AIRWAY OBSTRUCTION

Figure 36-1 demonstrates the three main types of airway obstruction that may be encountered: purely intrinsic (A), purely extrinsic (B), or a combination of both intrinsic and extrinsic airway obstruction (C). Attention to preprocedural CT scan imaging allows fairly accurate assessment of these components and permits the therapeutic bronchoscopist to plan an approach. For lesions that are purely intrinsic, direct bronchoscopic debulking with rigid bronchoscopy, thermal ablation, or snare extraction, with or without stent placement, is appropriate. For purely extrinsic lesions, no tumor is present to debulk, and modalities used in purely intrinsic disease cannot be employed because of the risk of airway perforation. Extrinsic lesions are most amenable to balloon bronchoplastic dilatation and endoluminal stent placement. For mixed intrinsic–extrinsic lesions, all tumor removal modalities, as well as dilatation and stent placement, are feasible.

■ ENDOLUMINAL AIRWAY OBSTRUCTION

Endoluminal obstruction of the tracheobronchial tree may result from various benign and malignant processes. The most common cause of endobronchial obstruction is advanced lung carcinoma. In patients with inoperable central airway tumors, restoration of airway patency may provide palliation and may even prolong life, particularly in the case of impending respiratory failure or postobstructive pneumonia.

Signs and symptoms of central malignant airway obstruction vary, but often include progressive dyspnea and functional limitation, wheezing, cough, stridor, hoarseness, hemoptysis, and chest pain. A careful pretreatment evaluation should be performed to distinguish symptoms attributable to focal tracheobronchial lesions from those related to underlying obstructive lung disease, parenchymal lung disease, or both. Although pulmonary function testing and thoracic imaging techniques, such as chest CT, may be useful in the evaluation of a patient with suspected malignant airway obstruction, bronchoscopy, either rigid or flexible, remains the diagnostic and therapeutic "gold standard." Increasingly, however, three-dimensional reconstruction CT imaging, so-called "virtual bronchoscopy," is being applied as a reliable noninvasive method of assessing the nature and extent of malignant airway obstruction, thereby allowing preprocedural intervention planning.

The bronchoscopic approach to management of malignant airway obstruction depends on the lesion location, presence or absence of associated extrinsic compression, and degree of clinical urgency. Rigid bronchoscopic debulking using adjunctive thermal ablation is recommended when airway recanalization must be performed on an emergency basis. If endobronchial obstruction is accompanied by marked extrinsic compression, stent placement may be beneficial.

The complexity of a lesion is equally important in determining the best approach to therapeutic bronchoscopy. Benign tracheal webs often are managed using laser or electrocautery-mediated resection alone, whereas complex fibrotic strictures may warrant the combination of rigid bronchoscopic or balloon dilation, thermal incision, and stent placement. For focal tracheal stenosis in patients at low risk for complications, surgical resection with primary reanastomosis should remain the treatment of choice.

■ EXTRINSIC AIRWAY COMPRESSION

Extrinsic airway compression usually results from malignant involvement of structures adjacent to the central airways, such as mediastinal lymph nodes or the esophagus, but it may be associated with a benign process, such as fibrosing mediastinitis, tuberculosis, aneurysmal dilatation of the aorta, or sarcoidosis. The clinical signs and symptoms of extrinsic airway compression often mimic those of endobronchial obstruction. The diagnosis is established on the basis of bronchoscopic detection of marked airway narrowing in the absence of an endoluminal mass.

Therapeutic options in the management of extrinsic airway compression are limited. Ablative endoscopic approaches, such as laser therapy, cryotherapy, PDT, and electrocautery are contraindicated because of the lack of demonstrable benefit and risk of airway perforation. Although some patients with malignant disease may benefit from endobronchial brachytherapy, tracheobronchial stent placement is the palliative treatment of choice for patients with symptomatic extrinsic airway compression.

TYPES OF THERAPEUTIC BRONCHOSCOPY INTERVENTIONS

A wide variety of therapeutic bronchoscopic interventions may be offered. Each is described in subsequent sections.

■ RIGID BRONCHOSCOPY

The initial bronchoscope, developed by Killian, and further optimized by Chevalier Jackson, was a rigid metal tube that permitted either spontaneous or mechanical ventilation.[4] Over the decades, rigid bronchoscopes of various lengths and sizes that are adaptable for diverse applications in children and adults have become available. Although the flexible bronchoscope has, to a large extent, replaced the rigid scope for most diagnostic and some therapeutic indications, rigid bronchoscopy still has vital therapeutic applications.

Modern rigid bronchoscopy systems are equipped with optical capabilities to allow better direct, magnified, circumferential

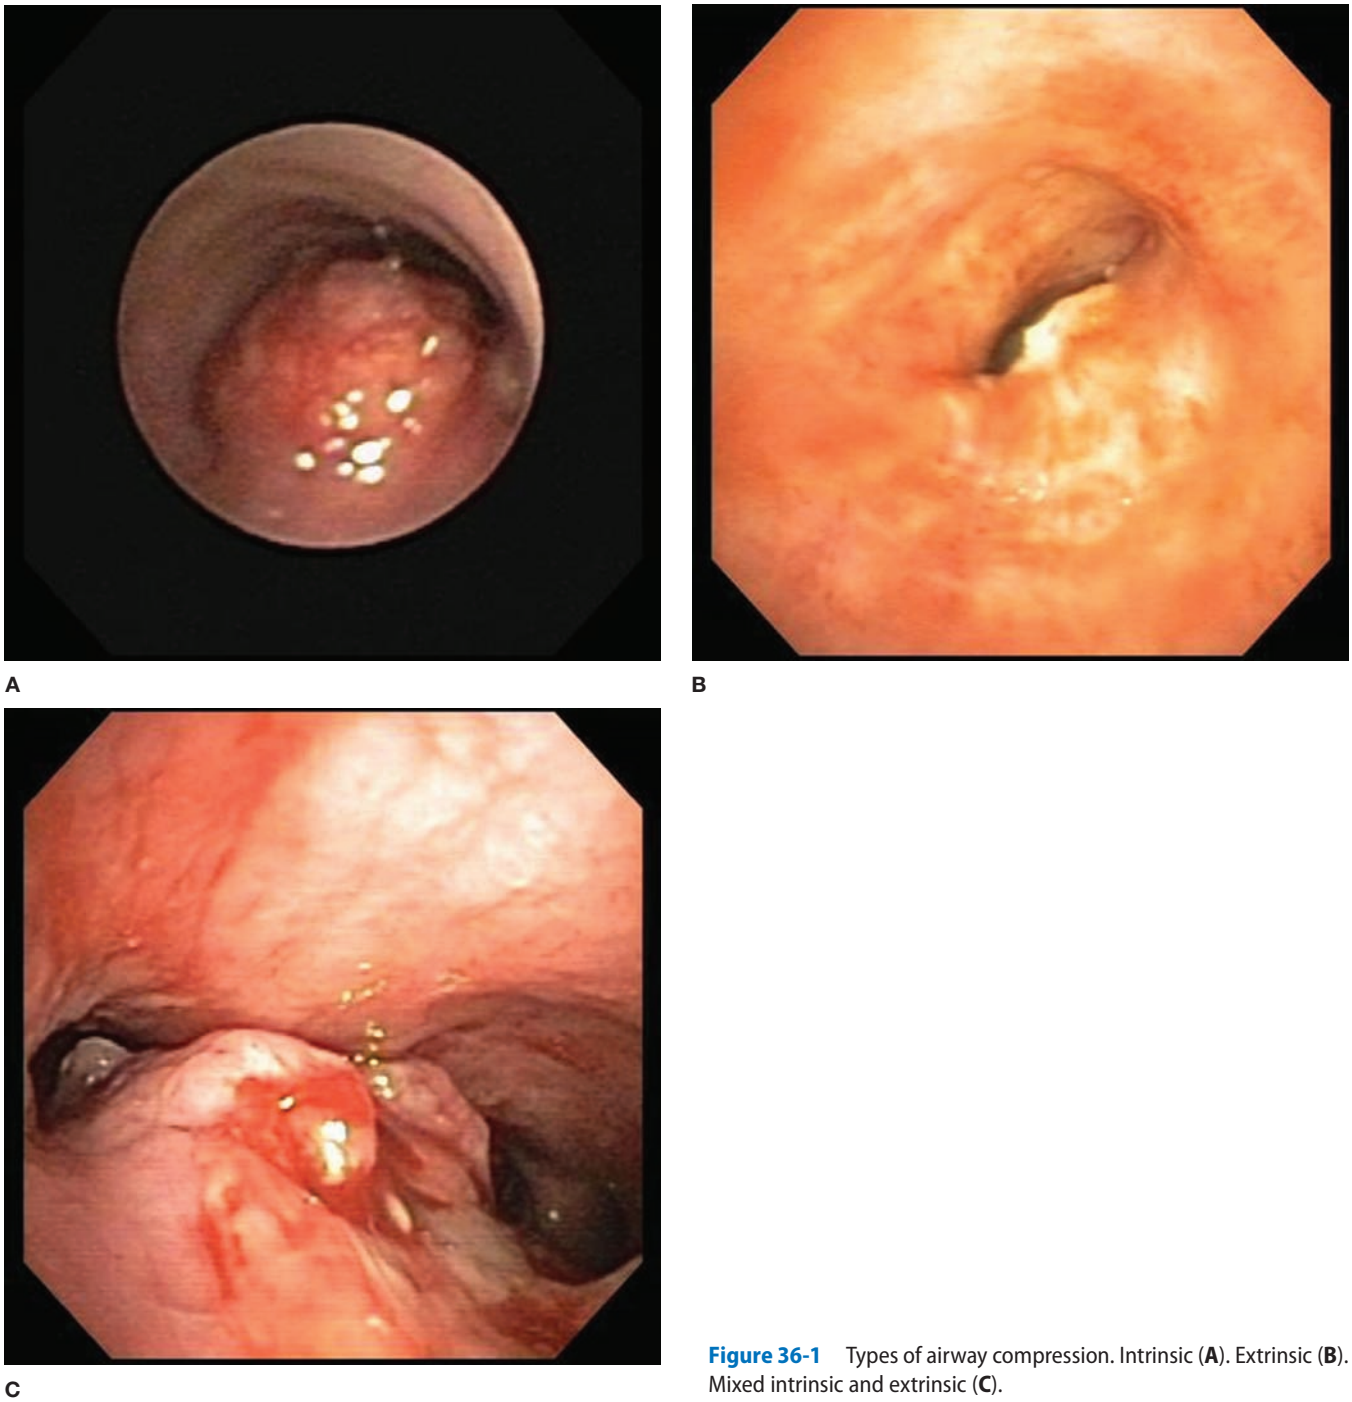

Figure 36-1 Types of airway compression. Intrinsic (**A**). Extrinsic (**B**). Mixed intrinsic and extrinsic (**C**).

illumination and visualization. The main advantage of rigid bronchoscopy over flexible bronchoscopy is its luminal working diameter, which allows multiple therapeutic instruments to be utilized simultaneously while ventilating the patient. Rigid bronchoscopy allows a number of therapies, such as laser photocoagulation, placement of endobronchial stents, balloon dilation, electrocautery, argon beam coagulation, and cryotherapy to be performed safely and effectively. Perhaps most importantly, in the setting of malignant airway disease or obstruction, a rigid bronchoscope can be used to "core out" large bulky airway tumors more efficiently and effectively than any thermal modalities (Video 36-1). Initial rigid bronchoscopic debulking, followed by thermal modality ablation to cauterize remaining tumor is common.[5] For benign, fibrotic airway stenosis, the rigid bronchoscope becomes a very effective modality to partially debulk stenotic tissue and to dilate the stenosis.[6] In experienced centers, rigid bronchoscopic airway recanalization remains the treatment of choice for serious or life-threatening tracheobronchial obstruction.

The main complication from rigid bronchoscopy is dental injury from the scope cracking or fracturing teeth. Other complications, such as oropharyngeal laceration, arytenoid cartilage disarticulation, or vocal cord injury, are possible. Meticulous care upon rigid

bronchoscope intubation is critical to avoid these possible complications. Intrathoracic complications, such as airway perforation, major bleeding from tumor debulking, and pneumothorax or pneumomediastinum are also possible but are infrequent in experienced hands.

■ BALLOON TRACHEOBRONCHOPLASTY

Balloon dilatation has become an attractive alternative to rigid bronchoscopy for management of airway obstruction in benign and malignant airway obstruction, especially in anatomic locations where a rigid bronchoscope cannot enter or the luminal diameter is too narrow to allow safe rigid bronchoscope passage. High-pressure balloons of various lengths and diameters specifically designed for the tracheobronchial tree are readily available. These balloons are filled with saline or radio-opaque contrast media, advanced to the site of interest through the bronchoscope, and inflated until the desired diameter is attained.

In the setting of benign stenosis, an initial defect in the stenosis is often made with a thermal modality so as to control the stenotic release point (Fig. 36-2). This approach has been used successfully in benign stenoses from endobronchial tuberculosis, idiopathic subglottic stenosis, and post-transplant anastomotic strictures.[7] It is less successful when used alone to treat airway compromise accompanied by extrinsic airway compression, as the initial bronchoscopic improvement often rapidly returns to its original position as the extrinsic process persists. Complications of balloon tracheobronchoplasty include bronchospasm, chest pain, mucosal laceration, airway perforation, bleeding, postprocedure airway edema, pneumothorax, and pneumomediastinum.

■ BRONCHOSCOPIC LASER THERAPY

Perhaps the most widely known technique in therapeutic bronchoscopy is laser photocoagulation or photoablation. Table 36-3

TABLE 36-3 Therapeutic Bronchoscopy Ablation Modalities

Therapy	Type of Lesion Therapy	Type of Bronchoscope	Rapidity of Positive Result	Repeatability
Mechanical debridement	Endoluminal or submucosal	Rigid or flexible (rigid preferable)	++++	+
Laser	Endoluminal	Rigid or flexible (rigid preferable)	++++	++++
Argon plasma	Endoluminal	Rigid or flexible	++++	++++
Brachytherapy	Endoluminal or submucosal	Flexible	+	+
Cryotherapy	Endoluminal	Rigid or flexible	++	+++
Balloon dilation	Endoluminal or submucosal with extraluminal compression	Rigid or flexible (rigid preferable)	++++	++++
Photodynamic therapy	Endoluminal	Flexible	++	+++
Electrocautery	Endoluminal	Rigid or flexible	+++	++++
Stent	Endoluminal with extraluminal compression	Rigid or flexible (Dumon stent requires rigid bronchoscope; Wall stents and Gianturco stents require fluoroscopy)	++++	+++

compares characteristics of the laser modality compared with other modalities to be presented later. Lasers produce a beam of monochromatic, coherent light that induces tissue vaporization, coagulation, hemostasis, and necrosis. Although primarily useful in endoluminal malignant tumor ablation, bronchoscopic laser therapy also is beneficial in other tracheobronchial disorders, including inflammatory strictures, obstructive granulation tissue, amyloidosis, and benign tumors, such as hamartomas and lipomas.

Since the initial report of endobronchial laser ablation of an obstructive neoplasm by Laforet in 1976, several types of lasers have become available for management of tracheobronchial obstruction.[8] The carbon dioxide (CO_2) laser, used primarily by otolaryngologists, allows shallow tissue penetration (to a depth of 0.1–0.5 mm) and very precise cutting, but it has minimal hemostatic properties. With the development of other laser modalities, the CO_2 laser has minimal current application in endobronchial tumor ablation, and its role remains primarily in management of laryngeal lesions.

For therapeutic bronchoscopy, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser ablation is most commonly used (Video 36-2). It provides tissue penetration to a depth of 3 to 5 mm, superior coagulation and improved hemostasis, but at the cost of less cutting precision. Nd:YAG laser procedures may be performed through a rigid or flexible bronchoscope. Success rates and complications directly related to laser therapy are not different when the procedure is performed through a rigid bronchoscope with the patient under general anesthesia, or through a flexible bronchoscope with use of topical anesthesia and moderate sedation.

Use of Nd:YAG laser photoablation therapy as a single modality is associated with a recanalization rate >90% for endobronchial obstruction of large central airways; however, it is less successful in treating peripheral lesions or extrinsic airway compression.[9,10] Nd:YAG laser photocoagulation may be an important treatment tool for patients with airway obstruction caused by benign endoluminal tumors. The Nd:Yap (yttrium-aluminum-perovskite) laser, with a patented wavelength of 1.34 μ wavelength, is purported to have better water absorption at that wavelength, improving the power-to-effective ratio compared with traditional Nd:YAG laser and carrying a lower complication risk.

Although endobronchial laser therapy generally is safe and well tolerated, it may be complicated by cardiac arrhythmias, airway perforation, pneumothorax, hemorrhage, hypoxemia, or endobronchial fire.[11,12] Endoluminal laser utilization requires careful consideration of the lesion anatomic location and configuration relative to vital intrathoracic structures. If the lesion is in close proximity to the esophagus or pulmonary artery, endobronchial laser therapy carries risk for fistula formation. Laser therapy in a patient with tracheobronchial narrowing caused by extrinsic compression may result in airway perforation. In rare cases, pulmonary edema or fatal pulmonary venous gas embolism have been reported.[13] Patients with standard silicone endotracheal tubes or silicone tracheobronchial stents, and those who require high concentrations of supplemental oxygen, are at increased risk for endobronchial fire. The bronchoscopist needs to ensure the inspired oxygen level is, ideally, <40%, especially if the patient is receiving mechanical ventilator support during the procedure. Fortunately, the overall risk of endobronchial fire is <0.1%.

■ ENDOBRONCHIAL ELECTROCAUTERY AND CRYOTHERAPY

Electrocautery and cryotherapy are cost-effective alternatives to laser therapy for the management of tracheobronchial lesions and obstruction, as equipment expenses are substantially less compared to laser therapy. Penetration depth and per treatment effectiveness may be less than with laser therapy.

Video 36-3 A patient with a history of renal cell carcinoma who presented with dyspnea and left lung atelectasis. CT scan demonstrated left mainstem bronchus obstruction. The video shows a rigid bronchoscopy with electrocautery snare excision and removal of a large polypoid renal carcinoma metastasis. The point of airway attachment was then cauterized using electrocautery. *Access at www.fishmansonline.com*

As with the Nd:YAG laser, both electrocautery and cryotherapy may be administered through either a rigid or flexible bronchoscope. Electrocautery effects on tissue are similar to those of Nd:YAG laser, with tissue destruction induced by coagulative necrosis (Video 36-3). Argon plasma coagulation (APC) is similar to electrocautery except that it uses argon gas to conduct the electrical current rather than a contact probe. Electrocautery and APC have a 1- to 3–mm penetration depth and are, therefore, more suitable for the treatment of superficial and spreading lesions (Video 36-4).

In contrast with electrocautery or APC, cryotherapy induces tissue necrosis through hypothermic intracellular crystallization and microthrombosis. Specially designed cryoprobes are inserted through the bronchoscope until they contact target tissue. Cryoprobe activation introduces liquid nitrous oxide or liquid nitrogen through a small orifice in the probe under pressure, resulting in rapid cryoprobe cooling with creation of an "ice ball" (approximate temperature, 20°C) at the probe tip on target tissue. This freezing effect is maintained for approximately 20 seconds; the area is then allowed to thaw, and freezing is repeated 2 to 3 times to achieve necrosis by cellular rupture from repeated cycles of intracellular micro-crystallization.

Electrocautery, APC, and cryotherapy have been used successfully to relieve airway obstruction and treat hemoptysis caused by benign and malignant tracheobronchial tumors, polyps, and granulation tissue.[5,9,14–19] These modalities have been used effectively in radiographically occult mucosal lung cancer, carcinoma in situ, and mucosal dysplasia. Cryotherapy may be advantageous in cryoextraction of foreign bodies that can be frozen to the probe and removed.[20] This technique works very well for mucoid plugs or blood clots in large airways where other modalities may be associated with some difficulty in successful removal. Due to the repeat treatment cycles needed to achieve effect, cryotherapy is not ideal for efficient relief of symptomatic airway obstruction.

Although the range of complications from electrocautery and cryotherapy are the same as those discussed for laser therapy, the most common complication of each is bleeding secondary to disruption of endobronchial tumor without full-tissue coagulation. The estimated incidence of clinically significant bleeding in patients treated with electrocautery is 2.5%. Rarely, gas embolism can occur with APC.[21,22]

■ ENDOBRONCHIAL BRACHYTHERAPY

Endobronchial brachytherapy refers to bronchoscopic radiation delivery to a localized airway lesion; it is often referred to as high dose-rate brachytherapy (HDRB) due to high radiation dosage delivery to a focused area. The technique aims to delivery therapeutic radiation to localized lesions while minimizing risk to nontarget tissues.

Video 36-4 This patient had a prior bronchoscopy for minor hemoptysis; endobronchial biopsies demonstrated carcinoma in situ. The video demonstrates argon plasma coagulation ablation of the involved sites from prior biopsies. *Access at www.fishmansonline.com*

Endobronchial brachytherapy involves the bronchoscopic insertion of a thin, hollow "afterloading" catheter across an area of interest (usually malignant) under direct bronchoscopic and fluoroscopic guidance. The catheter is left in place and the patient travels to a radiation oncology department where radioactive beads are inserted into the catheter at the desired location for a predetermined period, depending on the dose rate.

Relief of airway obstruction is the primary goal of HDRB, although curative treatment may be attempted in more advanced lesions by combining HDRB with external beam irradiation in selected patients. HDRB is not effective for rapid airway recanalization due to its delay in response of 14 to 21 days. It is best used as an adjunct to rigid bronchoscopy with or without thermal tumor ablation, endobronchial stent placement, or conventional external beam irradiation to recanalize an obstructed airway. HDRB appears safest and most effective for management of central airway lesions. Among patients with malignant airway obstruction, recanalization rates range from 60% to 90%, with decreased dyspnea, cessation of hemoptysis, and relief of cough in most cases.[16,23,24] HDRB has also been shown to be effective for radiographically occult, minimally invasive cancer in central airways, CIS, or mucosal dysplasia. Moreover, reports of the utility of HDRB in management of benign granulation tissue in lung transplant recipients or patients with or subglottic stenosis have been reported.[25–27]

Serious complications of HDRB can occur, particularly massive hemoptysis, from bronchovascular fistula formation secondary to necrosis of the airway wall and adjacent vascular structures. Because of the risk of fatal hemorrhage, every effort should be made to rule out central vascular tumor involvement before application of HDRB.

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) currently is FDA-approved for palliation of malignant airway obstruction and as an alternative to surgery in selected patients with minimally invasive central lung cancer or CIS. PDT works on the principle that certain compounds, such as hematoporphyrin derivatives or aminolevulinic acid (ALA), function as photosensitizing agents, rendering malignant cells susceptible to damage from monochromatic light. Tumor necrosis occurs as a result of oxygen free radical formation and ischemic vasculature necrosis mediated by thromboxane A_2 release.

The selective PDT effect on malignant cells is thought to be due to greater photosensitizing agent uptake and retention in neoplastic cells compared with normal cells; the exception is reticuloendothelial cells, particularly those in the skin. The relative tumor selectivity is most pronounced within 24 to 48 hours after photosensitizing agent infusion; therefore, treatment of the bronchoscopically targeted lesion should be performed within that time frame. Maximal tissue necrosis occurs 24 to 48 hours after light administration and requires repeat bronchoscopy to debride the necrotic and sloughed area treated. Due to the delayed onset of PDT action, it is not useful in patients with acute respiratory distress from evolving airway obstruction.

Ideal candidates for PDT include patients with airway obstruction caused by malignant endobronchial masses with minimal extrinsic airway compression, and patients with minimally invasive central airway tumors. Although surgical resection remains the treatment of choice for early lung cancer, some patients refuse surgery or have tumors that are deemed inoperable because of high surgical risk. In these cases, PDT may represent an appropriate alternative. Response rates are highest in patients with small tumors and minimal airway penetration depth.[28,29] In patients with bulky tumors, endobronchial PDT may substantially reduce the obstruction, with objective increases in spirometric measurements and subjective improvement in dyspnea and quality of life; however, treatment is not curative.[30] Endoluminal metastatic tumors may also be treated successfully with PDT.

Complications of PDT include increased skin photosensitivity and hemoptysis resulting from extensive tumor necrosis into a vascular structure. Cutaneous photosensitivity, similar to a sunburn, occurs in up to 20% of patients in various reported series; it may be obviated by adequate sunlight precautions. Sensitivity to sunlight after photosensitizer administration may persist for 6 weeks or longer.

TRACHEOBRONCHIAL STENTING

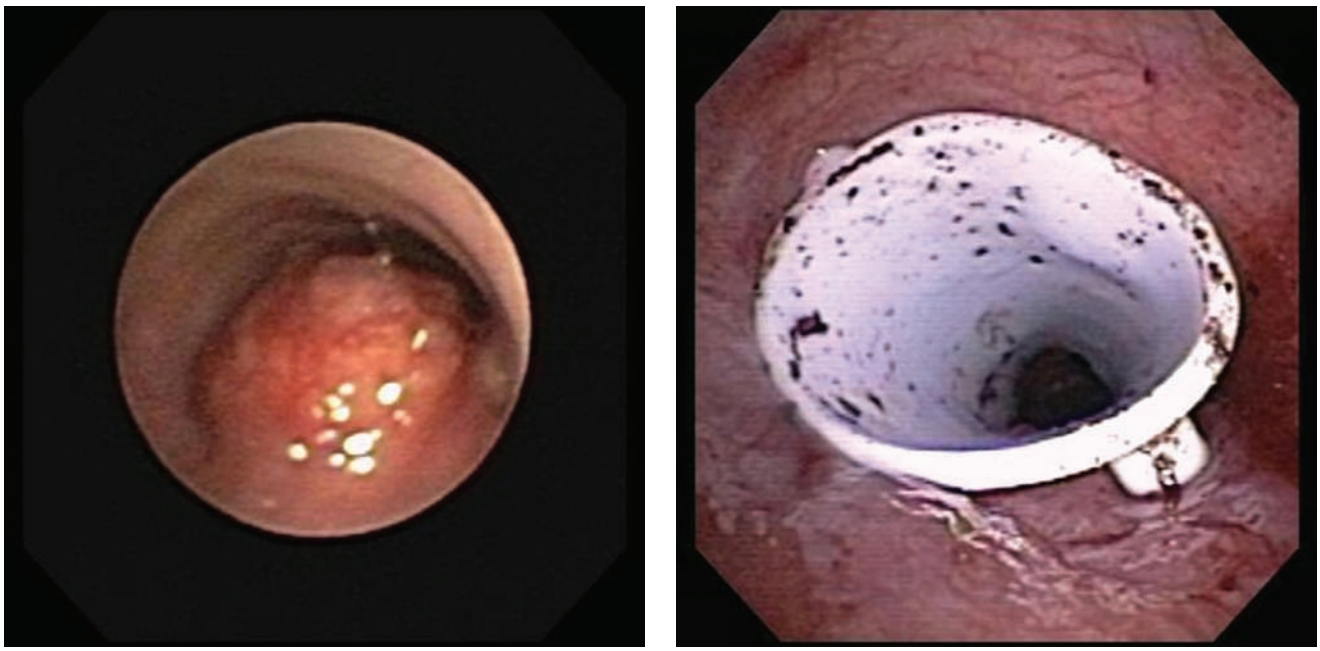
The medical term, "stent" refers to any device designed to maintain the integrity of hollow tubular structures, such as the airways, coronary arteries, or esophagus. Anecdotal reports of attempts to implant stents in the tracheobronchial tree date back to 1915. The Montgomery T-tube, designed in the 1960s, was the first reliable, dedicated airway stent.[31] However, stent implantation in the lower trachea and bronchi did not become standard medical practice until 1990, when Jean Francois Dumon reported the safety and ease of placement of a dedicated silicone airway stent.[32]

Two main types of endobronchial stents are in use today—silicone or self-expanding metal (SEMS). Silicone stents generally are placed by rigid bronchoscopy with the patient under general anesthesia. Silicone stents are relatively inexpensive (~$500 USD) compared with SEMSs (~$2000 USD). Bifurcated silicone stents also are available and have been effectively used in the management of carinal compression associated with malignant tumors, tracheoesophageal fistulas, and tracheobronchomalacia.

Unlike silicone stents, SEMSs may be placed using flexible bronchoscopy and require less technical rigor than silicone stent placement. The main limitation with SEMS is that uncovered varieties may induce mucosal inflammation and granulation tissue formation which may require repeat endoscopic intervention to maintain airway patency.[33–35] For this reason, SEMSs have an FDA black-box warning against their utilization in *benign* airway stenosis, unless all other treatment options, including silicone stenting, have been explored and failed. An exception to this warning applies in bronchial anastomotic dehiscence in lung transplantation. In this setting, insertion of a temporary uncovered SEMS across the dehiscence exploits the fact that focal granulation tissue may develop and promote dehiscence closure.[36]

Endobronchial stents have a critical role in multimodality bronchoscopic approaches to both benign and malignant airway obstruction. Airway obstruction caused by locally advanced lung carcinoma may be treated with a combination of thermal tumor ablation and stent implantation to regain and preserve airway lumen diameter by preventing tumor ingrowth (Fig. 36-3). Stent placement may be combined with balloon dilatation in the endoscopic management of benign fibrotic strictures. Most large studies of endobronchial stent placement have demonstrated impressive efficacy.

Dumon and colleagues reported excellent clinical outcomes and few complications with silicone stent placement in patients with malignant airway obstruction; a lower success rate was noted among patients with tracheal stenosis caused by other disorders.[32] Success, broadly defined as symptomatic relief, in limited studies has been reported to be achieved in between 78% and 98%, although none of the early trials used objective measures to determine efficacy.[37–39] In a small study in patients who were intubated because of respiratory failure secondary to unresectable tracheobronchial and mediastinal disease, stent placement facilitated extubation in most.[40] Stent placement benefits seem to persist in patients who survive for a period of several months or years after stent implantation. Long-term follow-up data are derived from patients with benign disease, since the mean follow-up period in patients with malignant airway obstruction usually does not exceed 3 to 4 months.



A B

Figure 36-3 A large tumor nearly completely obstructs the tracheal lumen (**A**). Manual debulking using a rigid bronchoscope dramatically improved airway luminal diameter. An endotracheal silicone stent was placed to prevent tracheal re-occlusion (**B**).

Complications from endobronchial stents include stent migration, granulation tissue formation, tumor overgrowth, stent bacterial colonization and recurring infection, stent fracture, and inspissated secretions clogging the stent. In addition, massive and fatal hemorrhage associated with stent erosion into central vascular structures can occur.

Stenting for Tracheobronchomalacia

Diffuse or focal tracheobronchomalacia is, perhaps, the most challenging disorder encountered by the therapeutic bronchoscopist. Cartilaginous tracheobronchomalacia reflects tracheal or main bronchi circumferential exhalation airway collapse due to loss of structural integrity of the airway cartilaginous rings. Membranous, or crescentic, tracheobronchomalacia, also known as excessive dynamic airway collapse (EDAC), is manifested by intact cartilaginous rings, but anterior displacement of the posterior membrane during exhalation to variable degree as a result of posterior membrane laxity. This condition is commonly seen with COPD, asthma, obesity, and chronic cough. Dynamic CT scanning may suggest tracheobronchomalacia or EDAC, but the gold standard remains flexible bronchoscopy performed to assess airway collapse with the patient breathing spontaneously.[41] Focal airway malacia may be a complication of long-standing intubation or an anastomotic complication after lung transplantation.[42]

The endoscopist must maintain restraint in therapeutic interventions for patients with tracheobronchomalacia or EDAC. Management of diffuse tracheobronchomalacia should focus on identifying and treating any underlying conditions that may perpetuate cartilaginous inflammation (e.g., relapsing polychondritis) and airway collapse. If the tracheobronchomalacia is symptomatic and progressive despite systemic therapy, initial consideration for tracheostomy should be entertained. If symptoms are not resolved with tracheostomy, or if they recur or progress after an initial improvement, evaluation for placement of a silicone bifurcation Y stent should be undertaken. These patients may also require nighttime ventilator support. Patients with EDAC may benefit from a trial of silicone stent placement as well, but this should not be considered definitive therapy.[43,44] For those who benefit in terms of decreased respiratory symptoms and improved pulmonary function, silicone stent removal, followed by surgical plication or buttressing of the posterior membrane, can be performed with acceptable clinical outcomes.[43,45] For many patients with focal tracheomalacia, particularly from postintubation injury, surgical resection with primary reanastomosis may be the best therapeutic option. If patients are not surgical candidates or prefer to avoid surgery, silicone stent placement often will provide the structural integrity necessary to obviate patient symptoms, but at the risk of long-term stent complications.

■ MANAGEMENT OF HEMOPTYSIS

Bronchoscopy may be of value in hemoptysis for several reasons: to identify site of bleeding, to provide endobronchial therapy to reduce or stop bleeding, to clear blood clots that might impair gas exchange, or to place an endoluminal blocking device to prevent further airway occlusion with blood. Because of visualization difficulties during active bleeding, instruments with large and maximally effective suction channels should be used. Rigid bronchoscopy generally is preferred with massive bleeding or when the need to remove large clots is anticipated.

In attempts to cease bleeding, iced saline or an epinephrine solution can be instilled into a bleeding airway or applied topically onto a proximal bleeding site in attempt to induce vasoconstriction. In addition, balloon catheters can be placed into the bleeding airway to tamponade bleeding and prevent proximal airway soilage in hope of generating a hemostatic clot. Large endobronchial blockers are available to occlude the entire right or left mainstem bronchus to control bleeding. Other effective methods for control of proximal visible bleeding sources, particularly from endobronchial neoplasms, are thermal modalities, such as Nd:YAG laser or APC photocoagulation.[46] Recent reports have demonstrated the benefit from endobronchial packing accomplished with either flexible or rigid bronchoscopy using oxidized regenerated cellulose, which isolates the segmental or subsegmental bleeding site and promotes endobronchial clot formation by induction of fibrin polymerization.[47,48] Frequently, these procedures are temporizing, while definitive management with surgery or bronchial artery embolization is considered.[49]

FOREIGN BODY REMOVAL

Bronchoscopy was developed primarily for foreign body removal; prior to the lung cancer epidemic, foreign body removal represented the overwhelming indication for bronchoscopy for decades.

Foreign body aspiration is more likely to occur in children than in adults, with most foreign bodies occurring in children younger than 3 years. In children, the foreign body most often lodges in a mainstem bronchus, whereas in adults foreign bodies usually are wedged distally, most commonly in the right lower lobe. Before bronchoscopic extraction was possible, most foreign body aspirations resulted in high morbidity and mortality, commonly from postobstructive pneumonia. Today, foreign bodies can be removed with either flexible or rigid bronchoscopy, depending on local expertise and foreign body size and composition. If available, rigid bronchoscopy remains the tool of choice for foreign body removal due to several factors: a larger access channel, which permits use of larger and more adaptable retrieval tools; protection of the vocal cords from trauma upon (foreign body) removal; and ability to provide and maintain ventilation.

Various instruments have been developed for use with bronchoscopy for foreign body removal, including grasping forceps, balloon catheters, retrieval baskets, snares, and magnetic extractors. The instrument choice depends on the foreign body material composition, size, shape, and location in the tracheobronchial tree. Grasping forceps may be helpful in the retrieval of hard objects with an irregular surface. Smooth objects or organic material (e.g., nuts, food particles) may require use of expandable baskets or a combination of balloon catheters, suction devices, and grasping forceps. Balloon catheters frequently are used to dislodge a foreign body and bring it proximally into a larger airway before its removal with other instruments.

SECRETION ASPIRATION

According to a survey of bronchoscopists in the United States, removal of retained secretions is cited as a leading indication for therapeutic bronchoscopy. Aspiration of bronchoscopic secretions may be indicated in patients with respiratory muscle weakness (e.g., due to underlying neuromuscular disease or the postoperative state) who cannot generate adequate cough for secretion clearance. In critically ill or mechanically ventilated patients, removal of secretions and mucus plugs usually can be rapidly achieved with flexible bronchoscopy. For ease of secretion removal, a flexible scope with a large diameter suction channel is ideal. The secretion volume and viscosity may dictate the interval necessary for bronchoscopy procedures to relieve segmental or lobar atelectasis from inspissated mucus plugs. Bronchoscopic secretion aspiration should not be considered "routine" in the postoperative period or in other conditions in which good chest physiotherapy and maintenance of adequate pulmonary toilet may be more effective.

Two specific disorders are worth highlighting in the context of therapeutic bronchoscopy: pulmonary alveolar proteinosis (PAP) and allergic bronchopulmonary aspergillosis (ABPA). In PAP, large-volume repeated bronchoalveolar lavage has been used for therapeutic clearance of alveolar material composed predominantly of surfactant.[50,51] For patients with more extensive disease or impaired gas exchange, the standard approach is sequential whole-lung lavage.[52] In ABPA, lavage with saline solution may be insufficient to remove tenacious secretion impactions (described as "plastic bronchitis"), and use of bronchoscopic forceps or snare may prove helpful.

CLOSURE OF BRONCHOPLEURAL FISTULA

Prolonged air leaks may be encountered following primary or secondary spontaneous pneumothorax, particularly in the setting of underlying parenchymal lung disease; however, they are more commonly seen pulmonary resection. Current management for prolonged air leaks usually includes prolonged chest tube drainage using a Heimlich valve, attempts at surgical repair, pleural blood patch, or pleurodesis.

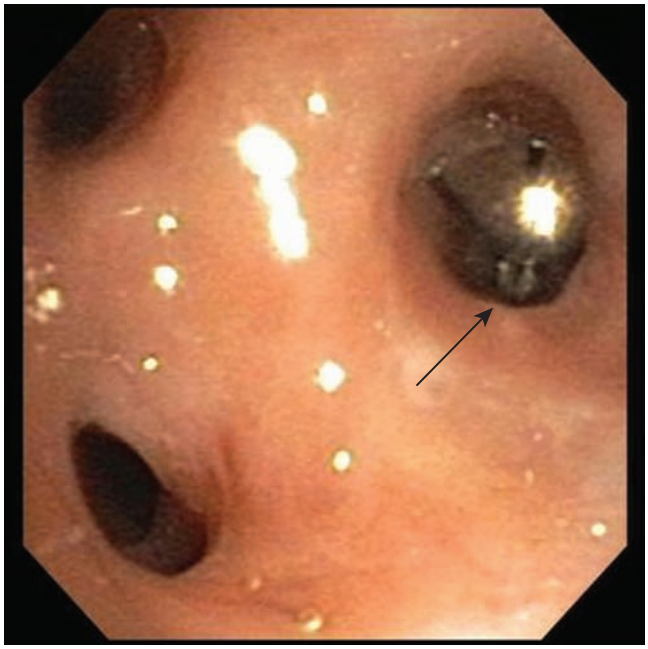


Figure 36-4 A patient presented with a spontaneous pneumothorax from severe emphysema. A chest tube was placed in the left chest and a persistent air leak was noted. Balloon occlusion localized the leak to the left upper lobe anterior segment. A one way endobronchial valve was placed *(arrow)* with complete air leak resolution.

Therapeutic bronchoscopy may be a useful adjunct to prolonged air-leak intervention in confirming suspected bronchopleural or alveolopleural fistulae and in specifying their precise location. The most common approach is to perform selective balloon catheter airway occlusion while observing the chest tube air-leak rate and volume. Depending on the fistula location and size, bronchoscopic procedures can be attempted with the goal of occluding and sealing the bronchopleural fistula. It is much more difficult to achieve fistula obliteration in an area of infected lung or recurrent malignancy. Many different techniques for permanent closure have been reported. Several potentially useful agents have been described, including surgical gel, autologous airway blood patch, and thrombin injection to create fibrin clot, among a variety of others.[53–55] In addition, laser photocoagulation or hypertonic saline injection surrounding small, proximal bronchopleural fistulas has been reported to be beneficial. Recent reports suggest that the placement of one-way endobronchial valves may effectively lead to complete or partial resolution in the large majority of patients with prolonged air leaks from diverse causes (Fig. 36-4).[56–59]

BRONCHOSCOPIC TREATMENTS FOR COMMON BENIGN LUNG CONDITIONS

One of the major advances in therapeutic bronchoscopic use over the past decade has been the development of experimental bronchoscopic interventions for highly prevalent lung diseases, such as asthma and emphysema.

BRONCHOSCOPIC EMPHYSEMA TREATMENT

The National Emphysema Treatment Trial (NETT) demonstrated the role of lung volume reduction surgery (LVRS) as the first major surgical intervention for emphysema to improve patient symptoms, as well as mortality, in certain patient subsets.[60] Unfortunately, these benefits were associated with an approximate 5% procedural mortality and substantial perioperative morbidity, including prolong air leaks and cardiac arrhythmias. These factors have spurred

Video 36-5 The video demonstrates fluoroscopic deployment of an investigational endobronchial coil for treatment of emphysema. *Access at www.fishmansonline.com*

development of minimally invasive, bronchoscopic approaches to achieve similar outcomes as the NETT trial, but without the considerable morbidity observed.

The bronchoscopic lung volume reduction (BLVR) approaches under ongoing evaluation utilize a range of techniques, including airway occlusion using silicone plugs (the Endobronchial Watanabe Spigot); insertion of one-way bronchial valves; creation of artificial noncompressible communications ("bypass tracts") between cartilaginous airways and emphysematous parenchyma,[61] injection of a biologic glue to promote scarring,[62] treatment of affected lung segments with steam,[63,64] and placement of endobronchial coils (Video 36-5).[65]

Endobronchial valves have been studied most extensively and are designed to limit ventilation to the most severely involved lung regions in emphysema in an effort to reduce total lung volume, residual volume, and dynamic hyperinflation.[66,67] When placed correctly, the valves allow one-way flow of secretions and air out of the occluded pulmonary segment but prevent air entry beyond the valve (Video 36-6). The major advantage of the bronchial valves is reversibility; that is, the valves generally are removable with minimal risk to the patient. Preliminary studies have suggested that collateral ventilation across incomplete fissures may reduce bronchial valve effectiveness.[68]

Results from the first randomized study of endobronchial valves, a double-blinded, sham-controlled multicenter trial of the Zephyr endobronchial valve, demonstrated modest increases in forced expiratory ventilation in 1 second (FEV_1) and 6-minute walk distance at 6 months; unfortunately, there was an increased rate of complications, including COPD exacerbations and hemoptysis.[69] This valve is available for placement in Europe and Asia, but it is not approved in the United States at this time. One of the major downsides of the biologic approaches to induce scarring and atelectasis is development of permanent lung tissue destruction, with no option for reversibility in the event of worsening lung function or development of cancer. These approaches remain under investigation. Selecting the best technology for use in appropriate patients will be key; it is unlikely that a single approach will apply to all patients with emphysema.

BRONCHIAL THERMOPLASTY

Chronic asthma is a major cause of morbidity, increased health care utilization and cost, and death. Bronchial thermoplasty (BT) is a new bronchoscopic procedure that delivers controlled radiofrequency energy to the bronchial wall of conducting airways with the intent of inhibiting airway smooth muscle contractile function and attenuating bronchoconstriction during asthma exacerbations.

BT is performed using a radiofrequency device that delivers thermal energy to the bronchial wall during an outpatient bronchoscopic procedure. Three separate procedures are performed in order to treat all accessible upper and lower lobe airways ranging from 3 to 10 mm in diameter (Fig. 36-5). The initial randomized, multicenter Airway Intervention with Radiofrequency (AIR) trial in patients with moderate-to-severe disease demonstrated decreased asthma exacerbations

Video 36-6 A patient with severe, heterogeneous, upper lobe-predominant emphysema who was enrolled in a clinical trial of endobronchial valves. The video demonstrates valve deployment device positioning and valve deployment. *Access at www.fishmansonline.com*

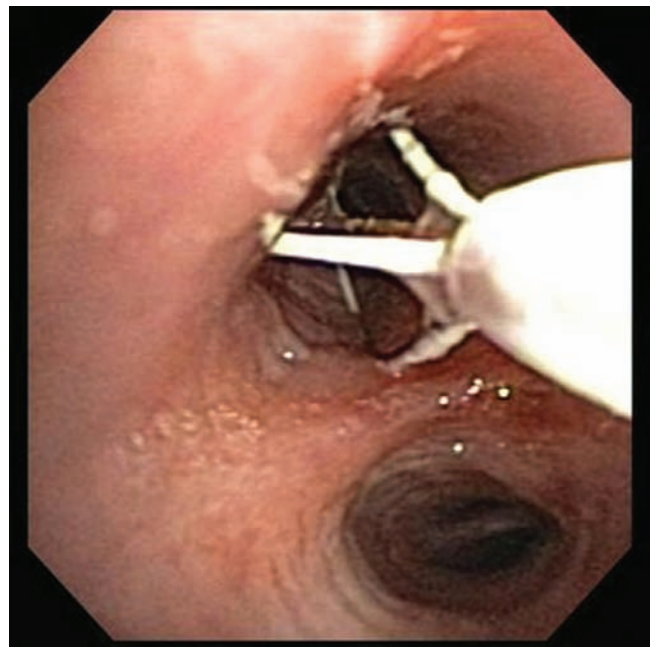

Figure 36-5 Radiofrequency array used in the airway for bronchial thermoplasty in patients with severe asthma.

in the group undergoing BT compared with patients on standard medical treatment alone.[70] This study was followed by a randomized, sham-controlled, multicenter trial (AIR2) which demonstrated significant improvement in the primary end point—asthma-related quality of life.[71] Although an increase was noted in early post-treatment asthma exacerbations requiring emergency department visits and hospitalizations, long-term follow-up data showed decreased asthma-related health care utilization for patients undergoing BT compared with those undergoing the sham procedure.[72] Based on these data, BT received FDA approval for patients with severe asthma in April 2010, but procedural reimbursement remains problematic with most private insurers. Studies are ongoing to collect additional safety data and to assess the durability of the treatment effect.

SUMMARY

Technologic advances in bronchoscopy continue to improve the pulmonologist's ability to perform minimally invasive, accurate evaluations of the tracheobronchial tree and to implement an ever-increasing array of therapeutic and palliative airway interventions. The role of therapeutic bronchoscopy will continue to evolve as further improvements are made in bronchoscopes, accessory equipment, imaging techniques, and novel technologies to treat lung diseases in which bronchoscopy was once thought to have no role. Therapeutic bronchoscopy may soon be used to provide treatment for conditions that traditionally have been treated with surgery. The major challenges in adopting many new bronchoscopic techniques into routine clinical practice will be ensuring adequate procedural competence and having well-designed studies to delineate the appropriate use of the interventions.

CHAPTER 37

Diagnostic Thoracic Surgical Procedures: Thoracoscopy, VATS, and Thoracotomy

Robert E. Merritt

INTRODUCTION

Thoracoscopy, video-assisted thoracic surgery (VATS), and thoracotomy are well-established surgical techniques used by thoracic surgeons to diagnose benign and malignant diseases involving the thorax.

Thoracoscopy first emerged as a diagnostic tool in the early 20th century when therapeutic pneumothorax became the surgical treatment of choice for tuberculosis. In 1910, Hans Christian Jacobaeus performed the first thoracoscopic intrapleural pneumolysis for collapse therapy in the treatment of tuberculosis.[1–3] He used a rigid cystoscope with a light source to access the pleural cavity and perform a pneumolysis. After development of effective antimicrobial therapy for tuberculosis, thoracoscopy evolved as an effective diagnostic procedure to evaluate pleural effusions and pleural disease.[4] During direct diagnostic thoracoscopy, a fiberoptic mediastinoscope or bronchoscope was placed through a small intercostal incision; pleural fluid could be aspirated and sent for analysis (Fig. 37-1). In addition, the parietal pleura, visceral pleura, fissures, hilum, and diaphragm could be inspected directly.[5]

By 1990, thoracoscopy evolved into VATS. Development of high-resolution video cameras and endoscopic linear mechanical stapling devices allowed the expansion of application of VATS into the diagnosis and treatment of pulmonary nodules and interstitial lung diseases (ILDs).[6,7] The use of diagnostic thoracotomy has declined significantly since the emergence of VATS; however, the diagnostic thoracotomy may be necessary in cases in which VATS is not feasible (Table 37-1).

TECHNICAL CONSIDERATIONS

VATS is performed in the operating room under general anesthesia. A double-lumen tube is placed to isolate the lungs to enable establishment of one-lung ventilation, which is essential for performing the procedure. The use of one-lung ventilation creates sufficient space for maneuvering within the hemithorax to perform the planned procedure. Carbon dioxide (CO_2) insufflation can also be used to provide additional working space within the chest cavity by lowering the position of the diaphragm. The more inferiorly located diaphragm provides better exposure of the costophrenic sulci and lower lobes. When CO_2 is used, the maximum insufflation pressure is maintained below 6 mm Hg to avoid decreased venous return to the right heart and associated hypotension.

The typical VATS procedure utilizes three to four incisions that range from 5 to 12 mm in size. The incisions are usually arranged in a triangular configuration, with the area of interest located in the center of the triangle. (Fig. 37-2) A 5- or 10-mm fiberoptic thoracoscope is connected to a video camera and is most commonly inserted into the most inferiorly placed VATS incision (Fig. 37-3). The chest cavity is clearly visualized on a video monitor and the parietal pleura, visceral pleura, hilum, diaphragm, and mediastinum can be directly inspected. Upon completion of the procedure, a chest tube is inserted under direct visualization through one of the VATS incisions to evacuate air and pleural fluid during the early postoperative period. Simple diagnostic VATS procedures are typically well tolerated, and patients can be discharged after 1 to 2 days in the hospital. Currently, the disease processes assessed using VATS are listed in Table 37-2.

MANAGEMENT OF PLEURAL DISEASE

Both malignant and benign diseases of the pleura may be diagnosed and managed with VATS. Although thoracentesis (including pleural fluid cytology analysis) is the initial diagnostic tool of choice for an undiagnosed pleural effusion, VATS procedures provide a higher diagnostic yield: 90% to 100% compared to 60% to 80% for thoracentesis.[8–10] When the diagnosis of a pleural effusion is not determined following thoracentesis, VATS can be utilized to obtained pleural fluid and pleural biopsies for definitive diagnosis.

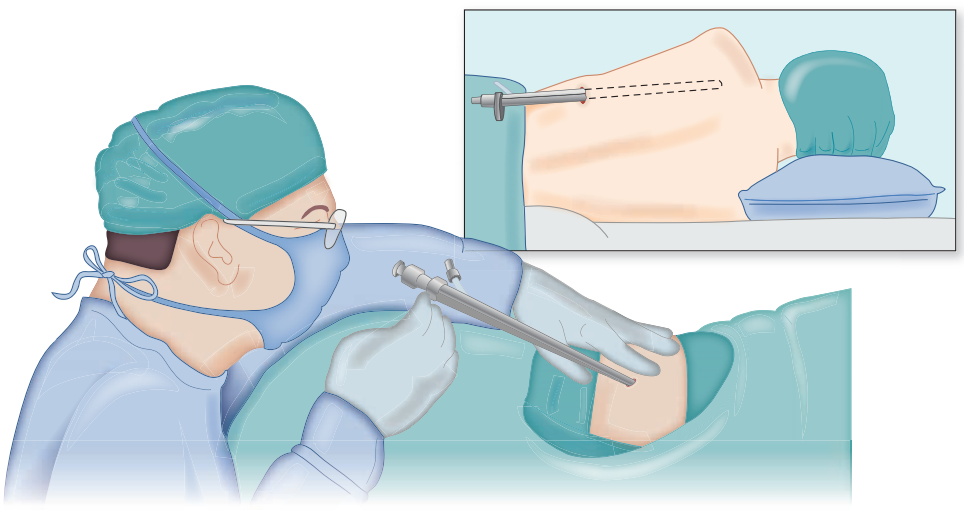

Figure 37-1 Use of a rigid bronchoscope as a thoracoscope.

TABLE 37-1 Contraindications to Video-Assisted Thoracic Surgery (VATS)

Severe hypoxia
Previous pneumonectomy or bilobectomy
Mechanical ventilator dependence
Severe chronic obstructive pulmonary disease
Pleural adhesions
Previous pleurodesis procedure
Coagulopathy
Recent acute myocardial infarction
Severe pulmonary hypertension

Malignant pleural effusions usually present as a result of an obstruction of subpleural lymphatics and are associated with advanced primary lung cancer or metastatic epithelial carcinomas that involve the lung. VATS may provide both diagnostic and therapeutic value in the management of malignant pleural effusions. A pleurodesis can be achieved by instilling chemical agents, such as talc, doxycycline, bleomycin, or tetracycline into the pleural cavity to promote pleural adhesion formation. The process obliterates the potential space between the parietal pleura and visceral pleura, thus preventing accumulation of pleural fluid. Efficacy rates in the range of 94% to 96% for VATS pleurodesis for malignant pleural effusions have been reported,[11,12] along with a morbidity rate of 2.6%.[12] In essence, the VATS approach for diagnosis and management of malignant pleural effusions is highly effective because it provides minimally invasive access to the thoracic cavity for sampling of fluid and pleural tissue, and it enables lysis of loculated adhesions and instillation of a chemical pleurodesis agent.

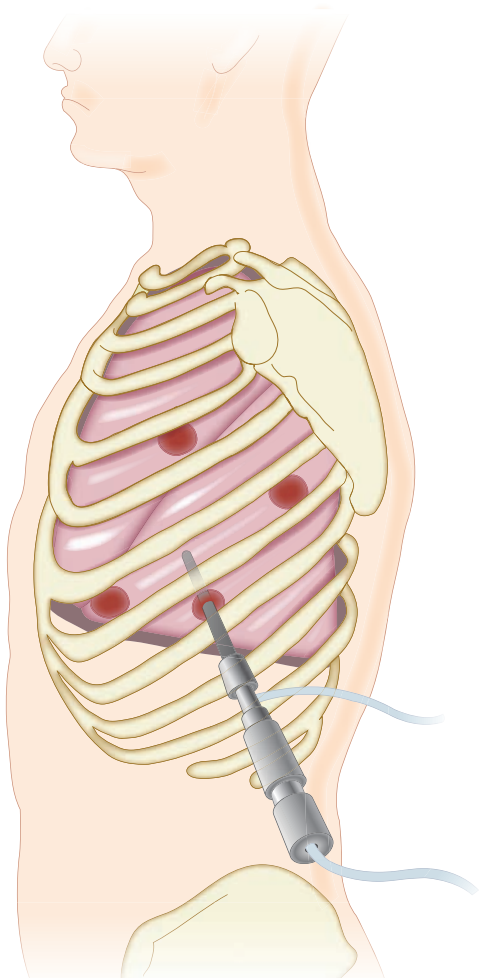

Figure 37-2 Placement of VATS incisions.

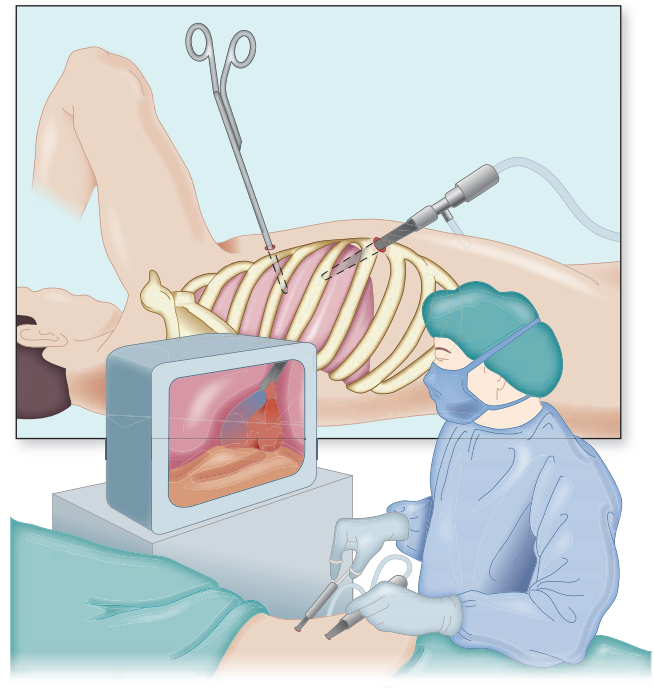

Figure 37-3 Placement of the thoracoscope through the most inferior of the VATS incisions. A video camera is connected to the thoracoscope and the image displayed on a video monitor.

The most common benign condition involving the pleura is an infection of the pleural space or empyema. Patients who present with pneumonia often have associated pleural effusions, which may be either a parapneumonic effusion or an empyema (see Chapter 76). The pleural fluid should be sampled with thoracentesis to enable the distinction between parapneumonic effusion and empyema. If the pleural fluid Gram stain or culture is positive for a pathogen, or if the fluid pH is less than 7.1, an empyema is diagnosed.

The classification of empyema is based on the temporal evolution of the pleural space infection and dictates the optimal management.

TABLE 37-2 Current Indications for Video-Assisted Thoracic Surgery (VATS)

Diagnosis of pleural effusion
Drainage of empyema
Pleurodesis
Diagnosis of a suspicious pulmonary nodule
Biopsy of the pleura
Lung biopsy for diagnosis of interstitial lung disease
Resection of pulmonary metastatic nodules
Resection of primary lung carcinoma
Biopsy of mediastinal lymph nodes
Resection of blebs or bullae for treatment of spontaneous pneumothorax
Drainage of pericardial effusion

Video 37-1 Use of VATS in drainage of empyema. *Access at www.fishmansonline.com*

Video 37-2 Use of VATS in evaluation of indeterminate pulmonary nodule. *Access at www.fishmansonline.com*

Three phases of empyema have been described: (1) The *exudative phase*, an initial phase characterized by free-flowing purulent fluid within the pleural space. Simple drainage with chest tube thoracostomy and intravenous antibiotics are usually sufficient to manage the pleural effusion. (2) The *fibropurulent phase*, characterized by loculated pleural fluid collections and fibrinous exudative deposits on the visceral pleural surfaces. In this phase, the empyema often requires a VATS or thoracotomy to lyse adhesions, break up loculations, and promote drainage of the purulent pleural fluid (Video 37-1). (3) The *fibrous phase*, characterized by formation of a thick, fibrous rind on the visceral pleural surface of the lung. A thoracotomy is usually required to achieve a complete decortication.

Early decortication using a VATS-based approach during the fibropurulent phase is highly effective and may significantly decrease morbidity associated with empyema.[13] VATS offers a decided advantage over simple chest tube thoracostomy because of multiple factors: (1) Loculated purulent fluid may be completely drained, since adhesions are directly visualized and lysed during VATS. (2) Atelectatic lung may be reexpanded under direct vision. (3) Chest tubes can be placed in the appropriate position for optimal drainage in the postoperative period.

The definitive drainage of purulent fluid associated with empyema using VATS can significantly improve patient outcomes and prevent progression to a fibrothorax, which often requires an open thoracotomy.

■ EVALUATION OF LUNG PARENCHYMAL DISEASE

Diagnosis of the solitary pulmonary nodule remains one of the most common indications for VATS. A widely cited, multi-institution, randomized study demonstrating a 20% reduction in lung cancer mortality using low-dose computed tomography (CT) to screen for lung nodules in patients at risk for lung cancer[14] will certainly increase enthusiasm for screening programs and enhance detection of indeterminate pulmonary nodules.

Currently available modalities for the diagnosis of indeterminate solitary pulmonary nodules include high-resolution CT, positron emission tomography (PET), CT-guided fine-needle aspiration (FNA), and VATS. In a randomized trial for evaluation of solitary lung nodules, CT scans performed with intravenous contrast administration have been shown to have an overall accuracy rate of 77%, sensitivity of 98%, and specificity of 58%.[15] The coupling of PET scan-based images with CT scans is often useful to determine if a lung nodule is hypermetabolic, which increases the probability of malignancy (see Chapter 32). In cases of granulomatous diseases, PET scans may generate false-positive results, as inflammatory cells readily accumulate the tracer employed, 18-fluorodeoxyglucose (18F-FDG). The sensitivity and specificity of PET–CT scanning in the evaluation of indeterminate solitary pulmonary nodules have been reported at 92% and 90%, respectively.[16]

Development of VATS has improved the diagnostic yield in evaluation of indeterminate solitary pulmonary nodules. This minimally invasive technique is well tolerated. Patients experience less postoperative pain and recover more quickly compared with patients who undergo conventional open thoracotomy.

Pulmonary nodules located in the outer third of the lung parenchyma are ideally suited for VATS wedge excisional biopsy. For lung lesions smaller than 10 mm, localization can be facilitated using transthoracic wire placement into the area of the lesion under CT guidance prior to the VATS procedure. In addition, the technique of navigational bronchoscopy (see Chapter 36, Sterman) can be employed to inject dye or place fiducial markers in close proximity to small nodules that might be difficult to locate during VATS. The diagnostic yield for VATS using wedge excision of a pulmonary nodule approaches 100%. Furthermore, since morbidity and mortality rates are exceedingly low, the VATS technique is ideal for evaluation of indeterminate pulmonary nodules (Video 37-2).

Although diffuse ILDs often present with characteristic patterns on CT scanning, histologic confirmation is often necessary to determine appropriate treatment. Reports indicate that in as many as 84% of cases of ILD evaluated with surgical lung biopsy, the course of therapy is altered by the biopsy findings.[17]

The VATS technique has been shown to result in less postoperative pain and lower morbidity compared with thoracotomy performed for purposes of lung biopsy.[18,19] Furthermore, in a randomized, controlled clinical trial, VATS and thoracotomy appear equivalent in postoperative outcomes when performed for diagnosis of ILD.[20]Given this diagnostic equivalency, and, in the author's experience, reduced postoperative pain, shorter hospital stay, and faster recovery associated with VATS, it remains the preferred diagnostic technique for patients with ILD who are ambulatory and have sufficient pulmonary reserve to tolerate one-lung ventilation. Thoracotomy is reserved for patients who are ventilator-dependent and too hypoxic to tolerate one-lung ventilation.

SUMMARY

Thoracoscopy, VATS, and thoracotomy are valuable diagnostic tools employed in the evaluation of benign and malignant diseases of the pleura and lung. VATS has emerged as a primary diagnostic method for diagnosis and treatment of malignant pleural effusions and empyema. In addition, VATS has improved the diagnostic yield in evaluation of indeterminate solitary pulmonary nodules. VATS has largely replaced diagnostic thoracotomy for ILD, since VATS results in less postoperative pain, shorter hospital stay, and faster postoperative recovery.

CHAPTER 38

Evaluation of Respiratory Impairment and Disability

Akshay Sood

INTRODUCTION

Management of a patient with chronic lung disease does not end with its treatment. Those with chronic pulmonary disorders need additional assistance and guidance on issues related to respiratory impairment, including causation or attribution; apportionment; eligibility for, and access to, various compensation systems; workplace modifications or removal from the workplace; and vocational and other forms of rehabilitation. Unfortunately, most physicians avoid providing these services, often with disastrous socioeconomic and medical consequences for the patient.

Multiple reasons underlie the general attitude of physician reluctance in addressing impairment. These include a fear and poor understanding of the legal system as it relates to work-related diseases, pervasive confusion about various compensation systems, a mistaken notion that those who seek impairment assistance are usually malingerers, lack of training in impairment evaluation, and a desire to avoid uncompensated efforts in the context of an already burdensome clinical schedule. This chapter provides an understanding of this complex, but ignored, area in clinical pulmonary medicine.

TERMINOLOGY

This field of impairment and disability evaluation bridges medicine and law; hence, its terminology, drawn from both fields, can be confusing. The terms, impairment and disability, are often used interchangeably, but they are not synonymous. In 1980, the World Health Organization issued a statement defining *impairment* as, "any loss or abnormality of psychological, physiologic, or anatomical structure or function," and *disability* as, "any restriction or lack, resulting from impairment, of ability to perform an activity within the range considered normal for a human being."[1] The resulting social and occupational disadvantage is designated as handicap.

For a patient with chronic lung disease, the goal of respiratory impairment evaluation is objective measurement of the extent of loss of function, primarily through application of pulmonary function or exercise testing. The physician plays a key role in impairment evaluation. On the other hand, the impact of the respiratory impairment on a person's ability to perform day-to-day activities is called disability, which is typically determined through application of administrative and legal instruments by experts in these areas. The experts not only rely upon the evaluation of impairment provided by the physician, but also take into consideration other social and legal issues, as well as the energy requirements of the occupation. Impairment may occur without disability, and disability may occur without measurable impairment. Furthermore, two individuals with exactly the same respiratory impairment may suffer differing impacts on their lives, and consequently, have different levels of disability.

Respiratory impairment may be *temporary* or *permanent*. In contrast to temporary impairment, permanent impairment is not expected to improve with time or treatment. Disability may be *partial* or *total*. Total disability implies that an individual is unable to perform any work of the kind that he or she has the skills and qualifications to perform. Partial disability implies that an individual is able to perform some, but not all, of the work.

Causation or *attribution* refers to whether an exposure has been a "substantial" contributing factor in either causing or exacerbating lung disease. The level of certainty required in determining causation for occupational lung disease is different from the usual standard of 95% certainty used in medical research. The commonly accepted standard of certainty for occupational cases is that the

illness is substantially caused, or exacerbated by, an occupational exposure on a "more probable than not" basis, or a level of certainty greater than 50%.

Apportionment describes the relative contribution of multiple factors to the total respiratory impairment. For instance, both chronic inhalational asbestos exposure and cigarette smoking may be contributory factors to lung cancer. From a scientific perspective, it is usually difficult, if not impossible, to "apportion" the relative roles of multiple exposures in causation of an individual's complex, multifactorial disease. Physicians are often asked to state their opinion on apportionment in the context of the body of available knowledge in that area.

IMPAIRMENT SYSTEMS COMMONLY USED IN THE UNITED STATES

Patients seeking an impairment evaluation can be usually classified into three general types: (1) Those with advanced lung disease who apply for disability benefits under the Social Security Impairment program, (2) those with work-related lung disease who apply under the Workers' Compensation System (but also other programs, such as the Black Lung Benefits Act for coal mine workers), and (3) those who develop lung disease while working for certain employers, such as the Veterans Administration. The most commonly used impairment guidelines in the United States are the Social Security Impairment program and the Workers' Compensation System. Each are discussed in greater detail in subsequent sections.

■ SOCIAL SECURITY IMPAIRMENT

The US Social Security Administration incorporates two programs that provide financial and rehabilitative benefits to disabled individuals. Both require objective demonstration of disability using medical standards set forth in the Social Security Act.

The first program is orchestrated through Title II of the Act, known as Social Security Disability Insurance. The program is available to individuals who are insured as a result of their contributions to the Social Security trust fund (through federal taxes paid on employment earnings during their work careers). The second is orchestrated through Title XVI of the Act, known as supplemental security income, or SSI. This program is available to disabled individuals who have limited income or resources and who are not covered by contributions to the Social Security trust fund. For adults, the definition of disability is the same whether application for benefits is made under Title II or Title XVI of the Social Security Act. The Social Security Administration defines disability as, "the inability to engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment(s) which can be expected to result in death or which has lasted or can be expected to last for a continuous period of not less than 12 months." The methods used for disability evaluation under Social Security are important for the physician to understand for two reasons: (1) Disability designation under Social Security is a common and important source of financial support for many patients who are under the care of pulmonary physicians and (2) the pulmonary physician often takes an active role in helping determine eligibility under this program.

Evaluation of disability under Social Security is a staged process, beginning with application to a local Social Security field office or the Office of Disability Determination Services (DDS). The Office of DDS gathers objective medical information primarily from the treating physician, who is the preferred source of medical evaluation. If the available information is insufficient to make a determination of disability, the DDS may purchase additional testing and/or request examination from a consultant, such as a pulmonary physician.

The Social Security Administration has decided that certain specific impairments of each major body system are severe enough to prevent a person from engaging in any gainful employment and, therefore, serve as prima facie evidence that disability exists. These impairments have been codified as the Listings of Impairments.[2] Listings under the respiratory system include specific categories of disease severity, including chronic respiratory disorders; asthma; cystic fibrosis; pneumoconiosis; bronchiectasis; mycobacterial, mycotic, and other chronic persistent infections of the lung; cor pulmonale due to chronic pulmonary vascular hypertension; sleep-related breathing disorders; and lung transplant.

If a claimant cannot meet the severity criteria of the Listings, the claimant may still receive an award of benefits by presenting pertinent medical information to the DDS. An initial judgment may then be made by the DDS, but the claimant has the right to challenge an unfavorable decision and to have it reviewed by other members of the DDS staff. If the decision is still unfavorable, the claimant may appeal to the Office of Hearings and Appeals for review by an administrative law judge, who may request expert physician testimony before making a decision. Once again, the claimant may request that an unfavorable decision be reviewed by an appeals council.

The Social Security program has some unusual requirements that distinguish it from other compensation programs: (1) The program requires a "hard copy" of the volume–time curve of a recent spirogram obtained following administration of inhaled bronchodilator when obstruction is present. (2) The program incorporates arbitrary, height-specific cut points for spirometric lung function for deciding impairment status; these cut points are not determined by race, ethnicity, age, or gender. (3) The program accepts an arterial blood gas measured during steady-state *submaximal* exercise at a work rate of 5 metabolic equivalents (METs) for rating impairment in gas exchange. (4) The program denotes the patient as either impaired or not impaired, rather than specifying a percent impairment. In this setting of binary categorization, those considered impaired under Social Security criteria are expected to have a level of impairment sufficient to prevent working for a period of 1 year or longer. (5) Unlike Workers' Compensation programs, the Social Security program does not focus on occupational causation. The sole criterion for granting benefits is whether or not the claimant is able to participate in gainful employment. (6) The Social Security program also takes into account impairment from coexisting nonpulmonary conditions, such as substance abuse.

A major revision to the Social Security impairment criteria was proposed in February 2013.[3] Although the revision has not yet been approved, it is expected that the program will drop its requirements for hard copy spirometric tracings, add age and gender to the spirometric criteria, and add height and gender to the diffusing capacity criteria. If approved, it is also expected to be the first major impairment program to accept graphical printouts of pulse oximetry on room air at rest or after a 6-minute walk test for evaluating gas exchange impairment.

■ WORKERS' COMPENSATION SYSTEM

The Workers' Compensation system is a "no-fault" system of medical care and disability insurance in which private insurers or self-insured employers pay benefits to an employee sustaining an injury or illness due to workplace exposure. Under Workers' Compensation rules, workers cannot sue their employer for injury or illness.

The rules for the Workers' Compensation system vary from one state to another, but they usually follow one of the six editions

of the American Medical Association (AMA) Guides to the Evaluation of Permanent Impairment.[4] The various editions of the AMA Guides contain markedly different sets of recommendations on impairment evaluation, so one must choose the right edition for the purpose. Use of the wrong edition may result in an erroneous impairment rating. While other guidelines are available on the Internet without charge, use of web-based AMA Guides carries a fee.

The sixth edition of the AMA Guides uses a standardized grid that incorporates five classes of impairment severity.[4] The grids incorporate objective, test-based key criteria for defining the impairment class, along with other criteria for fine-tuning the severity grade within a given class. Among the various objective tests, *the most severely affected test result is used to define the impairment class*.

Although the American Thoracic Society (ATS) has also developed consensus guidelines for rating impairment from chronic respiratory conditions and asthma,[5,6] these guidelines may not be accepted by a specific compensation program. While the AMA Guides generally follow the ATS schema, there exist substantial differences between the two guidelines.

FIVE GENERAL STEPS FOR IMPAIRMENT RATING

Five steps constitute the process of completing a respiratory impairment evaluation.

The first step is confirmation of the diagnosis of lung disease. Because of the medicolegal nature of the evaluation, the physician should have greater certainty of the medical diagnosis than is sometimes used in clinical practice. In other words, objective confirmation of the diagnosis is preferable.

The second step is defining maximal medical improvement (MMI). MMI occurs at the point when, following maximal therapy, no further clinical or physiologic improvement is expected to occur (although deterioration might). If therapy has not been maximized, the physician should either delay impairment evaluation or give a temporary rating. A permanent impairment evaluation should be performed only at, or after, MMI has been reached.

The third step is identifying the correct guideline for rating impairment. As discussed previously, several compensation systems exist, each with its own unique guideline. Therefore, identification of the compensation system for which the patient is eligible is essential, and the evaluating physician must be familiar with the specific guideline to be used. Of course, some patients may be eligible for more than one compensation program and may apply for more than one program contemporaneously.

The fourth step is to supplement the history and physical examination findings with appropriate objective tests. Performance of these tests should strictly adhere to standards of the ATS.[7–10]

The fifth and final step requires writing a comprehensive report of the patient's history, physical examination, and review of objective tests. The assessment should provide clear and accurate answers, in lay terms, to the questions asked. The evaluation should state the diagnosis and whether MMI has been reached, and it should make note of the presence and degree of respiratory impairment. The specific impairment scheme used, including the specific page and table of the guideline used, should be referenced. In work-related respiratory disorders, causation, apportionment, and work restrictions should also be addressed, as requested.

GENERAL APPROACH FOR EVALUATING RESPIRATORY IMPAIRMENT

After determining patient eligibility for a specific compensation system, as described previously, the physician gathers data that is relevant to rating respiratory impairment. In general, impairment criteria are based upon history, physical examination, and objective test results.

The medical history focuses on detailed past and present occupational history, tobacco use and environmental exposures, presence and severity of respiratory symptoms, such as dyspnea, cough, sputum production, and wheezing, and medication history. Relevant features in the physical examination include breathing pattern, shape of chest wall, adventitious lung sounds, cyanosis, digital clubbing, and evidence of cor pulmonale.

RESTING PULMONARY FUNCTION TESTS

Pulmonary function tests (PFTs) (Chapter 33) are the cornerstone for rating respiratory impairment and should be performed according to the most recent ATS standards.[7–10] Spirometry and diffusing capacity are the key PFTs for assessing respiratory impairment for chronic respiratory conditions. Postbronchodilator spirometry is used when airflow limitation is present. Methacholine challenge tests are used for rating impairment for asthma under the AMA Guides.[4]

Resting and exercise-related hypoxemia, derived from arterial blood gas results and adjusted for altitude and arterial P_{CO_2} level, may be used under the Social Security impairment system to classify gas exchange abnormalities. However, arterial blood gas sampling needs to be repeated within 3 weeks to 6 months of the first sample.[3] Although the presence of hypoxemia was previously used to rate impairment as severe under the fifth edition of the AMA Guides, the sixth edition does not include hypoxemia in the rating of respiratory impairment since it is considered invasive and difficult to standardize.[4]

Adjustment of PFTs for race, ethnicity, and gender is recommended by most impairment guidelines, with the notable exception of the Social Security impairment system, which currently uses uniform height-specific cut points for all individuals, irrespective of race, ethnicity, and gender.[2] Thus, under this system, older women are more likely to be rated as disabled than are younger men.

According to the sixth edition of the AMA Guides, specific NHANES III reference standards for spirometry should be used for Caucasian Americans, Mexican Americans, and African Americans.[4,11] For the remaining population subgroups, no clear guidelines are provided. Corrected single-breath carbon monoxide diffusing capacity (D_{LCO}) is used under the AMA Guides, ATS guidelines, and Social Security Impairment guidelines for impairment rating, but it is not used under the Veterans Administration guidelines. Crapo's reference standards for D_{LCO} are used for comparison with measured values.

The cut points for impairment classification, as suggested by the various impairment guidelines (Tables 38-1–38-3) are set arbitrarily and may differ from those recommended for assessing degree of lung disease severity by other professional organizations, such as the 2005 ATS statement[8] or by the Global Initiative for Chronic Obstructive Lung Disease (GOLD).[13] Some investigators have suggested that lung function thresholds should be expressed as a z-score, which converts a raw measurement on a test to a standardized score expressed in units of standard deviations.[14,15] This strategy, although scientifically valid, is not currently used for impairment evaluation.

Methacholine bronchoprovocation tests are useful for assessing bronchial hyperresponsiveness and in rating impairment from asthma under the AMA Guide and ATS guidelines (Tables 38-1 and 38-2).[4,6] The methacholine PC_{20} (provocative concentration of methacholine, expressed as mg/mL that results in at least 20% drop in FEV_1 compared to the pretest baseline) is a key parameter for rating asthma impairment under the sixth edition of the AMA Guides.[4] The performance of methacholine bronchoprovocation tests should also strictly adhere to the ATS guidelines.[16]

TABLE 38-1 Classification of Respiratory Impairment from Chronic Lung Diseases, Using the Sixth Edition of the American Medical Association (AMA) Guides to the Evaluation of Permanent Impairment

American Medical Association Class	Class 0	Class 1: 2–10% impairment of the whole person	Class 2: 11–23% impairment of the whole person	Class 3: 24–40% impairment of the whole person	Class 4: 45–65% impairment of the whole person
Severity grade (%)		A (2%), B (4%), C (6%), D (8%), E (10%)	A (11%), B (14%), C (17%), D (20%), E (23%)	A (24%), B (28%), C (32%), D (36%), E (40%)	A (45%), B (50%), C (55%), D (60%), E (65%)
Objective Tests					
FVC (% predicted)	≥80% predicted and	70–79% predicted or	60–69% predicted or	50–59% or	<50% or
FEV_1 (% predicted)	≥80% predicted and	65–79% predicted or	64–55% predicted or	45–54% or	<45% or
FEV_1/FVC%	>Lower limit of normal and/or >75% predicted) and	N/A	N/A	N/A	N/A
D_{LCO} (% predicted)	≥75% predicted	65–74% predicted	55–64% predicted	45–54%	<45%
$\dot{V}_{O_2max}$					
mL/kg/min	>25 or	22–25 or	21–18 or	15–17 or	<15 or
METs	>7.1	6.1–7.1	5.1–6.0	4.3–5.0	<4.3
History					
	No current symptoms and/or intermittent dyspnea that does not require treatment	Dyspnea controlled with intermittent or continuous treatment or intermittent mild dyspnea despite continuous treatment	Constant mild dyspnea despite continuous treatment or intermittent moderate dyspnea despite continuous treatment	Constant moderate dyspnea despite continuous treatment or intermittent severe dyspnea despite continuous treatment	Constant severe dyspnea despite continuous treatment or intermittent extreme dyspnea despite continuous treatment
Physical Findings					
	No current signs of disease	Physical findings not present with continuous treatment or intermittent mild physical findings	Constant mild physical findings despite continuous treatment or intermittent moderate physical findings	Constant moderate physical findings despite continuous treatment or intermittent severe physical findings	Constant severe physical findings despite continuous treatment or intermittent extreme physical findings

FVC, forced vital capacity; FEV_1, forced expiratory volume in the first second; D_{LCO}, diffusing capacity of carbon monoxide; $\dot{V}_{O_2max}$, measured maximal exercise capacity; MET or metabolic equivalent is the multiple of basal oxygen consumption, approximately 3.5 mL/kg/min; N/A, not applicable.

EXERCISE TESTS

Maximal cardiopulmonary exercise tests are difficult to perform due to need for specialized equipment and trained personnel, are expensive and not readily available, and carry a risk to the patient. Test performance should strictly adhere to the ATS guidelines.[17] Clear agreement on the role of exercise tests in the evaluation of respiratory impairment is lacking. Generally, in cases in which subjective dyspnea is disproportionate to the resting PFT results,

TABLE 38-2 American Thoracic Society's (ATS) Classification of Respiratory Impairment[5]

Impairment Class	Normal	Mildly Impaired	Moderately Impaired	Severely Impaired
Work ability		Usually able to perform most jobs	Diminished ability to perform many jobs	Unable to meet physical demands of most jobs including travel to work
FVC (% predicted)	≥80%	60–79%	51–59%	≤50%
FEV_1 (% predicted)	≥80%	60–79%	41–59%	≤40%
FEV_1/FVC	≥75%	60–74%	41–59%	≤40%
D_{LCO} (% predicted)	≥80%	60–79%	41–59%	≤40%
$\dot{V}_{O_2max}$ (mL/kg/min)	≥25 (or 7.1 METs)			≤15 (or 4.3 METs)

FVC, forced vital capacity; FEV_1, forced expiratory volume in the first second; D_{LCO}, diffusing capacity of carbon monoxide; $\dot{V}_{O_2max}$, measured maximal exercise capacity; MET or metabolic equivalent is the multiple of basal oxygen consumption, approximately 3.5 mL/kg/min.

Certain aspects of this document may be out of date and caution should be used when applying these in clinical practice or other usages.

TABLE 38-3 Impairment Rating Guidelines for Chronic Obstructive Lung Diseases using the Social Security, Veterans Administration, American Medical Association (AMA) Guides, and American Thoracic Society (ATS) Guidelines

(A) SOCIAL SECURITY		
Height without Shoes (cm)	**Height without Shoes (in)**	**FEV_1 Equal to or Less than (L, BTPS)**
≤154	≤60	1.05
155–160	61–63	1.15
161–165	64–65	1.25
166–170	66–67	1.35
171–175	68–69	1.45
176–180	70–71	1.55
≥181	≥72	1.65

(B) VETERANS ADMINISTRATION
Chronic Bronchitis
Pronounced (100% rating): with copious productive cough and dyspnea at rest; PFTs showing a severe degree of chronic airway obstruction with symptoms of associated severe emphysema or cyanosis and findings of right-sided heart involvement
Severe (60% rating): with severe productive cough and dyspnea on slight exertion and PFTs indicative of severe ventilatory impairment
Moderately severe (30% rating): persistent cough at intervals throughout the day, considerable expectoration, considerable dyspnea on exercise, rales throughout chest, beginning chronic airway obstruction
Moderate (10% rating): considerable night or morning cough, slight dyspnea on exercise, scattered bilateral rales
Mild (0% rating): slight cough, no dyspnea, few rales
Emphysema
Pronounced (100% rating): intractable and totally incapacitating; with dyspnea at rest, or marked dyspnea and cyanosis on mild exertion; severity of emphysema confirmed by CXR and PFTs
Severe (60% rating): exertional dyspnea sufficient to prevent climbing one flight of steps or walking one block without stopping; ventilatory impairment of severe degree confirmed by PFTs with marked impairment of health
Moderate (30% rating): with moderate dyspnea occurring after climbing one flight of steps or walking more than one block on a level surface; PFTs consistent with findings of moderate emphysema
Mild (10% rating): with evidence of ventilatory impairment on PFTs and/or definite dyspnea on prolonged exertion
(C) AMA GUIDES AND ATS GUIDELINES
Use criteria outlined in Tables A and B respectively in the text

FEV_1, forced expiratory volume in the first second; BTPS, body temperature and pressure saturated with water vapor.
For mixed obstructive and restrictive lung diseases with gas exchange impairment, evaluate under any of the criteria listed in Tables 38-3(A), 38-6(A), or 38-7.
Social Security impairment system has separate guidelines for patients with bronchiectasis.
Source: Data from Social Security Administration and Veterans Administration.[2,12]

or when PFTs are difficult to interpret because of submaximal performance, cardiopulmonary exercise tests may be considered. Such tests may also help identify unanticipated coexisting conditions, such as cardiovascular or pulmonary vascular disease, as the cause of exercise limitation.

Exercise testing may also be useful in determining whether an individual can perform a specific job with a known energy requirement. Under the ATS guidelines, the estimation of impairment from oxygen consumption at peak exercise ($\dot{V}_{O_2peak}$) is based on the widely held, but untested, assumptions that a worker involved in manual labor can comfortably work at 40% of $\dot{V}_{O_2peak}$ (corresponding to lower limit of generally accepted normal values for anaerobic threshold) for prolonged periods,[5] and that $\dot{V}_{O_2}$ requirements can be assigned to specific occupations. Individuals whose $\dot{V}_{O_2peak}$ is ≤15 mL/kg/min would be uncomfortable performing most jobs because they would find it difficult to travel back and forth to their place of employment (Table 38-2).[5] Unfortunately, data on $\dot{V}_{O_2}$ requirements of most jobs in modern workplaces are not currently available. Furthermore, jobs with the same title may vary considerably in their $\dot{V}_{O_2}$ requirements from one work site to another.

Submaximal exercise tests at a workload of approximately 17 mL O_2/kg/min (5 METs) or less of exercise can be performed at steady state to obtain arterial blood gases, which are then used to evaluate impairment of gas exchange under the Social Security impairment system when criteria for neither obstructive nor restrictive disorders are met. Use of submaximal exercise tests is however not currently recommended by any other impairment guideline.

IMAGING

Imaging studies are primarily useful for confirming the diagnosis of lung disease. They are less useful in rating respiratory impairment, since the correlation between radiographic abnormality and physiologic dysfunction is imperfect.

Chest radiographic evidence of pneumoconiosis is rated according to the 2011 International Labor Organization's (ILO) International Classification of Radiographs of Pneumoconiosis scheme (also called "B-reading"). The 2011 standards extended the applicability of the Classification to digital chest radiographs. The extent or profusion of small-sized parenchymal opacities is rated as 0, 1, 2, or 3. An intermediate score of 1/0 (i.e., profusion of small opacities greater than 0 but less than 1 profusion score) is often used to confirm the presence of pneumoconiosis.

Some determinations of respiratory impairment are not dependent on PFTs. They are based on environment-related diagnoses

(e.g., occupational asthma or hypersensitivity pneumonitis) and warrant proscription of continuing exposure to inciting agents). In addition, impairment may be based upon prognosis (e.g., unresectable lung cancer) or public health considerations (e.g., pulmonary tuberculosis).

SCIENTIFIC RATIONALE FOR CHOICE OF TESTS USED FOR IMPAIRMENT EVALUATION FOR CHRONIC RESPIRATORY DISORDERS

Impairment evaluation for chronic respiratory conditions is based upon PFT values at rest and with exercise. The premise for these tests is that $\dot{V}_{O_2peak}$ reasonably measures ability to work, and that resting PFTs, such as forced expiratory volume in 1 second (FEV_1) and D_{LCO}, reasonably predict $\dot{V}_{O_2peak}$ values.

OXYGEN CONSUMPTION AT PEAK EXERCISE AS THE GOLD STANDARD FOR MEASURING ABILITY TO WORK

Most of the available medical literature appears to support the view that $\dot{V}_{O_2peak}$ value, expressed as mL/kg/min, is the gold standard for assessing impairment.[18,19] With exercise on a cycle ergometer, $\dot{V}_{O_2}$ increases linearly with external work,[17] and $\dot{V}_{O_2peak}$ represents the maximal work an individual can perform during a short burst of activity. Some have advocated use of percent predicted $\dot{V}_{O_2peak}$ values (i.e., loss of aerobic capacity), instead of $\dot{V}_{O_2peak}$ expressed in mL/kg/min (i.e., remaining aerobic ability) for evaluating impairment in patients with respiratory disease, since the latter approach overestimates impairment in older and obese subjects Fig. 38-1.[20,21] In addition, some consider the value for $\dot{V}_{O_2}$ at anaerobic threshold ($\dot{V}_{O_2}AT$) as a better index for work ability than $\dot{V}_{O_2peak}$.[21] Individuals are unable to sustain work rates above anaerobic threshold values. However, no major guidelines currently use percent predicted $\dot{V}_{O_2peak}$ values or $\dot{V}_{O_2}AT$ to rate impairment.

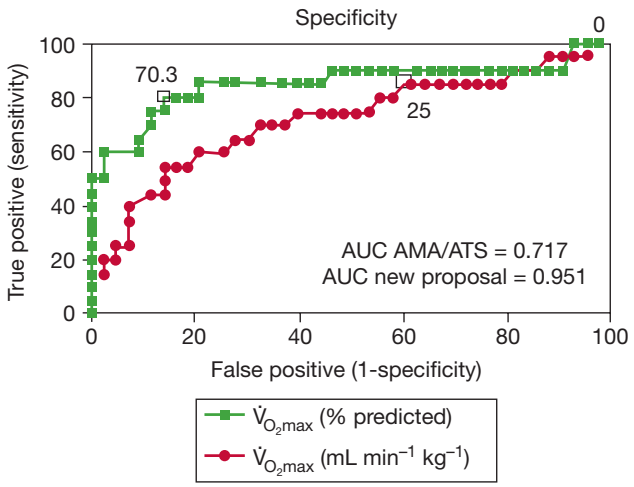

Figure 38-1 Receiver operating characteristics (ROC) curves of two classifications (AMA/ATS vs. new classification proposed by Neder et al.), using the $\dot{V}_{O_2}$ at anaerobic threshold ($\dot{V}_{O_2}AT$) as the "gold standard." The *open squares* represent the cutoffs for normality for $\dot{V}_{O_2peak}$ using the two classification schema. Neder et al. have advocated the use of percent predicted $\dot{V}_{O_2peak}$ values (i.e., loss of aerobic capacity) instead of $\dot{V}_{O_2peak}$ in mL/kg/min (i.e., remaining aerobic ability) for the evaluation of impairment in patients with respiratory disease since the latter approach overestimates impairment in older and obese subjects. AMA, American Medical Association; ATS, American Thoracic Society; AUC, area under the ROC curve; $\dot{V}_{O_2}$, oxygen consumption. *(Reproduced with permission from Neder JA, Nery LE, Bagatin E, Lucas SR, Ancao MS, Sue DY. Differences between remaining ability and loss of capacity in maximum aerobic impairment. Braz J Med Biol Res. 1998;31(5):639–646.)*

COMPARISON OF RESTING PULMONARY FUNCTION TESTS WITH OXYGEN CONSUMPTION AT PEAK EXERCISE

Low values for resting PFTs (i.e., FEV_1 or D_{LCO}) predict low $\dot{V}_{O_2peak}$ levels; poor scores on the Short Physical Performance Battery (tests that assess lower extremity function); less distance walked during the 6-minute walk test; and a greater risk of self-reported functional limitation.[22,23]

FEV_1 is linearly correlated with $\dot{V}_{O_2peak}$ levels,[23] but the reported correlations vary widely between studies, resulting in variance values ranging from 0.25 to 0.71.[23–28] Use of absolute versus percent predicted values largely yield similar correlation measures.[27] Although some studies demonstrate that FEV_1 and forced vital capacity (FVC) have similar predictive value for $\dot{V}_{O_2peak}$ levels,[27] most report FEV_1 to be a stronger predictor than FVC. A 2005 ATS statement indicated that percent predicted FEV_1, rather than FVC, should be used to categorize severity of impairment for all respiratory diseases.[8] The predictive ability of FEV_1 for $\dot{V}_{O_2peak}$ increases if it is used in combination with another variable, such as D_{LCO}, minute ventilation ($\dot{V}_E$), or dead space ventilation measure during exercise (V_D/V_T).[27] D_{LCO} does not predict $\dot{V}_{O_2peak}$ among healthy controls,[24] but it does so among subjects with COPD and those with occupational lung diseases, where it may account for a variance of 0.25 to 0.76 in various studies.[26,27,29]

Despite the previously noted correlations in population studies, resting PFTs cannot accurately predict $\dot{V}_{O_2peak}$ values among individuals, particularly those with occupational lung diseases. In a comparison study of impairment ratings obtained using simultaneous resting PFTs and cardiopulmonary exercise tests conducted in 216 ambulatory patients with COPD, the two methods resulted in similar impairment rating in only 30.1%. Ratings were similar between the two methods in the extreme subgroups of normal or severely impaired individuals. 61.1% were found to be less impaired according to exercise testing than according to resting PFTs, and 8.8% were more impaired according to exercise testing than resting PFTs (Table 38-4). These data suggest that use of resting PFTs and exercise testing for rating impairment often yields discrepant results.

TABLE 38-4 Degree of Impairment, as Assessed by Resting Pulmonary Function Tests and Cardiopulmonary Exercise Tests[a19]

Degree of Impairment	Resting PFT (%)	CPET (%)
None	6	28
Mild	26	36
Moderate	38	20
Severe	30	16

PFT, pulmonary function test; CPET, cardiopulmonary exercise test; FEV_1, Forced expiratory volume in 1 second.

[a]Among 216 ambulatory patients with COPD with mean percent predicted FEV_1 of 54.1 ± 16.8% and mean age of 57.9 ± 6.9 years

Source: Reproduced with permission from Fink G, Moshe S, Goshen J, et al. Functional evaluation in patients with chronic obstructive pulmonary disease: pulmonary function test versus cardiopulmonary exercise test. J Occup Environ Med. 2002;44(1):54–58.

PFTs other than FEV_1 and D_{LCO} may also help predict $\dot{V}_{O_2peak}$ values. These include inspiratory capacity in flow-limited obstructive diseases;[30] peak inspiratory pressure in chronic obstructive diseases;[26] exercise ventilation ($\dot{V}_E$) in both obstructive and restrictive lung diseases;[27] and submaximal exercise tests, including 6-minute walk test duration.[20] Use of these tests is however not currently recommended by any impairment guideline. Performance of maximal voluntary ventilation (MVV) is not recommended except under the Black Lung Benefits Act.[31] MVV is markedly effort dependent and bears a fixed relationship with FEV_1;[32] therefore, it is of limited value.

Further, both baseline oxygen saturation and the lowest oxygen saturation measured with a finger oximeter probe during a submaximal test correlate with $\dot{V}_{O_2peak}$ in patients with idiopathic pulmonary fibrosis,[20] but not in those with COPD.[33]

ASTHMA

Unlike most chronic respiratory conditions, asthma is an episodic disease, and impairment evaluation for asthma is particularly difficult. Therefore, most impairment rating schemes incorporate separate guidelines for rating asthma impairment.

DETERMINANTS OF WORK ABILITY IN ASTHMA

Among subjects with methacholine-confirmed asthma, a lower self-reported work ability is associated with lower PC_{20} value (i.e., higher degree of airway hyperresponsiveness), greater clinical severity of disease (based on minimum medication need to maintain asthma control), and the presence of respiratory symptoms in the workplace.[34] However, no relationships are evident with regard to baseline FEV_1 or FVC in both unadjusted and adjusted analyses.[34] Although controversial, methacholine PC_{20} (see Chapter 33) has been accepted as the key parameter for rating asthma impairment under the sixth edition of the AMA Guides.[4]

COMPARISON BETWEEN RESPIRATORY SYMPTOMS AND PC_{20}

For most subjects with asthma, greater breathlessness perceived during asthma attacks is not correlated with greater decline in peak expiratory flow rate [35] or with a lower PC_{20}.[36]

COMPARISON BETWEEN MINIMUM MEDICATION NEED AND PC_{20}

Almost all medications used to treat asthma improve PC_{20} values, that is, decrease bronchial hyperresponsiveness.[37–49] In one study, patients with asthma with the minimum medication needed to control symptoms were divided into four groups: (1) those who required no medication; (2) those who required short-acting β_2-agonist occasionally, but not daily; (3) those who required daily short-acting β_2-agonist; and (4) those who required additional inhaled corticosteroid dosing. The mean PC_{20} value was highest in group 1 and lowest in group 4; the differences between each group were significant.[50] Minimum medication need is, therefore, an important predictor for both work ability and airway hyperresponsiveness in asthma.

COMPARISON BETWEEN PERCENT PREDICTED FEV_1 AND PC_{20}

In a small clinical population of smokers and nonsmokers, as well as in a population of subjects with asthma with concomitant stable bronchiectasis, baseline FEV_1 has been shown to correlate with methacholine PC_{20} values.[51]

IMPAIRMENT RATING FOR ASTHMA

Impairment ratings for episodic diseases like asthma are problematic; the rating schemes differ dramatically as well (Tables 38-5A–38-5C).

The methacholine PC_{20} is the key parameter for rating asthma impairment under the sixth edition of the AMA Guides (Table 38-5B).[4] On the other hand, PC_{20} and extent of FEV_1 reversibility are given less weight than are either minimum medication need or postbronchodilator FEV_1 in the multicomponent asthma impairment scoring scheme recommended by the 1993 ATS guidelines (Table 38-5C).[6] Under Social Security impairment criteria, patients with asthma may be rated by FEV_1 or by a clinical history of frequent, severe exacerbations, despite maximal asthma therapy; a methacholine PC_{20} measurement is not required (Table 38-5A). On the contrary, AMA Guides and ATS guidelines do not

TABLE 38-5A Impairment Rating Guidelines for Asthma Using the Social Security, Veterans Administration, American Medical Association (AMA) Guides, and American Thoracic Society (ATS) Guidelines

(A) SOCIAL SECURITY
(1) Asthma with chronic asthmatic bronchitis: evaluate under the criteria for chronic obstructive airway disease (Table 38-3A)
(2) Attacks, in spite of prescribed treatment and requiring physician intervention, occurring at least once every 2 mo, or at least 6 times a year. Each in-patient hospitalization >24 h for control of asthma counts as two attacks. An evaluation period of at least 12 consecutive months must be used to determine the frequency of attacks
(B) VETERANS ADMINISTRATION[a]
Pronounced (100% rating): asthmatic attacks very frequently with severe dyspnea on slight exertion between attacks and with marked loss of weight or other evidence of severe impairment of health
Severe (60% rating): frequent attacks of asthma (one or more attacks weekly), marked dyspnea on exertion between attacks with only temporary relief by medication; more than light manual labor precluded
Moderate (30% rating): asthmatic attacks rather frequent (separated by only 10–14-d intervals) with moderate dyspnea on exertion between attacks
Mild (10% rating): paroxysms of asthmatic type breathing (high-pitched expiratory wheezing and dyspnea) occurring several times a year with no clinical findings between attacks
(C) AMA GUIDES AND ATS GUIDELINES
Use scoring criteria in Tables 38-5B and 38-5C, respectively

[a]*In the absence of clinical findings of asthma at time of examination, a verified history of asthmatic attacks must be on record.*

incorporate frequency of acute exacerbations in the impairment rating for asthma. Given the efficacy of currently recommended asthma therapies, frequent emergency room visits or hospitalizations generally reflect inadequate treatment and failure to achieve the objectives of treatment. The AMA Guides and ATS guidelines instead use minimum medication need for asthma control as a better reflection of the severity of disease for the purpose of impairment assessment than frequency of asthma exacerbations. Hence, it is easy to see why impairment ratings for the same patient with asthma might vary widely among various compensation systems.

Impairment rating for occupational asthma is even more problematic. In these cases, both temporary and long-term impairment evaluation should be performed.[6] Temporary impairment for patients with sensitizer-induced occupational asthma should be performed after removing the worker from exposure. Early cessation of exposure improves prognosis in sensitizer-induced occupational asthma. Sometimes, physiologic tests may be normal, and symptoms and need for treatment may subside after early cessation of exposure, resulting in 0% measureable impairment. However, such an individual should be considered as100% disabled on a permanent basis from working in a job that exposes him or her to the specific sensitizing agent.[6] It is not necessary to wait for long-term impairment rating to initiate vocational rehabilitation in such a case.[6] The long-term impairment evaluation is performed using the rating systems devised for nonoccupational asthma at least 2 years after cessation of exposure, when improvement has been shown to plateau.[52]

PNEUMOCONIOSES

According to the AMA Guides, those who develop pneumoconiosis should limit further exposure to the offending agent, "particularly if radiographic changes have occurred at a relatively young age or if there is associated physiologic impairment."[4] It follows that an older patient who is nearing retirement, with minimal radiographic change after a long history of exposure, could elect to continue in the workplace under the assumption of a lower risk of developing future disabling disease. Such discretionary decisions should be made based on a discussion between the patient and physician.[4] While the Veterans Administration has specific guidelines for impairment ratings for pneumoconiosis, the Social Security construct is based upon standard criteria for assessing impairment from any chronic respiratory disorder, as listed in Tables 38-3(A), 38-6(A), and 38-7.[2]

COAL WORKERS' PNEUMOCONIOSIS

In 1972, the Black Lung Benefits Act set eligibility criteria for the awarding of benefits to coal miners and their survivors in the United States. The Act defines pneumoconiosis as, "a chronic dust disease of the lung and its sequelae, including respiratory and pulmonary impairments arising out of coal mine employment." This definition encompasses two classes of coal dust–related lung diseases: medical or "clinical" pneumoconioses and statutory or legal pneumoconioses. Medical or "clinical" pneumoconioses include diseases that pulmonologists usually consider as pneumoconioses (such as coal workers' pneumoconiosis, anthracosis, anthracosilicosis, massive pulmonary fibrosis, silicosis, or silicotuberculosis). Statutory or legal pneumoconioses include any chronic restrictive or obstructive pulmonary disease arising out of coal mine employment, including chronic bronchitis and emphysema.

A coal miner applying for Black Lung benefits must show that he or she has pneumoconiosis, that the pneumoconiosis resulted from coal mine employment, and that it has resulted in "total disability," defined as inability to perform usual coal mine work. The miner must supply medical evidence of pneumoconiosis that includes (1) a chest radiograph, along with a report of the findings using the ILO classification system; (2) a physician report detailing the occupational, medical, and smoking history, as well as all manifestations of chronic respiratory disease; (3) spirometric results (including MVV); (4) altitude-adjusted arterial blood gas results; and (5) biopsy or autopsy evidence, if available.

TABLE 38-5C American Thoracic Society's (ATS) Asthma Impairment Rating Guideline

(A) POST-BRONCHODILATOR FEV_1	
Score	**FEV_1 (%Predicted)**
0	>lower limit of normal
1	70–lower limit of normal
2	60–69
3	50–59
4	<50

(B) REVERSIBILITY OF FEV_1 OR DEGREE OF AIRWAY HYPERRESPONSIVENESS[a]		
Score	**%FEV_1 Change**	**PC_{20} (mg/mL)**
0	<10	>8
1	10–19	8–>0.5
2	20–29	0.5–>0.125
3	≥30	≤0.125

(C) MINIMUM MEDICATION NEEDS[b]	
Score	**Medication**
0	No medication
1	Occasional bronchodilator, not daily, and/or occasional cromolyn, not daily
2	Daily bronchodilator and/or daily cromolyn and/or daily inhaled low-dose inhaled steroid (<800 µg beclomethasone or equivalent)
3	Bronchodilator on demand and daily high-dose inhaled steroid (>800 µg beclomethasone or equivalent) or occasional course (1–3/y) of systemic steroid
4	Bronchodilator on demand and daily high-dose inhaled steroid (>1000 µg beclomethasone or equivalent) and daily systemic steroid

(D) SUMMARY OF IMPAIRMENT RATING CLASSES	
Impairment Rating	**Sum of Scores from Sections A, B, and C**
0	0
I	1–3
II	4–6
III	7–9
IV	10–11
V	Asthma not controlled despite maximal treatment, i.e., FEV_1 remaining <50% despite use of ≥20 mg Prednisone per day

FEV_1, forced expiratory volume in the first second; PC_{20}, provocative concentration of methacholine associated with 20% decrease in FEV_1 from baseline.

[a]When the postbronchodilator FEV_1 value is above the lower limit of normal, the PC_{20} value should be determined and used for rating of impairment; when the postbronchodilator FEV_1 value is <70% of the predicted value, the degree of reversibility is used; when the FEV_1 value is between 70% of the predicted value and the lower limit of normal, either the degree of reversibility of FEV_1 or the PC_{20} can be used.

[b]The need for minimum medication should be demonstrated by the treating physician, for example, previous records of exacerbations when medications have been reduced.

American Thoracic Society. Medical Section of the American Lung Association. Am Rev Respir Dis. 1993;147(4):1056–1061. Official journal of the American Thoracic Society. This document was published in 1993 and is currently in revision. Certain aspects of this document may be out of date and caution should be used when applying these in clinical practice or other usages.

Chest radiographic findings are accepted to show pneumoconioses if they demonstrate the presence of either small parenchymal opacities of at least category 1/0 profusion or large opacities. The absence of radiographic evidence of pneumoconioses makes medical or clinical pneumoconioses unlikely, but it may be noted in patients with statutory or legal pneumoconiosis.[31] Spirometry must meet the 1979 ATS repeatability criteria that require the maximum FVC and FEV_1 be within 5% or 100 mL, whichever is greater.[53] The arterial blood gas analysis may be performed at rest or with exercise. The Department of Labor has published detailed tables of FEV_1, FVC, and MVV, as well as arterial blood gas values delineating criteria for "total disability."[31]

UNITED STATES DEPARTMENT OF ENERGY EMPLOYEES IN NUCLEAR WEAPONS FACTORIES

The US Energy Employees' Occupational Illness Compensation Program Act (EEOICPA) was enacted to provide compensation and medical benefits to workers who acquired disease in the course of their work in the nuclear defense industry. Those eligible include employees and former employees of the Department of Energy at nuclear weapons factories, as well as private contractors and subcontractors at those locations. In addition to exposure to silica, asbestos, or mixed dusts that occurred during uranium ore extraction, many workers were also exposed to beryllium (used in the manufacture of ballistic missile nose cones) and radiation.

TABLE 38-6 Impairment Rating Guidelines for Restrictive Lung Diseases using the Social Security, Veterans Administration, American Medical Association (AMA) Guides, and American Thoracic Society (ATS) Guidelines

(A) SOCIAL SECURITY		
Height without Shoes (cm)	**Height without Shoes (in)**	**Vital Capacity Equal to or Less than (L, BTPS)**
≤154	≤60	1.25
155–160	61–63	1.35
161–165	64–65	1.45
166–170	66–67	1.55
171–175	68–69	1.65
176–180	70–71	1.75
≥181	≥72	1.85
(B) VETERANS ADMINISTRATION		
Leaves the rating to the judgment of the physician, according to symptoms, anatomical extent, pulmonary functions and complications.		
(C) AMA GUIDES AND ATS GUIDELINES		
Use criteria outlined in Tables 38-6A and B, respectively		

BTPS, body temperature and pressure saturated with water vapor.
In severe kyphoscoliosis, the measured span between the fingertips when the upper extremities are abducted 90 degrees should be substituted for height.
For mixed obstructive and restrictive lung diseases with gas exchange impairment, evaluate under any of the criteria listed in Tables 38-3A,38-6A, or 7.
Source: Data from Social Security Administration and Veterans Administration.[2,12]

In contradistinction to Black Lung evaluation, the Part E of the EEOICPA has adopted the standards of the fifth edition of AMA Guides to the Evaluation of Permanent Impairment as the method of rating impairment.

LUNG CANCER

According to the AMA Guides, lung cancer is a cause of severe impairment for the period extending from the time of diagnosis to 1 year, thereafter. If no evidence of tumor is found at reevaluation at 1 year, then impairment is recalculated on the basis of the degree of physiologic impairment present at that time. On the other hand, if there is evidence of tumor, the patient remains classified as severely impaired.

Under the Social Security system, lung cancer produces impairment if it is unresectable, is incompletely resected, is recurrent or metastatic, is of small cell histology, is a squamous cell cancer with

TABLE 38-7 Social Security Impairment Criteria for Evaluating Chronic Impairments of Gas Exchange due to Clinically Documented Pulmonary Disease

(1) Arterial blood gases demonstrating values of Pa_{O_2} and simultaneously determined Pa_{CO_2} measured while at rest (breathing room air, awake and sitting, or standing), in a clinically stable condition on at least two occasions, 3 or more weeks apart within a 6-mo period, equal to or less than the values specified below or arterial blood gas values during steady-state exercise breathing room air (level of exercise equivalent to or less than 17.5 mL O_2 consumption/kg/min or 5 METs), equal to or less than the values specified below.

Pa_{CO_2} (in mm Hg) and	At test sites <3000 ft above sea level, Pa_{O_2} ≤ (in mm Hg)	At test sites 3000–6000 ft above sea level, Pa_{O_2} ≤ (in mm Hg)	At test sites >6000 ft above sea level, Pa_{O_2} ≤ (in mm Hg)
≤ 30	65	60	55

metastasis beyond hilar nodes, or is one of other histologic types with metastasis to hilar lymph nodes. Under the Veterans Administration system, degree of impairment is not categorized clearly, but rather, is left to the judgment of the physician.

SLEEP APNEA

Impairment ratings for sleep apnea are problematic and vary widely among compensation systems. Resting and exercise PFTs are not useful for rating impairment related to sleep apnea. Therefore, the AMA Guides recommend assessment of complications of sleep apnea, such as the presence of cor pulmonale or polycythemia, and rate the complications according to the appropriate organ systems. Any "add-on" for strictly defining respiratory impairment must be determined by a sleep specialist and should not exceed 3% of total impairment.[4] Under the Social Security system, sleep apnea is rated according to criteria for cor pulmonale, obesity, or organic mental disorders.[2]

AMERICANS WITH DISABILITIES ACT

Although many physicians think of impairment assessment as an evaluation that follows injury, or termination of employment, or is undertaken at an advanced stage of lung disease, in reality, important assessments are also made prior to the start of a job. Until recently, people with physical impairment were excluded from employment because of an unreasonable fear that an impaired employee would be a detriment at the workplace. The Americans with Disabilities Act (ADA), which was enacted by the United States in 1992, produced a fundamental change in the way in which physical impairments are viewed at the workplace.

Many of the regulations established by the ADA deal with removal of physical barriers that prevent impaired workers from entering and functioning within the workplace. Others are specifically directed at removing bias and prejudice from the opportunity to enter the workforce. While the ADA has not altered the methods of impairment evaluation used by physicians, it does have a substantial impact on the timing of evaluations and the way the evaluations are reported and used. For instance, while preemployment physical examinations were commonly requested by employers prior to enactment of the ADA, they are no longer allowed, due to the perceived risk that a qualified individual might be excluded from employment because of an impairment that has little or nothing to do with the job requirements. Before making a job offer, employers are no longer allowed to ask if a prospective employee has a physical impairment, although they may ask if he or she can perform the duties of the job. Once a job offer is made and accepted, physical examination is permissible to confirm that the job can be performed in a safe and acceptable manner. In fact, the employer is legally permitted to make a job offer conditional on the applicant passing a physical examination, as long as the same physical requirements are required for every employee in the same job category. These examinations, known as preplacement physicals, must deal only with job-related issues and must be consistent with business necessity.

The other major change in the determination of work-related physical fitness is that businesses are required to make "reasonable" accommodations for physical impairments, as long as the impairments do not interfere with the essential requirements of the job. Employers are not, however, required to make unreasonably extensive changes to a work area or to undertake "action requiring significant difficulty or expense" to accommodate an otherwise qualified applicant.

CHAPTER 39

Pathology of Chronic Obstructive Pulmonary Disease: Diagnostic Features and Differential Diagnosis

Joanne L. Wright
Andrew Churg

Chronic obstructive pulmonary disease (COPD) is a general name for the chronic airflow obstruction that develops most often as a result of chronic tobacco smoking, but also after exposure to biomass fuels. The pathology of COPD encompasses a variety of pathologic lesions in the airways, lung parenchyma, and pulmonary vasculature, and these lesions can be correlated, to a greater or lesser degree, with changes in pulmonary function tests and clinical appearances. In general, although the mechanisms involved are complex, airflow obstruction can be attributed largely to a marked increase in airway resistance secondary to a variable mix of structural abnormalities involving all or many of the compartments of the airway. However, in individual cases, it may be difficult to prove associations between physiologic abnormalities and pathologic changes. The Global Initiative on Obstructive Lung Disease (GOLD), recently revised,[1] classifies patients with COPD purely upon indices of airflow and thus far there is only limited integration with pathologic findings.

This chapter presents the pathologic features of COPD and how these findings can be differentiated from other lesions associated with airflow obstruction.

HISTORY OF PATHOLOGIC DESCRIPTIONS OF COPD

The word emphysema is derived from Greek and means "to blow into," hence "air-containing" or "inflated." Although "voluminous lungs" and lungs "turgid particularly from air" were described respectively by Bonet in 1679[2] and Morgagni in 1769,[3] the first description of enlarged airspaces in emphysema in the human, together with illustrations, was furnished by Ruysh in 1721,[4] followed by Matthew Baillie in 1807, who not only clearly recognized and illustrated emphysema, but also pointed out its essentially destructive character.[5,6]

Laennec,[7] writing in the early 1800s, made a number of seminal contributions to the basic descriptions of pathologic changes in COPD. He was the first to make a clear-cut distinction between interstitial emphysema and emphysema proper, and related the enlarged airspaces to the clinical syndrome of emphysema. He also recognized that air trapping and increased collateral ventilation were features of emphysematous lungs, and that the peripheral airways were the primary site of obstruction in emphysema. Furthermore, he noted that airspaces enlarged with increasing age, and he distinguished these changes from emphysema. He was the first to describe an association of emphysema with chronic bronchitis and to clearly describe the pathology of bronchiectasis.

Little of major importance was added to the gross descriptive morphology of emphysema for almost the next 150 years. The foundation of modern knowledge of the pathologic anatomy of pulmonary emphysema was laid by J. Gough in 1952[8] when he described centrilobular emphysema and distinguished it from panlobular emphysema. The paper section technique developed by Gough and Wentworth[9] was largely responsible for this advance, as it made examinations of sections of entire inflated lungs possible and simple (Fig. 39-1). A comprehensive microscopic description of emphysema was then provided by McLean,[10,11] who demonstrated the relationship of destruction to inflammatory alterations of the bronchioles, and also discussed alterations of the vasculature.

LESIONS OF THE LUNG PARENCHYMA IN COPD: EMPHYSEMA

A major problem in describing the pathologic features of emphysema has been the lack of a generally accepted and easy to apply definition. In 1959, a Ciba Guest Symposium defined emphysema in anatomic terms as "a condition of the lung characterized by increase beyond the normal of airspaces, distal to the terminal bronchiole, either from dilatation or from destruction of their walls."[12] Subsequent definitions differed in that destruction of respiratory tissue became a requirement[13–15]: "Emphysema is a condition of the lung characterized by abnormal, permanent enlargement of the airspaces distal to the terminal bronchiole, accompanied by destruction of their walls." This requirement separates emphysema from enlargement of airspaces unaccompanied by destruction, the latter now being termed overinflation.

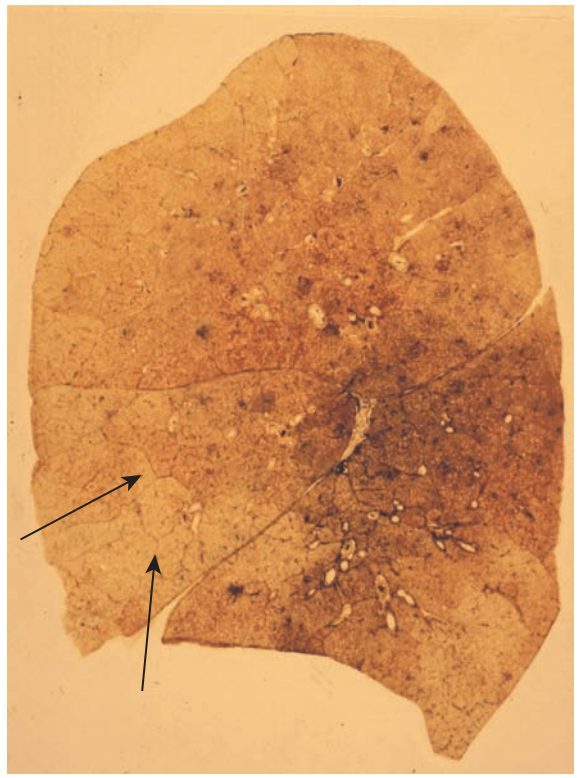

Figure 39-1 Gough sagittal section. Paper mount. Normal lung.

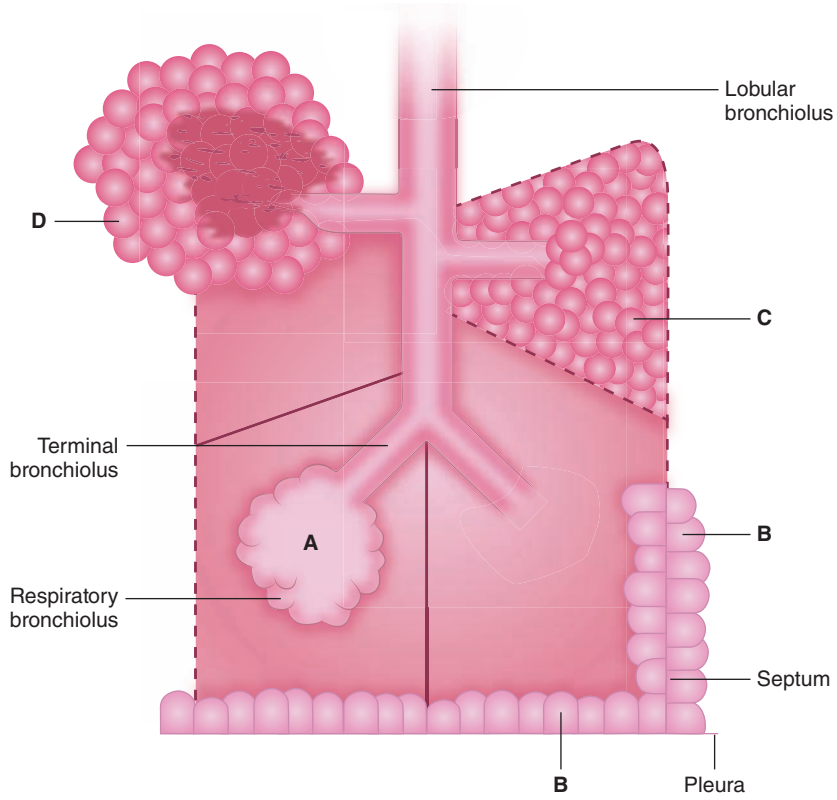

Figure 39-2 Anatomic varieties of emphysema. **A.** Centriacinar (centrilobular). **B.** Paraseptal (distal acinar). **C.** Panacinar (panlobular). **D.** Irregular (scar). The *dashed lines* mark the edge of the acinus. Only centriacinar and panacinar emphysema are commonly observed in COPD, although paraseptal emphysema often can be found in focal areas in lungs with centriacinar emphysema.

Destruction has been similarly difficult to define in an unambiguous way. A committee of the National Institutes of Health[16] proposed that destruction was present when "there was nonuniformity in the pattern of respiratory airspace enlargement so that the orderly appearance of the acinus and its components is disturbed and may be lost." They recognized that emphysema was a subset of airspace enlargement defined as "an increase in airspace size as compared with the airspace of normal lungs. The term applies to all varieties of airspace enlargement distal to the terminal bronchioles, whether occurring with or without fibrosis or destruction." While these definitions, when strictly applied, would eliminate airspace enlargement due to overinflation or failure of septation, they would not eliminate airspace enlargement due to reorganization of the airspaces, such as is found in honeycomb lung. This may be part of the confusion when combined emphysema and fibrosis is considered (see the section below).

CLASSIFICATION OF EMPHYSEMA

Not only is emphysema defined in terms of lung structure, it is also classified in similar terms; therefore, several anatomic definitions are important. The part of the lung involved in emphysema is the acinus, which is defined as the unit of lung structure distal to the terminal bronchiole (final generation membranous bronchiole) and that consists of three orders of respiratory bronchioles: a single order of alveolar ducts, followed by the alveolar sacs, and finally the alveoli. Alveolar ducts are entirely alveolated and characteristically contain smooth muscle around the mouths of their alveoli. While the walls of alveolar sacs are also formed entirely by alveoli, muscle is absent. Alveolar pores of Kohn (also known as vents, stomata, or fenestrae) are normal components of adult alveoli, responsible for collateral ventilation. However, they may also be an initial site of destruction in the development of emphysema, particularly centriacinar emphysema.

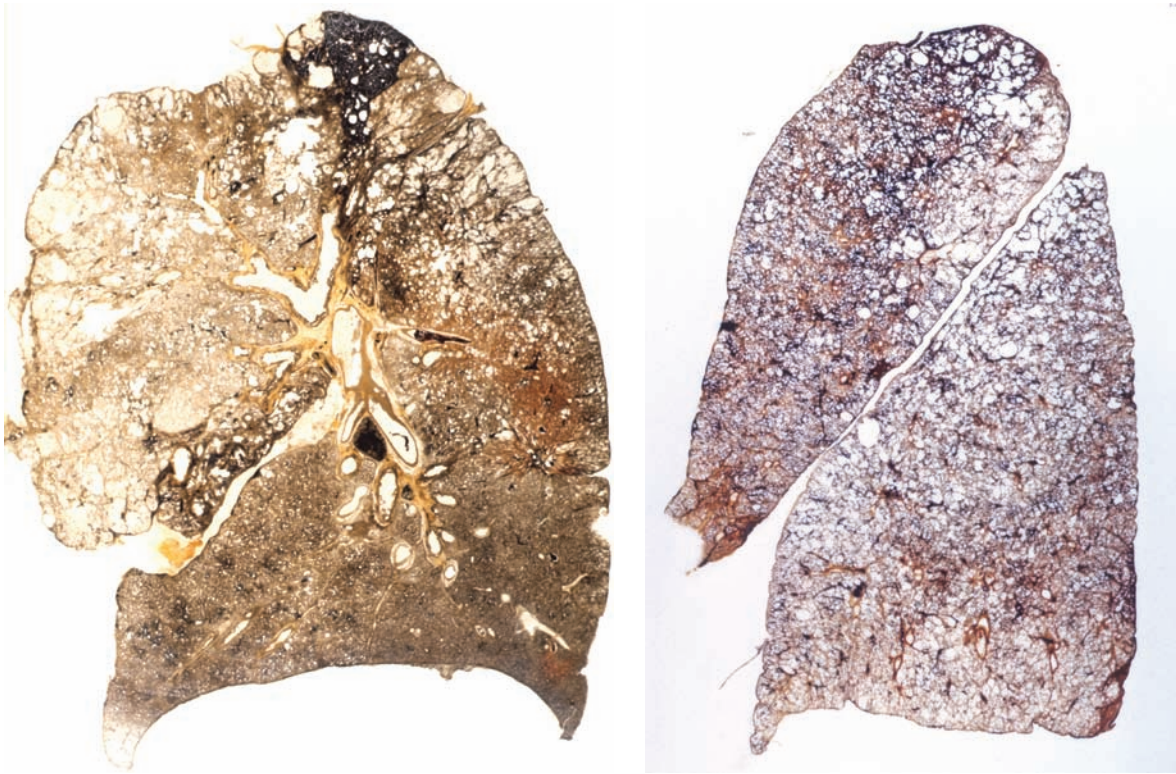
The acinus is a three-dimensional anatomic structure, but it cannot be easily identified by gross examination. What can be seen instead on the surface of lung slices is the secondary lobule of Miller, defined as the tissue bounded on four sides by interlobular septa or pleura (see Fig. 39-1). Lobules vary tremendously in size, but are generally 2 to 4 cm on a side, and contain between three to five acini. The terminal bronchiole and subtending respiratory bronchioles tend to be situated in the center of the lobule. For this reason "centrilobular" emphysema and "panlobular" emphysema are reasonable and widely used approximations for the more accurate "centriacinar" and "panacinar" emphysema (see below).

The ways in which the acini are involved determine the classification of emphysema. There are four recognized patterns (Fig. 39-2). The acinus (and lobule) may be more or less uniformly involved; this is panacinar (panlobular) emphysema. The proximal portion of the acinus (center of the lobule) may be dominantly involved; the best term for this lesion is proximal acinar emphysema, although the usual term is centrilobular or centriacinar emphysema. Alternately, the proximal portion of the acinus may be normal, and the distal part (alveolar sacs and ducts) may be dominantly involved. This is distal acinar emphysema, more commonly referred to as paraseptal emphysema since the lesion is accentuated along lobular septa where the peripheral parts of the acini lie. Finally, the acinus may be irregularly involved, producing irregular emphysema or paracicatricial emphysema, so called because it is usually associated with obvious adjacent scarring.

MORPHOLOGY OF EMPHYSEMA

CENTRILOBULAR EMPHYSEMA

This destructive lesion of the respiratory bronchioles has a number of characteristic features on gross examination of the lung. In the *classical* lesion, the enlarged, destroyed respiratory bronchioles coalesce in series and in parallel to produce sharply demarcated



A B

Figure 39-3 Pathologic subtypes of emphysema. **A.** Predominantly centriacinar emphysema. Emphysema is more severe in upper lobes. **B.** Predominant panacinar emphysema. Emphysema is more severe in the lower lobes.

emphysematous spaces, separated from the acinar periphery (the lobular septa), by intact alveolar ducts and sacs of normal size. The walls of the emphysematous spaces and adjacent tissue characteristically contain variable amounts of black pigment.

The lesions vary qualitatively as well as quantitatively even within the same lung. There is striking irregularity of involvement of lobules, and even within the same lobule.[17,18] The lesions are usually more common and become more severe in the upper than in the lower zones of the lung (Figs. 39-3A and 39-4A,B).[19–24] Most affected are the upper lobe, particularly the posterior and apical segments, and the superior segment of the lower lobe. In cases of severe CLE, the destruction proceeds toward the periphery of the lobule, and the distinction between CLE and PLE becomes blurred.

In CLE, alveolar pores are abnormal in size and shape, and occasionally contain epithelial debris and macrophages. Although there are numerous pores of variable size in the emphysematous areas,[25] there are also increased numbers of pores in the grossly normal areas, and accentuation of these changes in the center of the lobule.[26] Thus, it appears that in CLE the pores of Kohn are possibly the initial site of destruction.

There is increased cellularity in the alveolar walls of cigarette smokers,[27] and when this has been quantified, the parenchyma in severe emphysema has increased numbers of neutrophils, macrophages, eosinophils, and both CD4 and CD8 T lymphocytes.[28] There is also a significant inflammatory cell infiltrate in the airspaces in severe emphysema, with the same cell types increased.[28] Although not readily apparent grossly or on standard histologic stains, use of histochemical stains or biochemical analysis demonstrates that collagen is increased in both centrilobular and panlobular emphysema.[29–31]

■ PANLOBULAR EMPHYSEMA

The recognition of mild panlobular emphysema is very difficult. The normal lung has a very characteristic appearance when seen through a dissecting microscope: The multifaceted alveoli form a contrast to the larger, cylindrical conducting structures that are alveolar ducts and respiratory bronchioles. In panlobular emphysema the distinction between alveolar ducts and alveoli becomes lost as alveoli lose their sharp angles, enlarge, and then lose their contrast in size and shape with the ducts, resulting in simplification of the lung architecture, with formation of small box-like structures. As the process becomes worse, the architectural derangement becomes more obvious, with progressive effacement and loss of the orderly arrangement of the lung until little remains other than the supporting framework of vessels, septa, and bronchi. The best way to see panlobular emphysema grossly is to examine lung slices immersed in a water or fixative bath and then immediately after removal from the bath. The immersed specimen shows enlarged airspaces and, when the slices are lifted from the bath, panlobular emphysema can be suspected because the lung parenchyma "falls away" from the supporting structures and protrudes slightly above them. In contrast to centrilobular emphysema, panlobular emphysema is usually worse in the lower lobes (Fig. 39-3B).

Histologic examination is a sensitive method of recognizing panlobular emphysema. The pattern is again one of simplification with diminishing contrast between alveoli and alveolar ducts (Fig. 39-4C,D). Despite the greater extent of tissue destruction, in panlobular emphysema the pores of Kohn are more uniform and inconspicuous than those found in centrilobular emphysema.[32]

Panlobular emphysema is the characteristic lung lesion seen in α1-antitrypsin deficiency,[33] but may also occur as a consequence of permanent obliteration of airways (obliterative bronchiolitis, constrictive bronchiolitis). Most often, obliteration of airways results in collapse of the distal lung parenchyma and dilatation of the bronchi proximal to the obliterated airways. This is the sequence of events in postinfective bronchiectasis. In some instances, however, the lung parenchyma does not collapse, but remains fully expanded or

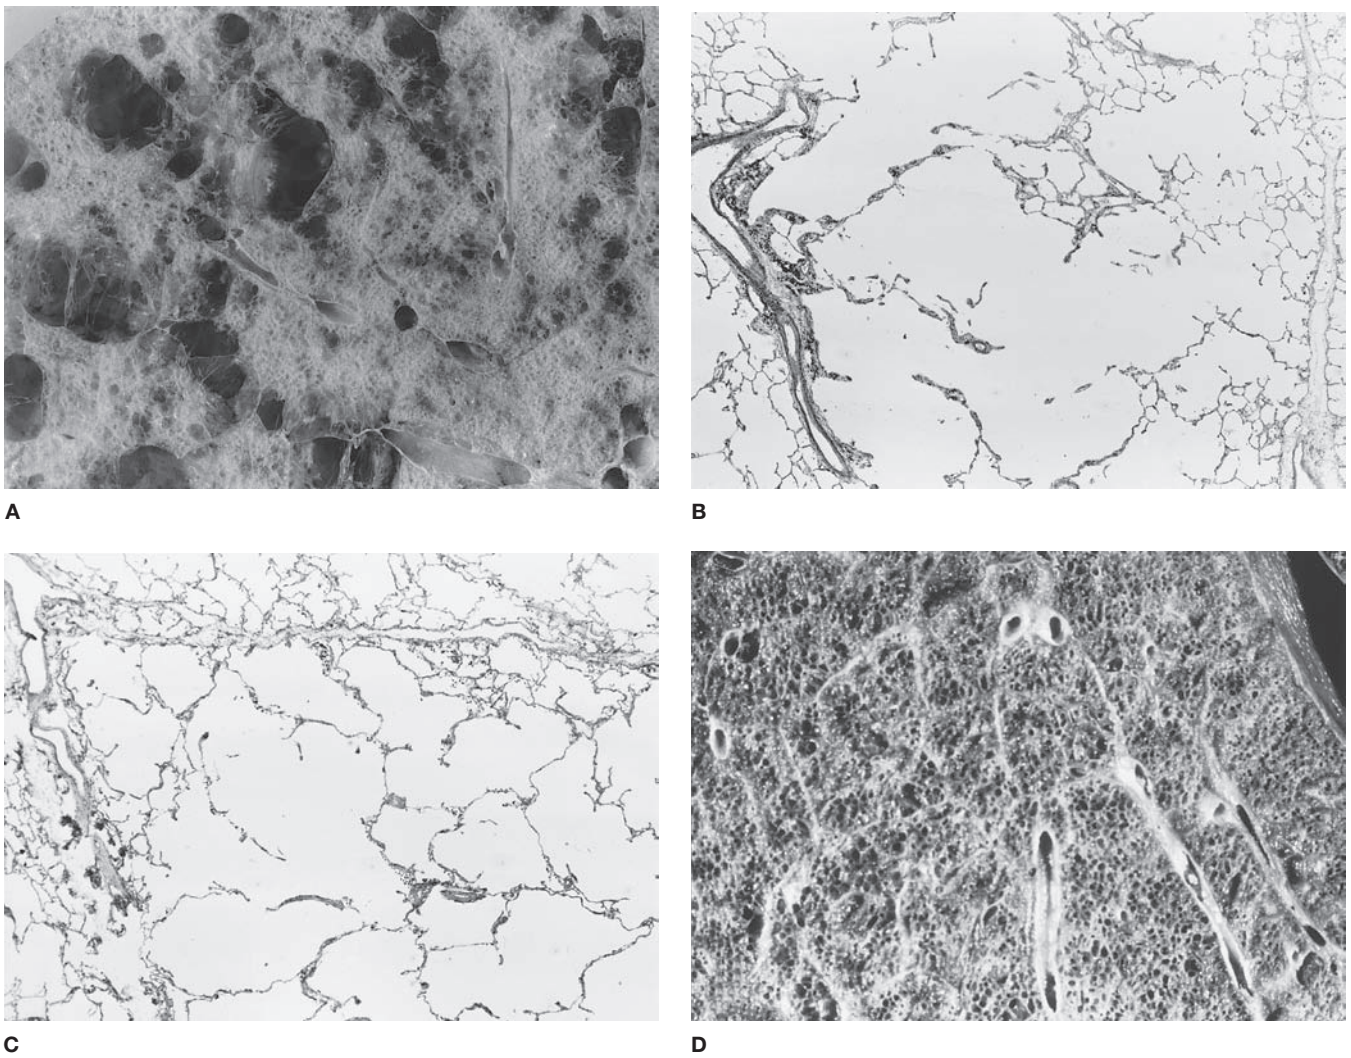


Figure 39-4 **A, B.** Gross and histologic sections illustrating centriacinar; and (**C, D**) panacinar emphysema. **A.** Cut surface from a lung with centriacinar emphysema showing holes in the center of lobules surrounded by relatively normal parenchyma. The severity varies among lobules. **B.** Microscopic section showing that the airspace enlargement in centriacinar emphysema is most marked adjacent to the abnormal respiratory bronchiole, corresponding to the center of the lobule. Also, some of the alveolar walls of the abnormal airspaces are thickened and fibrotic (H&E, ×16). **C.** Cut surface of a lung slice showing how the entire lobule is uniformly affected in panacinar emphysema. **D.** Microscopic section demonstrating that in panacinar emphysema, the airspaces adjacent to the lobular septa are enlarged to the same degree as those in the center of the lobule (H&E, ×16).

becomes emphysematous. The parenchymal sequel to bronchial and bronchiolar obliteration depends on the extent of the obliteration and the amount of collateral ventilation between adjacent airspaces distal to unobstructed airways. If collateral ventilation is present, then the units distal to the obliterated airways will remain expanded by virtue of the air reaching them by collateral ventilation, producing overexpansion and destruction of lung parenchyma beyond the obliterated airways. The terms Swyer–James or MacLeod syndrome are applied when this process affects most of one lung but spares the other.

■ DISTAL ACINAR EMPHYSEMA: PARASEPTAL EMPHYSEMA

The original description of distal acinar emphysema is generally credited to Loeschcke,[34] who described collections of subpleural bullae. It was Heard,[24,35] however, who first noted that the lesions could extend into the substance of the lung, where they lay along the septa, and coined the term "paraseptal" emphysema. Since the distal part of the acinus (alveolar sacs and ducts) is dominantly involved, emphysema is most striking adjacent to the pleura (superficial emphysema or mantel emphysema), along lobular septa (paraseptal emphysema), at the margins of lobules and acini (periacinar emphysema), and along vessels and airways, which, when cut longitudinally, display a linear pattern. The characteristic morphology is that of multiple contiguous, enlarged airspaces, varying from <0.5 mm to >2 cm in diameter.

Paraseptal emphysema is usually limited in extent, and is found most commonly along the anterior and posterior parts of the upper lobe and along the posterior surface of the lower lobe. When extensive, it is usually more severe in the upper half of the lung. Gough has stressed that it is associated with fibrosis of the tissue between the enlarged airspaces, and this is certainly a common finding.[36] Paraseptal emphysema is frequently found in association with centriacinar emphysema,[20] but it is most known for its association with spontaneous pneumothoraces in young thin adults.[37]

■ IRREGULAR EMPHYSEMA

Irregular emphysema is logically named, because the acinus is indeed irregularly involved in it. Irregular emphysema is almost invariably

TABLE 39-1 Differential Diagnosis of Airspace Enlargement

	Distribution	Enlarged Structure
Centrilobular emphysema	Upper lobes, center of lobule	Alveolar ducts, alveoli
Panlobular emphysema	Lower lobe, uniform in lobule	Alveoli
Paraseptal emphysema	Apical, adjacent to septum	Alveoli
Irregular emphysema	No typical site, adjacent to scars	Alveoli
Aging	Uniform in lung	Alveolar ducts
Compensatory alterations	Uniform in lung	Alveoli
Obstructive alterations	Affected area	Alveoli
Genetic alterations	Uniform in lung	Lack of septation
Asthma	During acute attack	Alveoli
Honeycomb lung	Variable—often subpleural	Total remodeling

adjacent to a scar, giving name to the synonyms scar or paracicatricial emphysema. Most scars within the lung are usually small and the emphysema is limited in extent. The severity of irregular emphysema depends on the extent of damage to lung tissue, and multiple scars through the lung may lead to multiple foci of irregular emphysema.

DIFFERENTIAL DIAGNOSIS OF EMPHYSEMA

GAS TRAPPING

The lungs of an asthmatic who has succumbed during an attack are usually characterized by gas trapping, and thus remain inflated, with focal areas of atelectasis (Table 39-1). In a patient with long-standing asthma who has died from other causes, or has had a lung resection, there may still be areas of atelectasis. Focal bronchiectasis can be found also, particularly in the anterior segment of the upper lobe. However, parenchymal destruction is not a feature of asthma, and thus gross, microscopic, and morphometric analyses will all be normal in the chronic asthmatic.

NONEMPHYSEMATOUS AIRSPACE ENLARGEMENT

Although not part of the differential diagnosis of COPD, non-emphysematous airspace enlargement also occurs in infancy. In congenital lobar hyperinflation (emphysema), the lobes are over-inflated rather than emphysematous, but in some instances they may be polyalveolar.[38,39] Some other genetic abnormalities will also give enlarged airspaces, but this is due to failure of septation with a simplified rather than a destroyed alveolar framework.

At the other side of the age spectrum, the term senile emphysema was once used to describe the enlarged airspaces found in the aged. On gross examination, lungs round out with increasing age. An analysis of Gough sections showed increases in anteroposterior distance, height, perimeter, and area of the lung up to the age of 59 years. After this age, only the anteroposterior diameter continued to increase significantly, thus "rounding" the lung dimensions.[40] This change is due to an increase in the volume proportion of alveolar duct air,[41] with shallower and flatter alveoli,[42] a process termed ductectasia. There is no evidence of lung destruction; thus, the condition does not fulfill the criteria for emphysema.

If a part of the lung collapses or is removed, the remaining lung can expand to fill the increased amount of space available, a process known as compensatory overinflation. The exact way that this happens and the limits of the process are unknown. However, no tissue destruction has occurred and, by definition, this is not emphysema. It is not clear how much larger the overinflated lung can become, or how it expands to reach the new and larger volume. It is generally thought that the possible extent of overinflation is modest and that all the parts of the acinus are equally expanded.

Obstructive overinflation can occur in adults, and two mechanisms may be involved. In one, the obstruction in the bronchus may act as a ball valve, so that air enters on inspiration but does not leave on expiration. Alternatively, the bronchus may be completely obstructed and air may be trapped behind channels of collateral ventilation. Whatever the mechanism, the affected part of the lung can expand considerably. Obstructive overinflation differs in a number of ways from compensatory overinflation, although, in both, the lung contains too much air per unit of lung and lung tissue.

HONEYCOMB LUNG

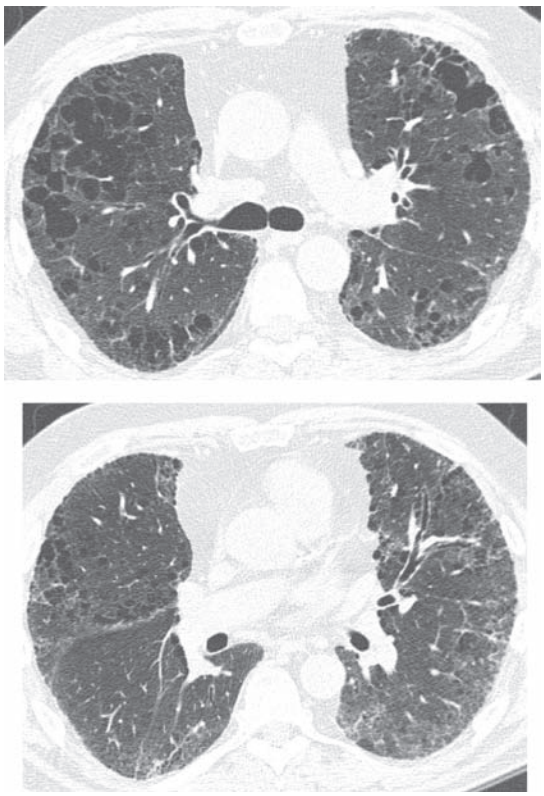
The airspace enlargement that occurs in cryptogenic fibrosing alveolitis (usual interstitial pneumonia [UIP]) and other fibrotic lung diseases could possibly be confused with emphysema. While honeycomb spaces are enlarged airspaces, they are the result of parenchymal remodeling with formation of new airspaces, rather than destruction of normal airspaces, and thus have thickened and irregular walls with none of the structure of an acinus. They are lined by bronchiolar epithelium, and often contain mucus; the walls have abundant and well-collagenized connective tissue, which may also contain impressive amounts of muscle and sometimes fat. There is usually interstitial inflammation in the form of varying degrees of lymphocytic and plasma cell infiltration.

COMBINED EMPHYSEMA AND FIBROSIS

Despite the definition of emphysema, which limits fibrosis, the significance of a mixture of fibrosis and emphysema has recently been reevaluated in relationship to its clinical, radiologic, and pathologic components.[43] The problem is that people who smoke cigarettes not only can develop respiratory bronchiolitis-interstitial lung disease (RB-ILD), but also have a higher incidence of developing UIP (idiopathic interstitial fibrosis), and mixtures of these with emphysema are not uncommon. When the combination of emphysema and UIP occurs, lung volumes can be preserved, but the diffusing capacity becomes markedly decreased, and pulmonary hypertension develops, with its associated significant negative prognosis. CT scans generally show centrilobular or mixed centrilobular and paraseptal emphysema in the upper lobes, with increased reticular markings and honeycomb remodeling in the lower lobes. Pathologically, there is both gross and microscopic emphysema and interstitial fibrosis with fibroblast foci in the areas of active fibrosis.[44] We have recently reviewed this topic with a focus on the pathologic differential diagnosis (Fig. 39-5A–D).[45]

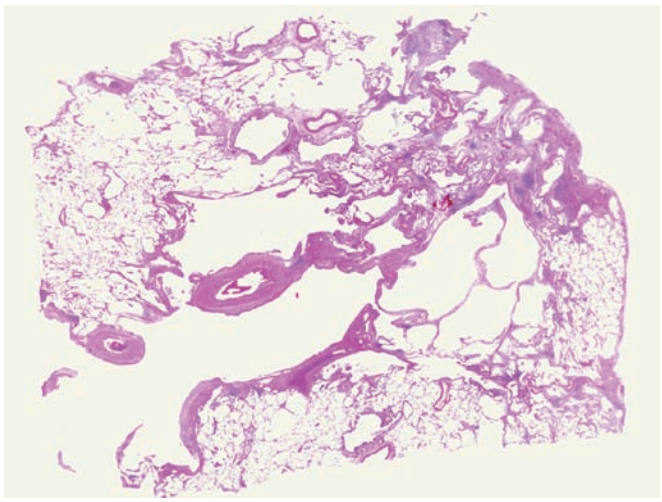
LESIONS OF THE LARGE AIRWAYS IN COPD

The majority of studies in this area have focused upon the lesions present when the clinical signs and symptoms of chronic bronchitis are also present.

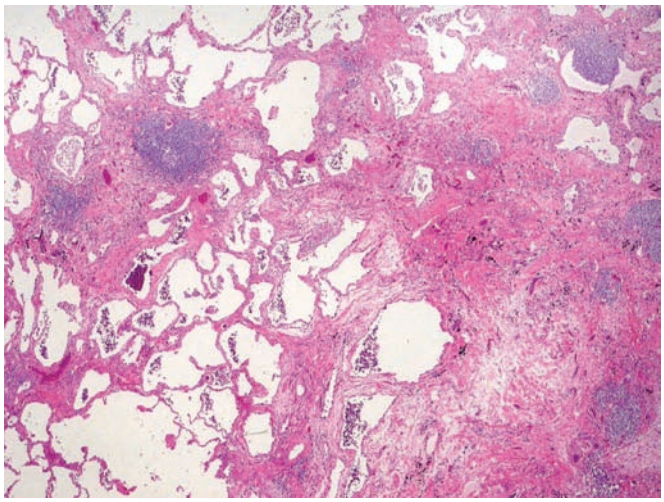


A

B



C



D

Figure 39-5 Combined fibrosis and emphysema in a case of chronic (fibrotic) hypersensitivity pneumonitis. **A.** Computed tomography scan from upper zone *(top)* shows emphysema and a suggestive of reticulation; lower image from midlung zone shows extensive reticulation indicating the presence of underlying fibrosis. **B.** Gross photo (sagittal slice) from this case showing marked upper zone emphysema, with fibrosis evident in the most posterior portion of the upper lobe, and the posterior portions of the lower lobe. **C.** Whole mount from the upper lobe. There are large emphysematous spaces, several with extensive surrounding fibrosis; at higher magnification, many of these fibrotic rims had fibroblast foci (not shown), indicating that this process is really interstitial fibrosis stretched around pre-existing emphysema. **D.** Image from lower lobe showing a UIP-like area, a common finding in chronic hypersensitivity pneumonitis. Elsewhere there were noncaseating granulomas (not shown). *(Reproduced with permission from Wright JL, Tazelaar H, Churg A. Fibrosis with Emphysema. Histopathology. 2011;58(4):517–524 (This document was published in 1993. Certain aspects of this document may be out of date and caution should be used when applying the information in clinical practice and other usages).)*

■ GROSS FINDINGS

Gross lesions in the large airways are few and subtle. Bronchial pits are the dilated openings of one or more mucus glands into the epithelium. They are most often found along the margins of the cartilaginous rings and at the bifurcations of the airways. In nonbronchitis the pits can be seen using a hand lens or a dissecting microscope, but in chronic bronchitis, the ducts may be distended with mucus and the mucus may protrude into the lumen of the bronchus and be visible grossly. It is not correct to refer to these as diverticula. First, these are protrusions of normal ducts; and second, they do not extend through all of the muscle coats of the bronchial wall.

While enlarged bronchial pits are the most obvious gross lesions in COPD, careful examination of lung specimens will show that the bronchi do not taper progressively as they approach the pleura,[46] and they also display prominent circular ridges, probably due to bands

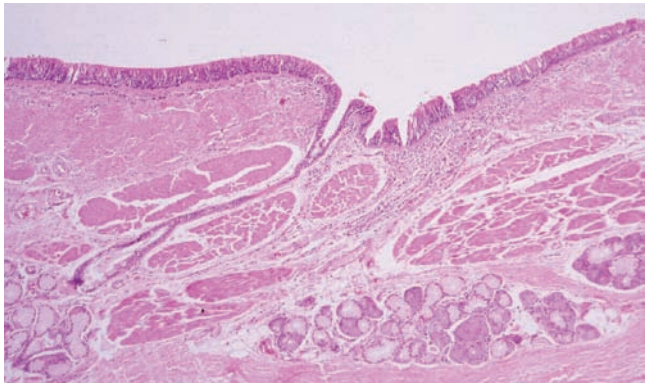


Figure 39-6 Large airway from a subject with chronic bronchitis. The overall wall is thickened with inflammation and fibrosis, and there is prominence of the smooth muscle in addition to the bronchial mucus glands.

of hypertrophic smooth muscle.[47,48] Gross mucus may be present in the airway lumen, particularly in subjects with chronic bronchitis.[49]

■ MICROSCOPIC FINDINGS

The intraluminal mucus found in the airways of subjects with COPD contains a mixed population of epithelial cells and acute and chronic inflammatory cells; large numbers of neutrophils can be found during an exacerbation.

Detailed microscopic analysis of the large airways in COPD reveals alterations in the entire airway wall (Fig. 39-6). Epithelial changes are mild in degree and are not necessarily consistent from patient to patient. Epithelial sloughing can occur, but in most instances the epithelium is generally intact and shows only mild goblet cell or squamous cell metaplasia, both of which appear to be more marked if the subject has symptoms of chronic bronchitis.[50,51] The reticular basement membrane thickness is within the normal range.

The thickness or area of mucus glands in subjects with COPD in general, or chronic bronchitis in particular, is increased over a population mean, but has a distribution that extensively overlaps that of normals and asthmatics.[52–55] Interestingly, there appears to be a decreased percentage of serous acini in these glands, a feature that apparently does not occur in asthma (discussed below).[56]

Thickening of the inner wall (area internal to the muscular layer) appears to be the most consistent component of airway wall thickening in the large airways of subjects with COPD, and appears to be generalized.[57,58] This increase in thickness can be partially attributed to edema and hyperemia of the bronchi,[59] but is also due to an increase in fibrous tissue or other matrix proteins.

In the large airways of subjects with COPD, increases in the thickness of the muscular layer have not been consistently identified. Although some studies[60] have found that the average proportion of muscle in main, lobar, and segmental bronchi was approximately doubled in patients with chronic bronchitis and airflow obstruction, others have found that a substantial number of patients fell within the normal range.[54,55,61]

Alteration in the amount of cartilage in COPD does not appear to be a consistent finding. While some studies[59,62,63] described cartilage atrophy in chronic bronchitis and/or emphysema, or circumferentially arranged cartilage that extended farther distally in nonbronchitis than bronchitis,[64] this was not supported by other reports.[54,65] However, histologic signs of cartilage damage, as judged by loss of cellular or pericellular metachromasia and vacuolated or empty lacunae can be consistently identified.[66]

The large airways in COPD show a mild, usually mixed, inflammatory infiltrate. Bronchus-associated lymphoid tissues (BALT) is not consistently found, but its frequency appears to be considerably higher (82%) in smokers than nonsmokers (14%).[67] Bronchial biopsy analysis consistently shows an increase in CD8 T cells, with eosinophils and neutrophils found during exacerbations (reviewed in Refs.[50,68]). Chronic inflammation can also be found around the bronchial glands, particularly in subjects with chronic bronchitis.[69]

DIFFERENTIAL DIAGNOSIS

■ ASTHMA

In asthma the large airways are not dilated, but mucus plugs are classically identified in the large airways of subjects with fatal or near-fatal asthma,[70] and the mucus may be continuous with that present in the ducts of the mucus glands (Table 39-2). Visible bronchial pits are not a standard feature of asthma, and although the airway wall may be thickened, this is usually not apparent grossly.

In the large airways of subjects with asthma, desquamation of the epithelium is a common feature,[71,72] and this may be worse in people who have persistent rather than intermittent activity. Sloughing of cohesive epithelial clusters produces the creola bodies found in cytology specimens. Goblet cell metaplasia can be marked in both asthma and bronchiectasis,[73] but there is a considerable degree of variability, so that this feature cannot be used in isolation to distinguish among

TABLE 39-2 Pathologic Differential Diagnosis of Large Airway Lesions in COPD

Check mark indicates that the feature is present; X indicates that the feature is absent.

the airways of subjects with COPD, asthma, and bronchiectasis. These epithelial cell changes result in an overall thickening of the epithelium in asthma, but not in COPD.[58] In asthma, the reticular basement membrane (lamina reticularis) is characteristically thickened. This alteration occurs early in the course of disease, and remains even when the asthma is mild or well controlled (reviewed in Ref.[56]).

The airways of asthmatics demonstrate a greater severity of inner wall thickening, with values double those found in patients with COPD.[58] The increase in thickness is due to variable increases in fibrous tissue, inflammatory cells, edema fluid, and vascular prominence.[50,56] Analysis of the muscular wall in subjects with severe or fatal asthma compared with normals or those with COPD shows a marked increase in amount of muscle, with a lesser increase in asthmatics who died with rather than from their asthma (discussed in Ref.[74]). There has also been a suggestion that the increase in muscle mass may occur relatively early during childhood.[56]

Neutrophils are the predominant cells present in the mucus of patients with bronchiectasis, while eosinophils and accompanying Charcot Leyden crystals are the hallmark of asthmatic mucus. As noted, the cartilaginous destruction present in polychondritis is severe and associated with chronic inflammation, thus easily distinguishing the two processes. Depending upon the severity of the inflammation in bronchiectasis, there may be significant cartilaginous destruction.

Airways from fatal and near-fatal asthma also contain isolated aggregates of lymphoid cells, roughly in the same proportion as that present in COPD.[75] However, in asthma, by contrast to COPD, there is an inflammatory infiltrate consisting of activated eosinophils, and activated CD4 T cells in the submucosa,[76] and both mast cells and neutrophils within the glands.[70] There is little in the literature regarding the inflammatory cell infiltrates present in the airway walls in bronchiectasis. Compared with asthma, there appear to be fewer eosinophils, but a similar population of CD45 (as opposed to any specific subtype) lymphocytes, with both cell types having a greater density in the inner, as opposed to the outer aspect of the airway.[77]

BRONCHIECTASIS

In bronchiectasis, there is by definition an abnormal and permanent dilatation of the bronchi, and this is usually present to a much greater degree than is found in COPD, and is often accompanied by airway distortion. There is exaggeration of the muscular ridges and the presence of multiple bronchial gland–based pits. The large airway walls can be thickened and/or irregularly thinned as a result of inflammation and fibrosis, and there is often inspissated mucus or actual purulent material.

MISCELLANEOUS CONDITIONS

Tracheobronchomegaly (Mounier-Kuhn syndrome) is characterized by a marked dilatation of the trachea and major bronchi, with diameters 5 to 10 cm above normal values.[78] In this condition there are multiple true diverticula, with out-pouchings formed of membranous tracheal tissue between the cartilaginous rings,[79] with atrophy or absence of elastic fibers.[80]

Patients with tracheobronchopathia osteoplastica have an obstructive pulmonary function pattern[81]; however, unlike the trachea and large airways in COPD, cartilaginous and bony nodules are present in the subepithelial space (submucosa). Relapsing polychondritis[82,83] shows variable dynamic expiratory and/or inspiratory obstruction depending on the size and location of the airways involved. In this disease, however, the obstruction is due to impaired airway clearance of inflammatory debris, and an ineffective cough because of dynamic upper airway collapse. The airways are dilated and the walls are thickened because of the extensive fibrosis and chronic inflammation due to the immunologic nature of this condition. In particular, the cartilaginous plates show extensive destruction.

LESIONS OF THE SMALL AIRWAYS IN COPD

In the context of COPD, small airways refer to airways with an internal diameter of 2 mm or less. In COPD, intraluminal mucus can be found in the small airways, and there appears to be an overall relationship between the degree to which the airways are occluded by mucus and the FEV_1.[84] Goblet cells are rare in normal small airways, but goblet cell metaplasia is a frequent finding in the airways of patients with COPD.[85–87]

Similar to the large airways, there is alteration of all of the small airway wall compartments in patients with COPD (Fig. 39-7). These changes result in an overall decrease in the internal bronchiolar diameter and, as assessed by a conformity index, produce significant deformity. Similar results are obtained from three-dimensional reconstructions.[74] Detailed measurements of the airway walls show that the increased wall thickness is due to increases in the epithelium, subepithelial fibrous tissue compartment (submucosa, lamina propria), smooth muscle, and adventitia.[58,84] While there is no direct evidence, it seems appropriate that these changes would result in airway obliteration, a process which appears to happen relatively early in airflow obstruction, with the number of airways in patients with severe airflow obstruction reduced to one-tenth of the numbers calculated in the normal lung (see Fig. 39-8A,B).[88] Although the adventitia is thickened, there is a loss of alveolar attachments to the airway wall,[89] an important process because it allows early airway collapse on expiration.

One of the earliest histologic abnormalities that can be detected in cigarette smokers is the presence of macrophages in the lumen of the respiratory bronchioles.[90] However, an inflammatory infiltrate can also be identified within the walls of both membranous and respiratory bronchioles in subjects with COPD. When examined in conjunction with the GOLD (Global Strategy for the Diagnosis, Management, and Prevention of COPD) stage, the proportion of airways which had measurable neutrophils appear to be increased in GOLD stages 2 to 4, and airways with measurable macrophages show a progressive increase from GOLD stage 0 to 4, while there does not seem to be any alteration in the percentage of airways that contain eosinophils among the GOLD stages.[91] The percentage of airways with CD4, CD8, and B cells also increase with GOLD stage, but when these data are expressed as total accumulated volume, only the B cells and CD8 cells show progressive increases. The presence of lymphoid follicles is markedly increased in GOLD stages 3 and 4. Interestingly, histone deacetylase 2 (HDAC2) appears to be downregulated in the

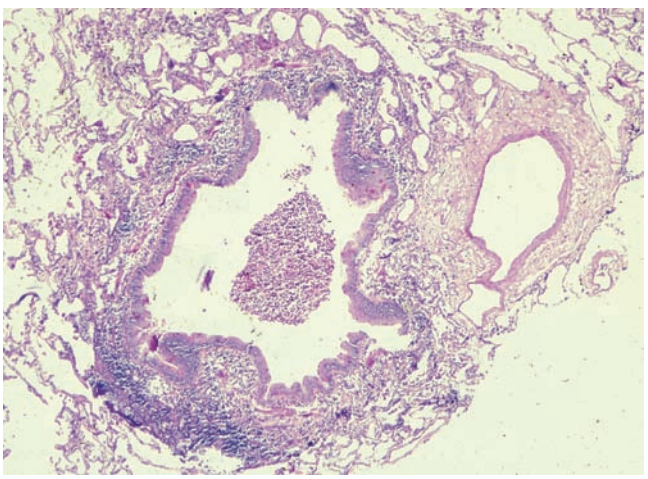

Figure 39-7 A small airway from a subject with COPD. The lumen contains mucus and inflammatory debris. There is goblet cell metaplasia of the epithelium. The subepithelial (submucosal) layer is increased in thickness due to an increase in fibrous tissue and inflammatory cells.

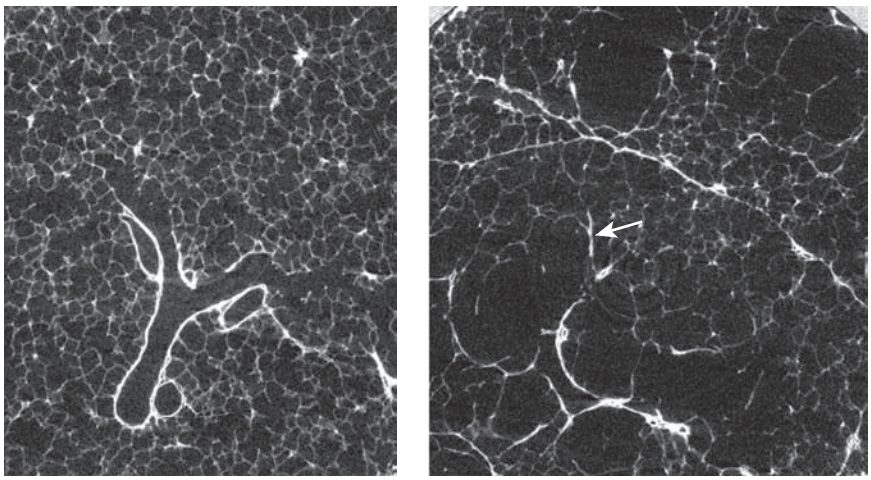

A B

small airways of smokers with COPD,[92] a finding which may be of considerable importance since downregulation of the HDAC system is associated with a pro-inflammatory cytokine profile.

DIFFERENTIAL DIAGNOSIS

ASTHMA

Mucus plugs and goblet cell hyperplasia are markedly increased in the small airways of asthmatics[73,93] and this increase is generally much greater than that seen in COPD. In addition, the basement membrane thickness is approximately 20% greater than that found in either normals or patients with COPD.[73] The peripheral airways of asthmatics have an inflammatory infiltrate that features lymphocytes and eosinophils,[73,77,94] with many of the inflammatory cells in the adventitial, as opposed to the submucosal compartment. The data regarding the vessels in the submucosa are controversial, with some studies suggesting that they are congested, but not increased in number, in asthmatics compared with COPD (discussed in Ref.[74]), and others demonstrating an increased number of vessels, but a lesser total area in asthma compared with COPD.[95] Although smooth muscle is increased in asthmatics, the increase is not as great as that present in the large airways.[96] Moreover, the distribution of smooth muscle increase in the bronchial tree may be quite different, with some patients displaying a generalized increase, while in others the increase is restricted to the larger airways.[97] Overall, the small airways in asthmatic subjects who have died because of their disease have a greater area of subepithelial fibrous tissue, smooth muscle, and adventitial fibrous tissue than do subjects who died with their disease, which in turn have a greater area than do the airways of subjects with COPD.[98] Thus, although the same qualitative changes are present in both asthmatics and COPD, they are more severe in asthmatics and most severe in cases of fatal asthma. Interestingly, there appears to be a loss of alveolar attachments in cases of fatal asthma,[99] although this is less than that present in the airways of patients with COPD.

FOLLICULAR BRONCHIOLITIS

Follicular bronchiolitis is characterized by narrowing of the bronchioles due to adventitial and subepithelial lymphoid follicles, and accompanied by a lymphoplasmacytic inflammatory infiltrate.[100] The condition is classically found in patients with rheumatoid arthritis or those with IgA deficiency. This process can mimic severe COPD small airway disease, but the inflammatory infiltrate is generally magnified compared to COPD, while there is little goblet cell metaplasia in the airway epithelium.

PANBRONCHIOLITIS

The presence of foamy macrophages in the airway wall and lumen and extending down into the alveolar ducts and alveoli is a feature of the condition known as panbronchiolitis, originally described in Japan but now known to occur worldwide.[101,102] Follicular hyperplasia of the peribronchiolar lymphoid tissue is frequent, and bronchiolectasis is found in the more advanced lesions.

CONSTRICTIVE BRONCHIOLITIS

The term constrictive bronchiolitis appears to have been coined by Gosink et al.[103] In constrictive bronchiolitis, the airway lumen is occluded by a progressive thickening of the subepithelial (submucosal) space. Both the membranous and respiratory bronchioles are involved, and show transmural inflammatory cell infiltrates, occasionally with epithelial necrosis. Mucus plugs can also be identified. As the process evolves, the inflammatory infiltrate wanes, and greater amounts of fibrous tissue can be demonstrated both in the peribronchial and subepithelial portions of the airway, acting to narrow or obliterate the airway lumen.[104] Lesions of constrictive bronchiolitis, particularly in the organized phase, may be difficult to demonstrate, and may require elastic stains to outline the obliterated airway. Thus, the lesions in COPD differ from constrictive bronchiolitis only in degree.

Mineral dust–induced airway disease is a distinctive type of constrictive bronchiolitis, characterized by a stereotypic response of the small airways to high doses of particulate, regardless of the specific mineral dust involved. The lesions consist of fibrosis and thickening of the walls of both the membranous and respiratory bronchioles, sometimes extending down the alveolar ducts, the latter finding providing diagnostic discrimination from tobacco smoke–induced airway disease, which tends not to involve the alveolar ducts. Pigment deposition is highly variable, and is not a diagnostic feature.[105] Other forms of constrictive bronchiolitis may be related to ingestion of toxic compounds such as *Sauropus androgynus* ingestion,[106–109] *or* related to diffuse neuroendocrine cell hyperplasia.[110–113]

PROLIFERATIVE BRONCHIOLITIS

The lesions of proliferative bronchiolitis have been elegantly described and illustrated.[114–116] Within the lumens of the membranous and respiratory bronchioles are plugs of organizing fibroblastic (granulation) tissue. Occasionally, ulceration of the epithelium can be seen, and early lesions may have fibrin. The granulation tissue is formed of a pale matrix with proliferating spindle cells, accompanied by chronic inflammatory cells. As the lesions age, the granulation tissue usually shrinks and contracts. However, in a certain proportion of cases, the bronchiolar cells proliferate over the granulation tissue, and incorporate it into the subepithelial space, leaving an irregular airway lumen.

Although acute bronchiolitis, be it bacterial or viral in nature, is usually easily distinguished from the lesions of COPD by the presence of extensive epithelial damage, healed lesions may

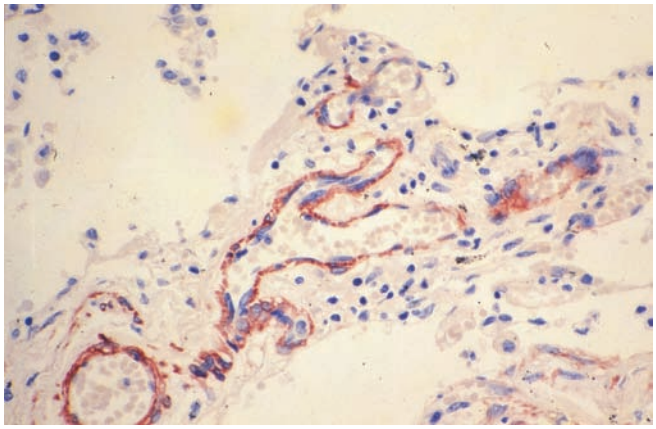

Figure 39-9 A small pulmonary artery from a subject with COPD. These vessels, situated adjacent to the alveolar ducts, are normally poorly muscularized, but in this case, the vessel has a distinct circumferential muscular layer.

show nonspecific airway fibrosis and chronic inflammation, or the residua of proliferative bronchiolitis. Interestingly, latent adenoviral infection has been suggested as a contributor to airflow obstruction in adults by amplifying the inflammatory response in the bronchioles of cigarette smokers.[117] Airway disease complicating other diseases may also need to be distinguished from that of COPD. For example, posttransplant bronchiolitis[115,118] or airway disease in patients with inflammatory bowel disease (both Crohn disease and ulcerative colitis)[119] include both proliferative and constrictive bronchiolitis. Inflammatory bowel disease may also have large airway involvement.

LESIONS OF THE VESSELS IN COPD

There are no consistent alterations in the large elastic pulmonary arteries of subjects with COPD. Atheromata can be found,[120] but unless there is pulmonary hypertension, the incidence is probably not greater than that found in a carefully matched population.

Cigarette smokers, with or without pulmonary hypertension, have an increase in arterial muscle media thickness as well as intimal fibrosis in the muscular arteries, and progressive muscularization of the small arterioles (reviewed in Ref.[121]). Increases in intimal thickness with longitudinal muscle formation are a common feature in lungs of patients with COPD (Fig. 39-9).[11,122,123] There appears to be a progressive increase in the numbers of smaller muscularized arteries, percent medial thickness, and percent intimal thickness of muscularized arteries from nonsmokers, to smokers without obstruction, to smokers with airflow obstruction.[124]

The lesions of primary pulmonary hypertension and hypertension secondary to vascular shunting also include intimal fibrosis and increased muscular media thickness. Intimal fibrosis is often cellular in its early phases, but progresses to concentric laminar fibrosis, which can almost totally obliterate the vessel lumen. These changes are of much greater severity than those identified secondary to COPD. Vasculitis, fibrinoid necrosis, and plexiform lesions are never found in COPD. Lesions of chronic thromboembolic disease include eccentric intimal thickening, and the occasional formation of webs due to recanalization of the thrombi.

NONPATHOLOGIC, CT SCAN–BASED, EVALUATION OF TISSUE COMPARTMENTS IN COPD

CT scanning has provided useful information on the lung parenchyma, airways, and pulmonary vasculature in patients with COPD.

EMPHYSEMA

The advent of high-resolution CT scanners has allowed identification of even mild emphysema, and can distinguish between emphysema and senile lung airspace enlargement. When combined with general morphometric principles, emphysema can be quantified, and emphysema progression can be monitored.[125–128]

AIRWAYS

Evaluation of this compartment is in its developmental phase, with much of the work being performed on phantom airways or in large animals. In humans, thin-section CT scans are able to demonstrate evidence of airway wall remodeling in the more proximal airways (first- to sixth-generation airways) of subjects with COPD or asthma, and it has been suggested that changes in these airways can be extrapolated to the smaller airways.[129] Certainly, the data do suggest that these measurements correlate with lung physiology, independent from emphysema.[130]

PULMONARY ARTERIES

Measurements of the mainstem pulmonary artery are easily performed on CT scans using contrast, and these data have shown prognostic significance. Evaluation of the smaller vessels is much more difficult, but initial work has found that determination of the total cross-sectional area of the vessels which have an individual cross-sectional area of less than 5 mm^2 have a significant negative correlation with pulmonary arterial pressure, at least in patients with severe emphysema.[131,132]

SUMMARY

There are a number of pathologic alterations of the lung in COPD. These involve almost all of the lung compartments, including the parenchyma, vasculature, and large and small airways. These changes can overlap the pathologic findings present in other diseases associated with airflow obstruction, or other diseases that are manifested in the lung. It is important to be able to make the distinction among these diseases. Although the pathologic alterations roughly correlate to alterations in pulmonary function, it is important to remember that their individual contributions are not well worked out. Thus, it may be difficult on an individual patient basis to proceed from a clinical classification such as the GOLD classification to a mechanistic/pathologic explanation of the airflow obstruction. Advances in CT scanning technology have allowed evaluation and quantification of emphysema, and there is developing work suggesting that evaluation of the airways and pulmonary arterial system may also be possible.

CHAPTER 40

Chronic Obstructive Pulmonary Disease: Epidemiology, Pathophysiology, Pathogenesis, and α1-Antitrypsin Deficiency

Robert M. Senior
Richard A. Pierce
Jeffrey J. Atkinson

Chronic obstructive pulmonary disease (COPD) is defined as a disease state characterized by airflow obstruction that is not fully reversible and for which there is no other explanation for the obstruction. The obstruction is usually progressive and associated with an abnormal inflammatory response of the lungs to noxious particles and gas. Unlike earlier definitions, this definition does not mention emphysema or chronic bronchitis. According to criteria set by the Global Initiative for Obstructive Lung Disease,[1] airflow obstruction is present when there is a reduction of the postbronchodilator FEV_1/FVC ratio below 0.7 and its severity is graded by the percentage of the postbronchodilator FEV_1 of the predicted normal FEV_1 (Table 40-1). However, 0.7 as the cutoff value for the FEV_1/FVC ratio has been controversial as it may be too high for all age groups and lead to misdiagnosis of COPD in healthy middle-aged and older individuals.[2] Alternatively, use of the lower limit of normal (LLN) for the FEV_1/FVC ratio has been recommended,[3] but it is uncertain whether this criterion improves the detection of clinically significant COPD or prognosis in elderly individuals.[4,5] Classification of COPD by GOLD has undergone further refinement recently with addition of self-reported severity of dyspnea and history of COPD exacerbations.[1] Chapter 42 comments further about risk stratification.[6]

EPIDEMIOLOGY

COPD is a major health problem worldwide.[7,8] Its prevalence is being recognized increasingly in countries at all levels of development.[9] An ever-increasing number of smokers and an expanding number of elderly people are major factors in the surge in the worldwide prevalence of COPD. In a study from Canada, 27.6% of individuals reaching the age of 80 were diagnosed with COPD by a physician over the preceding 14 years.[10] In large areas of the world where indoor air pollution is generated by burning biomass for heating and cooking, COPD is prevalent among nonsmokers, especially women.[11] Moreover, COPD is not restricted to smokers in developed countries. Of 4291 never-smokers over age 40, involving 14 developed countries, 5.6% met criteria for moderate to severe COPD, of whom 81.2% were undiagnosed.[12]

At present, COPD is the third most common cause of death in the United States.[13,14] As might be expected from the mortality figures, surveys indicate a high prevalence of COPD. The 2011 Behavioral Risk Factor Surveillance System (BRFSS), which is a state-based telephone survey of the US civilian adult population aged >18 years, found that 6.3% of US adults (an estimated 15 million nationwide) were told that they have COPD by a healthcare provider and a large percentage of these individuals reported having had spirometry.[15] Another survey, the 2010 National Health Interview Survey of approximately 27,000 adults in US households, yielded an estimate of 5 million adults in the United States with emphysema and

TABLE 40-1 Classification of Airflow Limitation in Patients with $FEV_1/FVC < 0.7$

Severity Stage	Postbronchodilator FEV_1
1: Mild	$FEV_1 \geq 80\%$ predicted
2: Moderate	$50\% \geq FEV_1 < 80\%$ predicted
3: Severe	$30\% \geq FEV_1 < 50\%$ predicted
4: Very severe	$FEV_1 < 30\%$ predicted

Low socioeconomic status	

10 million with chronic bronchitis, not all of whom may have airflow obstruction.[16] Although these figures are impressive, they may be an underestimate, since COPD is likely to be unrecognized in some groups such as elderly persons living in poverty. Other statistics support these national surveys. Among 1575 cigarette smokers, aged 30 or older, with a 10 or more pack-year smoking history, approximately 20% met spirometric criteria for COPD.[17]

The number of deaths due to COPD in the United States has been rising. In 2008, COPD was the primary cause of death in 141,090 Americans.[14] and was a comorbidity in many other deaths. The number of women dying of COPD now exceeds men and has more than doubled in recent decades. Based on the Third National Health and Nutrition Examination Survey (NHANES III), life expectancy is shortened by 5.8 years for men aged 65 with GOLD stage 4 COPD and by an additional 3.5 years if smoking has continued.[18]

ETIOLOGY

Risk factors for the development of COPD are environmental and host based (Table 40-2). In developed countries, smoking tobacco is the predominant risk factor. However, as noted above, never-smokers also develop COPD and women predominate in this cohort.[11,12] In places where solid fuels are burned, indoor air pollution is probably the dominant risk factor. Other factors associated with COPD include second-hand tobacco exposure, age, level of education, tuberculosis, hospitalization for respiratory illness before the age of 10 years (see further comment below), a family history of COPD, and the number of years worked in dusty jobs.[19] Clearly, multiple risk factors may be present in a single individual.

■ ENVIRONMENTAL

Smoking

A history of smoking is present in 80% to 90% of the individuals with COPD in developed countries. In the United States an impressive level of overlap exists between the geographic distribution of smokers and the geographic distribution of individuals who have been told they have COPD (Fig. 40-1). In a European study involving 6836 individuals with normal spirometry, age 20 to 44, smoking was the most commonly recognized risk factor for the development of new COPD over a decade.[20] Deterioration of FEV_1 correlates with pack-years of smoking, but the relationship between amount of smoking and risk of COPD is unpredictable on an individual basis (Fig. 40-2), In the Million Women Study conducted in the United Kingdom, that involved 232,461 current, 328,417 former smokers, and 619,774 never-smokers at baseline, the relative risk of death from chronic lung disease, presumably mostly COPD, over a 12-year follow-up was increased about 35-fold among middle-aged women who smoked.[21] Among former smokers, the age at smoking cessation affects the subsequent rate of deterioration of lung function. The rate is closest to never smokers for those who quit prior to age 30, but even for those who quit after age 40, deterioration is less than in continued smokers (Fig. 40-3).

The effects of gender on the risk of developing COPD from smoking are unclear. Women may be more susceptible to lung injury from smoking than men as they show more lung function reduction in association with lower total exposure and they predominate among individuals with early onset of COPD[22] and never-smokers with COPD. However, among individuals with advanced COPD treated with long-term oxygen therapy, men have a higher mortality rate than women, a difference that cannot be explained by comorbidities.[23] Some data indicate racial disparities in the risk of developing COPD, with African Americans showing similar severity of COPD to whites with lesser pack-years of smoking.[24,25] Hispanic ethnicity appears to confer protection from the risk of COPD and a reduced risk of accelerated decline in lung function due to smoking.[26]

According to statistics from the Center for Disease Control and Prevention (CDC), in 2010 there were an estimated 45.3 million smokers in the United States representing 19.3% of all adults over age 18.[27] The percentage was similar in African Americans and whites. Smoking was present in 21% of men and 17% of women. Hispanics and Asians had the lowest percentage of smokers at 12% and 9%, respectively, while the percentage was highest at 27% among American Indian/Alaska Natives. Beyond age 65 the incidence of smoking was 9.5%. The number of smokers worldwide is predicted to be 1.5 to 1.9 billion in 2025.[28] Thus, COPD will continue to be a profound health problem well into the future.

Among smokers who have already sustained reductions in FEV_1, the consequences of continued smoking on ventilatory function are more impressive than when all smokers are grouped together.[29] The Lung Health Study, which followed middle-aged smokers for 11 years, found accelerated decline in those who already had a reduced FEV_1 at the start.[30] Despite these findings, progressive decline in the FEV_1 is not inevitable among individuals with COPD (Fig. 40-4).[31,32]

Environmental Tobacco Smoke Exposure or Second-Hand Smoke

Environmental tobacco smoke exposure (ETS) is implicated in loss of many years of life of adults and children in the United States, with notable sensitivity among African Americans,[33] but COPD, specifically, as a cause of the life shortening due to ETS is not clear[34] Controlled experimental studies with normal volunteers indicate that short-term exposures to ETS at levels comparable to those in real-life situations have effects on serum cytokine levels and pulmonary function that if recurrent or chronic might translate into COPD.[35,36] However, when smoking and other risk factors are controlled both workplace and home ETS but not prenatal ETS increase the risk of development of COPD.[37] Data regarding in utero effects of maternal smoking on lung growth and subsequent risk of childhood wheezing or asthma are becoming evident. However, doubt exists regarding the quantitative impact on the development of COPD in individuals with only prenatal exposure. It seems likely that similar to cystic fibrosis, individuals with enhanced genetic risk factors could be adversely modulated by ETS,[38] but to date no definitive proof of gene-by-environment interactions for ETS have been demonstrated. The data does not suggest that ETS is harmless but rather it is less definitively causal of COPD as an independent risk than chronic smoking or occupational exposures.[37] Avoidance in individuals with existing lung disease is clearly indicated given the association with exacerbation. The attitude that there is no risk-free dose of ETS, is likely the safest approach; this applies to all ETS-related diseases and not just COPD.[34]

Indoor Air Pollution

As stated above, indoor air pollution from burning solid fuels such as wood and animal dung for cooking and heating is widespread in parts of the world. This practice exposes women and children to high concentrations of smoke containing respirable particles and complex gas mixtures for many hours daily and thus the risk of COPD. It compounds the risk of COPD in smokers who are more likely to be men in these settings. Cough and sputum occur among those

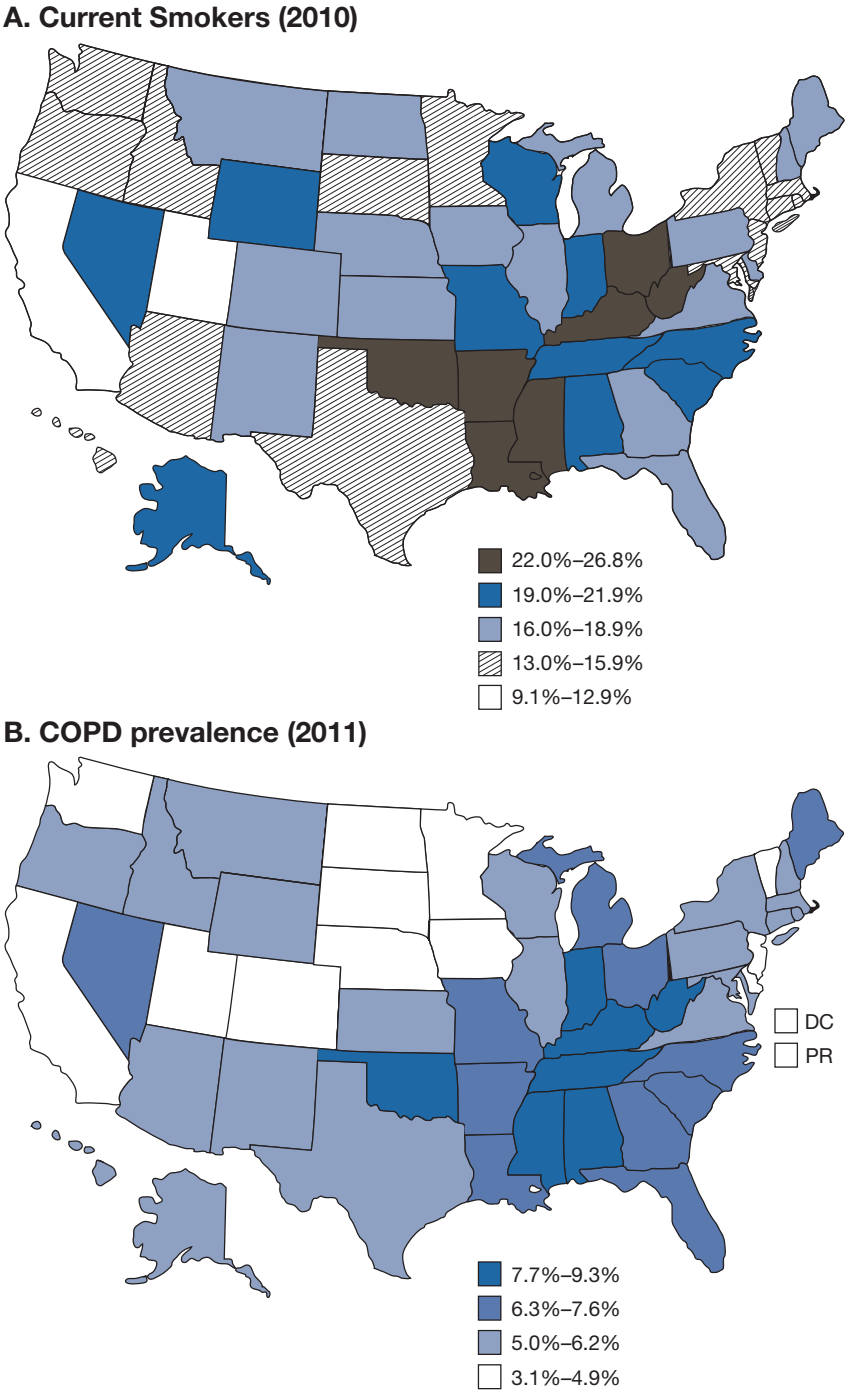

Figure 40-1 **A.** Percentage of persons aged ≥18 years who were current cigarette smokers, by state. Behavioral Risk Factor Surveillance System, United States, 2010. Persons who reported smoking at least 100 cigarettes during their lifetime and who, at the time of the survey, reported smoking cigarettes every day or some days. **B.** Age-adjusted prevalence of chronic obstructive pulmonary disease (COPD) among adults—Behavioral Risk Factor Surveillance System, United States, 2011. Based on an affirmative response to the question, "Has a doctor, nurse, or other health professional ever told you that you have COPD, emphysema, or chronic bronchitis?" (***A.*** *Reproduced with permission from Vital Signs. Current Cigarette Smoking Among Adults Aged ≥18 Years—United States, 2005–2010. exposed to indoor air pollution and an association with COPD is evident.[39,40] Abatement of bronchitic symptoms coincident with measures that reduce the levels of smoke strongly implicates the indoor air pollution.[41] The World Health Organization estimates that more than 1 million people a year die of COPD precipitated by indoor air pollution.[42] International advocacy organizations such as the Global Alliance for Clean Cook-stoves seek to curb indoor air pollution.

Occupation

The possibility that occupation-related inhalation of particulates and gases carries a risk for COPD was slow in gaining acceptance, but acceptance is widespread now.[43,44] The delay was understandable since smoking among workers in certain occupations was a confounding factor. Also, workers beginning jobs with a high risk of causing lung disease typically have better lung function than normal (the "healthy worker" phenomenon), obscuring work-related effects among relatively young workers. In addition, among cohorts of workers, those with COPD may drop out, causing an underestimate of risk in follow-up studies of individuals still working.

Despite these problems, studies from different groups around the world, urban and rural, workforce-based and community-based, clearly implicate occupations producing exposures to dusts, gases, and fumes as risk factors for COPD.[44] The American Thoracic Society has estimated that the occupational contribution to the population burden of COPD is 15%.[45] Apart from the well-recognized risk of occupations involving exposure to organic and inorganic dusts, less obviously "risky" occupations, such as construction, plastics manufacturing, and utility work may carry an increased risk of COPD.[46] The risk of adverse occupational exposure is particularly

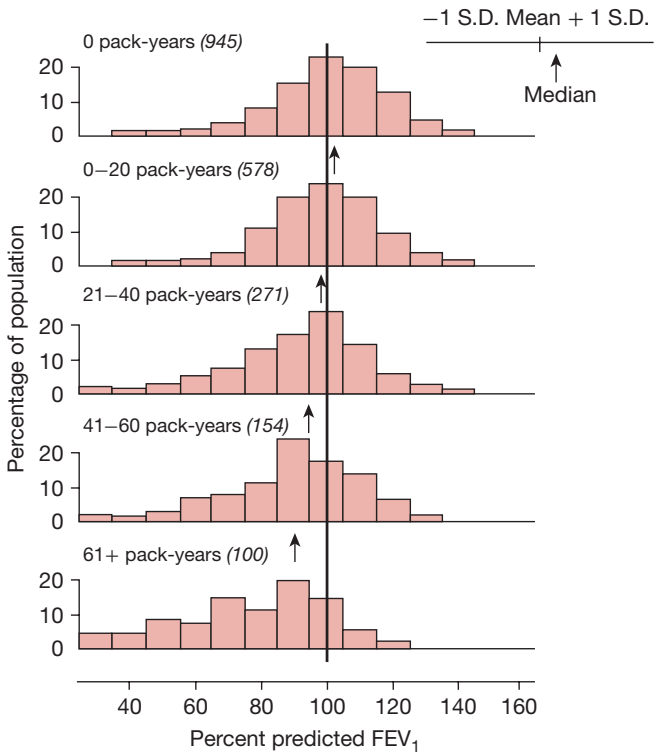

Figure 40-2 Distribution of percent predicted FEV_1 in adults with varying pack-years of smoking. Subjects with "respiratory trouble" before age 16 are excluded. The proportion of smokers with normal expiratory airflow decreases with increasing pack-years. Nevertheless, many smokers have a normal FEV_1 despite large cigarette-smoking histories. Means, medians, and ± standard deviation of the data for each group are shown in the abscissas. The numbers in parentheses are the numbers of subjects. *(Reproduced with permission from Burrows B, Knudson RJ, Cline M, et al. Quantitative relationships between cigarette smoking and ventilatory function. Am Rev Respir Dis. 1977;115:195–205.)*

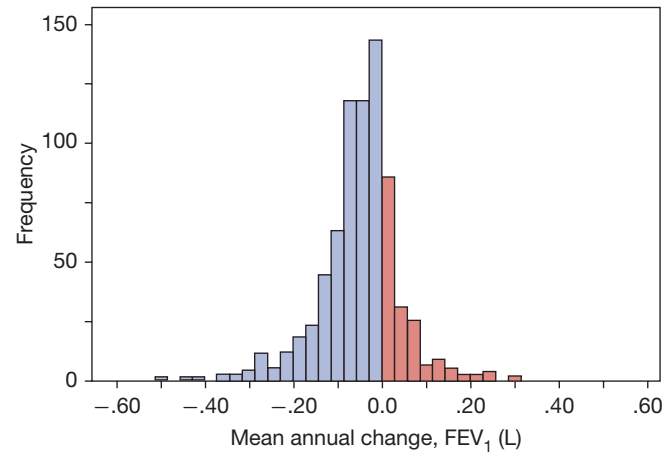

Figure 40-3 Histogram of the mean annual FEV_1 decline (L) for 751 patients with COPD followed for a median of 64 months and up to 10 years, having an average of 5.44 annual measurements, average age 66 years, 92% male, stratified by ATS/ERS and GOLD severity classification as follows: 32 (4%) mild (FEV_1% ≥80); 256 (34%) moderate (FEV_1% 50–79); 245 (33%) severe (FEV_1% 30–49); and 218 (29%) very severe (FEV_1% <30). *(Reproduced with permission from Casanova C, de Torres JP, Aguirre-Jaíme A, et al. The progression of chronic obstructive pulmonary disease is heterogeneous: the experience of the BODE cohort. Am J Respir Crit Care Med. 2011;184(9):1015–1021.)*

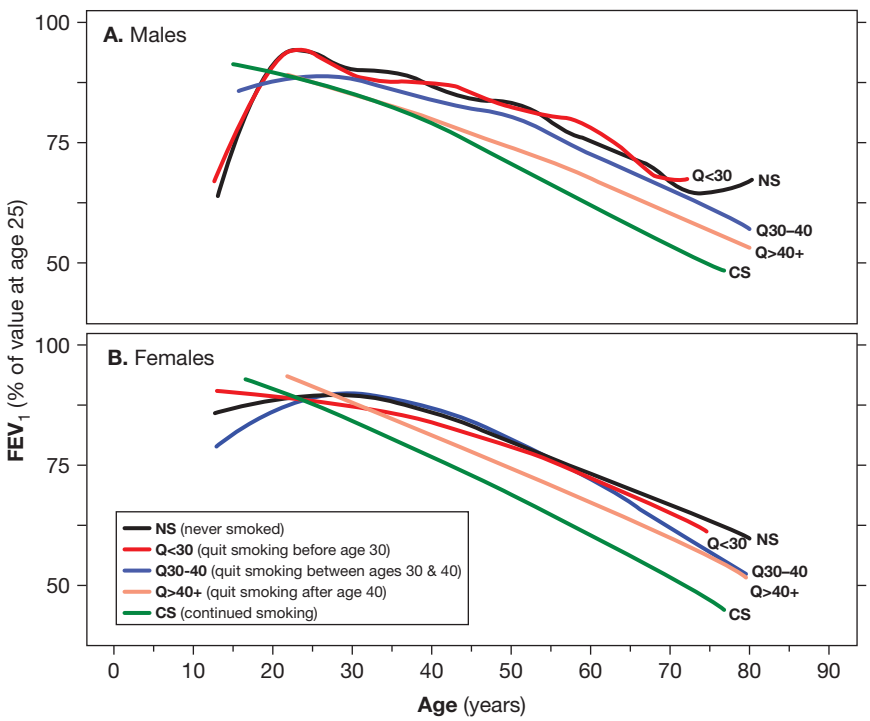

Figure 40-4 The effect of age of quitting smoking on FEV_1. Mean FEV_1 values (expressed as percent of its value at age 25) in smokers who quit smoking before the age 30 (Q < 30), between 30 and 40 years of age (Q30–40) and after age 40 (Q40+). Curves from healthy never smokers (NS) and continuous smokers (CS) are included for comparison. **A.** Males. **B.** Females. The mean annual FEV_1 decline for males was 15.5 mL in quitters before age 30, 24.0 mL in quitters 30 to 40 years of age, and 28.9 mL in quitters after age 40; for females, the values were 10.4 mL quitting before age 30, 16.5 mL in quitters between 30 and 40 years of age, and 21.0 mL in quitters after the age of 40. *(Reproduced with permission from Kohansal R, Martinez-Camblor P, Agustí A, et al. The natural history of chronic airflow obstruction revisited: an analysis of the Framingham offspring cohort. Am J Respir Crit Care Med. 2009;180(1):3–10.)*

important in workers who smoke or have other factors that raise their risk for COPD, such as α1-antitrypsin deficiency.[47]

Childhood Lower Respiratory Tract Infections

Since the status of lung function in very early childhood predicts ventilatory function many years later,[48] it is plausible that lower respiratory tract infections (LRIs) during childhood might adversely affect lung development and increase the risk of developing COPD later in life. However, lung function in children who had pneumonia up to age 2 infrequently had reduced lung function 10 years after the infection.[49] If there was a ventilatory defect, it was most often restrictive. Where reduced airflow was observed, an adenovirus was the predominant class of pathogens responsible for the pneumonia. It is notable that COPD exacerbations may leave only a minor lasting effect on airflow. Continued smokers enrolled in the Lung Health Study had only an additional loss of 7 mL of FEV_1 per year for those having one exacerbation per year, while among those who had quit smoking, exacerbations had no permanent effect on the FEV_1.[50]

LOW SOCIOECONOMIC STATUS

A low socioeconomic status is a risk factor for COPD. The relationship may be linked to an increased amount of smoking and other factors, including deficient medical care for respiratory infections, occupational exposure to inhaled particulates, and increased exposure to household allergens. The importance of smoking is evident. In the United States in 2011, 45% of adults with a General Education Diploma (GED) were smokers compared to 10% of individuals with a college degree, and among adults living below the poverty level, 33% were smokers in contrast to 20% of individuals living above the poverty level.[51]

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Individuals with human immunodeficiency virus (HIV) who smoke have an increased risk of COPD or more specifically emphysema development.[52–54] The risk appears to be modulated by activation of alveolar macrophages with evidence of enhanced production of matrix metalloproteinases (MMPs) in these individuals.[55] Although HIV can infect macrophages,[56] it is unclear if this is a direct alteration due to HIV infection or a response to some downstream alteration of the suppression of innate immune responses, like chronic *Pneumocystis* infection.[57] The occurrence of COPD and pulmonary hypertension in smokers with HIV appears to be more common in individuals with a high viral load and lower CD4 cell counts and not an adverse consequence of antiretroviral therapy.[58] However, emphysema is not reversible and relation to viral load or recovery of CD4 cell counts is not straightforward. Other health issues like malnutrition may contribute. A multicenter study about the lung in HIV supported by the National Insitutes of Health is underway.

HOST BASED

Genetics

The field of COPD genetics is moving rapidly so that capturing this subject is aiming at a moving target. Aggregation of COPD in families and concordance of pulmonary function in twin studies have established a role for genetic predisposition to COPD.[59–61] Moreover, the occurrence of reduced maximal expiratory airflow among nonsmoking first-degree relatives of individuals with early-onset COPD provides further support.[62] Perhaps most compelling is the marked variability in development of COPD among smokers. Dissecting specific genetic factors that increase the risk of COPD has proven difficult. α_1-AT deficiency illustrates this difficulty,[63] where even among individuals with an identified genetic risk factor, wide, unexplained variability in the occurrence of COPD exists.[64]

However, deficiency of functional α_1-AT represents the best-known genetic risk for COPD (see below). In this example genetic mutations discovered in small initial sample sizes can be replicated in larger analysis despite a significant gene-by-environment interaction. To this end, very rare mutations in the coding sequence of elastin cause cutus laxa and can also lead to COPD.[65–67] Although Marfan and Ehler–Danlos syndromes cause lung parenchymal blebs[68] and in mouse models demonstrate developmental of airspace enlargement,[69,70] no human cohort has demonstrated clear penetration of a fixed obstructive lung disease phenotype.[71]

Polymorphisms of genes involved in protease–antiprotease balance, antioxidant function, inflammation, and immune responses have been implicated in COPD in studies utilizing candidate gene approaches (Table 40-3).[72–74] However, none of these polymorphisms are consistently confirmed in other cohorts or large genome-wide association studies of lung function or COPD (Table 40-4).[75–78] Failure of confirmation may indicate flaws in previous studies, but differences in COPD phenotypes, ethnic background, or other factors might explain discrepancies between previous studies and subsequent data. Despite misgivings of reproducibility in candidate gene studies it should be noted a minor allele frequency (MAF) of less than 5% typically excludes rare polymorphisms from GWAS style studies. Rare alleles may be quite important if the effect is large as demonstrated by α_1-AT (SerpinA1) (Table 40-3).

TABLE 40-3 Examples of COPD-Related Genes from Candidate Approach Studies

Gene Symbol	Functional Category	Locus	Polymorphism	MAF[a]
SERPINA1	Antiprotease	14q32	rs28929474=A	0.01

[b]*Polymorphism no longer significant for association with physiology measures when only nonsmokers evaluated.*

Traits like emphysema quantified by CT lung density, subjective dyspnea, and 6-minute walk distance can also be utilized as each trait has been independently associated with prognosis in COPD. Of note, analysis based on radiographic emphysema characterization does not seem to reveal the same genetic locations as airway physiology–based phenotyping (Table 40-4),[79] possibly reflecting the advantage of extending genetic evaluation to other reproducible quantitative phenotypes, as differential genetic susceptibility to disease characteristics may reveal distinct independent pathways within the larger COPD population.

Very large GWAS studies of physiologic traits used to define COPD (FEV_1, FEV_1/FVC ratio) in populations that include nonsmokers and individuals too young to have COPD increase the understanding of how genetic factors interact with the environmental etiologic factors. For example, lung development and smoking habit may be teased out by examining COPD-susceptibility loci for association with the same traits in nonsmokers or younger individuals. This is important, as polymorphisms related to nicotine addiction[80] (e.g., CHRNA3/5) need to be separated from polymorphisms that mark susceptibility to smoke exposure given the difficulty with quantifying lifetime smoke exposure. On the other hand, polymorphisms related to genes involved predominantly in lung development (e.g., HHIP) will result in alterations of the physiologic traits even in never-smokers, but may also augment increased susceptibility to smoking.[81] It is notable that the different approaches of genetic analysis have not yielded as much cross-confirmation in COPD as has been seen in other diseases, despite the fairly large size of recent GWAS studies. In addition, although the same approaches have been utilized in asthma, a diagnosis that relies on the same physiologic traits, the polymorphisms discovered in asthma do not overlap COPD associated pathways.[82–84] This distinct genetic framework of COPD versus asthma supports many years of work in mouse models defining divergent immune pathways in these two common airway diseases.[85]

Airway Hyperresponsiveness

Airway hyperresponsiveness (AHR) is present when there is an acute, temporary decline in maximal expiratory airflow in response to inhaling potential bronchoconstricting agents such as methacholine or histamine. In individuals with COPD, AHR is associated with accelerated decline of FEV_1 and therefore is a negative prognostic marker.[86] In the Lung Health Study, AHR was second to smoking as an important determinant of decline in FEV_1 and was not related to the initial level of obstruction. AHR was greater in women smokers than men smokers.[86] Although AHR decreased after smoking cessation and bronchodilator responsiveness improved, bronchodilator responsiveness did not correlate with the rate of FEV_1 decline.[87]

A major question about the relationship of AHR to COPD involves consideration of the so-called "Dutch hypothesis," which ascribes a role of allergy to the development of COPD. Observations that argue against AHR as a cause of COPD are that smokers typically do not show AHR until their FEV_1 is already reduced and that experimental induction of emphysema can lead to AHR.[88] It is plausible that AHR may be a consequence of emphysema, as airway wall stiffness and parenchymal tethering are affected by the extracellular matrix.[89] If unmeasured emphysema is also connected to AHR, this may contribute to the gender bias and decline rate findings as emphysema presence may predict accelerated future decline regardless of smoking habit.[90] As noted, the genetic distinction of asthma and COPD polymorphisms would also favor a great proportion of COPD having a nonasthmatic origin.

PATHOPHYSIOLOGY

A persistent reduction in FEV_1/FVC is the defining physiological feature of COPD. Increased airway resistance, increased residual volume (RV), increased RV/total lung capacity ratio (RV/TLC), decreased inspiratory capacity, decreased maximum voluntary ventilation (MVV), abnormal distribution of ventilation, and ventilation–perfusion mismatching are also typical physiological features.

■ AIRFLOW OBSTRUCTION

The low FEV_1 and low FEV_1/FVC in COPD are not reversible with inhaled bronchodilators, although small improvements are common, especially if responsiveness is tested with both ipratropium and albuterol.[91] Thus, COPD differs from asthma, in which inhaled bronchodilators can produce large improvements in FEV_1. Maximal inspiratory flow may be relatively well preserved in the presence of a low FEV_1/FVC and a low FEV_1. A reduced FEV_1 with a normal FEV_1/FVC and normal TLC should not be interpreted as an obstructive ventilatory defect. This pulmonary function pattern is called nonspecific and infrequently progresses to COPD.[92]

The FEV_1 is the result of the balance between the elastic recoil of the lungs promoting expiratory flow and the resistance of the airways that limits flow during performance of an FVC. In normal lungs, as well as in lungs affected by COPD, maximal expiratory flow diminishes as the lungs empty because the lung parenchyma provides progressively less elastic recoil and the cross-sectional area of the airways falls leading to an increase in airway resistance. The decrease in

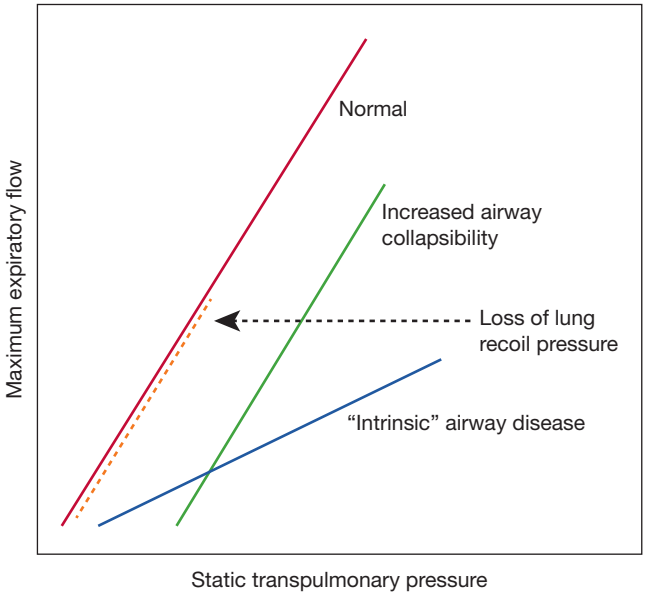

Figure 40-5 Analysis of reduced maximum expiratory flow in COPD from maximum expiratory flow versus lung recoil pressure curves. With loss of lung recoil pressure – that is, "emphysema" (heavy interrupted line) – the slope of the flow–pressure curve remains normal, but the curve terminates at lower pressure than normal. With intrinsic airway obstruction – that is, "bronchitis" – the slope is reduced. Increased airway collapsibility, which may be a result of decreased elastic recoil, causes the curve to be displaced to the right. Commonly in COPD, the flow–pressure curve has premature termination and a decreased slope and is shifted rightward, indicating that decreased elastic recoil, increased airway resistance, and increased airway collapsibility are all involved in causing the reduced maximum expiratory flow. *(From Pride NB, Milic-Emili J. Lung mechanics, in Calverley PMA, Pride NB [eds]. Chronic Obstructive Pulmonary Disease. London, Chapman & Hall; 1995.)*

flow coincident with the decrease in lung volume is apparent on the expiratory limb of the flow–volume curve (Fig. 40-5). In mild COPD the abnormality in airflow is evident only at lung volumes at or below functional residual capacity, appearing as a "scooped out" lower part of the descending limb of the flow–volume curve. In advanced COPD, the entire curve demonstrates decreased expiratory flow. By measuring pressure–volume and pressure–flow relationships it is theoretically possible to assess the relative importance of decreased elastic recoil ("emphysema") from increased airway resistance ("small airway disease") as the cause for the reduced FEV_1 As discussed below, the correlation between FEV_1 and small airway pathology is strong and likely contributes to the reduction independent of the correlation of FEV_1 with emphysema.

There is wide variability in COPD in the relationships between FEV_1, exercise tolerance, and quality of life.[93] Variability also extends to the relationship between the FEV_1 and alveolar gas exchange. However, the Pa_{O_2} and oxygen saturation usually remain near normal until the FEV_1 has decreased to about half of the predicted normal while elevation of the Pa_{CO_2} seldom occurs until the FEV_1 is less than about one-fourth of the predicted.[94] Thus, other causes of hypoxemia or an elevated Pa_{CO_2}, such as the obesity hypoventilation syndrome, should be considered in patients with abnormal arterial blood gases and only mild to moderate COPD. Similarly, pulmonary hypertension and right ventricular failure do not occur unless COPD is severe and associated with chronic hypoxemia (Pa_{O_2} <55 mm Hg). Diastolic dysfunction is common in the general population, where COPD is prevalent, and should be considered when pulmonary hypertension is discrepant with COPD severity.

ABNORMAL DISTRIBUTION OF VENTILATION AND VENTILATION–PERFUSION MISMATCHING

Abnormal distribution of ventilation results from the heterogeneity of the pathologic process affecting airways and lung parenchyma. This heterogeneous ventilation results in ventilation–perfusion mismatching that is characteristic of COPD. Abnormality in the distribution of ventilation is evident in the pattern of nitrogen washout during breathing of 100% oxygen. The nitrogen washout is delayed because of regions that are poorly ventilated, and the shape of the nitrogen washout curve reflects compartments with different washout rates due to regional differences in compliance and airway resistance. Radioisotopic ventilation scanning with ^{133}xenon also reveals regional heterogeneity of ventilation in COPD, but can also demonstrate the ability of airway mucus to trap xenon tracer.

The multiple inert gas elimination technique (MIGET), which enables quantification of the ventilation–perfusion profile, has demonstrated different ventilation–perfusion patterns among patients with advanced COPD (Fig. 40-6). In one pattern, the

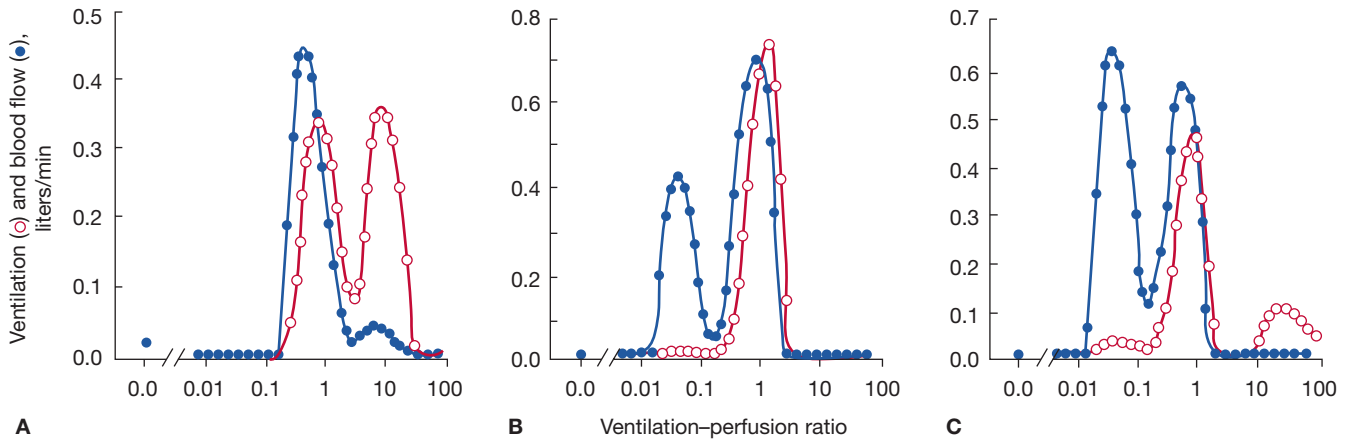

Figure 40-6 Ventilation–perfusion distributions in three persons with COPD determined by the multiple inert gas elimination technique (MIGET). **A.** Regions of high ventilation–perfusion characteristic of "emphysematous," type A COPD. **B.** Regions of low ventilation–perfusion characteristic of "chronic bronchitis," type B COPD. **C.** Regions of both high and low ventilation–perfusion characteristic of many people with COPD. In the normal person, not shown, ventilation–perfusion virtually overlaps and peaks at about a ventilation–perfusion ratio of 1. *(Reproduced with permission from Wagner PD, Dantzker DR, Dueck R, et al. Ventilation-perfusion inequality in chronic obstructive pulmonary disease. J Clin Invest. 1977;59(2):203–216.)*

so-called type A ("pink puffer") COPD, there is a substantial amount of ventilation distributed to high ventilation–perfusion regions. This likely reflects actual loss of vascular elements in conjunction with the pathologic changes of the gas exchange parenchyma. In a second pattern, called type B ("blue bloater") COPD, there is a substantial amount of pulmonary blood flow perfusing low ventilation regions. This simple classification was important historically in the development of understanding COPD pathophysiology, but has fallen out of use because most people with COPD are not easily classified as either type A or type B. They have both high and low ventilation–perfusion regions.

Ventilation–perfusion mismatching accounts for essentially all of the reduction in Pa_{O_2} that occurs in COPD, so modest elevations of the inspired oxygen concentration are effective in treating hypoxemia. If hypoxemia is difficult to correct, other problems such as right- to left-sided intracardiac or intrapulmonary shunting need to be considered in addition to COPD.

HYPERINFLATION

Increases in total lung capacity, functional residual capacity (FRC), residual volume, and the residual volume to total lung capacity ratio (RV/TLC) are common in COPD. These abnormalities may be beneficial in that they help to preserve expiratory airflow by increasing lung elastic recoil and the cross-sectional areas of airway lumens. However, they have adverse effects. They displace the diaphragm into a flattened position causing a number of adverse effects (Fig. 40-7). In addition, they put the thoracic cage at a mechanical disadvantage so that inspiration requires work rather than being passively assisted by the elastic recoil of the chest wall. These abnormalities of increased lung volume may increase further with exertion because reductions in airflow in diseased lungs reduce expiratory volume during rapid breathing. This phenomenon, called dynamic hyperinflation, adds to the workload on the inspiratory muscles while further reducing their mechanical advantage. Dynamic hyperinflation is an important mechanism of dyspnea with exertion in COPD.[95]

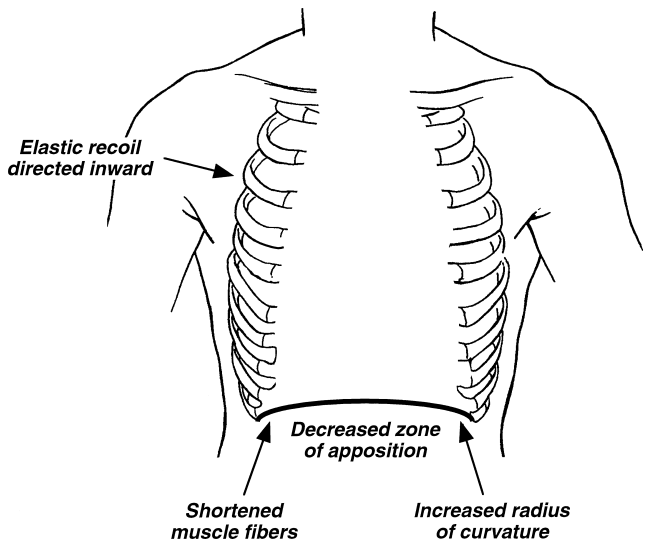

Figure 40-7 Detrimental effects of hyperinflation on diaphragmatic function. Hyperinflation causes flattening of the diaphragm, which (1) decreases the zone of apposition between the diaphragm and the abdominal wall, hindering rib cage movement; (2) shortens diaphragmatic muscle fiber length, decreasing the force that can be generated by the diaphragm; (3) increases the radius of curvature of the diaphragm, thereby decreasing transpulmonary pressure (at constant tension); and (4) directs diaphragmatic muscle fibers medially, impairing inflation with diaphragmatic contraction. In addition, hyperinflation prevents the thorax from assisting inspiration during tidal breathing because the resting volume of the thorax is above the volume at which the rib cage recoils outward during inspiration. *(Reproduced with permission from Yusen RD, Lefrak SS. Evaluation of patients with emphysema for lung volume reduction surgery. Washington University Emphysema Surgery Group, Semin Thorac Cardiovasc Surg. 1996;8(1):83–93.)*

Hyperinflation of the residual volume and FRC reduce the inspiratory capacity, which has prognostic significance that is independent of FEV_1. In one study of individuals with moderate to severe COPD, those whose ratio of inspiratory capacity to total lung capacity was less than 25% had a much shorter life span than those with a ratio greater than 25%, even though the two groups had comparable percent predicted FEV_1.[96]

DYSPNEA

People with COPD typically seek medical care because shortness of breath limits their activities and quality of life. Dyspnea is seldom a complaint until the FEV_1 has fallen below about 60% of predicted. However, the correlation between FEV_1 and exercise limitation is not strong. Some individuals are relatively free of dyspnea despite a severely reduced FEV_1. Commonly, the discomfort associated with breathing is associated with inspiration rather than expiration.[97] Measurement of dyspnea has proven complicated.[98] A number of indices are in use.

An increased sense of effort relating to the pressures needed from the respiratory muscles relative to their maximum pressure-generating capacity is thought to be an important factor in causing the dyspnea associated with COPD. Signals of "length-tension inappropriateness" from the respiratory muscles due to hyperinflation are another factor. Dynamic hyperinflation, as described above, exaggerates these problems for respiratory muscles. Also, impulses from airways undergoing abnormal dynamic compression during exhalation have been described. Hypoxemia and hypercapnia play only a small role during periods of clinical stability. Oxygen administration may decrease breathlessness by reducing ventilation during exertion and through poorly understood direct effects not associated with changes in ventilation.

PHYSIOLOGICAL–PATHOLOGICAL CORRELATIONS

In 1968, Hogg and colleagues observed that airways 2 mm or less in internal diameter normally contribute only a minor part of the total airway resistance, but that these airways are the principal sites of increased airway resistance in COPD.[99] For many years, the physical basis for small airway resistance in COPD was considered to be a combined result of emphysema causing small airway instability and collapse along with multiple anatomic abnormalities narrowing the lumens of small airways. Because emphysema and small airway pathology are both common in individuals with COPD their relative contributions to airflow obstruction have been difficult to discern.

Fixed reduction in airflow is associated with several specific pathologic findings in the small airways of advanced COPD (Fig. 40-8). Small airways in the lungs of individuals with COPD typically show goblet cell metaplasia, replacement of Clara cells with mucus-secreting cells, and infiltration of the airway walls by inflammatory cells that, in severe disease, include an increased surface area of lymphoid follicles.[100] The cellular changes are accompanied by increased connective tissue in the subepithelial and adventitial compartments of the airway walls.[100] Alveolar tissue surrounding small airways normally provides radial traction on bronchioles at points where alveolar septa attach. Loss of these bronchiolar attachments as a result of proteolytic destruction may contribute to airway distortion, narrowing, and instability.

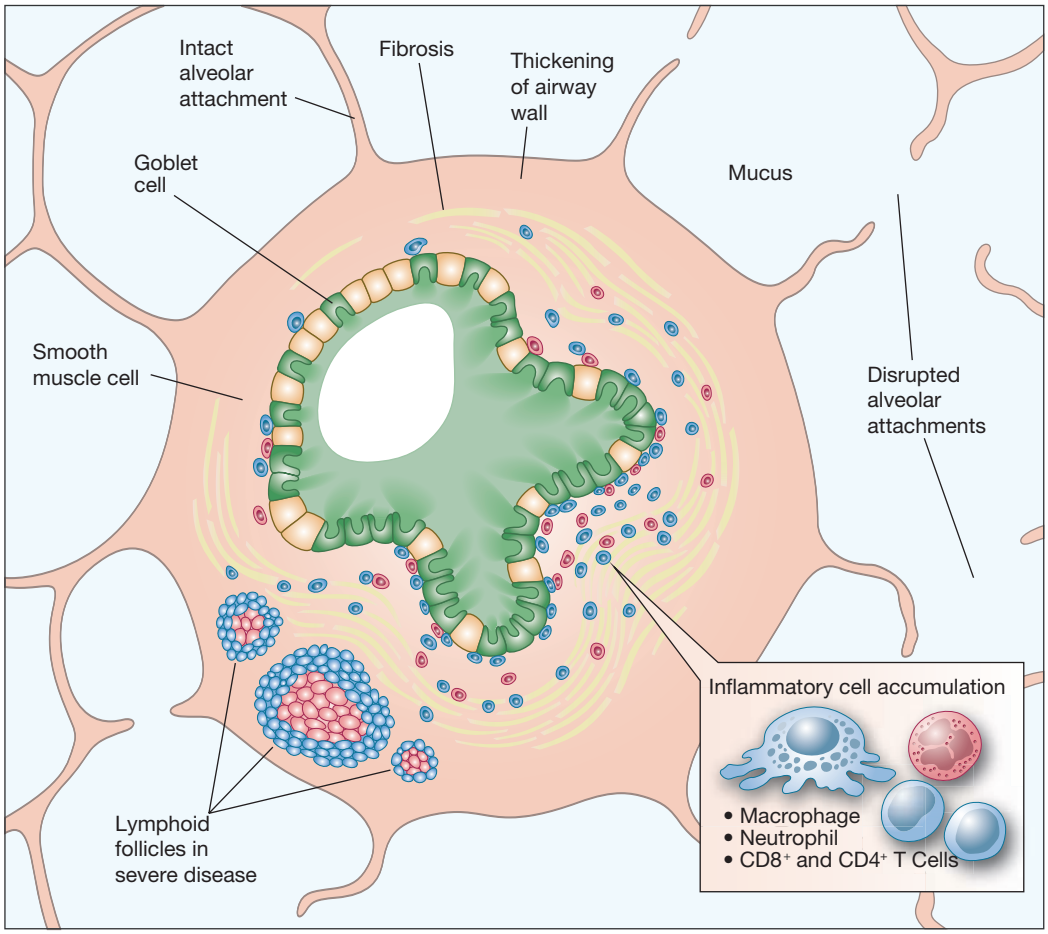

Figure 40-8 Pathologic lesions in small airways in COPD. Multiple abnormalities lead to partial obstruction of the lumen and altered shape and mechanical properties of the airways. *(Reproduced with permission from Senior RM, Silverman EK. Chronic obstructive pulmonary disease. In: Nabel EG, ed. ACP Medicine: Pulmonary, Hamilton, Ontario. Canada: Decker Publishing; 2011.)*

Although pathologic studies suggested the numeric loss of very small airways seen at autopsy is insufficient to produce the degree of airway resistance increases seen early in COPD, recent radiologic studies have confirmed there is a significant loss of visible (2–2.5-mm diameter) airways before radiographic emphysema is present.[101] Indeed, the loss of small airways can be impressive, reaching 90% in severe COPD. The large-scale pathologic loss of terminal airways in advanced disease will contribute significantly to the small airway resistance[101] but whether radiographic loss of small airway surface area in early disease is pathologic destruction, severe wall thickening or mucus plugging that obscures the lumen below the radiographic resolution is not yet clear. However, more severe airflow obstruction is clearly associated with increases in thickness of all components of the airway wall.[100] The greatest relative increase in components of the airway wall is in the connective tissue–rich adventitial layer but the epithelial layer, the lamina propria, and the smooth muscle–containing layer all demonstrate significant increases in advanced disease and small airway mucus plugs have been demonstrated to be significantly associated with airflow limitation in severe disease. Thus, overall, compared to small airway pathology and radiologic loss of small airways, emphysema occurs late in the development of COPD and appears to have a limited role in causing the airflow obstruction in early COPD.[102]

PATHOGENETIC MECHANISMS

COPD represents the clinical expression of complex alterations in structure and function of alveolar tissue and small airways. Many processes at the tissue and cellular levels can be implicated, including inflammation, cell proliferation, apoptosis, altered phenotype of lung cells, and remodeling of the extracellular matrix (Fig. 40-9). Numerous mediators, most notably proteinases, oxidants, and cytokines, are involved in these processes. Studies in genetically altered mice have proven invaluable in helping to elucidate the pathogenesis of COPD, especially emphysema.

■ INFLAMMATION

Innate Immune Responses

As reflected in the definition of COPD, inflammation occupies a central role in current thinking about the pathogenesis of COPD. The inflammation paradigm is that smoking and other types of inhaled irritants lead to recruitment of innate inflammatory cells to the lungs and airways and that products of these recruited cells injure lung tissue and disrupt normal mechanisms of lung repair. Indeed, inflammation is prominent in airways and lung parenchyma in biopsies, surgical specimens, and postmortem material from individuals with COPD.[100,103–105] Other indicators of inflammation are increased inflammatory cells in bronchoalveolar lavage fluid (BALF)[106–108] and sputum[109–111] and increased volatile products of inflammatory cells in exhaled breath.[112,113] Systemic inflammation is also present in current smokers, with elevations in white blood cell counts, neutrophil subsets, or liver-derived acute phase reactants.[114–116] Inflammatory cells associated with COPD in the lung include predominantly neutrophils,

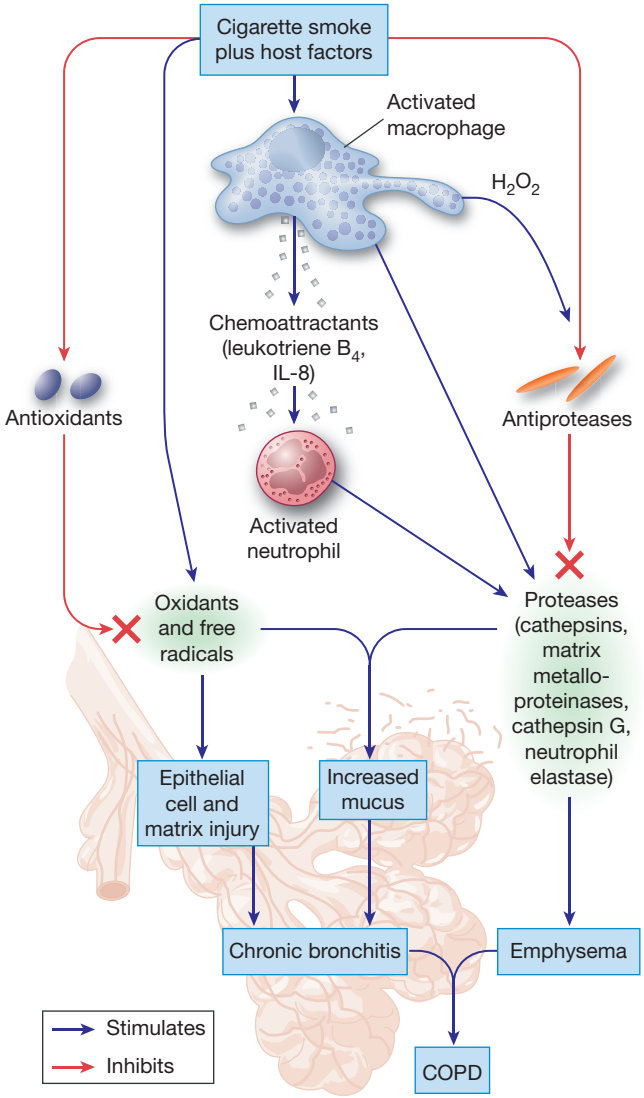

FIGURE 40-9 The pathogenesis of COPD from smoking. Smoking stimulates resident cells to release factors that recruit inflammatory cells to the lungs. The various inflammatory cells that accumulate in the peripheral tissues of the lungs release proteinases and oxidants that damage or degrade extracellular matrix in the walls of alveoli, alveolar ducts, and respiratory bronchioles. In addition, agents in smoke and those released by inflammatory cells inactivate proteinase inhibitors such as α1-antitrypsin, and cause senescence and apoptosis of lung cells that produce extracellular matrix. Products of the damaged extracellular matrix, such as peptides of degraded elastin, are chemotactic for inflammatory cells; thus degradation of the extracellular matrix may lead to a feedback loop that perpetuates inflammation. These matrix-derived products may also elicit immune responses that lead to destruction of extracellular matrix. Not shown are the role of mechanical forces that may also promote deformation of lung tissue. *(Reproduced with permission from Senior RM, Silverman EK. Chronic obstructive pulmonary disease. In: Nabel EG, ed. ACP Medicine: Pulmonary, Hamilton, Ontario. Canada: Decker Publishing; 2011.)*

macrophages, and sometimes eosinophils, but also dendritic cells and lymphocytes (see Acquired Immune Responses). Once the inflammatory process is initiated by smoking the process may persist long after smoking has stopped.[117] Systemic neutrophil counts generally decrease within weeks but activated alveolar macrophages may be present even years after smoking cessation.[117–119]

Unlike nonsmokers, macrophage accumulations are found specifically in respiratory bronchioles, even in young smokers, and BALF from smokers contains many fold increases in macrophages compared to the numbers in BALF from nonsmokers.[120,121] Besides releasing proteinases that might degrade the extracellular matrix of the lung,[122] alveolar macrophages in COPD make chemotactic factors that recruit other inflammatory cells to the lungs. Likewise, structural cells of the lungs in COPD produce proteinases and chemotactic factors for inflammatory cells.[123,124] Expression of interleukin-8 (IL-8), macrophage inflammatory protein-1α (MIP-1α), and monocyte chemoattractant protein-1 (MCP-1), for example, are upregulated in bronchiolar epithelium in COPD.[125,126] Peptides of elastin are chemotactic for inflammatory cells and may act as epitopes for T-cell responses.[127–129] In mice, genetically induced overexpression of cytokines, such as IL-13 or γ-interferon by lung cells leads to emphysema via a robust innate immune response, with inflammatory cell proteinases being integral in emphysema pathogenesis.[130–132]

Acquired Immune Responses

Cellular and humoral immunity may also be involved in emphysema pathogenesis or the continued progression after smoking cessation. CD4+ and CD8+ T cells and B cells accumulate in alveolar and airway tissue in COPD and form bronchus-associated lymphoid tissue (BALT) in the walls of small airways.[100] The increasing BALT presence in small airways correlates with severity of GOLD stage.[100] In mice, exposure to antibodies directed at endothelial cells alone elicits alveolar septal cell destruction and emphysema.[133] Speculation about antigens for immunologically driven emphysema in patients include microbial pathogens, peptides altered by tobacco smoke, and peptides released from lung extracellular matrix.[128,129,134] Difficulties in distinguishing cellular and humoral responses to microbial colonization of advanced airway disease in COPD from pathologic self-directed immune responses will require further study,[135] but more targeted immunosuppresion in treating advanced COPD has not yet shown benefit.[136,137] Intrinsic in this issue is the accelerated emphysema in smokers with HIV, but that may be complicated by direct virus infection inducing macrophage alterations, rather than suppression of acquired immune responses.[55,56]

■ PROTEINASE–ANTIPROTEINASE IMBALANCE

The discovery in the 1960s of α_1-AT deficiency associated early-onset emphysema and the production of emphysema in experimental animal models with elastolytic enzymes have promoted the imbalance of proteinases relative to their inhibitors as a key factor in emphysema development.[138,139] Although additional mechanisms, like apoptosis and oxidant stress, have been uncovered in recent years, the importance of proteinase excess continues to prevail as an important mechanism in emphysema development.

Proteinases of several biochemical classes, and different specific inhibitors, are implicated in the pathogenesis of emphysema. Serine proteinases, especially neutrophil elastase, and several matrix metalloproteinases, have been the proteinases for which there are the most data.[140–143] It is notable that both neutrophils, which are the source of neutrophil elastase and MMP-12 from alveolar macrophages are largely related to continued smoking. Progression after smoking cessation may follow different pathways. As discussed in the genetics section many of these genes have been implicated in candidate gene studies but not genome-wide association studies (Tables 40-4 and 40-5).[144–146] Although neutrophil elastase and its main inhibitor α_1-AT have predominated the proteinase–antiproteinase imbalance hypothesis, MMPs appear prominent in mouse models and in samples from smokers and individuals with COPD. It is likely a combination of many local imbalances involving different proteinases and antiproteinases contribute to the progressive lung destruction.

TABLE 40-5 Proteinases That May Affect the Lung Parenchyma

Proteinase	Cell of Origin
Neutrophil elastase	Neutrophil (monocyte)
Proteinase 3	Neutrophil (monocyte)
Cathepsin G	Neutrophil (monocyte, mast cell)
MMP-1[a]	Macrophage, epithelial cell
MMP-9 (Gelatinase B)	Macrophage, neutrophil, eosinophil, fibroblast, epithelial cell
MMP-12 (Macrophage elastase)	Macrophage
Cathepsin L	Macrophage
Cathepsin S	Macrophage

Note: Parentheses denote minor cellular sources.
[a]Lacks elastase activity.

Several aspects of proteinases in COPD should be noted, as a straightforward destructive mechanism only is likely an oversimplification. In addition to destruction of lung elastin and other matrix components, proteinases process cytokines and surface receptors involved in the inflammatory and immune responses.[147–151] Inflammatory cells may not be the exclusive sources of the proteinases as structural cells also produce matrix-degrading proteinases.[152] Even the apparently simple emphysema model of placing elastases in the lungs of experimental animals results in complex responses that can be altered by nonproteinase-related mechanisms including stem cell and immunologic responses.[153,154] It must also be emphasized that little is known about proteinases in the pathogenesis of the small airway pathology of COPD. Virtually all of the information about proteinases in COPD pertains to emphysema pathogenesis despite clear evidence of small airway obliteration in advanced disease.

OXIDANT–ANTIOXIDANT IMBALANCE

Reactive oxygen species in cigarette smoke or released by inflammatory cells and structural cells of the lungs in response to smoke may lead to lung injury (see Chapter 41). Up to 20 mg of tar may be deposited in a smoker's lung per cigarette smoked. This tar contains more than 10^{17} stable, long-lived radicals per gram. The gas phase of tobacco smoke contains 10^{15} organic radicals per puff of smoke, although in general these small oxygen- and carbon-centered species are more short-lived and reactive than the radicals in the particulate phase. In addition, tobacco smoke appears to "prime" neutrophils and alveolar macrophages to generate elevated amounts of reactive oxygen species, such as hydrogen peroxide, hydroxyl radicals, and superoxide radicals. The lung tissue of smokers contains significantly more iron than that of nonsmokers,[155] providing a catalyst for the production of hydroxyl radicals from H_2O_2. This is of interest given the finding of an iron-binding protein polymorphism in the genome wide association studies of smokers with COPD, IREB2 (Table 40-4). Smokers also demonstrate increased production of neutrophil myeloperoxidase,[106,112] which is capable of yielding oxidized halogens such as hypochlorous acid (HOCl). Oxidants modify and inactivate proteins, such as protease inhibitors (α_1-AT and secretory leukoprotease inhibitor), and histone deacetylase 2 (HDAC2), which is involved in glucocorticoid mediated anti-inflammatory responses. Oxidants can affect lipids, DNA, and some specific end products, such as 4-hydroxy-2-nonenal (4-HNE) and 8-hydroxy-2′-deoxyguanosine (8-OHdG), may be markers of COPD.[156,157]

Oxidants can promote inflammation and proteinase expression, facilitate proteinase-mediated extracellular matrix degradation by enhancing matrix molecule susceptibility to proteolytic cleavage, and participate in nonenzymatic degradation of matrix molecules like type I collagen. In experimental animals the combination of cigarette smoke and elastase leads to greater emphysema than either insult alone, suggesting that these insults do not elicit identical responses.[158] Animal models of antioxidant deficiency result in increased susceptibility to both cigarette smoke and direct elastase-induced disease.[159–161]

APOPTOSIS AND SENESCENCE

Emphysematous human lung specimens demonstrate increased apoptotic and senescent cells compared to healthy lung specimens.[162,163] An early theory of emphysema development was that alveolar vascular destruction preceded loss of alveolar tissue. Consistent with this early theory, the blockade of vascular endothelial growth factor (VEGF) signaling in alveolar endothelial cells or genetic downregulation of VEGF production in alveolar epithelium produces apoptosis and noninflammatory emphysema in rodents.[164] In vitro, cigarette smoke induces apoptosis of several lung cell types.[157,165,166] An important feature of experimental models of emphysema due to apoptosis is that there is minimal inflammation.[167] Of interest, the BICD1 gene polymorphism linked to emphysema (Table 40-4) encodes for a protein in the apoptosis pathway.[79] In contrast to the expanding body of information linking emphysema to apoptosis, there is only scant information about apoptosis of the cells of small airways in COPD.[168] Much remains to be learned about apoptosis in the context of COPD airway disease.

Senescence of lung cells as a cause of emphysema stems from the knowledge of alveolar loss with aging and animal models[169,170] where accelerated aging results in emphysematous changes. Lung fibroblasts isolated from human lungs with COPD demonstrate increased markers of senescence and senescent fibroblasts do not maintain the extracellular matrix.[171] However, much of the information regarding telomeres in human COPD relates to inflammatory cell telomere shortening, with telomere length being a biomarker of chronic lifelong inflammatory excess present in individuals with COPD.[172] Whether lung epithelial cells are driven to an injury-related replicative senescence is unknown, but human diseases of telomere deficiency and excess alveolar epithelial apoptosis tend to result in pulmonary fibrosis and not COPD.[173,174]

MUCUS HYPERSECRETION

Airway mucus is a normal protective barrier that is constantly replenished and cleared in health (see Chapter 6). Mucin glycoproteins, the main components of mucus, have a core protein rich in serine and threonine, to which carbohydrates and cysteine residues are attached. Mucus is secreted from submucosal glands and airway goblet cells. In COPD there is hyperplasia of goblet cells and hypertrophy of glands with an increase in the ratio of glandular mucus cells to serous cells. The changes in COPD are associated with an alteration of the mucus proteins (MUCs) to favor a predominance of MUC5B over the typical MUC5AC form, and an increase in the MUC2 form, which is uncommon in normal lung mucus.[175,176] Other alterations in the mucus layer in COPD include greater acidity, less mucin glycosylation, and decreased antimicrobial peptides. Mediators responsible for mucus hypersecretion include proteinases, cytokines, oxidants, and epidermal growth factor receptor (EGFR) ligands.[177,178] The negative charge of mucus glycoproteins results in sequestration of proteases, volatile hydrocarbons and possibly preservation of the hydration of the ciliated layer, resulting in protection of the underlying lung and likely improved carcinogen clearance. However, the symptoms of mucus hypersecretion are common complaints in individuals with COPD; quantity and location of mucus may be particularly important in symptomantic COPD.

Determining the relationship between chronic cough and sputum in patients with COPD and the natural history of COPD

has been elusive.[179] Reports vary from finding weak to strong correlations between cough and sputum production and COPD progression, COPD exacerbations, and mortality.[180–182] A relationship between chronic mucus hypersecretion in small airways and adverse outcomes is plausible as histological analysis of small airway pathology in COPD demonstrated that the extent of small airway luminal obstruction by mucus correlated with the GOLD stage and was inversely correlated with survival after lung volume reduction surgery.[104] Whether the mucus glycoproteins are a beneficial factor that mark the degree of inflammation (e.g., a biomarker of inflammation) or are themselves a pathologic factor in the severity of symptoms or progression of disease is an important question, as treatment of mucus hypersecretion without adequate suppression of the inciting inflammation may result in undesired consequences.[182,183]

PATHOGENESIS OF EMPHYSEMA

GENERAL CONCEPTS

Emphysema is defined as "a condition of the lung characterized by abnormal, permanent enlargement of airspaces distal to the terminal bronchiole, accompanied by destruction of their walls, and without obvious fibrosis."[184] However, studies since this definition was enunciated indicate increased collagen per unit volume of airspace wall in emphysematous tissue[185] and active expression of elastin production (Fig. 40-10).[186] Thus, emphysematous lung tissue should be viewed as actively undergoing remodeling rather than as inert. Further indications of activity in emphysematous lung tissue include the presence of many inflammatory cells[103] and cellular changes of apoptosis and senescence.[187]

Degradation of lung elastin by elastase activity from inflammatory cells is probably the predominant mechanism for emphysema in most smokers. However, the biology of emphysema is clearly complex and still incompletely understood. It includes inflammatory cell recruitment, proteinase–antiproteinase imbalance, oxidant–antioxidant imbalance, and responses of lung cells to proteinases and oxidants from inflammatory cells and to constituents of tobacco smoke. It may also involve humoral and cellular immunity. Degradation of extracellular matrix components besides elastin, particularly collagens, may be an important feature. In some situations, apoptosis of lung cells may precede degradation of extracellular matrix. Senescence of lung cells, a recently identified phenomenon in emphysema, has unclear implications, but suggests that lung repair mechanisms are depressed.

According to the proteinase–antiproteinase hypothesis, there is a constant or episodic release of proteinases, active at neutral pH, into the lung parenchyma. These proteinases come principally from inflammatory cells (Table 40-5). Under normal conditions circulating proteinase inhibitors, especially α_1-AT, and inhibitors produced locally in the lungs, permeate lung tissue and prevent these proteinases from digesting the structural proteins of the lungs (Table 40-6). Emphysema results when the balance between proteinases and

TABLE 40-6 Proteinase Inhibitors in the Lung

Inhibitor	Cell of Origin	Class of Proteinases Inhibited
α1-antitrypsin	Hepatocyte (mononuclear phagocyte)	Serine[a]
α2-macroglobulin	Hepatocyte, lung fibroblast (macrophage)	Serine, MMP[b], Cysteine
TIMPs (1,2,3,4)[c]	Resident lung cell	MMP

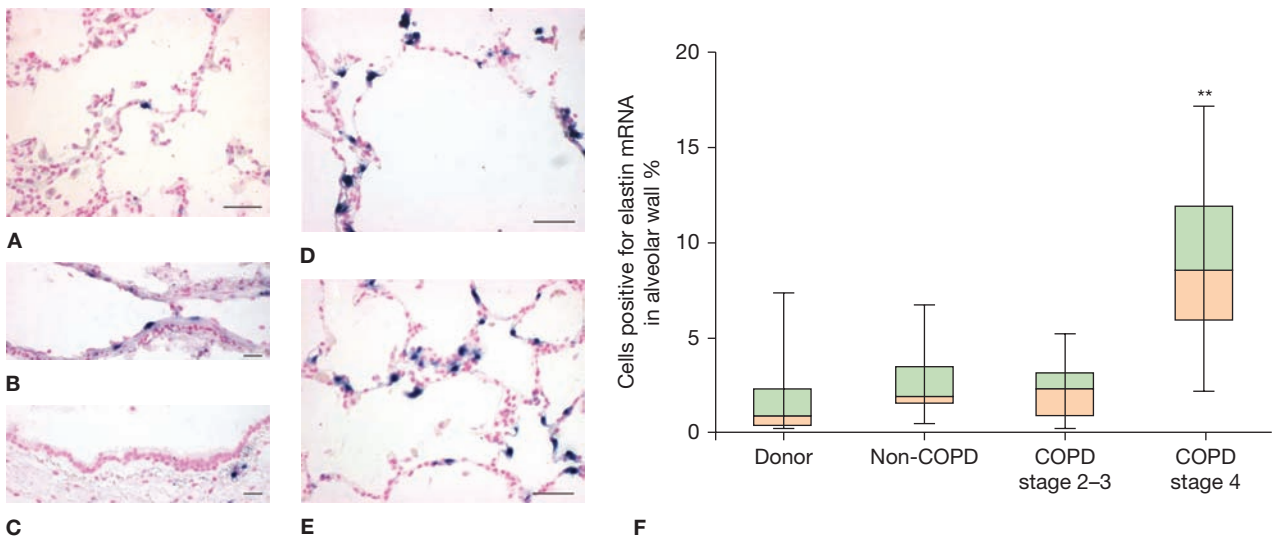

Figure 40-10 Active expression of elastin production in severely emphysematous lung removed for lung transplantation. Elastin mRNA *(blue signal)* as detected by in situ hybridization is rarely detected in donor lungs in (**A**) parenchyma, (**B**) intralobal pulmonary arteries or (**C**) airways, but is prevalent in parenchyma of GOLD 4 COPD lungs in regions with moderate (**D**) and severe (**E**) alveolar enlargement. Quantification of cells positive for elastin mRNA (**F**) reveals significantly higher elastin expression in alveolar walls of GOLD 4 COPD lungs compared to donor lungs or less severe COPD lungs. *(Reproduced with permission Deslee G, Woods JC, Moore CM, et al. Elastin expression in very severe human COPD. Eur Respir J. 2009;34(2):324–331.)*

antiproteinases in lung tissue tilts in favor of proteinases due to increased proteinase release into the tissue and/or a reduction in the antiproteinase content in the tissue. The proteolytic events leading to emphysema occur in microenvironments adjacent to lung cells; proteinase–antiproteinase balance may not be reflected in measurements of large samples of emphysematous lung tissue.

An important addition to ideas about proteinases and destruction of lung extracellular matrix has come from studies linking mechanical stresses on lung tissue and proteolytic events. Proteolytic damage resulting in local loss of structural integrity of lung tissue increases tissue susceptibility to proteinases.[187] As some fibers are lost, the load on remaining fibers increases, propagating mechanical failure analogous to mechanical failure of a partially cut rope under strain.[188] Biochemically, when lung tissue is overstretched new binding sites for proteases are exposed, increasing the rate of proteolysis.[189] Accordingly, a vicious cycle linking proteinases and tissue destruction may exist.

LUNG ELASTIC FIBERS

Because α_1-AT inhibits neutrophil elastase and papain is a potent elastase, the original observations linking proteinases to emphysema led to the concept that destruction of alveolar elastic fibers is key to emphysema development.[139] Indeed the proteinase–antiproteinase hypothesis of emphysema pathogenesis was originally the "elastase–antielastase hypothesis."

Structurally, the extracellular matrix of the lung is organized into three interdependent cable systems: (1) an axial system that extends from the central airways through the peripheral airways to the alveolar ducts; (2) a parenchymal system that comprises the matrix of the alveolar septae; and (3) a peripheral system that arises from the visceral pleura and extends into the interlobular septae, forming a fibrous sac around the lung. Distal to the respiratory bronchioles, the axial system forms a helix encircling the alveolar ducts, extending into the interstitium of alveolar walls. Elastic fibers, of which elastin is the main component, loop around alveolar ducts, form rings at the mouths of the alveoli, and penetrate as wisps into the alveolar septae, where they are concentrated at bends and junctions (Fig. 40-11). Elastic fibers, which possess rubberlike reversible extensibility, come under tension and provide elastic recoil throughout the respiratory cycle. Unlike elastic fibers, the interstitial collagen fibers in alveolar septa are nondistensible and have high tensile strength. They can be thought of as relaxed ropes that straighten during inspiration and become taut at total lung capacity.

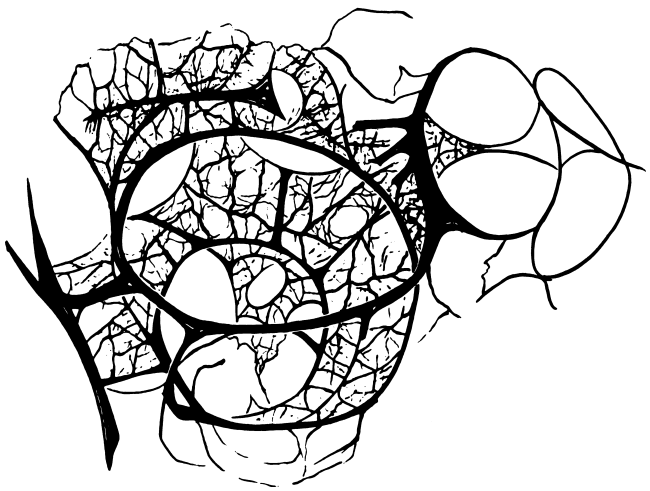

Figure 40-11 Alveolar elastic fiber network. Artist's sketch of the elastic fibers in the parenchyma of human lung showing how elastic fibers form a helix encircling the alveolar ducts and penetrate into alveolar septae. *(Reproduced with permission from Pierce JA, Ebert RV. Fibrous network of the lung and its change with age. Thorax. 1965;20(5):469–476.)*

Elastin is resistant to many proteinases, most notably the collagenases that cleave interstitial collagens. However, there are a number of enzymes that may come into contact with the lung that can degrade elastin (Table 40-5). Elastic fibers in the lung normally last a full human life span.[190] Histological studies of emphysematous lung tissue support the hypothesis that elastic fibers are perturbed in emphysema. There are fragmented elastic fibers in α_1-AT deficiency and poorly formed elastic fibers and clumps of elastin in smokers with centriacinar emphysema.[191] The latter changes appear to be from aberrant synthesis of new elastin and resemble the findings in the lungs in emphysema induced experimentally with elastase.

Animal models employing elastase-induced emphysema have shown acute depletion of elastin following an intratracheal injection of human neutrophil elastase, followed by a burst of synthesis of extracellular matrix including elastin.[192] Over a few weeks, the elastin content of the lungs returns to normal, although the lungs still display emphysema. The elastic fibers, like the elastic fibers in human emphysema, appear disorganized. New elastin gene expression occurs even in severe emphysema in humans (Fig. 40-10). However, there are significant barriers to effective repair of damaged elastic fibers in the mature lung. When elastic fibers are damaged enough to fail under load, there is no mechanism for cells to recreate a structure with a length many times the size of each cell. The injured adult lung lacks the mechanical and morphogen gradients that initiate alveolar formation during development, and may also be unable to coordinate the expression of the many components necessary for functional elastic fiber synthesis.

LUNG COLLAGEN TURNOVER

Although elastic fiber destruction dominates thinking about the proteolytic basis for the pathogenesis of emphysema, degradation of alveolar wall collagen and aberrant collagen deposition in alveolar tissue may also be involved. Indeed, in some forms of experimental emphysema collagen destruction appears to be the critical event. Mice genetically engineered to harbor a transgene that leads to expression of human MMP-1 (collagenase) in lung tissue develop structural changes typical of emphysema.[140] and these changes are due to destruction of alveolar type III collagen.[193] In these models, emphysema occurs without obvious disruption and faulty resynthesis of elastic fibers as the elastic fibers in these lungs look normal. Expression of MMP-1 by alveolar epithelial cells in human emphysematous tissue fits with the idea that collagenolytic activity plays a role in emphysema.[152]

Analogous to elastin peptides promoting emphysema in mice exposed to cigarette smoke (128), a peptide derived from collagen, proline–glycine–proline (PGP), is a neutrophil chemoattractant, associated with COPD and experimental emphysema.[194] PGP is generated by the sequential breakdown of collagen by MMPs 8 and 9 and prolyl endopopetidase.[195] Blocking PGP reduces emphysema in mice exposed to cigarette smoke.[196]

In emphysematous lungs the pores of Kohn are larger and more numerous than in normal lungs (Fig. 40-12). Because interstitial collagens and basement membrane collagens are prominent in alveolar walls, it is plausible that collagenous structures undergo degradation in the process of generating of these interalveolar pores.

ALPHA 1-ANTITRYPSIN DEFICIENCY

In 1963 Laurell and Erikson described α_1-AT deficiency and its association with COPD.[197] Ever since then, α_1-AT deficiency has played an important role in the clinical and basic science aspects of COPD.[198]

■ BACKGROUND

Human plasma contains at least six proteins that function as proteinase inhibitors. Together, they make up about 10% of the total plasma protein. At a concentration of 100 to 273 mg/dL (~18–50 μmol/L) in adults with a normal phenotype, Pi MM,[199] α_1-AT has the highest concentration of all of the plasma proteinase inhibitors. α_1-AT is a member of a family of serine proteinase inhibitors called serpins (SERPINA1).

α_1-AT is a glycoprotein of 52 kDa synthesized primarily by hepatocytes. Mononuclear phagocytes and bronchial epithelial cells are other less abundant cellular sources. α_1-AT consists of a single polypeptide chain of 394 amino acids. Carbohydrate side chains account for 12% of the α_1-AT molecular mass. The 12.2-kb gene, *SERPINA1*, that encodes α_1-AT is on the proteinase inhibitor (PI) locus on chromosome 14. The α_1-AT gene has seven exons and six introns. Exons four through seven code for the mature protein. The first two exons and a segment of the third exon are encoded in the transcript expressed in macrophages, but not in hepatocytes. α_1-AT is an acute-phase reactant. Plasma levels rise with trauma, estrogen therapy, use of birth-control pills, and during pregnancy, however the levels do not rise to normal among individuals with severe deficiency.

Inhibition of neutrophil elastase and other serine proteinases by α_1-AT involves cleavage by the proteinase of the reactive site of α_1-AT between methionine[358] and serine[359] and formation of an enzyme-inhibitor complex that renders the proteinase inactive. Because the complex is quite stable, inactivation is essentially permanent. α_1-AT has a higher affinity for neutrophil elastase than trypsin or other serine proteinases. It is notable that oxidation of the critical methionine residue results in a 2000-fold reduction in the rate of association with neutrophil elastase.[200] The capacity of α_1-AT to inhibit serine proteinases besides trypsin has led some authors to call the protein α_1-PI or α_1-antiproteinase, but the name α_1-AT has become a fixture.

Apart from inhibition of serine proteinases, α_1-AT has numerous other activities. These include promoting immune tolerance, reducing production of proinflammmatory cytokines, and protecting various cell types from cell death through inhibition of caspases.[201–207]

From the genetic standpoint, α_1-AT disease is an autosomal recessive disorder, which means that one mutated α_1-AT allele from each parent must be transmitted to the affected offspring. Thus, for example, on average if MZ parents have four children, there will be two that are MZ and one each will be MM and ZZ. More than 120 different α_1-AT alleles are known,[208] most of which are single nucleotide polymorphisms (SNPs) that do not alter expression of the protein or

its function and so have no clinical significance. Letters are used to specify the allelic variants. The original letters were chosen to reflect electrophoretic mobility: F = fast, M = medium, S = slow, and Z = ultraslow. Homozygosity for the M allele, Pi MM, is present in about 95% of adults in the United States. Homozygosity for the Z allele, Pi ZZ, is associated with severe deficiency of α_1-AT (<15% of normal) and accounts for virtually all of the individuals with severe α_1-AT deficiency. In the United States, the prevalence of the Pi ZZ phenotype is about 1 in 3000 people; worldwide, it is estimated that there are 3.4 million persons with severe α_1-AT deficiency, mainly Pi ZZ.[209]

Heterozygosity of the M allele with an S or Z allele is very common. In the United States, 3% to 8% of the adult population are Pi MS heterozygotes and 2% to 4% are Pi MZ heterozygotes. Pi MS and Pi MZ individuals have mean blood α_1-AT levels 75% and 57% of normal, respectively. Pi MS heterozygosity does not carry an increased risk of COPD.[210] The relationship of Pi MZ heterozygosity to the risk of COPD has been controversial, but recent studies indicate that Pi MZ individuals have slightly impaired air flow, measured as FEV_1/FVC or FEV_1/VC ratios, and slightly more emphysema on CT scans than matched Pi MM individuals.[211]

The abnormality in the Z α_1-AT protein is a point mutation in a single nucleotide at codon 342 that results in coding for lysine instead of glutamic acid. This amino acid substitution changes the charge attraction between the amino acids normally present in positions 342 and 290 in α_1-AT and prevents the formation of a fold in the molecule. With this change in tertiary structure, the molecule is susceptible to dimerization with another α_1-AT molecule that can result in polymerization of α_1-AT in the endoplasmic reticulum. Polymerization impedes secretion of the protein from hepatocytes and explains the low levels of α_1-AT in plasma and other body fluids. In contrast to the Z variant, the S variant of α_1-AT, which involves a single nucleotide substitution of glutamic acid[264] with valine, polymerizes more slowly than the Z protein and does not accumulate in the liver.

Polymers of Z type α_1-AT are chemotactic and recruit neutrophils to the lungs.[212,213] Oxidation of α_1-AT, as occurs with exposure to cigarette smoke, promotes polymerization of Z type α_1-AT.[214] Together, these findings suggest a pathway for the increased risk of COPD in Pi ZZ smokers. An unfolded protein response (UPR) in monocytes and other cell types may be another pathway for increasing the risk of COPD associated with Pi ZZ. According to this paradigm, activation of a UPR occurs in cells that make ZZ α_1-AT which leads to an inflammatory phenotype of increased cytokine production and activation of the NF-kB pathway.[215] Thus, in both of these pathways, a key feature is increased inflammation, which leads to increased proteinase and oxidant stress burdens in tissues. Moreover, compared to M α_1-AT, Z type α_1-AT has a slower rate of association with neutrophil elastase than does M α_1-AT.[216] The net result is that the α_1-AT produced by Pi ZZ individuals is less effective than M protein.

Quantification of serum α_1-AT is done routinely by immunoassay. To confirm an immunoassay showing severe deficiency, specialized laboratories use isoelectric focusing to phenotype α_1-AT (Fig. 40-13). To definitively identify α_1-AT genotypes, analysis is performed with molecular probes.[217]

CLINICAL ASPECTS

Severe α_1-AT deficiency may present in adults as chronic respiratory symptoms (COPD, unremitting asthma, and bronchiectasis), liver disease, (chronic virus–negative hepatitis, cirrhosis, and hepatoma) or skin disease (panniculitis).[198] In practice, however, about 80% of patients are discovered because of respiratory symptoms and most of the rest are detected by screening for α_1-AT deficiency prompted by finding the deficiency in a family member with lung disease. In middle-aged and older individuals with chronic respiratory symptoms, the disease is often not diagnosed for more than 5 years after the onset of the symptoms.[218]

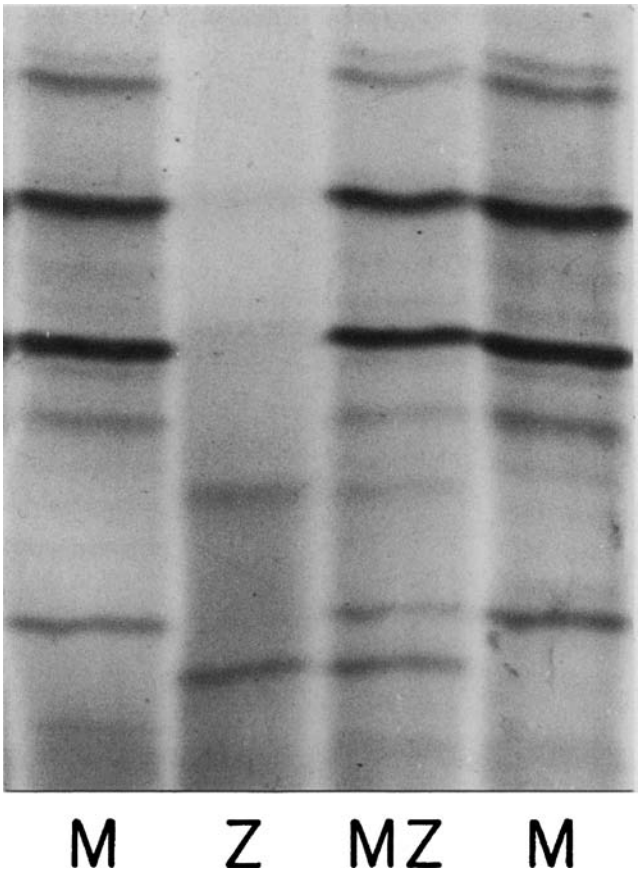

Figure 40-13 Patterns of Pi M, Pi Z, and Pi MZ α_1-AT on isoelectric focus. By this analysis, α_1-AT has microheterogeneity and thus appears as multiple bands. Pi M and Pi Z have distinctly different band patterns, while Pi MZ has a pattern that combines the patterns of both Pi M and Pi Z. *(Used with permission of John A. Pierce, MD.)*

Lung Disease

The classic patient with Pi Z α_1-AT deficiency presents with the typical symptoms of COPD, but is younger than usual, often around age 40. The patient has an increased total lung capacity, a decreased D_{LCO} and radiographic studies show hyperlucent lower lung fields reflecting the predominance of emphysema in those regions (Fig. 40-14). This classic patient reports a mild smoking history relative to the severity of COPD and a family history of chronic respiratory symptoms in parents, siblings, and other close relatives.

In fact, however, there are many exceptions to this classic clinical picture of Pi Z α_1-AT deficiency. Wheezing, cough and sputum mimicking asthma, or chronic bronchitis, that are poorly responsive to standard therapy may be the predominant symptoms. Radiographic emphysema may be modest relative to the severity of the airflow obstruction and may have upper lobe predominance of emphysema,[219] and no other family members may have chronic respiratory symptoms, including siblings who are discovered to have the same level of deficiency as the patient. Discovery of SNPs in genes associated with COPD indicate that modifier genes may account for the differences in COPD occurrence between individuals who share the PiZ phenotype.[220] Because the pulmonary presentation of α_1-AT deficiency often deviates from the classic presentation, experts in this field have advised that everyone diagnosed with COPD be screened for α_1-AT deficiency and that screening be extended to people with certain other conditions (Table 40-7).[221]

About 10,000 individuals in the United States are recognized to have severe α_1-AT deficiency, but estimates from gene frequency

Figure 40-14 Lung pathology of Pi Z-type α_1-AT deficiency. Panacinar emphysema that is worst in the lung base. Paper-mounted whole lung section.

TABLE 40-7 Clinical Situations for Assessment of α_1-AT Status

Early-onset COPD (age of 45 yr or less)
Early-onset emphysema (age 45 yr or less)
Emphysema in the absence of a recognized risk factor (smoking, occupational dust exposure, etc.)
Emphysema with prominent basilar hyperlucency
Asthma with airflow obstruction that is incompletely reversed after aggressive treatment
Bronchiectasis without evident etiology
Otherwise unexplained liver disease
Necrotizing panniculitis
Antiproteinase 3-positive vasculitis (C-ANCA [antineutrophil cytoplasmic antibody] positive vasculitis)
Family history of any of the following: emphysema, bronchiectasis, liver disease, panniculitis

Source: Data from American Thoracic Society; European Respiratory Society. American Thoracic Society/European Respiratory Society Statement: standards for the diagnosis and management of individuals with alpha-1 antitrypsin deficiency. Am J Respir Crit Care Med. 2003;168(7):818–900.

calculations suggest a much larger number, at least 100,000. The discrepancy between known and unknown individuals reflects the fact that many severely deficient individuals are clinically well and, as noted above, clinicians commonly do not consider the diagnosis even among symptomatic individuals. Irrespective of the precise number, the point is that unrecognized deficiency is common. In a recent study involving 3457 individuals with moderate or more severe fixed airflow obstruction undergoing routine pulmonary function testing at 19 US medical centers, 0.63% had severe α_1-AT deficiency (ZZ and SZ) and 10.88% were MS or MZ heterozygotes.[222] Extrapolating these figures to the large number of people with COPD countrywide yields a large number of severely deficient people.

Smoking hastens the development of COPD in most people with severe α_1-AT deficiency. The typical Pi Z individual who smokes has respiratory symptoms by age 40. Besides smoking, male gender and a history of asthma are also associated with worse lung function among deficient individuals.[223] Specific occupational exposures may also impart increased risk of disease,[224–226] but studies of nonindex cases and screened individuals confirm that smoking is the predominant risk factor associated with increased mortality.[227]

Although emphysema is the predominant lung pathology associated with Pi Z α_1-AT, bronchiectasis has been reported to be common.[228] However, this finding has not been universal and it

remains unknown whether bronchiectasis is more prevalent in these individuals than among individuals with comparable COPD and a normal α_1-AT phenotype.[229] Among patients with bronchiectasis due to nontuberculous mycobacterial (ATM) pulmonary infections, heterozygous α_1-AT abnormalities are common, but the basis for this association is obscure as most of the affected individuals do not have severe α_1-AT deficiency.[230]

Liver Disease

Pi Z α_1-AT deficiency can present as liver dysfunction in infancy ranging from asymptomatic jaundice to liver failure. In most instances, the clinical manifestations are mild and resolve spontaneously, but α_1-AT deficiency represents one of the main indications for liver transplantation in children. In adults, liver abnormalities may be limited to tests of liver function. However, among Pi Z individuals who live beyond age 60, liver abnormalities are common and may overshadow respiratory symptoms. Indeed, among those individuals who have not smoked and for other unexplained reasons have avoided significant pulmonary function deterioration, hepatic cirrhosis and associated complications is the predominant terminal illness. In such individuals there is also a high incidence of hepatic cell carcinoma.[231]

THERAPY

Therapy for COPD associated with α_1-AT deficiency includes the standard measures for COPD—cessation of smoking, inhaled bronchodilators and inhaled corticosteroids, pulmonary rehabilitation, pneumococcal and influenza vaccinations, and supplemental oxygen (see Chapter 42). Lung volume reduction surgery has not proven as successful as in individuals with normal α_1-AT.[232] Because progression of disease tends to be slow, qualifying for lung transplantation seldom has urgency.

Up to the present time, the only specific treatment has been the so-called augmentation therapy that consists of weekly intravenous administration of α_1-AT isolated from pooled plasma obtained from healthy individuals, of which several preparations are commercially available. This therapy should be limited to individuals with severe α_1-AT deficiency; for lack of need and expense it is not recommended for MZ heterozygotes.[233] The effectiveness of augmentation therapy has been most evident in individuals with reductions in FEV1 of 30% to 65% predicted.[221] Delivery of α_1-AT by inhalation may improve the convenience of augmentation in the future. Safe and effective genetic approaches to achieve permanent correction of α_1-AT deficiency have not yet been developed, despite efforts with α_1-AT–carrying vectors and transplantation with stem cell–derived hepatocytes that carry normal genes.[234–237]

From the standpoint of liver disease, α_1-AT antitrypsin deficiency is a paradoxical situation in that there is a severe systemic deficiency of α_1-AT despite substantial production of α_1-AT by the liver. The distinction between what is happening in the liver and what is happening systemically is clinically important. Infusions of α_1-AT, or other techniques under investigation for boosting systemic α_1-AT levels, can compensate for severe systemic α_1-AT deficiency and so help protect the lung, but these approaches do not correct or ameliorate problems associated with the accumulation of abnormal α_1-AT in liver cells. At present, liver transplantation is the only treatment for the liver defect. Drugs to promote degradation of hepatocyte accumulations of Z antitrypsin, presumably the underlying mechanisms for liver injury,[238,239] or to prevent α_1-AT polymerization in the liver are under investigation.[240]

CONCLUDING COMMENT

Better understanding of COPD is imperative. This potentially disabling and fatal disease is already epidemic in many countries and appears destined to become a worldwide epidemic in coming decades due to indoor air pollution from use of solid fuels and trends of smoking prevalence.

CHAPTER 41

Cigarette Smoking and Smoking Cessation

Stephen I. Rennard
David M. Daughton

GENERAL BACKGROUND

Native Americans discovered the use of the tobacco plant, *Nicotiana tabacum*, during antiquity. By the time Columbus arrived in America, tobacco use was widespread throughout the Western Hemisphere and was well integrated into Native American cultures. Production of tobacco and its trade represented a major economic activity in the pre-Columbian Americas. Early European explorers learned of the tobacco plant from Native Americans, and by the mid-17th century tobacco was widely used in Europe.

The most important, but not the only, active psychopharmaceutical drug contained in the leaves of the tobacco plant is nicotine.[1,2] Nicotine is a major metabolic product of the tobacco plant, and it is likely that it evolved as a protection against insect predators, as nicotine is a potent insect neurotoxin.[3] Interestingly, nicotine has been exploited in this regard as a commercial insecticide. Nicotine, however, is the major addicting substance in tobacco, although the addiction to tobacco is more complex than addiction to nicotine alone. Other psychoactive compounds are also present in tobacco smoke, including monoamine oxidase inhibitors.[4] These may have either direct effects or interact with other psychoactive drugs.[1,2] In addition, conditioned behavior and social interactions are important drivers of smoking.[5–8]

Nicotine is a potent euphoriant. On a molar basis, nicotine is more active than such euphoria-inducing drugs as cocaine, amphetamine, or morphine.[9] Nicotine elicits complex effects on the central nervous system (CNS), which are discussed in more detail below. Many of these effects, however, are perceived as desirable, accounting for the popularity of smoking. For example, nicotine ameliorates anxiety, reduces perception of pain,[10] mitigates symptoms of depression,[11] and induces a sense of well-being[9] while causing a state of arousal.[12] In contrast to many euphoriants that impair cognition, nicotine can improve task performance and attention time by measurable degrees in nonhabituated individuals and may have beneficial effects on cognition.[12]

Despite its perceived benefits, smoking of tobacco has long been controversial. King James of England wrote in 1604 "[Smoking is] a custom loathsome to the eye, hateful to the nose, harmful to the brain, dangerous to the lungs, and in the black stinking fume thereof, nearest resembling the horrible Stygian smoke of the pit that is bottomless.[13]" The Surgeon General's Report of 1964 outlined the convincing evidence for the health consequences of smoking.[14] Since that time there has been a gradual increase in efforts to control tobacco use and the associated health consequences. Changes in social attitude, public health efforts, and both pharmacologic and nonpharmacologic approaches have been developed that have meaningful benefits. The current chapter will focus on treatment designed to help a smoker achieve abstinence.

NICOTINE ADDICTION

Nicotine exerts its biologic effects on "nicotinic" receptors, a subset of cholinergic receptors, whose endogenous ligand is acetylcholine.[15,16] Nicotinic receptors are homo- or heteropentamers that bind two ligand molecules and form an ion channel.[17] In man, 17 genes code for distinct component chains, resulting in a very large number of potential pentamers, although only a relatively few are believed to have a biologic role. In the brain, nine alpha and three beta receptors are expressed. However the major receptors are composed of complexes (alpha4)(beta2), (alpha3)(beta4), and (alpha7). The (alpha4)(beta2) complex incorporates other subunits, particularly (alpha5), (alpha6), or (beta3), and these may modulate the effects of ligands, including nicotine.[17] The $(alpha4)_3(beta2)_2$ receptor is believed to be particularly important in the addicting effects of nicotine. Deleting the (beta2) receptor in mice eliminates behavioral responses to nicotine, while mutations in the gene can result in markedly increased sensitivity to nicotine.[18] The $(alpha7)_5$ receptor, for example, is believed to mediate some of the cognitive effects of nicotine, including sensory gating and learning.[18,19] In contrast the muscarinic receptors, the other major class of cholinergic receptors, are single chain G-protein–coupled receptors. Nicotine has no effect on these receptors.

Nicotinic receptors are ion channels and upon binding of nicotine, permeability of the channel is increased.[15–18] For example, binding of nicotine to the $(alpha4)_3(beta2)_2$ allows influx of calcium. This, in turn, modulates release of neurotransmitters. It is likely that the behavioral responses to nicotine result from the actions of many neurotransmitters, but dopamine is believed to be a major mediator of nicotine effects. In this context, dopamine is a key mediator of pleasure and reward and is required for the reinforcing effects that lead to drug self-administration in animal models.[20] As such, dopaminergic signaling is believed to be key in the pathogenesis of many addictions and compulsive behaviors. Nicotine also modulates the release of other neurotransmitters, including glutamate and gamma-amino butyric acid (GABA). Interestingly, chronic administration of nicotine desensitizes neurons that release GABA, which inhibits dopamine release. In contrast, there is no desensitization of glutamate release, which augments dopamine release. Chronic nicotine exposure, therefore, can lead to further augmentation, nicotine-induced dopamine release.[21,22] Moreover, the CNS alterations that occur following nicotine administration can be very long lasting; for example, alterations in nicotine receptor levels in rats exposed in utero persist until adult life.[23] The adolescent brain may be particularly sensitive to long-term alterations induced by nicotine.[24] This may account for the sensitivity of adolescents to addiction. Persistent changes in the brain may also account for the observation that, even after achieving abstinence, a smoker is at risk for relapse and if relapse occurs, the smoker reverts to the previous "steady-state" habit much more rapidly than that habit developed initially.

Nicotine is contained in the leaves of the tobacco plant. Nicotine is a weak base and as a result will be charged in acidic environments. Many forms of tobacco, such as cigars and chewing tobacco, are alkalinized, which results in uncharged nicotine that can be more readily absorbed through the buccal mucosa. Thus, cigar smokers do not have to inhale to achieve desired blood nicotine levels. The process of smoking a cigarette is more complex.[25] Air sucked through the burning end of a cigarette becomes heated. As the hot air passes down the bole of a cigarette, it causes the nicotine in the tobacco to volatilize. As the mixture cools, the nicotine condenses on smoke particles resulting in a nicotine aerosol. Conventional cigarettes have been designed so that the resulting particle size is ideal to reach the alveolar structures of the lung. Uncharged nicotine is lipid soluble and is rapidly absorbed from the alveolar gas into the

pulmonary capillary blood and then into the arterial circulation. Inhaled nicotine, therefore, reaches the brain in about ½ a circulation time or about 15 to 20 seconds. In its neutral form, nicotine readily crosses the blood–brain barrier and exerts its psychoactive effects. A cigarette, therefore, is a very effective means of delivering nicotine to the brain. It also allows a smoker to control the dose of delivered drug with considerable precision.

After absorption, nicotine distributes into various body pools. This results in a marked difference between arterial and venous nicotine levels and a rapid drop in nicotine levels upon completion of a cigarette.[26] Nicotine is then catabolized by several enzymes. The most important of these is CYP2A6 which oxidizes nicotine to cotinine and cotinine to hydroxycotinine.[27] Nicotine can also be oxidized by alternative CYP450 enzymes and may be inactivated and excreted by glucuronidation. Genetic variants in nicotine metabolizing enzymes can influence smoking behavior. In normal metabolizers, nicotine is cleared with a half-life of about 2 hours. As a result, nicotine levels increase throughout the day for individuals who smoke steadily. The increase in nicotine levels can result in levels believed to fully saturate all nicotinic receptors.[1,2] In this setting, it is likely that smoking behavior is more dependent on conditioned responses than on psychopharmacologic effects of nicotine. Conversely, nicotine levels fall at night. The drop in nicotine levels is thought to initiate the early stages of withdrawal. Importantly, the lower levels allow for nicotinic receptors to be in the unbound state. As a result, the first cigarette in the morning can have a large psychodynamic effect. This is well recognized by smokers who will often report that the "most enjoyable" cigarette is the first one smoked in the morning. In addition, the drop in nicotine levels is thought to initiate the early stages of withdrawal. How long it takes a smoker to smoke the first cigarette of the day, therefore, serves as a gauge of addiction, with short times indicating stronger addiction. Smoking within 30 minutes of awakening is a key question in the Fagerstrom test for nicotine dependence.[28]

Several lines of evidence support genetic influences on smoking behavior.[29–32] Twin studies suggest that genetics accounts for about 50% of the variance in smoking. Interestingly, there appears to be a genetic basis for withdrawal symptoms.[33] A number of genes have been suggested to play a role in both candidate gene and in genome-wide association studies. Although many of the candidate genes have been difficult to reproduce, an extremely strong signal has been consistently observed in a region of chromosome 15 that includes the genes for three nicotinic receptors.[34] Among COPD patients, this region is also associated with intensity of smoking assessed by cigarettes smoked per day, suggesting it may be related to intensity of addiction.[35] As might be expected of a gene related to smoking behavior, this region has also been strongly linked to the risk for several smoking-related diseases.[36–39] Candidate genes include not only genes in the dopamine pathway, but also other neurotransmitter pathways as well as cell adhesion molecules that are thought to contribute to long-term memory and neural adaptation.

Genetic variation in nicotine metabolizing enzymes has received particular attention.[31] Many, but not all studies have demonstrated that individuals with variants in CYP2A6 who metabolize nicotine slowly smoke fewer cigarettes and maintain lower cotinine and carbon monoxide levels consistent with their requiring less total intake.[35,40,41] Consistent with a reduced level of smoking, some studies have shown reduced risk for cancer in slow metabolizers.[42,43] Similarly, better lung function has been reported among individuals with haplotypes associated with slow metabolism compared to those with genes associated with rapid metabolism who smoke the same number of cigarettes.[44]

It is plausible that the slower decline in blood nicotine levels associated with slow nicotine metabolism makes these individuals less likely to experience withdrawal. In addition, the persistence of nicotine may decrease the "reward" of smoking. Both of these effects may contribute to increased likelihood that a slow metabolizer can achieve abstinence from smoking[40] and better quit rates have been observed among slow metabolizers in clinical trials.[31,45] On the other hand, slow metabolizers who are experimenting with smoking may have higher and more sustained nicotine levels. Consistent with this, a prospective study of adolescents observed a threefold risk of becoming a regular smoker among slow metabolizers.[46]

Smoking cigarettes is more complex than nicotine addiction. Conditioned behaviors also play a key role.[1,2] In this context, a smoker typically inhales 10 puffs per cigarette. This would be 300 puffs for a 1½ pack per day smoker or more than 100,000 puffs annually. In addition, smoking frequently occurs in recurrent settings: after eating, when irritated, when bored, when sad, in specific social settings, etc. As such, smoking becomes associated with these settings which serve as operant cues to induce smoking behavior. Nicotine, moreover, has been demonstrated to increase both the intensity of operant conditioning as well as its persistence.[6,47] The development of addiction to tobacco, therefore, involves not only development of addiction to nicotine, but also acquisition of conditioned behaviors, which nicotine facilitates. Because these cue-mediated behaviors can be very persistent, they are major causes of relapse.

Tobacco addiction most commonly begins in late childhood or adolescence,[48–51] although smoking can begin in young adulthood.[52,53] Historically, in the United States, the peak incidence for developing a regular tobacco habit is in adolescence. Individuals who do not acquire a habit prior to age 20 were unlikely to do so as adults.[48] The demographics of smoking initiation were well known to the tobacco industry. Marketing campaigns designed to promote the image of specific brands of cigarettes were carefully designed and were exceedingly effective in leading to logo recognition among children as young as kindergartners[51,54] and contributed to brand selection among American adolescents. The susceptibility of children to these campaigns was a major driver in leading to the current ban on tobacco advertising in media likely to be seen by children. Importantly, since most exploratory smoking occurs in peer-related social settings, the social context of smoking is a crucial variable in determining smoking initiation.[51,55,56]

Most children who begin to smoke do so on an occasional basis. Within a few years, however, a regular habit may develop. Most often this habit is characterized by smoking only a few cigarettes daily. As noted above, slow metabolizers may be particularly susceptible to addiction due to higher nicotine levels and longer persistence.[46] The number of cigarettes smoked, however, generally increases for the first 8 to 10 years. Important variations on this pattern exist, suggesting biologic differences among smokers. Some smokers achieve a "mature addiction" very rapidly. In contrast, as many as 15% of smokers, termed "chippers," may continue to smoke episodically and may not be fully addicted.[57,58]

Smoking is more common among those with psychiatric disorders.[59–61] This includes individuals with depression, anxiety disorders, and cognitive disorders such as schizophrenia as well as other drug dependencies. The basis for this relationship is unclear. Nicotine has modest antidepressant and antianxiety effects, and the suggestion has been made that some individuals with mood disorders may smoke to "auto-medicate." Alternatively, it has been suggested that smoking and psychiatric disorders may share common genetic risk factors. Another possibility is that smoking early in life may lead to alterations in the CNS that may lead, in turn, to psychiatric disorders. In support of this, smoking more commonly precedes first psychotic episodes.[61] Whatever the mechanisms, the concurrent presence of psychiatric disorders can complicate efforts to achieve smoking abstinence.

Once a smoker achieves a "mature" addiction, cigarette consumption typically remains very constant. Interestingly, the smoker

appears to adjust both nicotine intake and number of cigarettes smoked independently. If supplemental nicotine is administered, smokers will often reduce their nicotine consumption.[62] Alternatively, if smoking is restricted, for example, by decreasing the number of cigarettes available, smokers will alter their smoking strategy, for example, by smoking each cigarette more deeply, to maintain a relatively constant nicotine intake.[63] Similarly, acidification of the urine increases while alkalinization slows nicotine clearance, and there are corresponding increases and decreases in nicotine intake that are achieved with no change in the number of cigarettes smoked.[64] Rather, smokers alter the way in which individual cigarettes are smoked, that is, the depth and duration of inhalation and the number of puffs, thus modifying the nicotine absorbed. Consistent with self-regulation of nicotine administration, low–nicotine-content cigarettes do not result in lower nicotine consumption.[65] This illustrates the complexity of smoking where both nicotine addiction and conditioned behaviors contribute.

While the pathogenetic mechanisms underlying withdrawal symptoms are incompletely understood, it is generally believed that some withdrawal symptoms are related to decreases in nicotine blood levels below certain thresholds. Variations in nicotine metabolism would be expected to affect the timing of symptom onset. Some smokers, for example, may experience nicotine withdrawal at night when sleep interferes with nicotine intake.[66] The concept that nicotine replacement can help ameliorate withdrawal symptoms by maintaining nicotine blood levels is also an important concept underlying nicotine replacement as an aid to smoking cessation. In addition, susceptibility to specific symptoms may be genetically determined.[67,68]

SMOKING AS A PUBLIC HEALTH PROBLEM

Cigarette smoking is a major public health problem and is perhaps the most important cause of preventable disease. The number of deaths attributed to cigarette smoking in the United States has been estimated to be well in excess of 400,000 annually and has been for many years.[69,70] This exceeds deaths attributed to other specific causes.[71] The health burden attributable to smoking parallels smoking prevalence. As a result, smoking-induced disease is becoming more common in the developing world where smoking prevalence has been increasing, particularly in specific subpopulations such as young and middle-aged males.[72] In the United States, where comprehensive tobacco control programs have reduced smoking prevalence, the burden of tobacco-related disease has begun to decrease.[73–75] Smoking can cause disease through a variety of mechanisms, which are reviewed in other chapters. However, some pathophysiologic effects persist after cessation. Smoking-related disease, therefore, will continue to be a major health problem for many decades.

Since Dr. Luther Terry released the first Surgeon General's report on smoking and health in 1964,[14] the prevalence of adult smokers in the United States has dropped from 40% to under 20%.[75] Antismoking awareness has increased worldwide to the extent that smoking bans have become commonplace in public buildings, workplaces, and public transportation. In 1984, Surgeon General C. Everett Koop[76] proclaimed that the United States' number one health goal was to achieve a smoke-free society by the year 2000." Unfortunately, this goal was not achieved, but the importance of the public health initiatives that followed, evidenced by the overall incidence of smokers in the adult population in the United States, continues to decrease.[73–75] A more realistic goal of adult smoking reduction to 12% in the United States was put into place through the Healthy People 2010.[77] Whether this goal will be obtained remains to be determined; however, it still highlights the importance of a smoke-free society. The greatest reductions in smoking have been in states with the most comprehensive tobacco control programs, supporting the effectiveness of currently available interventions.

Public health approaches to control smoking-related disease begin with the social factors that are key in initiating and maintaining smoking.[51] The experience a child has with the initial attempts at smoking appear to be important as is an individual's attitude toward smoking, that is, the "image" of the smoker, peer pressure, parental cigarette use, and availability.[51,78,79] Social attitudes can account for very low smoking prevalence in some groups. These observations support attempts to place restrictions on smoking in public places and other efforts to "de-normalize" smoking.[51]

As in ancient America, the use of tobacco products has become well integrated into modern cultures worldwide. Tobacco is a multibillion dollar industry. In some regions, tobacco is a crucial cash crop in an agricultural economy. In addition, the manufacturing, distribution, marketing, and sale of tobacco products employ many individuals worldwide. Taxation on tobacco products has become an important means for the support of many governments. Thus, any changes in tobacco usage are likely to have economic impacts well beyond any health effects.

The use of tobacco not only has an economic role, but a cultural one as well. In some societies, for example, certain Native American tribes, tobacco usage has religious significance. In other groups, tobacco usage is associated with a strong cultural "image." Often this image may have been created through direct efforts of the tobacco industry to market their product. In this regard, advertising messages promoting the image of the cigarette smoker as rugged, independent, and masculine or as sophisticated, independent, and feminine have been developed.[80,81] While these images of cigarette smoking have their origins in advertising campaigns, the effectiveness of such marketing programs cannot be underestimated.[51,79] The portrayal of these images in media, such as film, may help promote smoking, which supports restrictions on advertisements as part of public health initiatives directed at tobacco control.[51,82,83] Whatever the reasons, cigarettes clearly have a cultural significance. The social and economic impact of tobacco usage, therefore, must be considered when attempting to deal with smoking as a public health problem.

In an effort to combat the public health ramifications of tobacco usage in the United States, the Master Settlement Agreement was signed into effect in 1998.[84] It served as a measure to recoup what states had lost through Medicaid expenditures due to smoking-related illnesses and as a measure to fine the tobacco industry for deceitful actions. Four major United States tobacco companies awarded 46 states $206 billion to be paid over 25 years and to be utilized as the states saw fit. Four states had previously settled separately. Unfortunately, since its inception, many states have failed to use the funding for tobacco control causes, instead using it to fill budget deficits or to support other state programs. Among many other actions, the agreement also prohibited advertisements targeted at youth and permitted access to tobacco industry documents. Based on current understanding of the complex factors that interact to cause tobacco addiction, these approaches are rational. The issues are also complex and controversial. It is likely that social and public health interventions will continue to evolve and be part of ongoing political debate.

Smoking prevention. As noted above, smoking initiation is generally a pediatric problem.[51] Precisely why some children begin smoking is not fully understood, although both social and genetic factors contribute as discussed above.[51] Currently as many as 40% of American children will experiment with cigarettes, of whom one-fourth will eventually smoke by the twelfth grade.[85] A number of factors are believed to contribute, including the child's social environment and the child's attitude toward smoking, which appears to be based, in large part, on the smoking behavior of parents, friends, and peer group role models.[51,78,79] Attitudes toward smoking appear

to be important factors leading to smoking initiation, which may depend, at least in part, on advertising and marketing programs, hence the effectiveness of bans on advertising. The reasons for initiating smoking, however, are not entirely environmental, as several lines of investigation (see above) suggest a genetic basis for smoking as well. These concepts support the basis for interventions to reduce smoking initiation. Interventions aimed at altering the social milieu have benefit.[86] Participation in sporting activities is associated with lower rates of smoking initiation.[48,87]

A second approach to limiting smoking initiation is to restrict the sale of tobacco products to minors. Many states have legal restrictions on such sales. In many cases, however, these laws are not enforced. Active enforcement, however, can lead to a decrease in sales to minors[88] and a decrease in both experimental smoking and in regular cigarette use among younger smokers,[89] although the general effectiveness of these measures is unclear.[90] For such measures to be effective, they must be uniformly enforced in the community, and vending machines must be made inaccessible to minors.[91,92] Another approach to restrict tobacco usage by minors is taxation.[93] While there is controversy over how "elastic" purchase of tobacco is,[94] increasing price decreases use, and this effect may be particularly prominent among less addicted smokers.[93] Inasmuch as adolescents may have less disposable income, the effect may be even greater among adolescents. Some analyses support an association between higher price, particularly through taxation and lower smoking initiation and prevalence.[95] However assessment of the specific effectiveness is difficult methodologically.

Measures aimed at restricting tobacco sales to minors may lead to a deferral for smoking initiation, as young adults remain at risk for[52,53] smoking initiation. Thus, if measures are effective at delaying smoking initiation among children, parallel measures may also be required to affect smoking initiation among older adolescents and young adults. Currently available data suggest that smoking behavior among high school students decreased steadily since the initiation of efforts designed to reduce initiation (Fig. 41-1). There does not appear to be a corresponding increase in smoking among older individuals, which supports the concept that smoking prevention is a legitimate and achievable public health goal. While it is difficult to determine the effectiveness of specific public health initiatives,[96] the evidence is clear that smoking rates can be decreased by population-based measures and that states with the most comprehensive programs have achieved the greatest gains.[51,73–75]

SMOKING CESSATION

BACKGROUND AND GENERAL APPROACH

Smoking should be regarded as a primary addictive disorder.[97] This contrasts with the "classic" view of smoking as a "habit" or "life style choice." An estimated 75% of Americans wish to quit but only 3% are able to achieve prolonged abstinence in any year, which indicates the involuntary nature of the established addiction.[98] In addition, current concepts suggest smoking should be regarded as a chronic relapsing disorder. In this context, a "cessation attempt" should be regarded as an attempt to induce a remission. The abstinent smoker, moreover, should always be viewed as at risk for relapse. The goal for therapy is to induce a remission that is as durable as possible. However, the clinician needs to be prepared to reinduce remission in the event that relapse occurs. In this context, smokers who are "quit" should remain in active surveillance, and relapses should not be regarded as "failures." In this model, the health consequences of smoking should be regarded as secondary effects. Importantly, there are health benefits of cessation that are well established. These are the subject of the Surgeon General's Report (2014).

Current recommendations are to assess smoking and willingness to quit at every visit.[97,99,100] Interestingly, success in quitting may be related to acute problems that may have motivated a patient to be willing to consider quitting (see Stages of Change).[101] This acute motivation may be present even if the acute event is not directly related to smoking, and the clinician should be ready to utilize these windows of opportunity. In contrast, not inquiring about smoking can have adverse effects. Not asking is thought to send three messages: (1) that the physician does not care if the patient smokes; (2) that the physician does not have an effective intervention to offer; and/or (3) that the physician does not think that the patient will be able to quit. All of these "nonmessages" have negative effects, particularly as smokers gradually make the decision to quit. A sense of empowerment and control over the behavior is believed to be key to making and succeeding in a quit attempt[102] and to subsequent risk of relapse.[103] Inadvertently eroding a patient's sense of mastery is an unanticipated adverse consequence of not asking about smoking. In addition, many patients are unaware of the potential available therapies; appropriate information can increase motivation to engage in quit attempts. Smokers unwilling to make a quit attempt should be encouraged as much as possible, provided with specific information if desired and reminded that the issue will be brought up again in the future.

Approach to a Quit Attempt

A smoking quit attempt should be approached in a similar way to induction of remission from cancer. As with cancer, each patient should be given the best chance of achieving remission. In general this will require two classes of intervention: nonpharmacologic approaches and pharmacotherapy, which should be used together to optimize success.

Evaluation

As with the management of any complex disease, smokers should undergo an initial organized assessment.[97,100] Motivation or reason to

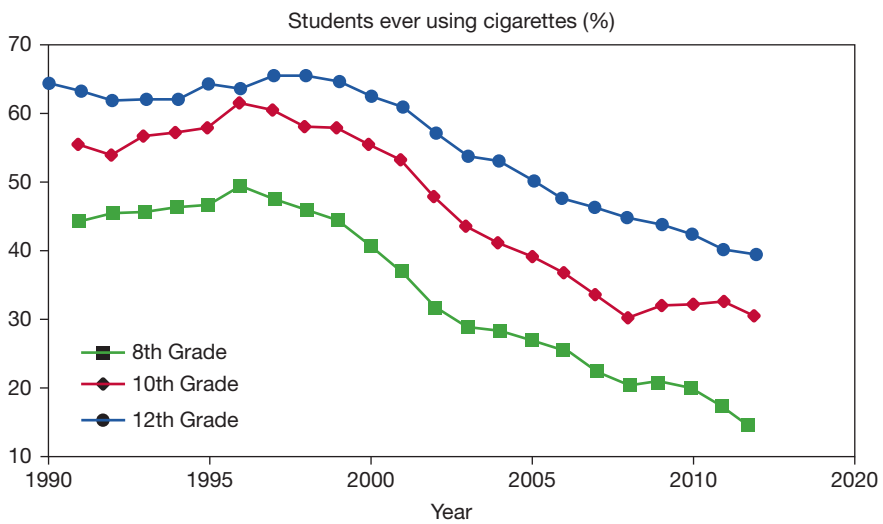

Figure 41-1 Prevalence of ever smoking among American Youth. *(Data from Johnston LD, O'Malley PM, Bachman JG, Schulenberg JE. Decline in teen smoking continues into 2012. Monitoring the Future Press Release. University of Michigan News Service, Ann Arbor.)*

TABLE 41-1 Items and Scoring for Fagerstrom Test for Nicotine Dependence

Questions	Answers	Points
1. How soon after you wake up do you smoke your first cigarette?	Within 5 min	3
	6–30 min	2
	31–60 min	1
	After 60 min	0
2. Do you find it difficult to refrain from smoking in places where it is forbidden, e.g., in church, at the library, in cinema, etc.?	Yes	1
	No	0
3. Which cigarette would you hate most to give up?	The first one in the morning	1
	All others	0
4. How many cigarettes/day do you smoke?	10 or less	0
	11–20	1
	21–30	2
	31 or more	3
5. Do you smoke more frequently during the first hours after waking than during the rest of the day?	Yes	1
	No	0
6. Do you smoke if you are so ill that you are in bed most of the day?	Yes	1
	No	0

quit and the patient's confidence in their ability to stop smoking, that is, self-efficacy, should be assessed. For patients who indicate they are not currently interested in quitting, the goal is simple: to move them through the stages of change[104] so a quit attempt will be made. For some, this may be as simple as providing information about health risks. For others, it may be information about effective interventions.

The intensity of addiction can be assessed with the Fagerstrom test for nicotine dependence (Table 41-1).[28] The most important question is time to first cigarette, and smokers who smoke within 30 minutes of awakening are usually heavily addicted to nicotine. These patients and those with Fagerstrom scores ≥7 comprise a group of individuals likely to benefit from nicotine replacement therapy (NRT) or varenicline. In contrast, patients with low Fagerstrom scores who are able to cope with smoke-free environments for an extended time period (>4 hours) without developing discomforting withdrawal symptoms, may not require NRT. For these individuals, the benefit of pharmacologic support is unknown.

Past experience with quit attempts should be reviewed. Many patients will have a number of prior tries. Individuals who had particular difficulty with withdrawal symptoms should be prepared for this, and medications can be gauged to attempt to mitigate their intensity. Approaches that achieved abstinence, but were followed by relapse, should be considered as they are likely to succeed again. In these cases, interventions should be guided by reducing risks of relapse.

■ NONPHARMACOLOGIC APPROACHES

Nonpharmacologic approaches provide the smoker with guidance and support as progress is made through a quit attempt.[97,99,100] It is likely that effective support improves adherence with pharmacotherapy and results in therapeutic synergy. In addition, conditioned responses, that is, cue-driven behaviors, are largely dealt with thorough behavioral strategies. This generally requires individual interviews to define individual smoking patterns. These patterns can also help identify situations that increase risk of relapse. In general, success increases with the intensity of support,[97,99,100] but most smokers will decline referral to intensive programs and will receive only the support provided in the office setting. The remainder of this section summarizes commonly used approaches.[97,99,100,105]

Stages of Change and Smoking Cessation

The Stages of Change model has been very useful to guide behavioral support. Prochaska and DiClemente[104] described the smoking cessation process as involving five stages: precontemplation, contemplation, preparation, action, and maintenance. These stages are viewed as a continuum with smokers progressing sequentially through each stage. In the precontemplation stage, smokers are not interested in quitting smoking and will likely be nonresponsive to direct intervention. Smokers in the contemplation stage are considering quitting smoking and may be receptive to a physician's advice about the risks and benefits of quitting. In the preparation stage, smokers are actively preparing to quit. The action stage encompasses both initial abstinence and the 6-month postcessation period. The maintenance period commences after the 6-month abstinence period. It is rare for a smoker to progress successfully through these stages in the initial quit attempt. The cycle will likely be repeated several times before smoking a prolonged abstinence, that is remission, is achieved. Thus the clinician must be encouraging and willing to support repeated attempts.

The National Cancer Institute's (NCI) recommended model for smoking intervention is based, in part, on five NCI supported trials involving more than 30,000 patients and was later expanded by the Public Health Service.[97,99,100] This approach, popularly referred to as "the five A's," emphasizes the role of medical professionals to ask patients about their smoking status, assess their willingness to make a quit attempt, advise smokers to stop, assist them in their stop smoking efforts, and arrange for follow-up visits to support the patient's efforts. This approach utilizes brief intervention techniques and emphasizes the role of physicians as facilitators in the quitting process.

Simple advice has been assessed in a number of studies, and meta-analysis suggests a small but significant benefit of these limited interventions.[100] Physician advice is effective both in the outpatient and hospital setting and may also be effective when given by letter, email, or telephone.[106–108]

Group Counseling

Group counseling programs for smoking cessation are offered by several commercial and voluntary health organizations. These programs are similar in content and typically include lectures, group interactions, exercises on self-recognition of one's habit, some form of tapering method leading to a quit day, development of coping skills, and suggestions for relapse prevention. Group counseling programs sponsored by voluntary health organizations are generally the best cost value for smokers.[97,99,100] However, these programs are generally limited to large metropolitan areas and are offered on a sporadic basis. One-year success rates associated with group counseling programs are typically in the 15% to 35% range.[97,99,100] The high success rates are likely affected by selection bias, that is, participants may be more motivated to quit.

Gradual Reduction Versus Abrupt Abstinence

Gradual reduction or tapering intuitively appears to offer smokers the least abrasive way to stop smoking, and may be effective for some.[109–111] However, gradually cutting down can be stressful when smokers attempt to reduce their cigarette use below their critical blood nicotine threshold. At this stage, smokers may begin to experience tobacco withdrawal symptoms. Rather than suffer prolonged discomfort, many taperers will gradually return to their customary cigarette levels and will not succeed in quitting. One of the negative consequences of tapering is that this method can strongly reinforce

the smoker's belief of their underlying need for cigarettes, that is, it can undermine self-efficacy. Combining tapering with pharmacotherapy to prevent withdrawal may be useful in this setting,[110] but this is not an FDA-approved use for any medication. Abrupt abstinence is often stressful and can lead to tobacco withdrawal symptoms. However, within a few weeks of total abstinence, complete abstainers experience less frequent cigarette cravings than taperers and are less prone to relapse. Cigarette tapering is often a component of many group programs in which gradual cigarette reduction is used as a preparatory stage leading toward a target quit day.

Educational Techniques

For years, cigarette smoking was viewed as largely a social or psychological habit. As such, the ability to quit was viewed as a measure of personal motivation and psychological willpower. Motivation to stop smoking, combined with sufficient psychological resources, was seen as a driving force behind successful cigarette abstinence. Thus, if smokers could be educated about the health risks of cigarette smoking, they could theoretically become sufficiently motivated and psychologically empowered to quit. Unfortunately, anticipated benefits of the smoking cessation value of educational awareness messages were overly optimistic and simplistic. Educational programs to aid smoking cessation have produced disappointing results with high long-term failure rates.[97,99,100] Nevertheless, education about smoking is still regarded as a useful activity, particularly when the information can address problems of specific interest to individual patients. In this regard, as noted above, a major predictor of success is "self-efficacy," which is the patient's sense that they are likely to succeed. Education that improves self-efficacy should be a therapeutic goal.

Other Modes

The goal of hypnosis in smoking cessation is to enable the smoker to achieve an altered state of consciousness to enhance the ability to quit. Controlled trials of hypnosis have generally been unable to document long-term smoking cessation efficacy. While one meta-analysis suggested the possibility of a treatment effect,[112] this was not supported in another meta-analysis.[113] Aversive conditioning is based on the premise that smoking is a learned response that can be extinguished by creating an association between smoking and a negative sensation. By design, adversive conditioning techniques can produce smoker discomfort and are now rarely employed. However, there are few recent studies, and a treatment benefit cannot be excluded.[112] Acupuncture has been advocated, but controlled trials with "sham" acupuncture have not clearly demonstrated an effect. Meta-analyses have not been conclusive, but suggest the possibility of an effect.[112,114]

Resources Available

The resources available to support smoking cessation vary among communities. Some have readily available and affordable group programs, while these may be unavailable in other places. Toll-free tobacco quit lines are currently provided by many countries, including the United States and Canada. Telephone counseling is an effective smoking intervention.[108] Thus, clinicians should encourage every smoker who wishes to quit to utilize a National Quit Line (e.g., in the United States: 1-800-Quit-Now). Additional support can be found via the internet using smokefree.gov. Using this approach, a smoker can choose to talk with a telephone specialist with either internet instant messaging or telephone support. Both methods are designed to provide smokers with a personalized quit plan that would be available in most clinical settings.

■ PHARMACOLOGIC TREATMENT

Three classes of agents, nicotine replacement, bupropion, and varenicline, are approved to aid smoking cessation.[115] In addition, two other agents, clonidine and nortriptyline are supported by guidelines for "off-label" use as secondary agents. In addition, several other agents are under active investigation and have shown promise.[97,99,100] As noted above, combination of nonpharmacologic support and pharmacotherapy optimizes success in achieving abstinence.[97,99,100] The remainder of this section summarizes currently available pharmacotherapy.

Nicotine Replacement Therapies

Five nicotine replacement therapies are approved for use to aid in smoking cessation. Lozenges, polacrilex (gum), and transdermal systems are available over the counter (OTC). Nasal spray and a nicotine inhaler are available with a prescription. Other nicotine preparations, including nicotine toothpicks and e-cigarettes, have been developed and marketed as consumer products. Their efficacy and safety in smoking cessation remains undetermined. Initial concerns about potential hazards of concurrent smoking while using NRT led to warnings against this practice. However, the Food and Drug Administration recently (April, 2013) removed this warning from the OTC formulations, as the benefits of smoking cessation greatly exceed any potential hazards.

NRT is usually started on the scheduled quit day. The concept is to replace nicotine that would be absorbed from cigarettes and thereby reduce the intensity of withdrawal. Smokers will, however, experience withdrawal symptoms albeit with less intensity. In clinical trials, the five approved formulations have demonstrated about twofold increases in quit rates above placebo when used alone[97,99,100] and one trial comparing gum, inhaler, and nasal spray found no difference in efficacy.[116] They differ, however, in their pharmacokinetics.[117] The transdermal systems provide the slowest delivery of nicotine, but maintain steady-state levels throughout the day. The other formulations allow episodic dosing. A common practice is to combine a transdermal system with another formulation, a "patch-plus" regimen.[118,119] This allows a smoker to increase nicotine delivery at times of urges. Clinical trial data supports better success with combined NRT compared to monotherapy.[97,99,100]

Nicotine Polacrilex Gum Nicotine polacrilex gum was the first NRT to gain FDA approval. It is now commercially available OTC in 2 and 4-mg forms. In nicotine polacrilex, nicotine is bound to a resin that contains a buffering agent to improve delivery of nicotine through the buccal mucosa. The rate of chewing can influence the rate of nicotine release. In addition, acid foods or drinks convert nicotine base to its salt, which, because of its charge, does not cross the buccal mucosa. To be absorbed into the venous circulation, the nicotine-containing saliva must be retained in the mouth as long as possible. If swallowed, the nicotine can cause local irritation of the stomach. When absorbed into the portal circulation, high first-pass metabolism in the liver limits blood nicotine levels. If chewed properly, absorption takes place gradually, and blood levels peak after about 30 minutes.[117] Ad lib use of 2-mg nicotine polacrilex is associated with blood nicotine levels less than 40% of customary smoking. The 4-mg dose is recommended for individuals who are heavier smokers or who have had discomforting tobacco withdrawal symptoms on the 2-mg dose.[97] A fixed dosage regimen rather than ad lib usage may have better success,[120] perhaps because it can produce higher blood nicotine levels. A common recommendation is that a smoker use one piece of gum every 1 to 2 hours for the first 6 weeks after quitting followed by gradual reduction over 6 weeks. Many smokers continue to use gum at times of craving for an extended time and some can use sufficient gum to sustain nicotine addiction without smoking.

Although effective in clinical trials, less successful results have been observed with nicotine gum in general practice and unsupervised settings. This may be due, in part, to requirement that the gum

be chewed properly. Adverse effects from the gum include exacerbation of local effects: temporomandibular joint (TMJ) disease, trauma to dental appliances, sore jaw, oral irritation or ulcers, and excess salivation; effects from swallowed nicotine: hiccups; and effects from systemic absorption of nicotine: nausea, vomiting, abdominal pain, constipation, diarrhea, palpitations, and headache. Use of the gum is not recommended in individuals with poor dentition or who have dental appliances.[115]

Nicotine Polacrilex Lozenge A nicotine polacrilex lozenge is also available "over the counter." Chewing is not required, but acid food and/or beverages will impair absorption as with gum. Dosing, absorption, and duration of therapy with the lozenge are similar to those for the gum.[121] Because it is not chewed, the lozenge does not share the problems of exacerbating TMJ disease or damaging dental appliances. Other side effects are similar to those of the gum.

Transdermal Nicotine The primary advantage of transdermal patch delivery systems are ease of use and controlled drug delivery. Several formulations are available "over the counter." In general, they achieve nicotine blood levels roughly 40% to 50% of that achieved by customary smoking of about 30 cigarettes daily.[117] Transdermal nicotine systems have been repeatedly found to reduce tobacco withdrawal symptoms and significantly enhance smoking cessation rates.[97,99,100] Unlike nicotine polacrilex gum, transdermal nicotine systems and the nicotine lozenge have improved quit rates in primary care settings.[101,122] This difference is likely due to the ease of patch use in this setting. The recommended use period for patches varies according to product, but a minimum of 4 weeks of therapy is probably required to help achieve long-term abstinence.

Patches are most commonly worn at night, which provides a level of nicotine when a smoker awakes. Often this is a time when the individual is at risk to relapse, since the low nicotine levels are associated both with withdrawal and with increased effect of the smoked cigarette. On the other hand, delivery of nicotine at night may disturb sleep, particularly through vivid dreams or insomnia. Spontaneous long-term use of the patch has not been observed, suggesting that the very slow kinetics of nicotine delivery with this system is insufficient to sustain addiction effectively.[123] In addition, perhaps due to the partial replacement of nicotine, most smokers on patches will still experience some tobacco withdrawal symptoms during the first few days of quitting. While these symptoms will likely be less severe compared to quitting cold turkey, some patients will be tempted to smoke and wear patches. Early concerns about increased cardiac risk among individuals who smoked while wearing the patch have not been substantiated. In fact, reduced smoking may decrease cardiac events.[124–126]

Nicotine Inhaler The nicotine inhaler is a plastic nicotine-containing cartridge that fits on a mouthpiece. Nicotine is released when air is inhaled through the device, which is similar in size to a cigarette. The nicotine is not effectively delivered to the lungs as the particle size is too large. Rather, it is deposited and absorbed through the buccal mucosa, which results in pharmacokinetics that resemble nicotine polacrilex. Blood levels depend on the frequency of inhalations but can be about one-third of conventional smoking. Usual dosing is 6 to 16 cartridges per day for 6 to 12 weeks followed by gradual reduction over 6 to 12 weeks. Because the use of the inhaler recapitulates many of the actions associated with smoking: preparation of the device, oral stimulation, inhalation, etc.; it may be particularly effective in smokers for whom these behaviors are particularly strongly conditioned. In addition to the adverse effects described for the lozenge, the inhaler may cause irritation of the throat and mouth and may precipitate bronchospasm in individuals with reactive airways.

Nicotine Nasal Spray The nasal spray delivers nicotine to the nasal mucosa through which it is absorbed. It has the most rapid pharmacokinetics of the currently available nicotine replacement formulations but does not reproduce that of a cigarette.[117] Nasal irritation is very common, particularly when initiating therapy. The recommended dose is one to two sprays per hour for 3 months with a maximum of 80 sprays per day. Because the spray can deliver large amounts of nicotine, it may be particularly effective for heavily addicted smokers. It also likely has a greater risk of nicotine overdose and may have a greater potential to sustain a long-term addiction.

Combination Therapy Although not approved by drug regulatory agencies, various combinations of nicotine replacement may have utility for selected individuals who need higher doses. In particular, combination of a transdermal system with an ad lib modality has been demonstrated to increase quit rates.[97,99,100,122,127] Because of its increased success, it is recommended by some as initial therapy.[115]

Bupropion

Bupropion is approved as an antidepressant, and it is also effective as an aid for smoking cessation.[97,99,100,128] It is believed to act by potentiating dopaminergic and noradrenergic signaling. The formulations for depression and for smoking cessation have different trade names, which has clinical relevance. First, an appropriate diagnosis is often required for reimbursement. Second, care is needed not to prescribe bupropion under one name to an individual already taking it under its other name, as over dosage can result.

In clinical trials, bupropion approximately doubles quit rates compared to placebo. Subjects with a history of depression, however, appeared to benefit from bupropion but did not with nicotine replacement, suggesting that bupropion may be a superior initial choice in such individuals. Combination of nicotine replacement with bupropion has been assessed and appears more effective than either agent alone.

The currently recommended dose is 150-mg daily for 3 days followed by 150-mg twice daily. Because the drug is excreted slowly, steady state-levels are achieved after 6 to 7 days. For this reason, the quit date should be scheduled after a week of therapy so that blood levels are established. As the 150-mg once daily dose was nearly as effective as the 150-mg twice daily,[129,130] many practitioners use the lower dose routinely. The appropriate duration of therapy is not established. Clinical trials that formed the basis for approval treated for 7 weeks, although a 12-week course is commonly recommended. With prolonged therapy, there is an increase in secondary quits, and therapy for 1 year resulted in more quits than therapy for 7 weeks.

The drug is generally well tolerated. The most common adverse effects are dry mouth, insomnia, agitation, and headache. In combination with nicotine replacement, an increase in blood pressure may also occur. Bupropion reduces seizure threshold and a seizure risk of 0.1% has been reported. Because of its reduction in seizure threshold, bupropion is contraindicated among those predisposed to seizures, or with anorexia nervosa or bulimia.

In 2008, the FDA first noted that both bupropion and varenicline (see below) had a "possible association (with) suicidal events."[131] The benefits of smoking cessation were felt to outweigh any potential risks, and the medicines were not withdrawn from the market. However, both labels now contain a black box warning, suggesting that patients and their caregivers should be alerted to the possibility of neuropsychiatric symptoms, and patients should be monitored for changes in behavior, hostility, agitation, depressed mood, suicidal ideation, and suicide attempts. Most practitioners make a routine practice of reassessing patients 3 to 7 days after the quit day to both monitor for adverse effects and to provide additional support for the quit attempt. In this context, a second visit has been demonstrated to greatly improve success.[97,99,100]

Varenicline

Varenicline is a partial agonist at the (alpha4)(beta2) nicotinic receptor.[132] As such, it can partially activate the receptor thereby mitigating withdrawal symptoms. In addition, by occupying the receptor, it can

prevent nicotine from acting, and thus can reduce the rewarding and reinforcement effects associated with nicotine. This may be particularly important in preventing a lapse from becoming a full relapse once abstinence has been achieved. Both of these effects are supported by evidence from clinical trials.[133–136] Varenicline consistently improves success in quitting compared to placebo by an effect of two- to fourfold.[97,136] In addition, head-to-head trials have demonstrated superiority compared to bupropion.[133,134] Fewer data compare varenicline to NRT, and a recent meta-analysis failed to show a difference, though superiority of varenicline could not be excluded.[136]

Varenicline is given orally. Usually medicine is started at 0.5-mg once daily for 3 days followed by 0.5-mg twice daily for 4 days and then 1-mg twice daily for 3 months. Individuals who have achieved abstinence at 3 months may have less relapse if therapy is continued for an additional 3 months. A quit date is usually recommended for 1 week after starting medication, but success has been reported with a broader window of quit dates from 1 to 5 weeks that was comparable to a fixed quit rate.[137,138] This increased flexibility may be an advantage in starting a quit attempt when patients are seen for problems other than smoking cessation.

The most common adverse reactions are nausea, insomnia, visual disturbances, syncope, and skin reactions. The incidence of nausea is reduced with the dose titration described above.[139] The most serious concerns with varenicline have been with psychiatric and cardiovascular side effects. Varenicline has the same boxed warning as bupropion, indicating that patients and their caregivers should be alerted to the possibility of neuropsychiatric symptoms, and patients should be monitored for changes in behavior, hostility, agitation, depressed mood, suicidal ideation, and suicide attempts.[131] However, clinical trials have failed to confirm psychiatric adverse effects, although they cannot be fully excluded.[140] A meta-analysis that reported significant increase in cardiovascular events[141] was felt to be methodologically flawed as it excluded studies with no events.[142] A subsequent meta-analysis that included all available studies found no difference between varenicline and placebo, although a small difference may be present.[142] Currently the FDA recommends that patients taking varenicline be alert for development of new or worsening symptoms of cardiovascular disease.[143] Varenicline has also been associated with accidental injuries from falls and vehicular accidents.[144] This has resulted in an FDA advisory regarding operating heavy machinery while using varenicline.[145]

Off-Label Agents

Clonidine Clonidine is an α-adrenergic agonist active in the CNS that is used to treat hypertension. A number of clinical trials have evaluated its efficacy in smoking cessation and have generally shown a trend toward benefit, although individual trials have generally not been statistically significant, and its use is supported by a meta-analysis.[146] The Department of Health and Human Services (DHHS) guidelines suggest it can be used by experienced practitioners comfortable with the drug.[97,99,100] Major adverse effects of clonidine are drowsiness, fatigue, dry mouth, and postural hypotension.

Nortriptyline Nortriptyline is a tricyclic antidepressant that has been evaluated for efficacy in smoking cessation in several studies. Both individual studies and meta-analyses support its benefit as an aid to smoking cessation,[128,147] and it is also recommended as a possible second-line agent for practitioners comfortable with its use by the DHHS guidelines.[97,99,100] Major adverse effects of nortriptyline include drowsiness and dry mouth. As with other tricyclics, CNS and cardiovascular effects, including arrhythmias, may occur.

Investigational Drugs

A number of other agents approved for other uses have also been assessed for smoking cessation. None are currently recommended off-label by established guidelines, although several are under investigation. These include topiramate, an antiseizure medication that has been evaluated for several addictions, including combined alcohol and tobacco addiction, and selegiline, an agent used as an adjunct in the treatment of Parkinson disease that has also shown promise in smoking cessation.[148] Several other agents have been assessed. Selective serotonin reuptake inhibitor (SSRI) antidepressants have been demonstrated to be without benefit.[128] Opiate antagonists and anxiolytics have generally been without benefit,[97,99,100,149] but buspirone remains controversial as studies have been mixed.

Nicotine vaccines are also under investigation. Antibodies can be made to nicotine, if it is presented bound to an appropriate carrier.[150,151] The antibodies then bind nicotine reversibly. By slowing the delivery of nicotine to the brain, the vaccine would distort the pharmacokinetics of a cigarette. These investigational agents may have utility for long-term relapse prevention or for prevention of smoking initiation. However, phase 3 trials have not shown clinical benefits to date.[150]

■ PRACTICAL CONCERNS DURING THE QUIT ATTEMPT

Approach

As noted above, the first step is to have a patient willing to make a quit attempt. Current practice is to optimize the chance for success with each attempt. In general this will be achieved with nonpharmacologic support combined with pharmacotherapy. The more active the nonpharmacologic support the greater the likelihood of success. Patients will vary, however, in the type of support they will accept. It is also important to select an appropriate pharmacotherapy. Many practitioners initiate treatment with NRT, because of greater experience and reduced potential for adverse effects. The "patch-plus" regimen that combines a transdermal system with an ad lib formulation is often recommended.[97,99,100,115] Bupropion may be more appropriate for individuals with a history of depression.[152] Varenicline has the greatest efficacy, but is often reserved for secondary attempts to induce a remission from smoking.[115] The quit date should be linked to the pharmacotherapy: generally this is 1 week after initiating bupropion or varenicline and on the same day as initiating NRT. Varenicline may offer some flexibility, with a quit date 1 to 5 weeks after starting treatment.[138] A follow-up visit should be scheduled about 10 days after initiating bupropion or varenicline to check for side effects. A follow-up in the immediate postquitting period is associated with improved success. This may be particularly important for cessation attempts that begin in hospital.[153]

Withdrawal Symptoms

The first 3 days of abstinence are usually the most difficult. Tobacco withdrawal symptoms (Table 41-2) generally peak during the first 72 hours then gradually subside over a 3- to 4-week period. These symptoms can include restlessness, anxiety, difficulty concentrating, irritability, frustration, depression, and an almost unrelenting craving for cigarettes. Common suggestions to help smokers cope with these

TABLE 41-2 Nicotine Withdrawal Symptoms (DSM-IV)

Dysphoric or depressed mood
Insomnia
Irritability, frustration, or anger
Anxiety
Difficulty concentrating
Restlessness
Decreased heart rate
Increased appetite or weight gain

early withdrawal symptoms in addition to NRT can include: (1) Be active. Increased activity may curtail some of the drive to smoke. (2) Use deep breathing exercises. The simplest breathing exercise involves nothing more than extended breath holding followed by slow exhalation through pursed lips. (3) Avoid high-risk situations for smoking during the first 3 weeks of quitting. (4) Use plenty of cinnamon gum or chewable candies. (5) Combat strong urges to smoke: The urge to smoke will go away whether one smokes or not.

Cravings

Of all the symptoms associated with nicotine withdrawal, cravings to smoke are the most persistent. Unlike the other symptoms, cravings can also recur long after abstinence is achieved. During the second and third weeks of abstinence, the craving waves usually occur less frequently, but can sometimes catch smokers off guard because of their unexpected intensity. The decrease in frequency is greater than the decrease in intensity, and cravings can be precipitated months and years after abstinence if precipitated by specific cues. In this context, cravings recapitulate, in some ways, the grief response. Relapse is commonly associated with concurrent alcohol consumption. It is likely that alcohol, and the associated situations in which it is consumed, serves both as a cue leading to craving and decreases the inhibitions that may prevent smoking. Ex-smokers should be aware of these moments of hazard.

Depression

At some time during the first 3 months of abstinence, some smokers may experience depression. For many this depression is mild and transient. For a small minority of smokers, quitting smoking may produce a clinical depression that may require antidepressant therapy, counseling, or return to smoking. Depressive symptoms are associated with relapse.[154]

Weight Gain

One of the most disheartening components of quitting smoking is weight gain.[97,99,100] Rapid weight gain is common during the first 6 to 8 weeks of cigarette abstinence. This is followed by a more gradual increase in weight to roughly 4-kg at 6 months. Average weight gain at 10 years following cessation is 4.4 and 5.0-kg for males and females, respectively. The health risks associated with postcessation weight gain are unknown but are likely surpassed by the health benefits of stopping smoking.

■ RISKS OF SMOKING CESSATION

Smoking cessation may be associated with some hazards in selected cases. Nicotine and other components of cigarette smoke may have a significant antidepressant effect, and many endogenously depressed individuals may have empirically found smoking helped alleviate their symptoms. Depression is a well-recognized manifestation of the nicotine withdrawal syndrome. At times, this depression can be of major clinical importance. Exacerbations of ulcerative colitis are more common in former smokers and may develop at times long after smoking cessation.[155] These potential adverse effects should not minimize the importance of smoking cessation, but the clinician should be prepared to address them when necessary. Anecdotal reports have suggested that asthma may worsen following cessation. However, smoking generally makes asthmatics worse[156] and induces resistance to the therapeutic effects of inhaled glucocorticoids. Thus, asthma symptoms generally improve with smoking cessation.[157] Some smokers report an increase in cough in the weeks following cessation. However, among individuals with chronic bronchitis, symptoms of cough and sputum production decrease dramatically in the months following cessation.[158,159]

■ SPECIAL POPULATIONS

Smoking cessation approaches for special populations are generally the same as for the general population.[97,99,100] Smoking cessation treatment can be started in hospital at the time of acute illness.[153] Success will be dependent on adequate follow-up and support. Interestingly, withdrawal symptoms may be particularly mild in hospital, perhaps because there are few options to smoke. Concurrent treatment of individuals hospitalized with psychiatric illness for smoking cessation can be successful and does not compromise treatment of the comorbid psychiatric problem.[97,99,100] Treatment of pregnant smokers has been extensively reviewed.[97,99,100]

Smoking is a major risk factor for COPD. All three approved forms of pharmacotherapy: NRT,[160] bupropion,[161] and varenicline[162] have demonstrated efficacy in the COPD population.

HARM REDUCTION

A more controversial approach for smokers who are unwilling or unable to quit at all, is that the health consequences may be partially addressed by reducing the exposure to smoke-derived toxins. This approach, termed "harm reduction," has been the subject of several reviews, including an Institute of Medicine report.[163,164] Four general categories of harm reduction are theoretically possible: (1) administration of agents to counteract the effects of cigarette smoking; (2) smoking reduction; (3) development of less toxic tobacco products; and (4) alternate nicotine delivery systems. It is important to recognize that clear health benefits have not been established for any of these approaches, however.

Since cigarette smoking is thought to cause its effects through pathogenetic mechanisms that are at least partially defined, it is appealing to use such mechanisms as targets for therapeutic intervention. In this regard, antioxidants to ameliorate the oxidant-induced injury caused by cigarette smoke, and protease inhibitors to bolster the antiprotease defenses are both potential therapies. While conceptually appealing, no data exist to suggest that any such approach is of benefit in continuing smokers.

Pharmacologic support may facilitate reduction in smoking. The observation that most smokers maintain a relatively constant nicotine intake creates the possibility that nicotine replacement can help sustain smoking reduction. Smoking reduction has also been achieved with several formulations of nicotine replacement, and there is some evidence for physiologic benefit. Short-term smoking reduction, facilitated with the use of nicotine polacrilex gum, was associated with improvements in lower respiratory tract inflammation assessed by bronchoscopy and bronchoalveolar lavage in a group of heavy smokers.[165,166] In patients with cardiac disease who reduced smoking, there were measurable improvements in cardiac function that were associated with improved oxygen delivery to the heart due to reduced carbon monoxide.[125]

Reducing the delivery of cigarette smoke toxins while still providing the smoker with a satisfactory cigarette has been pursued by some tobacco companies. This was a major motivation in the development of filtered cigarettes and of low-tar, low-nicotine cigarettes. Unfortunately these approaches do not reduce, and may actually increase, exposure to smoke-derived toxins. As most smokers maintain constant nicotine intake, many smokers compensate for altered smoke composition by simply smoking more or by changing the way in which they smoke each cigarette.[167,168] By causing an altered smoking strategy, filtered and low-yield cigarettes may actually deliver more toxins.

Many of the cigarette-derived toxins are generated as a result of pyrolysis.[25] As a result, tobacco products that do not burn have the promise to yield fewer toxins. Several cigarette-like devices have been developed with similar goals. Some burn small amounts of processed tobacco together with a carbon heat source to have a taste that more closely resembles a cigarette.[169] Others electrically heat the tobacco.

Whether the electronic cigarette will be effective as an alternative to smoking at present remains to be determined.[164] Because of its widespread use, the electronic cigarette has become particularly controversial. This has led to reviews and position statements relating to these products.[170,171] Potential harm-reduction products appear to deliver less toxins in standardized smoking regimes. However, limited data are available on physiologic effects. In one study, a reduction in lower respiratory tract inflammation and airway metaplasia was observed among heavy smokers who switched to a harm-reduction product.[172] Whether such products are associated with health benefits, however, remains to be determined.

Nonburned tobacco products may also have advantages. Moist snuff, which has low nitrosamine content due to its processing, has been widely used for several decades in Sweden. It has been associated with a measurable decrease in a number of tobacco-related diseases among Swedish men compared to cigarettes, but not compared to abstinence.[173–176]

Harm-reduction strategies may have unforeseen problems. Reduced-risk products, or smoking reduction strategies may encourage smokers to continue and thus discourage quit attempts. Available data, however, suggest the opposite. Smokers who switch to harm-reduction products or who reduce with pharmacologic support appear to have an increased rate of subsequent quits. It may be that the sense of mastery that comes with the reduction effort helps make smokers "able" to quit. There are other potential hazards. Reduced-risk products, for example, might be particularly appealing for individuals beginning smoking both because they may be easier to smoke and because they are not perceived as having significant risks. Finally, if use of reduced-risk products erodes the social climate that discourages smoking, such products could increase use of conventional cigarettes.

CONCLUSION

Cigarette smoking is a complex social and medical issue. The physician has a particularly important role in curbing smoking. Not only must the physician participate in efforts to reduce smoking as a citizen, but as a protector of public health and a possessor of specific expertise in healthcare matters, the physician must take an active role in health promotion. Such a role includes discouraging smoking initiation among younger patients, encouraging and assisting smoking patients to quit, and participating in social efforts designed to reduce smoking at various levels.

For individuals who are smokers, the clinician needs to approach smoking as a chronic relapsing disorder for which a range of effective treatments are available. These include nonpharmacologic and pharmacologic therapies and optimal results from a combined approach.

CHAPTER 42

Course and Treatment of Chronic Obstructive Pulmonary Disease

M. Bradley Drummond
Robert A. Wise

In past decades, the treatment of chronic obstructive pulmonary disease (COPD) has been approached by many physicians and patients alike with a nihilistic attitude, assuming that the disease was progressive, incurable, and untreatable. More recently, as our understanding of the clinical epidemiology and value of therapy of COPD has improved, this attitude has changed. Physicians have come to approach COPD in the same way as other chronic diseases, such as diabetes, rheumatoid arthritis, and coronary artery disease. With modern comprehensive treatment, the diagnosis of COPD is compatible with prolonged survival, good quality of life, and independent functional status for many who have this illness. The purpose of this chapter is to summarize the current understanding of the course of COPD and best approaches to treatment.

OVERVIEW OF COPD

COPD is a disorder that is characterized by slow emptying of the lung during a forced expiration. In practice, this is measured as the forced expiratory volume in 1 second/forced vital capacity (FEV_1/FVC) ratio, and the arbitrary definition of airflow obstruction is generally taken to be an FEV_1/FVC ratio lower than 0.70.[1] Because the rate of emptying of the lung falls with advancing age, many elderly individuals demonstrate airflow obstruction even in the absence of a clinical diagnosis of COPD. For this reason, an alternative criterion to define airflow obstruction incorporates lower limit of normal thresholds instead of the fixed ratio criteria.[2] Several disorders cause chronic airflow obstruction—long-standing asthma, cystic fibrosis, bronchiectasis, bronchiolitis obliterans, lymphangioleiomyomatosis, panbronchiolitis, silicosis, Sjögren syndrome, and diffuse interstitial processes such as eosinophilic granuloma and sarcoidosis. The diagnosis of COPD is usually limited to individuals who have chronic airflow obstruction associated with tobacco smoke or some other noxious inhalant, and it is usually not difficult to distinguish it from other causes of chronic airflow obstruction. The most commonly associated clinical disorders associated with COPD are emphysema and chronic bronchitis. *Emphysema* is defined anatomically by airspace enlargement due to disappearance of alveolar septae (see Chapter 39). This leads to the characteristic loss of elastic recoil, which, in turn, causes slowing of airflow from the lungs, hyperinflation, and air trapping (see Chapter 40). *Chronic bronchitis* is characterized by chronic cough and sputum production, which is present in about one out of three people with early COPD. Chronic cough and sputum production in cigarette smokers is often, but not always, associated with chronic airflow obstruction. When chronic mucus hypersecretion is associated with airflow obstruction, it is often called *chronic obstructive bronchitis*. The anatomic correlates of chronic bronchitis are mucus gland hyperplasia and goblet cell metaplasia in large- and medium-sized airways.[3] Patients with COPD also have *small- and medium-sized airway involvement* with inflammation, narrowing, tortuosity, mucus plugging, and fibrosis that contributes to the airflow limitation. As the disease evolves, there is obliteration of small airways. Some patients with a long-standing history of asthma develop airflow obstruction that is not completely reversible, episodes of cough and wheeze, and chronic sputum production. These individuals are often classified as having *chronic asthmatic bronchitis* and tend to have a somewhat better prognosis for survival than those with typical tobacco-related COPD. Physicians have a tendency to classify women as having asthma and men as having COPD despite similar medical histories.

NATURAL HISTORY OF COPD

COPD results from an increase in the rate of decline in lung function over time. Normal nonsmoking adults lose FEV_1 at a rate of 30 mL/yr, thought to be the consequence of the aging-related loss of elastic recoil of the lung. Persons who develop COPD may start in early adulthood with lower levels of lung function and also have increased rates of decline.[4,5] Studies of patients with COPD show an average annual decline in FEV_1 of 45 to 69 mL/yr (Fig. 42-1A). However, there may be considerable heterogeneity between patients and over time.[6,7] This leads to the insidious loss of ventilatory reserve capacity that often is asymptomatic and unrecognized by patients and physicians alike. Chronic bronchitis may be dismissed as an innocent "smoker's cough" because patients fail to understand that it is abnormal to produce daily sputum. As ventilatory reserve decreases, people with mild COPD tend to limit strenuous activities, so breathlessness with activities of daily living is not ordinarily an early symptom of the disease. When the ventilatory reserve decreases to the extent that mild exertion such as climbing stairs, bed making, or carrying groceries is limited, patients tend to seek medical advice. In some cases, the first clinical presentation of disease is an acute episode of bronchospasm, dyspnea, or even respiratory failure in association with a respiratory infection or exposure to respiratory irritants. Thus, the onset of COPD may appear precipitous even though it is the cumulative result of decades of progression.

People who discontinue smoking with mild to moderate degrees of airflow obstruction cease the rapid decline in FEV_1, and have better survival (Fig. 42-1B).[8] The improvement in survival depends largely upon the stage of disease. Persons who quit smoking with earlier disease have better outcomes compared with those who continue to smoke or those who quit smoking later in the disease. Once the disease is advanced, the inflammatory response persists and the proportional loss of lung function tends to progress. Because there are many years of asymptomatic decline in lung function, it is possible to diagnose COPD with forced expiratory spirometry before the disease is apparent and implement aggressive smoking intervention programs. There is a consensus that smokers with respiratory symptoms should be tested for COPD with spirometry. However, there is debate whether it is of value to screen for COPD among all cigarette smokers.[9] Opponents of using spirometry for case-finding argue that the finding of a normal test would not alter physician behavior because all smokers should be encouraged to quit. It has also been argued that a normal spirometry test might provide a false sense of complacency for active smokers. Those who support the use of spirometry for COPD case-finding argue that early detection and aggressive smoking intervention have been proved to halt disease progression and improve survival, and the finding of abnormal spirometry may encourage patients and healthcare professionals to be more aggressive with smoking cessation. Moreover, some evidence points to the benefits of drug therapy in terms of lung function decline and survival in patients with mild to moderate airflow obstruction.[10–12] While these data arise from post hoc analysis, the findings are promising.

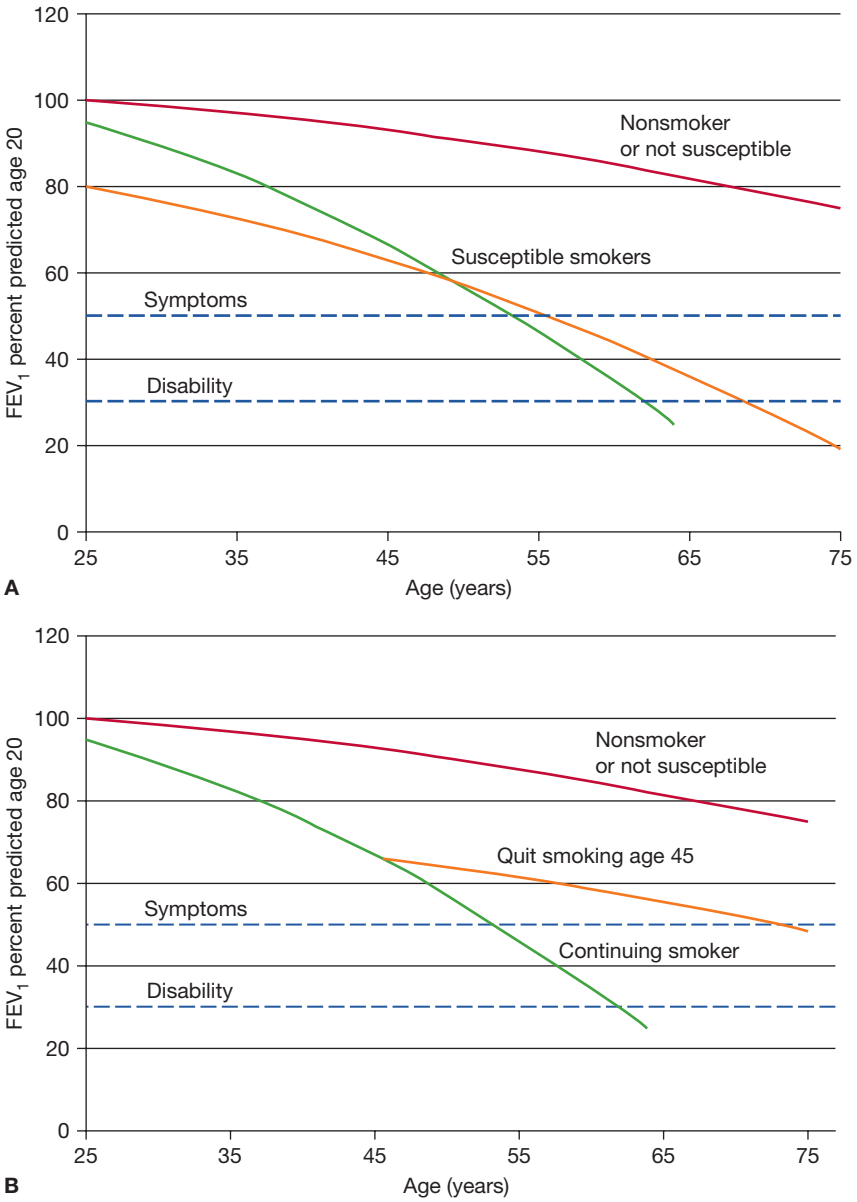

Figure 42-1 **A.** The natural history of COPD is presented for three hypothetical individuals. Pulmonary function is plotted as the percent of predicted lung function for a young adult who has attained maximal lung growth. Those who do not smoke, or are not susceptible to cigarette smoke typically lose about 25% of their young adult lung function throughout life. Individuals are susceptible to the adverse effects of smoking because of increased decline of lung function, or low lung function in young adult life. Although the abnormality of lung function is detectable for many years, symptoms do not develop until there is loss of approximately 50% of lung function *(upper dashed line)*, which occurs in middle age or later. If the disease progresses, it may lead to substantial disability within a decade of the onset of symptoms *(lower dashed line)*. **B.** The natural history of COPD is displayed for a hypothetical continuing smoker, and an individual who quit smoking at age 45. The axes are identical to those in (**A**). If an individual ceases smoking in the asymptomatic phase of COPD, the rate of decline of lung function reverts toward normal. In this example, the detection of abnormal lung function and cessation of smoking has a substantial effect of delaying the onset of respiratory symptoms. This plot is modified from the work of Fletcher and Peto and is commonly referred to as Fletcher curves. *(Reproduced with permission from Fletcher C, Peto R. The natural history of chronic airflow obstruction. Br Med J. 1977;1(6077):1645–1648.)*

With the progression of COPD comes progressive exercise limitation.[13] This is due to the increased work of breathing as ventilation increases with exercise. With increased respiratory rate, patients develop dynamic hyperinflation—a condition in which the end-expiratory lung volume does not return to the static end-expiratory volume of functional residual capacity (FRC). The hyperinflation that occurs causes increased work of breathing and exacerbates dyspnea. An indicator of dynamic hyperinflation is the inspiratory capacity (IC), which progressively falls with increasing ventilation. Measures that reduce dynamic hyperinflation, increasing IC, can improve exercise capacity. These include alterations in breathing pattern, oxygen supplementation, and use of inhaled bronchodilators.

As COPD progresses, ventilation–perfusion inhomogeneity causes an increase in the alveolar–arterial oxygen difference. Eventually, alveolar hypoxemia leads to pulmonary hypertension, which becomes manifested as cor pulmonale. The alveolar hypoxemia may be compounded by alveolar hypoventilation—manifested by arterial hypercapnia. Physical findings indicative of cor pulmonale are venous engorgement, edema, and physical findings of pulmonary hypertension and right ventricular failure including accentuated pulmonic second heart sound, right ventricular heave, tricuspid regurgitation murmur, hepatojugular reflux, and ascites. Chest imaging shows central enlargement of the pulmonary arteries. Once cor pulmonale is clinically apparent, survival is markedly reduced in proportion to the elevation of pulmonary artery pressure. Chronic respiratory failure is defined by chronic hypoxemia (sea-level resting Pa_{O_2} ≤60 mm Hg or 8 kPa) with or without attendant hypercapnia (Pa_{CO_2} >45 mm Hg).

Patients with advanced COPD may restrict their activities to a bed-and-chair lifestyle because of severe exercise incapacitation. This limitation can lead to social isolation, depression, and skeletal muscle deconditioning, which, in turn, further restrict activity and impair quality of life. Protein and calorie malnutrition occurs as the consequence of impaired nutritional intake caused by dyspnea.[14] Malnutrition is augmented by increased metabolic demands caused by increased basal oxygen consumption, inefficient skeletal muscle oxygen utilization, and cachexia-producing cytokines such as tumor necrosis factor-α (TNF-α).[15]

DIAGNOSIS OF COPD

Physical examination and chest imaging are insensitive methods for diagnosis of COPD. Physical findings of hyperinflated lungs such as low-lying diaphragm, decreased breath sounds, and hyperresonant chest percussion are highly specific for COPD, but usually only in

TABLE 42-1 Conditions Suggesting α1-Antitrypsin Deficiency

Early-onset emphysema (age under 45 yr)

Family history of early-onset emphysema or non–smoking-related emphysema
Bronchiectasis without other etiology

advanced disease.[16] One study has suggested that a distance between the thyroid cartilage and the sternal notch less than 4 cm in a smoker older than age 45 is highly indicative of the presence of COPD.[17] Clubbing of the fingers is rare in COPD and, if present, suggests another diagnosis such as bronchiectasis, asbestosis, or lung cancer. High-resolution computed tomography (HRCT) of the lung is useful in establishing the presence of emphysema. Quantitative analysis of HRCT is a promising technique for early detection of emphysema. α_1-Antitrypsin deficiency is an uncommon, but not rare, condition associated with premature emphysema. Testing for α_1-antitrypsin deficiency is indicated in those most likely to have the disorder (see Chapter 40 and Table 42-1). Some experts advise that all patients with COPD should be tested for α_1-antitrypsin deficiency because treatments are available for those with the most severe form of deficiency.[18] HIV/AIDS is also associated with premature emphysema and accelerated lung function decline,[19,20] and screening for HIV should be performed for persons with emphysema and HIV risk factors such as intravenous drug use or high-risk sexual activity.

The diagnosis of COPD, classification of its severity, and progression of the disease can be monitored with spirometry, a simple, noninvasive, and inexpensive test. The FEV_1/FVC ratio, reflecting the rate of emptying of the lung, is used to define the presence of an obstructive ventilatory defect, commonly defined as a ratio less than 0.70 or below the lower limit of normal. Once airflow obstruction is established, the severity of the airflow limitation is classified by the reduction of FEV_1 compared with a healthy reference population. Table 42-2 shows the widely used GOLD classification of severity based on the FEV_1. Lung volume measurements, by plethysmography, helium dilution, nitrogen washout, or single-breath methods typically show hyperinflation (elevated TLC) and air trapping (elevated residual volume [RV]), and thus are useful to exclude restrictive lung diseases. The carbon monoxide diffusing capacity (D_{CO}) is an indicator of emphysema and is roughly inversely correlated with the anatomic extent of emphysema in patients who have an FEV_1 greater than 1.0 L.

TABLE 42-2 Classification of Severity of Airflow Limitation in COPD

GOLD Classification	Characteristics
I Mild COPD[a]	FEV_1 ≥80% predicted
II Moderate COPD[a]	FEV_1 50–79% predicted
III Severe COPD[a]	FEV_1 30–49% predicted
IV Very severe COPD[a]	FEV_1 <30% predicted or <50% predicted with room air Pa_{O_2} <60 mm Hg (8.0 kPa)

[a]*Postbronchodilator FEV_1/FVC less than or equal to 0.70.*

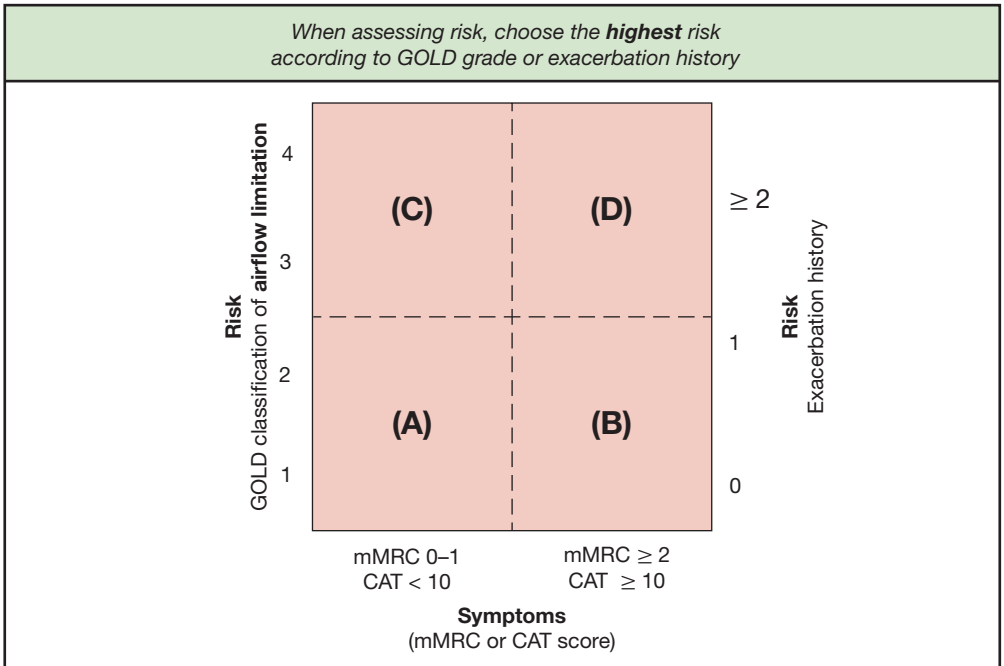
CLASSIFICATION OF COPD

Classification of COPD involves determination of symptoms and assessment of risk. Symptoms are determined using standardized questionnaires (**see** Table 42-3 and **www.catsonline.org**), while risk assessment is defined by severity of ventilatory limitation and exacerbation history. Based on symptoms and risk of exacerbations, individuals are grouped into one of four different patient categories (see Fig. 42-2). The categories are informative for determining prognosis and treatment of COPD. Additional instruments are available for quantifying the impact of COPD.[21]

PROGNOSIS OF COPD

The prognosis in COPD may vary widely. Physicians are poor prognosticators of survival in COPD.[22] In part, this is because the disease is one of widely varying rates of progression, and, in part because death is often due to susceptibility to intercurrent illness and other smoking-related illness such as lung cancer rather than progressive respiratory failure. Recent studies have demonstrated heterogeneity in lung function decline, with some patients with COPD having little or no decline in FEV_1 over time.[6,7]

Several factors have been identified that predict poor survival in COPD. These include low FEV_1, active smoking status, hypoxemia, poor nutrition, the presence of cor pulmonale, resting tachycardia, low exercise capacity, severe dyspnea, poor health–related quality of life, anemia, frequent exacerbations, comorbid illnesses, and low D_{CO}.[23] Patients with an FEV_1 less than 35% predicted have about 10% mortality per year.[24] If a patient reports that they are unable to walk 100 m without stopping because of breathlessness, the 5-year survival is only 30%.[25] A multidimensional prognostic index that takes into account several indicators of COPD prognosis is the BODE index (*b*ody mass index [BMI], *o*bstructive ventilatory defect severity, *d*yspnea severity, and *e*xercise capacity).[26] See Table 42-4 for calculation of the BODE prognostic score. The components are derived from measures of the BMI (weight in kg/height m^2), FEV_1 percent predicted, and the modified Medical Research Council dyspnea score (Table 42-3). A BODE score greater than 7 is associated with a 30% 2-year mortality; whereas a score of 5 to 6 is associated with 15% 2-year mortality. If the BODE score is less than 5, the 2-year mortality is less than 10%. In settings where the 6-minute



Patient category	Characteristics	Spirometric classification	Exacerbations per year	mMRC	CAT
A	Low risk, Less symptoms	GOLD 1–2	≤1	0–1	<10
B	Low risk, More symptoms	GOLD 1–2	≤1	≥2	≥10
C	High risk, Less symptoms	GOLD 3–4	≥2	0–1	<10
D	High risk, More symptoms	GOLD 3–4	≥2	≥2	≥10

Figure 42-2 Combined COPD assessment. An understanding of the impact of COPD on an individual patient combines assessment of symptoms and future risk of exacerbation. To use this figure, first assess symptoms with the modified medical research council (mMRC) or COPD assessment test (CAT) scale and determine if the patient has less symptoms (mMRC <2 or CAT <10) or more symptoms (mMRC ≥2 or CAT ≥10). Next, assess the risk of future exacerbation by determining prior exacerbation history and severity of airflow limitation with high risk of future exacerbation in individuals with GOLD airflow classification 3 to 4 or ≥2 exacerbations in the prior year (future risk should be determined by the method indicating higher risk). With this figure, individuals are stratified into one of four categories (A, B, C, D). which helps describe the burden of disease and informs potential treatments. *(Reproduced with permission from Global Strategy for the Diagnosis, Management, Prevention of COPD, © Global Initiative for Chronic Obstructive Lung Disease (GOLD), all rights reserved. Available from http://www.goldcopd.org.)*

walk test is not available, the ADO index (*a*ge, *d*yspnea and *o*bstruction) also provides useful prognostic information (Table 42-5).[27] The ADO index ranges from 0 to 10 points, with each point increase in the index associated with a 42% increase in odds of death at 3 years for patients with longstanding and severe COPD.

TREATMENT OF STABLE COPD

The goals of treatment of COPD are to prevent progression and complications of the disease, relieve symptoms, improve exercise capacity, improve quality of life, treat exacerbations, and improve survival.[28,29] Efforts are being made to standardize the most optimal treatment guidelines for COPD.[30]

■ EDUCATION

The diagnosis of COPD can be a life-changing event for people, so understanding the nature and prognosis of the disease is an important and underemphasized aspect of care. There is a wide divergence of understanding of the implications of having COPD, and many patients do not understand that COPD comprises both the diagnoses of emphysema and chronic bronchitis. Table 42-6 lists

TABLE 42-4 Calculation of the BODE Index[a]

Variable	Points on the BODE Index 0	1	2	3
FEV_1 (% predicted)	≥65	50–64	36–49	≤35

TABLE 42-6 Patient Education Topics for Office Management of COPD

Risk factors for COPD
Smoking cessation advice and instruction
Reduction of noxious environmental exposures
Immunization for influenza and pneumococcus
Respiratory hygiene and avoidance of infections
Nature and prognosis of COPD
Indications, dose, benefits, and adverse effects of medications
Proper inhaler and nebulizer use
Strategies to improve adherence with prescribed treatment
Pacing, arm support, and other strategies to minimize dyspnea
Importance of regular exercise and social interaction
Options for pulmonary rehabilitation programs
Recognition and early treatment of exacerbations
Indications for and proper use of supplemental oxygen
Options for surgical management if indicated
Advanced directives for end-of-life care

topics that should be discussed with COPD patients. It is neither possible nor effective to cover all of these topics in a single session, so several sessions with repetition and expansion of the educational messages are necessary. Supplemental written materials or referral to a health educator is also necessary for many patients. Local and national volunteer health organizations provide useful educational materials and group educational sessions (e.g., www.copdfoundation.org, www.lung.org). Special counseling is needed for patients with α_1-antitrypsin deficiency and their family members to determine whether genetic testing is necessary or desired. In patients with advanced disease, discussions about end-of-life planning and advance directives regarding life support are often welcomed by patients and initiate discussions between the patient and family. Patients should be encouraged to discuss information that they obtain from newspapers or the Internet, as some may be instructive, but others are incorrect. Physicians should be prepared to deal with patients' sense of guilt, as many view COPD as a self-induced disease. Caregivers need to address the reality that COPD is often stigmatized by patients, their families, and other healthcare providers. The physician should let the patient understand that nicotine dependence is a strong physical addiction and difficulty quitting smoking is not a measure of moral weakness or lack of will. The general message provided should be realistic, but positive. Current treatments for COPD can usually improve quality of life, restore activity levels, maintain social interactions, and reduce the frequency of complications.

PREVENTION OF COPD PROGRESSION AND COMPLICATIONS

Presently, there are no proven treatments that prevent the progression of COPD in patients who continue to smoke cigarettes. *Smoking cessation*, however, does prevent the excessive decline in lung function and should be a primary goal for physicians caring for COPD patients. Patients with mild or moderate COPD may not know that they have underlying lung disease that can be halted by smoking cessation,[4] or may adopt a fatalistic attitude that it is too late for help. Even severely impaired patients who are dyspneic at rest or use continuous oxygen may continue to smoke cigarettes or relapse after quitting. A smoking history should be obtained at each patient encounter because many patients fail to volunteer the extent of their smoking or report a smoking relapse following cessation. In patients who do smoke, achieving cessation should be a primary and persistent goal of treatment.[31] Approaches to smoking cessation are given in detail in Chapter 41. For patients who do smoke, a direct, unambiguous, and personalized smoking cessation message should be given by the physician. The message should emphasize the harm of continued smoking, the benefits of cessation in terms of activities that are meaningful for the individual, and the understanding that smoking cessation is a realistic and achievable goal. Techniques of motivational interviewing are readily learned and are effective in changing health behaviors.[32] Assistance with pharmacologic adjuncts such as nicotine replacement therapy, varenicline, or bupropion and referral to smoking cessation groups should be offered. Follow-up of smoking status and repeated smoking cessation messages should be performed at each encounter.

Exposure to respiratory irritants should be avoided in the workplace as well as the home. Although heavy occupational dust exposure rarely is the primary cause of COPD, exposure to dusty occupational jobs in smokers can increase the lung function deterioration from smoking and increase symptoms of cough and sputum.[33] In developing countries, heavy exposure to particulates from burning of biomass fuels is associated with COPD, even in the absence of cigarette smoking.[34] Efforts to improve indoor air quality may be effective in reducing symptoms and disease progression. Respiratory protective equipment should be worn by COPD patients exposed to heavy dust concentrations. There is no level of FEV_1 that absolutely prohibits the use of respiratory protective equipment, but patients with COPD often experience untoward breathlessness with these masks because of the increased dead space and increased inspiratory resistance. Thus, many COPD patients need to change their work environment if they cannot tolerate protective devices. If COPD is complicated by allergy or overlaps with allergic asthma, environmental control measures should be instituted to the extent that these strategies are helpful. Smoking of marijuana and cocaine may cause airway irritation, and although there is no convincing evidence that they contribute to progression of COPD, their use ought to be discouraged.[35]

Pneumococcal vaccination is recommended, although the evidence of its particular efficacy in COPD is lacking.[36] Annual *influenza immunization* can prevent or attenuate this potentially fatal infection. The killed vaccine is preferred, as cold-attenuated live influenza vaccines have not been approved for use in older patients and those with underlying lung disease. High-potency influenza immunization is recommended for older patients who may have an impaired immune response to the vaccine. During influenza epidemics, the use of neuraminidase inhibitors such as zanamivir and oseltamivir can minimize severity of infection if taken within 48 hours of onset of illness and are useful against both influenza A and B, and may limit the spread of infection. Peramivir, an injectable form of neuraminidase inhibitor, is now available for treatment of individuals with respiratory failure.

Replacement therapy with α_1-antitrypsin should be considered for those individuals with severe deficiency. Observational studies suggest that individuals with moderate degrees of impairment (FEV_1 35%–65% predicted) appear to benefit most in terms of preservation of lung function and improved survival.[37] The human plasma–derived preparation of α_1-antitrypsin is administered intravenously in a dose of 60 mg/kg weekly. Although the replacement treatment is derived from pooled human plasma, the risk of viral transmission is low and immunization for hepatitis B is not mandatory before initiating therapy.

DRUG THERAPY

Over the past several decades, the evidence base for use of drug therapy in COPD has expanded, and provides an objective and generally optimistic picture that such treatment is effective. Bronchodilators and anti-inflammatory agents are used to reverse bronchoconstriction, improve lung function, improve quality of life, exercise capacity, and prevent exacerbations. Recent evidence however suggests that a

combination of inhaled steroids and long-acting bronchodilators may improve survival as well as reduce exacerbations.[38–40] Proposed future drug treatments that might alter progression of COPD are under active investigation, including inhibitors of cytokines, proteases, and oxidative stress. There is a poor correlation between the effect of bronchodilating drugs on lung function and symptom relief, so monitoring of treatment requires attention to patient-centered outcomes as well as lung function. Small amounts of bronchodilation can cause considerable improvement in functional capacity through decrease in dynamic exercise hyperinflation; and reduction in days of exacerbation can make considerable improvement in patients' quality of life.

The usual approach to drug treatment for COPD is to sequentially add agents using the minimum number of agents and the most convenient dosing schedule, starting with the agents having the greatest benefit, best tolerance, and lowest cost. One approach to step-up therapy is provided in Figure 42-3. Inhaled bronchodilators are the foundation of treatment for COPD. They are given on a regular basis to maintain bronchodilation and on an as needed basis for relief of symptoms.[41,42] Most breathless patients benefit from regular use of a maintenance bronchodilator. Both β-agonist and anticholinergic classes are available in short-duration (4–6 hours) and long-duration (12–24 hours) forms (Table 42-7). The choice of bronchodilator class and duration of effect depends upon the preference of the patient and the cost of the preparation. Combination of different classes of bronchodilators is often more effective than increasing the dose of a single agent, and combination inhalers can simplify treatment regimens. Patients with advanced COPD often use a combination of bronchodilators, including long-acting maintenance anticholinergics and β-agonists as well as symptomatic use of shorter-acting bronchodilators. Individuals with exacerbations may benefit from a combination inhaler of corticosteroids and long-acting bronchodilator. Long-acting oral preparations of theophylline are useful adjuncts in cases in which inhaled medication is too expensive or not acceptable for the patient. Chronic use of systemic corticosteroids should be reserved for individuals with very frequent or life-threatening exacerbations in those cases where discontinuation of steroids

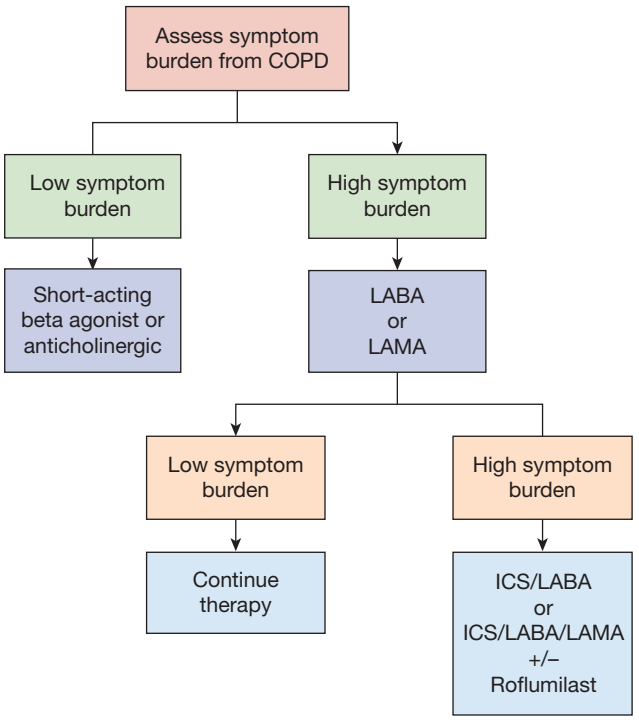

Figure 42-3 Decision tree for pharmacologic treatment of COPD. Treatments are determined by symptom burden, which is determined by assessment of dyspnea and COPD exacerbation risk. If patients are stable for 6 to 12 months, consideration should be given to trial reductions of treatment. In addition to pharmacologic interventions described here, treatment should also include preventative measures, smoking cessation counseling, pulmonary rehabilitation, and advanced therapies. LABA, long-acting beta agonist; LAMA, long-acting muscarinic antagonist; ICS, inhaled corticosteroid.

TABLE 42-7 Inhaled Bronchodilators

Drug Name	Dosage/Frequency	Formulation
β-Sympathomimetics		
Olodaterol		Soft Mist inhaler, 5 μg
Albuterol	2 inhalations q4–6h	Metered-dose inhaler, 90 μg/puff
	3 mL nebulized q4–6h	Nebulized solution 1.25–2.5 mg/3 mL
Levalbuterol	2 inhalations q4–6h	Metered-dose inhaler, 45 μg/puff
	3 mL nebulized TID	Nebulized solution 0.63–1.25 mg/3 mL
Salmeterol	1 inhalation BID	Dry powder inhaler, 50 μg/dose
Formoterol	1 capsule inhaled BID	Dry powder inhaler, 12 μg/capsule
	2 mL nebulized BID	Nebulized solution 20 μg/2 mL
Arformoterol	2 mL nebulized BID	Nebulized solution 15 μg/2 mL
Indacaterol	1 capsule daily	Dry powder inhaler, 75 μg/capsule
Anticholinergic Bronchodilators		
Ipratropium	2 puffs q4–6h	Metered-dose inhaler, 17 μg/puff
	2.5 mL nebulized q6–8h	Nebulized solution 0.5 mg/2.5 mL
Tiotropium	1 inhalation daily	Dry powder inhaler 18 μg/dose
Aclidinium	1 inhalation BID	Dry powder inhaler 400 μg/dose
Combination Therapies		
Ipratropium/albuterol	1 puff q6h	Soft Mist inhaler, 20 μg ipratropium and 100 μg albuterol
Umeclidinium/vilanterol		Dry powder inhaler, 62.5 μg/25 μg

cannot be tolerated. Response to treatment is judged by symptomatic improvement, functional status, frequency of exacerbations, and spirometry. If patients are doing well for 6 to 12 months on a stable treatment regimen, then it is reasonable to see if a trial withdrawal of one of the drug components can be tolerated.

Inhaled corticosteroids do not effectively alter the progression of COPD in those who continue to smoke. Inhaled corticosteroids are most useful in patients who have an overlap between asthma and COPD and those who have frequent exacerbations. Inhaled corticosteroids can reduce the frequency of exacerbations and slow the decline in quality of life.[39] In patients with chronic bronchitis and obstructive lung disease, inhaled corticosteroids improve pulmonary function, and the results are additive to those achieved with long-acting bronchodilators.[39,43] The efficacy of inhaled corticosteroids cannot be predicted based on the response to oral corticosteroids, so it is not necessary to conduct an oral steroid trial before initiating this treatment. Combined corticosteroid and long-acting bronchodilator inhalers are available in the United States and throughout the rest of the world and can simplify the treatment regimen. Inhaled corticosteroids, although poorly absorbed, probably do contribute to steroid side effects such as cataracts, capillary fragility, and osteoporosis in susceptible individuals. High doses of inhaled corticosteroids are associated with increased risk of pneumonia.[44] In most cases, the risk is low compared to the benefit of treatment, but it is prudent to prescribe the lowest effective dose. In patients who are at risk for osteoporosis (i.e., older age, cigarette smoking, low exercise) as most patients with COPD are, it is prudent to recommend prophylactic treatment such as calcium supplements and vitamin D. In those with established osteoporosis, bisphosphonates are advised. Monitoring for osteoporosis with DEXA bone scans is guided by the overall clinical situation and is not required for all patients using inhaled corticosteroids.

Adverse effects of inhaled therapy can occur. Inhaled anticholinergic agents are generally very safe. They may lead to an increased frequency of supraventricular arrhythmias, acute urinary retention in those with bladder outlet obstruction, or acute narrow-angle glaucoma if sprayed in the eye. β-Agonists, both short acting and long acting, may lead to side effects such as tremor, tachycardia, or hypokalemia.

Inhaled agents are administered by metered-dose inhaler (MDI), dry powder inhaler (DPI), or as a nebulized solution. The selection of route of administration is made by cost and convenience of the device because all are similarly effective if used properly. Many patients find that it is difficult to coordinate an MDI, and addition of a spacer device is helpful. There are many forms of DPI, some more intuitive to use than others, so specific instruction and demonstration is required by most patients. Nebulizers are easier for patients to coordinate, but each treatment takes longer to complete, and they require additional effort to maintain cleanliness. Although nebulized medications are more expensive overall, the cost of the medication is often covered by insurance, so many patients prefer nebulizers for financial considerations.

Adherence with inhaled medication, particularly when it does not provide immediate symptom relief is poor. Typically about half of patients do not take their medication in the dose or quantity prescribed. Reasons for this include a lack of understanding of the role of the medication, failure of the medication to provide meaningful benefit, complexity of the treatment program, and expense of the treatment. Many patients do not want to confide poor adherence to their physician, so it is important for the physician to ascertain this information in a way that does not interfere with the relationship with the patient. For example, a physician could inquire, "It is often difficult for patients to remember to take all of their medications. Has this been a problem for you?" or "Are you able to afford all your medication?" or "Do you think that your medicines are working for you?" If nonadherence is a problem, the treating physician can undertake actions to improve adherence, such as simplification of the medication program, education about the benefits of treatment, linking drug use to established habits such as meals or tooth brushing, or prescribing less costly drugs.

Proper use of MDIs is difficult for many patients to learn and retain. Repeated review and training of patients in MDI use is an important component of treatment of COPD and asthma. The inhaler should be held about 4 cm from the mouth to minimize deposition of larger droplets in the mouth. The patient should exhale to FRC and take a slow inhalation to TLC over about 5 seconds. The slow inhalation diminishes impaction of particles in the mouth and larynx. At the initiation of inspiration the patient should actuate the MDI one time. After full inspiration, the patient should hold the breath for about 10 seconds to permit settling of particles in the distal airspaces. If the patient finds that hoarseness or mouth irritation occurs with inhaler use, this can often be corrected by use of a spacer, slowing the rate of inspiration, and rinsing the mouth after each inhaler use. Although waiting a period of time between inhalations or between different MDIs is sometimes recommended for optimal effect, the benefit is small compared with the inconvenience and risk of worsening adherence. Therefore, it is usually appropriate to permit the patient to take additional inhalations as soon as he or she has rested a few seconds.

If the patient has difficulty coordinating the actuation of the MDI with inspiration, a spacer device or holding chamber can be used. This device is placed directly in the mouth and the MDI can be actuated prior to inspiration. DPIs usually require less coordination than MDIs, but there are many different devices, some rather complicated to use. Very frail patients may not have adequate inspiratory flow to effectively use a DPI. Therefore, each device requires individual instruction and review of technique. (For a compendium of patient instructions, see http://www.ginasthma.com/OtherResources.asp.)

Theophylline is taken as a long-acting oral preparation once or twice daily. Although it is possible to monitor blood levels, because the drug is protein bound there is a poor correlation between efficacy or adverse effects and serum levels. Theophylline is a bronchodilator; it improves arterial oxygenation and exercise tolerance.[45] If typical side effects such as nausea, vomiting, tremor, or tachyarrhythmias occur, the dose should be adjusted irrespective of serum levels. Prescriptions for theophylline to treat COPD have diminished in recent years because of the availability of long-acting inhaled agents. However, theophylline is still an effective second-line drug for patients who show benefit or prefer inexpensive oral medications. Theophylline has other putative pharmacologic actions that might be beneficial for the COPD patient: improvement in diaphragm contractility, prevention of respiratory muscle fatigue, increased ventilatory drive, potentiation of catecholamine function, prevention of microvascular permeability, increased mucociliary clearance, prevention of late-phase antigen responses, inhibition of mast cell histamine release, and suppression of leukocyte activation. Evidence has suggested that the anti-inflammatory effect of theophylline is mediated by augmentation of steroid effects through activation of histone deacetylase (HDAC), an effect that is of particular importance in COPD patients who have lower HDAC activity.[46]

Roflumilast is a more specific inhibitor of phosphodiesterase-4, which is a mild bronchodilator with anti-inflammatory properties. It is marketed in the United States for reduction of exacerbations of COPD in individuals with chronic bronchitis.[47]

Oral corticosteroids are effective for treatment of COPD exacerbations. About 10% to 20% of chronic symptomatic patients show substantial short-term improvement in pulmonary function, but it is not possible to identify these patients based on clinical characteristics alone. Because of the well-defined long-term adverse effects of systemic corticosteroids, and the ill-defined long-term benefits, most patients should not be maintained on long-term oral or systemic corticosteroids. Patients with COPD who are on

chronic corticosteroids can most often taper the dose at the equivalent of 5 mg of prednisone per week, and exclusively reserve their use for exacerbations. Long-term low doses of oral corticosteroids are occasionally needed by patients who cannot afford or tolerate inhaled agents, and who suffer frequent exacerbations. Patients on long-term systemic steroids should receive prophylaxis for osteoporosis with calcium and vitamin D or bisphosphonates, and should be instructed about the need for stress-dose steroids for acute illnesses.

Long-term macrolide antibiotics should be used sparingly in patients with COPD who do not have symptomatic bronchiectasis. Macrolides, which have immunomodulatory properties, have been demonstrated to reduce the frequency of exacerbations in patients susceptible to frequent exacerbations.[48] Thus, the use of long-term antibiotics may have a role in those susceptible to frequent, severe exacerbations.

Mucolytic agents to control mucus hypersecretion with the use of expectorants and physical means such as high-frequency chest wall oscillation is not of proven benefit in improving lung function, although symptoms are sometimes improved. N-acetylcysteine is a mucolytic with antioxidant properties does not prevent exacerbations, nor does it alter the decline in FEV_1. The role of antioxidant mucolytics such as N-acetylcysteine or carbocysteine is unclear but may have a role in reducing exacerbations.[49,50]

Opiates can be effective in the management of severe dyspnea related to COPD. Given differential response to these therapies, as well as the associated potential for respiratory depression, short acting and low-dose preparations should be initially used. While typically associated with severe, end-stage management in the hospice setting, short-acting opiates can be considered in patients with less severe lung impairment but symptomatic dyspnea refractory to pharmacotherapy, oxygen supplementation, and rehabilitation.

EXERCISE AND REHABILITATION

Regular prudent self-directed exercise is recommended for all individuals with COPD to prevent the muscle deconditioning that often accompanies the disorder. Individuals should be encouraged to perform at least 20 to 30 minutes of constant low-intensity aerobic exercise such as walking at least three times per week. Even the most severely impaired patients with COPD can usually attain an exercise regimen of 30 minutes of walking at 1 mph (i.e., one-half mile in 30 minutes). It is important to instruct patients that they should exercise to a level of dyspnea that is tolerable for the entire exercise period. Patients should understand that dyspnea, by itself, is not injurious to the heart or lungs, but patients should pace themselves to avoid severe dyspnea that disrupts activity, can lead to panic reactions, and is distressing to onlookers. Patients who demonstrate desaturation with exertion may be prescribed supplemental oxygen for exercise. Some may benefit in terms of exercise capacity and training effect even if they do not have demonstrable oxygen desaturation.[51] Many patients, particularly those with marked hyperinflation, find that they can ambulate better with the use of a rolling walker that supports the arms, improving the mechanical advantage of the accessory muscles in the neck.

Formal rehabilitation programs offer a comprehensive approach to exercise training, patient education, nutritional counseling, group support, and psychological support that cannot be efficiently provided in the physician's office. Rehabilitation programs are established as an effective component of COPD management and should be offered to patients who have substantial limitation in daily activities. A detailed discussion of rehabilitation is provided in Chapter 43.

NUTRITIONAL SUPPORT

In patients with very severe COPD (FEV_1 less than 35% predicted) about half show protein–calorie malnutrition.[52] Reasons for this include increased resting metabolic demands, inadequate caloric intake due to dyspnea and anorexia, and possibly elaboration of cachexia-associated inflammatory cytokines such as TNF-α, IL-1, and IL-6. Patients with a BMI of less than 90% of normal have increased mortality and decreased exercise capacity. Muscle wasting and loss of bone mass may be present even in patients who have normal BMI.[53] Although clinical trials of nutritional supplementation have been disappointing, it is prudent to monitor body weight in COPD patients and encourage caloric supplementation as needed since those patients who do gain weight show improved survival.[54] High-fat diets have the theoretical advantage of offering higher caloric content with lower CO_2 production than high carbohydrate diets, but there is no convincing evidence that this strategy is clinically superior to a well-balanced diet. For patients with less advanced disease, a balanced diet with avoidance of overweight or underweight is a rational goal. In particular, patients with mild to moderate disease who quit smoking tend to gain excessive weight, which might adversely affect lung function.[55]

SLEEP DISORDERS IN COPD

Sleep disturbances, including insomnia and daytime hypersomnolence, are common symptoms in patients with COPD,[56,57] and are often overlooked because of the focus on breathlessness and exercise intolerance. The causes for sleep symptoms are multifactorial and include anxiety, depression, resting hypoxemia, nocturnal bronchospasm, sleep apnea, and nocturnal oxygen desaturation (NOD). Patients with COPD often relate insomnia to a fear of suffocation or death during sleep, a situation that may respond to repeated reassurance, cognitive therapy, or small doses of anxiolytics or antidepressants. Patients with resting hypoxemia treated with low-flow nasal oxygen often report improved sleep quality. Nocturnal bronchospasm, more common among those with an asthmatic component to their disease, may respond to longer-acting bronchodilators, or rearrangement of the dosing schedule to provide nocturnal coverage. In some cases, treatment for gastroesophageal reflux by elevation of the head of the bed and prescription of acid suppressant drugs can help. Sleep apnea syndrome, probably not more common in COPD patients than the general community, has particularly severe complications in COPD. Patients with COPD and sleep apnea, the so-called "overlap syndrome" are prone to develop pulmonary hypertension and daytime hypercapnia.[58] Accordingly, symptoms of sleep apnea such as snoring, intermittent nocturnal breathing, and daytime hypersomnolence should be sought in patients with COPD. If present, then formal sleep studies and treatment with continuous positive airway pressure (CPAP) are indicated. NOD is common during rapid eye movement sleep in patients with COPD. The causes are not entirely understood, but contributing factors include hypoventilation, ventilation–perfusion mismatch, respiratory muscle dysfunction, and increases in upper airway resistance. NOD is thought to be associated with poorer sleep quality and pulmonary hypertension. It is controversial whether NOD is associated with poorer survival. However, small studies have shown inconclusive results about the utility of treating NOD.

Current guidelines do not recommend that all patients with COPD have nocturnal oxygen monitoring, nor do they recommend treatment with supplemental oxygen or nocturnal ventilation if NOD is found. Many physicians, though, will prescribe these diagnostic studies and treatments for selected symptomatic patients, and most insurance companies will provide reimbursement for such treatment. Patients who have resting room air daytime hypoxemia should be prescribed nocturnal oxygen at the same flow rate as used during the day, and it is usually not necessary to monitor nocturnal oxygen saturation in such patients.

MANAGEMENT OF DEPRESSION

Depression is a common comorbidity in individuals with COPD. The recognition and treatment of depression is important as this comorbidity is associated with poorer prognosis, increased risk of

exacerbations, and poor health status. While there is little evidence to suggest that depression should be treated differently in COPD patients, pulmonary rehabilitation has been shown to reduce depression with COPD.

AIR TRAVEL

Patients with COPD should not avoid air travel, but must be aware of the medical and regulatory issues that are involved.[59] Modern airplanes are pressurized to an equivalent altitude of approximately 5000 to 8000 ft, but may, on occasion, pressurize to an equivalent altitude of 10,000 ft without providing emergency oxygen. Many patients with COPD who do not use sea-level oxygen can tolerate short flights without supplemental oxygen. As flight distance becomes longer, the flying altitude becomes higher and the cabin pressure becomes lower, so transcontinental or transoceanic flights should prompt medical advice. The general rule of thumb used by the commercial airline industry is that patients who can ambulate 50 m without stopping are safe for air travel. A more conservative approach is to estimate the Pa_{O_2} during air travel by performing a high altitude simulation test. High altitude simulation can be performed by administering 15% oxygen via a face mask or by using 100% nitrogen in a 40% Venturi mask.[60] If the oxygen saturation falls below 86% or 50 mm Hg, then supplemental oxygen is recommended. Formulas are available to estimate altitude hypoxemia from sea-level room-air blood gases. Figure 42-4 provides a nomogram for estimating altitude Pa_{O_2} from sea-level room-air arterial oxygen tensions.[61] If estimated altitude Pa_{O_2} is used, it is prudent to prescribe oxygen for estimated altitude Pa_{O_2} of 54 mm Hg or lower. Patients who use oxygen supplementation at sea level should increase their resting oxygen prescription by a flow rate of 2 L/min. For patients with COPD who travel by air frequently, low-cost finger pulse-oximeters that are marketed to airplane pilots can be used to adjust their oxygen flow.

Airlines have inconsistent policies with respect to providing supplemental oxygen for travelers, so it is important to check with the airline service desk before booking travel. The United States Federal Aviation Administration has promulgated regulations that permit some approved portable oxygen concentrators to be carried on board by passengers as personal luggage with a physician's statement of need. These may be rented from oxygen supply companies or specialized websites.

LONG-TERM OXYGEN THERAPY

In addition to smoking intervention in early COPD, treatment of resting daytime hypoxemia with oxygen is a treatment that prolongs survival.[62–64] The two strongest indications for prescription of long-term oxygen therapy are (1) resting room-air Pa_{O_2} ≤55 mm Hg or oxygen saturation ≤88% while a person is in usual state of health; and (2) resting room-air Pa_{O_2} 56 to 60 mm Hg or oxygen saturation 88% to 89% with supporting evidence of chronic hypoxemia such as polycythemia, pulmonary hypertension, cor pulmonale, or psychological impairment. Oxygen is usually administered by nasal cannula, with the flow rate adjusted to maintain a resting saturation greater than 90%. The usual starting flow rate is 2 L/min, although some patients with severe hypercapnia require lower flows. A few patients, particularly those with concomitant interstitial pulmonary disease or cardiac disorders, require higher flow rates.

The most convenient and cost-effective oxygen source at home is usually a concentrator device that uses a molecular sieve to extract oxygen from room air. For ambulation, small compressed air cylinders, portable concentrators, or liquid oxygen reservoirs that can be carried provide patients with the ability to leave their homes. Conserving devices such as reservoirs or demand valves permit portable ambulatory oxygen tanks to last up to 10 hours. Compressed oxygen cylinders or liquid oxygen reservoirs should be provided to patients who use electrically driven oxygen concentrators for emergency use in the event of a power failure. Ideally, oxygen should be used constantly 24 hours per day. At least 18 hours of oxygen per day, however, has been shown to have substantial benefit over 12 hours per day. If continuous oxygen supplementation is prescribed following an exacerbation of COPD, it is recommended to check arterial oxygen levels in 6 weeks, as many patients will no longer require oxygen.

Nasal drying or congestion is a common symptom for those who use continuous oxygen. This may be alleviated to some extent by alternating the nasal cannula from one nostril to the other or placing it in the mouth for periods. Copious watery nasal secretions often respond well to ipratropium nasal spray, and dry, crusted nasal mucosa is treated with hourly instillations of saline nasal spray.

Smoking or exposure to any open flame is prohibited by the danger of fire and airway burns in those who use oxygen. This is a surprisingly common cause of burns in the United States, with estimates that up to 50% of patients on oxygen continue to smoke to some extent.[65] Accordingly, it is safer to counsel patients to discontinue oxygen while smoking or cooking over an open flame if they insist on doing these activities. Patients at particular risk are those who live alone, have cognitive impairment, and do not have functioning smoke detectors.

Oxygen delivery via a transtracheal catheter is an option for selected patients who cannot tolerate other oxygen delivery methods, and who can attend to the regular maintenance of the catheter. High-flow humidified nasal cannulas are also an option for individuals who need high concentrations of oxygen but who cannot tolerate a facemask.

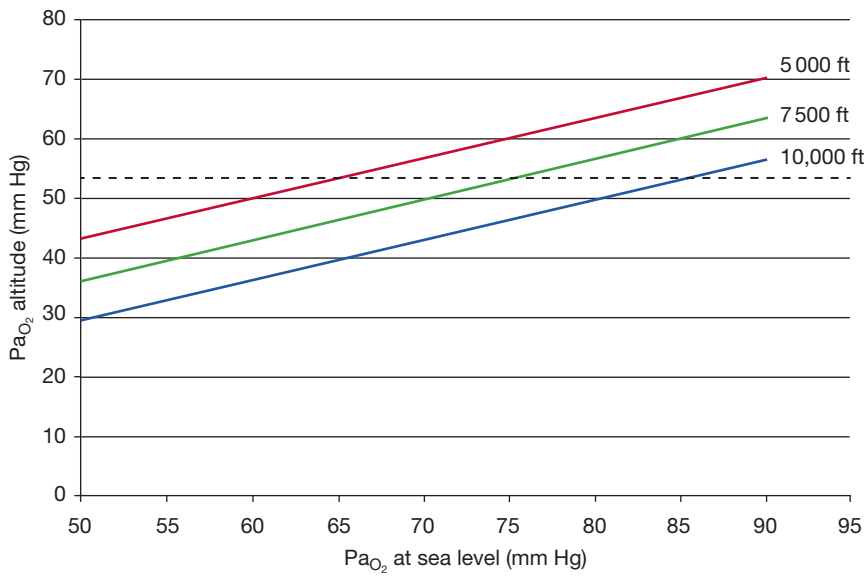

Figure 42-4 Estimated Pa_{O_2} at altitude based on resting sea-level arterial oxygen tension. Isopleths are drawn for the range of cabin pressures that occur on commercial aircraft. The dashed line is drawn at 54 mm Hg, which indicates a threshold for prescribing supplemental oxygen for air travel. *(Data of Gong H Jr, Tashkin DP, Lee EY, et al. Hypoxia-altitude simulation test. Evaluation of patients with chronic airway obstruction. Am Rev Respir Dis. 1984;130:980–986.)*

Ambulatory oxygen, although not shown to improve survival, may be provided for patients who desaturate with exertion. Some, but not all, patients show improved exercise capacity and reduced breathlessness. There is a growing body of evidence that suggests that oxygen supplementation may also benefit COPD patients who do not have exercise desaturation by reduction in minute ventilation and diminution of dynamic hyperinflation.[51] Because it permits greater exercise intensity, oxygen supplementation is also a useful adjunct for aerobic conditioning during pulmonary rehabilitation.

COMPLICATIONS

COPD EXACERBATIONS

Exacerbations are characterized by worsening cough, dyspnea, and sputum production beyond normal day-to-day variation. These exacerbations are associated with acute deterioration of lung function during the exacerbation and may also accelerate the longitudinal loss of lung function. Acute exacerbations of COPD are a major cause of hospitalization, healthcare costs, morbidity, and mortality in COPD. Exacerbations have been associated with respiratory viral infections including rhinovirus, respiratory syncytial virus, influenza, adenovirus, and metapneumovirus. Bacterial infections or superinfections are also associated with COPD exacerbations. The most frequent pathogens are *Haemophilus influenzae, Moraxella catarrhalis,* and *Streptoccous pneumoniae*. In patients who have been treated with antibiotics, gram-negative bacteria may also be present. Severe air pollution, especially particulates, sulfur dioxide, ozone, and nitrogen dioxide have been associated with elevated risk for hospitalization due to COPD. On average, patients with COPD have two to three exacerbations per year, but there is wide variation, and the frequency of exacerbations is only roughly correlated with severity of airflow obstruction. The best predictor of future exacerbations is a past history of frequent exacerbations,[66] and these are more common in patients with chronic cough and sputum production. Only half of COPD exacerbations come to the attention of treating physicians, and many of these eventually resolve without specific treatment. The management of these exacerbations depends upon the severity. Indications for hospital evaluation or hospitalization are listed in Table 42-8. Arterial blood gas studies and chest radiographs are useful for evaluating etiology and severity of acutely ill patients. Spirometry during the acute exacerbation is usually not helpful in predicting the severity or duration of the exacerbation.

For patients treated at home, increasing the frequency and intensity of inhaled short-acting bronchodilators for several days is effective in mild exacerbations. A hand-held inhaler and spacer are usually effective, but a nebulizer may be needed for those who cannot coordinate well or who have severe dyspnea. Increasing dyspnea accompanied by a change in the quantity or color of phlegm is usually an indication of bacterial infection and should prompt initiation of antibiotics. The choice of antibiotic is determined by severity of the underlying disease, resistance patterns of likely pathogens, and likelihood of treatment failure (Table 42-9). After initiation of therapy, the antibiotic treatment should be tailored based on sputum cultures.

A course of corticosteroids, equivalent to 30 to 60 mg of prednisone for 7 to 14 days, will shorten the duration of symptoms for patients with exacerbations managed as outpatients.[67,68]

For patients admitted to the hospital, intensification of inhaled bronchodilator treatment, systemic corticosteroids, and antibiotics are administered.[69] Controlled oxygen supplementation should be provided at the lowest level needed to reverse hypoxemia and minimize the induction of hypercapnia. The selection of the oral or intravenous route for antibiotics and corticosteroids is determined by the severity of the illness and the ability of the patient to tolerate oral medication. Evaluation for the cause of the exacerbation does not have to be extensive if it responds to initial treatment and conforms to the patient's usual exacerbation pattern. Sputum culture for resistant bacterial strains, a chest radiograph for exclusion of pneumonia and pneumothorax, and an electrocardiogram for exclusion of myocardial ischemia and arrhythmia are useful tests in all hospitalized patients. Echocardiography for assessment of ventricular function, and Doppler venous flow studies, radionuclide, or computed tomographic lung imaging for evaluation of pulmonary thromboembolism need to be performed in selected cases. Usually a 2-week course of steroids is sufficient for hospitalized patients.

Treatment in an intensive care setting should be undertaken for patients with severe exacerbations or those who require more constant attention (Table 42-8). For patients with respiratory failure,

TABLE 42-8 Indications for Hospitalization in COPD

Indications for Hospital Assessment or Admission for COPD Exacerbation
Sudden onset of new or severe symptoms (e.g., dyspnea)
Inability to sleep or eat because of dyspnea
Severe or very severe underlying COPD
Onset of new physical findings (e.g., edema, cyanosis, change in mental status)
Failure to respond to initial medical treatment
Associated comorbidities (e.g., cardiac, renal, hepatic failure, or diabetes)
Diagnostic uncertainty (e.g., suspected pneumonia or pulmonary embolism)
Unusual presenting symptoms
Older age or frailty
Inadequate home or social support
History of poor adherence with treatment
Indications for ICU Admission for COPD Exacerbation
Severe dyspnea unresponsive to initial treatment
Change in mental status (e.g., confusion, lethargy, coma)
Persistent or worsening hypoxemia, hypercapnia, or respiratory acidosis
Need for sedation or narcotic pain control

Source: Data from 2011 GOLD COPD guidelines (www.goldcopd.com) and 2004 ATS/ERS Standards for treatment of COPD.

TABLE 42-9 Antimicrobial Treatment of COPD Exacerbations

First Line
Amoxicillin 500–875 mg PO TID
Doxycycline 100 mg PO BID
Alternatives
Amoxicillin/clavulanate 875 mg PO BID
Azithromycin 500 mg, then 250 mg PO QD × 4 d
Clarithromycin 500 mg PO BID
Second-generation cephalosporins
Severe COPD or previous antibiotics
Levofloxacin 500–750 mg PO QD × 7 d
Ciprofloxacin 500 mg PO QD × 7 d

noninvasive mask ventilation has proved to be an effective strategy to avert endotracheal intubation, shorten duration of illness, and improve outcomes.[70] Attention needs to be paid to selecting and fitting a comfortable well-sealed mask, and providing a ventilator that minimizes the patient's work of breathing and triggering effort. When noninvasive mask ventilation is not successful in sustaining ventilation, or the patient is too ill to use the mask, endotracheal intubation and mechanical ventilation are needed to treat respiratory failure. The mechanical ventilator should be set to provide minute ventilation that does not overventilate the patient and cause alkalemia, which may ultimately impede liberation from the ventilator. The inspiratory flow rates and inspiratory to expiratory time ratios should be adjusted to provide a prolonged duration of expiration to minimize dynamic hyperinflation (auto-PEEP), which can lead to dyspnea, discoordination, and barotrauma. Weaning and liberation from mechanical ventilation can be hindered by anxiety, oversedation, mucus secretions, intravascular volume overload, myocardial ischemia, or respiratory muscle deconditioning. Survival after an episode of acute respiratory failure for COPD patient with hypercarbia is about 50% at 2 years after discharge, with about half of the patients being readmitted to the hospital within 6 months.[71]

PNEUMOTHORAX

COPD is thought to be the most common cause for secondary spontaneous pneumothorax. A pneumothorax can either cause an acute symptomatic exacerbation of COPD from rupture of a bleb, or may occur during the course of an exacerbation as a consequence of hyperinflation or mechanical ventilation. Because this is a life-threatening but quickly treatable cause for worsening respiratory failure in COPD, it should always be considered in the differential diagnosis for worsening dyspnea in COPD. The physical examination can be misleading because diminished breath sounds are a component of the underlying disease. Imaging studies are usually diagnostic, but at times it can be difficult to distinguish a pneumothorax from an over-distended bulla. If the patient's clinical situation can tolerate it, imaging with inspiratory and expiratory views, or chest computed tomograms can be helpful. In the intensive care unit, upright and cross-table lateral views sometimes show mobility of the pleural air.

Urgent treatment for the patient in extremis is performed by aspirating the pleural space at the second intercostal space anteriorly in the midclavicular line. Definitive emergency treatment is placement of a thoracostomy tube, which should be done with care to avoid laceration of a bulla and creation of a bronchopleural fistula. In patients with advanced COPD, recurrence of a pneumothorax can be life-threatening, so definitive pleural sclerosis with surgical or medical thoracoscopy should be considered.

COR PULMONALE

Pulmonary hypertension and consequent right ventricular failure, *cor pulmonale*, are usually the consequence of chronic alveolar hypoxia, with secondary contributions from destruction of the alveolar capillary bed, lung hyperinflation, and increased blood viscosity.[72] Diagnosis of pulmonary hypertension and right ventricular failure can be difficult, as physical findings of venous engorgement, and right ventricular hypertrophy and dilatation are late signs. Peripheral edema is poorly correlated with resting right atrial pressure and may reflect fluid retention from activation of the renin–angiotensin–aldosterone system. Functional imaging studies including echocardiography or radionuclide ventriculography are more probative for evaluation of right ventricular function. Doppler echocardiographic measures of pulmonary artery systolic pressure correlate weakly with severity of pulmonary hypertension by right heart catheterization.[73] Once cor pulmonale is present, survival is diminished. If the pulmonary artery pressure exceeds 25 mm Hg, the average 5-year survival is diminished by 50%.[74]

The primary treatment of cor pulmonale consists of continuous oxygen to overcome hypoxemia and diuretic to optimize volume status. Calcium channel blockers and other vasodilators can dilate the pulmonary circulation, but they worsen hypoxemia and their benefit is not established. Phlebotomy increases exercise capacity when the hematocrit exceeds 55%, but persistent erythrocytosis suggests inadequate oxygen supplementation or another cause. Anticoagulation, which is considered beneficial in severe pulmonary vascular hypertension of other causes, is of uncertain benefit in patients with pulmonary hypertension caused by COPD.

SUPRAVENTRICULAR ARRHYTHMIAS

Supraventricular tachyarrhythmias are common in patients with COPD, as a consequence of right atrial enlargement, increased endogenous adrenergic tone, hypoxemia, and drug treatment—specifically theophylline and anticholinergic bronchodilators. Treatment is similar to that in nonpulmonary patients; however, the presence of COPD should not prevent evaluation for treatable causes of arrhythmias such as pulmonary embolism, hyperthyroidism, or valvular heart disease, which may be difficult to diagnose in COPD patients.

HYPERCAPNIA

Chronic hypercapnia secondary to alveolar hypoventilation can be considered an adaptive response to obstructive lung disease by decreasing the work of breathing, preventing respiratory muscle fatigue, and allowing a diminished sensation of dyspnea. The adverse effect of chronic hypercapnia is the development of alveolar hypoxia and consequent pulmonary hypertension. Accordingly, the approach to chronic hypercapnia is the use of supplemental oxygen in controlled concentrations. In patients who are very sensitive to oxygen, it is preferable to provide oxygen in controlled concentrations with Venturi masks rather than nasal cannula.

Nocturnal ventilation has been effective in reducing daytime hypercapnia in patients with neuromuscular disease and kyphoscoliosis. Short-term trials have shown divergent effects of nocturnal ventilation in patients with COPD. A 2-year controlled long-term trial of nocturnal ventilation in hypercapnic patients with COPD has shown modest improvement in symptoms and quality of life, and a trend toward reduced hospitalization, but only small improvements in daytime hypercapnia.[75] Thus, based on our current state of knowledge, long-term nocturnal ventilation ought to be reserved for selected symptomatic patients with frequent hospitalizations who can tolerate the treatment.

ADVANCED TREATMENTS

For patients who have far-advanced disease evidenced either by severe breathlessness or short life expectancy, more aggressive treatments should be considered. Undertaking these treatments requires thoughtful consideration by patients and their families, and frank discussion of the risks and benefits by the medical caregivers.

LUNG VOLUME REDUCTION SURGERY

Lung volume reduction surgery (LVRS) is a surgical procedure that involves stapled resection of 20% to 30% of the lung bilaterally, usually from the apices. The procedure is equally safe and effective, done by median sternotomy or video-assisted thoracoscopy (VATS). The theory behind this procedure is that the remaining lung expands to fill the thorax, thereby increasing its elastic recoil pressure, which improves expiratory airflow. The reduction of lung volume permits the diaphragm to attain a more normal, domed configuration, which improves its mechanical efficiency. Moreover, the preferential removal of unventilated bullae reduces residual volume, permitting an increase in the vital capacity. While some patients show substantial

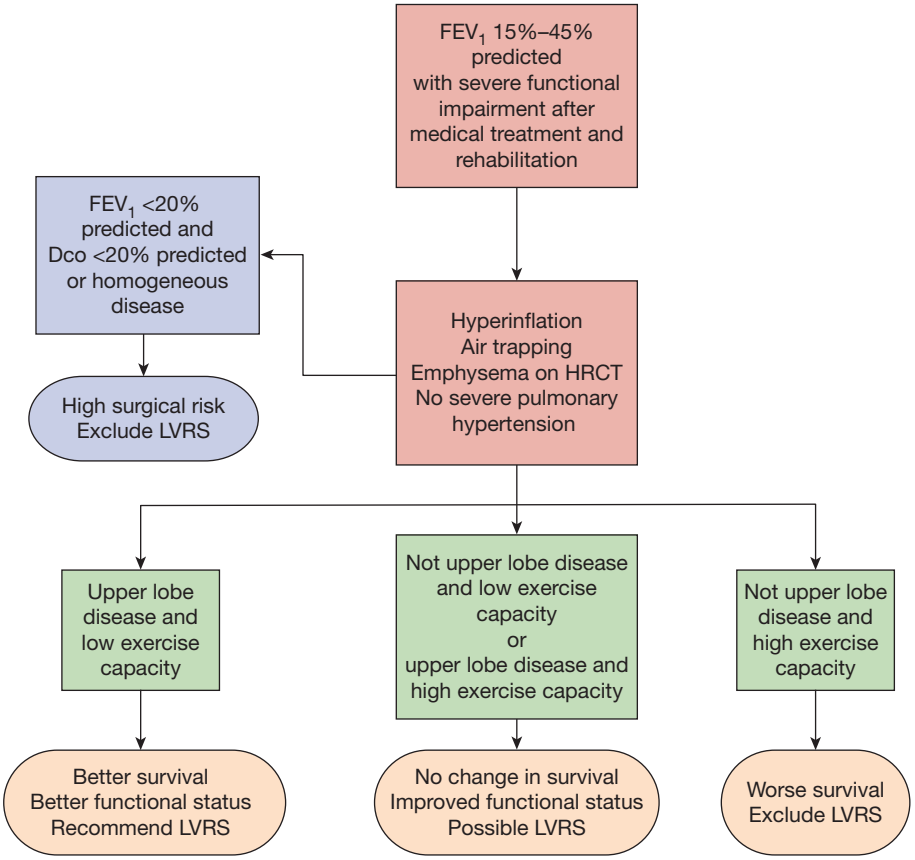

Figure 42-5 Decision tree for selection of candidates for lung volume reduction surgery (LVRS) based on distribution of emphysema on high-resolution computed tomogram (HRCT) and functional impairments.

physiological and symptomatic improvement following LVRS, many do not.[76] An algorithm for selection of patients for LVRS, based on distribution of emphysema and functional measures, is presented in Figure 42-5. Generally, LVRS should not be done on patients with an FEV_1 less than 20% predicted and either diffusing capacity less than 20% predicted or diffuse homogeneous emphysema on HRCT, because these patients have high surgical mortality. The group of patients who fare best with LVRS are those who have emphysema predominantly in the upper lung zones and low exercise capacity despite pulmonary rehabilitation. These patients have improved survival after LVRS and show improved functional status and quality of life. Conversely, patients without upper lobe predominance (i.e., lower lobe emphysema or homogeneous emphysema) and who have adequate exercise capacity after rehabilitation, have worse outcomes after LVRS. In selected cases, resection of a pulmonary nodule may be accompanied by LVRS as an attempt to improve postoperative functional status. Although LVRS was originally proposed as a temporizing measure while patients were awaiting lung transplantation, most LVRS candidates are not suitable candidates for lung transplantation. However, prior LVRS does not alter the outcome of subsequent lung transplantation.

Surgical resection of a single large bulla is rarely indicated for treatment of COPD. Isolated giant bullae are usually the result of an expanding congenital cyst. The generally accepted indication for resection of a single large bulla is that it occupies more than one-third of the hemithorax and causes compression of normal lung. Some believe that a preserved D_{CO} is an indicator of those most likely to improve following a bullectomy.

Preliminary studies with nonsurgical approaches to lung volume reduction using a variety of techniques to induce atelectasis of a target lobe are under investigation. In a study of COPD patients with severe airflow obstruction, hyperinflation and heterogeneous emphysema, placement of endobronchial valves for a bronchoscopic LVRS was associated with modest improvements in relevant clinical outcomes, although these results are balanced by an increased risk of infection and COPD exacerbation.[77,78] Selection of patients with proper anatomy appears to be important predictors of success to these nonsurgical approaches. These methods may ultimately provide an alternative approach to surgical LVRS for patients with severe COPD.

LUNG TRANSPLANTATION

In younger patients with advanced disease, lung transplantation should be a treatment consideration. Criteria for lung transplantation referral in patients with COPD are an FEV_1 below 25% predicted, BODE index greater than 5, hypercapnia, resting hypoxemia, secondary pulmonary hypertension, and accelerated decline in FEV_1 in patients under the age of 60 to 65 years.[79] For additional information see Chapter 107 (lung transplantation).

CHRONIC VENTILATOR SUPPORT

Some patients remain on long-term ventilator support following an episode of acute respiratory failure. Most often these patients are treated in a long-term ventilator unit, but some can be managed at home with adequate support. In some cases, the goal of long-term ventilator support is to provide rehabilitation via respiratory care, nutrition, and exercise to eventually be liberated from the ventilator entirely or for substantial portions of the day. In other cases, the goal of care is to provide comfort and support for terminal care without attempts at rehabilitation. Whatever the goal, a coordinated team of physicians, respiratory therapists, physical therapists, nutritionists, social workers, psychologists, and nurses are needed to undertake the care of these patients. The treatment of long-term ventilator patients differs from the treatment of acute respiratory failure in the intensive care unit. Ventilators are less sophisticated in terms of modes of ventilation and monitoring, but more portable. Ventilation is often performed with an uncuffed tracheostomy with

an air leak to avoid complications at the cuff site. Sufficiency of ventilation is judged by noninvasive measures of oxygenation and patient comfort. Narcotics in small doses are administered for relief of dyspnea. Diagnostic studies and invasive testing are performed less frequently than in critical care units. Although the care in long-term ventilator units is complex and expensive, the quality of life experienced by patients in chronic ventilator units is similar to that of patients confined to a bed-and-chair existence by other chronic maladies. The survival of COPD patients on long-term mechanical ventilation is less than those on such treatment for neuromuscular diseases, in part, because of their older age and comorbidities.[80]

CONCLUSIONS

COPD develops insidiously. However, the disease can be easily detected with simple spirometric testing before symptoms occur, and cessation of smoking can slow or even halt the disease progression and prolong survival. Once the disease is symptomatic, a coordinated, comprehensive, and individualized approach to treatment, both pharmacologic and nonpharmacologic, can increase functional status, prevent complications, and improve the quality of life. Exacerbations of COPD can range from those that are nuisances to those that are life-threatening, but treatment can shorten the duration of illness and improve outcomes. In advanced disease, treatments including surgical approaches are directed toward relief of symptoms and prolongation of survival. Thus, although there is certainly need for improvement in our treatment of symptomatic COPD, current treatments are effective and a nihilistic attitude is not warranted.

DISCLOSURES

Disclosure of financial conflicts: During the preceding 5 years, Dr. Wise has received fees for consultation or support of research from the following companies: Astra-Zeneca, Boehringer-Ingelheim, GlaxoSmithKline, InterMune, Merck, MedImmune, Mylan, Novartis, Pfizer, Pulmonx, Sunovion, Spiration. Financial conflicts of interest are managed by the Johns Hopkins University School of Medicine.

During the preceding 5 years, Dr. Drummond has received fees for consultation from Boehringer-Ingelheim and Lupin Pharmaceuticals.

CHAPTER 43

Rehabilitation in Chronic Obstructive Pulmonary Disease and Other Respiratory Disorders

Andrew L. Ries

Rehabilitation for patients with chronic lung diseases is well established as a means of enhancing standard pharmacologic and other therapies in controlling and alleviating symptoms and optimizing functional capacity.[1–4] The primary goal of any rehabilitation program is to restore the patient to the highest possible level of independent function. This goal is accomplished by helping patients and significant others learn more about the underlying disease, treatment options, and coping strategies. Patients are encouraged to participate actively in providing their own health care, become more independent in daily activities, and be less dependent on health professionals and expensive medical resources. Rather than addressing solely reversal of the disease process, rehabilitation focuses on improving disability from disease.

Historically, pulmonary rehabilitation strategies were developed and have been used primarily for patients with chronic obstructive pulmonary disease (COPD). However, pulmonary rehabilitation has also been applied successfully to patients with other chronic lung conditions, including interstitial diseases, cystic fibrosis, bronchiectasis, and thoracic cage abnormalities.[3,5–7] It has been used successfully in the evaluation and preparation of patients for surgery, such as lung transplantation and volume reduction lung surgery, and in maximizing recovery after surgery.[8–11] Pulmonary rehabilitation has been used to facilitate patient recovery from acute processes such as acute lung injury, or exacerbations of chronic lung disease requiring mechanical ventilation or acute hospital care. Pulmonary rehabilitation is appropriate for any patient with stable lung disease who is disabled by respiratory symptoms. Even patients with advanced disease may benefit if they are selected appropriately and realistic goals are set.

This chapter defines pulmonary rehabilitation and outlines issues related to patient selection and evaluation. Key components of a pulmonary rehabilitation program are described and results of rehabilitation programs reviewed. Finally, the role of rehabilitation prior to and following lung surgery is reviewed.

DEFINITION

In 2006, the American Thoracic Society and European Respiratory Society adopted the following definition:

> Pulmonary rehabilitation is an evidence-based, multidisciplinary, and comprehensive intervention for patients with chronic respiratory diseases who are symptomatic and often have decreased daily life activities. Integrated into the individualized treatment of the patient, pulmonary rehabilitation is designed to reduce symptoms, optimize functional status, increase participation, and reduce healthcare costs through stabilizing or reversing systemic manifestations of the disease.[2]

This definition focuses on three important features of successful rehabilitation. First, the program is *multidisciplinary.* Pulmonary rehabilitation programs utilize expertise from various healthcare disciplines that is integrated into a comprehensive, cohesive program tailored to the needs of each patient. Second, the program is tailored to the *individual.* Patients with disabling lung disease require individual assessment of needs, individual attention, and a program designed to meet realistic individual goals. Third, the program addresses *multidimensional outcomes* that include physical, psychological, and social function as well as healthcare utilization.

The interdisciplinary team of healthcare professionals in pulmonary rehabilitation may include physicians, nurses, respiratory and physical therapists, psychologists, exercise specialists, and others with appropriate expertise. The specific team make up depends upon the resources and expertise available, but it usually includes at least one full-time staff member. Responsibilities of team members generally cross disciplines.[12]

Within this general framework, successful pulmonary rehabilitation programs have been established in both outpatient and inpatient settings and with different formats. A key to success is a dedicated, enthusiastic staff that is familiar with respiratory problems and can relate well to pulmonary patients and motivate them.

PATIENT SELECTION

Any patient with symptomatic chronic lung disease is a candidate for pulmonary rehabilitation (Table 43-1). Appropriate patients are aware of disability from their disease and are motivated to participate actively in their own care to improve their health status. Patients with mild chronic disease may not perceive their symptoms to be severe enough to warrant a comprehensive care program. On the other hand, patients with severe disease who are bed bound may be too limited to benefit greatly.

Criteria based on arbitrary lung function parameters or age alone should not be used in selecting patients.[1] Pulmonary function is not a good predictor of symptoms, function, or improvement after rehabilitation.[13] Chronic lung disease is commonly associated with systemic features that contribute to functional limitations and may benefit from rehabilitation.[14] In general, selection should be based upon a person's disability from their disease, potential for improvement, and motivation to participate actively in a comprehensive self-care program. Also, pulmonary rehabilitation is not a primary mode of therapy. Patients should be stabilized on standard medical therapy and should not have other disabling or unstable conditions that might limit their ability to participate fully in the program and to concentrate on the necessary tasks.

The ideal patient for pulmonary rehabilitation, then, is one with functional limitation from moderate to severe lung disease who is stable on standard therapy, not distracted or limited by other serious or unstable medical conditions, willing and able to learn about his or her disease, and motivated to devote the time and effort necessary to benefit from a comprehensive care program.

TABLE 43-1 Patient Selection Criteria for Pulmonary Rehabilitation

Symptomatic chronic lung disease
Stable on standard therapy
Functional limitation from disease
Relationship with primary care provider
Motivated to be actively involved in and take responsibility for own health care
No other interfering or unstable medical conditions
No arbitrary lung function or age criteria

PATIENT EVALUATION

The initial step is screening patients to ensure appropriate selection and to set realistic individual and program goals. The evaluation process includes the following components: interview, medical evaluation, psychosocial assessment, diagnostic testing, and goal setting (Table 43-2).

INTERVIEW

The screening interview is an important first step. It serves to introduce the patient to the program, review the medical history, and identify psychosocial problems and needs. Family members and significant others should be included. Communication with the primary care provider is important to establish the vital link for the rehabilitation staff to clarify medical questions prior to the program and facilitate subsequent recommendations. Care and attention in this initial evaluation helps in setting goals compatible with everyone's expectations as well as appropriate programmatic objectives.

MEDICAL EVALUATION

Reviewing medical history helps to identify the patient's lung disease and assess its severity. Other medical problems that might preclude or delay participation may be identified. Available laboratory data should be reviewed, including pulmonary function and exercise tests, rest and exercise arterial blood gas measurements, chest radiographs, electrocardiogram, and pertinent blood tests. Program

Exercise
Psychosocial support

staff can then determine the need for any additional information or action before the program begins.

PSYCHOSOCIAL ASSESSMENT

Successful rehabilitation requires attention not only to the patient's physical problems but also to psychological, emotional, and social issues. Patients with chronic illnesses experience psychosocial difficulties as they struggle to deal with symptoms they may not fully understand.[15]

Neuropsychological impairment is common in patients with chronic lung diseases and cannot be accounted for solely on the basis of age, depression, or organic disease. Commonly, such patients become depressed, frightened, anxious, and more dependent on others to care for their needs. Progressive dyspnea is a frightening symptom and may lead to a vicious "fear–dyspnea" cycle: With progressive disease, less exertion results in more dyspnea, which produces more fear and anxiety, which, in turn, lead to more dyspnea. Ultimately, the patient avoids any physical activity associated with both of these unpleasant symptoms.

In addressing these problems, the initial evaluation should assess the patient's psychological state and pay attention to "psychosocial clues" that may be apparent during the screening interview (e.g., level of family and social support, the patient's living arrangement, activities of daily living, hobbies, and employment potential). Important clues in initial interviews to the patient's emotional state may be evident in nonverbal communication, such as facial expression, physical appearance, handshake, and personal space (distance between individuals when conversing). Cognitive impairment that may limit the patient's ability to participate fully in the rehabilitation program may be identified. Family members and significant others may provide valuable insight and should be included in the screening process and program whenever possible.

DIAGNOSTIC TESTING

Planning an appropriate rehabilitation program requires accurate, current information. The complexity of the testing procedures performed depends upon individual patient and program goals as well as the facilities and expertise available.

Pulmonary function testing is used to characterize lung disease and quantify impairment. Spirometry and lung volume measurements are most useful. Other tests (e.g., diffusing capacity, maximal respiratory pressures to assess muscle strength) can be added as needed.

Exercise testing helps to assess the patient's exercise tolerance and to evaluate changes in arterial blood gases (e.g., hypoxemia or hypercapnia) with exercise.[16,17] This may also uncover coexisting diseases (e.g., heart disease). The exercise test is also used to establish a safe and appropriate prescription for subsequent training.

Maximal exercise of patients with chronic lung disease is limited largely by their breathing reserve, though chronic lung diseases are increasingly recognized as being associated with systemic effects that may also contribute to exertional symptoms (e.g., muscle fatigue). Simple pulmonary function tests such as spirometry can be used to estimate a patient's capacity for sustained breathing (maximal ventilation) during exercise. The forced expiratory volume in 1 second (FEV_1) is most useful in this regard. However, lung function only provides an estimate of an individual patient's maximum work capacity. Exercise tolerance depends also on the patient's perception and tolerance of the subjective symptom of breathlessness. Therefore, it is important to exercise patients to assess their physical function and symptom tolerance.

Exercise evaluation for rehabilitation is most easily performed with the type of activity planned for training (e.g., treadmill for a walking training program). Laboratory exercise testing is most commonly performed using either (1) rapid, progressive, incremental levels to a symptom-limited maximum or (2) defined steady-state levels.[16,18] The former is most useful for determining exercise tolerance and the limitations to maximum performance. The latter may be preferred for assessing training prescriptions. Simpler exercise tests, such as the 6-minute walk test, have been used increasingly in recent years to measure exercise tolerance outside of a laboratory setting.[19] These timed distance walk tests measure the maximum distance a person can walk within a defined period (e.g., 6 minutes). Such tests have the advantage of requiring less equipment and technical expertise; however, attention must be paid to the details of testing procedures because variations in factors such as the walking course, patient instructions, encouragement during tests, use of oxygen or monitoring devices, and number of tests performed will influence the results. Also, these tests do not provide the detailed physiologic data typically included in more formal laboratory exercise tests.

Measurement of arterial blood gases at rest and during exercise is important because of the frequent but unpredictable occurrence of exercise-induced hypoxemia.[20] Arterial blood gas sampling during exercise makes testing more complex. The noninvasive estimate of arterial oxygen saturation by cutaneous (e.g., pulse) oximetry is useful for continuous monitoring, but it has limited accuracy (95% confidence limits, ±4–5%).[21]

GOALS
